
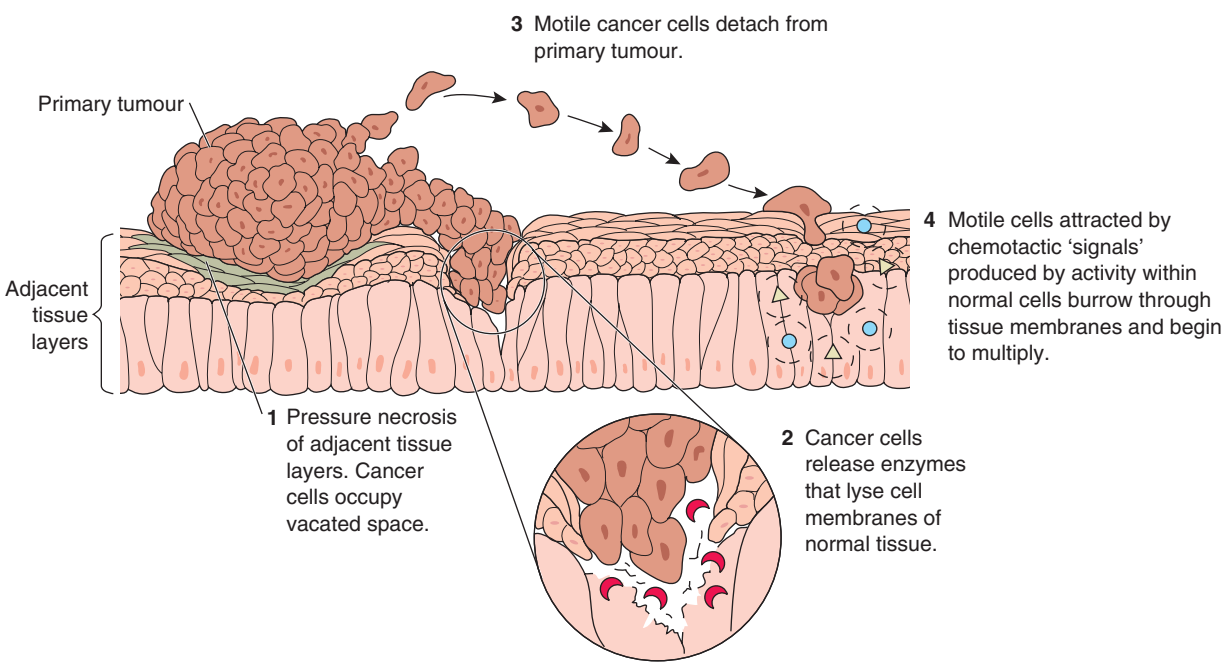

FIGURE 13.2 ■ How cancer cells invade normal tissue

tissues, possibly as a result of the degrading of the basement membranes of the normal cells. This breakdown of normal cellular membranes releases the chemical stimulus physiologically designed to draw normal phagocytic cells to clean up the debris. (See Chapter 11, on the inflammatory response, for more information on chemotaxis.) Malignant cells are also known to respond chemotactically to the end product of cellular metabolism. Some cancer cells even produce a substance called autocrine motility factor, which calls other malignant cells to a normal tissue. The first invading cells produce this substance, which then actively draws other malignant cells from the primary tumour into the invaded normal tissue.

Metastasis

The factors that favour invasion also contribute to the process of metastasis. **Metastasis** can occur by means of one or more mechanisms including embolism in the blood or lymph or spread by way of body cavities.

A blood- or lymph-borne metastasis allows a new tumour to be established in a distant organ. Figure 13.3 shows metastasis through the bloodstream. A tumour's ability to metastasise in this manner requires the following steps:

1. Intravasation of malignant cells through blood or lymphatic vessel walls and into the circulation.
2. Survival of the malignant cells in the blood. (To survive, the cells must escape the notice of the body's immune surveillance; only about 1 in 1000 cells does so.)
3. Extravasation from the circulation and implantation in a new tissue.

The tumour cells tend to clump together, forming an embolus, and continue growing until their size prevents further travel in the vessel or lymph channel. The growing neoplastic mass then uses its invasive abilities (secreting enzymes and motility factor) to move into the nearest organ.

About 60% of metastatic lesions tend to occur in a schema reflecting the pattern of blood or lymph circulation. However, it has been demonstrated that some malignant cells defy a blood-borne pattern and actually target specific organs to which they prefer to metastasise. For example, lung cancer frequently metastasises to the adrenal glands, and breast cancer frequently metastasises to bone. Malignant cells that gain access to the lymph channels may travel to a preferred organ and then move into it the same way they emigrate through blood vessels. Alternatively, the malignant cells may become trapped in the lymph node and continue to grow. Eventually, the malignant cells replace the node's tissues. At this point, emboli from the cancerous node disseminate to other nodes, creating a cascade reaction. The malignant cascade causes widespread transfer of the tumour to uncharacteristic sites.

A malignant tumour may break through the walls of the organ in which it is primarily housed, shedding cells into the nearby body cavity. The cells are then free to establish new tumours in a distant area of that cavity. For example, malignant cells from a colon cancer may be seeded into the peritoneal cavity, establishing a new tumour in the mesenteric epithelium.

Metastatic lesions are differentiated from primary neoplasms by cell morphology: metastatic cells do not resemble the tissue in which they reside. The most common sites of metastasis are the lymph nodes, liver, lungs, bones and brain. Table 13.3 lists different cancers and common sites of metastasis.

For metastasis to occur, the cancerous cells must avoid detection by the immune system. Thus, impairment of the immune system is a major factor in the establishment of metastatic lesions. Cells may escape detection in several different ways:

- Aggressive cancer cells may compile a large mass (greater than 1 cm) so rapidly that the immune system is unable to overcome the tumour before it takes hold in a new tissue.

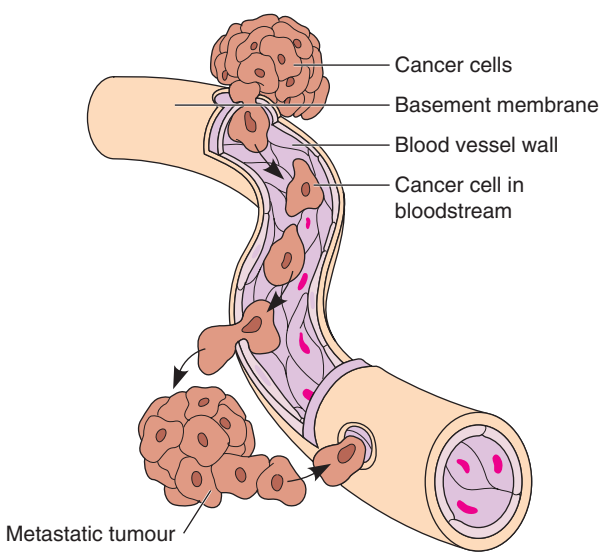

FIGURE 13.3 ■ Metastasis through the bloodstream. Cancer cells secrete enzymes and a motility factor that disrupt the basement membrane in the blood vessel. In this way, the cancer cells gain access to the circulation. Once in the blood, only about 1 cell in 1000 escapes immune detection, but that can be enough. Undetected cells move out of the blood, again secreting enzymes and cutting through the vessel wall into new tissue. The tissue selected for establishing a new tumour may be downstream from the original tumour or a chemical attraction may cause the malignant cells to target a specific site. Once in the new site, the malignant cells multiply and establish a metastatic tumour

TABLE 13.3 Various cancers and sites of metastases

PRIMARY TUMOUR	COMMON METASTATIC SITES
Bronchogenic (lung)	Spinal cord, brain, liver, bone
Breast	Regional lymph nodes, vertebrae, brain, liver, lung, bone
Colon	Liver, lung, brain, ovary, bone
Prostate	Bladder, bone (especially vertebrae), liver
Malignant melanoma	Lung, liver, spleen, regional lymph nodes, brain

BOX 13.4 Factors that may weaken or alter the immune response

- Accumulated stress
- Depression
- Increased age
- Pregnancy
- Chronic disease
- Chemotherapy treatment for the primary cancer

- For tumour cells to be recognised as foreign by the immune system, they must display on their surface a special antigen called tumour-associated antigen (TAA). TAA marks tumour cells for destruction by the lymphocytes. Some oncogenic viruses depress the expression of TAA on infected cells. Also, some tumours in advanced stages of growth no longer display TAA. Thus, such tumour cells escape detection as they travel through the blood or lymph.
- If the person's immune response is weakened or altered, then a metastatic tumour may take hold with little opposition. Factors that may weaken or alter the immune response are listed in Box 13.4.

An estimated 50% to 60% of all cancers have already metastasised by the time the primary tumour is identified. This may account for the current 50% death rate and certainly supports the need to educate people to facilitate early diagnosis. The time it takes for metastasis to occur is extremely variable and often difficult to predict. Some cancers, such as basal cell carcinomas, do not metastasise. The aggressiveness and location of the tumour and the state of the person's immune system determine how rapidly and whether metastasis will take place.

PHYSIOLOGICAL AND PSYCHOLOGICAL EFFECTS OF CANCER

Much of the nursing care for people with cancer is related to the generalised effects of cancer on the body and the side effects of the treatments used to remove or destroy the cancer. Although pathophysiological effects of the cancer vary with the type and location of the cancer, the following effects usually are observed.

Disruption of function

Physiological functioning can be upset by obstruction or pressure. For example, a large tumour in the bowel can stop intestinal motility, resulting in a bowel obstruction. Prostate tumours can obstruct the bladder neck or urethra, resulting in urine retention. Intracranial pressure can be dangerously increased by a glioma. Obstruction or pressure can cause anoxia and necrosis of surrounding tissues, which in turn cause a loss of function of the involved organ or tissue. For example, a kidney tumour may progress to renal failure. Pressure against the superior vena cava from an adjacent lung tumour or tumour-infiltrated lymph nodes can interrupt the blood flow to the heart.

In the liver, either a primary hepatocellular cancer or metastatic lesion can have several significant effects:

- In liver parenchymal tissue, it impairs the multiple life-sustaining functions of the liver, such as carbohydrate metabolism, synthesis of plasma proteins, detoxification and immunological functions. These functional impairments result in severe nutritional, hormonal, haematological and immunological problems. (See Chapter 20 for a more complete discussion of liver functions and effects of disruption.)
- Because more than 1 L of blood per minute passes through the liver via the portal vein, obstruction to this flow by a tumour can cause portal hypertension. This results in backup of fluid and increased pressure in the splanchnic circulation. The end result is ascites (third-spaced fluid in the peritoneal cavity) and varices (friable, over-distended blood vessels) of the oesophageal, gastric, mesenteric and haemorrhoidal vessels.

Haematological alterations

Haematological alterations can impair the normal function of blood cells. For example, in leukaemia, a malignant proliferative disease of the haematopoietic (blood-cell-producing) system, the immature leucocytes cannot perform the normal protective phagocytic functions and immunity is compromised. The excessive numbers of immature leucocytes in the bone marrow diminish erythrocyte and thrombocyte (platelet) production, resulting in secondary anaemia and clotting disorders.

Other examples of haematological alteration include the following:

- Gastrointestinal tumours disrupt the absorption of vitamin B12 and iron.
- Growing tumours need purines and folate and have a unique ability to accumulate and store these substances. Thus, the tumour deprives the bone marrow of these substances, which are needed for erythropoiesis (red blood cell production).
- Renal cell carcinoma produces its own erythropoietin hormone, which causes an excessively large number of red blood cells to be produced and dumped into the bloodstream. The resulting polycythaemia causes viscous blood, which impairs circulation, plugs small capillaries and promotes thrombus formation.

Infection

If the tumour invades and connects two incompatible organs, such as the bowel and bladder, and thus creates a fistula, infection becomes a serious problem. As they destroy viable tissue and thus their source of nutrition, tumours may become necrotic and septicaemia may result. Some tumours are less efficient in creating capillaries and, as a consequence, the centre of the tumour may become necrotic and infected. When a tumour grows near the surface of the body, it may erode through to the surface, thus breaking down the natural defences of intact skin and mucous membranes and providing a site for the entry of microorganisms. Any malignant involvement of the organs or tissues of immunity—such as the liver, bone

marrow, Peyer's patches in the small intestine, spleen or lymph nodes—can seriously impair the immune response, allowing infections to develop in vulnerable tissues.

Haemorrhage

Tumour erosion through blood vessels can cause extensive bleeding, giving rise to severe anaemia. Haemorrhage can be serious enough to cause life-threatening hypovolaemic shock.

Anorexia–cachexia syndrome

A characteristic feature of cancer is the wasted appearance of its victims, called **cachexia**. In many cases, unexplained rapid weight loss is the first symptom that brings the person to a healthcare provider. This can be due to a variety of problems associated with cancer, such as pain, infection, depression or the side effects of chemotherapy and radiation. However, usually the emaciation, malnutrition and loss of energy are attributed to the anorexia–cachexia syndrome.

This syndrome is specific to cancer because of the effect of cancer cells on the host's metabolism. The neoplastic cells divert nutrition to their own use while causing changes that reduce the person's appetite. Early in the disease, glucose metabolism is altered, causing an increase in serum glucose levels. Through the process of negative feedback, anorexia (loss of appetite) results. In addition, the tumour secretes substances that decrease appetite by altering taste and smell and producing early satiety. Pain, infection and depression also contribute to anorexia. Some types of cancers cause specific food aversions, such as to red meat, coffee or chocolate.

Avaricious cancer cells support their growth through widespread catabolism of the body's tissue and muscle proteins. This catabolism, coupled with inadequate nutrient intake, results in the typical cachexia. Normally, a starvation state reduces the body's basal metabolic rate. However, in many people with cancer, the metabolic rate is increased, probably because of the hyperactive metabolic and reproductive activities of the malignant cells. One theory suggests that cytokinins the body produces in response to the tumour are responsible for both early satiety and cachexia. One specific cytokine—called tumour necrosis factor alpha, or cachectin—is believed to enhance the increased metabolic consumption of nutrients. Cancers of the gastrointestinal system further promote anorexia–cachexia by decreasing absorption and use of nutrients; the side effects of some treatment modalities enhance this effect. Figure 13.4 shows the characteristic appearance of a cachectic person.

Paraneoplastic syndromes

Paraneoplastic syndromes are indirect effects of cancer. They may be early warning signs of cancer or indicate complications or return of a malignancy. The most frequently occurring paraneoplastic syndromes are endocrine, occurring when cancers set up ectopic sites of hormone production (Grossman & Porth, 2014). Table 13.4 lists laboratory indicators of ectopic functioning. These ectopic sites produce excessive amounts of the hormone, which harm the host. Consider the following examples:

FIGURE 13.4 ■ A cachectic person. Cancer robs its host of nutrients and increases body catabolism of fat and muscle to meet its metabolic needs

Source: Carole Gomez/Getty Images.

- Breast, ovarian and renal cancers may set up ectopic parathyroid hormone sites, causing severe hypercalcaemia.
- Oat cell and other lung cancers may produce ectopic secretions of insulin (causing hypoglycaemia), parathyroid hormone (PTH), antidiuretic hormone (ADH, which causes excessive fluid retention, hypertension and peripheral oedema) and adrenocorticotropic hormone (ACTH). See Chapter 18 for a description of the multiple problems caused by excessive secretions of cortisone.

Other paraneoplastic syndromes include haematological abnormalities such as anaemia, thrombocytopenia and coagulation abnormalities; nephrotic syndrome; cutaneous syndromes and neurological syndromes, such as distant tumours that produce increased ICP.

TABLE 13.4 Laboratory indicators of ectopic functioning

HORMONE	SPECIFIC LABORATORY TEST
Antidiuretic hormone (ADH)	Serum and urine osmolality
Adrenocorticotropic hormone (ACTH)	Plasma ACTH ACTH suppression test ACTH stimulation test Urine catecholamines
Calcitonin	Serum calcitonin
Insulin	Serum glucose Glucose tolerance test
Parathyroid hormone (PTH)	Serum PTH Serum calcium
Thyroxine	Serum thyroid-stimulating hormone (TSH), T_3, T_4

Pain

Pain is ranked as one of the most serious concerns of people with cancer, their families and oncology healthcare professionals. Despite extensive progress in the scientific understanding of pain, more than 60% of people with cancer experience moderate to severe pain at some time during their illness (Ogboli-Nwasor, Makama & Yusufu, 2013). Because pain management for people with cancer has a reputation for being ineffective, the anticipation of pain may engender fear in even the most stoic people. Most people fear pain and suffering even more than possible death, although pain management strategies have improved tremendously. The findings from a 10-year study of more than 2000 people in a palliative care program are encouraging. Following the World Health Organization guidelines for cancer pain relief, 88% of people reported good to satisfactory pain relief (Zech et al., 1995). Research on pain with its devastating statistics has led to great improvement in pain management strategies.

Types of cancer pain

Cancer pain can be divided into two main categories, acute and chronic, with subgroupings. These classifications serve to indicate appropriate therapeutic approaches. Acute pain has a well-defined pattern of onset, exhibits common signs and symptoms, and is often identified with hyperactivity of the autonomic system. Chronic pain, which lasts more than 6 months, frequently lacks the objective manifestations of acute pain, primarily because the autonomic nervous system adapts to this chronic stress. Unfortunately, chronic pain often results in personality changes, alterations in functional abilities and lifestyle disruptions that can seriously affect compliance with treatment and the quality of life.

Most people with cancer who cite acute pain as the primary symptom that led to the diagnosis tend to associate pain with the introduction to their disease. If these people experience pain during the illness or after therapy, they often perceive the pain as introducing another cancer or as a recurrence of the original cancer. Other people report experiencing pain as a component of cancer therapy. These people are often able to endure the pain in anticipation of a successful outcome of treatment (Rosedale & Fu, 2010).

Chronic pain may be related to treatment or may indicate progression of the disease. Identifying the pain as treatment-related rather than tumour-related is extremely important because it has a definite effect on the person's psychological outlook. For the person whose pain is due to the advancement of the disease, psychological factors play an even more important role. Hopelessness and fear of impending death intensify physiological pain and contribute to overall suffering, which goes well beyond just physical pain.

Three other categories used to classify people with cancer pain are worth mentioning: people with pre-existing pain, those with a history of drug abuse and people dying with cancer-related pain. The first two groups may have altered perceptions of pain and may not have the anticipated response to pain medication. For the dying person, pain is strongly associated with both the person and their family's confrontation of issues of hopelessness and death. Confronting these issues can intensify the perception of pain (see Chapter 4).

Causes of cancer pain

Direct tumour involvement is the primary cause of the pain experienced by people with cancer. This includes metastatic bone disease, nerve compression and involvement of visceral organs. The pain from tumour involvement is believed to be mechanical, resulting from stretching of tissues and compression. Chemicals from ischaemia or tumour metabolites and toxins that activate and sensitise nociceptors and mechanoreceptors are also responsible for tumour pain. See Chapter 8 for a more complete discussion of the mechanics of pain.

Side effects or toxic effects of cancer therapies (e.g. surgery, radiation and chemotherapy) may also cause cancer pain. These are usually the result of traumatised tissue; one example of this is the oropharyngeal ulcerations that occur with some types of chemotherapy. However, these therapies may also be used to manage pain, such as radiation to decrease pain associated with bone metastasis.

Physical stress

When the immune system discovers a neoplasm, it tries to destroy it using the resources of the body. The body mounts an all-out assault on the foreign invader, calling on many resources including chemical mediators, hormones and enzymes, blood cells, antibodies, proteins and inflammatory and immune responses.

These protective responses also mobilise fluid, electrolytes and nutritional systems. This massive effort requires tremendous energy. See Chapters 9 and 21 for specific information on these systems. If the neoplasm is small enough (i.e. microscopic), the immune system can destroy it and a tumour will never manifest. A neoplasm of 1 cm is large enough to overwhelm most immune systems; however, the body will continue to try to fight it until it reaches the stage of exhaustion and is no longer capable (Selye, 1984). Thus, many people with cancer present with fatigue, weight loss, anaemia, dehydration and altered blood chemistries (e.g. decreases in electrolytes).

Psychological stress

People confronted with the diagnosis of cancer exhibit a variety of psychological and emotional responses. Some people see cancer as a death sentence and experience overwhelming grief, often giving up. Others may feel guilt, considering the cancer a punishment for past behaviours, such as smoking or unhealthy eating habits, or for delaying diagnosis or treatment. The person may experience anger, especially if they believe that they had been practising a healthy lifestyle; beneath that anger may reside feelings of powerlessness. Fear is common: fear of the outcome of the illness, fear of the effects of treatment, fear of pain, fear of death. Some people feel isolated because of the stigma of cancer and old beliefs of contagion. Body image concerns and sexual dysfunction may be present but often unexpressed, especially if the cancer is of the breast or sexual organs or causes visible body changes. Box 13.5 summarises the physiological and psychosocial effects of cancer.

BOX 13.5 Physiological and psychosocial effects of cancer

- Disruption of function (due to obstruction or pressure)
- Haematological alterations
  a. Decreased leucocytes, erythrocytes and thrombocytes
  b. Altered erythropoiesis
- Infections
  a. Fistula between non-compatible organs
  b. Necrosis of tumour centre
  c. Malignant involvement of organs of immunity
- Haemorrhage (caused by erosion of neoplasm through blood vessels or surface of skin)
- Anorexia–cachexia syndrome
  a. Hyperglycaemia
  b. Catabolism of tissue and muscle proteins
  c. Altered taste and smell
- Creation of ectopic sites of hormones
  a. PTH
  b. Insulin
  c. ADH
  d. ACTH
- Paraneoplastic syndromes
  a. Deep venous thrombosis
  b. Peripheral nerve problems
  c. Increased intracranial pressure
  d. Anorexia–cachexia syndrome
  e. Nephrotic syndrome
- Pain
  a. Acute and chronic
  b. Caused by direct tumour involvement or side effects of therapy
- Physical stress
  a. Increased general adaptation syndrome activity
  b. Increased immunological activity
  c. Increased inflammatory response activity
  d. Nutritional, fluid and electrolyte alterations
- Psychological stress
  a. Grief
  b. Hopelessness
  c. Guilt
  d. Anger
  e. Fear
  f. Isolation
  g. Body image concerns
  h. Sexual dysfunction

Note: Manifestations depend on the type and location of the cancer.

INTERPROFESSIONAL CARE

Interprofessional care for the person with cancer begins with a variety of specialised laboratory and diagnostic tests.

Diagnosis

Several procedures are used to diagnose cancer. X-ray imaging, computed tomography (CT), ultrasonography and magnetic resonance imaging (MRI) can locate abnormal tissues or tumours. However, only microscopic histological examination of the tissue reveals the type of cell and its structural difference from the parent tissue. Tissue samples are acquired through biopsy, shedded cells (e.g. Papanicolaou smear) or collections of secretions (e.g. sputum). Lymph nodes are also biopsied to determine whether metastasis has begun. Simple screening procedures can be used to pick up substances secreted by the tumour, such as the prostatic-specific antigen (PSA) blood test which is being used to identify early prostatic cancers. Increases in enzymes or hormones released by normal tissues when they are damaged can also contribute to the diagnosis. Increased alkaline phosphatase noted in bone metastases and osteosarcoma is one example of an enzyme increase associated with cancer. Tumour markers are used for early diagnosis, for tracking responses to therapy and for devising immunological treatments.

Some investigators studying chemical mediators of the immune system have noted that there seems to be communication between the chemical mediators and the emotional centres of the brain. A person who states 'I feel I have cancer' should be listened to and the complaint investigated thoroughly.

CLASSIFICATION To help standardise diagnosis and treatment protocols, an elaborate identification system has been developed. This consists of naming the tumour (classification) and describing its aggressiveness (grading) and spread within or beyond the tissue of origin (staging).

Tumours are classified and named by the tissue or cell of origin. Tumour nomenclature often incorporates the Latin stem identifying the tissue from which the tumour arises. For example, a carcinoma arises from epithelial tissue; adjectives are added to further specify the location. A glandular malignancy arising from epithelial tissue is classified as an adenocarcinoma. A tumour arising from supportive tissues is called a sarcoma; the specific type of tissue is added as a prefix. For example, a cancer of fibrous connective tissue is called fibrosarcoma and a smooth muscle cancer is a leiomyosarcoma. A tumour from seminal or germ tissue is called a seminoma. Table 13.5 compares the nomenclature of benign and malignant neoplasms.

Other names for tumours incorporate the name of the discoverer of that particular cancer, such as Burkitt's lymphoma or Hodgkin's disease. Haematopoietic malignancies (also known as 'liquid tumours') are usually named by the type of immature blood cell that predominates. An example is myelocytic leukaemia, named for the immature form of the granulocyte that is predominant in this malignancy.

GRADING AND STAGING Grading evaluates the amount of differentiation (level of functional maturity) of the cell and estimates the rate of growth based on the mitotic rate. Cells that are the most differentiated—that is, most like the parent tissue

TABLE 13.5 Nomenclature for benign and malignant neoplasms

	TISSUE OF ORIGIN	BENIGN	MALIGNANT
Ectoderm/endoderm	Epithelium	Papilloma	Carcinoma
	Gland	Adenoma	Adenocarcinoma
	Liver cells	Hepatocellular adenoma	Hepatocellular carcinoma
	Neuroglia	Glioma	Glioma
	Melanocytes	Melanoma	Malignant melanoma
	Basal cells		Basal cell carcinoma
	Germ cells	Tetroma	Seminoma
Mesoderm	*Connective tissue*		
	Adipose tissue	Lipoma	Liposarcoma
	Fibrous tissue	Fibroma	Fibrosarcoma
	Bone tissue	Osteoma	Osteosarcoma
	Cartilage	Chondroma	Chondrosarcoma
	Muscle		
	Smooth muscle	Leiomyoma	Leiomyosarcoma
	Striated muscle	Rhabdomyoma	Rhabdomyosarcoma
	Neural tissue		
	Nerve cells	Ganglioneuroma	Neuroblastoma
	Endothelial tissues		
	Blood vessels	Haemangioma	Angiosarcoma
			Kaposi's sarcoma
	Meninges	Meningioma	Malignant meningioma
Haematopoietic tissues	Granulocytes	Granulocytosis	Leukaemia
	Plasma cells		Multiple myeloma
	Lymphocytes		Lymphoma

and therefore the least malignant—are classified as grade 1 and are associated with a better prognosis. Grade 4 is reserved for the least differentiated and most aggressively malignant cells. Because of the differences inherent in tumour appearance and biological behaviour, grading criteria may vary with different locations and types of tumours.

Staging is used to classify solid tumours and refers to the relative size of the tumour and extent of the disease. The TNM classification system is an internationally recognised staging system: T stands for the relative tumour size, depth of invasion and surface spread; N indicates the presence and extent of lymph node involvement; and M denotes the presence or absence of distant metastases. Table 13.6 shows the basic outline of the TNM system; however, other systems are also used to differentiate types and locations of tumours (e.g. melanomas, cervical cancer, Hodgkin's disease).

CYTOLOGICAL EXAMINATION

For malignant tissues to be identified by name, grade and stage, they must first be subjected to histological and cytological examination by light or electron microscope. Specimens are collected by three basic methods:

1. *Exfoliation from an epithelial surface*. Examples include scraping cells from the cervix (Pap smear) or bronchial washings.
2. *Aspiration of fluid from body cavities or blood*. Examples include white blood cells for evaluation of haematopoietic cancers, pleural fluid and cerebrospinal fluid.
3. *Needle aspiration of solid tumours*. This could include the breast, lung or prostate.

Cytological examination is also carried out on specimens from biopsied tissues or tumours and on collected body secretions, such as sputum or urine.

After collection, specimens are spread on a glass slide, fixed and stained if necessary. The morphological features of the cells are examined, with special attention to the nucleus and cytoplasm. Other special pathological procedures can be carried out on the specimen, but they must be ordered ahead of time if special preparations of the specimen are necessary. Several special diagnostic cytological procedures, such as cytogenetics, are proving useful in diagnosing and monitoring a person's response to treatment.

TUMOUR MARKERS

A **tumour marker** is a protein molecule detectable in serum or other body fluids. This marker is used as a biochemical indicator of the presence of a malignancy. Small amounts of tumour marker proteins are found in normal body tissues or benign tumours and are not specific for malignancy. However, high levels are suspicious and mandate follow-up diagnostic studies. Tumour marker tests are most useful for monitoring the person's response to therapy and for

TABLE 13.6 TNM staging classification system

	STAGE	MANIFESTATIONS
Tumour	T_0	No evidence of primary tumour
	T_{IS}	Tumour in situ
	T_1, T_2, T_3, T_4	Ascending degrees of tumour size and involvement
Nodes	N_0	No abnormal regional nodes
	N_{1a}, N_{2a}	Regional nodes—no metastasis
	N_{1b}, N_{2b}, N_{3b}	Regional lymph nodes—metastasis suspected
	N_x	Regional nodes cannot be assessed clinically
Metastasis	M_0	No evidence of distant metastasis
	M_1, M_2, M_3	Ascending degrees of metastatic involvement of the host including distant nodes

detecting residual disease. However, one marker, PSA, is a detector of prostate cancer. As a result, many healthcare practitioners recommend screening for it in men aged over 40, much as Pap smears and mammograms are recommended for women.

Tumour markers fall into two general categories: those derived from the tumour itself and those associated with host (immune) response to the tumour. Examples of tumour markers include the following:

- *Antigens.* These are present in foetal tissue but are normally suppressed after birth. Thus, their presence in large amounts may reflect an anaplastic process in tumour cells. Alpha-fetoprotein (AFP) and carcinoembryonic antigen (CEA) are oncofetal antigens.
- *Hormones.* Hormones are, of course, present in considerable amounts in human blood and tissues, but very high levels not related to other conditions may signify the presence of a hormone-secreting malignancy. Some common hormones seen as tumour markers include human chorionic gonadotropin (HCG), antidiuretic hormone (ADH), parathyroid hormone (PTH), calcitonin and catecholamines.
- *Proteins.* These narrow down the type of tissue that may be malignant, although they can also be increased in hyperplastic disorders. Examples of tissue-specific proeins include serum immunoglobin and beta-2 microglobulin.
- *Enzymes.* Rapid, excessive growth of a tissue may cause some of the enzymes and isoenzymes normally present in that particular tissue to spill into the bloodstream. Elevated levels can point to either hyperplasia of the tissue or cancer. Prostatic acid phosphatase (PAP) and neuron-specific enolase (NSE) are examples. Table 13.7 compares selected tumour-derived markers with their presence in neoplasms and other conditions.

ONCOLOGICAL IMAGING

Because physical assessment usually cannot detect cancer until the tumour has reached a size that poses a major risk of metastasis, radiological examination is extremely important in early diagnosis. This diagnostic process may involve routine x-ray imaging (usually for screening only), CT, MRI, ultrasonography, nuclear imaging, angiography and positron emission tomography.

TABLE 13.7 Tumour-derived markers associated with specific neoplasms

	TUMOUR MARKER	ASSOCIATED NEOPLASM
Oncofetal antigens	Carcinoembryonic antigen (CEA)	Adenocarcinomas of colon, lung, breast, ovary, stomach, pancreas
	Alpha-fetoprotein (AFP)	Hepatocellular carcinoma, gonadal germ-cell tumours (seminoma)
Hormones	Human chorionic gonadotropin (HCG)	Gonadal germ-cell tumours
	Calcitonin	Medullary cancer of thyroid
	Catecholamines/metabolites	Pheochromocytoma
Isoenzymes	Prostatic acid phosphatase (PAP)	Adenocarcinoma of prostate
	Neuron-specific enolase (NSE)	Small-cell lung carcinoma, neuroblastoma
Specific proteins	Prostate-specific antigen (PSA)	Adenocarcinoma of prostate
	Immunoglobin	Multiple myeloma
	CA 125	Epithelial ovarian cancer
	CA 19-9	Adenocarcinoma of pancreas, colon
	CA 15-3	Breast cancer

Source: Adapted from The pathologic evaluation of neoplastic disease by J. D. Pfeifer & M. R. Wick (1995). In A. I. Holleb, D. J. Fink & G. P. Murphy (eds), *American Cancer Society Textbook of Clinical Oncology*, pp. 75–95. Atlanta: American Cancer Society.

X-ray imaging Considered the least expensive and least invasive diagnostic procedure, film screen imaging (standard x-ray imaging) is the method of choice for screening such body areas as the breast (mammography), lung and bone to identify changes in tissue density that may indicate malignancies. X-ray studies are limited in that they do not easily distinguish between calcifications, benign cystic growths and true malignancies. However, as a screening tool, x-ray imaging can usually reassure the person if findings are negative or encourage follow-up studies if findings are suspicious. X-ray imaging is still the method of choice for lung cancer. Unfortunately, it does not usually reveal tumours until they have reached about 1 cm in size, which is late in their development.

Computed tomography CT has vastly advanced the effectiveness of traditional x-ray methods. CT allows the visualisation of cross-sections of the anatomy, and can reveal subtle differences in tissue densities; they provide much greater accuracy in tumour diagnosis. This procedure is useful in the screening for some cancers such as renal cell and most gastrointestinal tumours. CT scans are especially useful to evaluate possible lymph node involvement.

Magnetic resonance imaging MRI involves computerised mathematical technology. The person is placed within a strong magnetic field, pulsed radio waves are directed at the person and transmitted signals, based on tissue characteristics, are analysed by a computer. Related diagnostic imaging procedures—positron emission tomography (PET) and single photon emission computed tomography (SPECT)—create visible images by measuring electrical impulses from different body structures. MRI is the diagnostic tool of choice for both screening and follow-up of cranial and head and neck tumours.

Some people become claustrophobic during the MRI procedure because they must be placed inside the diagnostic imaging machine. The machines make loud thumping sounds that can be frightening if the person is not informed beforehand that this is normal.

Ultrasonography Ultrasonography measures sound waves as they bounce off various body structures, giving an image of normal anatomy as well as revealing abnormalities that indicate tumours. Ultrasonography has been adapted for diagnosing some specific tumours. For example, transrectal ultrasonography has provided excellent imaging of early prostate cancers and is used to guide needle biopsy. Ultrasound imaging is also more useful for detecting masses in the denser breast tissue of young women.

Nuclear imaging Nuclear imaging involves the use of a special scintillation scanner in conjunction with the ingestion or injection of specific radioactive isotopes. This is an invasive but usually safe diagnostic method for identifying tumours in various body tissues. This procedure is often used to check for possible bone or other organ metastases. This evaluation helps the healthcare provider determine appropriate treatment.

The procedure is usually minimally distressing for people. Drinking the isotope solution is not pleasant but is tolerable; some anxious people may have difficulty lying still during the scan. Anti-anxiety medication may help. Some people may experience nausea from drinking the isotope and require antiemetic drugs to complete the procedure. Preparation for the person may include allowing nothing by mouth or clear fluids only after midnight.

Angiography An expensive and invasive procedure, angiography is used infrequently for tumour diagnosis. Angiography is performed when the precise location of the tumour cannot be identified or there is a need to visualise the tumour's extent prior to surgery. The procedure involves injecting a radiopaque dye into a major blood vessel proximal to the organ or tissue to be examined. The movement of the dye through the vasculature of the organ or tissue is then traced by means of fluoroscopy or serial x-ray films. In some cases, small catheters are threaded through the vein under fluoroscopy to ensure the specific placement of the dye. Blockage to the flow of the dye indicates the tumour's location. Dye may also be used to identify blood vessels supplying a tumour, allowing the surgeon to know where to safely ligate vessels. Angiography requires preparation similar to that for minor surgery. This includes ensuring that the person takes in only fluids on the day of the examination, performing skin preparation at the insertion site and administering sedative drugs prior to the procedure. People should be informed that injection of the dye used to enhance imaging may cause a hot, flushing sensation or nausea and vomiting. Although angiography is usually done on an outpatient basis, the person will be kept in a short-stay unit for several hours and monitored for such complications as bleeding at the catheter insertion site.

DIRECT VISUALISATION Direct visualisation procedures are invasive but do not require the use of radiography. Examples include the following:

- sigmoidoscopy (viewing the sigmoid colon with a fibre-optic flexible sigmoidoscope)
- cystoscopy (viewing the urethra and bladder)
- endoscopy (viewing the upper gastrointestinal tract)
- bronchoscopy (inspecting the tracheobronchial tree).

These methods allow the visual identification of the organs within the limits of the scope and usually permit biopsy of suspicious lesions or masses. Flexible fibre-optic scopes may be more useful, because they allow deeper penetration than do traditional scopes. These procedures all require the person to complete some preparation, cause moderate to considerable discomfort and may require sedation or even anaesthesia, as in the case of bronchoscopy. Some procedures, such as sigmoidoscopy and cystoscopy, may be performed in the doctor's surgery and therefore cost less, making them more accessible screening procedures.

Preparation of the person includes a thorough bowel cleansing prior to sigmoidoscopy and cystoscopy; the person may ingest only liquids the morning of the procedure. Because anaesthesia may be required, people undergoing bronchoscopy and endoscopy may be instructed to have nothing by mouth from midnight until the procedure. These procedures are discussed in greater detail in later chapters of this textbook. When the tumour is exposed, a sample of tissue (biopsy) is sent to the pathology laboratory for a 'frozen-section' histological examination. This can be done rapidly while the person remains on the operating table under anaesthesia. If the initial report is

negative, the benign mass is usually removed to prevent further symptoms. If the report is positive for cancer, the tumour and, often, adjacent lymph nodes are resected, along with any other suspicious tissue. The tumour, nodes and any other specimens are sent to the pathology laboratory for more in-depth analysis. The person then receives the usual postoperative care.

LABORATORY TESTS Most laboratory tests of blood, urine and other body fluids are used to rule out nutritional disorders and other non-cancerous conditions that may be causing the person's symptoms. For example, a full blood count (FBC) helps screen for such problems as anaemia, infection and impaired immunity. Blood chemistries can point out nutritional disturbances and electrolyte imbalances. In conjunction with other diagnostic studies, some laboratory tests can be quite useful either in screening for other pathological conditions or for validating the cancer diagnosis (Kee, 2014). These tests include evaluating levels of enzymes such as alanine aminotransferase (alT), aspartate aminotransferase (AST) and lactic dehydrogenase (LDH) for liver metastases. Special protein tumour markers such as PSA for prostate cancer and CEA for colon cancer are also used. Table 13.8 identifies some useful laboratory tests, their normal values and their possible indications.

TABLE 13.8 Laboratory tests used for cancer diagnosis*

TEST	REFERENCE VALUE	ABNORMALITY INDICATED
Acid phosphatase (ACP)		No longer used for prostatic cancer diagnosis
Adrenocorticotropic hormone (ACTH)	8–80 pg/mL	Decreased in adrenal cancer Elevated in pituitary cancer or with tumour that secretes ACTH (bronchiogenic cancer)
Alanine aminotransferase (alT)	Female < 35 u/L Male < 40 u/L	Moderate elevation in liver cancer
Albumin	35–40 g/L	Decreased in malnutrition, metastatic liver cancer
Alkaline phosphatase (alP)	Adult 35–135 u/L	Elevated in cancer of liver, bone, breast and prostate, in leukaemia and in multiple myeloma
Alpha-fetoprotein (AFP)	Male and non-pregnant female: < 11 ng/mL	Elevated in germ-cell tumours (e.g. seminoma), testicular cancer
Aspartate aminotransferase (AST)	< 42 u/L	Elevated in liver cancer
Bilirubin	< 20 mg/dL	Elevated in liver and gallbladder cancer
Bleeding time	Ivy method: 2–9 minutes	Prolonged in leukaemia and metastatic liver cancer
Blood urea nitrogen (BUN)	3.0–8.0 mmol/L	Decreased in malnutrition; increased in renal cancer
Calcitonin	Male: < 40 pg/mL Female: < 20 pg/mL	Elevated to > 500 pg/mL in thyroid medullary cancer, breast cancer and lung cancer
Calcium (Ca)	2.15–2.65 mmol/L	Elevated in bone cancer and ectopic parathyroid hormone production (paraplastic syndrome)
Carcinoembryonic antigen (CEA)	2.5 ng/mL in non-smokers 5 ng/mL in smokers; > 12 ng/mL neoplasms	Elevated with GI cancers, lung, breast, bladder, kidney, cervical cancers and leukaemias. Used to evaluate effectiveness of cancer treatment
Chloride (Cl)	95–108 mmol/L	Decreased in vomiting, diarrhoea, syndrome of inappropriate antidiuretic hormone (SIADH)
C-reactive protein	< 10 mg/L	Elevated in metastatic cancer and Burkitt's lymphoma
Creatinine	Male: 50–110 µmol/L Female: 40–80 µmol/L	Decreased in malnutrition; elevated in most cancers
Dexamethasone suppression test	> 50% reduction in plasma cortisol	Non-suppression in adrenal cancer and ACTH-producing tumours, severe stress
Oestradiol	Female: 20–300 pg/mL Menopausal female: < 20 pg/mL Male: 15–50 pg/Ml	Elevated in oestrogen-producing tumours and testicular tumours
Fibrinogen	2.0–4.0 g/L	Decreased in leukaemia and as a side effect of chemotherapy
Gamma glutamyltransferase (GammaGT)	Male: < 60 u/L Female: < 40 u/L	Elevated in cancer of liver, pancreas, prostate, breast, kidney, lung and brain
Fasting blood sugar	3.5–5.5 mmol/L	Decreased in malnutrition, cancer of stomach, liver and lung

(continued)

TABLE 13.8 Laboratory tests used for cancer diagnosis* (continued)

TEST	REFERENCE VALUE	ABNORMALITY INDICATED
Haptoglobin	0.3–2.0 g/L	Elevated in Hodgkin's disease and cancer of lung, large intestine, stomach, breast and liver
Haemoglobin (Hgb)	Male: 132–170 g/L Female: 115–155 g/L	Decreased in anaemia, many cancers, Hodgkin's disease, leukaemia and malnutrition, and as a side effect of chemotherapy
Human chorionic gonadotropin (HCG)	Non-pregnant female: < 0.01 international unit/L	Elevated in choriocarcinoma
Insulin	5–25 microunit/mL	Elevated in insulinoma (islet cell tumour) and insulin-secreting cancers (e.g. lung cancer)
Lactic dehydrogenase (LDH)	200–400 u/L	Elevated in liver, brain, kidney, muscle cancers, acute leukaemia, anaemia
Occult blood	Negative	Positive in gastric and colon cancers
Serum osmolality	280–300 mOsm/kg H_2O	Decreased in SIADH
Urine osmolality	50–1200 mOsm/kg H_2O	Increased in SIADH
Parathyroid hormone (PTH)	1.5–6.5 pg/mL	Increased in PTH-secreting tumours
Platelet (thrombocyte) count	150–400 ($\times 10^9$/L)	Decreased in bone, gastric and brain cancer, in leukaemia and as a side effect of chemotherapy
Potassium (K)	3.4–5.5 mmol/L	Decreased in vomiting and diarrhoea, and in malnutrition
Prostatic-specific antigen (PSA)	Age-dependent 2.5–6.5 mg/L	Elevated from 10 to 120+ in prostate cancer
Total protein	60–80 g/L	Decreased in malnutrition, gastrointestinal cancer, Hodgkin's disease; elevated in vomiting, diarrhoea, multiple myeloma
Red cell count (RBCs)	Male: 4.5–5.5 million/mm^3 Female: 3.8–4.8 million/mm^3	Decreased in anaemia, leukaemia, infection, multiple myeloma
Sodium (Na)	134–146 mmol/L	Decreased in SIADH, vomiting; elevated in dehydration
Uric acid	Male: < 0.44 mmol/L Female: < 0.38 mmol/L	Increased in leukaemia, metastatic cancer, multiple myeloma, Burkitt's lymphoma and after vigorous chemotherapy
White blood cells (WBC)		
Total leucocytes	4500–10 000/mm^3	Elevated in acute infection, leukaemias, tissue necrosis; decreased as a side effect of chemotherapy
Neutrophils	50–70%	Elevated in bacterial infection and Hodgkin's disease; decreased in leukaemia and malnutrition, and as a side effect of chemotherapy
Eosinophils	1–3%	Elevated in cancer of bone, ovary, testes and brain
Basophils	0.4–1.0%	Elevated in leukaemia and healing stage of infection
Monocytes	4–6%	Elevated in infection, monocytic leukaemia and cancer; decreased in lymphocytic leukaemia and as a side effect of chemotherapy
Lymphocytes	25–35%	Elevated in lymphocytic leukaemia, Hodgkin's disease, multiple myeloma, viral infections and chronic infections; decreased in malnutrition, cancer and other leukaemias, and as a side effect of chemotherapy

*All values refer to serum values unless otherwise indicated. Values are approximate; check the reference standards specified by your own organisation's laboratory.

PSYCHOLOGICAL SUPPORT DURING DIAGNOSIS

Preparing for and awaiting the results of diagnostic tests can create extreme anxiety. Many people compare the experience to that of a prisoner awaiting trial and sentencing: after they know what the 'sentence' is, they can then prepare for the future. In addition to coping with the possibility of a life-threatening disease or at least a life-altering one, people often also face the prospect of uncomfortable, even painful, diagnostic procedures. They have important decisions to make that depend on the outcome of those tests. Many unspoken questions may exist, including the following:

- Do I have cancer?
- If so, what kind and how serious?
- Has it spread?
- Will I survive?
- What kind of treatment is needed?

- How will this affect my lifestyle?
- How will this affect my family members and friends?

Denial or intellectualisation serves some people well, but others display signs of anxiety and stress as they attempt to cope. The nurse can provide valuable support during this very difficult stage by helping people become actively involved in managing their life and disease. Talk with the person as soon as they enter the healthcare system, asking what they know already about what is going to happen and soliciting questions from them. Taking this approach and encouraging people to share what knowledge and experience they have allows them to maintain control. From there, the nurse can provide the information needed.

It is essential that people thoroughly understand the preparation required for their tests, especially if they will be preparing at home. They also need to be informed of any unusual effects that may occur as a result of the procedure, such as nausea from radioactive dye. If possible, a phone call the evening before to verify the person's understanding of the procedure and to answer questions can be helpful and supportive.

As the person begins to feel more comfortable with the nurse, they may express concerns, fears and other emotions. The nurse should actively listen and be supportive, but avoid giving advice and false reassurance, providing appropriate information when needed. For people who are not ready to discuss their concerns, or for those who appear angry, being non-judgmental and providing non-verbal support may facilitate more open communication. An atmosphere of calmness, warmth, caring and respect can ease the tension and often unspoken terror of this initial period.

Support of and communication with the person's significant others is extremely important. Often they try to be strong for the person but have many fears and emotional concerns that they do not feel comfortable expressing. The nurse needs to be available to the family while the person is undergoing diagnostic procedures. Allowing them to talk without the need to edit for the person's benefit can help them manage their own difficulties in coping with their loved one's potential cancer diagnosis.

Cancer treatment

The goals of cancer treatment are aimed at cure, control or palliation of symptoms. These goals may overlap. Cancer may be treated through surgery, chemotherapy, radiation therapy, biotherapy, photodynamic therapy, bone marrow and stem cell transplants, and complementary therapies. Once cancer is diagnosed, the initial focus is on surgical and medical treatment. The goals of treatment are:

- eliminating the tumour or malignant cells
- preventing metastasis
- reducing cellular growth and the tumour burden
- promoting functional abilities and providing pain relief to those whose disease has not responded to treatment.

SURGERY Surgery was once considered the only treatment for cancer before the mechanisms of cancer were understood. Today, surgery remains an important approach in cancer care. Surgical resection is used for diagnosis and staging of more than 90% of all cancers and for primary treatment of more than 60% of cancers. The goals of surgery have also expanded to include prophylaxis, diagnosis, treatment, reconstruction and palliation.

Prophylactic surgery aims to remove tissues or organs that are likely to develop cancer. Advances in identification of genetic markers make prophylactic surgery an option for individuals with a strong family history and genetic predisposition for the development of cancer. For example, a woman with a strong history of breast cancer, positive findings of BRCA-1 or BRCA-2 and abnormal finding on mammography may consider prophylactic mastectomy as one of the selective options. Other examples of prophylactic operations include colectomy and oophorectomy. With limited research on the long-term physiological and psychological effects on individuals undergoing prophylactic surgery for cancer, it is vital for nurses and other healthcare professionals to discuss the potential risks and postoperative outcomes of the prophylactic surgery thoroughly with the person and their family prior to the surgery. Nurses should respect the person's decision whether or not to pursue the prophylactic surgery. For those people who choose prophylactic surgery as a preventive measure for cancer, comprehensive preoperative teaching and counselling should be provided and long-term postoperative follow-up should be ensured to monitor the person's physiological and psychological adjustment to the surgery.

Diagnostic surgery aims to ensure histological diagnosis and staging of cancer through biopsy, endoscopy, laparoscopy and open surgical exploration. Table 13.9 provides information about common surgical diagnostic procedures.

As a primary treatment for cancer, the goal of surgery is to remove the entire tumour and involved surrounding tissue and lymph nodes as much as possible and feasible. This sometimes

TABLE 13.9 Surgical diagnostic procedures

PROCEDURE	EXPLANATION
Fine-needle biopsy	Use of a very thin needle to aspirate a small amount of tissue from the tumours
Needle core biopsy	Use of a slightly larger needle than that used for a fine-needle biopsy to extract a small amount of tissue from tumours that cannot be aspirated by fine-needle aspiration
Incisional biopsy	Removal of part of a larger tumour by cutting through the skin
Excisional biopsy	Removal of an entire tumour through operation
Endoscopy	Use of a small viewing lens or video camera through natural body openings to view tumours such as cancer of the oesophagus, stomach or colon
Laparoscopy	Use of a small viewing lens or video camera through a small incision in the abdominal wall

necessitates mutilation of the body and the creation of new structures to assume the function of the lost structures. For example, removal of the distal sigmoid colon and rectum requires a new means of bowel elimination, so the remaining healthy segment of the bowel is brought out through a created opening (stoma) in the abdominal wall, resulting in a permanent colostomy (see Chapter 23). In like manner, when the bladder is removed, the ureters are transplanted into a created pouch just under the abdominal wall. This serves as a continent ileostomy, a substitute reservoir for urine (see Chapter 26). Surgery can also destroy sensitive nerve plexuses, resulting in alteration or loss of normal functioning; for example, prostate surgery may result in incontinence and impotence. Surgical removal of involved regional lymph nodes can also lead to long-term lymphoedema (swelling in the affected area) that greatly inpacts on cancer survivors' quality of life; for instance, lymphoedema following surgery for breast cancer and melanoma (Norman et al., 2009).

Not all surgery results in such radical changes in functioning. The following surgeries can eliminate cancer successfully with less distressing results:

- removing a non-essential portion of the organ or tissue containing the tumour, such as in situ small-bowel tumours
- removing an organ whose function can be replaced chemically, such as the thyroid
- resecting one of a pair of organs when the unaffected organ can take over the function of the missing one, such as a lung.

Although the removal of any major body part has physiological and psychological consequences, the alternative—terminal disease—is usually less desirable.

If the tumour is in a non-resectable location or deeply invasive with metastases, surgery may be a palliative measure to allow the involved organs to function as long as possible, to relieve pain and provide comfort, or to bypass an obstruction. Surgery may also be done to reduce the bulk of the tumour in advanced disease, both at primary and metastatic sites. Decreasing the tumour size enhances the ability to control the remaining disease through other modalities. Surgery is often used in conjunction with other treatments to effect a cure. In cases when extensive removal of tissue is contraindicated (e.g. in surgical removal of a brain tumour), radiation may be used prior to surgery in an attempt to shrink the tumour before it is removed.

Surgical intervention may also be used for reconstruction and rehabilitation to achieve more desirable functional and cosmetic effects after curative or radical surgery. One example is the construction of transabdominal myocutaneous (TRAM) flaps in conjunction with or following modified radical mastectomy (see Chapter 48). For surgical interventions for cancers affecting specific body systems, refer to later chapters.

Surgical oncologists are working with researchers to identify premalignant disease earlier in high-risk populations and to conduct studies on ways to reverse oncogenic cell activity. Surgeons also work with molecular biologists using sophisticated techniques to develop monoclonal antibodies. Laser technology is being explored for use in different types of cancer surgery because it minimises blood loss, reduces deformity, increases the accuracy of tissue resection and enhances healing. Lasers are currently being used to treat radical prostatectomy in order to preserve urinary continence and sexual functioning. Another collaborative strategy under development is intraoperative radiation therapy, in which radiosensitive, non-diseased organs that may be damaged by radiation therapy are moved away from the radiation field and shielded. Radiation is then administered while the person is on the operating table. This technique allows more penetrating radiation to be directed to the malignant tumour with less trauma to normal, vulnerable tissues or organs.

Nursing responsibilities focus on preparing the person physically and psychologically for the specific surgery, as well as teaching routine postoperative care in which the person is expected to participate. For example, the nurse teaches the person about respiratory care and deep breathing to improve postoperative ventilation, about early ambulation to prevent circulatory problems and about how the person will receive fluids and nutrition (intravenously or orally, depending on the type of surgery). In addition, the nurse explains the specific surgical procedure and any anticipated alterations to the person's body, especially those that require major lifestyle adjustments, such as a colostomy. Before surgery, the nurse should give the person the opportunity to ask questions and to discuss concerns and fears. In some cases, the person may want to discuss alternative treatment options. In the latter case, the nurse should contact the oncologist and the surgeon and set up a conference for the person before surgery.

CHEMOTHERAPY

Chemotherapy involves the use of cytotoxic medications to cure some cancers, such as leukaemias, lymphomas and some solid tumours; to decrease tumour size, adjunctive to surgery or radiation therapy; or to prevent or treat suspected metastases. Chemotherapy may also be used in conjunction with biotherapy. All chemotherapy has side effects or toxic effects. The type and severity depend on the drugs used.

Chemotherapy disrupts the cell cycle in various phases by interrupting cell metabolism and replication. It also works by interfering with the ability of the malignant cell to synthesise vital enzymes and chemicals. Phase-specific drugs work during only some phases of the cell cycle; non-phase-specific drugs work through the entire cell cycle. Figure 13.5 lists some of the drugs useful in each phase of the cell cycle.

Most chemical treatment involves combinations of drugs in specific protocols given over varying periods of time. One protocol for adult acute lymphocytic leukaemia (alL) uses the acronym DVPA: daunorubicin given on days 1 to 3; vincristine given on days 1, 8, 15 and 22; prednisone given on days 1 to 28 and asparaginase given on days 17 to 28. The treatment regimen is given in cycles with rest periods allowed, especially if toxic effects such as liver dysfunction or severe neutropenia occur. The treatment is continued until the disease goes into remission. If the disease progresses, the particular protocol is abandoned and a new one may be tried.

The cell-kill hypothesis explains why several courses of chemotherapy are necessary. A 1-cm tumour contains about 10^9 (10 billion) total cells, most of which are viable. During

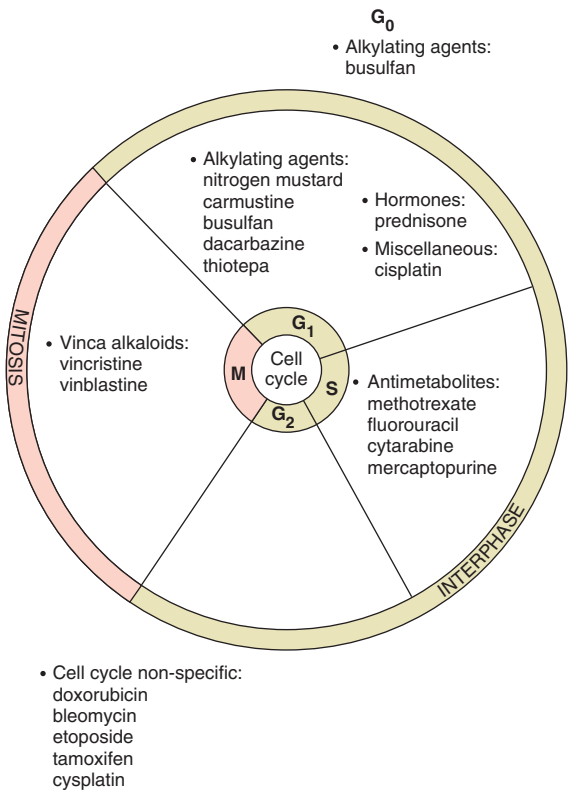

FIGURE 13.5 ■ Chemotherapeutic drugs useful in each phase of the cell cycle. Based on their chemical make-up and biological activity, different drugs used for cancer treatment act in specific phases and subphases of the cell cycle. Some drugs, called non-phase-specific drugs, are generalised and act throughout the cycle. Chemotherapy often involves combinations of drugs designed to attack the cancer cells at many different times in the cycle and thus to enhance effectiveness

each cell cycle, the chemotherapy kills a fixed percentage of cells, always leaving some behind. With each reduction, the tumour burden of cells decreases until the number of viable, clonogenic cells (i.e. those that are able to clone daughter cells) becomes small enough to allow the body's immune system to finish the job. Oncologists usually give the maximum amount of chemotherapy tolerated by the person. High-dose chemotherapy remains controversial.

Classes of chemotherapy drugs Chemotherapeutic agents can be classified either by the effects of the agent on the cell or by the pharmacological properties of the agent. According to the effects of the agent on the cell, chemotherapeutic agents can be divided into cell-cycle-specific and cell-cycle-non-specific agents. Cell-cycle-specific agents are effective at a specific phase (e.g. S and M phases) in the cell cycle to prevent cell replication by damaging cellular DNA and blocking production of protein necessary for DNA and RNA synthesis. Cell-cycle-non-specific agents are effective throughout all the phases of the cell cycle, including the resting phase. Both cell-cycle-specific and cell-cycle-non-specific agents are effective in rapidly dividing cells to prohibit the growth of fast-growing tumours.

The most common way of classifying chemotherapeutic agents is based on pharmacological properties of the agent. The classifications include alkylating agents, antimetabolites, antitumour antibiotics, mitotic inhibitors, hormones and hormone antagonists, and miscellaneous agents.

Alkylating agents Alkylating agents are not phase specific and basically act on preformed nucleic acids by creating defects in tumour DNA. They cause crosslinking of DNA strands, which can permanently interfere with replication and transcription.

Alkylating agents work with both proliferating and non-proliferating cells (those in the G_0 phase). Their toxicity relates to their ability to kill slowly cycling stem cells and manifests in delayed, prolonged or permanent bone marrow failure. Toxicity can also cause a mutagenic effect on bone marrow stem cells, culminating in a treatment-resistant form of acute myelogenous leukaemia. Because of the alkylating agents' effect on stem cells, they also cause irreversible infertility. Other common adverse effects include nephrotoxicity and haemorrhagic cystitis.

The several subclasses of alkylating agents include nitrogen mustard (mechlorethamine), nitrosoureas (carmustine), alkyl sulfonates (busulfan), triazines (dacarbazine), ethyleneimines (thiotepa) and cisplatin. Cisplatin is an alkylating agent containing platinum and chlorine atoms. It is most active in the G_1 subphase, but it is also not phase specific. Cisplatin binds to DNA and acts much like alkylating agents by forming intrastrand DNA crosslinks (gluing strands of DNA together so that they cannot separate). Its major toxic effect is reversible renal tubular necrosis. Cisplatin may be used alone or in combination with other chemotherapeutic drugs for testicular and ovarian cancers.

Antimetabolites The different types of antimetabolites include folic acid analogues (methotrexate), pyrimidine analogues (5-fluorouracil), cytosine arabinoside (ARA-C) and purine analogues (6-mercaptopurine). Antimetabolites are phase specific, working best in the S phase and having little effect in G_0. They interfere with nucleic acid synthesis by either displacing normal metabolites at the regulatory site of a key enzyme or by substituting for a metabolite that is incorporated into DNA or RNA molecules. Toxic effects usually do not occur until very high levels of the drug are administered. Toxicity is also more likely when the drugs accumulate in third-spaced fluid, such as pleural fluid (a characteristic that also makes them useful in treating malignant pleural effusions). Because the drug diffuses out slowly from the third-spaced fluid, exposure of the tissue to the drug is prolonged. Most toxic effects relate to rapidly proliferating cells, such as cells in the gastrointestinal tract, hair and skin, and white blood cells (WBCs). Signs and symptoms include nausea and vomiting, stomatitis, diarrhoea, alopecia and leukopenia. Some of the drugs can also cause liver and pulmonary toxicity.

Antitumour antibiotics Antitumour antibiotics derived from natural sources that are generally too toxic to be used as antibacterial agents. They are not phase specific and act in several ways: they disrupt DNA replication and RNA transcription; create free radicals, which generate breaks in DNA and other

forms of damage; and interfere with DNA repair. These drugs bind to cells and kill them, probably by damaging the cell membrane. Their main toxic effect is damage to the cardiac muscle. This limits the amount and duration of treatment. Examples of these antibiotics include actinomycin D, doxorubicin, bleomycin, mitomycin-C and mithramycin.

Mitotic inhibitors Mitotic inhibitors are drugs that act to prevent cell division during the M phase. Mitotic inhibitors include the plant alkaloids and taxoids. Plant alkaloids consist of medications extracted from plant sources: vinca alkaloids (e.g. vincristine and vinblastine) and etoposide (also called VP-16). The vinca alkaloids are phase specific, acting during mitosis. They bind to a specific protein in tumour cells that promotes chromosome migration during mitosis and serves as a conduit for neurotransmitter transport along axons. The toxicity of these drugs is characterised by depression of deep tendon reflexes, paraesthesias (pain and altered sensation), motor weakness, cranial nerve disruptions and paralytic ileus. Etoposide acts in all phases of the cell cycle, causing breaks in DNA and metaphase arrest. Although etoposide may cause bone marrow suppression and nausea and vomiting, the most common toxic effect is hypotension resulting from too rapid intravenous administration.

The taxoids act during the G_2 phase to inhibit cell division. Paclitaxel is used for the treatment of Kaposi's sarcoma and metastatic breast and ovarian cancer. Taxotere is used for breast cancer. Toxicities associated with these drugs include alopecia, bone marrow depression and severe hypersensitivity reactions (e.g. hypotension, dyspnoea and urticaria).

Hormones and hormone antagonists The main hormones used in cancer therapy are the corticosteroids (e.g. prednisone), which are phase specific (G_1). These act by binding to specific intracellular receptors, repressing transcription of mRNA and thereby altering cellular function and growth. Corticosteroids have multiple side effects such as impaired healing, hyperglycaemia, hypertension, osteoporosis and hirsutism.

Hormone antagonists work with hormone-binding tumours, usually those of the breast, prostate and endometrium. They block the hormone's receptor site on the tumour and prevent it from receiving normal hormonal growth stimulation. These drugs do not cure, but do cause regression of the tumour in about 40% of breast and endometrial tumours, and 80% of prostate tumours. Tamoxifen competes with oestradiol receptors in breast tumours. Raloxifene blocks oestrogen in the breast. Diethylstilbestrol competes with hormone receptors in endometrial and prostate tumours. Antiandrogen (Flutamide) and luteinising-hormone-releasing hormones block testosterone synthesis in prostate cancers. The main side effects of these drugs are alterations of the secondary sexual characteristics.

Miscellaneous agents Several miscellaneous agents act at different phases in the cell cycle. L-Asparaginase and hydroxyurea are examples of miscellaneous agents.

Effects of chemotherapeutic drugs As described, the side effects and toxic effects of chemotherapy vary with the drug used and the length of treatment. Because most of these drugs act on fast-growing cells, the side effects are manifestations of damage to normal rapidly dividing somatic cells. The side effects of hormones express the action of the hormone used or suppression of the normal hormone, such as the masculinising effects of male hormones administered for ovarian cancers.

Tissues usually affected by cytotoxic drugs include the following:

- Mucous membranes of the mouth, tongue, oesophagus, stomach, intestine and rectum. This may result in anorexia, loss of taste, aversion to food, erythema and painful ulcerations in any portion of the gastrointestinal tract, nausea, vomiting and diarrhoea.
- Hair cells, resulting in alopecia.
- Bone marrow depression affecting most blood cells (e.g. granulocytes, lymphocytes, thrombocytes and erythrocytes). This results in an impaired ability to respond to infection, a diminished ability to clot blood and severe anaemia.
- Organs, such as heart, lungs, bladder, kidneys. This kind of damage is related to specific agents, such as cardiac toxicity with doxorubicin or pneumonitis with bleomycin.
- Reproductive organs, resulting in impaired reproductive ability or altered foetal development.

Table 13.10 gives the classifications of chemotherapeutic drugs, common examples, target malignancies, adverse effects and side effects, and nursing implications. Consult current pharmacology textbooks for additional drugs and for new combination therapies as they are developed.

Preparation and administration Australia has legislative Acts and regulations (including, but not limited to, *Occupational Health and Safety Act (OH&S) 2000*, OH&S Regulations 2001, *Poisons & Therapeutic Goods Act 1966*, *Cytotoxic Drugs & Related Waste: Risk Management Guide 2008* and Australian Radiation Protection and Nuclear Safety Agency—Radiation Protection Series Codes and Guides) that govern the handling, labelling, transport, waste disposal, documentation and the designation, training and employee health monitoring of staff engaged in duties with the potential for exposure to radiation. Organisations are required to have procedures in place to minimise risk to staff (environmental and personal protective equipment) when preparing, administering and disposing of chemotherapeutic drugs, and individuals are required to demonstrate duty of care and to follow legislative and organisational guidelines. Refer to your organisation's policy/procedures. It is the nurse's responsibility to ensure they are working within their NMBA (formerly ANMC) competency standards. The nurse is required to teach people to dispose of their own body fluids safely. Oral medications pose a lesser risk of exposure, but a risk nonetheless, primarily through excretion in the urine.

Chemotherapeutic drugs, such as cyclophosphamide and chlorambucil, can be administered orally. Other drugs, such as hormones or hormone-blocking agents, may also be given intramuscularly. However, many drugs require intravenous infusion or direct injection into intraperitoneal or intrapleural body cavities. Intravenous preparations can be given through large peripheral veins, but the risk of extravasation or

TABLE 13.10 Classifications of chemotherapeutic drugs

DRUG CLASSIFICATION	COMMON DRUGS	TARGET MALIGNANCIES	ADVERSE EFFECTS OR SIDE EFFECTS	NURSING IMPLICATIONS
Alkylating agents	Mechlorethamine	Hodgkin's disease Lymphosarcoma Lung cancer Chronic leukaemia	Nausea and vomiting Leucopenia Thrombocytopenia Hyperuricaemia	Maintain good hydration. Alkalinise urine. Administer anti-emetics prior to chemotherapy. Monitor WBC, uric acid. Assess for infection.
	Busulfan	Chronic myelogenous leukaemia	Leucopenia Thrombocytopenia Renal failure Pulmonary fibrosis	Monitor WBCs, BUN. Maintain adequate fluid intake. Assess for infection. Assess lungs for fibrotic (coarse, loud) rales.
	Cyclophosphamide	Lymphomas Multiple myeloma Leukaemias Adenocarcinoma of lung and breast	Haemorrhagic cystitis Renal failure Alopecia Stomatitis Liver dysfunction Infertility	Encourage daily fluid intake of 2 to 3 L during treatment. Monitor WBCs, BUN, liver enzymes. Teach ways to manage hair loss.
Antimetabolites	Methotrexate	Acute lymphoblastic leukaemia Osteosarcoma Gestational trophoblastic carcinoma	Oral and gastrointestinal ulcerations Anorexia and nausea Leucopenia Thrombocytopenia Pancytopenia	Monitor CBC, WBC differential, BUN, uric acid, creatinine. Assess oral mucous membranes; treat ulcers prn. Assess for infection, bleeding.
	5-Fluorouracil (5-FU)	Colon carcinoma Rectal carcinoma Breast carcinoma Gastric carcinoma Pancreatic cancer	Stomatitis Alopecia Nausea and vomiting Gastritis Enteritis Diarrhoea Anaemia Leucopenia Thrombocytopenia Red sore peeling hands and feet	Monitor CBC with differential, BUN, uric acid. Administer anti-emetics prn. Assess for bleeding; check stool occult blood. Evaluate hydration and nutrition status. Teach oral care for stomatitis. Assess for infection. Teach care for hair loss.
Antitumour antibiotics	Doxorubicin	Acute lymphoblastic leukaemia (ALL) Acute myeloblastic leukaemia Neuroblastoma Wilms' tumour Breast, ovarian, thyroid, lung cancer	Stomatitis Alopecia Nausea and vomiting Gastritis Enteritis Diarrhoea Anaemia Leucopenia Thrombocytopenia Cardiac toxicity	Monitor ECG; assess for arrhythmias, gallops and congestive heart failure (CHF). Monitor CBC with differential, BUN, uric acid. Administer anti-emetics prn. Assess for bleeding; check stool for occult blood. Evaluate hydration and nutrition status. Teach oral care for stomatitis. Assess for infection. Teach care for hair loss.
Antitumour antibiotics	Bleomycin	Squamous cell carcinoma Lymphosarcoma Reticulum cell sarcoma Testicular carcinoma Hodgkin's disease	Mucocutaneous ulcerations Alopecia Nausea and vomiting Chills and fever Pneumonitis and pulmonary fibrosis	Check for fever 3 to 6 hours after administration. Have chest x-ray films taken every 2 to 3 weeks. Assess respiratory status and check for coarse rales. Evaluate hydration and nutrition status. Teach oral care for stomatitis. Assess for infection. Teach care for hair loss.

TABLE 13.10 Classifications of chemotherapeutic drugs (continued)

DRUG CLASSIFICATION	COMMON DRUGS	TARGET MALIGNANCIES	ADVERSE EFFECTS OR SIDE EFFECTS	NURSING IMPLICATIONS
Plant alkaloids	Vincristine	Combination therapy for acute leukaemia, Hodgkin's and non-Hodgkin's lymphomas, rhabdomyosarcoma, neuroblastoma, Wilms' tumour	Areflexia Peripheral neuritis Constipation Paralytic ileus Mild bone marrow Depression	Assess neuromuscular function. Monitor FBC with differential. Evaluate gastrointestinal function. Manage constipation.
	Vinblastine	Combination therapy for Hodgkin's disease, lymphocytic and histocytic lymphoma Kaposi's sarcoma, advanced testicular carcinoma, unresponsive breast cancer	Areflexia Alopecia Nausea and vomiting Bone marrow depression Tingling and numbness of fingers and toes	Assess neuromuscular function. Monitor FBC with differential. Administer anti-emetics prn. Teach ways to manage hair loss.
	Etoposide, also called VP-16	Non-responsive testicular tumours Small-cell lung cancer	Alopecia Hypotension with rapid infusion Facial flushing Sweating Difficulty breathing/ wheezing	Hydrate adequately before administration. Administer for 60 minutes. Monitor vital signs every 15 minutes during administration and every 2 to 4 hours thereafter. Teach ways to manage hair loss.
	Prednisolone	Combination therapy for many tumours Leukaemia Lymphoma	Fluid retention Hypertension Steroid diabetes Emotional lability Silent bleeding ulcers Increased risk of infection Euphoria or insomnia	Monitor vital signs. Administer diuretics prn. Check blood glucose regularly. Evaluate mental status. Administer oral medications with food. Administer hydrogen ion antagonist drugs (antacids) as ordered. Monitor WBC with differential. Check for signs of systemic infection.
	Diethylstilbestrol (DES)	Advanced breast and prostrate cancers	Fluid retention Feminisation Uterine bleeding	Monitor vital signs. Administer diuretics prn as ordered. Explain reason for feminisation to men, bleeding to women. Monitor for excessive bleeding.
	Tamoxifen	Breast cancer	Hot flashes Nausea and vomiting	Explain reason for hot flashes. Teach ways to manage hot flashes. Administer anti-emetics as ordered.
Miscellaneous drugs	Cisplatin (CDDP) (Platinol)	Combination and single therapy for metastatic testicular and ovarian cancers, advanced bladder cancer, head and neck tumours, non-small-cell lung carcinoma, osteogenic sarcoma, neuroblastoma	Bone marrow depression: leucopenia and thrombocytopenia Renal tubular damage Deafness	Monitor WBC with differential and platelets, BUN, creatinine, uric acid. Watch for bleeding. Monitor for signs of infection. Evaluate hearing; check for tinnitus. Ensure that person is well hydrated before drug is administered. Encourage 2 to 3 L of fluid intake daily.

irritation to the vein may preclude this method for long-term therapy. Many people now receive central venous access devices (CVADs), especially if their treatment requires several cycles over weeks or months. CVADs are also useful for adjunctive parenteral nutrition in the person who needs continuous intravenous infusions to manage pain or frequent blood drawing to monitor blood counts. Different types of CVADs are available:

- Catheters inserted non-surgically by threading them through a large peripheral vein into the vena cava. Called *peripherally inserted central catheters (PICCs)*, they have multiple lumens that facilitate blood drawing. Placement is usually monitored by fluoroscopy.
- Catheters tunnelled under the skin on the chest into a major vein, such as the subclavian vein. Hickman or Groshong catheters may be used.
- Surgically implanted ports, placed under the skin with a connected catheter inserted into a major vein. These are accessed by means of a special needle with a 90-degree angle inserted through the skin directly into the rubber dome of the port, which has a hard plastic back to prevent tissue damage.

Figure 13.6 shows examples of different catheters and vascular access ports.

Risk of infection, catheter obstruction and extravasation are the main problems associated with CVADs. Nurses therefore must teach people and family members to observe for redness, swelling, pain or exudate at the insertion site, which may indicate infection; to observe for swelling of the neck or skin near the CVAD for extravasation and infiltration; and to flush catheters and provide site care (cleaning and dressing changes) on a regular basis. During each encounter with the person, the nurse always inspects the site; observes for infection, infiltration and catheter occlusion, and provides site care when necessary.

Management of people receiving chemotherapy In addition to providing the above nursing interventions, nurses help identify and manage toxic effects or side effects of the drugs and provide psychosocial support. Careful assessment and monitoring of the person's signs and symptoms, including appropriate laboratory tests, alert the nurse to the onset of toxicity. Nausea and vomiting, diarrhoea, inflammation and ulceration of oral mucous membranes, hair loss, skin changes, anorexia and fatigue require specific medical and nursing actions. These actions are discussed later in this chapter under the appropriate nursing diagnoses. Indicators of organ toxicities, such as nephrotoxicity, neurotoxicity or cardiac toxicity, must be reported immediately to the doctor. Another aspect of managing people undergoing chemotherapy is to teach them how to care for access sites and to dispose of used equipment and excretions safely. Nurses also teach people to increase fluid intake to flush out the drugs; to get extra rest, which can both assist therapy and help the person avoid other illnesses; to identify major complications of their particular drug protocol; to know when to call the doctor or emergency medical services; and, if their WBC count is low, to limit their exposure to other people, especially children or those with infections.

During chemotherapy, a number of psychological issues that can cause moderate to severe emotional distress may arise. The need to plan activities around chemotherapy treatments and their side effects can impair the person's ability to work, manage a household or care for family members, function sexually or participate in social and recreational activities. Weight loss and alopecia may prompt feelings of powerlessness and depression. The nurse can assist by carefully evaluating

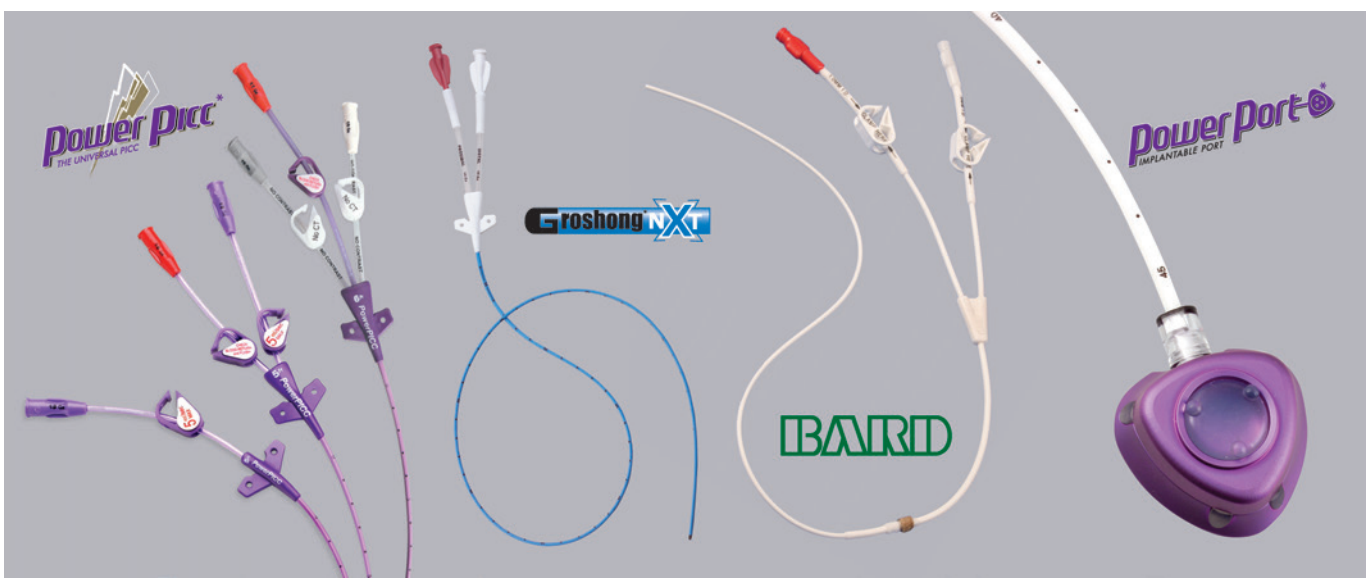

FIGURE 13.6 ■ Vascular access devices: peripherally inserted central catheters (single, dual and triple lumen PowerPICC and dual lumen Groshong), tunnelled central venous catheter (dual lumen Hickman) and implantable port (PowerPort)

symptoms, providing specific interventions as indicated and allowing people opportunities to express their fears, concerns and feelings. People should be encouraged to participate in their care and maintain control over their life as much as possible. Specific interventions are discussed later in the chapter under the appropriate nursing diagnoses. Table 13.10 includes nursing implications for specific adverse effects of common chemotherapy drugs.

RADIATION THERAPY Still the treatment of choice for some tumours or by some oncologists, radiation may be used to kill the tumour, reduce its size, decrease pain or relieve obstruction. Lymph nodes and adjacent tissues are irradiated when beginning metastasis is suspected. **Radiation therapy** consists of delivering ionising radiations of gamma and x-rays in one of two ways:

- *External radiation*, also known as teletherapy, involves delivery of radiation from a source at some distance from the person. A relatively uniform dosage is delivered to the tumour.
- *Brachytherapy*. In brachytherapy, the radioactive material is placed directly into or adjacent to the tumour, a technique that delivers a high dose to the tumour and a lower dose to the normal tissues. This allows delivery of high doses of radiation to the tumour while sparing adjacent tissue. Brachytherapy is also referred to as internal, interstitial or intracavitary radiation.

For many common neoplasms, a combination of these two therapies is used.

Lethal injury to DNA is believed to be the primary mechanism by which radiation kills cells, especially cells in faster-growing tumours and tissues. As a result, when given over time, radiation can destroy not only rapidly multiplying cancer cells but also rapidly dividing normal cells, such as those of the skin and mucous membranes. A malignant tumour is considered cured when there are no surviving tumour stem cells. The goal of radiation therapy is to achieve maximum tumour control with a minimum of damage to normal tissue.

Implanted or ingested radiation can be dangerous for those living with, taking care of or treating the person. Caregivers must use protection by shielding themselves from the source of radiation, limiting the time of exposure to the person, increasing the distance from the person and using specific safety procedures for handling secretions. Box 13.6 identifies safety principles to be followed by those caring for people undergoing internal radiation.

Tumours have differing sensitivities to radiation. Tumours that have the greatest number of rapidly proliferating cancer cells usually exhibit the best early response to radiation. The decision to use radiation rather than other modalities is based on balancing the probability of controlling the tumour against the probability of causing complications, such as tissue damage. The decision is usually made by risk–benefit analysis. Planning for radiation therapy includes assessing the disease site, tumour size and histological findings. Treatment schedules vary based on these factors.

BOX 13.6 General safety principles for radiation

These general procedures are taken from the *Code of Nursing Practice for Staff Exposed to Ionising Radiation* (Australian Radiation Protection and Nuclear Safety Agency, 1984):

- Maintain maximum distance from source of radiation (2.3) and work at a maximum practical distance when attending to people (4.1.5).
- Reduce time spent near a radioactive source (2.4).
- A single room should be used to minimise exposure to staff and other people (4.1.1).
- Nursing staff carrying out procedures with possibility of contamination should wear suitable gloves and gowns (4.6.5).
- It is preferable to assign staff who are unlikely to be pregnant (1.3).
- Staff should be subject to monitoring by personal monitors or an approved device. Records should be kept and available upon request (1.30).
- Nursing staff should never touch a radioactive source with the fingers (4.5.3). Special forceps or other remote control equipment should be used to handle radioactive sources (5.4).
- Specific precautions should be used to reduce risk of spill of body fluids that are radioactive (4.6.7).
- Handle bed linen and clothing with care and according to the organisation's protocol.
- Consult the organisation's radiation therapy department for any questions or problems in caring for people with radioactive implants.

Box 13.7 lists the degree of radiosensitivity for selected cancers.

The person receiving external radiation may experience skin changes such as blanching, erythema, desquamation, sloughing or haemorrhage. Ulcerations of mucous membranes may cause severe pain; in addition, oral secretions can decrease, making the person more vulnerable to infection and dental caries. Gastrointestinal effects include nausea and vomiting, diarrhoea or bleeding. Lungs may develop interstitial exudate, a condition called radiation pneumonia. Occasionally, external radiation therapy may cause fistulas or necrosis of adjacent tissues. Implanted radioactive materials can lead to similar problems; moreover, the excretory products of these people are usually considered dangerous and need special disposal. See the 'Nursing care' box below for nursing implications for people receiving radiation therapy.

BIOTHERAPY **Biotherapy** modifies the biological processes that result in malignant cells, primarily through enhancing the person's own immune responses. The development of this therapy was based on the immune surveillance hypothesis. Although it has been established that a competent immune system is the body's most important defence against any

BOX 13.7 Degree of radiosensitivity for selected cancers

Very radiosensitive
- Neuroblastoma
- Lymphomas
- Chronic leukaemia

Moderately radiosensitive
- Bronchogenic carcinoma
- Oesophageal carcinoma
- Squamous cell carcinoma
- Prostate carcinoma
- Cervical carcinoma
- Testicular carcinoma

Non-radiosensitive
- Many adenocarcinomas
- Fibrosarcoma
- Osteogenic carcinoma

disease, the role that various immune cells play in combatting different types of malignancies continues to be investigated. Currently, biotherapy is used for both haematological malignancies, such as lymphoma and hairy-cell leukaemia, and solid tumours, such as renal cancer and melanoma (Fox et al., 2013; Poust, Woolery & Green, 2013).

Tumour immunology has the following applications: detection screening in high-risk groups, differential diagnosis and classification of tumour cells, monitoring the course of the disease, with early detection of recurrence and active therapies to halt or limit the disease. The theory underlying tumour immunology is that most tumour cells have a structural appearance recognisable by the immune cells. Tumour-associated antigens (TAAs) exist on tumour cells but not on normal cells. TAAs elicit an immune response that, in a person with a competent immune system, destroys or inhibits tumour growth. Thus, TAAs can be isolated from serum and used for both diagnosis and various treatment modalities. The PSA is one such TAA currently in successful diagnostic use.

Tumour cells are often in a stage of arrested development (i.e. in the differentiation stage) for the cell type they represent; thus, they express antigens characteristic of that particular stage of development. The immaturity of the cells provides the doctor with information about the relative aggressiveness of the cancer.

Another aspect of immunotherapy is the development of monoclonal antibodies that enhance the immune system's ability to fight the cancer. Monoclonal antibodies are developed by inoculating an animal with the tumour antigen and recovering the specific antibodies produced. The antibodies are then given to the person with that cancer to assist in the destruction of the tumour. Monoclonal antibodies are also recreated or cloned in the genetic laboratory by recombining DNA to produce the specific antibody. Techniques involving recombinant DNA have been used to combine these antibodies with toxins and drugs that are then delivered selectively to the tumour sites.

A number of cytokines (normal growth-regulating molecules) with antitumour activity have been synthesised. Alpha interferon (IFN-α), bacillus Calmette-Guérin (BCG, which has been used for many years as an inoculation against tuberculosis) and interleukin-2 (IL-2) have shown some therapeutic benefit in eliciting increased immune responses. Combination strategies have also helped stimulate the function of macrophages.

A promising discovery has been the natural killer (NK) cells. These cells are like large granular lymphocytes, but have a cell surface phenotype different from that of T lymphocytes or macrophages. They have demonstrated a spontaneous cytotoxic effect on some types of cancer cells. They also provide a strong resistance to metastasis and secrete cytokines. When augmented by biological response modifiers such as IL-2, they show increased tumour destructive activity (Battiato & Wheeler, 2000).

The use of haematopoietic growth factors (HGFs) has been one of the most successful in biotherapy. HGFs, such as granulocyte colony-stimulating factor and erythropoietin, offset the suppression of granulocytes and erythrocytes that results from chemotherapy (Battiato & Wheeler, 2000).

Since the early 1990s, the combination of cytokines, particularly IFN-α and IL-2, with chemotherapy has been used in people with metastatic melanoma with promising results. Such a combination is referred to as either biochemotherapy or chemoimmunotherapy (Anderson et al., 1998; Cohen & Falkson, 1998; Legha et al., 1998). The rationale for biochemotherapy is based on the independent antitumour activity of both IFN-α and IL-2 against melanoma and their lack of cross-resistance with cytotoxic chemotherapy. Although the precise mechanism of the antitumour effect of biochemotherapy regimens is less well understood, two hypotheses have been proposed: (1) chemotherapy enhances the antitumour effect of biological agents; and (2) the biological agents enhance the antitumour cytotoxic effect of chemotherapy (Anderson et al., 1998; Legha et al., 1998).

As promising as these biotherapies or biochemotherapies are, they are accompanied by serious side effects and toxicities (Fu et al., 2002; Legha et al., 1998). IL-2 can cause acute alterations in renal, cardiac, liver, gastrointestinal and mental functioning. IFN-α causes mental slowing, confusion and lethargy and when used in combination with 5-fluorouracil or IL-2, severe flu-like symptoms—chills and fever of 39.4ºC to 41.1ºC, nausea, vomiting, diarrhoea, anorexia, severe fatigue and stomatitis—may result. The toxic effects are probably exaggerations of the normal systemic effects that these substances cause when fighting infection. For example, IL-2 is known to raise body temperature substantially in an attempt to create a hostile environment for foreign invaders.

The 'Nursing care' box below discusses nursing implications for people receiving immunotherapy. For nursing care of specific problems, refer to the appropriate nursing diagnoses later in this chapter.

NURSING CARE OF THE PERSON Receiving radiation therapy

NURSING RESPONSIBILITIES FOR EITHER EXTERNAL OR INTERNAL RADIATION THERAPY

- Assess and manage any complications, usually in collaboration with the radiation oncologist.
- Assist in documenting the results of the therapy; for example, people receiving radiation for metastases to the spine will show improved neurological functioning as tumour size diminishes.
- Provide emotional support, relief of physical and psychological discomfort, and opportunities to talk about fears and concerns. For some people, radiation therapy is a last chance for cure or even just for relief of physical discomfort.

EXTERNAL RADIATION

Prior to the start of treatments, the treatment area will be specifically located by the radiation oncologist and marked with coloured semi-permanent ink or tattoos. Treatment is usually given 5 days per week for 15 to 30 minutes per day over 2 to 7 weeks.

Nursing responsibilities

- Monitor for adverse effects: skin changes, such as blanching, erythema, desquamation, sloughing or haemorrhage; ulcerations of mucous membranes; nausea and vomiting, diarrhoea or gastrointestinal bleeding.
- Assess lungs for rales, which may indicate interstitial exudate. Observe for any dyspnoea or changes in respiratory pattern.
- Identify and record any medications that the person will be taking during the radiation treatment.
- Monitor white blood cell counts and platelet counts for significant decreases.

Health education for the person and family

- Wash the skin that is marked as the radiation site with plain water only, no soap; do not apply deodorant, lotions, medications, perfume or talcum powder to the site during the treatment period. Take care not to wash off the treatment marks.
- Do not rub, scratch or scrub treated skin areas. If necessary, use only an electric razor to shave the treated area.
- Apply neither heat nor cold (e.g. heating pad or ice pack) to the treatment site.
- Inspect the skin for damage or serious changes and report these to the radiologist or doctor.
- Wear loose, soft clothing over the treated area.
- Protect skin from sun exposure during treatment and for at least 1 year after radiation therapy is discontinued. Cover skin with protective clothing during treatment; once radiation is discontinued, use sun-blocking agents with a sun protection factor (SPF) of at least 15.
- External radiation poses no risk to other people for radiation exposure, even with intimate physical contact.
- Be sure to get plenty of rest and eat a balanced diet.

INTERNAL RADIATION

The radiation source, called an implant, is placed into the affected tissue or body cavity and is sealed in tubes, containers, wires, seeds, capsules or needles. An implant may be temporary or permanent. Internal radiation may also be ingested or injected as a solution into the bloodstream or a body cavity or be introduced into the tumour through a catheter. The radioactive substance may transmit rays outside the body or be excreted in body fluids.

Nursing responsibilities

- Place the person in a private room.
- Limit visits to 10 to 30 minutes and have visitors sit at least 2 metres from the person.
- Monitor for side effects such as burning sensations, excessive perspiration, chills and fever, nausea and vomiting, or diarrhoea.
- Assess for fistulas or necrosis of adjacent tissues.

Health education for the person and family

- While a temporary implant is in place, stay in bed and rest quietly to avoid dislodging the implant.
- For outpatient treatments, avoid close contact with others until treatment has been discontinued.
- If the radiologist indicates the need for such measures, dispose of excretory materials in special containers or in a toilet not used by others.
- Carry out daily activities as able; get extra rest if feeling fatigued.
- Eat a balanced diet; frequent, small meals often are better tolerated.
- Contact the nurse or doctor about any concerns or questions after discharge.

PHOTODYNAMIC THERAPY Photodynamic therapy is a method of treating certain kinds of superficial tumours. It is known by several different names: phototherapy, photoradiation and photochemotherapy. People suffering from tumours growing on the surface of the bladder, peritoneal cavity, chest wall, pleura, bronchus or head and neck are candidates for this treatment. The person is given an intravenous dose of a photosensitising compound, Photofrin, which is selectively retained in higher concentrations in malignant tissue. This drug is activated by a laser treatment that is started 3 days after the drug injection and administered for 3 days. The drug interacts with oxygen molecules in the tissue to produce a cytotoxic oxygen molecule called singlet oxygen.

At the time of the first intravenous injection, people are observed for adverse hypersensitivity reactions, such as nausea, chills and hives. Systemic or long-term toxicities are rare. The main side effects are local skin reactions and temporary photosensitivity, transiently elevated liver enzymes and inflammatory responses of the tissues being treated, such as peritoneal or pleural tissues. This treatment has been used successfully with early-stage lung cancer with response rates as high as 90% (Bruce, 2001).

The major nursing responsibilities associated with photodynamic therapy are to address the person and family's anxiety about undergoing a relatively new treatment procedure and

NURSING CARE OF THE PERSON Receiving immunotherapy

Immunotherapy can consist of various substances used alone, such as IL-2, or combination biotherapy, such as IFN-α with 5-fluorouracil. The nurse's role is to enhance the person's quality of life.

NURSING RESPONSIBILITIES

- Monitor for side effects: IFN-α may cause mental slowing, confusion and lethargy; combination therapy of 5-fluorouracil or IL-2 and IFN-α may cause severe flu-like symptoms, with chills and fever of 39.4°C to 41.1°C, nausea, vomiting, diarrhoea, anorexia, severe fatigue and stomatitis; erythropoietin may cause acute hypertension.
- Monitor enzymes and other appropriate biochemical indicators for acute alterations in renal, cardiac, liver or gastrointestinal functioning, which can be side effects of IL-2.
- Evaluate response to therapy by conducting a thorough evaluation of the person's symptoms.
- Assess the person's coping behaviours and teach new strategies as needed.
- Manage fatigue and depression.
- Encourage self-care and participation in decision making.
- Provide close supervision for people with altered mental functioning, either by caretakers or through frequent nursing visits to the person's home.
- If the person is unable to manage alone, teach medication administration and care of equipment to caregivers.

HEALTH EDUCATION FOR THE PERSON AND FAMILY

- Minimise symptoms by managing fever and flu-like symptoms: increase fluid intake, take analgesic and antipyretic medications, and maintain bed rest until symptoms abate.
- Seek help for serious problems not managed by usual means, such as dehydration from diarrhoea.
- Use correct techniques for providing subcutaneous injections.
- Identify how to work and care for ambulatory pumps when medication is administered through an intercatheter or vascular access device.

to educate them in managing side effects. The drug remains in the subcutaneous tissues for 4 to 6 weeks after injection. Any direct or indirect exposure to the sun activates the drug, resulting in a chemical sunburn. People are taught to protect themselves from sunlight (even on cloudy days) by covering themselves from head to toe in opaque clothing, including a wide-brimmed hat, gloves, shoes and stockings, and sunglasses with 100% ultraviolet block. Long-term care of treated skin includes moisturising lotions and protection from trauma or irritation.

BONE MARROW AND PERIPHERAL BLOOD STEM CELL TRANSPLANTATIONS Bone marrow transplantation (BMT) is an accepted treatment to stimulate a non-functioning marrow or to replace marrow. BMT is given as an intravenous infusion of bone marrow cells from donor to person. Most commonly used in leukaemias, this therapy is being expanded to include treatment of other cancers including melanoma and testicular cancer. Chapter 32 provides an in-depth discussion of this procedure. Peripheral blood stem cell transplantation (PBSCT) is the process of removing circulating stem cells from the peripheral blood through apheresis and returning these cells to the person after dose-intensive chemotherapy. PBSCT has fewer side effects, shorter hospitalisation and decreased cost compared to BMT.

COMPLEMENTARY THERAPIES Although advances in cancer treatment have increased 5-year survival rates, the uncertainty of cure of cancer and cancer reoccurrence often compel some people to look for complementary therapies. It is estimated that approximately 30% to 50% of people with cancer may have had the experience of using some kind of complementary therapy. Complementary therapies are those that people choose as a complement to medical treatment. Common complementary therapies for cancer can be categorised into botanical agents, nutritional supplements, dietary regimens, mind–body modalities, energy healing, spiritual approaches and miscellaneous therapies. Box 13.8 provides detailed information about complementary therapies.

To provide sensitive nursing care, nurses should be knowledgeable about common complementary therapies. Nurses should use ethical principles of autonomy, beneficence, non-maleficence and justice to guide their professional practice and care for people who choose to use complementary therapies. It is also important for nurses to provide truthful, non-judgmental responses to the questions or inquiries about complementary therapies from people with cancer. Nurses should encourage people to report the use of any complementary therapies to their oncologist to prevent potential interactions of the complementary therapies with their medical treatment.

Pain management

Pain management is an important component of oncology care and is considered a crucial part of the collaborative treatment plan. It is estimated that more than 50% of people with early-stage cancer and up to 95% of people with advanced cancer experience pain that requires analgesia (Ogboli-Nwasor et al., 2013). There are three main categories of pain syndromes in people with cancer, and the category influences the type of treatment:

1. *Pain associated with direct tumour involvement*. The most common causes are metastases to bone, nerve compression or infiltration, and involvement of hollow visceral organs.
2. *Pain associated with treatment*. This may include postsurgical incisional or wound pain; peripheral neuropathy, ulceration of mucous membranes and pain from herpes zoster outbreaks secondary to chemotherapy; and pain in nerve plexuses, muscles and peripheral nerves from radiation therapy.
3. *Pain from a cause not related to either the cancer or therapy,* such as diabetic neuropathy.

BOX 13.8 Common complementary therapies for cancer

Type	Description
Botanical agents	Herbs are believed to be the most 'natural' and 'safe' plants ingested with the hope for a cure of cancer. Commonly used botanical agents include echinacea, essiac, ginseng, green tea, pau d'arco and hoxsey. The safety of many of these botanical agents has not been proven, especially as a complement to medical treatment.
Nutritional supplements	Chemical compounds include vitamins, minerals, enzymes, amino acids and essential fatty acids or proteins (such as shark cartilage). They are believed to have the ability to promote health and to help cure cancer. The safety of certain compounds such as vitamins has been established; however, in megadoses, many of the compounds can be toxic and have potential interactions with some therapeutic agents used for cancer, such as chemotherapy.
Dietary regimens	The ingestion of only natural substances is believed to have the effect of purifying the body and slowing down the growth of cancer. Popular regimens include the grape diet, the carrot juice diet and garlic, onions and liver intake. However, the effectiveness of these dietary regimens remains to be established.
Mind–body modalities	The harmony of mind and body is believed to facilitate physiological and psychological healing. Such modalities include relaxation, meditation or imagery. Recent research has shown that these modalities have helped individuals with cancer adjust to the experience of cancer.
Energy healing	The human body is believed to be an energy field and cancer might be the result of a disturbed energy field. Energy therapies, such as therapeutic touch and healing touch, can affect the energy field of the human body and promote physiological healing. Therapeutic touch uses the hands on or near the body with the intent to promote healing. Healing touch uses energy healing techniques to heal by restoring the harmony and balance of the body. Clinical practice and research on energy healing have shown positive findings of energy healing in a variety of people.
Spiritual approaches	Faith in God or a higher power of the universe is believed to help cancer healing. Spiritual approaches include faith healing, prayer to God, prayer groups and chain prayer. Research has shown that faith in God or a higher power also helped individuals with cancer to adjust to the experience of cancer.
Miscellaneous therapies	Aromatherapy has been used for people with cancer to relieve nausea, vomiting or retching, and to decrease anxiety. However, aromatherapy might not be appropriate for people who are highly sensitive to strong fragrance. Music, art and humour therapies have also been used to help people with cancer to reduce anxiety, to express feeling of loss and to promote optimism.

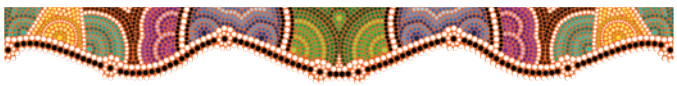
The goal of pain therapy is to provide relief that allows people to function as they wish and, in the case of terminally ill people, to die relatively free of pain. Drug therapy with opioid and non-opioid analgesics as well as adjuvant medications (those that enhance the effect of the analgesic) is the basis of most doctor-guided pain management. Other therapies include injection of anaesthetic drugs into spinal cord or specific nerve plexuses, surgical severing of nerves, radiation to reduce tumour size and pressure, and behavioural approaches. Pharmacological pain management follows these steps:

- Conduct careful initial and ongoing assessment of the pain.
- Evaluate the person's functional goals.
- Establish a plan with combinations of non-narcotic drugs (such as aspirin or ibuprofen) with adjuvants (such as corticosteroids or antidepressants).
- Evaluate the degree of pain relief.
- Progress to stronger drugs as needed, from mild narcotics such as oxycodone or propoxyphene to strong narcotics such as morphine or hydromorphone, and monitor side effects.
- Continue to try combinations and escalate dosages until maximal pain relief balanced with the person's need to function is achieved.

Medication is usually administered by the oral route as long as this route continues to be effective. Medication is given on a regular time schedule (e.g. every 4 hours), with additional medication prescribed to cover breakthrough pain. When the oral route alone becomes inadequate, the primary narcotic can be administered intramuscularly, subcutaneously or rectally on an intermittent schedule or continuously by transdermal patches, or intravenously by a continuous drip, usually controlled by an infusion pump. Some pumps are portable, deliver medication continuously and allow people to control their breakthrough pain with a limited number of boluses. When narcotic doses are increased gradually, there is no limit to the amount the person can receive, as long as adverse reactions can be managed. People have received up to 4800 mg daily (200 mg per hour) of morphine sulfate with up to six 200–400 mg breakthrough doses daily without major ill effects and with good pain control. The body develops tolerance to the sedative after a short period and most people are able to tolerate the level of medication needed to control the pain. Other side effects, such as constipation, nausea and vomiting, and itching, can be managed through the usual means and are discussed under the appropriate nursing diagnoses. If the person has persistent untoward

side effects that do not respond to treatment, or if the person does not get adequate relief from the narcotic, different narcotics and combinations are tried. Morphine sulfate and transdermal fentanyl are the most commonly used drugs for relief of cancer pain (Ferrell & McCaffery, 1997).

People receiving high-dose narcotics should not have the medication abruptly stopped, because withdrawal symptoms will occur. If the drug needs to be stopped, it must be tapered gradually. For more information on pain management, and on alternative therapies in particular, see Chapter 8.



Nursing care

Nurses face a major challenge in educating people about preventive measures and lifestyle changes to reduce the risk of cancer. At the same time, people with cancer must be reassured that they are not responsible for having acquired cancer.

Once a cancer diagnosis is established, nurses help people recover and support them during the rehabilitation phase. In cases of terminal cancer, nurses provide comfort and facilitate positive growth for the person and significant others.

Health promotion

Early detection and treatment are considered the most important factors influencing the prognosis of those who have cancer. However, many people do not seek early diagnosis and treatment because of denial, fear and anxiety, stigma or the absence of specific early signs such as pain or weight loss (which usually are late signs). For this reason, screening procedures such as mammograms, PSA, occult blood stool tests and sigmoidoscopy may be life saving.

Cancer Council Australia (CCA) advises the Australian government on policy and practices to help in the prevention, detection and treatment of cancer. CCA undertakes and funds cancer research as well as advocates for the rights of people with cancer to receive the best treatment, care and support. Recommendations on reducing preventable risk factors and early screening strategies are outlined in the *National Cancer Prevention Policy 2007–2009* by Cancer Council Australia (2007). The CCA highlights that one-third of cancer deaths in Australia can be attributed to known avoidable risk factors (CCA, 2007). Cancer Council Australia provides cancer-smart lifestyle fact sheets that provide information on common signs and symptoms that may indicate cancer. The signs and symptoms to look for (see Box 13.9) are helpful in promoting awareness but do not substitute for medical advice.

If a person is at special risk due to heredity, environment, occupation or lifestyle, special tests or more frequent examinations may be necessary. A routine cancer check-up should include counselling to improve health behaviours and physical examination with related tests of the breast, uterus, cervix, colon, rectum, testes, prostate, skin, thyroid and lymph nodes. Box 13.10 lists the recommendations for screening.

BOX 13.9 Cancer Council Australia: signs and symptoms to look for

- Lumps, sores or ulcers that do not heal.
- Coughs that persist or show blood, or a hoarseness that hangs around.
- Unexplained weight loss.
- Moles that have changed shape, size or colour or an inflamed skin sore that has not healed.
- Blood in a bowel motion.
- Persistent changes in toilet habits.

Men

- Unusual changes in your testicles—changes in shape, consistency or lumpiness.
- Urinary problems or changes.

Women

- Unusual changes in your breasts—lumps, thickening, unusual discharge, nipples that suddenly turn inwards, change in shape, colour or unusual pain.
- Blood loss between or following periods.
- Persistent abdominal pain or bloating.

These symptoms are often related to more common, less serious health problems. However, if you notice any unusual changes, or these symptoms persist, visit your doctor.

Source: Cancer Council Australia (2012). *Fact Sheets.* www.cancer.org.au.

Nurses have a special role in public education and should encourage all with whom they come into contact to schedule cancer check-ups. Nurses must be familiar with the cancer guidelines so that they can advise people, their families and significant others.

BOX 13.10 National Cancer Prevention Policy: cancer screening recommendations

Cervical screening

- Routine Pap tests from the age of 18, or within 1 to 2 years of becoming sexually active.

Breast cancer

- If you are over 40 you can have a free BreastScreen Australia mammogram (breast x-ray) every 2 years.
- Regular mammograms can reduce your risk of breast cancer death by 25%, particularly women in the 50–69 age group for whom the benefit is highest.

Bowel cancer

- Cancer Council Australia recommends all Australians aged over 50 have a faecal occult blood test (FOBT) every 2 years to screen for bowel cancer.

Assessment

Focused interview

During this initial phase of the nursing process, collect the following significant data about the person:

- history of the person's disease, including the signs and symptoms that led the person to seek healthcare
- other concurrent diseases, such as diabetes
- current physical or psychological problems resulting from the cancer, such as pain or depression
- understanding of the treatment plan
- expectations of the treatment plan
- functional limitations due to illness or treatment (see Box 13.11)
- effect of the disease on current lifestyle
- reliable support systems or caretakers for the person
- coping strategies and how well they are working.

INTERVIEW QUESTIONS The following are appropriate questions to ask the person during the initial interview and at subsequent assessments:

- *'What brought you in to see the doctor?'* Asking this question allows people to tell their story in their own way, which may elicit more information than asking specific questions. The answer should elicit not only data about the signs and symptoms but also fears or concerns. If the cancer was discovered during a routine physical examination or check-up, the person may have some difficulty accepting the disease, especially if there were no symptoms. For people who offer insufficient information in response to this open-ended question, more specific questions may be necessary, such as 'Did you have pain or any specific physical problems that caused you to seek healthcare?'
- *'Do you have any other medical conditions or problems that are troubling you at this time?'* It may be necessary to ask about specific diseases to help the person focus. For example, 'Do you have high blood pressure?' or 'Are you having any problems with your lungs?' Information gained from these questions can help you anticipate problems and formulate potential nursing diagnoses related to other diseases that may interact with the cancer.
- *'What kinds of physical problems are you having at this time? Do you have pain? Are you nauseated? Have you lost a great deal of weight? Are you so tired you have difficulty carrying on your daily activities? Are you feeling depressed or discouraged because of your illness?'* For each positive response, ask follow-up questions to narrow down or define the exact nature of the problem. Again, these data help identify what nursing diagnoses should be included in the care plan.
- *'What options has your doctor suggested for treating your cancer?'* The answer will indicate the person's knowledge about their treatment and, possibly, their communication with the doctor. Often, under the stress of a cancer diagnosis, people do not hear or understand what the doctor is saying and are afraid to ask questions. Lack of knowledge indicates a need to collaborate with the doctor to explain the information to the person so that the person can absorb and understand it. If the person has a good understanding of the treatment plan, discussing how he or she feels about it can be useful in exposing fears, concerns and emotional responses.
- *'What do you expect to happen as a result of this treatment?'* The answer may reveal unrealistic expectations or lack of understanding of consequences of the treatment.
- *'What effect is the disease and/or treatment having on your ability to carry on with your usual daily activities?'* Additional questions may also be needed to pinpoint the types of limitations. The response to this question should provide information on the person's functional status, such as those shown in Box 13.11. This information can also be used to identify the need to collaborate with professionals from other disciplines. For example, if the person is the sole financial support of the family and is unable to work, a social worker may be able to help with resources; if the person is extremely weak, referral to a physiotherapist may help with energy conservation strategies and strengthening exercises.

BOX 13.11 Example of an instrument for assessing functional status for cancer patients (Australia-modified Karnofsky Performance Scale (AKPS))

100	Normal; no complaints; no evidence of disease.
90	Able to carry on normal activity; minor signs or symptoms of disease.
80	Normal activity with effort; some signs or symptoms of disease.
70	Cares for self; unable to carry on normal activity or to do active work.
60	Able to care for most needs but requires occasional assistance.
50	Considerable assistance and frequent medical care.
40	In bed more than 50% of the time.
30	Almost completely bedfast.
20	Totally bedfast and requiring extensive nursing care by professionals and/or family.
10	Comatose or barely rousable.
0	Dead.

Source: Abernethy et al. (2005). The Australia-modified Karnofsky Performance Status (AKPS) Scale: A revised scale for contemporary palliative care clinical practice [electronic version]. *BioMed Central Palliative Care*, *4*(7), 1–12, Table 1. http://creativecommons.org/licenses/by/2.0/.

- *'Who is available to help you at home and run errands for you? Who can provide transportation for you to get to your appointments or treatments? Who can you rely on to be a good listener when you're sad or just to be a comfortable companion? Is there someone you would like to make healthcare decisions for you if there is a time when you are unable to make them for yourself?'* It often seems that the person with cancer is the one who takes care of everyone else; asking for help may be difficult for this person. This information can identify how much support and help the person has access to. The last question introduces the concept of advance directives and enduring power of attorney regarding healthcare (see Chapter 4).
- *'How do you manage your stress or your feelings of discomfort? What helps you feel better? Do you think these measures work well for you?'* The responses to these questions provide information about the person's coping strategies and may identify maladaptive strategies such as alcohol or drug use. Lack of appropriate coping methods can interfere with the person's response to treatment and decrease overall quality of life.

Other assessment questions may be useful at different stages of the person's illness. For example, if the person is not expected to survive the cancer, it is important to ask whether the person has made decisions about last wishes (e.g. for a funeral and burial), whether these have been discussed with significant others and whether the person has made out a will.

Physical assessment

As soon as the person is admitted to the healthcare service or organisation, conduct a complete physical assessment to establish a baseline against which to evaluate later changes. It is especially important to document the nutritional status of the person using anthropomorphic measurements (i.e. frame size, height, weight, body fat and muscle mass) and to evaluate laboratory results and note any specific signs and symptoms. Table 13.11 compares the manifestations of good nutrition with those of malnutrition.

BOX 13.12 Factors to consider in assessing hydration status

- Intake and output
- Rapid weight changes
- Skin turgor and moisture
- Venous filling
- Vital sign changes
- Tongue furrows and moisture
- Eyeball softness
- Lung sounds
- Laboratory values

It is also important to assess the person's hydration status, especially if the person is not taking oral food and fluids well or is having bouts of vomiting. Box 13.12 lists specific assessments for hydration status. Other recommended assessments are discussed under the specific nursing diagnoses that follow. They can also be found in other chapters that address specific body systems affected by the cancer.

Nursing diagnoses and interventions

Nursing goals focus on supporting the whole person and managing specific problems such as pain, poor nutrition, dehydration, fatigue, adverse emotional responses, altered individual and family coping, and the side effects of medical treatment. Nursing also focuses on improving the quality of life by promoting rehabilitation for survivors of cancer and helping those who succumb to the disease maintain their dignity in the dying process. Because cancer affects the whole family, nursing care includes everyone involved with the person from the onset of diagnosis through the entire disease and treatment process and the ultimate outcome. Many diagnoses are pertinent to people with cancer; this section addresses only the most common diagnoses. See the accompanying 'Nursing care plan'. (Diagnoses specific to individual diseases can be found in their respective chapters.)

TABLE 13.11 Signs of nutritional status

SYSTEM	GOOD NUTRITION	POOR NUTRITION
General	Alert, energetic, good endurance, psychologically stable Weight within range for height, age, body size	Withdrawn, apathetic, easily fatigued, irritable Over- or underweight
Integumentary	Skin glowing, good turgor, smooth, free of lesions Hair shiny, lustrous, minimal loss	Skin dull, pasty, scaly-dry, bruises, multiple lesions Hair brittle, dull, falls out easily
Head, eyes, ears, nose and throat	Eyes bright, clear, no fatigue circles Oral mucous membranes pink-red and moist Gums pink, firm Tongue pink, moderately smooth, no swelling	Eyes dull, conjunctiva pale, discolouration under eyes Oral mucous membranes pale Gums red, spongy and bleed easily Tongue bright to dark red, swollen
Abdomen	Abdomen flat, firm	Abdomen flaccid or distended (ascites)
Musculoskeletal	Firm, well-developed muscles Good posture No skeletal changes	Flaccid muscles, wasted appearance Stooped posture Skeletal malformations
Neurological	Good attention span, good concentration, astute thought processes Good reflexes	Inattentive, easily distracted, impaired thought processes Paraesthesias, reflexes diminished or hyperactive

NURSING CARE PLAN A person with cancer

James Casey, aged 72, is of northern European heritage. He has been receiving medical care for chronic obstructive pulmonary disease, chronic bronchitis, post myocardial infarction and type I diabetes mellitus for over 15 years. He reports that he lost his wife to lung cancer 5 years ago and still 'misses her terribly'. He describes his bad habits as smoking two packets of cigarettes a day for 52 years (104 packs/year), one to two six-packs of beer a week, one 'bourbon and water' a night and 'a lot of sugar-free junk food, like chips'. He assures the nurse that he quit smoking 2 years ago, when he could no longer walk a block without considerable shortness of breath, and just quit drinking alcohol a few weeks ago at his doctor's insistence. About a year ago, he had a basal cell carcinoma removed from his right ear. Six months ago, cancerous tumours were discovered in his bladder and he underwent two 6-week chemotherapy courses of bladder instillations of BCG. His latest report indicates that the tumours have grown back and no further chemotherapy would be useful. The urologist had considered surgery but believed that Mr Casey's other medical problems would compromise his chances of survival. Mr Casey decides to let the disease run its course and to be managed at home through hospice care. Because he lives alone in a modest home, he asks his daughter, Mary, and her family to move in with him to provide care and support during his final months. His daughter accepts, saying she is glad to be able to spend this time with her father; she has been informed of the physical and emotional stress this will entail.

ASSESSMENT

Glynis Jackson, RN, the hospice nurse assigned as case manager for James Casey, completes a health history and physical examination during her first two visits in his home, 1 day apart. She gathers this information over 2 days to conserve his strength and allow more time for Mr Casey and his daughter to talk about their concerns.

During the physical assessment, Glynis notes that Mr Casey is pale with pink mucous membranes, thin with a wasted appearance and has a strained, worried facial expression. He complains of severe back pain no longer adequately relieved by Oxycodone and Panadeine Forte alternating every 2 to 4 hours. His blood pressure is 90/50, right arm in the reclining position with no significant orthostatic change; his apical pulse is 102, regular and strong; respiratory rate 24 and unlaboured; breath sounds are clear but diminished in the bases; oral temperature is 36°C.

A tunneled Groshong catheter as a CVAD is present in the right anterior chest. There is no drainage, redness or swelling at the site. The catheter was placed last week when the Mr Casey was being evaluated at the anaesthetist's office for pain management, but no medication is running via the CVAD. Mary reports that his urinary output is adequate. Approximately 200 mL of yellow, cloudy, non-malodorous urine is present in the urinal at the bedside from his last voiding.

Mr Casey states that he spends most of his time either in bed or sitting up in a chair in his room. He reports that he has no energy anymore and is unable to walk to the bathroom unassisted, dress himself or take care of his own personal hygiene. Glynis rates Mr Casey's functional level at ECOG level 4: capable of only limited self-care, confined to bed or chair 50% or more of waking hours (Karnofsky 10 to 20). Mr Casey tells the nurse that his daughter 'is working day and night to help me and is looking awfully tired'.

Mary reports that Mr Casey is eating very poorly: he usually eats a small bowl of oatmeal with milk for breakfast and vegetable soup and crackers for lunch, but he tells her that he is too tired for dinner and wants only fruit juice. Mr Casey tells the nurse that he has no appetite and eats just to please Mary. He does drink at least three to four glasses of water a day plus juice. His blood sugar levels remain within normal range.

His current weight is 54.6 kg at 170 cm tall, down from 81.8 kg 2 months ago.

Available laboratory values from his visit with the doctor show the following:

Total protein: 41 g/L (normal range: 62 to 8.0 g/L)
Albumin: 22 g/L (normal range: 35 to 50 g/L)
Haemoglobin: 102 g/L (normal range: 132 to 170 g/L)
Haematocrit: 30.5% (normal range: 40.0–54.0%)
BUN: 30 mml/L (normal range: 5 to 25 mm/L, slightly higher in older people)
Creatinine: 116 µmol/L (normal range: 50 to 110 µmol/L).

DIAGNOSES

- *Imbalanced nutrition related to dietary intake being less than body requirements* as evidenced by loss of appetite and weight loss.
- *Risk of caregiver role strain* related to severity of her father's illness and lack of help from other family members as manifested by physical exhaustion and emotional stress.
- *Chronic pain* related to progression of the disease process as evidenced by increased frequency of analgesia with limited effect.
- *Impaired physical mobility* related to pain, fatigue and beginning of neuromuscular impairment as evidenced by lack of energy and inability to ambulate without assistance.
- *Risk of impaired skin integrity* related to decreased physical mobility and malnourished state as manifested by skin breakdown.

PLANNING

- Plan to have a home health aide come to the home, give Mr Casey a shower or bed bath daily and assist his daughter with some of the household chores.
- Plan for a volunteer to spend up to 4 hours a day, twice a week with Mr Casey so that Mary can attend to outside activities and chores.
- Order a hospital bed with electronic controls to be delivered to the house.
- Order a special foam pad for bed and chair, and a bedside commode from the medical supply house.
- Request a physiotherapy consultation to evaluate current level of functioning and determine how to maintain current level.

NURSING CARE PLAN A person with cancer (continued)

Expected outcomes

- Increase oral intake and show improvement in serum protein values.
- Minimal pain for the rest of his life.
- Able to continue his current activity level.
- Maintain skin integrity.
- Daughter will be able to maintain supportive caretaking activities as long as Mr Casey needs them.

IMPLEMENTATION

- Talk with the doctor about prescribing a medication to help stimulate the appetite.
- Ask about favourite foods and ask Mary to offer a small portion of one of these foods each day.
- Encourage drinking up to four cans of liquid nutritional supplement with fibre a day, sipping them throughout the day.
- Discuss a pain control program with the specialist, using the CVAD and a CADD-PCA infusion pump with a continuous morphine infusion.
- Call a community nurse to set up the equipment and supplies (including the medication) for the morphine infusion.
- Teach Mary how to use the pump and about the side effects of the morphine infusion, including those that require a call to the nurse for assistance. Teach which untoward effects should be reported.
- Instruct Mary to allow ample rest periods for her father between activities.
- Instruct Mary and the community carer to inspect skin daily, give good skin care with emollient lotion after bathing and report any beginning lesions immediately to the nurse.
- Talk with Mary about having her adult son and daughter relieve her of the housework and stay with Mr Casey so that she can get out of the house occasionally. Offer to talk with them if she is uncomfortable doing so.

EVALUATION

James Casey did increase his oral intake a little, sometimes eating the special treats his daughter prepared and drinking one or two cans of liquid nutritional supplement a day. However, his weight did not increase; it stayed at about 54.6 kg until his death 2 weeks later. His daughter was very grateful for the extra help from the community carers and the volunteer, although she could not bring herself to ask her son and daughter for help and did not want the nurse to do so. She did become more rested and reported that 'Dad and I had some wonderful 3 am talks when he couldn't sleep'.

Mr Casey was started on 20 mg of morphine per hour with boluses of 10 mg 4 times a day, for breakthrough pain. This medication relieved his pain quite well; after 2 days he was alert enough most of the time to carry on a normal conversation and still walk to the bathroom with help up until 2 days before he died.

The hospital bed simplified Mr Casey's care and made it much easier for him to rest comfortably and change position. His skin remained intact and in good condition.

Mary reported that Mr Casey died peacefully in his sleep, about 2 weeks after care was started. She said that spending the last weeks of his life with him was a healing experience for both of them.

CRITICAL THINKING IN THE NURSING PROCESS

1. What other tests could be done to evaluate James Casey's nutritional status?
2. Mr Casey had severe back pain. What were the possible pathophysiological reasons for his pain?
3. One of the specified interventions was to consult the doctor regarding medication to increase Mr Casey's appetite. What medications might fulfil that function? What side effects might they have that would contraindicate these medications for him?
4. If Mr Casey had developed signs and symptoms of sepsis, what manifestations would you expect to see? As the nurse making the home visits, what would be your nursing actions and in what order of priority?

REFLECTION ON THE NURSING PROCESS

1. What support strategies could you recommend to assist Mr Casey and his family with anticipatory grieving?
2. Outline what you have learned from this case study that you can implement in your future practice.

Anxiety

Early in the disease process—for example, during diagnosis and treatment—threats to or changes in health status, physical comfort, role functioning or even socioeconomic status can cause anxiety. Later, anxiety may result from the anticipation of pain, disfigurement or the threat of death. In particular, people whose coping skills have been poor in the past (e.g. in managing anger) may find themselves at a loss to manage this current crisis. The person may manifest overt signs of anxiety: trembling, restlessness, irritability, hyperactivity, stimulation of the sympathetic nervous system (increased blood pressure, pulse, respiration, excessive perspiration, pallor), withdrawal, worried facial expressions and poor eye contact. The person may report insomnia and feelings of tension and apprehension, or express concerns regarding perceived changes brought about by the disease and fear of future events.

- Carefully assess the person's level of anxiety (moderate anxiety, severe anxiety or panic) and the reality of the threats represented in the person's current situation. The level of anxiety and the reality of the perceived threat influence the type of intervention that is appropriate for the person. *A person in panic may need medical intervention with appropriate medications, whereas those with moderate or severe anxiety are often managed by the nurse through counselling and teaching new coping skills.*
- Establish a therapeutic relationship by conveying warmth and empathy and using non-judgmental and effective listening. *A person who feels safe in the relationship with the nurse more readily expresses their thoughts and feeling. The person will be able to develop trust the nurse and perhaps be willing to try new behaviours as suggested.*

The amount of time this relationship may take to develop depends on the person's current emotional and mental state and the stage of the disease process.

- Encourage the person to acknowledge and express feelings, no matter how inappropriate they may seem to the person. *Just by expressing their feelings, people often can significantly diminish anxiety. Expressing feelings also allows the person to direct energy towards healing and thus has a positive therapeutic effect. Moreover, by acknowledging feelings, especially those the person considers unacceptable, the person can lay the groundwork for new coping behaviours.*
- Review the coping strategies the person has used in the past and build on past successful behaviours, introducing new strategies as appropriate. Explain why inappropriate strategies, such as repressing anger or turning to alcohol, are not helpful. *The person will be more willing to make changes that build on what has already worked in the past. The person will also be more willing to reject inappropriate strategies if they are given a persuasive reason why they have not had the desired effect in managing previous crises.*
- Identify resources in the community, such as crisis hotlines and support groups, that can help the person manage anxiety-producing situations. *The person may not have support systems available or the person's significant others may be having their own difficulties in dealing with the cancer diagnosis. Cancer Council Australia provides programs, support groups and counselling in all states and territories throughout Australia.*
- Provide specific information for the person about the disease, its treatment and what may be expected, especially for those people with obvious misinformation. *Knowing what is to come gives the person a sense of control and enables them to make decisions. Also, knowing that every effort will be made to keep the person as free of pain as possible can do a great deal to relieve anxiety.*
- Provide a safe, calm and quiet environment for the person in panic. Remain with the person and administer anti-anxiety medications as ordered. *Staying with the person and displaying calmness and confidence can protect the person from injury and prevent further panic. If the panic does not subside with the nurse's presence and support, referral to the doctor for medication management may be necessary.*
- Use crisis intervention theory to promote growth in the person and their significant others, regardless of the outcome of the disease. *During a major crisis, people can, with assistance, transform the experience from one that causes defeat and despair to one that enhances personal and spiritual growth.* If you are not skilled in this area, a referral to an appropriate mental health professional may be helpful to the person and their family.

Disturbed body image

Cancer and cancer treatments frequently result in major physiological and psychological body image changes. See the following box for manifestations of cancer. Loss of a body part (e.g. amputation, prostatectomy or mastectomy), skin changes and hair loss from chemotherapy or radiation therapy, disfigurement of a body part (e.g. lymphoedema in the affected upper and lower extremities) or the creation of unnatural openings on the body for elimination (e.g. colostomy or ileostomy) may have a major effect on the person's self-image. The gaunt, wasted appearance of the cachectic person, or draining, malodorous lesions that result when cancer breaks through the skin, are other significant aetiologies of body image disturbance. This may also give rise to fear of rejection, which plays a major role in sexual dysfunction. In addition to all of the other afflictions that cancer brings about, the person may undergo major changes in appearance and function. The person may exhibit a visible physical alteration of some portion of the body, verbalise negative feelings about the body and/or fear of rejection by others, refuse to look at the affected site and depersonalise the body change or lost part (e.g. by calling the colostomy 'that thing').

- Discuss the meaning of the loss or change with the person. *Doing so helps the nurse discover the best approach for this particular person and involves the person more actively in interventions. A small, seemingly trivial loss may have a big impact, especially when viewed in light of the other changes that are occurring in the person's life. Likewise, a major loss may not be as important as the nurse might imagine. To ensure more appropriate and individualised care, evaluate each situation in terms of the reactions of the specific person.*
- Observe and evaluate interaction with significant others. *People who are important to the person may unintentionally reinforce negative feelings about body image; on the other hand, the person may perceive rejection where none exists.*
- Allow denial, but do not participate in the denial; for example, if a person does not want to look at the wound, the nurse may say, 'I am going to change the dressing to your breast incision now'. *During the initial stage of shock at the loss of a body part, denial is a protective mechanism and should not be challenged, nor should it be promoted. A matter-of-fact approach and an empathetic attitude will go far to facilitate the eventual acceptance of the change.*
- Assist the person and significant others to cope with the changes in appearance:
  a. Provide a supportive environment.
  b. Encourage the person and significant others to express feelings about the situation.
  c. Give matter-of-fact responses to questions and concerns.
  d. Identify new coping strategies to resolve feelings.
  e. Enlist family and friends in reaffirming the person's worth.
- *A supportive, safe environment in which feelings are respected and new coping strategies can be tried promotes acceptance, as does reaffirming that the person's worth is not diminished by any physical changes.*
- Teach the person or significant others to participate in the care of the afflicted body area. Provide support and validation of their efforts. *Active involvement in providing*

care, such as changing a dressing or emptying a colostomy bag, empowers the person and/or significant others. This intimate involvement also desensitises feelings about disfigurement and promotes acceptance. Involving significant others reduces the risk of them rejecting the person and can promote closeness. Positive reinforcement from the nurse encourages them to continue these behaviours.

- Teach strategies for minimising physical changes, such as providing skin care during radiation therapy and dressing to enhance appearance and minimise change in the body part. *Early intervention can limit the negative side effects of treatment and actually promote recovery. Involving the person provides an additional way for the person to be in control of a difficult situation.*
- Teach ways to reduce the alopecia that results from chemotherapy and to enhance appearance until the hair grows back:
  a. Discuss the pattern and timing of hair loss. *This allows the person to cope with changes and incorporate them into daily activities.*
  b. Encourage wearing cheerful, brightly coloured head coverings; assist in colour coordinating them with usual clothing. *Attractive head coverings protect the bald head while allowing the person to feel stylish and well dressed.*
  c. Refer to a good wig shop before hair loss is experienced. *Hair colour and texture can be matched to minimise obvious changes in appearance.*
  d. Refer to support programs such as cancer support workshops that are provided by the Cancer Council in each state and territory. *A support group can diminish feelings of isolation and provide practical tips for managing problems. For a list of community resources available to people with cancer or for confidential information and support, contact the Cancer Council Helpline on 13 11 20. (The cost is that of a local phone call from anywhere in Australia.)*
  e. Reassure that hair will grow back after chemotherapy is discontinued, but also inform that the colour and texture of the new hair may be different. Hair loss has been identified as the most distressing symptom by many people (Ferrell, 2000). *Interventions to reduce that loss can have a significant impact on body image concerns. Moreover, knowing what to expect may decrease anxiety and distress.*

Anticipatory grieving

Anticipatory grieving is a response to loss that has not yet occurred. Overall, only 50% of people with cancer fully recover and certain types of cancer have a much higher death rate; thus, the person with cancer is often confronted with facing death and making preparations for it. This can be a healthy response that allows the person and family to work through the dying process and achieve growth in the final stage of life. Perceived changes in body image and lifestyle can also prompt anticipatory grieving. The person or significant others may show sorrow, anger, depression or withdrawal, expressing distress at the potential loss or verbalising concern about unfinished life business. (See Chapter 4 for more on nursing care of the person who is grieving or dying.)

MANIFESTATIONS Cancer

- Hair loss
- Depression
- Fever
- Bleeding gums
- Oropharyngeal ulcerations
- Stomatitis
- Anorexia
- Nausea and vomiting
- Diarrhoea
- Emaciation
- General weakness
- Flaccid muscles
- Stooped posture
- Pallor
- Excessive bruising
- Radiation burns
- Visible tumour (abdomen)
- Odour of decay
- Hypotension

- Use the therapeutic communication skills of active listening, silence and non-verbal support to provide an open environment for the person and significant others to discuss their feelings realistically and to express anger or other negative feelings appropriately. *This helps the person and family to get in touch with feelings and confront the possibility of the loss or death.*
- Answer questions about illness and prognosis honestly, but always encourage hope. *This allows for realistic appraisal of the situation and planning, and helps to combat feelings of hopelessness and depression.*
- Encourage the dying person to make funeral and burial plans ahead of time and to be sure the will is in order. Make sure the necessary phone numbers can be easily located. *This gives a sense of control and relieves family members of these concerns at a time when the person is most in need of their support and when they themselves are extremely stressed.*
- Encourage the person to continue taking part in activities he or she enjoys, including maintaining employment as long as possible. *This gives a sense of continuity of life even in the face of severe losses.*

Risk of infection

Malnutrition, impaired skin and mucous membrane integrity, tumour necrosis and suppression of the white blood cells (WBC) from chemotherapy or radiation may contribute to the risk of infection. Anorexia, as well as the disease itself, deprives the body of nutrients needed for healing, while impaired integrity of skin and mucous membranes (a result of chemotherapy

and/or radiation therapy) compromise the first lines of defence against microbial invasion. Cells in the centre of large or not very vascular tumours may die from malnutrition, eventually eroding through tissues to increase the risk of sepsis. Bone marrow depression resulting from the effects of certain types of cancers and from chemotherapy undermine the body's ability to respond to infection. The person may exhibit the classic signs of infection: lassitude, fever, anorexia, pain in the affected area and physical evidence of infection, such as a purulent, draining lesion or wound. If the bone marrow is compromised, the usual signs and symptoms of infection may be absent or reduced.

- Monitor vital signs. *Fever and sympathetic nervous system responses, such as increased pulse and respiration, are usual early signs of infection. However, severely immunosuppressed people may be unable to mount a fever; therefore, the absence of fever cannot rule out infection.*
- Monitor WBC counts frequently, especially if the person is receiving chemotherapy known to cause bone marrow suppression. *This allows the nurse to notify the doctor at the first sign of diminishing WBC counts so that corrective action can be taken.*
- Teach the person to avoid crowds, small children and people with infections when WBC count is at nadir (lowest point during chemotherapy) and to practise scrupulous personal hygiene. *During periods of leucopenia, the person may lose immunity to his or her own natural flora. Careful attention to hygiene reduces the risk of infection. Crowds, which promote contact with a greater variety of infectious agents, and friends with minor infections can be very dangerous for the immunosuppressed. Small children should be avoided because they often have microbes to which most people are usually immune but which the person with cancer may not be able to resist.*
- Protect skin and mucous membranes from injury. Teach appropriate skin care measures, such as good hygiene, use of a moisturising lotion to prevent dryness and cracking, frequent changes of position for the bed-bound and immediate attention to skin breaks or lesions. *Ensuring intact skin strengthens the first line of defence against infection.*
- Encourage the person to consume a diet high in protein, minerals and vitamins, especially vitamin C. *Improving nutrition decreases the risk of infection. Vitamin C has been shown to help prevent certain types of infection, such as colds.*

Risk of injury

In addition to infection, cancer can pose a risk of injury from, for example, obstruction by a large tumour or one located in a limited body space (e.g. in the brain, bowel or bronchial airways). If the cancer is one that creates ectopic sites of hormones, elevated levels of hormones that are not under the control of the pituitary gland can injure the person in a variety of ways. Signs of obstruction depend on the organ involved: bowel obstruction presents with pain, distension and cessation of bowel activities; obstruction in the brain gives signs of increased intracranial pressure or personality/behavioural change; bronchial obstruction manifests as respiratory distress, cyanosis and altered arterial blood gases. Ectopic production of parathyroid hormone manifests as high serum calcium levels as well as signs of hypercalcaemia; ectopic production of antidiuretic hormone causes fluid retention and manifests as hypertension and peripheral and pulmonary oedema.

- Assess frequently for signs and symptoms indicating problems with organ obstruction. *Early detection of major problems allows the nurse to seek medical help before the problem evolves into a physiological crisis.*
- Teach to differentiate minor problems from those of a serious nature. Encourage the person to consult with the nurse or doctor if in doubt, or to call 000 if they become very ill. Box 13.13 provides guidelines to help people identify serious problems. *Having guidelines for when to call the doctor provides an anxiety-reducing safety net for the person and family and promotes early detection of complications.*
- Monitor laboratory values that may indicate the presence of ectopic functioning and report abnormal findings to doctors immediately. (See Table 13.4 for laboratory indicators of ectopic functions.) *Early detection promotes early medical intervention and prevents serious consequences from the ectopic secretion.* Refer to Chapters 9, 18 and 19 for specific signs and symptoms of electrolyte imbalances and endocrine disorders.

BOX 13.13 When to call for help

Instruct the person or family member to call the nurse or doctor if any of the following signs or symptoms occurs:

- Oral temperature greater than 38.6°C.
- Severe headache; significant increase in pain at usual site, especially if the pain is not relieved by the medication regimen; or severe pain at a new site.
- Difficulty breathing.
- New bleeding from any site, such as rectal or vaginal bleeding.
- Confusion, irritability or restlessness.
- Withdrawal, greatly decreased activity level or frequent crying.
- Verbalisations of deep sadness or a desire to end life.
- Changes in body functioning, such as the inability to void or severe diarrhoea or constipation.
- Changes in eating patterns, such as refusal to eat, extreme hunger or a significant increase in nausea and vomiting.
- Appearance of oedema in the extremities or significant increase in oedema already present.

Instruct the person or family member to call 000 if the person:

- is having much difficulty breathing or if the face or lips have a bluish tinge
- becomes unconscious or has a convulsion
- exhibits unmanageable behaviour, such as being physically abusive, hurting self or engaging in uncontrollable activity.

Imbalanced nutrition: less than body requirements

The anorexia–cachexia syndrome (described earlier in this chapter) is a common cause of malnutrition in people with cancer. Metabolism increases in response to increased cancer cell production, while the cancer's parasitic activity reduces the nutrients available to the body. Loss of appetite, food aversion, nausea and vomiting, and painful oral lesions from chemotherapy or radiation may contribute to impaired nutrition. Tumours of the gastrointestinal tract that affect absorption also contribute to the problem. Manifestations include wasted appearance, considerable weight loss over a relatively short period of time, anthropometric measurements below 85% of standard for fat and muscle tissue, decreases in serum proteins and negative responses to antigen testing.

- Assess current eating patterns, including usual likes and dislikes, and identify factors that impair food intake. *This allows for a more individualised plan based on needs and preferences.*
- Evaluate degree of malnutrition:
  a. Check laboratory values for total serum protein, serum albumin and globins, total lymphocyte count, serum transferrin, haemoglobin and haematocrit. *These values represent the laboratory values that are most likely to decrease with malnutrition.*
  b. Calculate nitrogen balance and creatinine height index. Calculate skeletal muscle mass and compare findings to normal ranges. *Urinary creatinine is an index of lean body mass and decreases in malnutrition. Lean muscle mass is catabolised for energy in people with cancer.*
  c. Take anthropometric measurements and compare them to standards: height, weight, elbow breadth, arm circumference, triceps skinfold thickness and arm muscle mass. *This estimates the degree of wasting; findings below 85% of standard are considered malnutrition.*
- Teach the principles of maintaining good nutrition and adapting the diet to medical restrictions and current preferences. *This tailors the food plan to the person's needs and thereby promotes compliance.*
- Manage problems that interfere with eating:
  a. Encourage eating whatever is appealing and consider adding nutritional supplements such as Ensure Plus or Isocal to the diet. *It is better to eat something even if it is not nutritionally balanced.*
  b. Eat small, frequent meals. *These are more easily digested and absorbed and are usually better tolerated by the person with anorexia.*
  c. Encourage trying icy cold foods (such as ice-cream) or those that are more highly seasoned if food has no taste. *Chemotherapy and radiation therapy may harm taste buds and prevent distinguishing the taste of foods. Strong seasonings and coldness make food more enjoyable to the person with diminished taste. However, spicy foods are not recommended for people with stomatitis.*
  d. Encourage cold and bland semi-soft and liquid foods with painful oropharyngeal ulcers; use a non-alcohol anaesthetic mouthwash prior to eating. *These foods are less irritating to sensitive mucous membranes; deadening the pain can make chewing and swallowing easier.*
  e. Manage nausea and vomiting by administering antiemetic drugs. (Around-the-clock medication may be an effective preventive measure.) Encourage the person to eat small, frequent, low-fat meals with dry foods such as crackers and toast, to avoid liquids with meals and to sit upright for an hour after meals. Remove emesis basins and encourage oral hygiene before eating. *Dry, low-fat foods are more readily tolerated when nauseated. Removing vomiting cues, such as odour and supplies associated with vomiting, can reduce nausea.*
- Teach to supplement meals with nutritional supplements such as Ensure Plus or Isocal and to take multivitamin and mineral tablets with meals. Suggest increasing kilojoules by adding ice-cream or frozen yoghurt to the liquid supplement or commercial protein–carbohydrate powders to milk or fruit juice. *Because the food intake is usually less than that needed to maintain or gain weight, these supplements can add kilojoules in a manner often tolerated.*
- Teach to keep a food diary to document daily intake. If the person can see how little is being consumed, he or she may eat more. *A food diary also helps the nurse keep a kilojoule count and alert the doctor if more drastic nutritional measures, such as a feeding tube or parenteral nutrition, need to be instituted.*
- Teach to administer parenteral nutrition via a central line or other CVAD. Teach safety measures and care of the CVAD and explain how the pump delivering the solution works. Provide an emergency phone number for help with administration problems. (See Chapter 21 for safety guidelines for administering parenteral nutrition.) *The person with chronic or terminal cancer requiring parenteral nutrition is usually managed at home, so information on how to manage the entire process may be needed.*

Impaired tissue integrity

The most common impairment of tissue integrity occurs in the oral–pharyngeal–oesophageal mucous membranes. It is secondary to the effects of some chemotherapeutic drugs and radiation treatment to the head and neck. The oral–pharyngeal–oesophageal tissues are lined with cells with a high mitotic turnover rate and are therefore vulnerable to many chemotherapeutic drugs. Leukaemias, bone marrow transplants and herpes viral infections are other aetiological factors in the disruption of oral–pharyngeal–oesophageal tissue. Manifestations of this problem may include the following:

- Small ulcers occur on the tongue and mucous membranes in the mouth and throat.
- Herpes simplex type 1 lesions or vesicles evolve into ulcerations.
- Fungal infections, such as thrush (due to *Candida* infections), are manifested by a white, yellow or tan coating with dry, red, fissured tissue underneath.

- Red, swollen, friable gums bleeding with minimal or no trauma.
- **Xerostomia** is excessive dryness of the mucous membranes (due to chemotherapy or radiation).

Manage such problems with the following interventions:

- Carefully assess and evaluate the type of tissue impairment present. Identify possible sources, such as chemotherapy or radiation therapy to head and neck. *This allows the nurse to implement corrective measures appropriate to the type of problem.*
- Implement and teach measures for preventing oropharyngeal infection:
  a. Observe for systemic signs of infection. Be suspicious of any fever that has no apparent cause. *This facilitates early identification of an infection before it spreads.*
  b. Encourage cleaning teeth gently and using a non-alcohol mouthwash several times a day. This can be done after waking in the morning, after any oral intake and before bedtime. Soak dentures nightly in hydrogen peroxide and floss gently with waxed floss after meals and bedtime; this measure may be contraindicated for people with leukaemia or thrombocytopenia. *Disrupted mucous membranes allow the normal oral bacterial flora into the systemic circulation, which can result in sepsis in the immunocompromised person. Reducing the oral flora by frequent hygiene decreases the risk of infection.*
  c. Culture any oral lesions and report the problem to the doctor. *Herpes lesions may not follow a typical pattern in immunosuppressed people. Identifying the cause of the infection, whether viral, fungal or bacterial, allows the doctor to prescribe the appropriate treatment.*
- Implement and teach measures for reducing trauma to delicate tissues:
  a. Counteract dry mouth (xerostomia) with lubricating and moisturising agents, such as Gatorade, sugarless gum and Blistex. *This protects mucous membranes from infection and trauma.*
  b. Avoid putting sharp instruments in the mouth. Use smooth plastic spoons and forks for eating, especially with a bleeding disorder. Dental work should be done by dental oncologists.
  c. Brush teeth with a very soft toothbrush and obtain a new toothbrush monthly. If gums are friable and bleeding, clean teeth with a soft cloth or toothpaste over finger. Chlorhexidine mouthwash (Savacol) may be used. *This protects gums from trauma and decreases risk of haemorrhage.*
- Administer specific medications as ordered to control infection and/or pain:
  a. Aciclovir is often used to treat viral infections.
  b. Systemic antibiotics are used to treat bacterial infections.
  c. Nystatin or clotrimazole solution for 'swish and swallow' or lozenges that dissolve slowly in the mouth are used for fungal infections.

BOX 13.14 Combination mouthwashes for oropharyngeal pain control

Kaiser mouthwash
- Nystatin
- Hydrocortisone
- Tetracycline

Stanford mouthwash
- Nystatin
- Tetracycline
- Lignocaine
- Hydrocortisone

Xyloxylin suspension
- Benylin syrup
- Lignocaine
- Maalox suspension

Stomafate suspension
- Sucralfate
- Sterile water
- Benylin syrup
- Maalox suspension

  d. Use viscous xylocaine or various combination mouthwashes before meals and as needed. These agents reduce pain and inflammation. See Box 13.14 for the ingredients of combination mouthwashes. *Knowing the contents of each mouthwash can prevent hypersensitivity reactions (e.g. lignocaine) and assist when teaching.*

Nursing interventions for oncological emergencies

In caring for people with cancer, nurses may encounter a number of emergency situations in which their role may be pivotal to the person's survival. Most of these emergencies require astute observations, accurate judgments and rapid action once the problem has been identified. A brief description of the more common oncological emergencies with nursing interventions follows. In all cases, immediate notification of the doctor or emergency team is the first step.

Pericardial effusions and neoplastic cardiac tamponade

Malignant pericardial effusion is an accumulation of excess fluid in the pericardial sac that compresses the heart, restricts heart movement and results in a cardiac tamponade. The signs of cardiac tamponade are caused by compression of the heart, which leads to decreased cardiac output and impaired cardiac function. Signs include hypotension, tachycardia, tachypnoea, dyspnoea, cyanosis, increased central venous pressure, anxiety, restlessness and impaired consciousness.

Interventions include the following:

- Start oxygen and alert respiratory therapy for other respiratory support as needed.
- Insert an intravenous cannula if one is not already in place.
- Monitor vital signs and initiate haemodynamic monitoring.

- Prepare vasopressor drugs as ordered.
- Bring emergency cart to bedside.
- Set up for and assist doctor with a pericardial tap (pericardiocentesis).
- Reassure the person.

Superior vena cava syndrome

The superior vena cava can be compressed by mediastinal tumours or adjacent thoracic tumours. The most common cause is small-cell or squamous cell lung cancers. Occasionally the problem is caused by thrombus around a central venous catheter that then plugs up the vena cava, resulting in obstruction and backup of the blood flowing into the superior vena cava.

Obstruction of the venous system causes increased venous pressure, venous stasis and engorgement of veins that are drained by the superior vena cava. Signs and symptoms may develop slowly; facial, periorbital and arm oedema are early signs. As the problem progresses, respiratory distress, dyspnoea, cyanosis, tachypnoea, altered consciousness and neurological deficits may occur. Figure 13.7 illustrates the superior vena cava syndrome.

Emergency measures include the following:

- Provide respiratory support with oxygen and prepare for tracheostomy.
- Monitor vital signs.
- Administer corticosteroids (e.g. dexamethasone) to reduce oedema.
- If the disorder is due to a clot, administer antifibrinolytic or anticoagulant drugs.
- Provide a safe environment, including seizure precautions.

After the emergency is managed, the person often receives radiation or chemotherapy to reduce the tumour size.

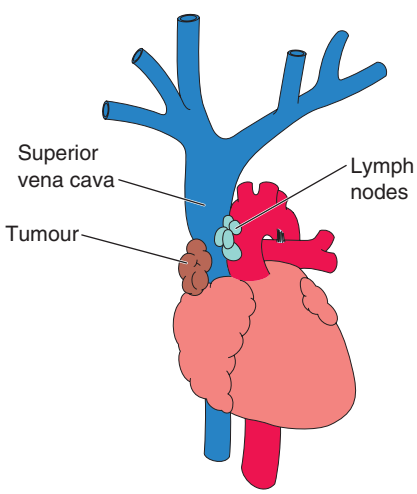

FIGURE 13.7 ■ The superior vena cava syndrome. The enlargement of a tumour adjacent to the superior vena cava (usually in the lung or mediastinum) compresses that major blood vessel, which leads into the right atrium of the heart. As a result, blood backs up into the venous system behind the obstruction, diminishing blood flow into the heart

Sepsis and septic shock

Tumour necrosis, immune deficiency, antineoplastic therapy, malnutrition and co-morbid conditions can lead to the development of sepsis. Bacteria gain entrance to the blood, grow rapidly and produce septicaemia. Because malignant tumours are more likely to use anaerobic metabolic pathways, the bacteria of tumour sepsis are usually Gram-negative and damage the body through a combination of bacterial endotoxins and an uncontrolled immune reaction. Gram-negative sepsis progresses to systemic shock and eventually results in multisystem failure. Signs and symptoms appear in two phases. The first phase is characterised by vasodilation with vascular dehydration, high fever, peripheral oedema, hypotension, tachycardia, tachypnoea, hot flushed skin with creeping mottling beginning in the lower extremities and anxiety or restlessness. Without treatment, the shock progresses to the second phase, which shows the more classic signs of shock: hypotension, rapid thready pulse, respiratory distress, cyanosis, subnormal temperature, cold clammy skin, decreased urinary output and altered mental state. Identifying the problem while the person is still in the hyperdynamic state is crucial to the person's survival. See Chapter 10 for further discussion of septic shock.

Spinal cord compression

Spinal cord compression is most commonly associated with pressure from expanding tumours of the breast, lung or prostate, and with lymphoma or metastatic disease. Spinal cord compression constitutes an emergency because of the potential for irreversible paraplegia. Back pain is the initial symptom in 95% of the cases of spinal cord compression. This may progress to leg pain, numbness, paraesthesias and coldness. Later, bowel and bladder dysfunction occur; finally, neurological dysfunction progresses from weakness to paralysis. Treatment often consists of radiation or surgical decompression, but early detection is essential. See Chapter 42 for further discussion of spinal cord compression.

Obstructive uropathy

People with intra-abdominal, retroperitoneal or pelvic malignancies, such as prostate, cervical or bladder cancers, may experience obstruction of the bladder neck or the ureters. Bladder neck obstruction usually manifests as urinary retention, flank pain, haematuria or persistent urinary tract infections, but ureteral obstruction is often not evident until the person is in renal failure. See Chapters 26 and 27 for further discussion of obstructive uropathy.

Hypercalcaemia

Hypercalcaemia in people with cancer results from the excessive ectopic production of parathyroid hormone and is most commonly associated with cancers of the breast, lung, oesophagus, thyroid, head and neck, and with multiple myeloma. Bone metastases may also cause hypercalcaemia. When the rate of calcium mobilisation from the bone exceeds the renal threshold for excretion, serum calcium levels can become dangerously elevated. People with hypercalcaemia often present with non-specific symptoms of fatigue, anorexia, nausea, polyuria and constipation. Neurological symptoms include muscle

weakness, lethargy, apathy and diminished reflexes. Without treatment, hypercalcaemia progresses to alterations in mental status, psychotic behaviour, cardiac arrhythmias, seizures, coma and death (see Chapter 9).

Hyperuricaemia

Hyperuricaemia usually is a complication of rapid necrosis of tumour cells after vigorous chemotherapy for lymphomas and leukaemias. Hyperuricaemia may be related to increased uric acid production or to the tumour lysis syndrome associated with Burkitt's lymphoma. Uric acid crystals are deposited in the urinary tract, causing renal failure and uraemia. People with hyperuricaemia manifest with nausea, vomiting, lethargy and oliguria.

Syndrome of inappropriate antidiuretic hormone secretion

Occurring in only about 2% of people with cancer, syndrome of inappropriate antidiuretic hormone secretion (SIADH) is related to an ectopic secretion of antidiuretic hormone that is usually associated with small-cell lung carcinoma, but also occasionally with prostate and adrenal cancers. The kidney secretes an excessive amount of sodium and conserves a disproportionate amount of free water, causing profound hyponatraemia. Signs and symptoms include anorexia, nausea, muscle aches and subtle neurological symptoms that can progress to lethargy, confusion, seizures and coma from cerebral oedema.

Tumour lysis syndrome

Tumour lysis syndrome (TLS) is a life-threatening emergency for people with cancer. TLS is characterised by a combination of two or more metabolic abnormalities, including hyperuricaemia, hyperphosphataemia, hyperkalaemia and/or hypocalcaemia (McBride & Westervelt, 2012). The syndrome develops because of massive and rapid destruction or death of cancer cells caused by cytotoxic treatment such as chemotherapy, radiation, biological therapy, hormonal therapy and surgery. It can also occur spontaneously with sudden death of tumour cell. A high incidence of TLS occurs in people with bulky, highly proliferating and chemosensitive tumours such as high-grade lymphomas (Burkitt's lymphoma) and acute lymphoblastic leukaemia (ALL). Although the incidence of TLS in solid tumours is rare, cases of TLS following chemotherapy have been reported in people with small-cell lung cancer, breast cancer, neuroblastoma, melanoma and ovarian cancer.

The major cause of TLS is chemotherapy to tumours with a high proliferative rate, a relatively large tumour burden and high sensitivity to cytotoxic agents, which leads to massive and rapid cell death. Usually, within a week of initiating chemotherapy, the body no longer can excrete the large amount of metabolic by-products from the cell death, resulting in the release of intracellular contents and metabolic by-products (such as potassium, phosphorus and nucleic acid) into the bloodstream (McBride & Westervelt, 2012). As a result, a combination of metabolic derangements occurs, including hyperkalaemia, hyperuricaemia and hyperphosphataemia with secondary hypocalcaemia. These metabolic abnormalities put people at risk of cardiac malfunction and renal failure.

Clinical manifestations of TLS include nausea, vomiting, lethargy, oedema, fluid overload, congestive heart failure, cardiac dysrhythmias, seizures, muscle cramps, tetany, syncope and possible sudden death. Diagnosis of TLS mainly depends on laboratory tests and clinical signs and symptoms. Prevention is crucial in management of TLS. People at risk of TLS include those with bulky chemosensitive cancer such as high-grade lymphomas and acute leukaemia, elevated serum uric acid, potassium, phosphorus and renal deficiency. Preventive and management measures include identifying people at risk, administration of allopurinol to inhibit the conversion of nucleic acid to uric acid, hydration and diuretic therapy to promote urinary excretion of uric acid and phosphate, urine alkalinisation to promote the urinary excretion of uric acid, administration of oral phosphate binder such as aluminium hydroxide to promote the excretion of phosphate through the bowel, administration of sodium polystyrene sulfonate (Kayexalate) to promote the excretion of potassium through the bowel and initiation of haemodialysis to people unresponsive to standard approaches to hyperkalaemia, hyperuricaemia or hyperphosphataemia.

Health education for the person and family

Prevention

Cancer Council Australia (2013b) promotes strategies to reduce cancer risk in addition to the screening measures discussed earlier in this chapter. Based on these strategies, nurses teach people and families to decrease risk factors by:

- quitting smoking
- eating healthy foods (see Box 13.15).
- staying in shape
  - maintain a healthy body weight range and body mass index
  - waist circumference below 94 cm for men and 80 cm for women
- being sun smart
  - slip on protective clothing
  - slop on SPF 30^+ sunscreen (20 minutes before going outside and re-apply every 2 hours)
  - slap on a broad-brimmed, legionnaire or bucket-style hat
  - seek shade
  - slide on some sunglasses
- limiting alcohol
  - limit intake—no more than two standard drinks per day
  - choose low-alcohol drinks
  - avoid binge drinking
  - have at least 2 alcohol-free days per week
  - eat some food when you drink
- moving your body
  - only 30 minutes of moderate intensity exercise each day is good for your health and 60 minutes can reduce your risk of developing cancer
  - increase walking—at lunchtime, park your car further away, take the stairs.

Source: Cancer Council Australia (2012; 2013b); www.cancer.org.au.

In addition, encourage people to report to the public health department any known leaking of chemicals or radioactive materials into the water or air and any noted increase in the incidence of cancer, especially of one specific type, in their communities.

BOX 13.15 Cancer Council Australia: strategies for eating healthy foods

Eat two serves of fruit and five serves of vegetables per day.
Eat cereals—preferably wholegrain.
Limit cured meats.
Red meat three to four times a week only and on other days eat fish, poultry, beans and lentils.
Choose foods low in salt, sugars and saturated fats.

Source: Cancer Council Australia (2013b). *Fact sheet: Maintain a healthy weight.* Retrieved from www.cancer.org.au/preventing-cancer/reduce-your-risk/maintain-a-healthy-weight.html, 8 January 2013. For more information visit www.cancer.org.au.

Rehabilitation and survival

Rehabilitation from cancer not only involves regaining strength, recovering from surgery or chemotherapy and learning to live with an altered body part or appliance, but also entails recovering from associated psychological and emotional turmoil.

Rehabilitation centres provide physiotherapy, occupational therapy, speech pathology, job retraining and an opportunity to recuperate before resuming full responsibilities. In addition, many people go home to convalesce and receive in-home support in the form of nursing supervision, direct care and teaching. Hygiene and home maintenance can be provided by home and community care organisations. Physiotherapists and occupational therapists provide muscle strengthening and mobility training (especially with prostheses) and home safety teaching.

Psychological rehabilitation of cancer survivors addresses quality-of-life issues. Three 'seasons of cancer survival' have been described (Mullan, 1985). The first starts with diagnosis but is dominated by treatment. The second stage is one of extended survival, which occurs when treatment ends and the watchful waiting period begins. This period is characterised by fear of recurrence. Permanent survival is said to begin when the survival period has gone on long enough that the risk of recurrence is small. In this period, the person has to deal with secondary problems related to health and social issues resulting from the cancer experience. Employment may be a problem, private health insurance may be cancelled and life insurance may be difficult to get. Relationships may have suffered from the strain of the illness on significant others and the essential self-focusing required for recovery. However, both the person and significant others may have undergone a personal and spiritual growth that ushers in a new and enriching period of their lives.

New self-help groups are emerging in many communities to support others through their 'seasons of survival'. Many cancer survivors speak to groups about assisting other cancer survivors. People and families need to be informed about the many resources available through community agencies as well as the survivor support groups.

Community-based care

Before the person is discharged, teach both the person and significant others or caregivers to manage the person at home. Discuss problems that may result from the type of cancer and the treatment received and provide information on how to manage these problems and when to call the doctor.

- Teach wound care to the person with an open wound or draining lesion and provide a referral to a community nurse to monitor progress.
- Explain special diets clearly or refer the person to a dietitian before discharge.
- Carefully review the doctor's instructions with the person and family, making sure they understand the medications to be taken, any other treatments and when to see the doctor for follow-up care.
- Provide or order equipment and supplies needed for home care, especially any specialised bed or equipment to aid mobility and ensure safety in the home.
- For the person who will need complex care, such as parenteral nutrition, provide a referral to the community nurse before discharge.

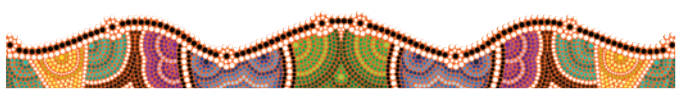
Because the hospital stay is often short, the person and family will benefit from follow-up phone calls at home for several days. People do not learn well under the stress of going home; give the person and family a number to call if they have concerns or questions.

Hospice care

More and more people with terminal disease are electing to die at home. This decision has been made easier by the increased availability of hospice programs. When a person and family or significant others elect **hospice** care, they are usually precluding additional hospitalisations other than those required to manage reversible problems. People in hospice care also refuse resuscitation measures (CPR and other extraordinary measures).

Many hospice services are connected with an inpatient respite care unit, where the person can receive 24-hour care for up to several weeks. This source provides the necessary care to the person if a family member becomes ill or needs to be relieved temporarily of the tremendous burden of caring for a dying loved one. Hospice care involves a multidisciplinary team and is designed to give the person comfort and to assist in a peaceful death with support to caretakers. The team usually consists of a nurse case manager, a doctor, an anaesthetist or pharmacist, an infusion therapist, a social worker, a physiotherapist, a home health aide and volunteers.

Studies of families that have participated in hospice services have found that family members were very positive about the experience (Teno et al., 2001). The aspects of hospice care they most appreciated were the 24-hour accessibility and availability of the healthcare team and the quality of communication from all team members. Family members emphasised that 'the nurses listened, answered questions honestly and prepared us for changes in the patient's condition'. Team members were rated as very professional, but more relaxed and friendly than hospital staff; they talked with the family and displayed accepting, non-judgmental attitudes. Team members were also seen as well informed, knowledgeable and competent with excellent problem-solving skills. Chapter 4 provides more information on hospice care.



CHAPTER HIGHLIGHTS

- Lung cancer was the leading cause of all cancer deaths in both men and women in Australia in 2005, accounting for 19% of all cancer deaths. Cancer can affect people of any age, gender, ethnicity or geographical region.
- The incidence of cancer increases with advancing age. The most commonly seen cancers in women are breast, colorectal and lung cancer, and melanoma of the skin. In men, prostate, lung and colorectal cancer, and melanoma of the skin occur most frequently.
- Oncogenes are genes that promote cell proliferation and are capable of triggering cancerous characteristics. Several oncogenes, such as BRCA-1 and BRCA-2, are associated with breast cancer.
- Tumour suppressor genes, which normally suppress oncogenes, can become inactive by deletion or mutation. Inherited cancers have been associated with tumour suppressor genes, such as *p53*, a suppressor gene that has been associated with sarcoma and cancer of the breast and brain.
- The diagnosis and treatment of cancer is a pivotal life-changing event that prompts individuals to make immediate and ongoing adjustment to this life-threatening illness.
- Effective physical and psychosocial adjustment to cancer diagnosis and treatment has been shown to lead to successful completion of treatment, enhancement of the person's ability to cope with disease, improvement of the person's quality of life and, ultimately, improvement of survival.
- The goals of cancer treatment are cure and control of cancer, as well as management of cancer-related and treatment-related symptoms.
- Chemotherapy uses cytotoxic medications to cure or control cancer by interrupting cell metabolism and replication and by interfering with the ability of the malignant cell to synthesise vital enzymes and chemicals.
- Pain management is an important component of care for people with cancer. It is estimated that 20% to 50% of people with early-stage cancer and up to 95% of people with advanced cancer experience pain.
- Complementary therapies are therapies that people choose as a complement to medical treatment. Common complementary therapies for cancer include botanical agents, nutritional supplements, dietary regimens, mind–body modalities, spiritual approaches and miscellaneous therapies.
- Tumour lysis syndrome (TLS), a combination of two or more metabolic abnormalities, is a life-threatening emergency for people with cancer. People at risk of TLS include those with bulky chemosensitive cancer such as high-grade lymphomas and acute leukaemia, elevated serum uric acid, potassium and phosphorus, and renal deficiency.

CONCEPT CHECK

1 Mr Lawrence has a history of colon cancer. He has been advised that the cells from the colon tumour have travelled to his liver. This process is called:
1. carcinogenesis
2. dysplasia
3. metastasis
4. mutation

2 A person diagnosed with lung cancer reports they are having difficulty sleeping and often feel tense. The most appropriate initial nursing intervention would be to:
1. encourage the person to express his feelings about the cancer diagnosis
2. document the person's report of difficulty sleeping and tenseness in the chart
3. obtain an order for medication for sleep from the doctor
4. offer an anti-anxiety drug such as Ativan (lorazepam)

3 Mr Palacci is receiving external radiation for treatment of lung cancer. Educating Mr Palacci to care for his skin in the marked area includes:
1. apply antibacterial ointment daily
2. avoid contact with others
3. avoid rubbing or scratching treated skin areas
4. cleanse the skin with plain water

4 Ms Hernandez complains of nausea and vomiting following her daily chemotherapy treatment. The most appropriate nursing intervention would be to:
1. keep Ms Hernandez on nil orally until her daily chemotherapy is completed
2. provide anti-emetic medication 30 to 40 minutes prior to each treatment
3. provide clear liquids until the chemotherapy is completed
4. schedule chemotherapy administration for bedtime

5 Mrs Smith experiences bone marrow depression as a result of chemotherapy. Which of the following would the nurse expect to find?
1. alopecia
2. nausea and vomiting
3. platelet count 50
4. temperature 38.9°C

6 Mr Wu, a 46-year-old businessman with a diagnosis of metastatic lung cancer, is going to have chemotherapy tomorrow. To help Mr Wu better understand chemotherapy, you have provided him with education about the role of the chemotherapeutic agents being used to treat his cancer. You determine that your teaching is effective when Mr Wu states:
1. 'Chemotherapy uses drugs that promote the normal growth of cells while killing the cancer cells.'
2. 'Chemotherapy only uses a single drug to treat cancer because drug resistance is rare.'
3. 'Chemotherapy includes drugs that not only attack cancer cells but also normal rapidly dividing cells.'
4. 'Chemotherapy is a preferred therapy because it has fewer adverse effects than radiation therapy.'

7 During training for new radiation nurses, you have learned that the delivery of high-energy radiation (e.g. electrons, x-rays, photons) to kill cancer cells by using a machine to focus a beam of radiation on the body is called:
1. external radiation therapy
2. internal-beam radiation therapy
3. brachytherapy
4. biochemotherapy

8 You are taking care of a person who just received the first cycle of chemotherapy for acute leukaemia 2 days ago. As an oncology nurse, you are closely monitoring the person's laboratory tests of uric acid, potassium, phosphorus and calcium as you are aware the person is at risk of:
1. spinal cord compression
2. tumour lysis syndrome
3. septic shock
4. superior vena cava syndrome

9 In which phase of the cell cycle does the DNA replicate to form two sets of chromosomes?
1 G_1
2 G_2
3 S
4 M

10 Oncogenes are genes that:
1 promote cell growth when activated
2 block cell growth
3 stimulate a complex signalling process
4 are strictly regulated

UNIT 3 BUILDING CLINICAL COMPETENCE

Pathophysiology and patterns of health

CLINICAL SCENARIO

You have been assigned to work with the following four people for the 0700 shift on a medical–surgical unit. Significant data obtained during report are as follows:

- Allen Barber is a 55 year old with diabetes mellitus who is 4 days postoperative abdominal surgery with an inflammation of the incision site. Vital signs are T 38.3°C, P 94, R 24, BP 138/82. The abdominal incision appears red with warmth and oedema around the incision. Mr Barber states that his pain level is 8 on a pain scale of 1 to 10. Labs and wound cultures have been ordered.
- Tamra Sanders is a 22 year old with Down syndrome. She is admitted in sickle cell crisis with T 38.9°C, P 90, R 30 and shallow and BP 110/84. Tamra is complaining of severe chest pain with shortness of breath. She states that her pain scale level is 10 of 10. She has an order to begin morphine PCA.
- Mia Windham is a 26 year old who was admitted yesterday with a maculopapular rash on the hands and feet that is spreading to the arms and legs. This morning she is complaining of abdominal pain, nausea and bloody diarrhoea. She has a history of having a bone marrow transplant 3 months ago as treatment for leukaemia.
- Harry Anderson is a 40 year old in the late stages of AIDS. He is confused, incontinent and has severe spasticity. He is on seizure precautions. He needs to be turned every 2 hours to prevent pressure sores. He is currently yelling that he needs help.

Critical thinking questions

1 In what order would you visit these people after report?

1. _____
2. _____
3. _____
4. _____

2 What would you prioritise as the two most important nursing diagnoses for each of the people presented above? Can you explain, if asked, the rationale for your choices?

	Priority Nursing Diagnosis #1	Priority Nursing Diagnosis #2
Allen Barber		
Tamra Sanders		
Mia Windham		
Harry Anderson		

3 In which position does the nurse place the person with hypovolaemic shock?

1. semi-Fowler's position with legs straight
2. Trendelenburg position with legs elevated 10 degrees
3. left lateral position with legs bent towards chest
4. supine position with legs elevated 20 degrees

4 Tamra Sanders' family asks the nurse how sickle cell anaemia is transmitted from one family member to another. Which statement by the nurse is the correct response?

1. 'The mother carries the gene for sickle cell anaemia and passes it to the children.'
2. 'The father carries the gene for sickle cell anaemia and passes it to the children.'
3. 'Both parents carry the gene for sickle cell anaemia and children have a 25% chance of getting the disease process.'
4. 'One parent has the disease and one parent carries the affected gene and they have a 50% chance of passing it to the children.'

5 Mr Anderson, who has AIDS, has experienced weight loss. The dietitian teaches him meal planning in which type of diet?

1. high protein, high fibre
2. high protein, high kilojoule
3. low fibre, low protein
4. high carbohydrate, high vitamins

6 The nurse performs wound cleansing with which procedure?

1. Cleanse the wound with soap and water.
2. Use normal saline to cleanse the wound.
3. Cleanse the wound with povidone-iodine.
4. Hydrogen peroxide (half strength) is used to cleanse the wound.

7 Prior to administering cytotoxic agents, such as cyclophosphamide (Cytoxan), the nurse needs to notify the doctor of which lab results?

1. haemoglobin of 108 g/L, haematocrit of 35%
2. potassium of 3.4 mmol/L, sodium of 130 mmol/L
3. creatinine of 2 mg/dL, blood urea nitrogen of 3.0 mmol/L
4. white blood cell count of 3.9 ($\times 10^9$/L), platelets of 74 ($\times 10^9$/L)

8 Due to diarrhoea, Ms Windham's arterial blood gas results are pH, 7.30, $PaCO_2$, 35 mmHg; PaO_2, 90 mmHg, HCO_3^-, 19 mEq/L. The nurse interprets these results as indicating the person has:

1. metabolic acidosis
2. metabolic alkalosis
3. respiratory acidosis
4. respiratory alkalosis

9 Which laboratory studies would you expect to draw on a person who is 4 days postoperative with an inflammation of the incision site?

1. white blood cell count/differential, erythrocyte sedimentation rate, C-reactive protein
2. troponins, metabolic panel for electrolytes, cultures of wound site
3. blood cultures, haematocrit and haemoglobin, blood glucose level
4. full blood count, alkaline phosphatase, urine creatinine and blood urea nitrogen

10 The person is admitted to the emergency department for a severe anaphylactic reaction to aspirin. Which medication is ordered to be administered?

1. 0.5 mL of 1:1000 adrenaline subcutaneously
2. 0.3 mL of 1:10 000 adrenaline subcutaneously
3. intravenous infusion of 1:10 000 adrenaline
4. intravenous infusion of 1:100 000 adrenaline

11 When administering a blood transfusion, which manifestations indicate a haemolytic reaction to the blood being administered?

1. abdominal cramps and diarrhoea
2. bradycardia and hypertension
3. dyspnoea and hypotension
4. diaphoresis and tachycardia

12 The nurse educates people and families to decrease risk factors of cancer by following which cancer prevention recommendations? (Select all that apply.)

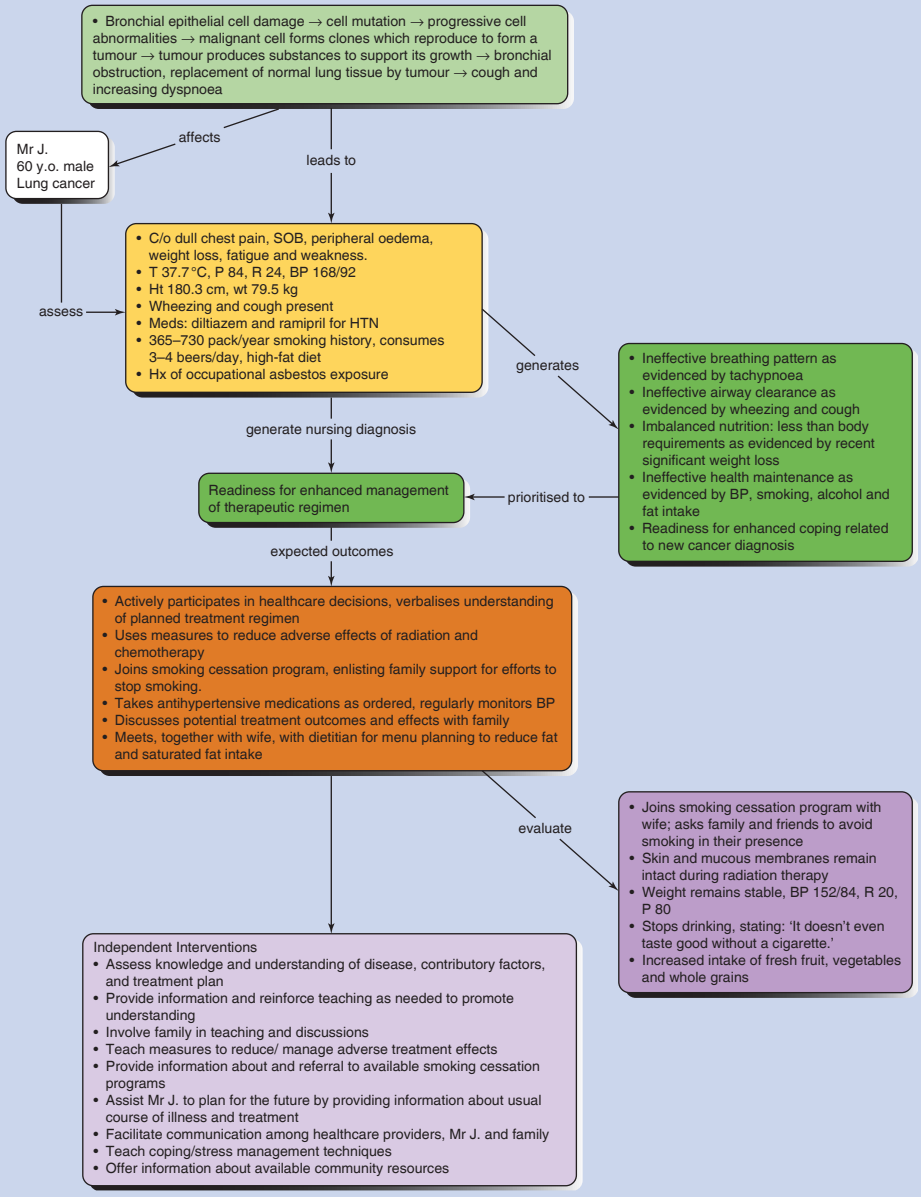
1. Avoid tobacco and excessive alcohol use.
2. Eat a diet low in fat and high in carbohydrates.
3. Increase intake of vitamins A, D, E and K.
4. Limit exposure in sun from 11 am to 4 pm.
5. Increase fruit and vegetables in the diet.
6. Eat meats grilled over a charcoal fire instead of fried.

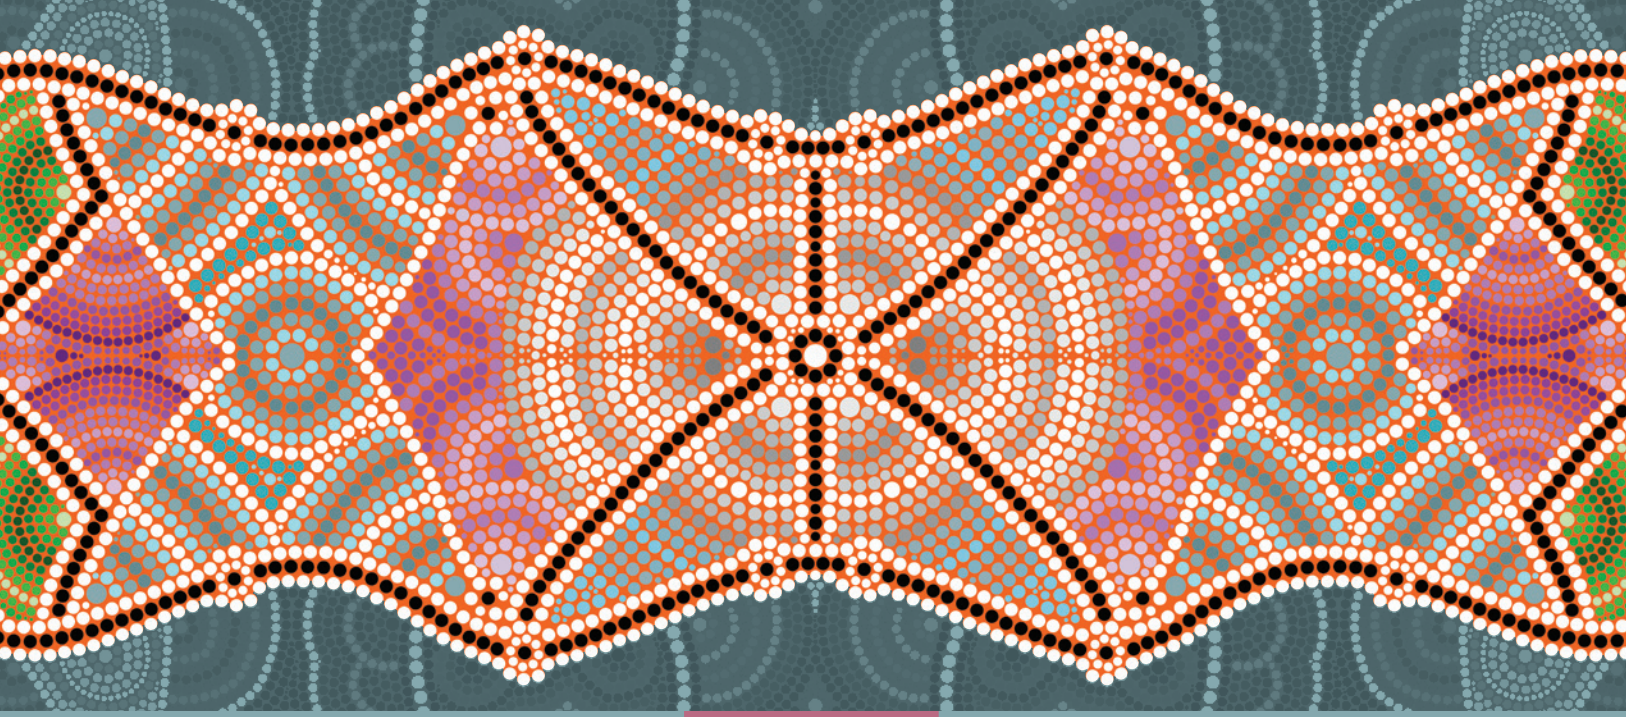
CASE STUDY

Mr Johnson is a 60-year-old construction worker who has presented at the doctors complaining of dull chest pain, shortness of breath, swelling of his hands and feet, weight loss, fatigue and weakness. On physical assessment, vital signs are temperature 37.7°C, pulse 84, respirations 24, blood pressure 168/92. His height is 180.3 cm and weight is 79.5 kg. Mr Johnson states that this is a loss of 15.9 kg during the past 3 months. Wheezing is heard when breath sounds are auscultated. Coughing is noted with deep breathing. The remainder of the physical assessment is unremarkable. He has a medical history of high blood pressure for which he takes diltiazem and ramipril. He has a history of smoking 1 to 2 packets of cigarettes a day since he was 15 years old. He states he has been exposed to asbestos in his employment. Mr Johnson's nutrition assessment indicates that his diet consists of fried meats (especially chicken), green vegetables cooked in pork fat, eggs and bacon for breakfast, and during breaks he eats biscuits. His fluid intake consists of coffee for breakfast and during breaks, soft drinks at lunch, and 3 to 4 beers at night.

Blood is drawn for a full blood count, electrolytes, blood glucose, calcitonin, CEA, haptoglobulin, GGT and creatinine. A sputum specimen is sent to the laboratory. A chest x-ray and CT scan are done. Based on the results of the chest x-ray, bronchoscopy and needle aspiration biopsies are performed to confirm a diagnosis of lung cancer. The oncologist recommends an initial treatment plan of radiation therapy followed by combination chemotherapy to reduce the tumour size prior to surgical resection of the tumour.

Based on Mr Johnson's medical diagnosis and treatment plan, *Readiness for enhanced therapeutic regimen management* is identified as the priority nursing diagnosis at this time.





UNIT 4

RESPONSES TO ALTERED INTEGUMENTARY STRUCTURE AND FUNCTION

CHAPTER 14

ASSESSING THE INTEGUMENTARY SYSTEM

KERYLN CARVILLE, KERRY REID-SEARL, KATE CROWLEY

KEY TERMS

alopecia 426
cyanosis 414
ecchymoses 421
erythema 414
hirsutism 426
jaundice 414
keratin 411
melanin 411
oedema 425
pallor 414
sebum 413
urticaria 421
vitiligo 421

LEARNING OUTCOMES

- Describe the anatomy, physiology and functions of the skin, hair and nails.
- Explain the integumentary assessment process, including the normal and abnormal findings which may arise.

CLINICAL COMPETENCIES

- Conduct and document a health history for people who have or are at risk of alterations in the skin, hair or nails.
- Conduct and document a physical assessment of the integumentary system.
- Monitor the results of diagnostic tests and report abnormal findings.

EQUIPMENT NEEDED

- Disposable gloves
- Ruler
- Torch or good light source

The skin and its accessory appendages, which include hair, nails and various glands, make up the integumentary system. The skin, the largest organ of the body, provides an external covering for the body, separating and protecting the body's organs and tissues from the external environment. Compared with all other body organs, it is the most exposed to infection and injury. In the average adult the skin receives one-third of the circulating blood volume. The pH of the skin is slightly acidic, ranging from 4.2 to 6, which ensures an 'acid mantle' for protective purposes and maintenance of normal skin flora. (Functions of the skin and its accessory structures are summarised in Table 14.1.)

Disorders of the integumentary structures may be caused by a variety of factors including environmental factors, allergies, infection, infestation, disease, malignancy, trauma and genetic influences.

ANATOMY, PHYSIOLOGY AND FUNCTIONS OF THE INTEGUMENTARY SYSTEM

The skin

The skin has an average total surface area of 7600 cm^2. It has been estimated that in 1 cm^2 there is almost 1 metre of blood vessels, 4 metres of nerves, 100 sweat glands, 15 sebaceous glands, 3000 sensory cells at the end of nerve fibres, 25 pressure apparatuses to record tactile stimuli, 200 nerve endings to record pain, 2 sensory apparatus for cold, 12 sensory apparatus for heat, 300 000 epidermal cells and 10 hairs (Klein, 1988). The appearance of the integumentary system is dependent upon age, ethnicity, general health and wellbeing, and cultural and occupational pursuits. Structurally, the skin consists of the epidermis, the dermis and the hypodermis (see Figure 14.1). Each layer will be discussed in the following sections of this chapter.

The epidermis

The epidermis, which comprises the surface or outermost part of the skin, consists of stratified squamous epithelium. It is avascular and is approximately 0.04 mm thick (Carville, 2012). The epidermis receives its nutrients from the dermal layer beneath it. The epidermis regenerates itself, and the normal epidermal turnover time of epidermal cells as they migrate from the stratum germinativum to the stratum corneum and are then shed is up to 28 days. The epidermis has either four or five layers, depending on its location; there are five layers over the palms of the hands and the soles of the feet, and four layers over the rest of the body.

The stratum germinativum, also known as the stratum basale, is the deepest layer of the epidermis. It is comprised of a single layer of basal cells that are mitotically active and constantly dividing. It contains melanocytes, cells that produce the pigment **melanin**, and keratinocytes, which produce **keratin**. Melanin forms a shield to protect the keratinocytes and the nerve endings in the dermis from the damaging effects of ultraviolet light. Melanocyte activity probably accounts for the difference in skin colour in humans. Keratin is a fibrous, water-repellent protein that gives the epidermis its tough, protective quality. As keratinocytes mature, they move upwards through the epidermal layers, eventually becoming dead cells at the surface of the skin. Millions of these cells are worn off by abrasion each day; simultaneously millions more are produced in the stratum germinativum.

TABLE 14.1 Functions of the skin and its appendages

STRUCTURE	FUNCTIONS
Epidermis	Protects tissues from physical, chemical and biological damage. Prevents water loss and serves as a water-repellent layer. Stores melanin, which protects tissues from harmful effects of ultraviolet radiation in sunlight. Converts cholesterol molecules to vitamin D when exposed to sunlight. Contains phagocytes, which prevent bacteria from penetrating the skin.
Dermis	Contains blood vessels, which supply nutrients to the stratum germinativum of the epidermis and the skin appendages. Regulates body temperature by dilating and constricting capillaries. Contains specialised sensory receptors and nerves, which transmit sensation signals to the central nervous system.
Hypodermis	Main support system for the skin. Protective layer for underlying organs and structures. Participates in temperature regulation. Storage depot for fat.
Sebaceous (oil) glands	Secrete sebum, which lubricates skin and hair. Play a role in maintaining the pH of the skin.
Eccrine sweat glands	Present at birth and regulate body heat by excretion of perspiration.
Apocrine sweat glands	Remnant of sexual scent gland, activated at pubescence.
Hair	Cushions the scalp. Eyelashes and cilia protect the body from foreign particles. Provides insulation in cold weather.
Nails	Protect the fingers and toes, aid in grasping and allow for various other activities, such as scratching the skin, picking up small items and so on.

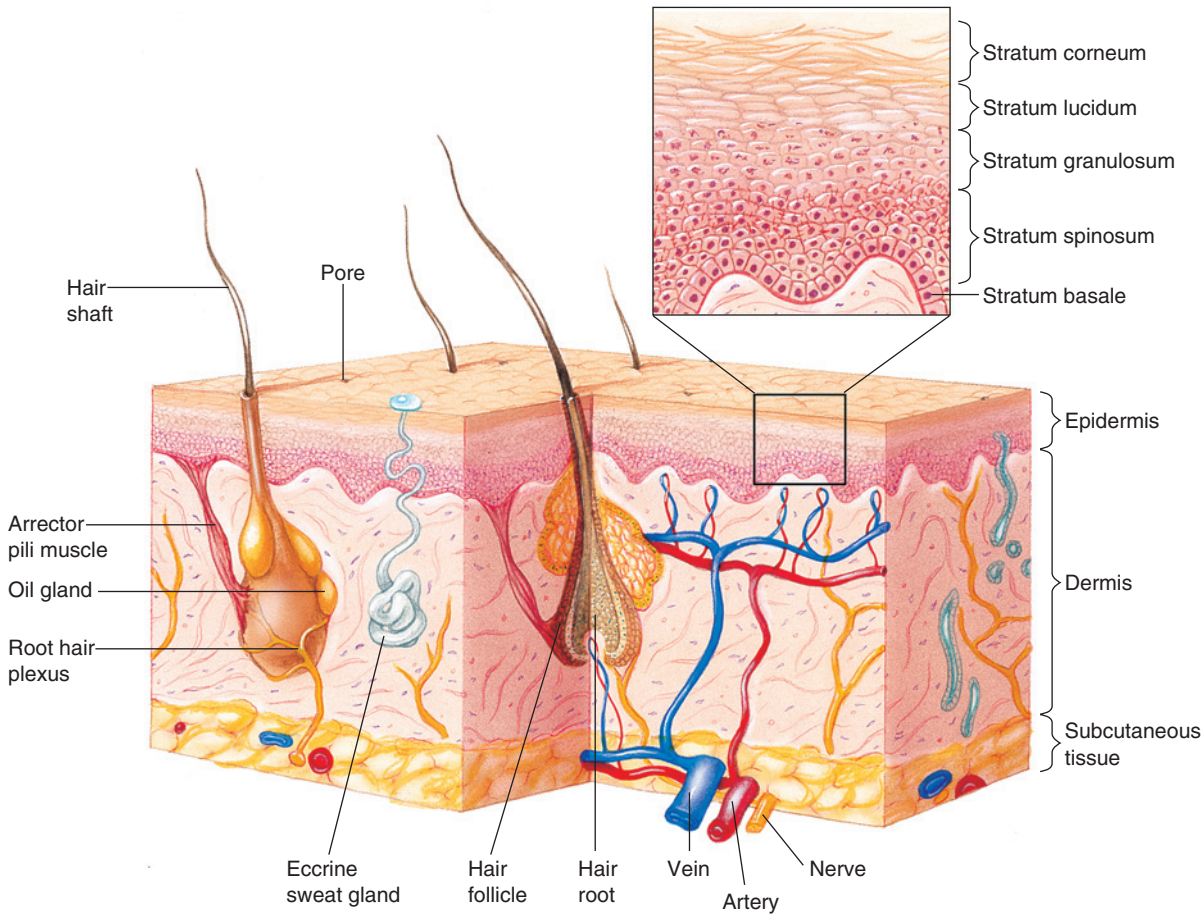


FIGURE 14.1 ■ Anatomy of the skin

The next layer of the epidermis is the stratum spinosum or prickle cell layer, which is composed of several stratified layers of polygonal cells which are attached by desmosomes, which appear as spiny processes. Mitosis occurs at this layer, although not as abundantly as in the stratum germinativum.

The stratum granulosum, the next layer, is two to three cells thick. The cells of the stratum granulosum contain a glycolipid that slows water loss across the epidermis. As cells migrate from stratum spinosum to stratum granulosum the nucleus is destroyed by enzymes, the cells flatten and cellular contents are converted into tough, insoluble keratin. Keratinisation, a thickening of the cells' plasma membranes, begins in the stratum granulosum.

The stratum lucidum is a transparent layer with no visible nuclei and is present only in areas of thick skin—for example, on the soles or palms. The outermost layer of the epidermis, the stratum corneum, is also the thickest, making up about 75% of the epidermis' total thickness. It consists of about 20 to 30 layers of dead cells filled with keratin fragments arranged in 'shingles' that flake off as dry skin.

THE BASEMENT MEMBRANE The basement membrane is an acellular, non-vascular and non-innervated membrane that separates the epidermis from the dermis. The basement membrane serves as an adherent and mechanical support layer between the epidermis and the dermis (Martini, Nath and Bartholomew, 2012). It is also thought to play a role in regulating the transfer of proteins, oxygen and nutrients across the dermal–epidermal junction (Carville, 2012).

The dermis

The dermis is attached to the basement membrane, but is often referred to as the second, deeper layer of skin. Made of a flexible connective tissue, this layer is richly supplied with blood cells, nerve fibres and lymphatic vessels. The hair follicles, sebaceous glands and sweat glands are located in the dermis, although they are derived from the epidermal layer. The dermis consists of a papillary (upper layer) and a reticular layer (deeper layer). The papillary layer contains reti ridges that indent the overlying epidermis. It also contains capillaries and receptors for pain and touch. The deeper, reticular layer contains blood vessels, sweat and sebaceous glands, deep pressure receptors and dense bundles of collagen fibres. The regions between these bundles form lines of cleavage in the skin, which are referred to as Langer's lines. Surgical incisions parallel to these lines of cleavage heal more easily and with less scarring than incisions or traumatic wounds across cleavage lines.

The hypodermis

The hypodermis (also called the subcutaneous layer) contains large blood vessels that supply the skin. Additionally, it serves as a storage depot for fat and thus contains adipose tissue as well as connective tissue. The function of the hypodermis is to insulate, afford protection to underlying structures and regulate temperature. The hypodermis plays a significant role as it acts as a support framework for the skin. This is because the fibres that extend from the dermis anchor the skin to the hypodermis, which then attaches to the underlying fascia (the connective tissue around muscles and bones) (Jenkins, Kemnitz & Tortora, 2010).

Skin appendages

Appendages of the skin include the glands (sebaceous, sudoriferous and ceruminous), the hair and the nails. The following section explains each appendage.

Glands of the skin

The skin contains sebaceous (oil) glands, sudoriferous (sweat) glands and ceruminous (cerumen or earwax) glands. Each of these glands has a different function.

Sebaceous glands enter halfway up the hair follicle; thus they are found all over the body except on the palms, soles, lips and nipples where there are no hair follicles. These glands secrete an oily substance called **sebum**, which is usually ducted into a hair follicle. Sebum softens and lubricates the skin and hair and also decreases water loss from the skin in low humidity. Sebum and sweat influence the pH of the skin, and the 'acid mantle' or slightly acidic pH protects the body against opportunistic infection. The secretion of sebum is stimulated by hormones, especially androgens. If a sebaceous gland becomes blocked, a pimple or whitehead appears on the surface of the skin; as the material oxidises and dries, it forms a comedone or blackhead. Acne vulgaris is an inflammation of the sebaceous glands.

There are two types of sweat glands: eccrine and apocrine. Eccrine sweat glands are present at birth and are more numerous on the forehead, palms and soles. The gland itself is located in the dermis; the duct to the skin rises through the epidermis to open in a pore at the surface. The secretion of the eccrine glands is composed mostly of water, but it also contains sodium, antibodies, small amounts of metabolic wastes, lactic acid and vitamin C. The production of sweat is regulated by the sympathetic nervous system and serves to maintain normal body temperature. Sweating also occurs in response to emotions.

Apocrine sweat glands are activated at pubescence. Most apocrine sweat glands are located in the axillary, anal and genital areas. The secretions from apocrine glands are similar to those of eccrine sweat glands, but they also contain fatty acids and proteins. Apocrine glands are a remnant of sexual scent glands.

Ceruminous glands are modified apocrine sweat glands. Located in the skin of the external ear canal, they secrete yellow-brown waxy cerumen. This substance provides a sticky trap for foreign materials.

The hair

Hair is distributed all over the body, except the lips, nipples, parts of the external genitals, the palms of the hands and the soles of the feet. Hair is composed of keratin. It is produced by a hair bulb and its root is enclosed in a hair follicle (see Figure 14.2). The exposed part, called the shaft, consists mainly of dead cells. Hair follicles extend into the dermis and in some places, such as the scalp, below the dermis. Many factors, including nutrition and hormones, influence hair growth. Humans have three types of hair. They are:

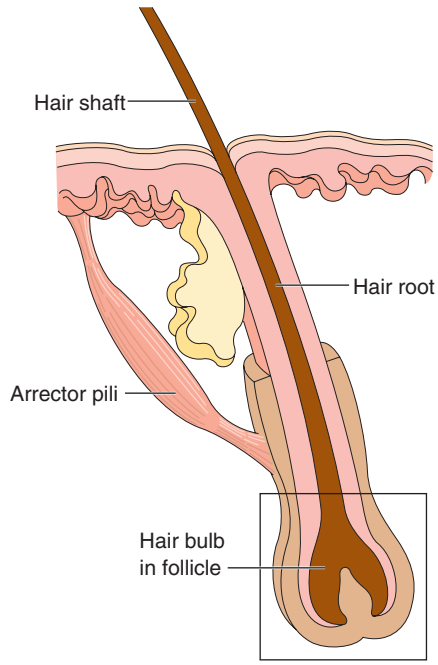

FIGURE 14.2 ■ Anatomy of a hair follicle

1. lanugo, the fine hair found on the body of premature neonates
2. vellus, the fine lightly coloured body hair that grows to 1 cm
3. terminal hair, which is found on the scalp, face of males, pubic region and armpits, and can grow to 50 cm.

Hair in various parts of the body has protective functions: the eyebrows and eyelashes protect the eyes; hair in the nose helps keep foreign materials out of the upper respiratory tract; and hair on the head protects the scalp from heat loss and sunlight. On average, an adult loses 50–100 head hairs a day. Scalp hair can last 2–4 years and eyelashes tend to last 3–5 months.

The nails

A nail is composed of keratin. Like hair, nails consist mainly of dead cells. They arise from the stratum germinativum of the epidermis. The body of the nail rests on the nail bed (see Figure 14.3). The nail matrix is the active, growing part of the nail. The proximal visible end of the nail has a white crescent, called a lunula. The sides of the nail are overlapped by skin, called nail folds. The proximal nail fold is thickened and is called the eponychium or cuticle. Nails form a protective coating over the dorsum of each digit on the fingers and toes.

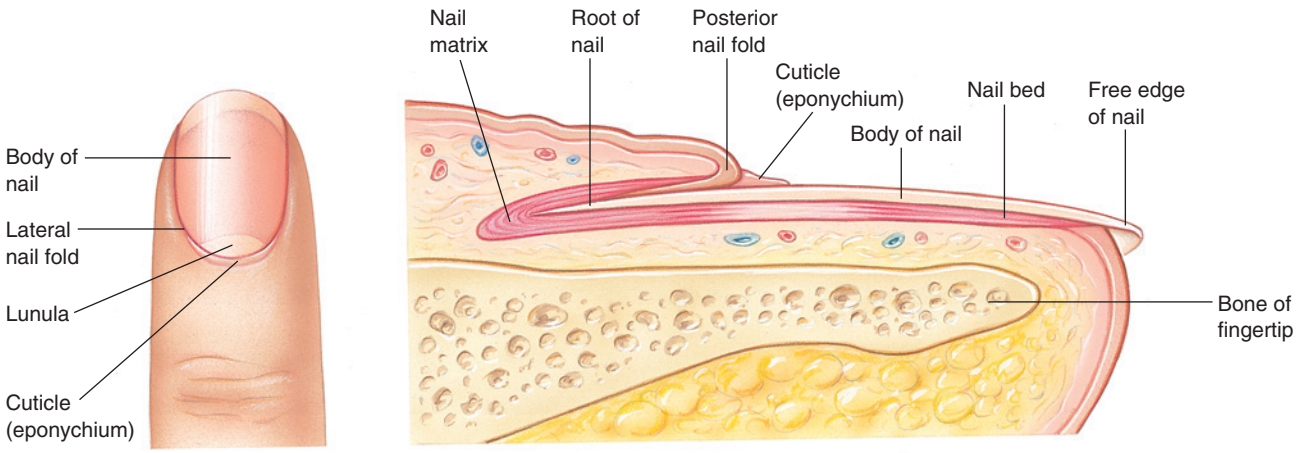

FIGURE 14.3 ■ Anatomy of a nail (frontal and side views)

Skin colour

Skin colour varies among individuals and among people of different races, ranging from a pinkish white to various shades of brown and black. Areas of the skin that are normally exposed to the sun and environment, such as the face and hands, may have a slightly different colour from areas that are usually covered with clothing. Special care must be taken when assessing changes in skin colour in people with darker skin, such as Indigenous Australians, Pacific Islanders, Asians, people of Mediterranean descent and Caucasians who are deeply suntanned.

Skin colour is the result of varying levels of pigmentation. Melanocytes produce melanin, a yellow-to-brown pigment, which is predominately responsible for skin tone and protects against damage from ultraviolet rays. All races have the same number of melanocytes, but melanin is produced in greater amounts in people with dark skin colour. Exposure to the sun causes a build-up of melanin and a darkening or tanning of the skin in people with light skin. Carotene, a yellow-to-orange pigment, is found mostly in areas of the body where the stratum corneum is thickest, such as the palms of the hands. Carotene is more abundant in the skins of people of Asian ancestry and, together with melanin, accounts for their golden skin tone. The epidermis in Caucasian skin has very little melanin and is almost transparent. Thus, the colour of the haemoglobin found in red blood cells (RBCs) circulating through the dermis shows through, lending Caucasians a pinkish skin tone.

Skin colour is influenced by emotions and illnesses. **Erythema**, a reddening of the skin, may occur with embarrassment (blushing), fever, hypertension or inflammation. It may also result from a drug reaction, sunburn, acne rosacea or other factors. A bluish discolouration of the skin and mucous membranes, called **cyanosis**, results from poor oxygenation of haemoglobin. **Pallor**, or paleness of skin, may occur with shock, fear or anger, or be a sign of anaemia and hypoxia. **Jaundice**, a yellow-to-orange colour visible in the skin and mucous membranes, is most often the result of a hepatic disorder or physiological jaundice in the newborn. Table 14.2 further defines these terms and compares and contrasts skin colour changes in people with light and dark skin.

ASSESSING THE INTEGUMENTARY SYSTEM

The functions of the integumentary system (skin, glands, hair and nails) are assessed by a health assessment interview to collect subjective data, a physical assessment to collect objective data and findings from diagnostic tests. See the box below for sample documentation of an assessment of the integument.

Health assessment interview

A health assessment interview to determine problems with the integumentary system may be conducted as part of a health screening or total health assessment, or it may focus on a chief complaint (such as itching or a rash). If the person has a skin problem, analyse its onset, characteristics and course, severity,

SAMPLE DOCUMENTATION

Assessment of the thyroid gland

21/01/2013
NURS 0900

A 27-year-old male with no history of skin lesions, hair loss or disorders of the nails. The person reports that he took an antibiotic for a respiratory infection approximately 10 days ago which resulted in the appearance of a fine, raised, red, itchy rash on his trunk and arms. The person further reports that he presented to the doctor, who prescribed an antihistamine and the rash cleared in 3 days. Upon current assessment the person's skin is light brown, warm, dry and supple. Patches of vitiligo are present over the dorsum of his hands. No lesions or oedema are noted. The person has a healed scar on his lower left abdomen (an appendectomy as a young adult). He has clean, dark brown hair which is greying at the temples. His nails are smooth, hard and immobile.———————— K Simpson
(KATE SIMPSON, RN)

TABLE 14.2 Skin colour assessment variations in people with light and dark skin

Pallor: *a decrease or absence in skin colour as the result of a decrease in tissue perfusion; a decrease in shape, size or amount of red blood cells (RBCs); or absence of melanin (local or generalised).*

DISORDER AND CAUSE	CHANGE IN LIGHT SKIN	CHANGE IN DARK SKIN
Anaemia (decreased or abnormal size and shape of RBCs)	Generalised paleness	Brown skin is dull and has a yellow cast; black skin is dull and has an ashen grey cast
Haemorrhage (decreased amount of circulating RBCs)	Generalised paleness	Brown skin is dull and has a yellow cast; black skin is dull and has an ashen grey cast
Shock (decreased amount of circulating RBCs or decreased perfusion)	Generalised paleness	Brown skin is dull and has a yellow cast; black skin is dull and has an ashen grey cast
Arterial insufficiency (trauma, acute arterial occlusion or arteriosclerosis)	Local paleness	Dull, ashen grey
Vitiligo (patchy loss of melanocytes)	Patches of white spots, most often found over skin of the face, hands or groin	Patches of white spots, most often found over skin of the face, hands or groin
Albinism (total absence of melanin)	White/pink	Light tan, cream or white

Cyanosis: *a bluish discolouration of the skin and mucous membranes resulting from a local or generalised excess of deoxygenated haemoglobin or a structural defect in the haemoglobin molecule.*

DISORDER AND CAUSE	CHANGE IN LIGHT SKIN	CHANGE IN DARK SKIN
Acute and chronic disorders of the structure and function of the heart and lungs (arterial insufficiency or respiratory distress). Peripheral cyanotic changes may also be due to exposure to cold or hypothermia)	Dusky blue (may be generalised or local, depending on cause)	Skin may appear darker, but will be dull; cyanosis is more readily assessed in the nail beds, oral mucous membranes and conjunctivae

Erythema: *redness of the skin or mucous membranes that is the result of dilatation and congestion of superficial capillaries.*

DISORDER AND CAUSE	CHANGE IN LIGHT SKIN	CHANGE IN DARK SKIN
Hyperaemia (inflammation, increased body temperature, hot environmental temperature, embarrassment, alcohol ingestion)	Red or bright pink	Difficult to assess; skin may have dark red cast
Carbon monoxide poisoning (carbon monoxide displaces oxygen on the haemoglobin molecule, causing hypoxia, carboxyhaemoglobinaemia)	Cherry red in face and upper torso	Cherry red lips, oral mucous membranes and nail beds
Pressure Reactive hyperaemia (a compensatory erythema in response to tissue pressure that fades when tissues are compensated). Non-reactive hyperaemia does not blanch after 30 minutes pressure relief and indicates a stage 1 pressure injury	Dusky red	Difficult to assess; may be warm to touch or bluish tint

Jaundice: *yellowish discolouration of the skin, mucous membranes and sclerae of the eyes, caused by increased amounts of bilirubin or other pigments such as elevated carotene in the blood.*

DISORDER AND CAUSE	CHANGE IN LIGHT SKIN	CHANGE IN DARK SKIN
Increased serum bilirubin to > 2–3 mg/100 mL or other pigments such as elevated carotene in haemolysis, such as following blood transfusion, severe burns or infections)	Yellowing of skin follows yellowing of sclerae and mucous membranes; may also be assessed in the fingernails and palms of the hands	Yellowing is best assessed at the junction of the hard palate and the soft palate or on the palms of the hands. Sclerae may be yellow near the limbus (do not confuse with normal yellow eye pigmentation)
Uraemia (retained urochrome pigments in the blood)	Orange-green or grey cast to skin. Yellowing of skin follows yellowing of sclerae and mucous membranes; may also be assessed in the fingernails and palms of the hands	Difficult to assess; may appear as yellowish green colour in the sclera
Physiological jaundice occurs in newborns around the third to fourth day and is due to haemolysing excess red cells	Obvious yellowing of the skin and sclerae	Yellowing is best assessed at the junction of the hard palate and the soft palate or on the palms of the hands. Sclerae may be yellow

precipitating and relieving factors, and note the timing and circumstances of any associated symptoms. For example, ask the person:

- When did the itching begin and how severe was it?
- When did you first notice a change in this mole?
- Did you change to any different kinds of shampoo or other hair products just before you started to lose your hair?

Ask about any change in health, rashes, itching, colour changes, dryness or oiliness, growth of or changes in warts or moles, and the presence of lesions. Precipitating causes, such as medications, the use of new soaps, skin care agents, cosmetics, pets, travel, stress or dietary changes, must also be explored. In assessing hair problems, ask about any thinning or baldness, excessive hair loss, change in distribution of hair, use of hair care products, diet and dieting. When assessing nail problems, ask about nail splitting or breakage, discolouration, change in shape, infection, diet and exposure to chemicals.

The person's medical history is important. Questions focus on identifying previous problems, allergies and the presence of lesions. Skin problems may be manifestations of other disorders, such as cardiovascular disease, endocrine disorders, hepatic disease and haematological disorders. The occupational and social history may provide cues to skin problems. It is important to ask the person about travel, exposure to toxic substances at work or socially, their use of alcohol and responses to stress. Family history may provide insight into hereditary-linked disorders such as atopic eczema or dermatitis (these terms are used interchangeably). Assess the presence of risk factors for skin cancer carefully. These include male gender; aged over 50; family history of skin cancer; extended exposure to sunlight; tendency to sunburn; history of sunburn or other skin trauma; light-coloured hair or eyes; residence in high altitudes or near the equator; and exposure to radiation, x-rays, coal, tar or petroleum products.

It is also important to explore the risk factors for malignant melanoma. These include the presence of a large number of moles, the presence of atypical moles, a family history of melanoma, prior melanoma, repeated severe sunburns, ease of freckling and sunburning, or inability to tan.

See 'Functional health pattern interview: integumentary system' below. Responses should be documented in the person's medical record.

Physical assessment

Physical assessment of the skin, hair and nails may either be performed as part of a total assessment, or it may be a focused assessment of the integument for people with known or suspected problems. Physical assessment of the skin, hair and nails is conducted using inspection and palpation techniques. Assess the skin for colour, presence and characteristics of lesions (observable changes from normal skin structure), temperature alterations, texture, moisture, turgor and presence of oedema (see Table 14.3).

TABLE 14.3 Age-related skin changes

AGE-RELATED CHANGE	SIGNIFICANCE
Epidermis: reduced thickness and miotic activity	• Skin is more fragile and at greater risk of tears or injury • Delayed wound healing • Hyperkeratoses and skin cancers in sun-exposed areas are more evident
Epidermis: increased permeability, reduced Langerhans cells	• Increased risk of reactions to irritants • Decreased inflammatory response
Epidermis: reduced number of active melanocytes	• Increased susceptibility to sun exposure
Epidermis: hyperplasia of melanocytes, especially in sun-exposed areas	• Small areas of hyperpigmentation (solar lentigines or 'liver spots')
Epidermis: impaired vitamin D production	• Increased risk of osteomalacia, osteoporosis
Epidermis: dermal–epidermal junction flattens	• Increased risk of skin tears, purpura and pressure injures
Dermis: reduced perfusion	• More susceptible to dry skin • Decreased sensation (pain, touch, temperature and peripheral vibration) • Increased risk of injury
Dermis: reduced vasomotor response	• Greater risk of hyperthermia and hypothermia
Dermis: elastic fibres degenerate	• Decreased tone and elasticity, with wrinkle formation
Dermis: proliferation of capillaries	• Cherry haemangiomas are common
Subcutaneous skin layer: thins	• Greater risk of hypothermia • Increased risk of pressure injuries
Subcutaneous skin layer: adipose tissue is redistributed	• Cellulite forms • Bags over and under the eyes • Double chin forms • Abdominal fat increases • Breasts sag • Skin returns to normal more slowly when pinched (tenting)
Glands: reduced eccrine and apocrine activity	• Dry skin is common • Reduced or absent perspiration

FUNCTIONAL HEALTH PATTERN INTERVIEW Integumentary system

FUNCTIONAL HEALTH PATTERN	INTERVIEW QUESTIONS AND LEADING STATEMENTS
Health perception–Health management	■ Describe your current problem. How long has it lasted? What have you done to treat it? ■ Describe any past skin problems or injuries you have had. How were these treated? ■ Did you undergo any surgical procedures and, if so, why and when? ■ List prescribed or over-the-counter medications, herbs and vitamins you currently take. ■ Do you have allergies to plants, chemicals or pets? ■ Describe what you do each day to care for your skin, hair and nails.
Nutritional–Metabolic	■ Describe the type and amount of food and drink you consume in a 24-hour period. ■ Do you have a history of food allergies? If so, describe what you are allergic to and how you respond. ■ Have you recently eaten any new foods? ■ How well do your cuts and scratches heal?
Integumentary condition	■ Is your skin and scalp dry, oily or itchy? ■ Have you noticed swelling around your eyes or ankles? ■ Have you noticed any changes in your hair or nails? ■ Do you perspire a lot? ■ Do you bruise easily?
Activity–Exercise	■ Describe your physical activities in a typical day. ■ Do you use a sunscreen when you are outside? If so, what SPF? ■ Do you visit tanning salons?
Sleep–Rest	■ How many hours do you sleep each night? ■ Do you have trouble sleeping because of itching or sweating?
Pain and discomfort	■ Do you have any of the following: pain, discomfort, itching, tingling, burning, tenderness or numbness? If so, where?
Self-perception–Self-concept	■ How does this condition make you feel about yourself?
Role–Relationships	■ How does this condition affect your relationships with others? ■ Is there anything in your work environment that may have caused this condition?
Sexuality–Reproductive	■ Has this condition interfered with your usual sexual activities? ■ If you use a birth control method, could it have caused this condition?
Coping–Stress tolerance	■ Have you experienced any type of stress that may have worsened this condition? ■ Has this condition created stress for you? ■ Describe what you do when you feel stressed.
Value–Belief	■ Tell me how specific relationships or activities help you cope with this condition. ■ Describe specific cultural beliefs or practices that affect how you care for and feel about this condition. ■ Are there any specific treatments that you would not use to treat this condition?

Characteristics of lesions are described in Table 14.4.

Common skin lesions found on older adults are outlined in Box 14.1. Examine the hair for hygiene status, infestations, colour, texture, quality and distribution, and the presence of scalp lesions. Determine the shape, colour, contour and condition of the nails. Terminology of skin lesions with examples is outlined in Table 14.5.

The examination should be conducted in a warm, private room. The person should remove all clothing and put on a gown. The areas to be examined should be fully exposed, but protect the person's modesty by keeping other areas covered.

TABLE 14.4 Lesion characteristics

Configuration and shape	Single, grouped cluster, linear, annular (ring-shaped) or round, artiform (bite)
Appearance	Dimensions, raised, indented, flush, colour, mobile, non-mobile
Edges	Raised, rolled, undermined, coloured
Fluid-filled lesion or draining exudate	Colour, type, amount, consistency, odour

BOX 14.1 Common skin lesions of older adults

- Skin tags: soft brown or flesh-coloured benign papules
- Keratoses: horny growth of keratinocytes; may be seborrhoeic (benign) or actinic (premalignant)
- Lentigines ('liver' or 'age' spots); brown or black benign macules with a defined border
- Angiomas (haemangioma): benign vascular tumours with dilated blood vessels, found in the middle to upper dermis
- Telangiectases: single dilated blood vessels, capillaries or terminal arteries
- Venous lakes (phlebectases): small, dark blue, slightly raised benign papules that usually occur on sun-exposed areas
- Photoageing: wrinkling, mottling, pigmented areas, loss of elasticity, benign or malignant lesions

TABLE 14.5 Terminology of skin lesions with associated disorders

LESION	EXAMPLES OF DISORDERS
Pigmented	Freckle, seborrhoeic keratosis, naevus, melanoma
Scaly	Psoriasis, dermatitis, xerosis, tinea, actinic keratoses
Pustular	Acne vulgaris, folliculitis, candidiasis
Vesicular	Herpes simplex, herpes zoster, scabies
Nodular	Warts, basal cell carcinoma, acne
Weepy, crusted	Acute contact allergic dermatitis, impetigo
Figurate (shaped) erythema	Urticaria, cellulitis
Bullous	Pemphigus, toxic epidermal necrolysis
Pruritic	Xerosis, scabies, pediculosis
Ulcerated	Pressure injury, skin cancer, herpes simplex

The person may be standing, sitting or lying down at various times of the examination. The assessor should don disposable gloves when palpating open lesions, skin surfaces suspicious of infections or infestations, or discharge from lesions of the skin and mucous membranes. Standard precautions should be adhered to when conducting a skin assessment. A disposable ruler is used to measure the size of lesions. A torch is used to better visualise lesions.

Diagnostic tests

The results of diagnostic tests of the structure and function of the integumentary system are used to support the diagnosis of a specific injury or disease, to provide information to identify or modify the appropriate medication or treatments used to treat the disease and to help nurses monitor the person's responses to nursing care interventions. Diagnostic tests to assess the integumentary system are described in the following box and summarised in the 'Integumentary assessments' section. More information is given in Chapters 15 and 16.

The use of laboratory tissue analysis, exudate cultures or skin scrapings will not be routine for all wounds but is restricted to situations when clinical assessment indicates infection to be the cause of delayed healing. Conditions that indicate the need for investigation include:

- acute or chronic wounds that demonstrate signs of infection (erythema, swelling, heat, pain and increased exudate or purulence) and that are not responding to standard management
- a clinical diagnosis of infection has been made and drug sensitivities are required to ensure correct coverage for the organisms in the wound
- infected chronic wounds are deteriorating, despite appropriate debridement and antimicrobial treatment
- local surveillance is required to identify drug-resistant organisms (Expert Working Group, World Union of Wound Healing Societies, 2008; Young, 2012).

There are several recognised methods for collecting a tissue or fluid sample for diagnosing infection. A wound swab can be collected using a sterile swab for microscopy culture and this will identify the species and semi-quantitatively the number of organisms (normally reported as scant, low, moderate or heavy growth). This method does not accurately identify organisms in deeper tissues, and surface contamination results in over-reporting of organisms.

Although there are several methods reported for collecting a wound swab, there is no single, universally accepted method. Methods include:

- *Random swab sampling:* risks contamination with surrounding skin and topical isolates.
- *Levine method:* a swab is rotated over a 1 cm^2 area (necrotic tissue is debrided prior to this) with sufficient pressure to express fluid from within the wound tissue (Levine et al., 1976).
- *Zig-zag stroke method:* rotation of the collection swab between the fingers as the swab is manipulated from close to wound margin to margin in a 10-point zig-zag (Z) fashion (Angel et al., 2011; Cuzzell, 1993).

The Levine technique is considered to be superior to the Z technique because of possible sampling of a greater concentration of microorganisms from both the surface and slightly below the surface of the wound (Angel et al., 2011).

The wound should be cleaned with sterile water or normal saline prior to taking any wound swab in order to minimise the risk of contamination. Topical antiseptics should be avoided prior to taking the wound swab as they may alter the result. Avoid the use of topical anaesthetics such as Emla which can reduce the number of bacteria and alter the result (Batai et al., 2004).

DIAGNOSTIC TESTS The integumentary system: tissue biopsy

There are several methods to obtain a tissue biopsy.

NAME OF TEST: Punch biopsy

PURPOSE AND DESCRIPTION Used to obtain a tissue sample for histological study. Helpful in diagnosing pathology which lies in the epidermis, dermis and subcutaneous tissue. Best biopsy technique for undiagnosed rashes and suspected neoplasms.

Punch biopsy instrument is used to remove a small section of epidermis, dermis and subcutaneous tissue. Depending on the size of the biopsy removed, the incision may need to be sutured.

RELATED NURSING CARE Explain procedure to the person and ensure a consent form is signed (if required). Assist with procedure. Apply appropriate dressing and provide information about self-care. If sutures are used, advise the person when to return for suture removal. Document procedure and send labelled specimen to the laboratory.

NAME OF TEST: Incisional skin biopsy

PURPOSE AND DESCRIPTION Used to excise a section of tissue from the wound bed and wound edge.

Incision is made using a scalpel extracting a block of tissue, quadrangular at the skin surface. Biopsy rarely needs to be more than 5 mm deep. The incision is closed with sutures.

RELATED NURSING CARE As for a punch biopsy.

NAME OF TEST: Excisional skin biopsy

PURPOSE AND DESCRIPTION Incision is made using a scalpel and the *entire* skin lesion or tumour is removed for analysis. Excision is closed with sutures.

RELATED NURSING CARE As for a punch biopsy.

NAME OF TEST: Shave biopsy

PURPOSE AND DESCRIPTION Helpful in diagnosing diseases where the pathology is in or near the epidermis. Lumps and bumps as opposed to rashes are best biopsied with the shave technique.

Using a scalpel or curette, a slice of the top layer of the raised area is taken. Stitches are not usually required.

RELATED NURSING CARE Individual should be advised to clean wound with tap water and apply dressing to keep the wound moist. Change as required generally twice a week initially, then weekly until healed.

NAME OF TEST: Skin scrapings

PURPOSE AND DESCRIPTION Useful where fungal infections and some parasite infestations are suspected.

Scalpel is used to collect the sample and the sample is transported dry.

RELATED NURSING CARE As for a punch biopsy.

NAME OF TEST: Immunofluorescent slides

PURPOSE AND DESCRIPTION Used to identify IgG antibodies (present in pemphigus vulgaris) and to identify varicella in skin cells (for herpes zoster). Skin or blood samples collected in a sterile specimen container. Procedure should be documented and specimen clearly labelled and sent to the laboratory where it will be placed on a slide and examined microscopically for analysis.

RELATED NURSING CARE As for a punch biopsy.

(continued)

DIAGNOSTIC TESTS The integumentary system: tissue biopsy (continued)

NAME OF TEST: Wood's lamp **PURPOSE AND DESCRIPTION** Used in the clinical setting and uses an ultraviolet light that causes certain organisms to fluoresce (such as *Pseudomonas* organisms and fungi). Skin is examined under a special lamp.	**RELATED NURSING CARE** Explain the procedure to the person. Document the procedure.
NAME OF TEST: KOH (potassium hydroxide) preparation **PURPOSE AND DESCRIPTION** Used to examine for a fungal infection. Specimen of hair or nails is obtained, placed in a sterile specimen-labelled container and sent with the supporting documentation to the laboratory for analysis. In the laboratory the specimen is placed on a slide, potassium hydroxide solution is added and the specimen is examined microscopically.	**RELATED NURSING CARE** Explain the procedure to the person. Assist with or obtain the specimen, document the procedure and send the labelled specimen to the laboratory for analysis.
NAME OF TEST: Tzanck test **PURPOSE AND DESCRIPTION** Used to diagnose herpes infections, but it does not differentiate herpes simplex from herpes zoster. Fluid and cells from the vesicles are obtained, sent to the laboratory where they are put on a slide, stained and examined microscopically.	**RELATED NURSING CARE** Explain the procedure to the person. Use sterile procedure to assist with or obtain the specimen. Document the procedure and send the labelled specimen to the laboratory for analysis.
NAME OF TEST: Patch test, scratch tests **PURPOSE AND DESCRIPTION** Used to determine a specific allergen. Small amount of the suspected material is placed on the skin under an occlusive bandage. Patch tests generally detect delayed allergic reactions. In a scratch test, a needle is used to prick a small amount of a suspected allergen into the skin of the forearm. The type of allergen is selected from the patient's history. A positive reaction will usually occur within 20–30 minutes after exposure in the form of itchy, raised red wheals.	**RELATED NURSING CARE** Explain the procedure to the person, including the need to return, usually in 48 hours, to have the patched area or scratched areas evaluated. Document the procedure.

A tissue biopsy can be collected using a punch or scalpel, and the numbers of organisms will be able to be quantified more accurately. This method requires technical expertise and is usually restricted to hospitals or doctors' rooms. Although considered the 'gold standard' approach by many, quantitative biopsy provides information from only a small area of the wound bed and can therefore have poor sensitivity and reliability in large wounds (Angel et al., 2011; Gjødsbøl et al., 2012; Rondas et al., 2013; Sibbald et al., 2003).

A needle aspiration of adjacent tissues for tissue fluid can be collected to identify tissue organisms. This method also requires technical expertise and, like biopsy, is usually restricted to hospitals and doctors' rooms. Increased pain can be associated with this technique and it can underestimate the number of organisms when compared to biopsy (Bowler, Duerden & Armstrong, 2001; Kingsley, 2003).

Skin scrapings may be collected for diagnosing fungal infection. Other tests used to identify infections include immunofluorescent studies, Wood's lamp, potassium hydroxide and the Tzanck test.

Allergies may be determined through analysis of patch tests or scratch tests.

Some studies are conducted to identify bacterial carriers. For example, if people have repeated bacterial skin infections or if a healthcare unit or agency experiences numerous bacterial infections of people, nasal cultures may be performed to determine if the people or the healthcare workers are carriers of the bacteria. Regardless of the type of diagnostic test, the nurse

is responsible for explaining the procedure and any special preparation needed; for assessing for medication use that may affect the outcome of the tests; for supporting the person during the examination as necessary; for documenting the procedures as appropriate; and for monitoring the results of the tests.

Genetic considerations

When conducting a health assessment interview and physical assessment, it is important for the nurse to consider genetic and ageing influences on the health of the adult.

Ascertain age and, during the health assessment interview, ask about integumentary disorders or abnormalities among immediate family members. During the physical assessment, assess for any manifestations that indicate a possible genetic disorder. If data are found that indicate genetic risk factors or alterations, ask about genetic testing and refer for appropriate genetic counselling and evaluation. Chapter 7 provides further information about genetics in medical–surgical nursing.

INTEGUMENTARY ASSESSMENTS

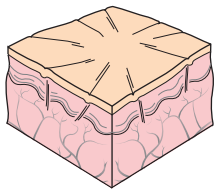
Technique/normal findings	Abnormal findings
Inspect skin colour and note any odours coming from the skin. *Skin colour should be even, appropriate to the age and race of the person, without foul odours.*	■ A strong odour of perspiration may indicate poor hygiene and a need for health education. A foul odour may indicate a disorder of the sweat glands. ■ Pallor and/or cyanosis are seen with exposure to cold and with decreased perfusion and oxygenation. In cyanotic dark-skinned people, skin appears dull. Cyanosis may be more visible in the mucous membranes and nail beds of these people. ■ In dark-skinned people, jaundice may be most apparent in the sclerae of the eyes. ■ Redness, swelling and pain are seen with various rashes, inflammations, infections and burns. Superficial burns cause areas of painful erythema and swelling. Red, painful blisters appear in superficial partial-thickness burns, whereas white or blackened areas are common in deep partial-thickness or full-thickness burns. ■ **Vitiligo**, an abnormal loss of melanin in patches, typically occurs over the face, hands or groin. Vitiligo can occur at any age and is thought to be an autoimmune disorder.
Inspect the skin for lesions and alterations, including calluses, scars, tattoos and piercings. Include inspection of skin creases and folds. *Skin should be intact without abnormal lesions.*	Primary, secondary and vascular lesions are described and shown in Tables 14.6 to 14.8. ■ Pearly edged nodules with a central ulcer are seen in basal cell carcinoma. ■ Scaly, red, fast-growing papules are seen in squamous cell carcinoma. ■ Dark, asymmetric, multicoloured patches (sometimes moles) with irregular edges appear in malignant melanoma. ■ Circular lesions are usually present in ringworm and in tinea versicolor. ■ Grouped vesicles may be seen in contact dermatitis. ■ Linear lesions appear in poison ivy and herpes zoster. ■ **Urticaria** (hives) appears as patches of pale, itchy wheals in an erythematous area. ■ In psoriasis, scaly red patches appear on the scalp, knees, back and genitals. ■ In herpes zoster, vesicles appear along sensory nerve paths, turn into pustules and then crust over. ■ Bruises (**ecchymoses**) are raised bluish or yellowish vascular lesions. Multiple bruises in various stages of healing suggest trauma or abuse.
Palpate skin temperature. *Skin should be warm.*	■ Skin is warm and red in inflammation and is generally warm with elevated body temperature. ■ Decreased blood flow decreases the skin temperature; this may be generalised, as in shock, or localised, as in arteriosclerosis.

TABLE 14.6 Primary skin lesions

Macule, patch 	Flat, non-palpable change in skin colour. Macules are smaller than 1 cm, with a circumscribed border, and patches are larger than 1 cm and may have an irregular border. **Examples** Macules: freckles, measles and petechiae. Patches: Mongolian spots, port-wine stains, vitiligo and chloasma.	Vesicle, bulla 	Elevated, fluid-filled, round or oval shaped, palpable mass with thin, translucent walls and circumscribed borders. Vesicles are smaller than 0.5 cm; bullae are larger than 0.5 cm. **Examples** Vesicles: herpes simplex/zoster, early chickenpox and small burn blisters. Bullae: contact dermatitis, friction blisters and large burn blisters.
Papule, plaque 	Elevated, solid, palpable mass with circumscribed border. Papules are smaller than 0.5 cm; plaques are groups of papules that form lesions larger than 0.5 cm. **Examples** Papules: elevated moles, warts and lichen planus. Plaques: psoriasis, actinic keratosis and also lichen planus.	Wheal 	Elevated, often reddish area with irregular border caused by diffuse fluid in tissues rather than free fluid in a cavity, as in vesicles. Size varies. **Examples** Insect bites and hives (extensive wheals).
Nodule, tumour 	Elevated, solid, hard or soft palpable mass extending deeper into the dermis than a papule. Nodules have circumscribed borders and are 0.5 to 2 cm; tumours may have irregular borders and are larger than 2 cm. **Examples** Nodules: small lipoma, squamous cell carcinoma, fibroma and intradermal nevi. Tumours: large lipoma, carcinoma and haemangioma.	Pustule 	Elevated, pus-filled vesicle or bulla with circumscribed border. Size varies. **Examples** Acne, impetigo and carbuncles (large boils).
		Cyst 	Elevated, encapsulated, fluid-filled or semisolid mass originating in the subcutaneous tissue or dermis, usually 1 cm or larger. **Examples** Varieties include sebaceous cysts and epidermoid cysts.

TABLE 14.7 Secondary skin lesions

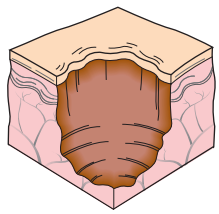
Atrophy



A translucent, dry, paper-like, sometimes wrinkled skin surface resulting from thinning or wasting of the skin due to loss of collagen and elastin.

Examples Striae, aged skin.

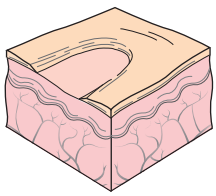
Ulcer



Deep, irregularly shaped area of skin loss extending into the dermis or sub cutaneous tissue. May bleed. May leave scar.

Examples Pressure injuries, venous stasis ulcers, chancres.

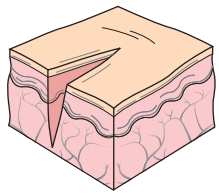
Erosion



Wearing away of the superficial epidermis causing a moist, shallow depression. Because erosions do not extend into the dermis, they heal without scarring.

Examples Scratch marks, ruptured vesicles.

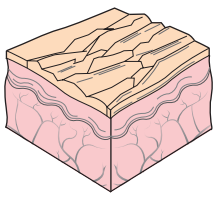
Fissure



Linear crack with sharp edges, extending into the dermis.

Examples Cracks at the corners of the mouth or in the hands, athlete's foot.

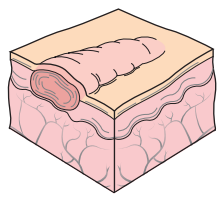
Lichenification



Rough, thickened, hardened area of epidermis resulting from chronic irritation such as scratching or rubbing.

Example Chronic dermatitis.

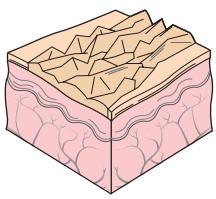
Scar



Flat, irregular area of connective tissue left after a lesion or wound has healed. New scars may be red or purple; older scars may be silvery or white.

Examples Healed surgical wound or injury, healed acne.

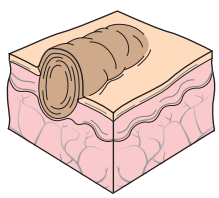
Scales



Shedding flakes of greasy, keratinised skin tissue. Colour may be white, grey or silver. Texture may vary from fine to thick.

Examples Dry skin, dandruff, psoriasis and eczema.

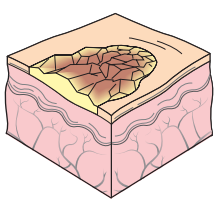
Keloid



Elevated, irregular, darkened area of excess scar tissue caused by excessive collagen formation during healing. Extends beyond the site of the original injury. Higher incidence in people of African descent.

Examples Keloid from ear piercing or surgery.

Crust



Dry blood, serum or pus left on the skin surface when vesicles or pustules burst. Can be red-brown, orange or yellow. Large crusts that adhere to the skin surface are called scabs.

Examples Eczema, impetigo, herpes or scabs following abrasion.

TABLE 14.8 Vascular skin lesions

Spider angioma	 *Source:* SPL/Custom Medical Stock Photo, Inc.	A flat, bright red dot with tiny radiating blood vessels ranging in size from a pinpoint to 2 cm. It blanches with pressure. **Cause** A type of telangiectasis (vascular dilatation) caused by elevated oestrogen levels, pregnancy, oestrogen therapy, vitamin B deficiency or liver disease, or may not be pathological. **Localisation/distribution** Most commonly appear on the upper half of the body.
Venous star	 *Source:* Photo Researchers, Inc./Science Source.	A flat blue lesion with radiating, cascading or linear veins extending from the centre. It ranges in size from 3 to 25 cm. **Cause** A type of telangiectasis (vascular dilatation) caused by increased intravenous pressure in superficial veins. **Localisation/distribution** Most commonly appear on the anterior chest and the lower legs near varicose veins.
Petechiae	 *Source:* Custom Medical Stock Photo, Inc.	Flat red or purple rounded freckles approximately 1 to 3 mm in diameter. Difficult to detect in dark skin. Do not blanch. **Cause** Minute haemorrhages resulting from fragile capillaries, petechiae are caused by septicaemias, liver disease or vitamin C or K deficiency. They may also be caused by anticoagulant therapy. **Localisation/distribution** Most commonly appear on the dependent surfaces of the body (e.g. back, buttocks). In the person with dark skin, look for them in the oral mucosa and conjunctivae.
Purpura	 *Source:* Custom Medical Stock Photo, Inc.	Flat, reddish blue, irregularly shaped extensive patches of varying size. **Cause** Bleeding disorders, scurvy and capillary fragility in the older adult (senile purpura). **Localisation/distribution** May appear anywhere on the body, but are most noticeable on the legs, arms and backs of hands.
Ecchymosis	 *Source:* Photo Researchers, Inc./Science Source.	A bruise. A flat, irregularly shaped lesion of varying size with no pulsation. Does not blanch with pressure. In light skin, it begins as a bluish purple mark that changes to greenish yellow. In brown skin, it varies from blue to deep purple. In dark skin, it appears as a darkened area. **Cause** Release of blood from superficial vessels into surrounding tissue due to trauma, haemophilia, liver disease or deficiency of vitamin C or K. **Localisation/distribution** Occurs anywhere on the body at the site of trauma or pressure.

Technique/normal findings	Abnormal findings
Palpate skin texture. *Skin should be smooth.*	■ Changes in the texture of the skin may indicate irritation or trauma. ■ The skin is soft and smooth in hyperthyroidism and coarse in hypothyroidism.
Palpate skin moisture. *Skin should be dry.*	■ Excessively dry skin often is present in older adults and people with hypothyroidism. ■ Oily skin is common in adolescents and young adults. Oily skin may be a normal finding or it may accompany a skin disorder such as acne vulgaris. ■ Excessive perspiration may be associated with shock, fever, increased activity or anxiety.
Palpate skin turgor. *Skin fold should return rapidly to normal position.*	■ Pinch the person's skin gently over the back of the hand or collarbone. Tenting, in which the skin remains pinched for a few moments before resuming its normal position, is common in older people who are thin (see Figure 14.4). ■ Skin turgor is decreased in dehydration. It is increased in oedema and scleroderma.

FIGURE 14.4 ■ Tenting in an older person

Assess for oedema. *No oedema should be present.*	■ Assess **oedema** (accumulation of fluid in the body's tissues) by depressing the person's skin (see Figure 14.5). Record findings as follows: 1+ Slight pitting, no obvious distortion 2+ Deeper pit, no obvious distortion 3+ Pitting is obvious; extremities are swollen 4+ Pitting remains with obvious distortion. ■ Oedema is common in cardiovascular disorders, renal failure and cirrhosis of the liver. It also may be a side effect of certain drugs.

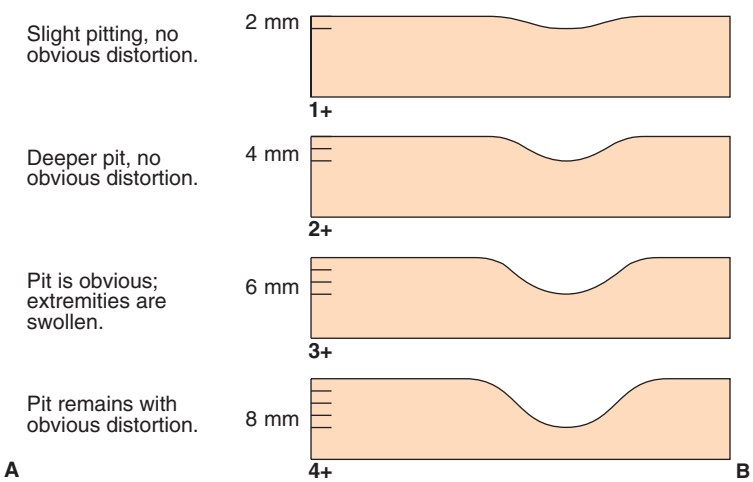


FIGURE 14.5 ■ *A*, Degrees of pitting in oedema. *B*, 4+ pitting

INTEGUMENTARY ASSESSMENTS (continued)

Technique/normal findings	Abnormal findings
Inspect distribution and quality of hair. *Hair should be evenly distributed for person's gender.*	■ A deviation in the normal hair distribution in the male or female genital area may indicate an endocrine disorder. **Hirsutism** (increased growth of coarse hair, usually on the face and trunk) is seen in Cushing's syndrome, acromegaly and ovarian dysfunction. **Alopecia** (hair loss) may be related to changes in hormones, chemical or drug treatment, or radiation. In adult males whose hair loss follows the normal male pattern, the cause is usually genetic.
Palpate hair texture. *Hair should be of even texture.*	■ Some systemic diseases change the texture of the hair. For instance, hypothyroidism causes the hair to coarsen, whereas hyperthyroidism causes the hair to become fine.
Inspect the scalp for lesions. *There should be no lesions on the scalp.*	■ Mild dandruff is normal, but excessive, greasy flakes indicate seborrhoea requiring treatment. ■ Hair loss, pustules and scales appear on the scalp in tinea capitis (scalp ringworm). ■ Red, swollen pustules appear around infected hair follicles and are called folliculitis. ■ Head lice may be seen as oval nits (eggs) adhering to the base of the hair shaft. Head lice are usually accompanied by itching.
Inspect nail curvature. *Nails should not be excessively curved.*	■ Clubbing (see Figure 14.6), in which the angle of the nail base is greater than 160 degrees, is seen in respiratory disorders, cardiovascular disorders, cirrhosis of the liver, colitis and thyroid disease. The nail becomes thick, hard, shiny and curved at the free end.

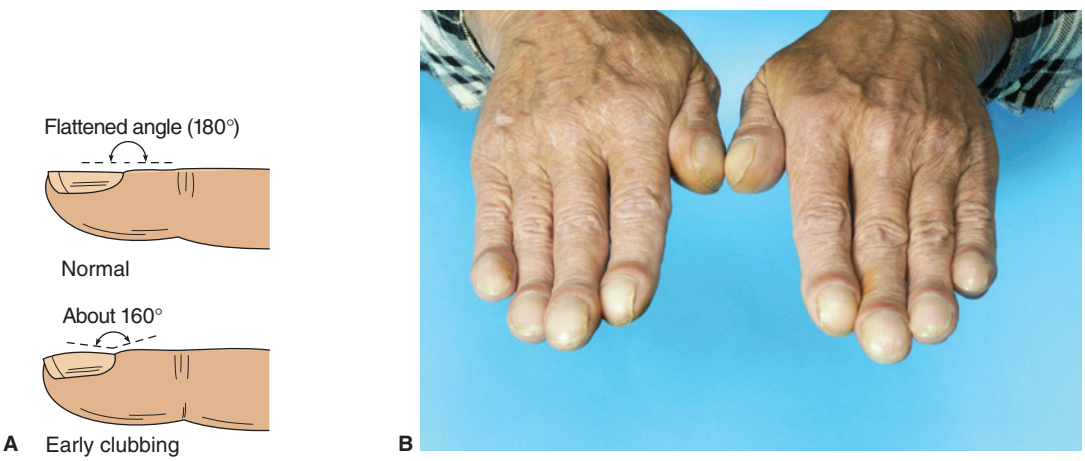

FIGURE 14.6 ■ *A*, Assessing clubbing of the nails. *B*, Hand with nail clubbing

Source: B, SPL/Science Source.

Inspect the surface of the nails. *Nail surfaces should be smooth and nail folds firm, without redness.*	■ The nail folds become inflamed and swollen and the nail may loosen in paronychia, an infection of the nail fold. ■ Inflammation and transverse rippling of the nail are associated with chronic paronychia and/or eczema. ■ The nail plate may separate from the nail bed in trauma, psoriasis and *Pseudomonas* and *Candida* infections. This separation is called oncolysis. ■ Nail grooves may be caused by inflammation, by lichen planus or by nail biting. ■ Nail pitting may be seen with psoriasis. ■ A transverse groove (Beau's line) may be seen in trachoma and/or acute diseases. ■ Thin spoon-shaped nails (see Figure 14.7) may be seen in anaemia.

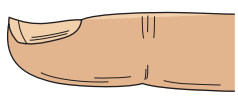

FIGURE 14.7 ■ Spoon-shaped nails

Technique/normal findings	Abnormal findings
Inspect nail colour. *Nail colour should be even.*	■ The sudden appearance of a pigmented band may indicate melanoma in Caucasians. ■ Yellowish nails are seen in psoriasis and fungal infections. ■ Dark nails occur with trauma, *Candida* infections and hyperbilirubinemia. ■ Blackish-green nails are apparent in injury and in *Pseudomonas* infection. ■ Red splinter longitudinal haemorrhages may be seen in injury and/or psoriasis.
Inspect nail thickness. *Nails should not be excessively thick.*	■ Trauma to the nails usually causes thickening. Other causes of thick nails include psoriasis, fungal infections and decreased peripheral vascular blood supply. ■ Thinning of the nails is seen in nutritional deficiencies.

CONCEPT CHECK

1 Which layer of the skin contains most of the hair follicles, sebaceous glands and sweat glands?
   1 epidermis
   2 dermis
   3 hypodermis
   4 stratum lucidium

2 What pigment is responsible for skin tanning?
   1 carotene
   2 red blood cells
   3 melanin
   4 sebum

3 Which of the four assessment techniques are used during assessment of the integumentary system? (Select all that apply.)
   1 inspection
   2 palpation
   3 percussion
   4 auscultation

4 Superficial skin damage that involves the epidermis only is referred to as:
   1 ulceration
   2 erosion
   3 atrophy
   4 lichenification

5 You are assessing a person who is complaining of severe itching. What would be an appropriate interview question?
   1 'Tell me how this itch feels.'
   2 'Why do you keep scratching it?'
   3 'Have you used a new soap?'
   4 'Describe your daily fluid intake.'

6 You are assessing the skin of an older person for dehydration. What finding would indicate this condition?
   1 decreased turgor
   2 increased moisture
   3 presence of lesions
   4 pallor or cyanosis

7 What part of the body would you commonly palpate to assess oedema in the older person?
   1 scalp
   2 fingers
   3 clavicle
   4 ankle/foot

8 You are assessing a person with chronic dermatitis and note that they have rough, thickened areas of skin. You document these areas as:
   1 ulcers
   2 papules
   3 atrophy
   4 lichenification

9 On assessment you observe clubbing of the fingernails. What disorders could this be related to?
   1 cirrhosis of the liver
   2 cardiovascular disorders
   3 emphysema
   4 excessive vitamin C intake

10 While assessing the hair, you note small white eggs on the hair shaft. What type of infestation are you assessing?
   1 bacterial
   2 viral
   3 head lice
   4 head lichens

CHAPTER 15

NURSING CARE OF PEOPLE WITH INTEGUMENTARY DISORDERS

KERYLN CARVILLE, KERRY REID-SEARL, KATE CROWLEY

LEARNING OUTCOMES

- Describe the manifestations and nursing care, including the effects of treatment and medications, of common skin problems and lesions.
- Compare and contrast the aetiology, pathophysiology, interprofessional care and nursing care of people with infections and infestations of the skin.
- Compare and contrast the aetiology, pathophysiology, interprofessional care and nursing care of people with inflammation disorders of the skin.
- Differentiate between the various malignant skin conditions, including the nursing implications and treatment options for people with these conditions.
- Explain the risk factors for, pathophysiology of and nursing interventions to prevent and care for skin trauma.

CLINICAL COMPETENCIES

- Assess functional health status of people with integumentary disorders and monitor, document and report abnormal manifestations.
- Use evidence-based research to plan and implement nursing care for people with pressure injuries and skin tears.
- Determine priority nursing diagnoses, based on assessed data, to select and implement individualised nursing interventions for people with integumentary disorders.
- Administer topical, oral and injectable medications used to treat integumentary disorders knowledgeably and safely.
- Integrate interprofessional care into care of people with integumentary disorders.
- Provide teaching appropriate for prevention and self-care of disorders of the integumentary system.
- Revise plan of care as needed to provide effective interventions to promote, maintain or restore functional health status to people with disorders of the integument.

KEY TERMS

The integumentary system is comprised of the skin and its accessory structures: hair, nails and glands (sebaceous, sudoriferous and ceruminous). The skin is the largest body organ, and provides protection by serving as a barrier between the internal and external environments. As described in Chapter 14, the functions of the skin are many, as the skin contains receptors for touch and sensation, helps regulate body temperature and maintains fluid and electrolyte balance. The skin also provides cues to racial and ethnic background and plays a major role in determining self-concept and cosmesis.

There are many disorders of the integument. Many of them are treated in an outpatient or community setting or by self-care. This chapter discusses disorders of the skin, hair and nails; Chapter 16 discusses the person with burns. Primary and secondary skin lesions are described and illustrated in Tables 14.6 and 14.7. The terms from these tables are used throughout this and the next chapter.

COMMON SKIN PROBLEMS AND LESIONS

The disorders discussed in this section are those experienced by a large number of people. Although they are considered minor health problems in terms of healthcare, they may cause major problems, such as impaired learning ability and earning potential for the person experiencing a high level of discomfort and loss of quality of life (Metz et al., 2013).

THE PERSON WITH PRURITUS

Pruritus is a subjective itching sensation that produces an urge to scratch. Pruritus may occur in a small, circumscribed area or it may involve a widespread area; it may or may not be associated with a rash. Pruritus is believed to result from either stimulation of itch receptors in the skin or as a response to the stimulation of skin receptors for pain and touch. The central nervous system (CNS) interprets these stimuli as an itch through central summation (Martini, Nath & Bartholomew, 2012).

Intrinsic and extrinsic factors can predispose a person to pruritus. Ingestion of foods or medications, contact with insects, animals, plants, fabrics or metals, allergic responses and even emotional distress are among the most common causes. Pruritus also may occur as a secondary manifestation of systemic disorders, such as certain types of cancer, diabetes mellitus, hepatic disease and renal failure. Although the exact physiology is unknown, it is known that heat and prostaglandins trigger pruritus and that histamine and morphine exacerbate the itch response.

The pathophysiological response of pruritus to stimulation or irritation follows a similar pathway, regardless of cause. The irritating agent stimulates receptors in the junction between the epidermis and dermis and may also trigger the release of histamine and other chemical mediators that either further stimulate or mediate the itch response. The response of the person experiencing the itch is to scratch or rub the affected area. This may irritate the skin and cause further inflammation, which in turn sets off a cycle of increasingly intense itching and scratching, called the *itch–scratch–itch cycle*.

Secondary effects of pruritus include skin excoriation, erythema, wheals, changes in pigmentation and infections. Persistent pruritus may interrupt sleep patterns, because the itching sensation is often more intense at night. Long-term pruritus may be debilitating and increases the risk of infection as excoriation occurs. In children, chronic pruritus has been shown to increase the risk of depression, anxiety and suicidal thoughts (Metz et al., 2013). Though not the most prevalent symptom in palliative care patients, pruritus remains the most puzzling. It can cause discomfort and has a major impact on the person's quality of life.

Treatment for this cohort remains challenging and requires an individualistic approach (Xander et al., 2013). Management of pruritus focuses on identifying and eliminating the cause and the topical application or the use of systemic medications to relieve the itch. Control of pruritus is crucial in breaking the itch/scratch cycle and preventing damage to the skin (excoriation and lichenification). A cool environment may cause vasoconstriction and decreasing itching. Antihistamines may relieve pruritus in some people. Tranquillisers may be prescribed to provide sedation, which may in turn relieve the emotional stress associated with pruritus. Systemic antibiotics are used to treat any infection resulting from the scratching and excoriation. Topical medications that contain corticosteroids are often used to relieve the pruritus and inflammation. Other topical preparations that contain menthol, camphor or phenol can be used to numb the itch receptors. Those with generalised itch may benefit from phototherapy (DermNet NZ, 2014). This is particularly useful for individuals with chronic renal failure on dialysis and eosinophilic infiltrations (DermNet NZ, 2014). Therapeutic baths or soaks with antipruritic agents such as cornflour, oatmeal, baking soda or coal tar concentrates may prove effective. Therapeutic baths are discussed in the following 'Medication administration' box. Table 15.1 lists examples of topical agents used to treat skin disorders. Creams containing a topical anaesthetic or antibiotic may also be prescribed.

THE PERSON WITH DRY SKIN (XEROSIS)

Dry skin, also called **xerosis**, is most often a problem in the older adult, as sebaceous and sweat gland activity reduces with ageing and this reduces the skin's lubrication and moisture retention. However, dry skin may occur at any age from overexposure to low humidity, sunlight, wind, excessive bathing and a decreased intake of liquids.

TABLE 15.1 Topical agents used to treat skin disorders

TYPE	USE	EXAMPLES
Creams and lotions	Moisturise the skin Cool the skin	Sorbolene Alpha Keri™ Ego QV™ skin lotion Calamine lotion (contains phenol which cools the skin, but limit use to a few days)
Ointments	Lubricate the skin Retard water loss	Urea Vaseline
Topical anaesthetics	Relieve itching	Xylocaine
Topical antibiotics (use prudently and only as prescribed)	Treat infection	Mupirocin (eye and nose mucous membrane) Silver sulfadiazine
Corticosteroids (use prudently and only as prescribed)	Suppress inflammation Relieve itching	Dexamethasone Hydrocortisone Betamethsone

MEDICATION ADMINISTRATION Therapeutic baths

AGENTS USED INTHERAPEUTIC BATHS

Saline or tap water
Antibacterial agents: potassium permanganate, Pinetarsol™ bath oil, hexachlorophene
Food substances: colloidal oatmeal, cornflour, sodium bicarbonate
Coal tar derivatives: Polytar™ and Alpha Keri™ tar bath preparations
Emollients: Alpha Keri™ and Ego QV™ bath oils

Coal tar preparations are not recommended for use under occlusive products, except under the direction and supervision of a physician; and coal tar preparations can cause skin irritation, rashes and skin photosensitivity (MIMS Online, 2013).

Therapeutic baths have a variety of uses in treating skin disorders. Depending on the agent used, therapeutic baths soothe the skin, lower the skin bacteria count, clean and hydrate the skin, loosen scales and relieve itching.

Nursing responsibilities

- Ensure that the bath water is at a comfortable tepid temperature that is neither too hot nor too cool, usually 45°C to 46°C.
- Fill the bath one-third to one-half full.
- Mix the agent well with the water.
- Assist the person into and out of the bath to prevent falls.
- Dry the person by blotting with the towel and avoid rubbing the skin.

Health education for the person and family

- Use a bath mat in the bath because the medications may cause the bath to become slippery.
- Keep the bathroom warm but adequately ventilated.
- If using a prescribed medication, follow directions carefully for the amount of medication to use in the bath.
- Fill the bath one-third to one-half full of water that is at a comfortable temperature.
- Stay in the bath for 20 to 30 minutes and immerse the areas to be treated.
- Do not get the medicated bathwater in your eyes.
- Dry by blotting (not rubbing) with the towel.
- If the medications cause staining, use old towels or linen.
- If the itching is not relieved or the skin becomes excessively dry, call your healthcare provider.

Two types of severe dry skin are xeroderma and ichthyosis. Xeroderma is a chronic skin condition characterised by dry, rough skin. Ichthyosis is an inherited dermatological condition in which the skin is dry, fissured and hyperkeratotic; the surface of the skin has the appearance of fish scales.

The primary manifestation of dry skin is pruritus. Other manifestations include visible flaking of surface skin and an observable pattern of fine lines over the area. If the skin has been excessively dry and pruritic for a long period, the person may have secondary skin lesions and lichenification (roughened thick epidermis with accentuated skin markings).

Nursing care focuses on teaching the person and family how to reduce the dry skin and relieve the pruritus, as outlined in Box 15.1.

THE PERSON WITH BENIGN SKIN LESIONS

The skin is subject to many different types and kinds of benign skin lesions, including cysts, hypertrophic scars, keloids, naevi, angiomas, skin tags and keratoses. Although these benign lesions are often considered more of a nuisance than an illness,

BOX 15.1 Teaching to reduce dry skin and relieve pruritus

- Wash clothing in a mild detergent and rinse twice; do not use fabric softeners.
- Avoid using perfumes and lotions containing alcohol.
- Apply skin moisturisers after a bath to help retain moisture.
- Soaps and hot water are drying. Clean the skin with tepid water and either a pH-neutral cleanser or mild soap. If soap is used, rinse it off thoroughly.
- It is not necessary to take a bath every day.
- If bath oils are used, add them to the bathwater at the end of the bath (the moist skin is more likely to retain the oil). Be careful not to slip in the bath.
- Pat the skin lightly and immediately apply a moisturising lotion or cream after bathing.
- Use a humidifier to humidify the air if the environment is very dry.
- Apply creams and lotions when the skin is slightly damp after bathing.
- Increase fluid intake.
- Keep nails trimmed short, wear loose clothing and keep the environment cool.
- A brief application of pressure or cold may relieve pruritus.
- Cotton gloves may be worn at night if scratching during sleep causes skin excoriation.
- Distraction or relaxation techniques may prove helpful.

they do require monitoring for malignant changes or an increase in size that interferes with the skin's appearance or function.

Most benign skin lesions do not require treatment, although excision or laser surgery may sometimes be desired or necessary for cosmetic or functional purposes. Cysts may enlarge, skin tags may become irritated and bleed, naevi may change in appearance or any of the lesions may cause discomfort with appearance.

Cysts

Cysts of the skin are benign closed sacs in or under the skin surface that are lined with epithelium and contain fluid or a semisolid material. Epidermal inclusion cysts and pilar cysts are the most common types.

Epidermal inclusion cysts may occur anywhere on the body, but are most often found on the head and trunk. Although they are painless, they may grow so large that they become irritated by contact with clothing (e.g. if located on the back of the neck) or cause obstruction (e.g. if located on the nose). The cysts contain a semisolid material composed mainly of keratin. Pilar cysts are painless and are found on the scalp and originate from sebaceous glands. Both types of cysts rarely require treatment unless they become large and bothersome.

Hypertrophic scar

Hypertrophic scars are characterised by an excess of collagen in the healed wound that results in excessive elevated scar; however, one which is contained within the perimeter of the original wound (Bullock & Hales, 2013). Hypertrophic scars can form following intentional or accidental trauma such as burns. Hypertrophic scarring is aberrant or abnormal wound healing (Carville, 2012). The mechanism and reasons for hypertrophic scarring are not fully understood, but such scarring commonly occurs following burn trauma. The use of custom-made pressure garments for the prevention and treatment of hypertrophic scarring is considered standard care. Although it is not definitively understood how pressure garments impact on scar formation, studies demonstrate that they do improve scar appearance and cause a scar to be softer and thinner (Monstrey et al., 2014). Pressure garments are often used in conjunction with silicone sheets which appear to aid in keeping the scar hydrated as they reduce moisture vapour transmission (Stavrou et al., 2010).

Keloids

Keloids are elevated, irregularly shaped, progressively enlarging scars that extend outside the perimeters of an original wound. Like hypertrophic scars, keloid formation is aberrant wound healing. They arise from excessive amounts of collagen in the stratum corneum during scar formation in connective tissue repair. These lesions are more common in young adults and appear within 1 year of the initial trauma.

This abnormal response most often occurs in people of African and Asian descent who sustain burns of the skin, but even seemingly minor trauma such as infection or an injection site can result in keloid formation (Bullock & Hales, 2013). There is a familial tendency to develop keloids. Other risk factors for keloid formation include excessive tension on a wound and poor alignment of skin edges following accidental or intentional skin trauma. Certain skin surfaces are also more likely to develop keloids: the chin, ears, shoulders, back and lower legs.

The excessive scar formation is associated with increased metabolic activity of fibroblasts and increased type III collagen. The principal cells of the keloids are myofibroblasts, which have characteristics of both fibroblasts and smooth muscle cells. The swollen appearance of the keloids is the result of an excess of extracellular material.

The keloids first appear as red, firm, rubbery plaques that persist for several months after the initial trauma (see Figure 15.1). Uncontrolled overgrowth over time causes the keloids to extend beyond the original scar. Eventually, the keloid becomes smooth and hyperpigmented. Intralesional steroid injections and excision may be tried to control keloid formation; however, they can recur following these treatments.

Naevi

Naevi, more commonly called *moles*, are flat or raised macules or papules with rounded, well-defined borders (see Figure 15.2). Naevi arise from melanocytes during early childhood, with the

FIGURE 15.1 ■ Keloids form as a result of deposits of excessive amounts of collagen during scar formation

Source: © photographer/Alamy.

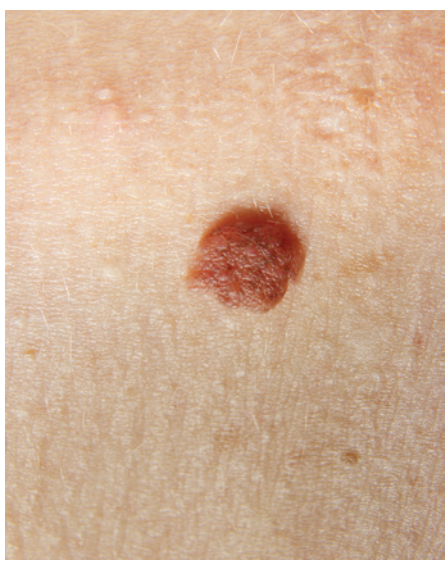

FIGURE 15.2 ■ Naevi (moles) arise from melanocytes and are common in all adults

Source: Nathalie Speliers Ufermann/Shutterstock.

cells initially accumulating at the junction of the dermis and epidermis. Over time, the cluster of cells moves into the dermis and the lesion becomes visible. Almost all adults have naevi.

Naevi range from flesh coloured to black and occasionally contain hair. They can occur on any skin surface of the body and may arise as single lesions or in groups. Some pigmented naevi can transform into malignant lesions. Australian malignant melanoma rates are on the rise. The whole body naevi count, when increased, is an independent risk factor for melanoma (Mar, Wolfe & Kelly, 2011). It is important to monitor naevi for changes in size, thickness, colour, bleeding or itching. If any of these changes occur, the person should seek immediate professional assessment.

Angiomas

Angiomas, also called *haemangiomas*, are benign vascular tumours. They appear in the adult in different forms:

- Naevus flammeus (port-wine stain) is a congenital vascular lesion that involves the capillaries. The lesions tend to occur on the upper body or face as macular patches that range from light red to dark purple. These lesions are present at birth and grow proportionately with the child into adulthood.
- Cherry angiomas are small, rounded papules that may occur at any age, but they most commonly arise in the forties and gradually increase in number. The lesions range in colour from bright red to purple. These lesions are often found on the trunk. They are also called senile angiomas or de Morgan spots, named after Campbell de Morgan, a 19th century British surgeon who first described them (Watkins, 2012).
- Spider angiomas are dilated superficial arteries. They are common in pregnant women and in people with hepatic disease. Spider angiomas occur most often on the face, neck and upper chest. The lesions are usually small, bright red papules with radiating lines, and they blanch with pressure.
- Telangiectases are single dilated capillaries or terminal arteries that appear often on the cheeks and nose. These lesions are most common in older adults and result from photoaged skin. The lesions look like broken veins.

Skin tags

Skin tags are soft papules on a pedicle. They can be as small as a pinhead or as large as a pea and are most often found on the front or side of the neck and in the axillae, as well as in areas where clothing (such as underwear) rubs the skin. These lesions have normal skin colour and texture.

Keratoses

A **keratosis** is any skin condition in which there is a benign overgrowth and thickening of the cornified epithelium. These lesions most often appear in adults after age 50. *Seborrhoeic keratoses* appear as superficial flat, smooth or warty-surfaced growths, 5 to 20 mm in diameter, most often on the face and trunk. The lesions may be tan, waxy yellow, dark brown or flesh coloured and they often appear greasy. They are most often seen in the older adult and do not appear to be related to damage from sun exposure.

THE PERSON WITH PSORIASIS

Psoriasis is a chronic immune skin disorder characterised by raised, reddened, round circumscribed plaques covered by silvery white scales (see Figure 15.3). The size of these lesions varies. The lesions may appear anywhere on the body, but they are most commonly found on the scalp, extensor surfaces of

FIGURE 15.3 ■ The characteristic lesions of psoriasis are raised, red, round plaques covered with thick, silvery white scales

Source: © olavs/Shutterstock.com.

the arms and legs, elbows, knees, sacrum and around the nails. As with any chronic illness, the skin manifestations may occur and disappear throughout life, with no discernible pattern to the recurrence.

The incidence of psoriasis is lower in warm, sunny climates. Onset usually occurs in the person's twenties, but it may occur at any age. Psoriasis occurs more often in Caucasians; men and women are affected equally. Sunlight, stress, seasonal changes, hormone fluctuations, steroid withdrawal and certain drugs (such as alcohol, corticosteroids, lithium and chloroquine) appear to exacerbate the disorder. For more than 40 years the evidence has been identifying that psoriasis is linked to genetic susceptibility (Witte & Sabat, 2014). About one-third of people have a family history of psoriasis. Trauma to the skin from such events as surgery, sunburn or excoriation is also a common precipitating factor; lesions that result from trauma are called Köbner's reaction (Bullock & Hales, 2013).

Pathophysiology

Normally, the keratinocyte (an epidermal cell making up 95% of the epidermis) migrates from the basal cell to the stratum corneum (the outer skin layer) in about 14 days and is sloughed off 14 days later. Psoriatic skin cells, by contrast, have a shorter cycle of growth, completing the journey to the stratum corneum in only 4 to 7 days, a condition called *hyperkeratosis*. These immature cells produce an abnormal keratin that forms thick, flaky scales at the surface of the skin. The more rapid cell metabolism stimulates increased vascularity, which contributes to the erythema of the lesions. As part of the abnormal process, certain immune cells become overactive and release proteins called cytokines. One of the cytokines is tumour necrosis factor (TNF); in psoriasis, TNF causes inflammation, further contributing to plaque formation.

Psoriasis vulgaris is the most common form of psoriasis. The lesions can be found anywhere on the skin but most commonly involve the skin over the elbows, knees and scalp. Initially, the lesions are papules that form into well-defined erythematous plaques with thick, silvery white scales. The plaques in people with darker skin may appear purple.

Permanent remission of psoriasis is rare. The prognosis depends on the type, extent and severity of the initial attack. The age of onset is also a factor; early-onset disease is usually more severe.

Manifestations

The characteristic lesions in psoriasis are well-demarcated regions of erythematous plaques that shed thick, silvery white flakes. Pruritus is common over the psoriatic lesions. If the lesions are located in an intertriginous zone, such as between the toes, under the breasts or in the perianal region, the psoriatic scales may soften, allowing painful fissures to form. When psoriasis affects the nails, pitting and a yellow or brown discolouration result. The nail may separate from the nail bed, thicken and crumble. The involved nails, which are more often fingernails than toenails, are at high risk of infection. The person may also exhibit manifestations of psoriatic arthritis, seen most often in the distal interphalangeal joints, especially if the fingernails are involved.

INTERPROFESSIONAL CARE

Treatment is based on the type of psoriasis, the extent and location of the lesions, the age of the person and the degree of disfigurement or disability.

Diagnosis

Skin biopsy may be done if the person presents with atypical manifestations or to differentiate psoriasis from other inflammatory or infectious skin disorders. In addition, an ultrasound may reveal typical psoriatic changes in the stratum corneum and inflammation of the dermis.

Medications

A variety of medications and treatments may be prescribed, including topical medications and photochemotherapy. Although there is no cure, treatment decreases the severity and pain of the lesions.

Topical medications are administered to decrease inflammation, prolong the maturity time of keratinocytes and increase remission time. Corticosteroids, tar preparations, anthralin and the retinoids are typically used. Box 15.2 outlines general guidelines for teaching the person to apply topical medications.

Topical corticosteroids decrease inflammation, suppress mitotic activity of psoriatic cells and delay the movement of keratinocytes to the surface of the skin. The most effective topical corticosteroids are potent preparations that are well absorbed through the skin and are used under an occlusive dressing. Corticosteroids may also be taken systemically or injected directly into the lesions. However, corticosteroids rarely cause a lasting remission and may cause the psoriasis to become unstable (Horn et al., 2010). They are therefore used for repeated short periods of treatment and combined with other measures, such as tar preparations, occlusions or a topical retinoid.

BOX 15.2 General guidelines for applying topical medications

Each time a medication is applied, the skin surface must be clean and dry. Remove any medication from the previous application. Remove creams by washing the skin with tap water and a pH-neutral skin cleanser or mild soap.

- *To apply gels, creams and pastes:* squeeze about 1 to 2.5 cm of the gel or cream into the gloved palm of the hand. Rub the hands together until they are covered. Apply gels and creams to the affected areas with long gentle strokes until the skin is thinly covered. Differences from these general guidelines follow:
  a. Corticosteroids are usually applied two to three times a day in small amounts and rubbed directly on to the lesions. Apply the medication after a bath; it can be covered with an occlusive dressing if prescribed.
  b. Apply medications containing tar in the direction of hair growth. Do not apply these medications to the face, to the genitals or in skin folds. If the tar is water-based or oil-based, it will stain clothing.
  c. Wear gloves when applying dithranol stains.
- *To apply lotions:* shake the bottle of lotion well. Pour a small amount into the palm of the gloved hand and pat the medication on to the skin. If the lotion is thin, apply it with a gauze pad.
- *To apply sprays:* hold the container about 15 cm from the skin and apply the medication in a short spray.
- *To apply medicated shampoo:* apply the shampoo, massage into the hair and over the scalp carefully and allow it to remain for the prescribed time. Rinse.
- *To apply pastes:* use enough paste on an applicator (such as a wooden tongue depressor) to cover the lesion thinly.

Tar preparations (such as Psor-Asist™) suppress mitotic activity and are also anti-inflammatory. Tar preparations are made from distillation of coal and wood and they can stain clothing and have a pungent odour. The exact mechanism of action of tar preparations is unknown, but they are effective in removing scales and increasing remission time; however, they can make a person more sun sensitive.

Topical dithranol, which is extracted from tree bark, inhibits the mitotic activity of epidermal cells and is effective in some cases of chronic, localised psoriasis that do not respond to other topical agents. The medication is applied to the plaque patches at bedtime and left in place for 8 to 12 hours. The person should be tested for sensitivity to the drug before use and it should not be applied to inflamed or open areas of skin.

Calcipotrial (Daivovex™, a vitamin D analogue) has been effective and safe in both the short-term and long-term treatment of psoriasis. It inhibits cell proliferation in the epidermis and facilitates cell differentiation. Although a derivative of topical vitamin D, calcipotrial does not seem to affect bone or calcium metabolism; however, periodic monitoring is prudent if used in children or large doses (Harkin, 2014).

Ultraviolet light therapy

Psoriasis that is widespread (i.e. involves more than 30% of the body surface) is difficult to treat with topical medications. Treatments for generalised psoriasis include ultraviolet light therapy and photochemotherapy. Natural sunlight contains ultraviolet-B (UVB) which penetrates the skin and slows the growth of affected skin cells (National Psoriasis Foundation, 2015). In Australia, narrowband UVB, broadband UVB and a combination of oral psoralens (natural substances derived from plants such as celery) and ultraviolet-A light (PUVA) are used to treat psoriasis. The light is delivered by specially designed fluorescent tubes either within a cabinet (full body application) or in panels (for application to individual body parts) (Better Health Channel, 2015).

The light therapy is administered in gradually increasing exposure times, until the person experiences a mild erythema, like a mild sunburn. Treatments are given three times a week as an outpatient and are measured in seconds of exposure. The eyes are shielded during the treatment. The erythema response occurs in about 8 hours. Careful assessment is necessary to prevent more severe burning, which could exacerbate the psoriasis. In the person with extensive psoriasis, UVB treatments may be combined with tar preparations, which increase the photosensitivity of the skin.

PHOTOCHEMOTHERAPY In photochemotherapy, a light-activated form of the drug methoxsalen is used. This drug is an antimetabolite that inhibits DNA synthesis and thereby prevents cell mitosis, decreasing hyperkeratosis. Exposure to ultraviolet-A (UVA) rays activates methoxsalen; it is administered orally and the person is exposed to UVA 2 hours later. The eyes are covered by dark glasses during the treatment. Treatments are administered two to three times a week; usually, 10 to 20 total treatments are given over 1 to 2 months. Treatment causes tanning and direct sunlight must be avoided for 8 to 12 hours thereafter. If the person exhibits erythema, the treatments are stopped until the redness and swelling resolve.

Photochemotherapy has had a high success rate in achieving remission of psoriasis, but it can accelerate ageing of exposed skin, induce cataract development, alter immune function and increase the risk of melanoma.

Nursing care

The person with psoriasis requires nursing care to meet physical and psychological responses to the illness. The nurse provides teaching for self-care and emotional support through non-judgmental acceptance.

Nursing diagnoses and planning

The nursing care discussed in this section focuses on the diagnoses of:

- *Impaired skin integrity* related to psoriasis as evidenced by open lesions on lower legs and lower arms.

- *Disturbed body image* related to psoriasis evidenced by reluctance to wear clothing that may expose lesions.

Impaired skin integrity related to psoriasis

Psoriatic lesions range from several scales to large, open areas. Typical psoriatic skin lesions increase the risk of infection, which can further compromise healing. In addition, certain treatments (e.g. the use of UVA or retinoids) may cause erythema or peeling of the skin, further altering skin integrity.

- Teach methods to reduce injury to the skin when taking therapeutic baths or treatments:
  - Use warm, not hot, water.
  - Gently rub lesions with a soft washcloth, using a circular motion.
  - Dry the skin with a soft towel, using a blotting or patting motion.
  - Keep the skin lubricated at all times.
- Explain application of topical medications:
  - Apply the medication as prescribed in a thin layer, using gloved hands, wooden tongue depressors or a gauze pad.
  - Avoid getting medications in the eyes, on mucous membranes or in skin folds.
  - Apply a covering such as an occlusive dressing over the medicated areas if prescribed. Topical corticosteroids are often covered with occlusive dressings or wraps to increase absorption and thus facilitate treatment. However, constant occlusion may increase the effects of the medications to undesired levels and also increases the risk of infections.
- Teach manifestations of infection and how to contact the healthcare provider if these occur: elevated temperature, increased swelling, redness, pain, increase in drainage and any change in the colour of the drainage.
- Teach manifestations of the complications of treatment: excoriation, increased erythema, increased peeling and blister formation. The topical medications or treatments may damage cells through chemical burns or excessive exposure to ultraviolet light.

Disturbed body image related to psoriasis

The chronic skin lesions of psoriasis often cause people to isolate themselves from social contacts, withdraw from normal roles and responsibilities, and feel helpless or powerless.

- Establish a trusting relationship by expressing acceptance of the person, both verbally and non-verbally. For example, touch the person during social communications, demonstrating that the lesions are not contagious or offensive.
- Encourage the person to verbalise feelings about self-perception in view of the chronic nature of psoriasis and to ask questions about the disease and treatment.
- Promote social interaction through family involvement in care and by referral to support groups of people with psoriasis or other chronic skin conditions.

Community-based care

Person and family teaching focuses on treatments and skin care needs. The following topics should be addressed:

- The chronic nature of the disease, factors that may precipitate an exacerbation and methods to reduce stress.
- Interventions for pruritus and dry skin and specific care for psoriasis:
  - Expose the skin to sunlight, but avoid sunburn.
  - Avoid trauma to the skin (e.g. do not scrub off scales and use only an electric razor).
  - Avoid exposure to contagious illnesses such as influenza and colds.
  - Discuss current medications with the healthcare provider. Certain drugs (such as indomethacin (Indocin™), lithium and beta-adrenergic blocking agents) are known to precipitate exacerbations of psoriasis.
  - Suggest contact with resources such as Psoriasis Australia www.psoriasisaustralia.org.au.

INFECTIONS AND INFESTATIONS OF THE SKIN

The skin's resistance to infections and infestations is provided by protective mechanisms, including skin flora, sebum and the immune response. Although the skin is normally resistant to infections and infestations, these disorders may occur as a result of a break in the skin surface, a virulent agent, and/or decreased resistance due to a compromised immune system. This section discusses skin disorders resulting from bacterial infections, fungal infections, parasitic infestations and viral infections.

THE PERSON WITH A BACTERIAL INFECTION OF THE SKIN

A number of bacteria normally inhabit the skin and do not cause an infection. However, when a break in the skin allows invasion by pathogenic bacteria, an infection may occur. The most common bacterial infections are caused by gram-positive organisms commonly found on the skin, such as *Staphylococcus aureus*.

Bacterial infections of the skin may be primary or secondary. Primary infections are caused by a single pathogen and arise from normal skin; secondary infections develop in injured or diseased skin.

Most bacterial infections are treated by a primary care provider within the home environment. If the infection becomes more serious, however, inpatient care may be required. In addition, nosocomial infections of wounds or open lesions in hospitalised people are often the result of bacterial infections, especially by methicillin-resistant *Staphylococcus aureus* (MRSA).

Pathophysiology

Bacterial infections of the intact skin arise from the hair follicle, where bacteria can accumulate and grow and cause a localised infection. However, the bacteria also can invade deeper tissues and cause a systemic infection, a potentially life-threatening disorder. Various types of bacterial infections involve the skin, including folliculitis, furuncles, carbuncles, cellulitis and erysipelas.

Folliculitis

Folliculitis is a bacterial infection of the hair follicle, most commonly caused by *Staphylococcus aureus*. The infection begins at the follicle opening and extends down into the follicle. The bacteria release enzymes and chemical agents that cause an inflammation. The lesions appear as pustules surrounded by an area of erythema on the surface of the skin (see Figure 15.4). The lesions are accompanied by discomfort ranging from slight burning to intense itching. A major complication is abscess formation. Folliculitis is found most often on the scalp and extremities. It is also often seen on the face of bearded men (called sycosis barbae), on the legs of women who shave and on the eyelids (called a stye).

Although folliculitis may appear without any apparent cause, contributing factors include poor hygiene, poor nutrition, prolonged skin moisture, tight heavy fabrics on the upper legs, shaving and trauma to the skin.

FIGURE 15.4 ■ The lesions of folliculitis are pustules surrounded by areas of erythema

Source: © Dr P Marazzi/Science Source.

CONSIDERATION FOR PRACTICE

A specific type of folliculitis, called 'hot tub folliculitis', is caused by *Pseudomonas aeruginosa* and is characterised by follicular or pustular lesions that occur 1 to 4 days after being in a hot tub or public swimming pool.

Furuncles

Furuncles, often called *boils*, are also inflammations of the hair follicle. They often begin as folliculitis, but the infection spreads down the hair shaft, through the wall of the follicle and into the dermis. The causative organism is commonly *Staphylococcus aureus*. A furuncle initially presents as a deep, firm, red, painful nodule from 1 to 5 cm in diameter (see Figure 15.5), but can result in a painful cystic nodule. The cysts may drain substantial amounts of purulent drainage.

Contributing factors include poor hygiene, heat and humidity, trauma to the skin, areas of excessive moisture (including perspiration) and systemic diseases such as diabetes mellitus and haematological malignancies.

Carbuncles

A **carbuncle** is a group of infected hair follicles. The lesion begins as a firm mass located in the subcutaneous tissue and the lower dermis. This mass becomes swollen and painful and has multiple openings to the skin surface. Carbuncles are most frequently found on the back of the neck, the upper back and the lateral thighs. In addition to the local manifestations, the person may experience chills, fever and malaise. The contributing factors for carbuncles are the same as for furuncles. Both infections are more common in hot, humid climates.

Cellulitis

Cellulitis is a localised infection of the dermis and subcutaneous tissue. Cellulitis can occur in intact skin or be associated with a wound or furuncles or carbuncles. The infection spreads as a result of a substance produced by the causative organism, called spreading factor (hyaluronidase). This factor breaks down the

FIGURE 15.5 ■ A furuncle (boil) is a deep, firm, red, painful nodule

Source: © Dr P Marazzi/Science Source.

FIGURE 15.6 ■ Cellulitis is a bacterial infection localised in the dermis and subcutaneous tissue. The involved area is red, swollen and painful

Source: © Charles Stewart MD FACEP, FAAEM.

fibrin network and other barriers that normally localise the infection. The area of cellulitis is red, swollen and painful (see Figure 15.6). In some cases, vesicles may form over the area of cellulitis. The person may also experience systemic signs and symptoms such as fever, chills, malaise, headache and swollen lymph glands.

Erysipelas

Erysipelas is an infection of the skin most often caused by group A streptococci. Chills, fever and malaise are prodromal symptoms, occurring from 4 hours to 20 days before the skin lesion appears. The initial infection appears as firm red spots that enlarge and join to form a circumscribed, bright red, raised, hot lesion. Vesicles may form over the surface of the erysipelas lesion. The area usually is painful, itches and burns. Erysipelas most commonly appears on the face, ears and lower legs.

INTERPROFESSIONAL CARE

The diagnosis of a bacterial infection of the skin is made by assessing the appearance of the lesion and by identifying the causative organism. Antibiotics specific to the organism are used in treatment.

Diagnosis

Wound aspirate or swab is collected and sent to pathology for microbiological culture and sensitivity to identify the causative organism and determine the most effective antibiotic. People who experience repeated bacterial skin infections or who provide care for others who exhibit infections may have a culture taken from the external nares to determine whether they are carriers of bacteria (e.g. MRSA) and are reinfecting themselves or others.

Medications

The primary treatment for bacterial infections of the skin is an antibiotic specific to the organism. The antibiotic is usually taken orally, but for extensive or severe infections antibiotics may be administered intravenously. Multiple furuncles and carbuncles may be treated with cloxacillin (a penicillinase-resistant penicillin); the cephalosporins also are often effective. Topical antibiotics are not commonly prescribed as overuse can increase the risk of antibiotic resistance. However, prudent use of antiseptic-impregnated dressings can restore bacterial balance in the tissue without undue tissue toxicity (see Box 15.12).

Nursing care

Nursing care focuses on preventing the spread of infection and restoring normal skin integrity. Most people provide self-care at home, but the incidence of secondary bacterial infections in the inpatient population is great enough to warrant their inclusion in planning and implementing care.

Nursing diagnoses and interventions

Potential risk of infection related to ineffective infection control practices by healthcare personnel

- Practise good hand hygiene and teach its importance to all people.
- Teach the person and their family how to identify the signs and symptoms of localised and spreading infection. Local signs and symptoms include pain, swelling, erythema, heat and purulent or increased exudate. Signs of spreading infection may be manifested systemically by fever, tachycardia, chills and malaise.
- Prudent preventive use of modern antiseptic dressings such as cadexomer iodine (Iodosorb™), wound honey preparations, silver or polyhexamethylene-biguanide-impregnated dressings may be warranted in high-risk people or wounds.

Community-based care

Person and family teaching focuses on facilitating tissue healing and eliminating the infection. Address the following topics:

- the importance of maintaining good nutrition
- the importance of maintaining cleanliness through careful hand hygiene, and proper handling and disposal of dressings or contaminated materials
- preventing the spread of infection in the home by not sharing bed linen and towels, and washing clothing and linen in hot water
- the importance of not squeezing or trying to open a bacterial lesion
- avoiding plucking of nasal hair or picking nose
- the importance of taking the full course of prescribed antibiotics on a regular schedule until the prescribed supply is finished
- showering daily and using an antibacterial soap or lotion if warranted when bacterial skin infections exist.

THE PERSON WITH A FUNGAL INFECTION

Fungi are free-living plant-like organisms that live in the soil, on animals and on humans. The fungi that cause superficial skin infections are called dermatophytes. In humans, the dermatophytes live on keratin in the stratum corneum, hair and nails. Fungal disorders are also called *mycoses*.

Pathophysiology

Fungal infections include dermatophytoses (tinea or ringworm) and candidiasis (yeast) infections.

Dermatophytoses (ringworm or tinea)

Superficial fungal infections of the skin are called **dermatophytoses** or, more commonly, *ringworm or tinea*. Fungal infections occur when a susceptible host comes in contact with the organism. The organism may be transmitted by direct contact with animals or other infected people or by inanimate objects such as combs, pillowcases, towels and hats. The most important factor in the development of the infection is moisture; the onset and spread of the fungal infection is greatest in areas where moisture content is high, such as within skin folds, between the toes and in the mouth. Other factors that increase the risk of a fungal infection include the use of broad-spectrum antibiotics that kill off normal skin or mucosal flora and allow the fungi to grow, and conditions such as diabetes mellitus, immunodeficiencies, nutritional deficiencies, pregnancy, increasing age and iron deficiency. Fungal infections of the skin are more common in warm, humid climates. The dermatophyte infections are named by the body part affected, as follows:

- *Tinea pedis* is a fungal infection of the soles of the feet, the space between the toes, and/or the toenails (see Figure 15.7). More often called *athlete's foot*, this is the most common tinea infection. The lesions vary from mild scaliness to painful fissures with drainage and they are usually accompanied by pruritus and a foul odour. The infection is often chronic, absent in winter but reappearing in hot weather when perspiring feet are encased in shoes.
- *Tinea capitis* is a fungal infection of the scalp. The primary lesions are grey, round, bald spots, often accompanied by erythema and crusting. The hair loss is usually temporary. Tinea capitis is seen more often in children than in adults.
- *Tinea corporis* is a fungal infection of the body. It can be caused by several different fungi and the lesions vary according to the causative organism. The most common lesions, often called *ringworm,* are large circular patches with raised red borders of vesicles, papules or pustules. Pruritus and erythema are also present.
- *Tinea versicolour* is a fungal infection of the upper chest, back and sometimes the arms. The lesions are yellow, pink or brown sheets of scaling skin. The patches do not have pigment and do not tan when exposed to ultraviolet light.
- *Tinea cruris* is a fungal infection of the groin that may extend to the inner thighs and buttocks. Often called 'jock itch', it is often associated with tinea pedis and is more common in people who are physically active, are obese, and/or wear tight underclothing.

Candidiasis

Candidiasis infections are caused by *Candida albicans*, a yeast-like fungus. This fungus is normally found on mucous membranes, on the skin, in the vagina and in the gastrointestinal tract. The fungus becomes a pathogen when the following factors encourage its growth:

- a local environment of moisture, warmth or altered skin integrity
- the administration of systemic antibiotics

FIGURE 15.7 ■ *Tinea pedis* (athlete's foot) is a fungal infection that often occurs between the toes

Source: © SPL/Science Source.

FIGURE 15.8 ■ *Candida albicans*, a fungus, causes a skin infection characterised by erythema, pustules and a typical white substance covering the area

Source: © CNRI/Science Photo Library.

TABLE 15.2 Characteristics of candidiasis infections by location

LOCATION	CHARACTERISTICS
Skin folds (under breasts, in groin, axillae, anus, umbilicus, abdominal pannus and between toes or fingers)	Erythematous lesions can be either dry or moist. The lesions have clear borders and satellite lesions are present.
Nails	Nail bed is red, swollen and painful.
Mouth (thrush)	Mucous membranes are red and may be swollen; surface is covered with white, creamy material. Eroded areas may be present over the tongue and the oral cavity.
Penis (balanitis) (glans and shaft)	The penis is covered with small, red, clearly demarcated lesions that are painful and itch. The lesions may be covered with a white plaque.
Vagina	Red mucous membranes contain brighter red, demarcated, oozing lesions. The cervix may be covered with white plaque. A white, cheesy, foul-smelling vaginal discharge is present, accompanied by itching and burning. The vaginal and labial membranes may be swollen; the infection may extend to the anus and groin.

- pregnancy
- the use of birth control pills
- poor nutrition
- the presence of diabetes mellitus, Cushing's disease or other chronic debilitating illnesses
- immunosuppression
- some malignancies of the blood.

Candidiasis affects the outer layers of the skin and mucous membranes of the mouth, vagina, uncircumcised penis, nails and deep skin folds (under large breasts or an abdominal pannus). The first sign of infection is a pustule that extends under the stratum corneum. The pustule has an inflamed base and often burns and itches. As the infection spreads, the accumulation of inflammatory cells and shedding of surface cells produce a white to yellow curd-like substance that covers the infected area (see Figure 15.8). Satellite lesions (maculopapular areas found outside the clearly demarcated border of the original infection) are characteristic of candidiasis. The appearance of the infection differs by location, as summarised in Table 15.2.

INTERPROFESSIONAL CARE

Fungal infections are primarily diagnosed in outpatient settings and treated at home, but may also occur in hospitalised people. The treatment is the same, regardless of the setting.

Diagnosis

Diagnostic tests are conducted to determine the causative fungi and may include cultures of skin scrapings and examination of the skin with ultraviolet light (Wood's lamp). See Chapter 14 for further information.

Medications

Fungal infections of the skin are treated by topical or systemic antifungal medications. Nursing implications for the antifungal medications are described in the 'Medication administration' box below.

- Candidiasis infections are treated, depending on the location, with oral medication or with powder or vaginal suppositories.

MEDICATION ADMINISTRATION Antifungal agents

Examples:

Nystatin (Mycostatin™, Nilstat™)
Itraconazole (Sporanox™)
Miconazole (Daktarin™)
Ketoconazole (Nizoral™)
Fluconazole (Diflucan™)
Amphotericin B (Fungilin™)
Griseofulvin (Fulcin™)
Terbinafine hydrocholoride (Lamisil™)

Antifungal medications are prepared in a variety of forms, depending on the specific drug: powders, creams, shampoos, suspensions, troches, vaginal suppositories and oral tablets. Some drugs interfere with the permeability of the fungal cell membrane; others interfere with DNA synthesis. Most of these medications are fungistatic, but in large doses they may be fungicidal.

Nursing responsibilities

- When taking the health history, ask about known hypersensitivity reactions to these agents; document carefully.
- Assess for side effects: skin rash, local irritation, gastrointestinal symptoms (if given orally) and cognitive status.
- Administer ketoconazole with food to minimise gastrointestinal irritation.
- Shake suspensions well before administration and ask the person to swish them around the mouth before swallowing.
- If advised by the manufacturer, advise the person to allow oral tablets to dissolve in the mouth.

Health education for the person and family

- Therapy usually continues over a long period of time, but regular use of medications for the recommended period

MEDICATION ADMINISTRATION Antifungal agents (continued)

is necessary. Do not miss doses and do complete the full treatment.
- *For griseofulvin:* take with meals or foods high in fat (such as ice-cream) to avoid stomach upset and help with absorption. Avoid alcohol (which may cause rapid pulse and flushing) and exposure to sunlight (this drug causes increased sensitivity).
- *For nystatin:* dissolve lozenges completely in the mouth. Hold suspensions in the mouth and swish throughout the mouth as long as possible before swallowing. Insert intravaginal medication high in the vagina. Continue with intravaginal applications throughout the menses.
- *For antifungal shampoo:* use two times a week for 4 weeks, allowing at least 3 days between each shampoo. Wet hair, apply shampoo to produce lather, leave in place for 1 minute, then rinse. Apply shampoo a second time, lather, leave in place for 3 minutes, then rinse thoroughly.
- *For topical application:* rub well into the affected areas, but do not get the medication in your eyes.
- *For vaginal candidiasis infections:* treatment with antifungal creams and pessaries can weaken condoms, so apply after sexual intercourse. Also, use plenty of lubricant during sexual intercourse as thrush can cause discomfort.
- A sexual partner will need to be treated at the same time so that you do not pass the infection back and forth to each other.

Nursing care

Many people treat themselves with over-the-counter antifungal medications. It is recommended, however, that the person be professionally diagnosed, especially if the infection is ongoing or repetitive. The interventions discussed for nursing care of the person with a bacterial infection are also appropriate for the person with a fungal infection. Teaching topics specific to fungal infections are as follows:
- Fungal diseases are contagious. Do not share linen or personal items with others.
- Use a clean towel and washcloth each day.
- Carefully dry all skin folds, including those under the breasts, arms, abdominal pannus and between the toes.
- Wear clean cotton underclothing each day.
- Fungi grow in moist environments, such as on sweaty feet. To prevent further infections:
  - Do not wear the same pair of shoes every day.
  - Wear socks that permit moisture to wick away from the skin surface.
  - Do not wear rubber- or plastic-soled shoes.
- For vaginal *Candida albicans* infection:
  - Avoid tight clothing, such as jeans and pantyhose.
  - Wear cotton or cotton-crotch underwear.
  - Shower more frequently and dry the genital area well.
  - Treat the sexual partner at the same time to avoid passing the infection back and forth to each other.

CONSIDERATION FOR PRACTICE

Recommend the person with repeated skin infections have a blood glucose test, because this may indicate diabetes mellitus.

THE PERSON WITH A VIRAL INFECTION

Viruses are pathogens that consist of an RNA or DNA core surrounded by a protein coat. They depend on live cells for reproduction and so are classified as intracellular pathogens. The viruses that cause skin lesions invade the keratinocyte, reproduce, and either increase cellular growth or cause cellular death.

An increase in the incidence of viral skin disorders has been attributed to a variety of causes. Some commonly used drugs, such as birth control medications and corticosteroids, are known to have immunosuppressive properties that allow the viruses to multiply. Other drugs, such as antibiotics, kill off normal skin bacteria that would otherwise serve as defence against viral infections.

Pathophysiology

Viral infections cause many different kinds of skin disorders, including warts, and herpes simplex and herpes zoster infections.

Warts

Warts or *verrucae*, are lesions of the skin caused by the human papillomavirus (HPV). More than 60 types of HPVs have been found on the human skin and mucous membranes (Bullock & Hales, 2013). Warts may be found on non-genital skin or genital skin and mucous membranes. Non-genital warts are benign lesions; genital warts may be precancerous. Warts are transmitted through skin contact. Wart lesions may be flat, fusiform (tapered at both ends) or round, but most are round and raised and have a rough, grey surface. There are many different types of warts; the location and appearance of the warts depend on the causative virus. Those most common are as follows:
- A common wart (*verruca vulgaris*) may appear anywhere on the skin and mucous membranes of the body, but it most commonly appears on the fingers. Common warts grow above the skin surface and may be dome-shaped with ragged borders (see Figure 15.9).

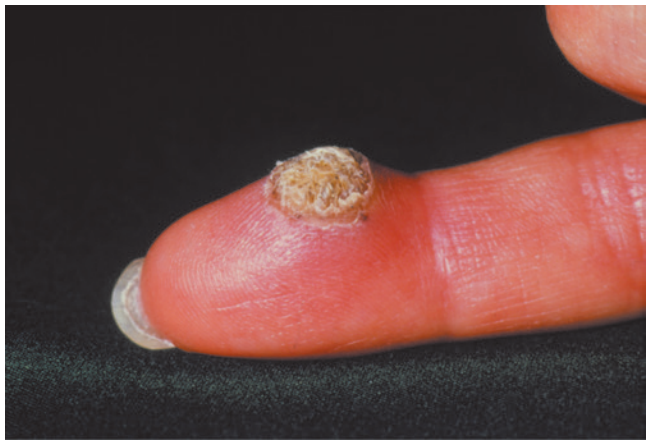

FIGURE 15.9 ■ The common wart, caused by a virus, appears as a raised, dome-shaped lesion

Source: Dr P Marazzi/Science Source.

FIGURE 15.10 ■ Herpes simplex is a viral infection of the skin and mucous membranes

Source: CDC/Dr Hermann.

- Plantar warts occur at pressure points on the soles of the feet. The pressure of shoes and walking prevents these warts from growing outwards, so they tend to extend deeper beneath the skin surface than do common warts. Plantar warts are often painful.
- A flat wart (*verruca plana*) is a small flat lesion, usually seen on the forehead or the dorsum of the hand.
- *Condylomata acuminata*, also called HPV or venereal warts, occur in moist areas, along the glans of the penis, in the anal region and on the vulva and cervix. They are usually cauliflower-like in appearance and have a pink or purple colour.

Warts resolve spontaneously when immunity to the virus develops. This response may take up to 5 years.

Herpes simplex

Herpes simplex (also called a *cold sore*) virus infections of the skin and mucous membranes are caused by two types of herpes virus: HSV-1 and HSV-2. Most infections above the waist are caused by HSV-1, with herpes simplex lesions most often found on the lips, face and mouth. (Genital herpes infections, which result from either HSV-1 or HSV-2, are classified as sexually transmitted infections and are discussed in Chapter 49.) The virus may be transmitted by physical contact, oral sex or kissing.

The infection begins with a burning or tingling sensation, followed by the development of erythema, vesicle formation and pain (see Figure 15.10). The vesicles progress through pustules, ulcers and crusting until healing occurs in 10 to 14 days.

The initial infection is often severe and accompanied by systemic manifestations, such as fever and sore throat; recurrences are more localised and less severe. The virus lives in nerve ganglia and may cause recurrent lesions in response to sunlight, menstruation, injury or stress. Oral aciclovir (Zovirax™) may be used prophylactically to prevent reoccurrences and to treat recurrent outbreaks.

Herpes zoster

Herpes zoster, also called *shingles*, is a viral infection of a dermatome section of the skin caused by varicella zoster (the herpesvirus that also causes chickenpox). The infection is believed to result from reactivation of a varicella virus remaining in the sensory dorsal ganglia after a childhood infection of chickenpox. When reactivated, the virus travels from the ganglia to the corresponding skin dermatome area.

Herpes zoster most often affects adults over the age of 60 (Porth & Matfin, 2009). People with Hodgkin's disease, certain types of leukaemia and lymphomas are more susceptible to an outbreak of the disease. Herpes zoster is more prevalent in immunocompromised people, such as those with human immunodeficiency virus (HIV) infections, those receiving radiation therapy or chemotherapy, and those who have had major organ transplants. The appearance of the lesions in people with HIV infections may be one of the first manifestations of immunocompromise. The herpes eruption lasts for about 2 to 3 weeks and usually does not recur.

Herpes zoster lesions are vesicles with an erythematous base. The vesicles appear on the skin area supplied by the neurons of a single or associated group of dorsal root ganglia (although they may occur beyond this area in immunosuppressed people). The lesions usually appear unilaterally on the face, trunk and thorax (see Figure 15.11). New lesions continue to erupt for 3 to 5 days, then crust and dry. Recovery occurs in 2 to 3 weeks. The person often experiences severe pain for up to 48 hours before and during eruption of the lesions. The pain may continue for weeks to months after the lesions have disappeared. The older adult is especially sensitive to the pain and often experiences more severe outbreaks of herpes zoster lesions.

Eruption of vesicles over a single dermatome usually only occurs one time. Generalised herpes zoster may indicate an associated immunocompromised disease, such as Hodgkin's disease or HIV infection. People infected with HIV are 20 times more likely to develop herpes zoster (McPhee, Papadakis & Tierney, 2008).

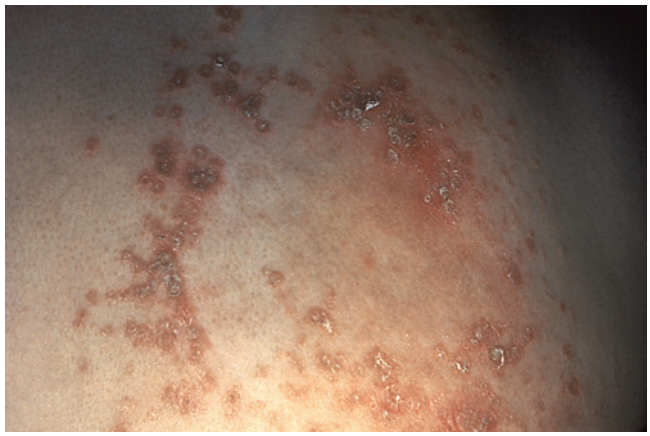

FIGURE 15.11 ■ Herpes zoster is a viral infection of a dermatome section of the skin. The typical lesions are painful vesicles lying along the path of the nerve

Source: CDC/Dr Dancewiez.

Complications of herpes zoster include post-herpetic neuralgia (a sharp, spasmodic pain along the course of one or more nerves) and visual loss. The neuralgia, described as burning or stabbing, results from inflammation of the root ganglia. This complication is more common in people over the age of 55 (McPhee et al., 2008). Permanent loss of vision may follow occurrence of lesions that arise from the ophthalmic division of the trigeminal nerve. The disease may disseminate in immunocompromised people, causing lesions beyond the dermatome, visceral lesions and encephalitis. This serious complication may cause death.

INTERPROFESSIONAL CARE

The treatment for viral skin infections focuses on stopping viral replication and treating the person's responses, such as itching and pain.

Diagnosis

Although diagnosis is usually based on manifestations and appearance of the lesions, laboratory tests may be necessary to differentiate herpes zoster from impetigo, contact dermatitis and herpes simplex. The laboratory tests include a Tzanck smear that identifies the herpesvirus but does not distinguish herpes zoster from herpes simplex. Cultures of fluid from the vesicles and antibody tests are used to make the differential diagnosis of herpesvirus types. HIV testing should be considered if the person has a history of HIV risk factors.

Medications

Most viral skin disorders are treated with antiviral medications, and other types of medications are used to relieve pruritus and pain in the person with herpes zoster.

- *Warts*. Depending on their size, location and any associated discomfort, warts may be treated with medications, cryotherapy or electrodesiccation and curettage. A common method of wart removal is acid therapy, using a colloidal solution of 16% salicylic acid and 16% lactic acid. The solution is applied to the wart every 12 to 24 hours; the wart disappears in 2 to 3 weeks. Other methods of eradicating warts are cryosurgery, freezing with liquid nitrogen and electrodesiccation of the wart with an electric current followed by excision of the dead tissue. Venereal warts are further described in Chapter 49.
- *Herpes simplex*. Herpes simplex lesions are treated with topical aciclovir (Zovirax™), an antiviral agent. Aciclovir shortens the time of symptoms and speeds healing.
- *Herpes zoster*. Antiviral drugs are used to treat herpes zoster infections. Aciclovir interferes with viral synthesis and replication. Although it does not cure herpes infections, it does decrease the severity of the illness and also decreases pain. It may be administered topically, orally or parenterally. It is more effective if administration begins within the first 1 to 2 days after the first vesicles appear. Nerve blocks may be needed to treat initial pain. Narcotic and non-narcotic analgesics are prescribed for pain management and antihistamines may be administered for relief of pruritus. People with eye involvement are treated with topical steroid ophthalmic ointments and mydriatics.

Nursing care

People with viral skin disorders require nursing care for infection, pruritus and pain. They also require teaching about preventing the spread of the virus to others. Of the viral disorders, herpes zoster is the most painful and debilitating. See below for nursing interventions that aim to relieve pain for the person with herpes zoster.

Nursing diagnoses and interventions

This section discusses the nursing care of the person with herpes zoster, focusing on the nursing diagnoses of *Acute pain* related to viral infection of herpes zoster.

Acute pain

The person with herpes zoster often experiences severe pain over the entire dermatome supplied by the affected nerve root. The pain is described as burning, tearing or stabbing. The person may avoid movement and does not want clothing or bed linen to touch the affected area.

- Monitor the location, duration and intensity of the pain.
- Explain the rationale for taking prescribed medications on a regular schedule.
- Teach measures to relieve pruritus:
  - Take prescribed antipruritic medications.
  - Topical application of amorphous hydrogels, especially those that contain tea tree oil, may soothe. Similarly, calamine lotion or wet compresses may be prescribed.
  - Keep the room temperature cool.
  - Use a bed cradle to keep sheets off affected areas of the body.

- Encourage the use of distraction (such as music) or a specific relaxation technique (such as progressive muscle relaxation or deep breathing).

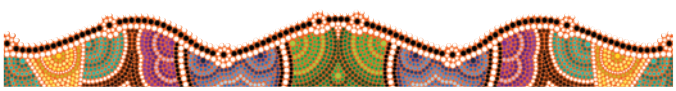
CONSIDERATION FOR PRACTICE

Pregnant women must avoid exposure to people with herpes zoster because the herpes virus can cross the placental barrier.

Community-based care

Most people with viral infections are self-caring in their home environment. Provide the following information and instructions:

- Herpes zoster infections are usually self-limiting and heal completely. Second occurrences of herpes zoster are rare.
- Do not have social contact with children or pregnant women until crusts have formed over the blistered areas with herpes zoster, because the disease is contagious to people who have not had chickenpox.
- Use pain medications regularly.
- Follow suggestions to help reduce itching, scratching and pain: use medications as prescribed, wear lightweight cotton clothing, keep room temperatures cool, wear cotton gloves at night if scratching is a problem and practise relaxation and distraction activities.
- Report to your healthcare provider any increase in pain, fever, chills, drainage that smells bad and has pus or a spread in the blisters.



THE PERSON WITH A PARASITIC INFESTATION

Infestations of the skin by parasites are more common in developing countries but may occur in any geographical area of the world. They affect people of all social classes but are associated with crowded or unsanitary living conditions.

Pathophysiology

In Australia, two of the more common parasitic infestations of the skin are caused by lice and scabies. These parasites do not normally live on the skin, but infest the skin through contact with an infested person or contact with clothing, linen or objects infested with the parasites.

Pediculosis

Pediculosis is an infestation with lice, parasites that live on the blood of an animal or human host. The louse is a 2 to 4 mm oval organism with a stylet that pierces the skin; an anticoagulant in its saliva prevents host blood from clotting while it eats. The female louse lays its eggs (small pearl-grey or brown eggs, called nits) on hair shafts. The louse within the egg hatches, reaches the adult reproductive stage and dies in 30 to 50 days (Bullock & Hales, 2013).

There are three types of human pediculosis:

1. Pediculosis corporis is an infestation with body lice. This type of infestation is more common in people who do not have access to facilities for bathing or washing clothes, such as the homeless. The lice live in clothing fibres and are transmitted primarily by contact with infested clothing and bed linen. The skin lesions occur at the site of a louse bite; macules appear initially, followed by wheals and papules. Pruritus is common and scratching often results in linear excoriations. Secondary infections cause hyperpigmentation and scarring. The lesions are most often seen on the shoulders, trunk and buttocks.
2. Pediculosis pubis is an infestation with pubic lice (often called crabs). This infestation is spread through sexual activity with someone already infested or by contact with infested clothing or linen. The lice are found in the pubic region and occasionally spread to the axillae or men's beards. The lice cause skin irritation and intense itching.
3. Pediculosis capitis is an infestation with head lice. The lice are most often found behind the ears and at the nape of the neck but may also spread to other hairy areas of the body: the eyebrows, pubic area or beard. The lice are transmitted by contact with an infected person or sharing combs, hairbrushes or hats. Manifestations of head lice include pruritus, scratching and erythema of the scalp. If untreated, the hair appears matted and crusted with a foul-smelling substance.

Scabies

Scabies is a parasitic infestation caused by a mite (*Sarcoptes scabiei*). The pregnant female mite burrows into the skin and lays two to three eggs each day for about a month. The eggs hatch in 3 to 5 days and the larvae migrate to the surface but burrow into the skin for food or protection. The larvae develop and the cycle repeats. Scabies infestation affects people of all socioeconomic classes. The infestation is found in webs between the fingers, the inner surfaces of the wrist and elbow, the axillae, the female nipple, the penis, the belt line and the gluteal crease. The lesions are a small red-brown burrow, about 2 mm in length, sometimes covered with vesicles, which appears as a rash. Pruritus in response to the mite or its faeces is common, especially at night, and excoriations may develop. The excoriations predispose the person to secondary bacterial infections (Bullock & Hales, 2013).

INTERPROFESSIONAL CARE

Parasitic infestations are diagnosed by identifying the organism and are treated with medications that kill the lice or scabies.

Diagnosis

When a person has manifestations of pediculosis, the hair shaft and the clothing are examined to identify the lice or the nits. Microscopic examination of the parasite provides a positive

diagnosis. Scabies is diagnosed by skin scrapings and microscopic examination for the mites or their faeces.

Medications

Lice are eradicated with agents that kill the parasite. Infestations of the body and pubic area are treated with topical medications that have a neurotoxic mode of action (permethrin, malathion, carbaril, spinosad) or a physical mode of action (demeicones, isopropyl myristate or herbal remedies). Ivermectin is the only oral treatment currently used as a pediculicide (Feldmeier, 2014).

Manufacturers' instructions are to be followed for use. Repeat applications may be required in some instances to kill newly hatched lice. A fine-toothed comb can be used to comb the dead nits off the hair shaft.

Scabies are treated with topical permethrin or lindane creams and the diligent treatment of other people who have been in close contact, as well as the laundry of contact linen and clothing to prevent reinfestation. Secondary skin infections are common with untreated scabies infestations or immunocompromised individuals.

The associated itching is treated with systemic or topical medications, including corticosteroids. Secondary bacterial infections are treated with the appropriate antibiotic.

Nursing care

Nursing care for the person with a parasite infestation most often focuses on teaching to prevent infestation or to eradicate an existing infestation.

Education for the person and family is necessary to facilitate treatment at home, to prevent the spread of the infestation and to dispel the myth that lice infest only people with poor hygiene or in dirty living conditions. Specific information includes the following:

- Wash clothing and linen in soap and hot water or have them dry-cleaned.
- Ironing the clothes kills any lice eggs.
- Personal care items, such as combs or brushes, may be boiled to kill the parasites.
- All family members and sexual partners must also be treated.
- Avoid using the combs, brushes or hats of others.
- Lice and mites may infest anyone.

INFLAMMATORY DISORDERS OF THE SKIN

The inflammatory skin disorders discussed in this section are dermatitis and acne.

THE PERSON WITH DERMATITIS

Dermatitis is an inflammation of the skin characterised by erythema and pain or pruritus. Dermatitis may be acute or chronic.

Pathophysiology

In dermatitis, various exogenous and endogenous agents cause an inflammatory response of the skin. Different types of skin eruptions occur, often specific to the causative allergen, infection or disease. The initial skin responses to these agents or illnesses include erythema, formation of vesicles and scales, and pruritus (see Figure 15.12). Subsequently, irritation from scratching promotes oedema, a serous discharge and crusting. Long-term irritation in chronic dermatitis causes the skin to become thickened and leathery and darker in colour.

Contact dermatitis

Contact dermatitis is a type of dermatitis caused by a hypersensitivity response or chemical irritation. The major sources known to cause contact dermatitis are dyes, perfumes, certain plants (ivy, oak, sumac), chemicals, latex and metals (see Box 15.3).

Allergic contact dermatitis is a cell-mediated or delayed hypersensitivity to a wide variety of allergens. Sensitising antigens include microorganisms, plants, chemicals, drugs, metals or foreign proteins. On initial contact with the skin, the allergen binds to a carrier protein, forming a sensitising antigen. The antigen is processed and carried to the T cells, which in turn become sensitised to the antigen. The first exposure is the sensitising contact and the person does not experience manifestations, which then occur with subsequent exposures. The manifestations include erythema, swelling and pruritic vesicles in the area of allergen contact. For example, a person hypersensitive to metal may have lesions under a ring or watch.

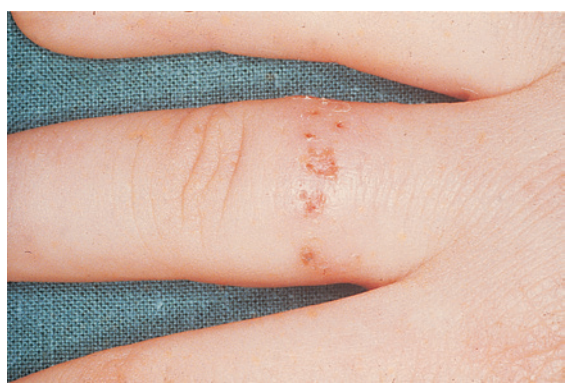


FIGURE 15.12 ■ Dermatitis may be a response to allergens, infections or chemicals. This person has contact dermatitis resulting from the metal salts in a ring

Source: © Biophoto Associates/Science Source.

BOX 15.3 Common causes of contact dermatitis

- Acids
- Alkalis: soaps, detergents, household ammonia, lye, cleaners
- Bromide
- Chlorine
- Cosmetics: perfumes, dyes, oils
- Dusts of lime, arsenic, wood
- Hydrocarbons: crude petroleum, lubricating oil, mineral oil, paraffin, asphalt, tar
- Iodine
- Insecticides
- Fabrics: wool, polyester, dyes, sizing
- Latex: gloves, catheters
- Metal salts: calcium chloride, zinc chloride, copper, mercury, nickel (common in costume jewellery and support bras), silver
- Plants: chrysanthemums, primula, tomato plants, grevillea, English ivy and rhus trees
- Colouring agents
- Rubber and leather products
- Soot

FAST FACTS

Latex allergy

- The increased use of latex gloves among healthcare providers has resulted in increased reporting of latex allergies. It is estimated that 10% to 17% of healthcare providers are allergic to latex (Gawchik, 2011).
- The most common type of allergic response to latex gloves is type IV, T-cell-mediated contact dermatitis.
- Type I, IgE-mediated hypersensitivity, manifested by urticaria, rhinoconjunctivitis, asthma or anaphylaxis, is far more serious than the T-cell-mediated type.
- The person with a latex allergy should be treated in a latex-free environment.
- Healthcare providers with severe allergic responses to latex may have to seek a different type of employment.

Irritant contact dermatitis is an inflammation of the skin from irritants; it is not a hypersensitivity response. Common sources of irritant contact dermatitis include chemicals (such as acids), soaps and detergents. The skin lesions are similar to those seen in allergic contact dermatitis.

Atopic dermatitis

Atopic dermatitis is an inflammatory skin disorder that is also called *eczema*. The exact cause is unknown, but related factors include depressed cell-mediated immunity, elevated IgE levels and increased histamine sensitivity. The disorder is seen more often in children, but chronic forms persist throughout life.

People with atopic dermatitis have a family history of hypersensitivity reactions, such as dry skin, eczema, asthma and allergic rhinitis. Although up to one-third of people with atopic dermatitis also have food allergies, a positive correlation has not been found.

The dermatitis results when mast cells, T lymphocytes, monocytes and other inflammatory cells are activated and release histamine, lymphokines and other inflammatory mediators. The immune response interacts with the allergen to create a chronic inflammatory condition. In the adult form of atopic dermatitis, characteristic lesions include chronic lichenification, erythema and scaling, the result of pruritus and scratching. The lesions are usually found on the hands, feet or flexor surfaces of the arms and legs (see Figure 15.13). Scratching and excoriation increase the risk of secondary infections, as well as invasion of the skin by viruses such as herpes simplex. Serum studies may find elevated eosinophil and IgE levels.

Seborrhoeic dermatitis

Seborrhoeic dermatitis is a chronic inflammatory disorder of the skin that involves the scalp, eyebrows, eyelids, ear canals, nasolabial folds, axillae and trunk. The cause is unknown. This disorder is seen in all ages, from the very young (called 'cradle cap') to the very old. People taking methyldopa (Aldomet™) for hypertension occasionally develop this disorder and it is a component of Parkinson's disease. Seborrhoeic dermatitis is also frequently seen in people with AIDS.

The lesions are yellow or white plaques with scales and crusts. The scales are often yellow or orange and have a greasy appearance. Mild pruritus is also present. Diffuse dandruff with erythema of the scalp often accompanies the skin lesions.

Exfoliative dermatitis

Exfoliative dermatitis is an inflammatory skin disorder characterised by excessive peeling or shedding of skin. The cause is unknown in about half of all cases, but a pre-existing skin disorder (such as psoriasis, atopic dermatitis, contact dermatitis or seborrhoeic dermatitis) is found in a majority of the cases (McPhee et al., 2008). Reactions to medications, such as sulfonamides, account for 20% to 40% of cases. Certain cancers (such as lymphoma) may also cause exfoliative dermatitis.

FIGURE 15.13 ■ Atopic dermatitis or eczema causes pruritus, resulting in lichenification, erythema and scaling

Source: Christine Langer-Pueschel/Shutterstock.

Both systemic and localised manifestations may appear. Systemic manifestations include weakness, malaise, fever, chills and weight loss. Scaling, erythema and pruritus may be localised or involve the entire body. In addition to peeling of skin, the person may lose their hair and nails. Generalised exfoliative dermatitis may cause debility and dehydration. The impairment of skin integrity increases the risk of local and systemic infections.

INTERPROFESSIONAL CARE

The person with dermatitis is treated primarily with topical medications and therapeutic baths. If the dermatitis is due to hypersensitivity to an allergen, the person avoids exposure to environmental irritants and suspected foods. The person also discontinues as many medications as possible to determine whether the dermatitis is the result of a drug allergy.

Diagnosis

The diagnosis is often based on the manifestations of the disorder and on a history of exposure to a known allergen. Patch tests and intradermal tests are used to identify a specific allergen.

Medications

The medications used depend on the cause of the dermatitis and the severity of the manifestations. Minor cases are treated with antipruritic medications, whereas more severe cases are treated with oral antihistamines, oral and/or topical corticosteroids and wet dressings. Topical anti-infectives may be prescribed.

Nursing care

Nursing care of the person with dermatitis focuses primarily on providing information for self-care at home. The person is responsible for managing skin problems and requires education and support. The following topics should be addressed in the person's management plan:

- Medications and treatments do not cure the disease; they only relieve the symptoms.
- Dry skin increases pruritus, which stimulates scratching. Scratching may in turn cause excoriation, and excoriation increases the risk of infection.
- It may be necessary to change the diet or environment to avoid contact with allergens.
- When using steroid preparations, apply only a thin layer to slightly damp skin (e.g. after taking a bath). See Box 15.4 for information on dosage for steroid preparations.
- Occlusive dressings or wraps may enhance the effect of topically applied steroids.
- When using oral corticosteroids, never abruptly stop taking the medication. Rather, follow instructions to taper the dosage gradually.

Box 15.4 Fingertip unit

It can be hard to know how much cream or ointment to apply to an area. If you apply too little, it may not work; too much, and you risk side effects (Australian Medicines Handbook (AMH), 2012).

Dose of cream in a fingertip unit varies with age:

- adult male: one fingertip unit provides 0.5 g
- adult female: one fingertip unit provides 0.4 g
- children of 4 years: approximately one-third of adult amount
- infants 6 months to 1 year: approximately one-quarter of adult amount

Amount of cream used varies with body part:

- one hand: apply one fingertip unit
- one arm: apply three fingertip units
- one foot: apply two fingertip units
- one leg: apply six fingertip units
- face and neck: apply 2.5 fingertip units
- trunk, front and back: 14 fingertip units
- entire body: about 40 fingertip units (DermNet NZ, 2014).

A fingertip unit describes the amount of cream squeezed out of its tube onto the end of the finger as shown

Source: © DermNetNZ.

- Antihistamines cause drowsiness. When using these medications, avoid alcohol and use caution when driving or working around machinery.

THE PERSON WITH ACNE

Acne is a disorder of the pilosebaceous (hair and sebaceous gland) structure, which opens to the skin surface through a pore. The sebaceous glands, which empty directly into the hair

follicle, produce sebum, a lipid substance. Sebaceous glands are present over the entire skin surface except the soles of the feet and the palms of the hands, but the largest glands are on the face, scalp and scrotum. Sebum production is a response to direct hormonal stimulation by testicular androgens in men and adrenal and ovarian androgens in women.

Pathophysiology

Acne may be non-inflammatory or inflammatory. Non-inflammatory acne lesions are primarily **comedones**, more commonly called pimples, whiteheads and blackheads. Whiteheads are pale, slightly elevated papules categorised as closed comedones. Blackheads are plugs of material that accumulate in the sebaceous glands. They are categorised as open comedones. The colour is the result of the movement of melanin into the plug from surrounding epidermal cells. Inflammatory acne lesions include comedones, erythematous pustules and cysts (see Figure 15.14). Inflammation close to the skin surface results in pustules; deeper inflammation results in cysts. The inflammation is believed to result from irritation from fatty acid constituents of the sebum and from substances produced by *Propionibacterium acnes* bacteria, both of which escape into the dermis when the follicular walls of closed comedones rupture.

Several forms of acne occur at different periods of the lifespan. The most common are acne vulgaris, acne rosacea and acne conglobata.

Acne vulgaris

Acne vulgaris is the form of acne common in adolescents and young to middle adults. The actual cause of acne vulgaris is unknown. Possible causes include an androgenic influence on the sebaceous glands, increased sebum production and proliferation of the organism *P. acnes*. Many factors once thought to cause acne vulgaris, including high-fat diets, chocolate, infections and cosmetics, have been disproved (Bullock & Hales, 2013).

FIGURE 15.14 ■ Acne vulgaris lesions include comedones, erythematous pustules and cysts

Source: Suzanne Tucker/Shutterstock.

FAST FACTS

Acne vulgaris

- Acne vulgaris is the most common of all skin conditions.
- 12% of women and 3% of men over the age of 25 have acne vulgaris and the rate does not begin to decrease until after age 44 (McPhee et al., 2008).
- Scarring may be a sequela of the disease or may result from the person picking and manipulating the comedones.

Mild cases may involve only a few scattered comedones, but severe cases are manifested by multiple lesions of all types. Most acne vulgaris lesions form on the face and neck, but they also occur on the back, chest and shoulders. Women in their thirties and forties, often with no prior acne, may develop papular lesions on the chin and around the mouth. The lesions are usually mildly painful and may itch. The complications of acne vulgaris, especially in severe cases, are formation of cysts, pigment changes in people with dark skin, severe scarring and lowered self-concept from the skin eruptions.

Acne rosacea

Acne rosacea is a chronic type of facial acne that occurs more often in middle and older adults. The cause is unknown. The lesions of acne rosacea begin with erythema over the cheeks and nose. Other skin lesions may appear. Over the years, the skin colour changes to dark red and the pores over the area become enlarged. The soft tissue of the nose may exhibit *rhinophyma*, an irregular bullous thickening.

Acne conglobata

Acne conglobata is a chronic type of acne of unknown cause that begins in middle adulthood. This type causes serious skin lesions. Comedones, papules, pustules, nodules, cysts and scars occur primarily on the back, buttocks and chest, but may occur on other body surfaces. The comedones have multiple openings and a discharge that ranges from serous to purulent with a foul odour.

INTERPROFESSIONAL CARE

The management of acne is similar, regardless of type. Because acne vulgaris is most common, the discussions of interprofessional and nursing care focus on that type. Treatment is based on the type and severity of the lesions.

Diagnosis

The disease is diagnosed by the typical location and appearance of lesions. If the person has pustules, a culture of the drainage is performed to differentiate viral or bacterial dermatitis from acne.

Medications

The treatment of acne is tailored to the individual and is based on the severity of the lesions. For acne with comedones, tretinoin or benzoyl peroxide preparations are prescribed. Azelaic acid may

also be used. The administration of these vitamin A analogues is discussed in the 'Medication administration' box below. Benzoyl peroxide preparations are found in over-the-counter medications, and these products are keratolytic and loosen the comedones.

Mild forms of papular inflammatory acne are treated with topical clindamycin, a bacteriostatic agent that decreases the amount of fatty acids on the skin surface. This medication may be combined with tretinoin therapy.

Moderate forms of papular inflammatory acne are treated with oral or topical antibiotics, such as tetracycline, erythromycin and minocycline. These anti-acne antibiotics are administered for 3 to 4 months; if the person's skin is clear, the dose is lowered gradually to a maintenance dose that will maintain clear skin.

Severe forms of papular inflammatory acne are treated with isotretinoin. This drug is effective, but has serious side effects. Isotretinoin, with nursing responsibilities, is discussed in the 'Medication administration' box.

Treatments

Acne scars may alter the individual's self-concept. They may be removed by dermabrasion and laser treatment. Dermabrasion of inactive acne lesions can improve the person's appearance, especially if the scars are flat. Laser excision of deep scars may also be performed.

Nursing care

Nursing care is individualised to the person's developmental needs and is conducted primarily through teaching in clinics or the home setting. Regardless of the person's age or gender, it is important to remember that almost everyone with acne is embarrassed by and self-conscious about their

MEDICATION ADMINISTRATION Anti-acne retinoids

ANTI-ACNE RETINOIDS

Tretinoin

Isotretinoin

Tretinoin is a vitamin A derivative classified as an acne agent. This topical agent acts as an irritant to decrease the cohesiveness of follicular epithelial cells, thereby decreasing comedone formation while increasing the extrusion of comedones from the skin surface.

Isotretinoin is a vitamin A analogue classified as an acne product. It reduces the size of sebaceous glands, inhibits sebaceous gland differentiation to decrease sebum production and alters sebum lipid composition.

Nursing responsibilities

- Administer tretinoin with caution to pregnant women, because the effects of absorption on the developing foetus are not clearly defined.
- Isotretinoin is absolutely contraindicated for pregnant women or for women who want to become pregnant. The medication poses a high risk of major deformities in the infant if pregnancy occurs during use, even use that continues only for short periods.
- Do not administer to people with eczema or to those who are hypersensitive to the sun.

Health education for the person and family

Tretinoin

- Use the prescribed cream in a test area twice at night to test for sensitivity; if no reaction occurs, increase applications gradually to the prescribed frequency.
- A pea-sized amount of the cream is enough to cover the entire face.
- Apply the cream to clean, dry skin.
- Do not apply the cream to the eyes, mouth, angles of the nose or mucous membranes.
- Wash the face no more than two to three times a day, using a pH neutral cleanser or mild soap. Do not use skin preparations (such as aftershave lotion or perfumes) that contain alcohol, menthol, spice or lime; they may irritate your skin.
- The medication may cause a temporary stinging or warm sensation but should not cause pain.
- The skin where you apply the cream will be mildly red and may peel; if you experience a more severe reaction, consult your healthcare provider.
- The medication may cause increased sensitivity to sunlight; use sunscreens and wear protective clothing when outdoors.
- Acne may become worse during the first 2 weeks of treatment; this is an expected response.

Isotretinoin

- Take the prescribed medication with food.
- Acne may become worse during the initial period of treatment; this is an expected response.
- The medication causes dryness of the eyes, so the person will have trouble wearing contact lenses during and after treatment.
- Do not take vitamin A supplements; they will increase the effects of the medication.
- Avoid prolonged exposure to sunlight; use sunscreen and protective clothing when in the sun.
- Notify the physician at once if abdominal pain, severe diarrhoea, rectal bleeding, headache, nausea or vomiting, or visual disturbances occur.
- Do not drink alcohol while taking this medication. (It causes an increase in triglycerides.)
- Night vision may become worse; use caution when driving at night.
- Do not donate blood while, or for 1 month after, taking this medication.
- (For *women*) Use two reliable forms of contraception simultaneously for at least 1 month before, during and at least 1 month after therapy with this medication. The medication may cause deformities in a baby conceived at this time.

appearance. Prior to teaching, establish rapport with the person and clarify beliefs; for example, the person may believe some myths such as the lesions result from poor hygiene, masturbation, use of cosmetics, eating the wrong types of foods or lack of sexual activity. It is critical to teach the person about the causes of and factors involved in acne prior to teaching self-care.

The teaching plan for the person with acne includes general guidelines for skin care and health, as well as specific guidelines for care of the acne lesions. The following topics should be addressed in the person's management plan:

- Wash the skin with a pH-neutral cleanser or mild soap and water at least twice a day to remove accumulated oils.
- Shampoo the hair often enough to prevent oiliness.
- Eat a regular, well-balanced diet. Foods do not cause or increase acne.
- Expose the skin to sunlight, but avoid sunburn.
- Get regular exercise and sleep.
- Try to avoid putting your hands on your face.
- Do not squeeze a pimple. Squeezing forces the material of the pimple deeper into the skin and may cause the pimple to become larger and infected.
- The treatment for acne lasts months, and in some cases for the rest of one's life. It is very important to take the medications each day for the prescribed length of time.

MALIGNANT SKIN DISORDERS

THE PERSON WITH ACTINIC KERATOSIS

Actinic keratosis, also called senile or solar keratosis, is an epidermal skin lesion directly related to chronic sun exposure and photo damage. The prevalence is highest in people with light-coloured skin; these lesions are rare in people with dark skin. Actinic keratosis may progress to squamous cell carcinoma. Fewer than 1% of early lesions become malignant, but many of those that persist progress to malignancy (Porth & Matfin, 2009). Because of this tendency, the lesions are classified as premalignant.

The lesions are erythematous rough macules a few millimetres in diameter. They are often shiny but may be scaly; if the scales are removed, the underlying skin bleeds. They occur in multiple patches, primarily on the face, dorsa of the hands, the forearms and sometimes on the upper trunk (see Figure 15.15). Enlargement or ulceration of the lesions suggests transformation to malignancy.

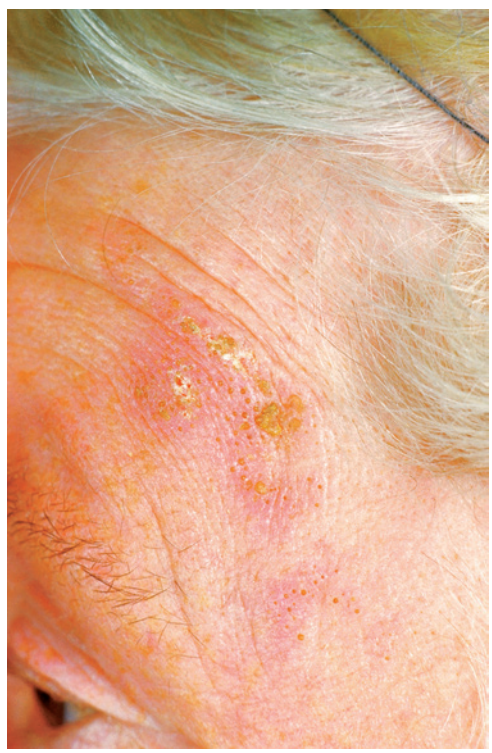

FIGURE 15.15 ■ The effects of long-term sun exposure are illustrated in this epidermal skin lesion, called actinic keratosis

THE PERSON WITH NON-MELANOMA SKIN CANCER

The skin, despite its ability to protect the internal body from external damage, is a fragile organ and is subject to damage from ultraviolet radiation and chemicals. Over time, this damage results in alterations in cellular structure and function, and malignancies of the skin occur. The common skin cancers found among Australians are non-melanoma skin cancers (NMSCs) such as basal cell carcinoma and squamous cell carcinoma, as well as malignant melanoma.

The health burden of non-melanoma skin cancer

The leading cause of death in Australia is cancer, and non-melanoma skin cancers are the most commonly diagnosed cancers (Cancer Council Australia, 2015). However, although other invasive cancers are reportable by law to cancer registries, there is no such requirement for NMSCs and the scope of the health burden is determined from review of hospital and general medical practice records. The Australian Institute of Health and Welfare (AIHW) and Australasian Association of Cancer Registries (AACR) (2012) estimated that 815 Australians were diagnosed with NMSCs in 2012. The mortality rate is

higher among fair-skinned Australian-born people (83%) and those born in the United Kingdom and Ireland (9%) (AIHW & Cancer Council Australia, 2013). The risk of dying also increases with age, and males are more affected than females (AIHW & AACR, 2012).

Risk factors

Multiple aetiological factors are involved in the development of non-melanoma skin cancer, including environmental factors and host factors.

Environmental factors

The environmental factors implicated in the non-melanoma skin cancers are ultraviolet radiation, pollutants, chemicals, ionising radiation, viruses and physical trauma.

FAST FACTS

Risk factors for non-melanoma skin cancer

- Fair skin, freckles, blue or green eyes, and blonde or red hair
- Family history of skin cancer
- Unprotected and/or excessive exposure to UV radiation (natural or artificial)
- Radiation treatment
- Occupational exposures to coal, tar, pitch, creosote, arsenic compounds or radium
- Severe sunburn episodes as a child

Ultraviolet radiation (UVR) from the sun is believed to be the cause of most non-melanoma skin cancers. Sunlight contains both short-length rays (UVB) and long-length rays (UVA). UVB rays are absorbed by the top layer of skin and cause sunburn. UVA rays penetrate deeper into the skin layers, causing tissue damage. Both types of rays are believed to cause DNA alterations and also suppress T-cell and B-cell immunity. The amount of UVR reaching the earth is increasing, most likely from depletion of the ozone layer surrounding the planet (Diaz & Nesbitt, 2013).

Geographical, environmental and lifestyle factors affect the amount of exposure to the sun and the risk of NMSC. People who live in latitudes close to the equator and those who live at higher altitudes receive greater ultraviolet radiation exposure. The amount of clothing worn, the time of day and the amount of time in the sun also determine the amount of exposure. Exposure to ultraviolet radiation in tanning booths has also been implicated in the development of NMSC.

Certain chemicals have long been associated with NMSC. Polycyclic aromatic hydrocarbons, found in mixtures of coal, tar, asphalt, soot and mineral oils, have been linked with skin cancers. Psoralens, used in conjunction with UVA for treatment of psoriasis and cutaneous T-cell lymphoma, increase the risk of squamous cell carcinoma.

Other factors associated with NMSC are the use of ionising radiation, viruses and physical trauma. X-ray therapy for tinea capitis and the use of radium to treat other malignancies are risk factors. Human papillomavirus is implicated in the development of squamous cell carcinoma. Squamous cell changes can also occur in scar or chronic wounds and are referred to as Marjolin's ulcers (Pekarek, Buck & Osher, 2011).

Host factors

Certain host factors increase the risk of non-melanoma skin cancer. These include skin pigmentation, as well as the presence of premalignant lesions.

Skin pigmentation is an important factor in the development of NMSC. The amount of melanin pigment produced by the melanocytes determines a person's skin colour. The more melanin, the more the skin is protected from the damage produced by ultraviolet rays. Indigenous Australians, African Americans, Asians and people of Mediterranean descent have a much lower incidence of NMSC than do people who have fair complexions and tend to freckle or sunburn easily, such as people of northern European ancestry.

A major risk factor in the development of NMSC is a change in an existing lesion or the presence of a premalignant lesion, such as actinic keratosis. Organ transplant recipients who undergo immunosuppression to prevent rejection are also at risk of the development of squamous cell carcinoma.

Pathophysiology

Basal cell carcinoma and squamous cell carcinoma arise from epithelial tissue but have different pathophysiology, classifications and manifestations.

Basal cell carcinoma

Basal cell carcinoma (BCC) is an epithelial tumour believed to originate either from the basal layer of the epidermis or from cells in the surrounding dermal structures. These tumours are characterised by an impaired ability of the basal cells of the epidermis to mature into keratinocytes, with mitotic division beyond the basal layer. This results in a bulky neoplasm that grows by direct extension and destroys surrounding tissue, including healthy skin, nerves, blood vessels, lymphatic tissue, cartilage and bone. Basal cell carcinoma is the most common but least aggressive type of skin cancer, rarely metastasising.

Basal cell carcinomas tend to recur. Tumours greater than 2 cm in diameter have a high recurrence rate. Predisposing factors for metastasis are the size of the tumour and the person's resistance to treatment with surgery or chemotherapy. Even though they rarely metastasise, untreated BCCs invade surrounding tissue and may destroy body parts, such as the nose or eyelid.

Basal cell carcinoma is classified into different types: nodular, superficial, pigmented, morpheaform and keratotic. These types are described below and are summarised in Table 15.3.

Nodular basal cell carcinoma is the most common type of BCC and most often appears on the face, neck and head. The tumour is made up of masses of cells that resemble epidermal basal cells and grow in a bulky, nodular form from lack of keratinisation. In the early stages, the tumour is a papule that looks like a smooth pimple. It is often pruritic and continues to grow at a steady rate, doubling in size every 6 to 12 months. As the tumour grows, the epidermis thins, but it remains intact. The skin over the tumour is shiny and either pearly white, pink or flesh coloured. Telangiectasis may be visible

TABLE 15.3 Types and characteristics of basal cell carcinomas

TYPE	COMMON LOCATION	MANIFESTATION
Nodular	Face, neck, head	Small, firm papule; pearly, white, pink or flesh coloured; telangiectasis; enlarges; may ulcerate.
Superficial	Trunk, extremities	Papules or plaque that is flat, erythematous or scaling; pink colour; well-defined borders; may have shallow erosions and surface crusting.
Pigmented	Head, neck, face	Dark brown, blue or black colour; border is shiny and well defined.
Morpheaform	Head, neck	Looks like a flat scar; ivory or flesh coloured.
Keratotic	Ear	Small, firm papule; pearly, white, pink or flesh coloured; may ulcerate.

over the area of the tumour. As the tumour continues to increase in size, the centre or periphery may ulcerate and the tumour develops well-circumscribed borders. It bleeds easily from mild injury.

Superficial basal cell carcinoma, found most often on the trunk and extremities, is the second most common type of BCC. This tumour is a proliferating tissue that attaches to the undersurface of the epithelium. The tumour is a flat papule or plaque, often erythematous, with well-defined borders. The tumour may ulcerate and be covered with crusts or shallow erosions (see Figure 15.16).

Pigmented basal cell carcinoma, found on the head, neck and face, is less common. This tumour concentrates melanin pigment in the centre of the basal cancer cells, giving it a dark brown, blue or black appearance. The border of the tumour is shiny and well defined.

Morpheaform basal cell carcinoma, the rarest form of BCC, usually develops on the head and neck. The tumour forms finger-like projections that extend in any direction along dermal tissue planes. The tumour resembles a flat ivory or flesh-coloured scar. This form is more likely to extend into and destroy adjacent tissue, especially muscle, nerve and bone. It is often more difficult to diagnose because of its appearance.

Keratotic basal cell carcinoma (basosquamous) is found on the preauricular and postauricular groove. It contains both basal cells and squamoid-appearing cells that keratinise. Its appearance is much like that of nodular basal cell carcinoma. This type of BCC tends to recur locally and also is the type most likely to metastasise.

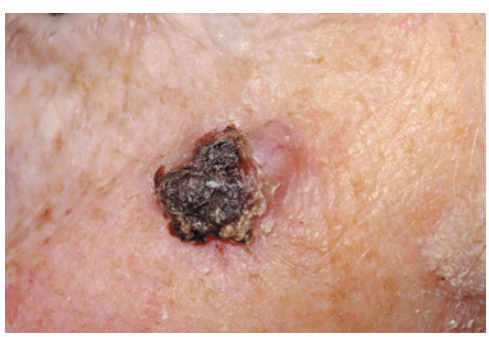

FIGURE 15.16 ■ A superficial basal cell carcinoma is characterised by erythema, ulcerations and well-defined borders

Source: Dr P. Marazzi/Science Source.

Squamous cell carcinoma

Squamous cell carcinoma (SCC) is a malignant tumour of the squamous epithelium of the skin or mucous membranes. It occurs most often on areas of skin exposed to ultraviolet rays and weather, such as the forehead, helix of the ear, top of the nose, lower lip and back of the hands. Squamous cell carcinoma may also arise on skin that has been burned or has chronic inflammation. This is a much more aggressive cancer than basal cell carcinoma, with a faster growth rate and a much greater potential for metastasis if untreated.

The tumours arise when the keratinising cells of the squamous epithelium proliferate, producing a growth that eventually fills the epidermis and invades the dermal tissue planes. Keratinisation of some cells is present and the formation of keratin 'pearls' is common. The keratin formation diminishes as the tumour grows. As the tumour grows, the tumour cells increase in number and rate of mitosis, forming odd shapes.

Squamous cell carcinoma begins as a small, firm red nodule. The tumour may be crusted with keratin products. As it grows, it may ulcerate, bleed and become painful. As the tumour extends into the surrounding tissue and becomes a nodule, the area around the nodule becomes indurated (hardened) (see Figure 15.17).

Recurrent squamous cell carcinoma can be invasive, increasing the risk of metastasis. Invasive squamous cell carcinoma

FIGURE 15.17 ■ As a squamous cell carcinoma grows, it tends to invade surrounding tissue. It also ulcerates, may bleed and is painful

Source: Dr P. Marazzi/Science Source.

may arise from pre-existing skin lesions, such as scars and actinic keratosis, and extend into the dermis (called intraepidermal squamous cell carcinoma). This form appears as a slightly raised erythematous plaque with well-defined borders. Metastasis occurs most often via the lymphatics. The degree of risk of metastasis depends on the size and depth of penetration of the tumour.

INTERPROFESSIONAL CARE

Treatment of non-melanoma skin cancer focuses on removal of all malignant tissue using such methods as surgery, curettage and electrodessication, cryotherapy or radiotherapy. These modalities offer a greater than 90% cure rate. After the malignant tissue is removed, the person should have regular examinations for recurrence.

Diagnosis

Non-melanoma skin cancer is diagnosed by microscopic examination of tissue biopsied from the tumour. The biopsy is usually done in a medical practice or clinic under local anaesthesia. The types of biopsy used are shave, punch, incisional and excisional. See Chapter 14 for further information.

Treatments

Depending on the type, size and location of a non-melanoma skin cancer, it may be treated with surgical excision, Mohs surgery, curettage and electrodessication, or radiation.

SURGICAL EXCISION Both basal cell carcinomas and squamous cell carcinomas are excised surgically. The surgery may be minor or major, depending on the size and location of the tumour. Surgery for small tumours is most often performed in the outpatient surgery department or in the surgeon's office. Surgical excision allows rapid healing and yields good cosmetic results, but, as with any surgery, carries the risk of infection.

The goal of surgical excision is to remove the tumour completely, so some surrounding tissue is excised along with the tumour. If the tumour is on the face, the incision is made along normal wrinkle or anatomical lines so that the scars will be less obvious. The incision is closed in layers to leave the smallest possible scar. A pressure dressing is usually applied over the incision to provide support.

If a large tumour is removed, a skin graft or skin flap may be performed in hospital to cover the excised area.

MOHS SURGERY In Mohs surgery (also known as chemosurgery), thin layers of the tumour are horizontally shaved off. A frozen section of the tissue is stained at each level to determine tumour margins. This method is the most accurate in assessing the extent of non-melanoma skin cancer and the method that conserves the most normal tissue. It is often used in areas such as the nose, the nasolabial fold, the medial canthus and the ear.

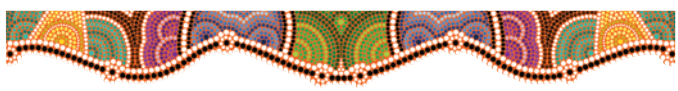
CURETTAGE AND ELECTRODESICCATION Curettage and electrodesiccation are used to treat BCCs that are less than 2 cm in diameter, are superficial or recur because of poor margin control. They may also be used for primary SCCs that are less than 1 cm in diameter and have distinct borders. This type of treatment is most successful for tumours on anatomical sites over a fixed underlying surface, such as the ear, chest and temple.

Abnormal tissue is scraped away (curettage) within 1 to 2 mm of the margin and then a low-voltage electrode is used to abrade the tumour base (electrodesiccation). Tumour tissue is much softer and more friable than normal tissue. Therefore, curettage and electrodesiccation is not used for lesions where the dermis is thin (such as the eyelid) or where the tumour extends into the subcutaneous tissue.

Curettage and electrodesiccation provide good cosmetic results and preserve normal tissue. However, healing time is longer and it is difficult to ensure that all tumour margins have been removed.

Instead of a low-voltage electrode, some physicians use a carbon dioxide laser to vaporise the tumour. When used in conjunction with curettage, this treatment is effective on superficial basal cell carcinomas. Carbon dioxide vaporisation results in minimal thermal injury to adjacent cells, less pain and quicker healing.

RADIATION THERAPY Radiation is most often used for lesions that are inoperable because of their location (such as tumours on the corner of the nose, the eyelid, the canthus and the lip) or size (between 1 and 8 cm). Radiotherapy is also used for people who are older or of poor surgical risk. Radiation is painless and can be used to treat areas surrounding the tumour if necessary. However, the treatment—given over 3 to 4 weeks in a clinical facility—does not allow control of tumour margins and may itself cause skin cancer.



Nursing care

The increasing number of people with skin cancer means that nurses must be involved in prevention and early detection. Nurses have the opportunity to teach preventive behaviours in all settings, including the hospital, home, community, school and clinic.

Nursing care for the person with non-melanoma skin cancer depends on the treatment used. Surgical excision is the most common form of treatment; nursing care depends on the extent of the procedure. However, regardless of the type of treatment, the person will have impaired skin integrity, an increased risk of infection and anxiety about the future following a diagnosis of cancer. Interventions with rationales for the person with any type of skin cancer are discussed in the following section on malignant melanoma.

Health promotion

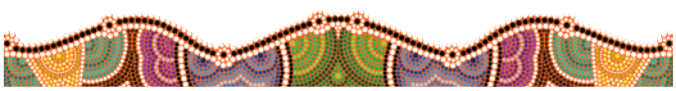
It is well known that cumulative sun exposure positively correlates with non-melanoma skin cancers. Many skin cancers can be prevented by limiting exposure to risk factors. Primary prevention behaviours are outlined in Box 15.5. Information about sunscreens is listed in Box 15.6.

BOX 15.5 Preventing skin cancer

- Minimise sun exposure between the hours of 10 am and 3 pm, when ultraviolet rays are the strongest.
- Cover up with a wide-brimmed hat, sunglasses, long-sleeved shirt and long pants made of tightly woven materials when in the sun.
- Apply a waterproof or water-resistant sunscreen with an SPF of 15 or higher at least 30 minutes before every exposure to the sun. If swimming or sweating heavily, reapply every hour.
- Apply sunscreen not only on sunny days but also on cloudy days (when ultraviolet rays can penetrate 70% to 80% of the cloud cover).
- Use sunscreen and protective clothing when you are on or near sand, snow, concrete or water (which can reflect more than 50% of the ultraviolet rays onto your skin).
- Avoid solariums as they emit ultraviolet radiation. Cancer Council Australia (2015) does not recommend solarium use for cosmetic tanning.

Nurses also provide person and family education for early detection of non-melanoma skin cancer. Numerous brochures describing the types of skin cancers, photographs of lesions and prevention behaviours are available from the Cancer Council Australia, health education and support agencies, and pharmaceutical companies that manufacture sunscreen. Most of this literature is free.

The person or family at risk of or diagnosed with a skin cancer must be taught how to conduct a regular self-examination of the skin, described in Box 15.7. The use of a mirror or assistance from family members can help with areas that are hard to examine, such as the ears, scalp and back.



THE PERSON WITH MALIGNANT MELANOMA

Malignant melanoma arises from melanocytes. Although melanoma is less common than NMSC, it is the most serious form of skin cancer and Australia and New Zealand have the highest incidence and mortality rates in the world (AIHW & AACR, 2012).

Incidence

In 2010, reported melanoma-related deaths were 11 545 in Australia. In the 15- to 24-years age group it is the most common cancer. There is a 1:24 for males, and 1:33 for females, risk of developing melanoma before the age of 75 years (Department of Health and Ageing, 2012). Melanoma is the third most common cancer after breast and bowel in women and the third most common in males after prostate and bowel (AIHW & AACR, 2010).

This disease is more than 10 times more common in fair-skinned people than in dark-skinned people. As with the non-melanoma skin cancers, an increase in the incidence of malignant melanoma is believed to be related to the thinning ozone layer and increased exposure to ultraviolet rays. The incidence is highest in Caucasian upper-middle-class professionals who work indoors. This group of people often had

BOX 15.6 Sunscreen information

Types of sunscreen

Chemical

Chemical sunscreens absorb ultraviolet light and act as a radiation filter. Examples follow:

- *p*-Aminobenzoic acid (PABA)
- Anthranilates
- Benzophenones
- Salicylates

Physical

Physical sunscreens reflect and scatter ultraviolet light. Examples follow:

- Zinc oxide
- Ferric chloride
- Titanium dioxide
- Kaolin
- Magnesium silicate
- Ichthyol

Adverse reactions associated with sunscreens

Adverse reactions associated with sunscreens include contact and photocontact dermatitis. People with previous hypersensitivity reactions to benzocaine, procaine, sulfonamides or paraphenylenediamine may develop hypersensitivity responses to PABA. People who are also taking systemic thiazide diuretics or sulfonamides may develop eczematous dermatitis.

Sunscreen ratings

Sunscreens need to be used in conjunction with other methods of sun protection, such as protective clothing and eliminating sun exposure times. Sun protection factor (SPF) ratings are awarded to sunscreen products subject to the amount of ultraviolet light they filter. In Australia, the ingredients in sunscreens are regulated by the Therapeutic Goods Administration (TGA, 2012). As well as preservatives, moisturisers, water, oils and emulsifiers, sunscreens contain agents that are described as either:

- chemical absorbers, which bind with the cells in the skin and absorb UV radiation and then release the energy as heat
- physical blockers, which reflect or scatter UV radiation (e.g. titanium dioxide and zinc oxide) (Cancer Council Western Australia, 2009).

The SPF value is the ratio of the time required to produce minimal skin redness through a sunscreen product with the time required to produce the same degree of redness without the sunscreen. A person who can tolerate half an hour of sun without a sunscreen should be able to tolerate 3 hours of sun when a sunscreen of SPF 6 is applied to the skin. SPF values of sunscreens range from 2 to 50.

BOX 15.7 Skin self-examination

1. Choose the same day each month (such as the first day) to conduct a thorough skin examination.
2. The best time to do the examination is after you take a bath or shower.
3. Examine yourself in a well-lit room in front of a full-length mirror. Have a hand mirror, a chair and a hair dryer available. If you have difficulty seeing your back and scalp (or any other parts of your body), ask someone to help you.
4. Follow the same pattern with each examination:

Examine head and face, using one or both mirrors. Use blow dryer to inspect scalp.

Check hands, including nails. In full-length mirror, examine elbows, arms, underarms.

Focus on neck, chest, torso. Women: Check under breasts.

With back to the mirror, use hand mirror to inspect back of neck and back, including buttocks.

Sitting down, check legs and feet, including soles, heels and nails. Use hand mirror to examine genitals.

severe sunburn with blistering during childhood and tend to holiday in areas of intense sun exposure. Malignant melanoma is also more common in people who live in sunny climates, burn easily and patronise tanning solariums. However, malignant melanoma may arise from already present lesions or from skin normally covered with clothing.

Risk factors

Although the exact cause of melanoma is unknown, it is known that certain risk factors are associated with the disease. The risk factors for melanoma are listed in Box 15.8.

Pathophysiology

Malignant melanomas arise from melanocytes, cells located at or near the basal layer (the deepest epidermal layer). These cells produce melanin, the dark skin pigment. Melanin is made in granules and transferred to keratinocytes, where it accumulates on the superficial side of each keratinocyte and forms a shield of pigment over the nucleus as protection against ultraviolet rays. Malignant melanomas can develop wherever there is pigment, but about one-third of them originate in existing naevi (moles).

Almost all malignant melanomas are more than 6 mm in diameter, are asymmetric and initially develop within the epidermis over a long period. While they are still confined to the epidermis, the lesions (called malignant melanoma in situ) are flat and relatively benign. However, when they penetrate the dermis, they mingle with blood and lymph vessels and are capable of metastasising. At this latter stage, the tumours develop a raised or nodular appearance and often have smaller nodules, called satellite lesions, around the periphery.

The prognosis for survival for people diagnosed with malignant melanoma is determined by several variables, including tumour thickness, ulceration, metastasis, site, age and gender. Younger people and women have a somewhat better chance of survival. Tumours on the hands, feet and scalp have a poorer prognosis; tumours of the feet and scalp are less visible and may not be diagnosed until they grow into the dermis.

Precursor lesions

The three specific precursor lesions for the development of malignant melanoma are congenital naevi, dysplastic naevi and lentigo maligna. A precursor lesion is also called a premalignant lesion, a name that indicates that the lesion's risk of becoming malignant is greater than normal.

BOX 15.8 Risk factors for melanoma skin cancer

- A high number of moles or large moles
- Fair skin, freckling, blonde hair or blue eyes
- Close relative with the disease
- Men with gene changes from a family history of breast or ovarian cancer
- Treatment with medications that suppress the immune system
- Too much exposure to UV radiation from sunlight, tanning lamps or solariums
- Over age 50
- Xeroderma pigmentosus, a rare inherited disease in which people are less able to repair damage caused by sunlight
- Past history of melanoma

CONGENITAL NAEVI Congenital naevi are present at birth. Some lesions are small; others are large enough to cover an entire body area. Their colour can range from brown to black. They are often slightly raised, with an irregular surface and a fairly regular border.

DYSPLASTIC NAEVI Dysplastic naevi are also called atypical moles. Although dysplastic naevi are not present at birth, they appear as normal naevi during childhood and become dysplastic (having abnormal development) after puberty. A person with classic dysplastic naevi has more than 100 naevi, at least one of which is larger than 8 mm in diameter, and at least one of which has the characteristics of malignant melanoma (asymmetry, irregular border, colour variegation and a diameter greater than 6 mm). A familial tendency to dysplastic naevi increases the risk of the development of malignant melanoma. However, it is not known whether people with dysplastic naevi and no family history of melanoma face a higher risk of melanoma.

Dysplastic naevi most often appear on the face, trunk and arms, but also are seen on the scalp, female breast, groin and buttocks. The pigmentation of the naevi is irregular, with mixtures of tan, brown, black, red and pink. An area of lighter pigmentation is surrounded by a papular area of deeper pigmentation (described as a 'fried egg appearance'). The borders of the naevi are irregular.

LENTIGO MALIGNA Lentigo maligna, also called Hutchinson's freckle, is a tan or black patch on the skin that looks like a freckle. It grows slowly, becoming mottled, dark, thick and nodular. It is usually seen on one side of the face of an older adult who has had a large amount of sun exposure.

Classification

Malignant melanomas are classified into different types. The major types are superficial spreading melanoma, lentigo maligna melanoma, nodular melanoma and acral lentiginous melanoma. Each of these tumours is characterised by a radial and/or vertical growth phase. During the initial radial phase, which may last from 1 to 25 years (depending on the type), the melanoma grows parallel to the skin surface. During this phase, the tumour rarely metastasises and is often curable by surgical excision. However, during the vertical growth phase, atypical melanocytes rapidly penetrate into the dermis and subcutaneous tissue, greatly increasing the risk of metastasis and death.

SUPERFICIAL SPREADING MELANOMA Superficial spreading melanoma is the most common type, comprising about 70% to 80% of all melanomas (Bullock & Hales, 2013). The lesions are usually flat and scaly or crusty and are about 2 cm in diameter. They often arise from a pre-existing naevus. This type of melanoma is found on the trunk and back of men and on the legs of women. Superficial spreading melanomas occur more often in women than in men. The median age of occurrence is the fifties.

The radial growth phase lasts from 1 to 5 or more years. When the lesion enters the vertical growth phase, it grows rapidly and its colour changes from a mixture of tan, brown and black to a characteristic red, white and blue. The lesion also develops irregular borders and often has raised nodules and ulcerations (see Figure 15.18).

FIGURE 15.18 ■ Malignant melanoma is a serious skin cancer that arises from melanocytes

Source: Dr P. Marazzi/Science Source.

LENTIGO MALIGNA MELANOMA Lentigo maligna melanoma often arises from the precursor lesion, lentigo maligna. The lesions are large and tan with different shades of brown. This type of melanoma makes up 5% to 10% of malignant melanomas and is the least serious form (Bullock & Hales, 2013). It occurs on skin that has had long-term sun exposure, such as the face, neck and sometimes the dorsal surface of the hands and lower extremities. Lentigo maligna melanoma affects women more than men. It is typically diagnosed in people in their sixties and seventies.

Lentigo maligna melanoma is characterised by a proliferation of atypical melanocytes parallel to the basal layer of the epidermis. The radial growth phase may last from 10 to 25 years, with the lesion growing to as large as 10 cm. The lesion becomes malignant as soon as the melanocytes invade the dermis. In the vertical growth phase, raised nodules may appear on the surface of the lesion. The lesion tends to acquire a freckled or mottled appearance.

NODULAR MELANOMA Nodular melanoma lesions are raised, dome-shaped, blue-black or red nodules on areas of the head, neck and trunk that may or may not have been exposed to the sun. The lesions may look like a blood blister or they may ulcerate and bleed. The lesions arise from unaffected skin rather than from a pre-existing lesion. This type makes up 10% to 15% of malignant melanomas and is often diagnosed in people in their fifties (Bullock & Hales, 2013).

Nodular melanoma has only a vertical growth phase, but it grows aggressively during that phase. However, the absence of a radial growth phase makes this type more difficult to diagnose before it metastasises.

ACRAL LENTIGINOUS MELANOMA Acral lentiginous melanoma, also called mucocutaneous melanoma, is less common in people with fair skin and more common in people with dark skin.

The lesions progress from tan, brown or black flat lesions to elevated nodules and are about 3 cm in diameter. The radial phase lasts from 2 to 5 years. They are found on the palms of the hands, soles of the feet, the mucous membranes and the nail beds. Acral lentiginous melanoma affects both men and women equally and is most often diagnosed in people in their fifties and sixties.

INTERPROFESSIONAL CARE

The management of the person with malignant melanoma begins with identification, diagnosis and tumour staging. If treatable, the tumour is removed through surgical excision. Malignant melanoma is also treated with chemotherapy, immunotherapy and radiation therapy. Other therapies used with success include biological therapies with interleukin-2 and interferon, and therapeutic vaccines containing melanoma antigens.

Identification

Malignant melanoma can be found anywhere on the body and is most often found on the trunk of men and on the lower extremities of women. Nevertheless, it is important for the person to have a complete physical examination and total skin assessment. In addition to a visual examination of all skin surfaces, palpation of regional lymph nodes, the liver and the spleen is essential to assess for metastasis when a melanoma is suspected or found.

A change in the colour or size of a naevus is reported in 70% of people diagnosed with a malignant melanoma. The ABCD rule is used to assess suspicious lesions.

FAST FACTS

The ABCD rule

Using the ABCD rule to assess for melanoma:

- A = asymmetry (one half of the naevus does not match the other half)
- B = border irregularity (edges are ragged, blurred or notched)
- C = colour variation or dark black colour
- D = diameter greater than 6 mm (size of a pencil eraser)

Diagnosis

In addition to biopsy of any suspicious lesion, diagnostic tests are conducted to determine whether the tumour has metastasised. Because malignant melanoma may metastasise to any organ or tissue of the body, a variety of tests may be conducted, including microscopic examination, biopsy and tests for metastasis (liver function tests and computed tomography (CT) scan of the liver, a complete blood count, serum blood chemistry profile, chest x-ray, bone scan and CT scan, or magnetic resonance imaging of the brain).

Microstaging

The term *microstaging* describes the assessment of the level of invasion of a malignant melanoma and the maximum tumour thickness. In the Clark system of microstaging, the vertical growth of the lesion is measured from the epidermis to the subcutaneous tissue to determine the level of invasion (see Figure 15.19).

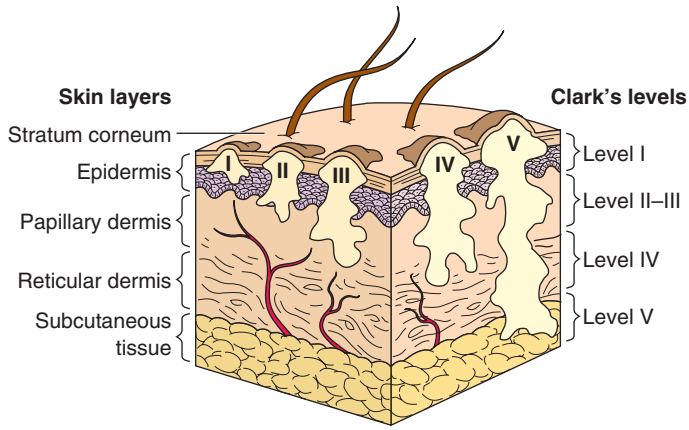


FIGURE 15.19 ■ Clark's levels for staging measure the invasion of a melanoma from the epidermis to the subcutaneous tissue

However, variations in individual skin thicknesses and different anatomical sites can affect the accuracy of the measurement. In the Breslow system, an adaptation of the Clark system of assessment, the vertical thickness is measured from the granular level of the epidermis to the deepest level of tumour invasion. This determination is important because as the thickness of the melanoma increases, survival rate decreases.

After the thickness and depth of the tumour are determined, a clinical stage is assigned. The traditional three-stage system is still used, although it does not include tumour thickness. The American Joint Committee on Cancer has adopted a four-stage system that includes tumour thickness, level of invasion, lymph node involvement and evidence of metastasis. This system is used in Australia.

Treatments

Surgical excision is the preferred treatment for malignant melanoma. Other methods of treatment are chemotherapy, immunotherapy and radiation therapy.

SURGERY If a biopsy identifies the lesion as a melanoma, a wide excision is performed that includes the full thickness of the skin and subcutaneous tissue. Because the risk of local recurrence for thin melanomas (those less than 0.76 mm) is quite low, margins of 0.5 to 1.0 cm of normal skin are excised around the tumour. Thick tumours require a 1 to 3 cm margin excision because they are at risk of local recurrence or satellite lesions.

Sentinel node biopsy is performed when a higher risk of primary melanoma has been diagnosed after an initial biopsy (melanoma 1.0 mm in depth, <40 years, Clark level ≥IV) (Keidan & Meyers, 2014). This will determine whether the melanoma has spread to the surrounding lymph nodes. This process starts with lymphatic mapping which will identify the first 'downstream' node—the sentinel node. This node is removed and sent to the pathologist to identify if malignant cells are present. Malignant cells are an indicator of the risk that melanoma may have spread to other parts of the body. Melanoma that has spread to sentinel nodes in the regional node groups in the armpits, neck or groin may linger before spreading to organs. In these cases melanoma

can sometimes be cured with surgery called regional lymph node clearance (Melanoma Institute of Australia, 2015). Regional lymph nodes are the most common sites for metastasis of malignant melanoma. Standard surgical treatment for clinically suspicious lymph node involvement includes excision of the primary lesions as well as surgical dissection of the involved lymph nodes. Elective lymph node dissection (ELND) in the treatment of localised malignant melanoma remains controversial. Advocates of ELND believe that the procedure benefits people with intermediate-thickness tumours because approximately 20% of people whose lymph nodes were clinically negative at diagnosis show some metastasis on removal of the nodes. Those opposed to ELND believe the risks associated with the procedure are too high for the 80% of people who have no evidence of metastasis after removal of the nodes.

Surgery may be indicated for palliative management of isolated metastasis. Removal of metastatic tumours in the brain, liver, lung, gastrointestinal tract or subcutaneous tissue may relieve symptoms and prolong life.

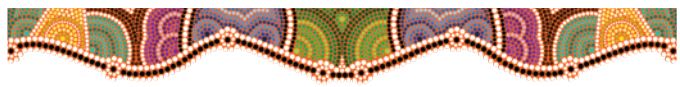
IMMUNOTHERAPY Immunotherapy is a relatively new treatment modality for malignant melanoma. The role of the immunological response initially was recognised because of the numerous spontaneous remissions seen in people with melanoma—a higher occurrence than with any other adult tumour. In addition, researchers have recently identified tumour-specific antigen antibodies in people with melanoma. This also has stimulated an interest in immunotherapeutic interventions for the treatment of malignant melanoma.

Agents such as interferons, interleukins, monoclonal antibodies, bacille Calmette-Guérin, levamisole, transfer factors and tumour vaccines have been used to treat melanoma, with varying response rates. The effectiveness of these agents, used either alone, in combination with chemotherapy or in combination with each other, is under investigation.

RADIATION THERAPY Melanoma responds to higher-dose radiation, especially if the tumour is small. Response rates to radiation therapy depend on the site of the tumour, its thickness, the type of melanoma and the person's general health, but may range from 0% to 71%. Radiation frequently is used for palliation of symptoms resulting from metastasis to the brain, bone, lymph nodes, gastrointestinal tract, skin or subcutaneous tissue. Liver and lung metastases are not treated with radiation therapy because a loss of organ function may result.

NEW METHODS OF TREATMENT Melanoma skin cancer research is ongoing and directed towards more specific methods of diagnosis and treatment. Examples are as follows:

- *Gene therapy:* clinical trials are in progress to test the effectiveness of adding certain genes to the malignant cells.
- *Melanoma DNA research:* knowledge of how ultraviolet light harms DNA is increasing, providing support for referral for genetic counselling for people with a strong family history of melanoma.
- *Targeted therapy:* this involves the development of drugs that attack the gene changes in melanoma cells. These drugs work differently from standard chemotherapy drugs. Sometimes targeted drugs work when chemotherapy does not and they can have less severe side effects. These drugs are new and we are still learning about the best way to use these drugs to treat melanoma (American Cancer Society 2015).
- *Immune therapy:* vaccines are being developed to make an individual immune to their own melanoma cells or to train the person's immune cells to fight the cancer.
- *Staging:* very sensitive new tests can better detect the spread of melanoma to lymph nodes and can possibly better identify people who could be helped by a treatment such as immunotherapy after surgery.



Nursing care

Nurses have the opportunity to assess the skin of people requiring care for many different health problems and may be the first healthcare provider to identify suspicious lesions. Wide excision and the high risk of metastasis from malignant melanoma usually require inpatient surgical treatment, with the nurse providing care and teaching.

Health promotion

The most important aspect of preventing malignant melanoma is identifying those at risk and performing regular skin assessments. Skin inspections should be performed monthly by those with actinic keratoses, at-risk individuals and those over 40 years of age. Mole clinics and summer beach skin inspection campaigns have become more popular and offer an alternative option for identification of sinister lesions. When self-assessing for melanoma, the person looks for a change in:

- colour, especially any lesion that becomes darker or variegated in shades of tan, brown, black, red, white or blue
- size, especially any lesion that becomes larger or spreads out
- shape, especially any lesion that protrudes more from the skin or begins to have an irregular outline
- appearance of a lesion, especially bleeding, drainage, oozing, ulceration, crusting, scaliness or development of a mushrooming outward growth
- consistency, especially any lesion that becomes softer or is more easily irritated
- skin around a lesion, such as redness, swelling or leaking of colour from a lesion into the surrounding skin
- sensation, such as itching or pain.

Assessment

Skin assessment is discussed in Chapter 14. Specific health history questions and assessments for skin cancer are outlined in Box 15.9.

Nursing diagnoses and interventions

Although many different nursing diagnoses may be appropriate for the person with a malignant melanoma, one potential diagnosis is as follows:

- *Impaired skin integrity* related to malignant melanoma.

BOX 15.9 Nursing assessment for skin cancer

Interview questions

- Have any members of your family ever been treated for skin cancer?
- Have you had a skin cancer removed from any part of your body?
- Have you noticed any change in the size, shape or colour of a mole, wart, birthmark or scar?
- Do you have any moles, warts, birthmarks or scars that itch, are painful, have crusting or bleed?
- In what parts of the country or world have you lived?
- Have you ever been badly sunburned?
- Do you visit tanning solariums?
- Are you exposed to any hazardous chemicals in your job?
- Have you been taught how to examine your skin? If so, how do you do this examination? How often?

Physical assessment

1. Ensure privacy and provide a warm environment. Ask the person to remove all clothing and put on an examination gown. Ensure good light; natural, bright light is best for inspection of lesions. The person may sit, stand or lie down.
2. Inspect and palpate the skin. Stretching the skin tightly during assessment facilitates assessment of nodular and scaly lesions and lesions in the dermis. Assess for:
   a. obvious lesions
   b. visible swellings
   c. alterations in normal contour and borders of naevi
   d. enlarged lymph glands
   e. skin or mucosal discolourations
   f. areas of ulceration, scaling, crusting or erosion.
3. The order of assessment follows:
   a. head and neck: entire scalp, eyelids, external ear, auditory canals, external surface of the nose, internal surface of the nose, the oral cavity, facial skin, the facial glands (parotid, submaxillary, sublingual)
   b. thyroid and neck, including lymph glands
   c. chest and abdomen, with special attention under pendulous breasts, in skin folds and in areas covered with hair
   d. back and buttocks, with special attention to the area between the buttocks
   e. extremities, with special attention to the axillae, nail beds, webs between the fingers and toes and soles of the feet
   f. external genitals, with special attention to skin folds, mucous membranes and areas covered with hair.
4. Measure and record a description of all skin lesions on an anatomical chart. Take photographs (if possible) of any suspicious lesion and include them in the person's record for future reference.

Impaired skin integrity related to malignant melanoma

Malignant melanomas not only destroy skin layers but also invade body structures. Certain types of melanomas may ulcerate prior to diagnosis, and treatment typically involves some type of surgical biopsy and excision. Any open lesion or incision increases the risk of secondary infection.

- Monitor for manifestations of infection: fever, tachycardia, malaise, erythema, swelling, pain or drainage that increases or becomes purulent. *Intact skin is the first line of defence against infection; impaired skin integrity increases the risk of infection.*
- Keep the incision line clean and dry by changing dressings as necessary.
- Follow principles of medical and surgical asepsis when caring for person's incision. Teach family members and visitors the importance of careful handwashing. Maintain standard precautions if drainage is present.
- Encourage and maintain adequate kilojoule and protein intake in the diet. Suggest a consultation with the dietitian if the person's appetite is poor. *Adequate kilojoules and protein are necessary for proper healing.*

CONSIDERATION FOR PRACTICE

Nurses must use standard precautions with blood and body fluids to protect themselves from exposure to blood-borne viruses.

Community-based care

Health education for the person and family experiencing the diagnosis and treatment of non-melanoma and malignant melanoma involves self-care and ongoing self-monitoring. Education for the person and family is specific to the type of treatment. In addition to wound care for people who have had a surgical removal or lymph node dissection, they will need instructions on how to protect the extremity from bleeding, trauma and infection. People who have undergone lymph node dissection may develop lymphoedema and can benefit from manual lymph drainage therapy and compression therapy in the form of bandages and garments. Address the following topics:

- Schedule regular medical check ups every 3 months for the first 2 years, every 6 months for the next 5 years and yearly thereafter.
- Proper self-care combined with regular medical care can help the person lead a fairly normal life.
- If assistance for home care is necessary, provide referrals to a community health or home care organisation. In addition, refer the person to a local cancer support group if desired. Other resources are:

SKIN TRAUMA

Trauma to the skin can be unintentional or intentional (as in the case of surgery). Pressure, friction and shear are common causes of skin trauma and can result in pressure injuries, while shear and friction can result in skin tears. Pressure injuries and skin tears are the most common wounds found in the elderly, and both types of wounds are largely preventable (Mulligan, Prentice & Scott, 2011). Thermal, chemical, electrical or radiation-induced burns are discussed in Chapter 16.

THE PERSON WITH A PRESSURE INJURY

Pressure injuries are synonymous with bed sores, decubitus ulcers and pressure ulcers, and are significant and preventable wounds. The term 'pressure injury' is the preferred term used in Australia (Australian Wound Management Association, 2012; Australian Commission on Safety and Quality in Health Care (ACSQHC), 2012). A pressure injury is 'a localised injury to the skin and/or underlying tissue. The injury is usually over a bony prominence and is caused as a result of pressure, or pressure in combination with shear and/or friction' (National Pressure Ulcer Advisory Panel (NPUAP), European Pressure Ulcer Advisory Panel (EUPAP) and Pan Pacific Pressure Injury Alliance (PPPIA), 2014; Australian Wound Management Association, 2012).

Pressure injuries are ischaemic lesions of the skin and underlying tissue caused by external pressure that impairs the flow of blood and lymph (Martini et al., 2012). The ischaemia causes tissue necrosis and eventual ulceration. Pressure injuries tend to develop over a bony prominence (such as the heels, greater trochanter, sacrum and ischia), but may appear on the skin of any part of the body subjected to external pressure, friction or shearing forces.

Incidence

The incidence of pressure injuries in hospitals, long-term care facilities and home settings is high enough to warrant the concern of healthcare providers. Pressure injury prevalence in the United Kingdom has been reported to range from 5.3% to 32% and in the United States from 1.4% to 36.4%. In Australia,

LINKS TO NATIONAL PATIENT SAFETY STANDARDS

NSQHS Standard 8:
Preventing and Managing Pressure Injuries

'The intention of this standard is to prevent patients from developing pressure injuries and effectively managing pressure injuries when they do occur.' (ACSQHC, 2012, p. 54).

Implementing this standard is achieved by the establishment of systems ensuring utilisation of best practice guidelines and risk assessment frameworks. This system includes implementation of processes which facilitate accurate identification and reporting, access to equipment and devices for prevention and treatment and best practice for treatment and monitoring. Meaningful communication regarding risk, prevention strategies and management should exist across all individuals involved in a person's care.

On admission, all patients, including children, should be screened for their risk of pressure injuries. Risk assessment, using a validated risk assessment scale, is conducted when screening indicates a patient is at risk of developing a pressure injury. Ongoing assessment and documentation should form part of the comprehensive nursing plan.

TRANSLATION TO PRACTICE Pressure injury risk assessment and prevention

Nurses need to have an understanding of pressure injury risk assessment and preventive strategies. It is nurses who assess and manage patients' skin on a daily basis. Unfortunately knowledge deficits have been identified among Australian nurses (Lawrence, Fulbrook & Miles, 2015), as they have in other countries (Chianca et al., 2010; Gunningberg et al., 2015). To address this deficit, the *Prevention and Treatment of Pressure Ulcers: Clinical Practice Guideline (2014),* which was produced by the European Pressure Ulcer Advisory Panel (EPUAP), National Pressure Ulcer Advisory Panel (NPUAP) and the Pan Pacific Pressure Injury Alliance (PPPIA—Australia, Hong Kong, New Zealand and Singapore), includes dedicated chapters with recommendations for implementation of best practice guidelines; advancing health professional, consumer and caregiver education; and detailing quality indicators for monitoring guideline implementation and translation in the healthcare setting. This document can be accessed from www.internationalguideline.com.

pressure injury prevalence in public hospital surveys conducted in Victoria, Queensland, Western Australian, Tasmania and the Australian Capital Territory between 2003 and 2009 ranged from 10% to 26.5%. In national aged care facilities the prevalence has been reported to range from 15.2% to 26%, while in the community setting the reported prevalence ranges from 6% to 42%. However, survey methodologies differ between agencies and researchers and this makes for difficult data comparisons nationally. A standardised approach was adopted for prevalence surveys conducted by WoundsWest across all 86 Western Australian public hospitals in 2007, 2008, 2009 and 2011, and demonstrated 9.5% to 12.5% prevalence (Mulligan et al., 2011).

Pathophysiology

Pressure injuries develop from external pressure that compresses blood vessels or from friction and shearing forces that tear and injure vessels. The primary cause of pressure injuries is a sustained mechanical load that is applied to soft biological tissues, generally near a bony prominence. Pressure gradients that induce sustained deformation of skin and subdermal tissues must be present in order for tissue damage that characterises a pressure injury to occur. The magnitude of the mechanical load that will lead to tissue damage depends on the duration of time for which the pressure is applied. High pressure applied for a short period or low pressure applied for a longer period can lead to tissue damage. Recent evidence suggests that there are two physiologically events leading to tissue damage. One is a lower threshold leading to occlusion of blood vessels which results in ischaemic-induced tissue damage, and the other is a higher threshold leading to direct-pressure-induced damage.

An increasing body of evidence suggests that the microclimate between skin and the supporting surface plays a role in the development of Stage I and II pressure injuries. Microclimate refers to the humidity and temperature between the person's skin and the surface they are lying on (NPUAP, EPUAP & PPPIA, 2014). The increase in humidity and temperature can make the skin less tolerant to pressure and shear force. The greater the body surface area in contact with the support surface, the lower the uniform pressure. The lesser the body surface area in contact with a support surface, the higher the point pressure (Lachenbruch et al., 2013). This principle can be clearly appreciated when one rests the knuckle of the index finger on a table and compares the level of discomfort to that experienced when one rests the whole palm against the same surface. When the body is in the supine position, the body's weight applies pressure to the sacrum, heels, scapula and occiput. The same amount of pressure causes more damage when it is applied to a small area such as the heels than when it is distributed over a large surface.

External pressure that is greater than capillary closing pressure and arteriolar pressure interrupts blood flow in capillary beds. Capillary closing pressure is frequently quoted to be 32 mmHg, as determined more than 80 years ago by Landis (1930). However, capillary closing pressure will differ greatly between individuals and be subject to underlying co-morbidities or factors that impact on vascularity and perfusion, body mass index, nutrition and hydration status.

Shearing forces result when one tissue layer slides over another. The stretching and bending of blood vessels cause injury and thrombosis. People in bed are subject to shearing forces when the head of the bed is elevated and the torso slides down towards the foot of the bed. Pulling the person up in bed or against a chair also subjects the person to shearing forces (for this reason, repositioning devices such as hoists and slide sheets should be used). Friction, particularly in the presence of moisture, causes the skin and superficial fascia to remain fixed to the bed sheet or chair, while the deep fascia and bony skeleton slides in the direction of body movement.

When a person lies or sits in one position for an extended length of time without moving, pressure on the tissue between a bony prominence and the external surface of the body distorts capillaries and interferes with normal blood flow. The healthy, sensate and mobile individual will respond to the discomfort and alter their position. The immediate physiological response to relieved pressure is reactive hyperaemia. Reactive hyperaemia is a compensatory physiological response to tissue hypoxia and is evident when there is a transient increased blood flow or erythematous flush to the tissue. An area of reactive hyperaemia will blanch when pressure is applied (Pieper, 2007). However, if the pressure continues, the capillaries become more permeable and metabolic wastes and oedema accumulate in the interstitial spaces. Oedema in the interstitial spaces inhibits perfusion to the skin. Platelets aggregate in the endothelial cells surrounding the capillaries and form microthrombi. These microthrombi further impede blood flow, resulting in ischaemia and hypoxia of tissues. The skin may appear red; in darkly pigmented people, bluish or purple hues are evident. If the area of skin does not blanch when pressure is applied after relieving the pressure for 30 minutes, a Stage 1 pressure injury is present (see Box 15.10). Eventually, the cells and tissues of the immediate area of pressure and the surrounding area become necrotic. The 2014 *Prevention and Treatment of Pressure Ulcers: Clinical Practice Guideline* outlines the pressure injury staging system most recommended internationally (NPUAP, EPUAP & PPPIA, 2014), and is found in the accompanying 'Translation to practice' box.

Risk factors

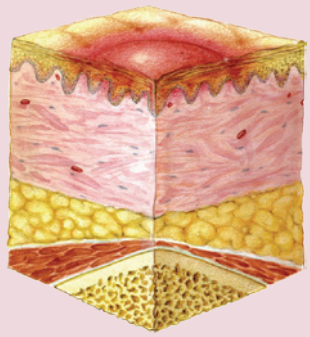
Predisposing factors for pressure injuries are both intrinsic (pertaining to the individual) and extrinsic (pertaining to extracorporeal factors). Intrinsic factors include extremes in age (the very young or elderly), immobility, inactivity, malnutrition, dehydration, poor skin condition, impaired sensory perception and co-morbidities that exacerbate these conditions, such as diabetes mellitus, malignancy, and renal, respiratory, vascular, lymphatic and hepatic disorders. Extrinsic factors include pressure, shear and friction forces, moisture (incontinence, wound exudate or perspiration) and contact with surfaces or devices such as plastic or vinyl which increase skin temperature.

The older immobile adult is at increased risk of the development of pressure injuries because of age-related skin changes that reduce the skin's tolerance to pressure, shear and friction. The skin changes in the older adult include: a thinner dermis with decreased vascularity, decreased sebaceous gland activity,

BOX 15.10 The International NPUAP/EPUAP Pressure Ulcer Classification System

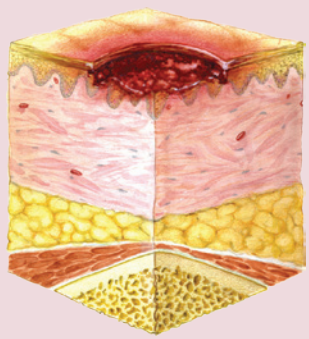
Stage 1: Non-blanchable erythema

- Intact skin with non-blanchable redness of a localised area usually over a bony prominence.
- Darkly pigmented skin may not have visible blanching; its colour may differ from the surrounding area.
- The area may be painful, firm, soft, warmer or cooler compared to adjacent tissue.
- May be difficult to detect in individuals with dark skin tones.
- May indicate 'at-risk' people (a heralding sign of risk).



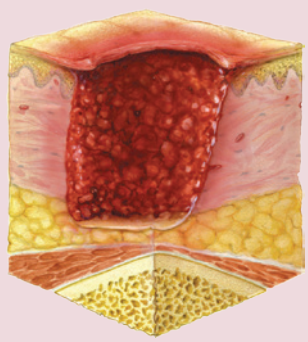
Stage 2: Partial-thickness skin loss

- Partial-thickness loss of dermis presenting as a shallow open ulcer with a red-pink wound bed, without slough.
- May also present as an intact or open/ruptured serum-filled blister. Presents as a shiny or dry shallow ulcer without slough or bruising (bruising indicates suspected deep tissue injury).
- Stage 2 should not be used to describe skin tears, tape burns, perineal dermatitis, maceration or excoriation.



Stage 3: Full-thickness skin loss

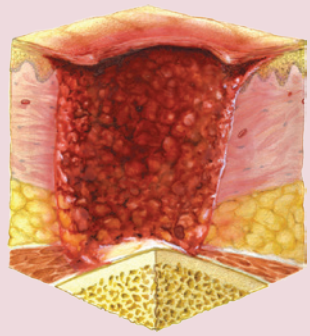
- Full-thickness tissue loss. Subcutaneous fat may be visible but bone, tendon or muscle are not exposed. Slough may be present but does not obscure the depth of tissue loss. May include undermining and tunnelling.
- The depth of a Stage 3 pressure ulcer varies by anatomical location. The bridge of the nose, ear, occiput and malleolus do not have subcutaneous tissue and Stage 3 ulcers can be shallow. In contrast, areas of significant adiposity can develop extremely deep Stage 3 pressure injuries. Bone/tendon is not visible or directly palpable.



BOX 15.10 The International NPUAP/EPUAP Pressure Ulcer Classification System (continued)

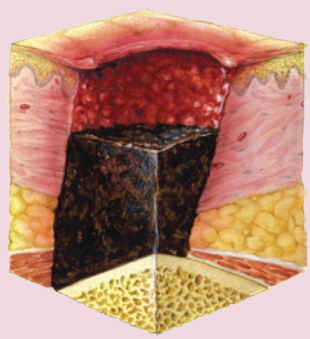
Stage 4: Full-thickness tissue loss

- Full-thickness tissue loss with exposed bone, tendon or muscle. Slough or eschar may be present on some parts of the wound bed. Often include undermining and tunnelling.
- The depth of a Stage 4 pressure injury varies by anatomical location. The bridge of the nose, ear, occiput and malleolus do not have subcutaneous tissue and these ulcers can be shallow. Stage 4 injuries can extend into muscle and/or supporting structures (e.g. fascia, tendon or joint capsule) making osteomyelitis possible. Exposed bone/tendon is visible or directly palpable.



Unstageable: Depth unknown

- Full-thickness tissue loss in which the base of the ulcer is covered by slough (yellow, tan, grey, green or brown) and/or eschar (tan, brown or black) in the pressure injury bed.
- Until enough slough and/or eschar is removed to expose the base of the wound, the stage cannot be determined. Stable (dry, adherent, intact without erythema or fluctuance) eschar on the heels serves as 'the body's natural (biological) cover' and should not be removed.



Suspected deep tissue injury: Depth unknown

- Purple or maroon localised area of discoloured intact skin or blood-filled blister due to damage of underlying soft tissue from pressure and/or shear. The area may be preceded by tissue that is painful, firm, mushy, boggy, warmer or cooler as compared to adjacent tissue.
- Deep tissue injury may be difficult to detect in individuals with dark skin tones.
- Evolution may include a thin blister over a dark wound bed. The pressure injury may further evolve and become covered by thin eschar. Evolution may be rapid exposing additional layers of tissue even with optimal treatment.

(continued)

TRANSLATION TO PRACTICE Pressure injury risk assessment

The WoundsWest wound prevalence surveys conducted in 2007, 2008, 2009 and 2011 found pressure injuries to be the second-largest group of wounds, following acute (surgical and traumatic) wounds. The majority of these pressure injuries were found to be hospital acquired (Mulligan et al., 2011). Furthermore, there were found to be significant deficits in the documentation of pressure injuries and the use of appropriate support surfaces.

The *Prevention and Treatment of Pressure Ulcers: Clinical Practice Guideline* (NPUAP, EPUAP & PPPIA, 2014) outlines six recommendations for the risk assessment of pressure injuries. These recommendations are supported and upheld by the Australian Commission on Safety and Quality in Health Care's NSQHS Standards. These recommendations are:

1. All patients should undergo a pressure injury risk assessment within 8 hours of admission. The risk assessment should be structured and incorporate the clinical judgment of the clinician.
2. The risk assessment should be performed as often as clinically required.
3. Risk should be reassessed if the patient's condition changes.
4. A comprehensive skin assessment should form part of every risk assessment.
5. Each risk assessment should be documented accurately so that changes to skin integrity can be detected and treated early.
6. A risk-based prevention plan should be developed for patients identified as being at risk of pressure injuries.

In addition, the Guideline makes evidence-based recommendations for optimising nutritional status, repositioning and early mobilisation of individuals, and the use of support surfaces in the prevention and treatment of pressure injuries (NPUAP, EPUAP & PPPIA, 2014).

and decreased strength and elasticity. As a result, the thinner and less nourished dermal layer is more prone to shear and friction forces. Furthermore, wound healing is inhibited in the older adult due to a myriad of factors such as increased co-morbidities, potential deficits in nutrition and hydration, polypharmacy and the effects of certain medications.

Since the early 1960s an increasing number of pressure injury risk prediction instruments have been developed to assist healthcare providers identify and assess the recognised clinical variables that contribute to pressure injury formation. The most commonly used instruments in Australia include the Braden Scale (1987), Norton Scale (1962), Waterlow Score (1985) and Braden Q Scale (1996) for paediatric populations (Australian Wound Management Association, 2012). Among these prediction instruments there is no consensus on subscales assessed, scoring systems, methodological testing for reliability, sensitivity, specificity or predictive value rating, nor specific populations for use. However, when used in conjunction with informed clinical judgment they can increase the effectiveness of pressure prevention interventions.

INTERPROFESSIONAL CARE

For the person at risk of pressure injuries, the goal is prevention. An interprofessional and collaborative approach to the prevention and management of pressure injuries is required. The most contemporary evidence for prevention and treatment of pressure injuries which should be used by all health professionals is presented in the 2014 *Prevention and Treatment of Pressure Ulcers: Clinical Practice Guidelines* available at www.internationalguideline.com.

Table 15.4 summarises contemporary pressure injury prevention recommendations described in the 2014 *Prevention and Treatment of Pressure Ulcers: Clinical Practice Guidelines*.

Pressure injury management

Pressure injuries are generally considered to be chronic wounds, as healing may be complicated by intrinsic and extrinsic factors that impact on the person, their wound and their healing environment. The principles of wound bed preparation were outlined in the original 'TIME' acronym (Schultz et al., 2003) and updated in 2012 (Leaper et al., 2012) (see Box 15.11).

TIME: TISSUE Wound debridement is the required intervention when assessment reveals the presence of non-viable or necrotic tissue. Chronic wounds may require ongoing debridement to remove necrotic tissue and reduce the levels of microbes and excessive proteases.

The methods of debridement include surgical sharp, conservative sharp, autolytic, mechanical, chemical, enzymatic and parasitic larvae. Surgical sharp debridement may be performed by the medical practitioner in an aseptic environment when there is infection or extensive slough or eschar in the wound. Conservative sharp wound debridement (CSWD), which is the removal of loose avascular tissue without pain or bleeding, may be performed by the competent nurse when there are no contraindications such as:

- lack of access to sterile sharp instruments (Adson toothed forceps, scalpel or iris scissors)
- densely adherent necrotic tissue when the interface between viable and non-viable tissue cannot be clearly identified
- impaired clotting mechanism or the person is on anticoagulant or antiplatelet medications
- increased risk of bleeding—for example, malignant wounds
- a non-infected ischaemic ulcer covered with dry eschar when tissue oxygenation is insufficient to support infection control and wound healing—for example, a diabetic person with a dry or gangrenous foot ulcer (Carville, 2012).

TABLE 15.4 Pressure injury prevention

STRATEGY	DESCRIPTION
Skin care	• Avoid positioning patients on reddened areas of skin (erythema). • Keep the skin clean (using a pH-balanced skin cleanser) and dry. • Do not massage or rub skin at risk of pressure injuries. • Develop and implement an individualised continence plan. • Use a barrier method to protect skin from prolonged exposure to excessive moisture. • Use skin moisturisers judiciously to hydrate the skin (do not use dimethyl sulfoxides).
Microclimate control	• Use correct materials to alter the moisture absorption and heat dissipation depending on the client's need. • Do not apply heating devices directly on the skin or on a pressure injury.
Prophylactic dressings	• Apply polyurethane foam dressings to bony prominences on clients identified as being at high risk of pressure injuries. • Select the above dressings paying consideration to the microclimate needs, ease of application and removal, ability to easily and regularly assess skin, anatomical location and correct sizing.
Fabrics and textiles	• Use silk fabrics over cotton-based fabrics to reduce sheer and friction.
Electrical stimulation	• Consider using electrical stimulation to areas at risk of pressure injuries on spinal cord injury patients.
Nutrition	• Screen all patients at risk of pressure injury with a validated screening tool and refer those identified as at risk of malnutrition to a dietician. • Assess each patient's weight status, ability to eat independently and adequacy of nutrient intake. • Develop an individualised care plan. • Ensure the patient's energy intake has been calculated according to their underlying pathology, weight needs and pressure injury risk. • Provide adequate protein for clients identified as being at risk of pressure injuries. • Provide adequate hydration and monitor for signs of dehydration. • Encourage a vitamin-rich intake or supplementation in patients at risk of pressure injuries.
Repositioning and early mobilisation	• Reposition all patients at risk of pressure injuries, unless contraindicated. • Take into consideration the patient's pressure redistribution support surface when determining the frequency of turns. • Reposition patients so that pressure is relieved or redistributed, avoiding bony prominences and shearing forces.
Support surfaces	• Use high-specification reactive foam mattress for all patients at risk of pressure injuries. • Use an active support surface for all patients at *high* risk of pressure injuries.

BOX 15.11 TIME acronym

T = Tissue, non-viable or deficit
I = Infection or inflammation
M = Moisture imbalance
E = Edge of wound on-advancing or undermined.

The extent of debridement required and patient risk are outside the scope of practice.

Other methods of debridement such as autolytic, 'safe' chemical (using antimicrobial agents), mechanical or parasitic debridement, may be employed when CSWD is inappropriate. At the time of publication there are no licensed enzymatic debridement agents available in Australia.

Dressings that hydrate the wound or maintain wound exudate at the wound interface and thus promote autolysis of eschar are used to promote autolytic debridement (see Table 15.5). Certain modern antiseptic dressings provide a means of autolytic and less toxic chemical debridement and are commonly used when infection or the risk of infection is present (see Table 15.5). Mechanical debridement is the use of wet to dry dressings for the physical removal of necrotic or infected tissue or exudate, and this method may be preferred when delayed primary intention is employed.

Low frequency ultrasound debridement (LFUD) is another form of mechanical debridement. It uses low ultrasonic frequencies of 20 kHz to 100 kHz and converts electrical current to vibrations. As ultrasound does not travel easily through air, saline solution is used as a transducing media, which allows the ultrasound waves to travel from the probe into the tissues. The mechanical energy produced converts into acoustic energy, or a cavitation phenomenon, which is the creation and destruction of small bubbles within the saline fluid surrounding the probe (Shannon, Williams & Bloomer, 2012). During cavitation, the bubbles oscillate and expand and rapidly collapse, causing shockwaves and selective fragmentation or debridement of devitalised tissues (Conner-Kerr et al., 2010). An available example of an LFUD device is the SONOCA-185® (Soring).

The use of fly larvae therapy or maggots for debridement is attracting increased interest in Australia, and laboratory-raised 'sterile' *Lucilia sericata* (greenbottle fly) larvae are being produced at Westmead Hospital in Sydney for this purpose. Parasitic or larval debridement is also known as biosurgical or myasitic

TABLE 15.5 Dressings for autolytic and 'safe' chemical debridement

AUTOLYTIC DEBRIDEMENT	AUTOLYTIC AND CHEMICAL DEBRIDEMENT
Hydrogel dressings	**Cadexomer iodine dressings**
Amorphous hydrogels	Iodosorb™ powder, paste and dressing

larval therapy and involves the deliberate infestation of laboratory-raised fly maggots into a necrotic wound. The *L. sericata* species is deemed to be the most suitable larvae as it secretes collagenases and trypsin enzymes and limits its interest to necrotic rather than healthy tissue (Polat et al., 2014). The enzymes facilitate liquidification of the necrotic tissue which is then digested by the larvae. Prior to application of the larvae, the periwound skin is best protected with a hydrocolloid dressing and the larvae entrapped under a semi-permeable film dressing which requires the insertion of small pin-pricked holes to facilitate air entry and survival of the maggots. Subject to the amount of necrotic tissue and the number of larvae, they are generally allowed to remain in the wound for 2 days or until they are engorged.

TIME: INFECTION OR INFLAMMATION The classic signs and symptoms of inflammation were noted by Celsus in the first century to be *tumor* (swelling), *rubor* (erythema), *calor* (heat) and *dolor* (pain) (Haeger, 1988). Inflammation can occur as a normal response to wound healing. It can also occur in response to wound infection with the added sign of purulence or increased malodorous exudate. Contamination, which is defined as the presence of non-replicating bacteria in a wound, does not inhibit wound healing (Bullock & Hales, 2013). However, tissue hypoxia or necrosis is conducive to colonisation, which is defined as the presence of replicating bacteria, but with no host reaction. Skin commensals such as *Staphylococcus epidermis* and *Corynebacterium* flora are to be expected in the wound and, in fact, have been found at low levels to demonstrate a positive effect on healing (Moffatt, 2004). Critical colonisation (also known as covert infection, local infection, occult infection) is defined as an increase in the bacterial burden of the wound in which healing is inhibited (World Union of Wound Healing Societies, 2008). Critically colonised wounds do not portray the classic signs of infection, although the wound may demonstrate one or more of the following signs: static healing; increased exudate; hypergranulated, bright-red, friable granulation tissue that bleeds easily; tissue bridging; granulation pocketing in the base of the wound; and rolled edges (Swanson, Grothier & Schultz 2014).

There is a lack of international consensus as to whether critical colonisation is a transitional stage between colonisation and overt infection, or is indicative of chronic inflammation in the presence of a biofilm in the wound. Bacteria react to threat in two ways: the development of resistance and the formation of biofilms. **Biofilms** are polymicrobial microbial communities which proliferate and are encased in a protective glycocalax matrix. The bacteria secrete glycocalyx which forms a biofilm (an extracellular polysaccharide (ESP)) that protects the organisms from immune responses by phagocytes and from topical and systemic antibiotics. Biofilms have been found in 60% of chronic wounds compared to 6% of acute wounds (James et al., 2008).

Biofilms form in the following manner:

1. Planktonic (free-floating) organisms attach to the surface of the wound.
2. Sessile (firmly attached) organisms communicate between microorganisms of the same or different species via a process referred to as quorum sensing. Quorum sensing is responsible for phenotypic diversity and some of the genotypic diversity seen in wound biofilms, and enhances the community's nutrient-gathering capacity, defence and reproductive abilities.
3. Firmly attached microorganisms secrete an extracellular polymeric substance (EPS) or protective matrix.
4. The EPS is comprised of polysaccharides, proteins, glycolipids and bacterial DNA.
5. The mature biofilm releases planktonic bacteria which disperse and attach to other parts of the wound, and the cycle is repeated (James et al., 2008; Phillips et al., 2010).

The prudent use of topical antiseptic dressings can restore the bacterial balance in the wound and there is some evidence that polyhexamethylene biguanide (PHMB) with a surfactant (betaine) (Andriessen et al., 2008; Forstner et al., 2013; Kaehn & Eberlein, 2009), cadexomer iodine (Phillips et al., 2010) and silver (Incani et al., 2015) can denature a biofilm. Because bacterial imbalance usually results in increased amounts of wound exudate, maintenance of moisture balance is an aligned goal (Carville, 2012). Examples of antiseptic dressings available for restoration of bacterial balance are outlined in Box 15.12.

TIME: MOISTURE IMBALANCE Desiccation of the wound inhibits epithelialisation, and excessive moisture leads to maceration and further breakdown of the tissues. Chronic wound fluid contains increased levels of matrix metalloproteases which have the potential to degrade much-needed extracellular matrix proteins such as fibronectin and vitronectin. Excessive fluid in chronic wounds can interfere with the activities of important cell mediators, such as growth factors (Dowsett, 2011). The goal is to maintain moisture balance while avoiding desiccation and maceration. Thus, dressing selection will be

BOX 15.12 Antiseptic dressings

Cadexomer iodine dressings

Hypertonic-impregnated dressings
Curasalt™ gauze
Mesalt™
Polyhexamethylene biguanide (PHMB)
Prontosan™ solution (with Betaine)
Prontosan™ gel
AMD™ foam and gauze

influenced by the assessment outcome, and the goal of care will be either to hydrate the wound bed or absorb excessive exudate. Cavity or sinus wounds such as Stage 3 and 4 pressure injuries will require a cavity-filling dressing to eliminate the dead space in the wound and facilitate controlled wound closure. Most generic groups of dressings (e.g. calcium alginates, hydrofibre, foams and hydrogel-impregnated gauzes) now come in forms suitable for filling cavity defects.

Dressing options for maintaining moisture balance in pressure injuries are outlined in Figure 15.20.

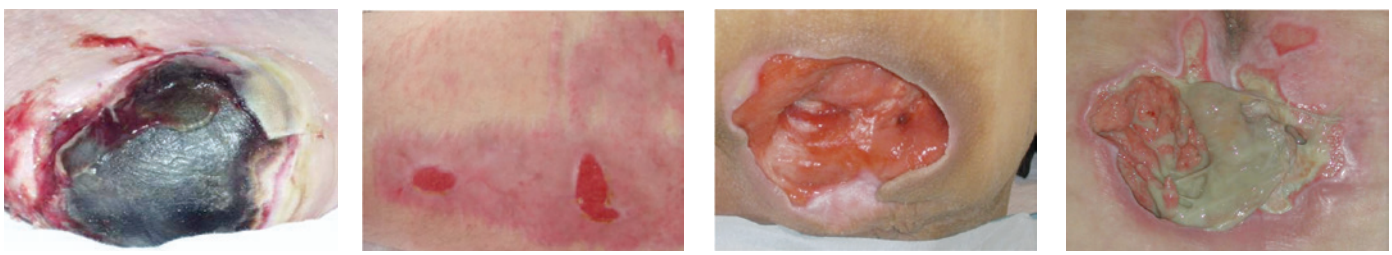
TIME: EDGES ADVANCING Assessment of wound edges is frequently overlooked, but coloured, raised, rolled or undermined wound edges can indicate delays in healing, abnormal pathologies or unrelieved pressure. Desiccation of the wound bed, hypergranulation and periwound debris (scale, scab or dried exudate) will inhibit epithelisation across the wound surface. Hypergranulation commonly results from bacterial imbalance or ongoing wound irritant trauma. Rolled or undermined edges can also indicate bacterial imbalance. Raised edges may indicate unrelieved trauma. However, further diagnostic investigations such as a wound biopsy may be indicated if the wound edge appearance indicates potential malignant changes. The use of negative pressure wound therapy (NPWT) for advancing wound closure is now a common intervention.

Surgical treatment

Surgical debridement may be performed by a medical practitioner when there is infection or extensive slough or eschar. Extensive pressure injuries may also require skin grafting or flap reconstruction to facilitate complete closure.

Nursing care

The person with a pressure injury not only has impaired skin integrity but also is at increased risk of other pressure injuries, infection, pain, decreased mobility and death. Pressure injuries prolong treatment for other health problems, increase healthcare costs and diminish the person's quality of life. Therefore, pressure injury prevention is the optimal principle of care (see Box 15.13).



Dry
Dressing options:
- Hydrogels
- Hydrocolloids
- Interactive wet dressings

Low exudate
Dressing options:
- Semi-permeable films
- Hydrocolloids
- Calcium alginates

Moderate exudate
Dressing options:
- Calcium alginate
- Hydrofibre
- Foams

Heavy exudate
Dressing options:
- Hydrofibre dressing
- Foam sheet/cavity
- Super-absorbent dry dressings
- Wound/ostomy bag
- Topical negative-pressure therapy systems

BOX 15.13 Nursing care of the person at risk of a pressure injury and the person with a pressure injury

Comprehensive recommendations for pressure injury prevention and management are to be found in the *Prevention and Treatment of Pressure Ulcers: Clinical Practice Guideline* (NPUAP, EPUAP & PPPIA, 2014) at www.internationalguideline.com.

The principle interventions for pressure injury prevention and management are as follows:

Risk assessment

1. Conduct a comprehensive assessment for all people to identify pressure injury risk factors. A comprehensive assessment should include:
   - clinical history
   - pressure injury risk scale
   - skin assessment
   - mobility and activity assessment
   - nutritional assessment
   - continence assessment
   - cognitive assessment
   - assessment of extrinsic risk factors.
2. Use a validated pressure injury risk assessment scale in conjunction with a comprehensive risk assessment to determine the person's risk of pressure injury and to inform the development of a prevention plan.
3. Inspect the skin of all people on admission and at each repositioning to identify indications of pressure injury including:
   - erythema
   - blanching response
   - localised heat
   - oedema
   - induration
   - skin breakdown.

Prevention of pressure injuries

1. Implement preventative strategies to protect the person's skin.
2. Provide high-protein oral nutritional supplements in addition to an appropriate diet for people at a high risk of pressure injury who have been identified at risk of having malnutrition.
3. Use a high-specification, constant-low-pressure support mattress on beds, trolleys, operating theatre tables and chairs for people at high risk of pressure injury (refer to the Guideline for information on characteristics of high-specification support surfaces).
4. Any device used to prevent heel pressure injuries should be selected and fitted appropriately to offload heel pressure.
5. Frequency of repositioning should consider the person's risk of pressure injury, comfort, functional level, medical condition and the support surface used.
6. Skin protection should include:
   - Individuals at risk of developing pressure injuries should have a comprehensive skin inspection at least daily for signs of impaired skin integrity.
   - The skin should be kept clean and free from all potentially irritating substances or those that substantially alter the skin pH.
   - All intrinsic and extrinsic factors that result in dryness or maceration of the skin should be eliminated or minimised by:
     a. treating dry, flaky or scaling skin with a topical moisturiser
     b. avoiding sustained or excessive contact with body fluids, and/or
     c. encouraging continence by employing interventions such as continence training or the use of continence aids.
7. Avoid extremes in skin temperature by avoiding skin contact with plastic support surfaces and ensuring that turning schedules do not exceed 2-hourly intervals for people at high risk.

Mechanical offloading and support surfaces

1. Alternating-pressure mattress replacements and overlays provide similar benefits to high-specification, constant-low-pressure support mattresses and could be used as an alternative in people at high risk of pressure injury.
2. Support surfaces should be used in conjunction with a comprehensive prevention strategy based on frequent observation and assessment, individualised turning regimens and measures to increase the tissues' tolerance to pressure.
3. Pillows and foam wedges can be used to avoid direct contact between bony prominences.
4. Avoid prolonged uninterrupted sitting in a chair or wheelchair. Repositioning or shifting of pressure points should occur as frequently as every 15 minutes to hourly depending on the tissues' tolerance to pressure.
5. Exposure to shear and friction should be reduced by:
   a. employing correct lifting and manual handling techniques
   b. protecting skin constantly exposed to friction with protective dressings or padding or medical-grade sheepskin
   c. elevating the foot of the bed to 20 degrees when sitting to prevent sliding
   d. maintaining the head of the bed at the lowest possible elevation consistent with the individual's medical condition and comfort.
6. Individuals who are bed-bound or have immobilised lower extremities should have total relief of pressure from their heels.
7. Individuals should be encouraged to maximise their activity and mobilisation consistent with their medical condition, ability and energy level.

Documentation

All individuals at risk of developing pressure injuries should have the following details recorded in the person's record on a regular, ongoing basis: risk assessment status (low, moderate

BOX 15.13 Nursing care of the person at risk of a pressure injury and the person with a pressure injury (continued)

or high); identified risk factors; management plan which includes interventions used such as turning schedules, support surface, referrals and the individual's response to treatment.

Evaluation

1. Any pressure injury risk management program should be based on a demonstrable need, relevant to the healthcare setting and supported by a policy and protocol based on the best available research.
2. All pressure injury risk management programs should include the individual at risk and significant family members. The individual should be considered an active participant in the management plan and should be informed of the relevant risk factors and the strategies employed to minimise or eliminate the risk of pressure injury development.
3. A pressure injury risk management program should be supported by a continuing educational program and a multidisciplinary continuous improvement process that is able to monitor and compare the impact of interventions over time.

NURSING CARE PLAN A person with a pressure injury

Mrs Sibutu is 85 years old and lives in a nursing home. Mrs Sibitu has been unable to walk since suffering a dense cerebral vascular accident (CVA) 2 years ago. She requires full assistance to transfer and change her position in bed. She has a history of type II diabetes which is reported to be diet controlled, chronic obstructive pulmonary disease (COPD) and osteoarthritis. Her medications include preventative inhaled corticosteroids (beclomethasone) twice daily and non-steroidal anti-inflammatory agents (naproxen 500 mg) twice daily. In addition, she takes aspirin (Cardiprin) 100 mg daily as a preventive anticoagulant. Her weight is average, but she has had a recent weight loss of 4 kg. While her appetite was previously good, over the past month she has required a lot of assistance and encouragement with fluid and foods. A deterioration in her general condition has been noted and she is reportedly increasingly drowsy and reluctant to be repositioned regularly. She is incontinent of faeces and urine. Her incontinence is managed with incontinent pads. She normally sits out of bed for 4 to 6 hours a day in a recliner chair but otherwise spends the remainder of the day in bed.

ASSESSMENT

On routine skin inspection Mrs Sibitu was assessed to have a pressure injury measuring 3 cm by 4 cm over her sacrum. The wound bed was covered in a layer of yellow slough that inhibited assessment of the depth of the wound. There was a moderate amount of yellow-stained, slightly malodorous exudate. On palpation the surrounding skin is noted to be indurated and dark red. The edges of the wound are level with the surrounding skin, which is macerated due to contact with wound exudate and urine. Although she cannot articulate her pain level, Mrs Sibitu appears restless when the wound is touched or she is repositioned. A pressure injury risk assessment using the Braden Scale was performed and she was assessed as being at high risk of pressure injury.

DIAGNOSIS

- *Impaired skin integrity* related to pressure, friction and shear—an Unstageable sacral pressure injury.
- *Infection* risk due to contamination of pressure injury with faeces and urine.
- *Pain* related to the pressure injury.
- *Anxiety* related to alterations in cognition, mobility and activity.

PLANNING

- Assess the person, their wound and their healing environment.
- Eliminate pressure, shear and friction.
- Control wound infection and manage the wound according to best evidence.
- Debride the slough.
- Manage urinary and faecal incontinence.
- Optimise nutritional status with supplements.
- Manage pain.

Expected outcomes

- Mrs Sibitu's pressure injury will be assessed daily, managed and progress to healing.
- Mrs Sibitu will be free of further pressure injuries or extension of her existing injury with appropriate assessment and intervention.
- Mrs Sibitu will be free of wound infection from faecal and urine contamination based on appropriate infection prevention and control strategies.
- Mrs Sibitu will be free of pain based on accurate assessment and appropriate interventions.

IMPLEMENTATION

- Assess pain and request a medical review for pain management medications.
- Perform a skin assessment and a pressure injury risk assessment on admission and on altered change of condition, or as directed by her risk score and the organisation's protocol.
- Conduct a skin inspection daily and document outcomes.
- Increase repositioning times and use pillows or wedges to secure position and elevate heels from bed and position off sacrum.

(continued)

NURSING CARE PLAN A person with a pressure injury (continued)

- Optimise pressure offloading—utilise an active alternating-pressure replacement mattress on her bed for sleeping.
- Optimise pressure offloading—utilise a constant-low-pressure cushion when seated. The occupational therapist will be requested to review Mrs Sibitu's seating.
- Request a dietitian to review Mrs Sibitu's nutritional intake and determine a plan of care for regular nutritional supplements and increased oral fluids.
- Keep Mrs Sibitu's skin clean and dry and use protective moisturisers and barrier films to protect against maceration.
- Review incontinence management strategies and quality of incontinence pads used. Implement a regular toileting regimen and review her bowel management plan.
- Request the physiotherapist to review her activity and mobility and implement a program of passive and active exercise as appropriate.
- Document wound assessment outcomes including stage of pressure injury, wound bed appearance and dimensions, type and amount of exudate, presence of malodour, status of surrounding skin and wound edges, and pain score, using a validated instrument.
- Document an individualised care plan for pressure injury management with the aim of reducing pain and discomfort, debridement of the slough, the need to maintain a bacterial balance in the wound, promote wound healing and prevent further pressure injury development.
- Observe for clinical signs of overt infection (increased pain, heat, redness, swelling or purulence, elevated temperature, malaise) and report to the medical practitioner.

Evaluation

Mrs Sibitu will require daily skin inspections and regular ongoing risk assessments for pressure injury risk. Ongoing wound assessments will be evaluated for healing progress and successful care planning. Her pain will be controlled. The occupational therapist will review Mrs Sibitu's seating on a regular basis and adapt it as appropriate. The alternating-pressure mattress will be checked each shift to ensure the correct pressure offloading is provided under her bony prominences. The dietitian will review the effectiveness of the nutritional plan. The physiotherapist will review the effectiveness of the exercise plan.

CRITICAL THINKING IN THE NURSING PROCESS

1. Consider Mrs Sibitu's risk factors for pressure injury development and why daily skin inspection of an 'at-risk' individual is of the utmost importance.
2. Use a validated risk assessment tool such as the Braden Scale, Norton Score or Waterlow Score to determine Mrs Sibitu's risk score.
3. What primary dressing would you most likely select to manage Mrs Sibitu's wound if your goal of care is bacterial balance and debridement?
4. What secondary dressing would you most likely select to control the moderate amount of exudate and protect against further contamination by body waste?

REFLECTION ON THE NURSING PROCESS

1. Outline what you have learned from Mrs Sibitu's situation that you will apply to your future practice.
2. What education strategies would you give to Mrs Sibitu and her family to prevent her developing further pressure injuries?

THE PERSON WITH A SKIN TEAR

A **skin tear** is defined as 'a traumatic wound occurring principally on the extremities of older adults, as a result of friction alone or shearing and friction forces which separate the epidermis from the dermis (partial-thickness wound) or which separate both the epidermis and the dermis from underlying structures (full-thickness wound)' (Payne & Martin, 1993).

Skin tears are the most common wound found in elderly populations. Reasons for this are related to the changes that occur in ageing skin and the increased incidence of knocks, falls and manual handling requirements (Carville, 2012). The risk factors associated with acquiring skin tears are poorly studied but anecdotally reported to be visual impairment, impaired mobility or balance, dementia and the use of certain medications such as steroids or anticoagulants (Crisp et al., 2013). Skin tears are all too frequently considered to be minor wounds, yet they can become extremely problematic and their treatment can be costly.

Until recently, skin tear prevalence was poorly reported in Australia. However, skin tears were found to be the third-largest group of wounds in Western Australia during surveys of all public hospitals conducted in 2007, 2008, 2009 and 2011 (Mulligan et al., 2011). Of particular concern was the fact that the majority of these injuries were hospital-acquired. In a Western Australian community setting, skin tears were found to comprise 20% of wounds in a population aged 70 years or older (Carville & Smith, 2004). Although dated data, in that same state, skin tears were found to be 41.5% of known wounds in an aged care agency (Everett & Powell, 1994).

In 1990, Payne and Martin outlined a system for classification of skin tears. They refined this system in 1993, although the classification is poorly utilised in Australia. The Payne–Martin Skin Tear Classification (1993) lists three categories and two subcategories of injury; however, it does not take into account the presence of haematoma or ischaemic changes in the skin or flap (see Box 15.14).

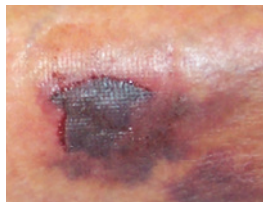
BOX 15.14 Payne–Martin Skin Tear Classification (1993)

Category 1: Able to approximate the wound borders within 1 mm, no tissue loss
A—linear tear
B—flap

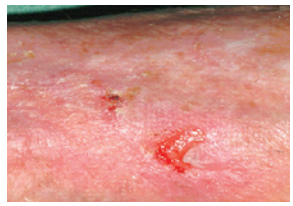
Category 2: Varying amounts of tissue loss
Type A <25% loss—scant
Type B <25% loss—moderate

Category 3: Total loss of flap

Category 1a
A skin tear where the edges can be realigned to the normal anatomical position (without undue stretching) and the skin or flap colour is not pale, dusky or darkened.



Category 1b
A skin tear where the edges can be realigned to the normal anatomical position (without undue stretching) and the skin or flap colour is pale, dusky or darkened.



Category 2a
A skin tear where the edges cannot be realigned to the normal anatomical position and the skin or flap colour is not pale, dusky or darkened.

Category 2b
A skin tear where the edges cannot be realigned to the normal anatomical position and the skin or flap colour is pale, dusky or darkened.

Category 3
A skin tear where the skin flap is completely absent.

FIGURE 15.21 ■ STAR Skin Tear Classification System

Source: Skin Tear Audit Research (2007). Silver Chain Foundation and Curtin University. Reprinted with permission.

The STAR Skin Tear Classification System (Carville et al., 2007) also lists three categories and two subcategories of skin injury and takes into account skin or flap colour changes that occur with haematoma or hypoxia (see Figure 15.21).

Preventing skin tears

At this time there is no validated risk assessment tool for predicting skin tears. However, individuals who require personal assistance with transfer or mobility, such as the frail, elderly or disabled, are at increased risk. Skin tears can also occur on any individual with the removal of adhesive agents such as tapes, dressings and devices, and due care must be taken during these procedures. A large randomised control trial found that twice-daily moisturising of extremities of aged care residents with a pH-friendly, perfume-free moisturiser reduced skin tear incidence by 50% (Carville et al., 2014). Prevention of skin tears is a fundamental aspect of caring for these populations (see Box 15.15).

BOX 15.15 Skin tear prevention

- Assess for falls risk and implement prevention strategies.
- Use gentle and timely handling on transfer and repositioning.
- Use devices that reduce shear and friction.
- Moisturise the skin twice a day with a pH-friendly, perfume-free moisturiser.
- Cover vulnerable skin surfaces with protective clothing or devices.
- Maintain position with pillows and foam wedges to prevent shear. (Satin or silk covers will further reduce shear forces.)
- Avoid perfumed soaps that dry and alter the skin's pH.
- Cease smoking.
- Maintain adequate hydration and optimal nutrition.
- Avoid adhesive tapes and dressings on fragile skin in favour of roller or tubular bandages.
- Review medications and eliminate if possible those that alter the skin's integrity.
- Control any co-morbidities that alter the skin's condition or risk of injury.
- Provide person and carer education on skin health and injury prevention.

Source: Wound care manual (6th ed.) by K. Carville (2012). Osborne Park, WA: Silver Chain Foundation.

Skin tear management

The principles of skin tear management focus on control of any bleeding, restoration of skin flaps if present and provision of an environment that is conducive to healing and protection from further injury. Skin tears are commonly managed by dressings alone; stabilisation of the skin flap can be achieved via the use of silicone dressings (Prentice, Morey & Rodriguez, 2014). If the skin tear is deep or extensive, primary closure using sutures or tissue adhesives such as Histacryl™ may be required. The use of skin closure strips such as Steri-Strips™ are not recommended across flexures as they can compromise perfusion on flexing of tissues. If tape is required, the use of skin-protective barrier film prior to application and an adhesive remover prior to removal is advised (Prentice et al., 2014).

Selection of an appropriate dressing is subject to the ideal features and benefits, which should include the following:

- easy to apply
- provides a protective anti-shear barrier
- tissue friendly, moulds to contours, flexible
- maintains wound physiological balance—moisture, temperature, pH
- secure, but not aggressive retention
- extended wear time
- non-traumatic removal
- optimises quality of life and cosmesis
- cost-effective.

THE PERSON WITH A DISORDER OF THE HAIR

Racial characteristics and gender influence the amount and type of hair. Caucasians typically have more facial and body hair than do Asians. The latter usually have straight hair, those of African descent have wavy to curly hair and Caucasians have straight to curly hair. In addition, male hair growth characteristics (such as facial hair and hair on the lower extremities) are normal in certain women of some races and families.

The hair grows at various rates. Facial hair grows the most rapidly, followed by the hair of the scalp, axillae, thighs and eyebrows. Normally, an adult's hair grows at a rate of 10 to 12 mm per month; however, the growth rate is influenced by both the person's state of health and the environment. (Hair grows faster in hot climates, more slowly in cold climates.)

Pathophysiology

Hair colour, growth and pattern vary from person to person and are determined largely by genetic inheritance. However, changes do occur. For example, in some instances, hair loss recurs in successive generations of males in a family; in other cases, hair loss may be the result of chemotherapy. Excessive facial hair may be a response to certain endocrine disorders or to the loss of oestrogen after menopause. These changes may seem minor, but they may create psychosocial problems for the person experiencing the changes.

Hirsutism

Hirsutism, also called hypertrichosis, is the appearance of excessive hair in normal and abnormal areas of the body in women. Hirsutism most often occurs in a male distribution (that is, on the upper lip, chin, abdomen and chest) in women. The excess hair is primarily the result of an increase in androgen levels (especially testosterone), which may be due to any of the following:

- familial predisposition (considered normal)
- polycystic ovary syndrome
- ovarian, adrenal or pituitary tumours
- Cushing's syndrome
- central nervous system disorders
- medications, such as minoxidil, cyclosporin, phenytoin, certain progestins and anabolic steroids.

The manifestations of hirsutism include increased male pattern hair growth, acne and menstrual irregularities. If the androgen excess is great, defeminisation (a decrease in breast size and loss of normal adipose tissue) and virilisation (frontal balding, increased muscle mass, deepening of the voice and enlargement of the clitoris) may occur. Virilisation indicates the presence of an androgen-producing tumour.

Alopecia

Alopecia is loss of hair or baldness (see Figure 15.22). Alopecia can affect both men and women and may result from scarring, various systemic diseases or genetic predisposition. Scarring from trauma, radiation and severe bacterial, fungal or viral infections causes permanent and irreversible hair loss over the scarred area. Systemic diseases that may cause alopecia include systemic lupus erythematosus, thyroid disorders and pituitary insufficiency. The hair loss from these disorders may be reversible. Hair loss from androgenic causes may also occur in postmenopausal woman. Alopecia may be drug induced and is a side effect of a variety of medications (see Box 15.16).

FIGURE 15.22 ■ Alopecia (baldness) may be the result of scarring, disease or genetic predisposition

Source: © Fresnel/Shutterstock.com.

Types of alopecia follow:

- Male pattern baldness is the most common cause of alopecia in men and is genetically predetermined. The hair loss begins at the temples, with recession of the hairline and baldness of the crown.
- Female pattern alopecia begins in women in their twenties and thirties, with progressive thinning and loss of hair over the central part of the scalp. Unlike men, women do not lose hair from the frontal hairline. Many of these women have elevated adrenal androgens.
- Alopecia areata is characterised by round or oval bald patches on the scalp, as well as on other hairy parts of the body. The cause is unknown. This type of alopecia is usually self-limiting and reverses without treatment, although it often recurs.

BOX 15.16 Medications causing alopecia

- Thallium
- Retinoids
- Anticoagulants
- Antimitotic agents
- Antithyroid drugs
- Oral contraceptives
- Trimethadione
- Excessive use of vitamin A
- Allopurinol
- Propranolol
- Indomethacin
- Amphetamines
- Salicylates
- Levodopa
- Gentamicin
- Chemotherapy

- Alopecia totalis is the loss of all hair on the scalp. This rare condition is irreversible.
- Alopecia universalis is the total loss of hair on all parts of the body.

INTERPROFESSIONAL CARE

Alopecia is diagnosed by assessing the appearance of the hair and hair loss, and by assessing the person for other systemic diseases and the use of medications that may cause hair loss. Various treatments are used to restore hair.

The person with hirsutism is examined for hormone levels and indications of other systemic illnesses. Hirsutism is treated by addressing the underlying systemic disorder and stopping medications that may be causing the problem.

Diagnosis

Diagnostic tests that may be ordered for the woman with hirsutism include serum testosterone levels and an adrenal CT scan. Testosterone levels greater than 200 ng/dL indicate the need for further tests, such as a pelvic examination and tests of ovarian function. Adrenal tumours, a possible cause of hirsutism, are identified with an adrenal CT scan.

Medications

Hirsutism is treated with medications specific to the underlying cause. Oral contraceptives containing oestrogen decrease ovarian androgen production and decrease free testosterone levels. Dexamethasone may be prescribed for people with high cortisol levels. Ketoconazole inhibits androgen production. Anti-androgenic medications cause congenital abnormalities in male infants and are therefore given only to non-pregnant women, who are cautioned to avoid pregnancy while taking the medications.

Male pattern baldness has been successfully treated with topical minoxidil. These drugs, which are vasodilators, stimulate vertex hair growth, probably by stimulating the epithelium of the hair follicle. These agents have been most successful in people who have a recent onset of alopecia or are less than 50 years of age. About 40% of people treated two times a day for a year will have moderate to dense regrowth of hair at the temples (Bullock & Hales, 2013).

Surgery

Hair transplant techniques are used to restore hair or reduce the size of areas of alopecia. Other types of surgical procedures include scalp reduction and flaps.

- Transplanting hairs as small hair plugs or single hairs taken from the back or sides of the scalp is an effective means of replacing hair to areas of alopecia. This procedure is done in an outpatient office or clinic.
- Scalp reduction is done by excising a portion of the affected scalp. In some cases, a tissue expander (such as a silicone balloon) is first implanted under the scalp to enlarge the hair-bearing scalp so that larger areas of alopecia can be removed.
- Flaps from hair-bearing areas of the scalp can be surgically transplanted from adjacent areas into areas of alopecia. This procedure may be done in stages.

Nursing care

The person with either hirsutism or alopecia is often self-conscious about their appearance and tries a variety of over-the-counter treatments before seeking medical care. Nursing care for the person with hair disorders focuses on teaching them self-care and providing support during long-term care. Women with hirsutism are taught to use various means of removing unwanted hair, such as shaving, applying depilatories, waxing, undergoing electrolysis or having laser treatments. Women with mild hirsutism may bleach facial hair to make it less obvious. People with alopecia may wear hair pieces or wigs.

THE PERSON WITH A DISORDER OF THE NAILS

Nail disorders may be due to systemic diseases, trauma, allergies or irritants. They may also be congenital or genetic. Nails may be discoloured, multicoloured, malformed, infected or separated from underlying tissue.

Pathophysiology

The nail disorders discussed here are separation of the nail, infection and ingrown toenails:

- *Onycholysis* is the separation of the distal nail plate from the nail bed. It occurs most often in the fingernails. This disorder may result from many different factors, including excessive or prolonged exposure to water, soaps, detergent, alkalines and industrial keratolytic agents; *Candida* infections; nail hardeners; and thyroid disorders. Prolonged application of false fingernails may also cause this disorder.
- A *paronychia* is an infection of the cuticle of the fingernails or toenails. The disorder often follows a minor trauma and secondary infection with staphylococci, streptococci.
- or *Candida*. The acute form begins with a painful inflammation that may progress to an abscess. The chronic form is seen most often in people who have frequent exposure to water. In the chronic form, the skin around the nail is painful, oedematous and infected. The nail plate may become ridged and discoloured.
- An *onychomycosis* is a fungal or dermatophyte infection of the nail plate. The nail plate elevates and becomes yellow or white. Psoriasis infections of the nail plate cause the nails to pit.
- An *ingrown toenail (unguis incarnatus)* results when the edge of the nail plate grows into the soft tissue of the toe. Pain and infection may occur. The infection, if untreated,

may spread to the bone. This disorder is especially dangerous for the person with diabetes mellitus or peripheral vascular disease.

INTERPROFESSIONAL CARE

The treatments of disorders of the nail vary from pharmacological treatment to surgical removal. Infections of the nails are treated, depending on the causative agent, with antifungal or antibiotic medications. If the causative agent is a fungus or chronic dermatological disorder, treatment is difficult and may not be effective. Persistently painful and/or infected nails are in some cases surgically removed.

Nursing care

Nursing care of the person with a disorder of the nail focuses on teaching self-care. People with nail disorders that are caused by frequent exposure to water are taught to protect the hands or feet by wearing rubber gloves or boots, and to keep the nails as clean and dry as possible. People with ingrown toenails are cautioned not to cut into the lateral nail bed, but rather to soak the nail twice a day and insert a piece of cotton or gauze under the softened nail until the nail has grown out enough to trim.

CHAPTER HIGHLIGHTS

- Pruritus (itching) accompanies dry skin (xerosis) and many skin disorders and may result in excoriation and infection as a result of scratching.
- Cysts, hypertrophic scars, keloids, naevi, angiomas, skin tags and keratoses are benign skin lesions. However, naevi should be monitored for changes indicating transformation into a malignant lesion.
- Psoriasis is a chronic immune skin disorder arising from keratinocytes. A variety of medications and treatments are used, with ultraviolet light therapy being most effective for generalised lesions.
- Skin disorders may be caused by a variety of bacterial infections, fungal infections, parasitic infestations and viral infections. The disorders are treated with a specific antibiotic, fungicide, antiviral agent or agents that kill the parasites. Herpes zoster, believed to follow a childhood infection with chickenpox, causes acute pain.
- Inflammatory disorders of the skin range from mild dermatitis to potentially lethal toxic epidermal necrolysis. Acne, a disorder of the hair and sebaceous glands opening to the skin surface, is characterised by comedones, pustules and cysts.
- Malignant skin disorders include actinic keratosis, non-melanoma skin cancer (basal cell carcinoma and squamous cell carcinoma) and malignant melanoma skin cancer. Skin cancer is the most common malignancy found in fair-skinned Australians. Prevention by avoiding sunburn, using sunscreen and maintaining monthly skin self-examination is critical in preventing loss of tissue or metastasis and death.
- Skin trauma may be intentional (as in the case of cutaneous and plastic surgery) or unintentional (as from trauma and pressure). Older adults with limited mobility, as well as people who are unable to move or are in critical care units, are at greater risk of pressure injuries and skin tears. Prevention is the goal of both interprofessional and nursing care.
- Disorders of the hair include alopecia (loss of hair) and hirsutism (excess hair in women). Nails may be discoloured, multicoloured, malformed, infected or separated from underlying tissue.

CONCEPT CHECK

1 You are caring for an elderly person with severe xerosis. What topic should be included in your teaching plan?
1. Take a hot bath every day.
2. Use fabric softeners when laundering clothing.
3. Apply skin lotions after a bath.
4. Maintain a warm environment.

2 Which of the following common skin lesions has the potential of becoming malignant?
1. naevi
2. angiomas
3. skin tags
4. keloids

3 You have been asked to teach a woman with generalised psoriasis about ultraviolet light therapy (UVB). What should be included in teaching?
1. 'The exact effect of UVB is unknown, but it decreases severe itching.'
2. 'When combined with hot baths, UVB is very effective.'
3. 'Treatments with UVB have to be given in the hospital to be safe.'
4. 'UVB slows the growth of epidermal cells and decreases keratosis.'

4 Which of the following people is at risk of the development of a candidiasis infection?
1. an older adult with pruritus
2. a young woman who is pregnant
3. an older man with a premalignant skin condition
4. a young man with multiple naevi

5 What question should be included in a health history of a person with a linear pattern of painful vesicles over the left thorax?
1. Do you remember being sunburned as a child?
2. Are you a regular patron of tanning booths?
3. Have you ever been diagnosed with acne?
4. Did you have chickenpox when you were young?

6 Which of the following statements is true of an infestation with lice?
1 Only dirty people have lice.
2 Anyone can have lice.
3 Lice do not like to live on humans.
4 Lice are a form of fungus.

7 Which assessments would indicate a greater risk to develop a non-melanoma skin cancer?
1 blonde hair, freckles, fair skin
2 alopecia, thin hair, itching
3 dark hair, dark skin, dry skin
4 tanned skin, dark hair, oedema

8 Of the following, which is most significant to the development of a malignant melanoma?
1 a change in the colour or size of a naevus
2 sexual contact with a person who has a herpesvirus infection
3 inadequate knowledge about infection prevention
4 a dietary intake of high-kilojoule foods

9 The rationale for lifting, rather than pulling, a person up in bed is that:
1 lifting a person allows a brief period of increased capillary circulation
2 lifting a person prevents tissue injury from shearing forces
3 pulling a person up in bed decreases tissue ischaemia and hypoxia
4 pulling a person up in bed promotes capillary blood flow

10 What STAR Skin Tear Classification would you assign to a skin tear where the edges can be aligned to the normal anatomical position without undue stretching and the skin or flap is pale, dusky or darkened?

CHAPTER 16

NURSING CARE OF PEOPLE WITH BURNS

SHARON ROWE, KERYLN CARVILLE, FIONA WOOD, DALE EDGAR, MICHELLE CORK, ROSEMARY KENDELL, KERRY REID-SEARL, KATE CROWLEY

LEARNING OUTCOMES

- Discuss the types and causative agents of burns.
- Explain burn classification by depth and extent of injury.
- Describe the pathophysiology of a minor burn.
- Describe the pathophysiology of a major burn.
- Outline the role of the nurse as part of the interprofessional team in the provision of first aid, acute care and rehabilitation of a burned person.

CLINICAL COMPETENCIES

- Assess the functional health status of peoples with burns and monitor, document and report abnormal manifestations.
- Use evidence-based research to plan and implement nursing care for people with burns.
- Determine priority nursing diagnoses, based on assessed data, to select and implement individualised nursing interventions for the person with burns.
- Administer medications knowledgeably and safely to people with burns.
- Integrate interprofessional care into care of people with burns.
- Provide teaching appropriate for prevention of burns.
- Revise plan of care as needed to provide effective interventions to promote, maintain or restore functional health status to people with burns.

KEY TERMS

A **burn** is an injury resulting from exposure to heat, chemicals, radiation, cold injuries or electric current. A transfer of energy from a source of heat to the human body initiates a sequence of physiological events that in the most severe cases leads to irreversible tissue destruction. Burns range in severity from a minor loss of small segments of the outermost layer of the skin to a complex injury involving all body systems. Treatments vary from simple application of a topical wound dressing in an outpatient clinic or general practice to an invasive, multisystem, interprofessional team approach in the aseptic environment of a burn centre.

Over the past two decades there have been worldwide improvements in the overall care of burns victims and, ultimately, an increased survival rate. These improvements include nutrition, management of hypermetabolism, resuscitation, understanding of the post-burn immune response and technological advances in surgery and wound care products. All are a result of the continuous research into thermal injury.

The data presented in Tables 16.1 and 16.2 are excerpts from the Australian and New Zealand Burn Association (ANZBA) (2011) *Bi-National Burns Registry Annual Report Year 2, 1 July 2010–30 June 2011*. This report shows that 69.5% of burn cases were adults, with those 20 to 29 years of age making up 27% of adult cases. Children 13 to 24 months made up 34% of paediatric cases. The majority of admissions to burn centres were males in both adult and paediatric populations.

Flame injuries are the most common burn injury in the Australian adult population (see Table 16.1). Scalds are the greatest cause of burns injury in the paediatric population (see Table 16.2).

Older adults and young children are susceptible to deep burns from scalds because of their thinner skin. Burns in the older adult are complicated by co-morbidities, lower threshold for infection, higher risk of pulmonary problems, a decrease in lean body mass, micronutrient deficiency or malnutrition. These factors all lead to an increased recovery time, and rebuilding of muscle tissue is slow. There is a thinning of the dermis in older adults and epidermal replacement is slowed. When combined with a decreased blood flow, the result is slower healing of partial-thickness burns and the occurrence of deep burns in older people. Scalds are the most common cause of burns in children, typically from hot tap water or from pulling a hot beverage onto themselves. Children are inquisitive and do not necessarily have a concept of danger, particularly if something looks interesting. Children and older people have decreased reserves and there is little room for error in the treatment of a burned child or older person.

People in occupations involving work with chemicals, petrol and electricity, and those in military service, are at higher risk of burn injury. Burn and scald injuries caused by physical abuse to children or disabled or older people are also a possibility. Abuse is suspected when scald burns show a clear line of demarcation, as this could indicate deliberate immersion. The presence of small, circular burns may be the result of cigarette burns. Abused individuals may also present with poor personal hygiene status, evidence of malnutrition or behavioural problems. There may be associated soft tissue injury or fractures and old scars. In older adults the burn may be a result of self-neglect, rather than neglect by others (Wong et al., 2007). Healthcare workers should be careful when using heat packs, heat lamps and electrical equipment when caring for older people or the young.

Older people are vulnerable to fire and burn injury because of potentially impaired visual acuity, depth perception, sense of smell, hearing and mobility. All of these factors increase the risk of accidental burn injury and increased mortality.

Many burns can be prevented. Nurses can play a part in educating the public about prevention of burns, burns first aid and care of minor burn injuries at home. Box 16.1 identifies some common tips for preventing burns that nurses can advocate to the wider public.

FAST FACTS

High-risk populations

- Children
- Disabled
- Older adults
- Military

TABLE 16.1 Adults—primary cause of burn

PRIMARY CAUSE OF BURN	TOTAL	%
Flame	757	44.0
Scald	494	28.2
Contact	259	15.0
Chemical	80	4.7
Friction	63	3.7
Electrical	30	1.7
Radiant heat (no contact to source)	34	2.0
Other	12	0.7

FAST FACTS

The aims of early burn management are to:

1. Preserve life
2. Preserve quality of life: functional and cosmetic.

BOX 16.1 Burn prevention tips

- Keep matches and lighters out of reach of children.
- Never leave children unattended around fire or in the bathroom or bathtub.
- Install and maintain smoke detectors in the home.
- Develop and practise a home-exit fire drill with all members of the household.
- Set the water heater temperature no higher than 50°C.
- Do not smoke in bed.
- Do not throw flammable liquids onto an already burning fire.
- Do not use flammable liquids to start fires.
- Do not remove a radiator cap from a hot engine.
- Watch for overhead electric wires and underground wires when working outside.
- Never store flammable liquids near a fire source, such as a pilot light.
- Use caution when cooking.
- Keep a working fire extinguisher and fire blanket in your home and workplace (Farrell, 2005, p. 1713).

For further information on injury prevention for children, contact www.kidsafe.com.au.

TYPES OF BURN INJURY

The types of burn injury are thermal, chemical, electrical, radiation, cold injury and friction. The extent of the injury is determined by the causative agent, length of time the tissue is exposed, body part involved and depth of burn. Although all burns can lead to generalised tissue damage and multisystem involvement, the causative agents and priority treatment measures are unique to each.

Thermal burns

Thermal burns result from exposure to dry heat (flames) or moist heat (steam and hot liquids). Direct exposure to the source of heat causes cellular destruction, resulting in damage to the skin and underlying structures.

Immediate management of thermal burns

In the case of flames, the person should stop, drop and roll to extinguish the flames. Clothing should be removed where possible and first aid commenced. First aid is the application of cool running water for at least 20 minutes. Management of thermal burns is discussed in detail later in this chapter.

Chemical burns

Chemical burns are caused by direct skin contact with acids, alkaline agents or toxic organic compounds (see Box 16.2 for specific household agents). The chemical denatures tissue protein, leading to necrosis. Chemical elements may also have a systemic effect as their elements circulate through the injured person.

BOX 16.2 Household cleaning agents that may cause burns

- Drain cleaners
- Lye
- Industrial-strength ammonia
- Household ammonia
- Oven cleaners
- Toilet bowl cleaners
- Dishwasher detergents
- Bleach

Chemical burn severity is determined by the:

- strength or concentration of the agent
- type of agent
- duration of contact
- amount of body surface area involved
- mechanism of action of the agent.

Chemical agents are further classified according to the manner by which they structurally alter proteins. Chemical burns are classified according to six mechanisms of action: reduction, oxidation, corrosive agents, protoplasmic poison, vesicants and desiccants. Chemicals can also cause eye injuries, as well as other systemic problems. Burning chemicals and substances give off toxic gases that cause inhalation injuries (Elijah, Sanford & Lee, 2012).

Alkalis

Alkalis cause liquefaction of the skin, which allows the alkali to move deeper into the tissue. Examples of alkalis include lime, sodium hydroxide and potassium hydroxide. These are present in many household cleaning products and workplace chemicals. Cement is both an alkali and a desiccant. It can penetrate clothing and when combined with sweat causes an exothermic reaction (Elijah et al., 2012).

Acids

Acids are found in many household agents and include oxalic acid, hydrofluoric acid and hydrochloric acid. Acids often cause hard, dry eschar to form. However, hydrochloric acid fumes can also cause inhalation injury. Hydrofluoric acid is a common industrial acid which causes coagulation necrosis and cellular death. The resultant chelating of calcium and magnesium causes a depletion of intracellular calcium, leading to death (Elijah et al., 2012).

Organic compounds

Organic compounds such as petroleum distillates cause damage by dissolving the lipid wall of cell membranes and may also cause renal and liver failure if absorbed. Some organic compounds such as phenols and petroleum products cause both a contact burn and systemic toxicity. Protoplasmic poisons, such as organic compounds, form salts with proteins, inhibiting calcium and other ions needed for cell viability.

Immediate management of chemical burns

Following a chemical burn the most important first aid intervention is to remove the chemical from the skin. This should

include removing all contaminated clothing and irrigation of the area with large amounts of tepid water. Care should be taken to prevent spread of the chemical on unaffected skin or on the person giving assistance. If there is dry alkali residue, it should be brushed off carefully prior to irrigation with cool running water that should be directed 'to the floor' or down a suitable drain, not in a bath where the chemical will spread to other areas of the body. The pH of the affected skin can be monitored with the use of pH indicator sticks to determine the efficacy of first aid measures. Remember to monitor for hypothermia as irrigation periods may be from 20 minutes to 2 hours.

Irrigation should not be performed with elemental metals such as lithium, potassium, sodium and magnesium. Combining these metals with water produces an exothermic reaction causing thermal injury. The area should be soaked in mineral oil and the metallic pieces removed with forceps, or the area should be covered in gauze soaked in mineral oil (e.g. liquid paraffin).

The use of neutralising agents is generally unreliable as there may be a large number of chemicals present in the workplace. During an emergency, errors in selecting the correct neutralising agent can occur, which can result in further injury. Irrigation with tepid water is the safest, and still the most effective, option.

Wound management principles for chemical burns are the same as for thermal burns. General advanced trauma life support principles—that is, the ABCs of basic life support—should always be followed and include maintenance of haemodynamics (Elijah et al., 2012; Tan & Wong, 2015).

Electrical burns

The severity of electrical burns depends on the type (alternating or direct current), duration of current, amount of voltage, resistance at point of contact and individual susceptibility. In Australia, electrical injuries are classified as low or high voltage. Low-voltage injuries are caused by electric currents below 1000 volts, and high-voltage injuries are caused by over 1000 volts or up to 33 000 volts in high-tension cables. However, less than 12 volts—for instance, that produced by a car battery—can cause a burn due to a short circuit if the person is wearing a ring or a watch (ANZBA, 2013). A high-voltage burn is associated with deep, underlying tissue damage similar to a crush injury. Low-voltage burns are usually more localised. Immediate death can occur as a result of current-induced ventricular fibrillation or asystole, or from respiratory arrest resulting from paralysis of the central respiratory control system and respiratory muscles (Aghakhani et al., 2014; Arnoldo et al., 2012.)

Electric current exists in two forms: alternating current (AC), in which the electrons move back and forth through a conductor in a cyclical fashion; and direct current (DC), in which the electrons flow in one direction. An AC current, like that found in conventional households, produces repeated electrical surges that lead to tetanic muscle contractions that can cause further injury through prolonged contact with the source or if the person is thrown. Loss of consciousness can also result in longer contact exposure. Any differences in potential injuries caused by AC and DC currents are in relation to low-voltage injuries, as high-voltage currents have a similar effect. The heart can be affected either by direct necrosis of the heart tissue or by arrhythmias. Cardiac complications are the most serious injuries associated with electrical burns and are fatal unless resuscitation measures are commenced. Respiratory arrest can occur as a result of injury to the respiratory control centre in the brain or as a result of muscle contractions causing a form of suffocation.

In addition to the injury caused by the electric current passing through vital organs, the person can receive an arc injury and a flame injury if clothing catches fire. Electric current follows the line of least resistance, and in the body this is along blood vessels and through organs, rather than through bone and fat. Deeper tissues retain the heat, and structures between bones sustain more damage than superficial structures (Arnoldo et al., 2012; Aghakhani et al., 2014).

Direct current injury—for example, caused by lightning—exposes the body to very high voltage for a short period of time. Lightning is the result of the electrical difference between a thundercloud and the ground overcoming the insulating properties of the surrounding air. Lightning injuries can range from minor to major burns. Formation of cataracts are the most common permanent injury resulting from lightning strikes. Cardiac and respiratory arrest can occur, as can damage to tympanic membranes in the middle and inner ear (Vogt, Niederbichler & Jokuszies, 2012).

Immediate management of electrical burns

Advanced trauma life support principles should be followed as soon as possible. The person should be transferred to a hospital with a burns unit. Initially, an electrical injury can look less severe than it actually is, as most of the damage is beneath the skin surface. A thorough history of the event may assist in determining the pathway of the current and the areas of injury. The person should be checked for any fractures that may have occurred and cervical spine precautions should be adhered to, particularly if the person was thrown or fell. Cardiac arrest, arrhythmias, metabolic acidosis and myoglobinuria are complications of electrical injury and need specialist medical treatment at a burn centre. The person should be monitored for cardiac complications and have an ECG performed. Pigments from muscle damage (myoglobin) and red blood cell damage (haemoglobin) can cause the urine to become dark. If untreated, myoglobinuria can lead to acute renal failure (Vogt et al., 2012). Urine output should be maintained at 1–2 mL/kg/hr (ANZBA, 2013).

Radiation burns

Ionising radiation is mediated by energy transference. It can, for example, be the result of exposure to electromagnetic radiation, x-ray or particulate radiation (alpha and beta particles or neutrons). Exposure can be from small accidents occurring in a laboratory or x-ray in a hospital. Major accidents may stretch hospital resources, as in the case of multi-trauma from military detonation of nuclear devices.

The overall extent of damage depends on the dose of radiation exposure. Skin changes usually range from erythema to dry desquamation of epidermal cells. Partial-thickness burns may

occur and are known as moist desquamation. Full-thickness burns can occur a few weeks to months after exposure. The most severe radiation injuries result from nuclear weapons and are a combination of thermal and radiation injuries (Milner & Feldman, 2012).

Sunburn tends to be superficial, involving only the epidermis; however, sunburned neonates, infants, children and older people can have significant injuries. Associated sunburn symptoms can include local discomfort, oedema, heat stroke and dehydration.

Immediate management of radiation burns

The management of radiation burns will differ subject to the cause (sunburn or exposure to radioactive substances) and local and systemic effects experienced. Management of relatively minor radiation burns involves removing patient from source, ABC of resuscitation procedures, removing contaminated clothing and copious irrigation to neutralise particles.

Management of radiation burns that occur following treatment for cancer tends to be subject to the policies of each radiotherapy unit.

Long-term effects of exposure to radiation include cancer and slow wound healing. Larger exposures or incidents can overwhelm hospital resources (Milner & Feldman, 2012).

Cold injury

Cold-induced injury (also called frostbite or localised hypothermia) is more common among homeless people, those with an interest in winter outdoor activities or individuals with alterations in cognition or perception due to dementia, high alcohol consumption or psychiatric disorders. Frostbite results when tissue temperatures fall below freezing and decreased blood flow causes tissue necrosis. Depth of injury from frostbite is classified similarly to burn injury.

If the exposure to freezing temperatures is limited, only the skin and subcutaneous tissues become involved; however, as exposure increases, deeper structures freeze. Frostbite is most common on exposed or peripheral areas of the body, such as the nose, ears, feet and hands.

As human tissues freeze, ice crystals form and increase intracellular sodium content. Small blood vessels initially vasoconstrict, but then vasodilate and become more permeable, causing cellular and tissue swelling. Continued exposure increases vasoconstriction, and increased viscosity of the blood causes infarction and necrosis of the affected tissue.

Superficial frostbite causes numbness, itching and prickling. The skin appears cyanotic, reddened or white. Deeper frostbite causes stiffness and paraesthesias. As the skin and tissues thaw, the skin becomes white or yellow and loses its elasticity. The person experiences burning pain. Oedema, blisters, necrosis and gangrene may present (Cochran, Morris & Saffle, 2012).

Immediate management of cold injuries

The biggest challenge in the field is to not cause further injury. Remove jewellery from affected area. Protect affected area from injury as the area is likely to be insensate.

Rapid thawing may significantly decrease tissue necrosis. General guidelines for re-warming areas of frostbite are:

- If outdoors, treat superficial frostbite by applying firm pressure with a warm hand or by placing frostbitten hands in the axillae. If the feet are frostbitten, remove wet footwear, dry the feet and put on dry footwear. Re-warming should not be commenced in the field unless there is certainty that the re-warming can continue uninterrupted. Refreezing of affected parts causes further damage. Monitor person for hypothermia as well (Cochran et al., 2012).
- Do not rub the areas with snow.
- In the hospital, rapidly re-warm affected areas in circulating warm water—40°C to 40.5°C—for 20 to 30 minutes. Do not rub or massage the areas.

Following re-warming, the person is kept on bed rest with the affected parts elevated. Pain medications and anti-inflammatory agents are administered. Topical wound management is instigated subject to assessment outcomes. Recovery from frostbite is usually complete if the involved area has not become necrotic. Necrotic tissue may require debridement or amputation of affected digits or limbs (Cochran et al., 2012).

Inhalation injury

An inhalation injury occurs as a result of inhalation of toxic by-products of combustion or smoke inhalation. This is discussed later in this chapter.

Friction burns

Friction burns occur as a result of the heat caused when the body is moved across a hard surface, such as a road or grass. Depth can vary from an abrasion to a wound that has blistered. Examples of injuries that may cause a friction burn are a rope that is pulled through a person's hand, or a fall from a bike onto a hard surface.

BURN CLASSIFICATION

Tissue damage following a burn is determined primarily by two factors: depth of the burn (the layers of underlying tissue affected) and extent of the burn (the percentage of body surface area involved). The assessment of the total body surface area and depth is then used to guide resuscitation and management protocols.

FAST FACTS

Factors to be considered when determining the depth of burn include:

- How the injury occurred
- Causative agent (flame, chemical, electricity, radiation)
- Temperature of burning agent
- Duration of contact
- Age-related skin thickness
- Anatomical location of burn
- First aid measures employed

Depth of the burn

The depth of a burn injury is determined by the elements of the skin that have been damaged or destroyed. Burn depth results from a combination of the temperature of the burning agent and the length of contact. Burns are classified as either superficial, partial-thickness or full-thickness burns. Characteristics of burns are outlined in Table 16.3 and illustrated in Figure 16.1.

TABLE 16.3 The characteristics of burns

	BURN DEPTH			
	SUPERFICIAL	SUPERFICIAL PARTIAL	DEEP PARTIAL	FULL THICKNESS
Wound appearance	Involves the epithelium • Painful • Red or pink	Epidermis and superficial (papillary) dermis destroyed • Painful • Often blistered • Pink, moist • Blanches	Involves epidermis and reticular dermis • May blister • Mottled pink or white • Fairly dry > day 2 • Discomfort rather than pain • Slow or no capillary refill	Involves epidermis and dermis, and may include fat • Does not blanch • May be mottled, dry, translucent, black or pale in appearance • Full-thickness scalds may have red non-blanching appearance
Healing and scarring	Complete scarless healing within 7–10 days	Heals by epithelial migration within 2 weeks • Can convert to a deeper burn	Will take more than 3 weeks to heal • Will leave a scar if > 3 weeks to heal	Will require surgery unless very small wound • Will have a scar if left to heal without surgery • Early excision and grafting reduce scarring and contracture

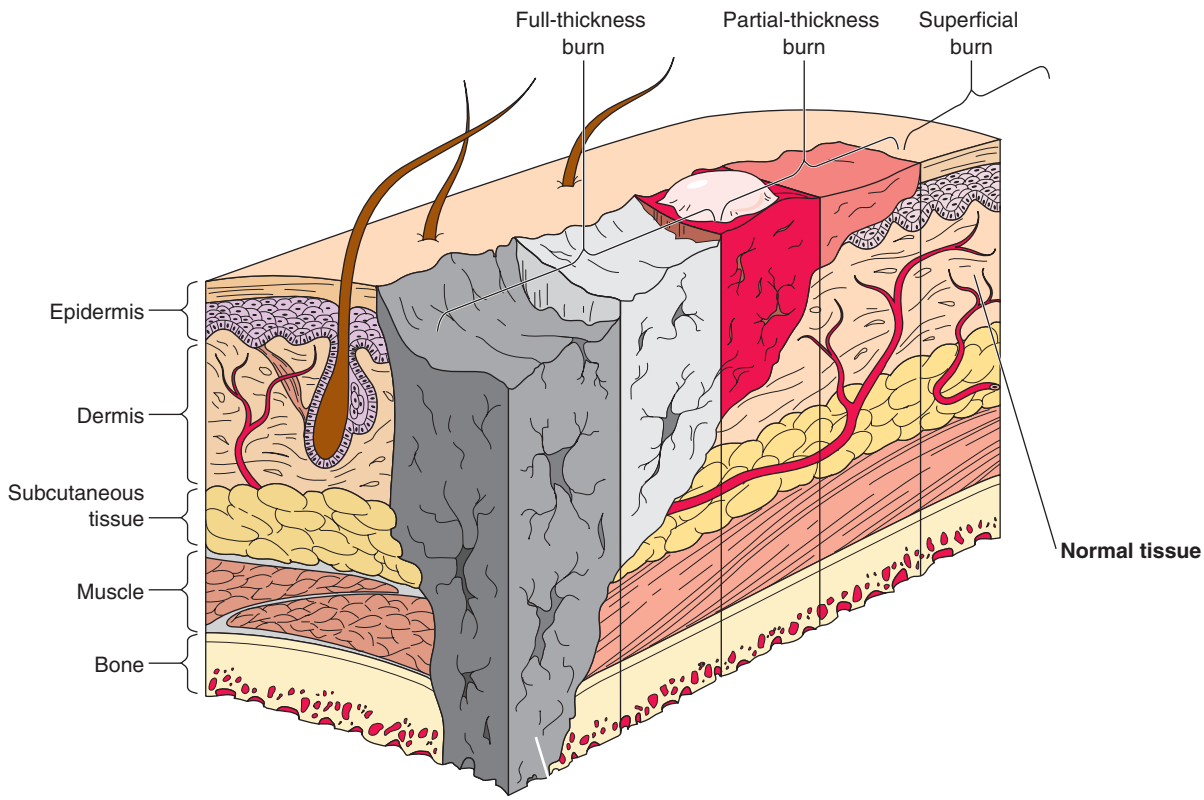

FIGURE 16.1 ■ Burn injury classification according to the depth of the burn

Superficial burns

A **superficial burn** involves only the epidermal layer of the skin (see Figure 16.2). This type of burn most often results from damage from sunburn, ultraviolet light, minor flash injury (from a sudden ignition or explosion) or mild radiation burn associated with cancer treatment. Because the skin remains intact, this degree of burn is not calculated into the estimates of burn injury. Due to the increased blood supply to the area, the erythema ranges from pink to bright red and there may be slight oedema over the burned area. Superficial burns involving large body surface areas may be accompanied by chills, headache, nausea and vomiting. The injury usually heals in 3 to 6 days, with dryness and peeling of the outer layer of skin. There is no scar formation. Superficial burns are treated with analgesia and the application of non-perfumed moisturising ointments and lotions. Extensive superficial burns, especially in infants and older

FIGURE 16.2 ■ Superficial burn injury

Source: Royal Perth Hospital.

people, may require intravenous fluid treatment. Superficial burns can convert to partial-thickness wounds if inappropriate treatment is administered or infection and swelling are untreated.

Partial-thickness burns

Partial-thickness burns may be subdivided into superficial partial-thickness and deep partial-thickness burns. The classification depends on the depth of the burn.

A *superficial partial-thickness burn* involves the entire epidermis and the papillae of the dermis. Causes may include such injuries as brief exposure to a flash flame or dilute chemical agents, or contact with a hot surface. This burn is often bright red, but has a moist, glistening appearance with blister formation (see Figure 16.3). The burned area will blanch on pressure, and touch and pain sensation remains intact. Pain in response to temperature and air is usually severe. These injuries heal within 14 days with minimal or no scarring, but pigment changes are common. Analgesics are administered and the wound will require a dressing. Superficial partial-thickness burns can convert to a deep partial if inappropriate treatment is administered or infection and oedema go untreated.

FIGURE 16.3 ■ Mid-dermal or partial-thickness burn injury

Source: Royal Perth Hospital.

A *deep partial-thickness burn* also involves the entire dermis, but extends further into the dermis than a superficial partial-thickness burn. Hair follicles, sebaceous glands and epidermal sweat glands remain intact. Hot liquids or solids, flash flame, direct flame, intense radiant energy or chemical agents may cause this level of burn injury. The surface of the burn wound can appear pale, blotchy red or mottled, and may be moist or dry. Large, easily ruptured blisters may be present or the blisters may look like flat, dry tissue paper. Capillary refill is decreased, and sensation to deep pressure is present. The burn wound is less painful than a superficial partial-thickness burn, but areas of pain and areas of decreased sensation may be present. Deep partial-thickness burn wounds will take more than 21 days for healing and may convert to a full-thickness injury if necrosis extends the depth of the injury. **Contractures** are possible, as are hypertrophic scarring and functional impairment (see Figure 16.4). Excision and grafting may be necessary to decrease scarring and loss of function.

Full-thickness burns

A **full-thickness burn** involves all layers of the skin, including the epidermis, the dermis and the epidermal appendages (see Figure 16.5). The burn wound may extend to the subdermal level involving the subcutaneous fat, connective tissue, muscle

FIGURE 16.4 ■ Deep partial-thickness burn injury

FIGURE 16.5 ■ Full-thickness burn injury

Source: Royal Perth Hospital.

and bone. Full-thickness burns are caused by prolonged contact with flames, steam, chemicals or high-voltage electric current.

Depending on the cause of injury, the burn wound may appear pale, waxy, yellow, brown, mottled, charred or non-blanching red, and the wound surface is dry, leathery and firm to the touch. Thrombosed blood vessels may be visible under the surface of the wound. There is no sensation of pain on light touch, because pain and touch receptors have been destroyed, although there may be deeper discomfort or pain felt. Full-thickness burns require skin grafting to heal. In dark-skinned people, assessment of burned area should be done with gloved hands assessing for skin turgor and pain. The dead skin of the full-thickness burn wound is called **eschar** (Lewis, Heimbach & Gibran, 2012).

Extent of the burn

Accurate assessment of the extent of burn injury is one of the most important aspects of initial care in the emergency treatment of burn injury.

The extent of the burn injury is expressed as a percentage of the total body surface area (TBSA) or body surface area (BSA) and is determined according to validated guides.

Two of the most commonly used guides to estimate TBSA and extent of burn wound are the Wallace (1951) rule of nines (see Figure 16.6) and the Lund and Browder (1944) burn assessment chart (see Figure 16.7).

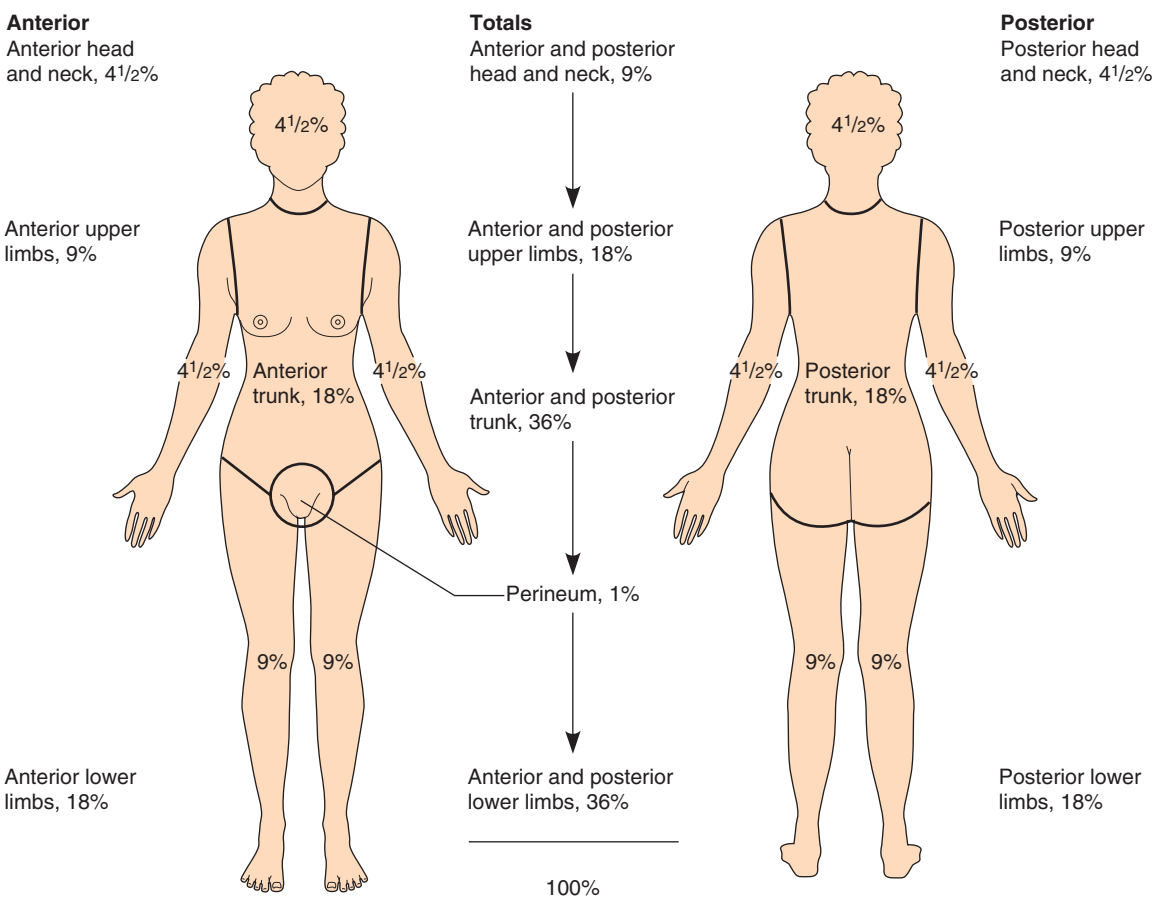

FIGURE 16.6 ■ The rule of nines (Wallace, 1951) is one method for quickly estimating the percentage of TBSA affected by a burn injury. Although useful in emergency care situations, the rule of nines is not accurate for estimating TBSA for adults who are short, obese or very thin, or for children

Area	Age (years)					% 1∞	% 2∞	% 3∞	% Total
	0–1	1–4	5–9	10–15	Adult				
Head	19	17	13	10	7				
Neck	2	2	2	2	2				
Ant. trunk	13	13	13	13	13

					Total				

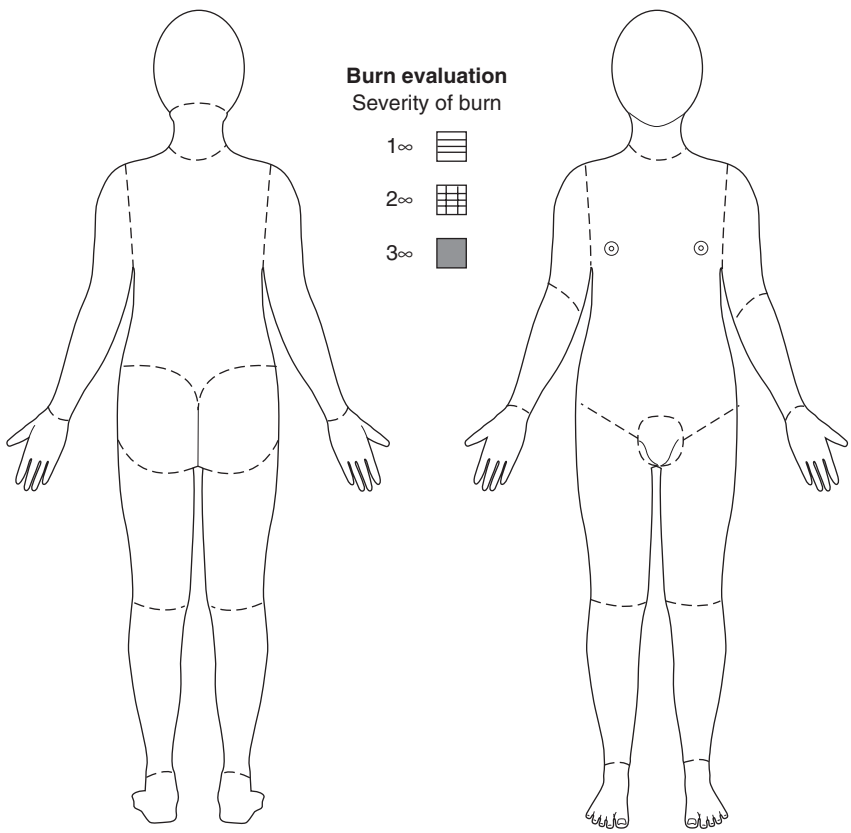

FIGURE 16.7 ■ The Lund and Browder (1944) burn assessment chart. This method of estimating TBSA affected by a burn injury is more accurate than the rule of nines because it accounts for changes in body surface area across the lifespan. As individual burn units may use a modified Lund and Browder chart, practitioners are advised to familiarise themselves with local assessment guidelines

Only partial-thickness and full-thickness burns are included in the estimation; superficial erythema is not classified as a percentage of TBSA. The rule of nines is adequate for initial assessment, but for irregularly shaped burns the palmar surface of the patient's hand (including fingers) is considered 1% TBSA. The percentage of TBSA is reassessed after oedema has subsided and demarcation of zones of injury has occurred. The rule of nines is relatively accurate in adults, but is not suitable for children as children's body surface area proportions differ. Children have relatively large heads and smaller lower bodies than adults. Using the rule of nines on a child could lead to overestimation of TBSA and subsequent inaccurate **fluid resuscitation**. The Lund and Browder burn assessment chart is used for paediatric burn injuries.

The Wallace rule of nines

The Wallace rule of nines divides the surface area of the body into segments of 9%, 18% and 1%.

Head and neck	9% TBSA
Anterior torso	18% TBSA
Posterior torso	18% TBSA
Legs	18% TBSA
Arms	9% TBSA
Groin	1% TBSA

See Figure 16.6 for an example.

Lund and Browder burn assessment chart

Fluid loss in children is proportionally greater than in adults due to their body weight to body surface area ratio. Fluid loss is directly proportional to the burned surface area, so the rule of nines is inadequate in children under 15 years of age (Lee, Norbury & Herndon, 2012). Resuscitation fluid formulae for children are based on body surface area and take into account age, height and weight. This formulae was initially proposed by Lund and Browder (1944) and an assessment chart that takes these factors into account has been named after these practitioners (see Figure 16.7).

For example, a person with burns to the face, anterior right arm and anterior trunk has the following burn injury:

Face = 4.5%
Arm = 4.5%
Trunk = 18%
= 27% TBSA.

Phases of burn management

Management of burn injuries is divided into the resuscitative, acute and rehabilitative phases, although there is overlap of all phased interventions, particularly those involving wound management and rehabilitation:

1. Resuscitative phase:
   - First aid
   - Primary survey
   - Secondary survey.
2. Acute-wound healing phase.
3. Rehabilitative phase.

The resuscitative phase begins at the time of injury and lasts until the fluid resuscitation phase is completed, which usually lasts 48 to 72 hours. The acute-wound healing phase commences as part of the secondary survey. The rehabilitative phase commences on day one; all interventions from first aid through the continuum potentially impact on rehabilitation. The acute-wound healing phase and the rehabilitative phase are discussed in depth later in the chapter (see p. 494).

Resuscitative phase

During this phase, first aid is administered, the size of the burn is calculated, fluid resuscitation is initiated and lifesaving measures are implemented. Of primary concern is the onset of hypovolaemic or **burn shock** and the onset of oedema. The phase ends with the diuresis phase of burn fluid mobilisation. The person is assessed for signs of respiratory distress and shock. Intravenous access is obtained and the person may be prophylactically intubated. A decision should be made as to whether the person requires transfer to a specialist burn centre for complex care (see Box 16.3).

Any concurrent injuries may need to take priority over the burn wound. Communication is vital to the wellbeing of the injured person. All relevant information should be relayed to the receiving hospital, including circumstances surrounding the accident. This is especially important if the person was trapped in an enclosed space or there were chemicals involved or possible trauma (ANZBA, 2013; Knighton & Fong, 2008; Warden, 2012).

FIRST AID At the scene of the burn, priority is given to removing the person from any danger, managing life-threatening conditions and cooling the burn. Rescuers must take care not to be injured as well. Table 16.4 outlines the procedures that must be undertaken at the scene of a burn. For large burns it is not advisable to immerse the whole person in water for cooling, as this will cause too much heat loss. Never put ice in the water as

BOX 16.3 The Australian and New Zealand Burn Association referral criteria for transfer to a burns unit

- Burns greater than 10% of total body surface area (TBSA)
- Burns greater than 4% of TBSA in children
- Burns of specialised areas—face, hands, feet, genitalia, perineum and major joints
- Full-thickness burns greater than 5% of TBSA
- Electrical burns
- Chemical burns
- Burns associated with inhalation injury
- Circumferential burns of the limbs and chest
- Burns in children and older adults
- Burns in people with pre-existing medical disorders that could complicate management, prolong recovery or increase risk of mortality
- Burn injury in pregnant women
- Burns with associated trauma
- Non-accidental burns

Source: Australian and New Zealand Burn Association Ltd (ANZBA) (2013). *Emergency Management of Severe Burns.* Course manual (version 17). © Australian and New Zealand Burn Association Ltd. Reproduced with permission.

TABLE 16.4 First aid procedures at the scene of a burn

Electrical burn	Switch off power. Remove the person from the source of electricity using a non-conducting object; preferably by a trained person. Put out flames if the person has sustained a flame injury as well. Begin primary survey. Protect cervical spine. Ensure rescuer safety. Remember high-voltage electricity will discharge through air.
Chemical burn	Brush residual dry chemical from person. Copious irrigation of area 'to the floor' with water. Ensure rescuer safety. Observe for signs of hypothermia. Begin primary survey.
Flame burn	Stop, drop and roll. Extinguish flames, remove clothing if possible and restrictive jewellery. Irrigate under cool, clean water for at least 20 minutes. If water for copious cool-water irrigation is not available, apply cool wet towels and change when they become warm. Observe for hypothermia. Ensure rescuer safety. Begin primary survey.
Scald	Remove clothing where possible. Irrigate with copious cool, clean water for at least 20 minutes. If water for copious cool-water irrigation is not available, apply cool wet towels and replace when they become warm. Observe for signs of hypothermia.

Source: Australian and New Zealand Burn Association (ANZBA) (2013). *Emergency Management of Severe Burns.* Course manual (version 17). © Australian and New Zealand Burn Association Ltd. Reproduced with permission.

this can cause cold injuries. Remove as much burned clothing as possible and replace with a clean sheet. Cover the person with a blanket to keep them warm.

PRIMARY SURVEY Life-threatening issues are identified and commencement of emergency management is done in this phase. The ABCDEF acronym (see Table 16.5) provides a guide to emergency resuscitative interventions (ANZBA, 2013).

SECONDARY SURVEY This phase is a head-to-toe examination commencing after any life-threatening conditions are dealt with. Secondary survey commences after the primary survey has been completed and the person is stabilised. It includes a comprehensive assessment of the person and records their allergies, medications, health history, the last time they ate and the events surrounding the incident. Identification of the mechanism of injury is vital, and the presence of any penetrating wounds or blunt trauma needs to be ascertained.

CONSIDERATION FOR PRACTICE

Narcotics are always administered intravenously, rather than orally, subcutaneously or intramuscularly in the resuscitative or acute phase of a burn due to decreased circulation and absorption of medications.

PREPARATION FOR TRANSFER TO A BURNS UNIT

Once the referral criteria for transfer to a specialised burns unit have been met (see Box 16.3), preparation of the stabilised person for transfer to that unit involves the following measures and interventions. The following points are covered as part of the primary and secondary survey:

1. *Respiratory system.* Establish and maintain airway; administer humidified 100% oxygen. Consider the need for endotracheal intubation (before transfer) if there is a possibility of upper airway obstruction. Transfer

TABLE 16.5 Emergency resuscitative interventions—ABCDEF

PROBLEM	INTERVENTION
Airway	Check for patency, soot around mouth and nares, singed nasal hairs. Use cervical spine precautions at all times. Injuries above the clavicles or facial injuries can indicate spinal injuries.
Breathing and ventilation	Assess chest movement to ensure chest is rising equally. Administer humidified 100% oxygen. Ventilate with bag and mask if necessary; prepare for possible intubation. Assess for carbon monoxide poisoning (i.e. decreased conscious level, cherry red appearance). Respiratory rate of over 20/minute is not necessarily a good thing. Circumferential chest burns can restrict air entry. Non-circumferential full-thickness torso burns can also restrict air entry.
Circulation	Check for strength, regularity and presence of pulses. Capillary refill of nail beds should be 2 seconds. Longer capillary refill times could indicate hypovolaemia, hypothermia or the need for escharotomies. Stop any bleeding. Elevate any burned or oedematous limb above the level of the heart if not contraindicated. Electrical burns should be monitored for cardiac complications.
Disability and neurological status	Establish level of consciousness using Glasgow Coma Scale. Examine pupil reaction to light. Hypoxia and shock can cause restlessness and decreased level of consciousness.
Exposure and environment	Remove all jewellery and burned clothing. Prevent hypothermia. If clothing is stuck, trim loose pieces.
Fluid resuscitation	Insert two large-bore cannulae into non-burned tissue. Take blood specimen for crossmatching. Commence intravenous fluids as per formula.

Philadelphia: Saunders.

the person with their head elevated unless contraindicated (for instance, associated spinal injuries) as this will help decrease swelling and aid breathing.

2. *Circulation.* Insert two large-bore intravenous cannulae (size 16 for adults, size 20 for children) through non-burned skin where possible. Maintain resuscitation fluid as per formula for burn resuscitation. All limbs that are burned should be elevated where not contraindicated and cervical spine precautions maintained at all times.
3. *Urinary output.* Insert an indwelling catheter for burns above 10% TBSA in children and above 15% to 20% TBSA in adults or in burns of genitalia. Maintain urine output at:
   - adults 0.5 mL/kg/hr = 30–50 mL/hr
   - children (< 30 kg) 1.0 mL/kg/hr (range 0.5–2 mL/kg/hr).
   - Accurate fluid balance monitoring is the most effective way of determining adequacy of fluid resuscitation measures. In the case of an electrical injury, urine should be maintained at 1.0–2.0 mL/kg/hr. Weighing of nappies for children is not an accurate assessment of urine output.
4. *Wound management.* Wash the burn area with chlorhexidine 4% or normal saline and then cover with a clean dry sheet or, if possible, a silver-impregnated dressing. In remote Australian regions, time delays in transferring people to a burns unit may be prolonged. The use of cling wrap products is not advised as they can cause retention of heat in the burn; the application of a silver-impregnated dressing (e.g. Acticoat®) is preferred if transfer is to be delayed over 2 hours from the time of injury.
5. *Analgesia.* Liaise with burns unit as to the preferred protocol for analgesia administration, particularly if children are involved. Oral analgesia is not recommended except in minor burns. Narcotic analgesia given intravenously is essential for the person's comfort. Monitoring of level of consciousness, respiratory status and effectiveness of analgesia should be maintained.
6. *Gastrointestinal system.* Insert a nasogastric or orogastric tube in a person who has sustained a burn of >15% TBSA in adults and >10% TBSA in children. This is to decrease the risk of vomiting and potential aspiration. If the transfer of the person is delayed, this intervention also allows for enteral feeding, if required and following consultation with the burns unit team.
7. *Tetanus status.* Tetanus prophylaxis is recommended for all people who sustain a burn injury. A correct history should be taken where possible to ascertain if a booster or immune globulin is required (Allison & Porter, 2004; Mlcak, Buffalo & Jimenez, 2012).

Acute wound healing phase

The acute wound healing phase commences as part of the secondary survey and is discussed in depth later in the chapter.

Rehabilitative phase

The rehabilitative phase also commences on day one. All interventions from first aid through the continuum potentially impact on rehabilitation. This is discussed later in the chapter.

BURN WOUND HEALING

Minor burns heal via spontaneous regeneration and repair, while major burns will require surgical debridement, skin grafts or flaps. The healing process involves three phases: inflammation, reconstruction and remodelling. The degree of injury will influence the nature of healing and the amount of regeneration and repair that will occur (Porth & Matfin, 2009).

- *Inflammation*. Immediately following the injury, platelets coming in contact with the damaged tissue aggregate. Fibrin is deposited, trapping further platelets and a thrombus is formed. The thrombus, combined with local vasoconstriction, leads to haemostasis, which inhibits bleeding.

  Local vasodilation and an increase in capillary permeability follow haemostasis. Neutrophils infiltrate the wound and peak in about 24 hours, and then monocytes predominate. The monocytes are converted into macrophages, which consume pathogens and dead cells and also secrete various growth factors. These growth factors stimulate the proliferation of fibroblasts and the deposit of a provisional wound matrix.
- *Reconstruction.* Within 2 to 3 days post burn, fibroblasts are the major cell within the wound. Their number peaks at about 14 days after the injury. Granulation tissue begins to form, with complete re-epithelialisation occurring during this phase. Epithelial cells cover the wound, as each cell stretches across the wound surface to join with other epithelial cell sheets on the other side of the wound. The proliferation phase lasts until complete re-epithelialisation occurs, by epithelial cell migration, surgical intervention or a combination of the two.
- *Remodelling or maturation*. This phase may last for years. Collagen fibres, laid down during the proliferative phase, are reorganised to improve the tensile strength of the wound. Scars contract and fade in colour. In normal healing following a superficial minor burn injury, the newly formed skin closely resembles its neighbouring tissue. However, when a burn injury extends into the dermal layer of skin, two types of excessive scar may develop. A **hypertrophic scar** is an overgrowth of dermal tissue that remains within the boundaries of the wound. A **keloid** is a scar that extends beyond the boundaries of the original wound. People with dark skin, such as Indigenous Australians, Pacific Islanders, Asian, African and Middle Eastern populations, are at greater risk of hypertrophic scars and keloids.

The length of time a wound takes to heal influences scar formation. Time to healing is an outcome measure for treatment effectiveness, regardless of treatment choice. Healing after a 2-week period is known to be a predictor of hypertrophic scarring. Surgery may be needed to speed up healing time to minimise scarring. All wound management decisions should focus on achieving re-epithelialisation within 2 weeks of the burn injury.

Post-burn itch

Although the exact cause of post-burn itch is not known, it is considered to be due to both peripheral and central mechanisms. Mediators which relay itch sensations peripherally are released when keratinocytes are damaged. These mediators include

histamine, interleukins, protease-activated receptors and nerve growth factors. Itch is a common and disruptive part of burn injury. It can start in the first 2 weeks after the burn and can last for a long time. Itch can lead to further damage to fragile skin as the person scratches in an attempt to relieve the itch. Consensus on successful treatment of the pruritus is scarce in the literature; however, there are a number of pharmacological and non-pharmacological treatments employed. Oral and topically applied antihistamines are commonly used. Non-pharmacological treatments include massaging the scar or healed burned area. Colloidal oatmeal baths and shower washes are also recommended, along with ice packs and instructions for keeping the area cool. Treatment of itch should be as much a priority as treatment of pain. Further research into the causes and treatment of post-burn itch is required (Bell & Gabriel, 2009).

THE PERSON WITH MINOR BURNS

Minor burn injuries consist of superficial burns that are not extensive, and superficial partial-thickness burns that involve less than 10% of TBSA, excluding the special care areas (eyes, ears, face, hands, feet, perineum and joints). Minor burns can also be a small area of full-thickness eschar that is to be treated conservatively rather than with surgical debridement. Minor burn injuries are not associated with immunosuppression or hypermetabolism.

People with a minor burn injury are usually treated as an outpatient. The goal of therapy is to promote wound healing, eliminate discomfort, maintain mobility and prevent infection.

Pathophysiology

Sunburn

Sunburns result from exposure to ultraviolet light. Such injuries, which tend to be superficial, are more commonly seen in people with lighter skin. Because the skin remains intact, the manifestations in most cases are mild and are limited to pain, nausea, vomiting, skin redness, chills and headache. Treatment is performed on an outpatient basis and generally consists of applying non-perfumed lotions, increasing fluid intake, administering mild analgesics and maintaining warmth. Older people should be monitored for evidence of dehydration. Proper use of sunscreen and limiting sun exposure to the less hazardous hours of the day can prevent sunburn.

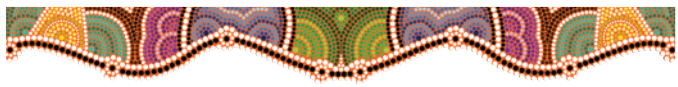
Scald burn

Scald burns result from exposure to moist heat, and the depth of a scald depends on the temperature of the water, the thickness of the skin and the duration of contact. Water at 60°C from fluids such as hot coffee or soup can cause deep partial-thickness burns.

For scalds that are minor, the person can be treated as an outpatient with appropriate dressings and analgesia to allow for a full range of movement and to keep them comfortable. Tetanus toxoid prophylaxis is administered as appropriate.

Contact burn

Contact burns usually result from hot metals, plastics, hot footpaths or motorbike exhaust pipes. They are usually small in circumference, but can be deep partial thickness. Treatment may include dressings and/or surgery. Tetanus toxoid prophylaxis is administered as appropriate. Burns from sun-heated surfaces are not uncommon. Children and adults with diabetes are particularly susceptible. The focus for these kinds of burns should be on prevention and education of vulnerable people (Asquith, Kimble & Stockton, 2014).



Nursing care

Management of a minor burn

Regardless of the care setting, the principles of management are the same. The aim is to promote wound healing and prevent infection while maintaining a full range of movement. Adequate analgesia should be prescribed to keep the person comfortable and to enable the person to maintain full range of movement.

Nursing care includes taking a comprehensive history of the incident and health history, administration of prescribed analgesics, ongoing wound assessments, wound care planning, referrals for physiotherapy and/or occupational therapy and arranging follow-up appointments. Initially, the wound is washed using chlorhexidine liquid soap, or a mild soap if this isn't available. Remove any loose, non-viable skin with sterile scissors.

Deroof blisters where necessary and in accordance with hospital policy as blisters that extend over a joint can decrease function and movement. Blister fluid can also cause pressure over the wound bed, which compromises perfusion and increases pain. If blisters are on the pads of fingers or toes they may be debrided on day 3 or 4 post burn injury, but should be slit to release fluid and decrease pressure on first presentation (Sargent, 2006).

Once the burn has been cleaned and the non-viable tissue removed a more thorough assessment can be made of the wound. Wounds with a pink wound bed, free of slough or eschar, are likely to be superficial or superficial partial thickness and should heal within 7 to 14 days and leave no permanent scarring. It should be noted that infection, poor dressing choice and oedema can cause the burn to convert to a deeper burn. Superficial burns where there is no skin loss may only require non-perfumed moisturising creams. A plethora of wound dressings are used in the treatment of burns, and individual health agencies and burn health professionals will have preferred protocols.

Hydrocolloids are a suitable choice for the low-to-moderate exudating superficial/partial-thickness wounds. They are not suitable for wounds with a large amount of exudate as maceration may occur with the accumulation of exudate. Hydrocolloids are waterproof and for this reason a good choice for an outpatient. Dressing changes are required every 3–4 days depending on the amount of exudate.

Calcium alginates are useful for moderate-to-highly exudating wounds but require a secondary dressing. Alginates require dressing changes every 2–4 days, depending on the amount of exudate, and can be removed in the shower or bath if they have dried out.

Foams are a suitable choice for superficial/partial and deep partial burns if there are moderate-to-high amounts of exudate. Foams are used in conjunction with a hydrogel on full-thickness burns in order to assist debridement of eschar. Foams come in adhesive and non-adhesive forms.

Hydrogels are a suitable choice for low-exudating wounds or wounds with dry eschar as they help to maintain a moist wound environment and assist in debridement of slough and eschar. Hydrogels are available in amorphous gels, or gel-impregnated gauzes or sheets.

Antimicrobial dressings will be required if infection is suspected or confirmed.

Community-based care

The nurse should address the following topics to facilitate self-care at home of minor burns.

- Educate the person and carer about the signs and symptoms of infection—that is, increase in pain, swelling and redness of the wound area. Provide instructions on:
  - how to care for the wound and dressing
  - how to take prescribed analgesia correctly and effectively
  - contact details for a clinic or a burns unit in case of any problems or concerns
  - how to change dressings if needed and equipment to do so
  - non-pharmacological pain-relieving measures—for example, elevation of the limb when sitting.

THE PERSON WITH MAJOR BURNS

The Australian and New Zealand Burn Association (ANZBA) identifies a major burn as above 15% to 20% TBSA in adults (in older adults or the infirm 15% TBSA) or above 10% TBSA in children. In addition, burns of certain anatomical sites, such as the perineum, or those that occur as a result of certain agents, require specialised burn treatment and consultation should be sought (see Box 16.3).

Pathophysiology

There is a local and a general response to a burn injury. The local response is explained by Jackson's zones of burn injury model (1950) (see Figure 16.8). The general response is a multi-system response that requires specialised care in order to preserve life and result in the best possible outcome for the person.

The pathophysiological changes that result from major burn injuries involve all body systems. Extensive loss of skin (the body's protective barrier) can result in infection, fluid and electrolyte imbalances, and hypothermia. Cytokines and other mediators are released into the systemic circulation causing a systemic inflammatory response. If the person inhales the products of combustion, an inhalation injury can result, thus compromising respiratory function. Cardiac arrhythmias and circulatory failure are potential complications of serious burn injuries. A hypermetabolic state dramatically increases kilojoule expenditure and nutritional deficiencies. The increase in metabolic rate can last for up to 1 year post injury (Bourdeaux & Manara, 2008). An alteration in gastrointestinal motility predisposes the person to developing paralytic ileus, and hyperacidity can lead to gastric and duodenal ulcerations. Translocation of gut bacteria due to increased permeability can lead to infection. The person is centrally dehydrated, so glomerular filtration rates and renal clearance of toxic wastes are less effective; this can result in acute tubular necrosis and renal failure. Systemic responses to burns are outlined below.

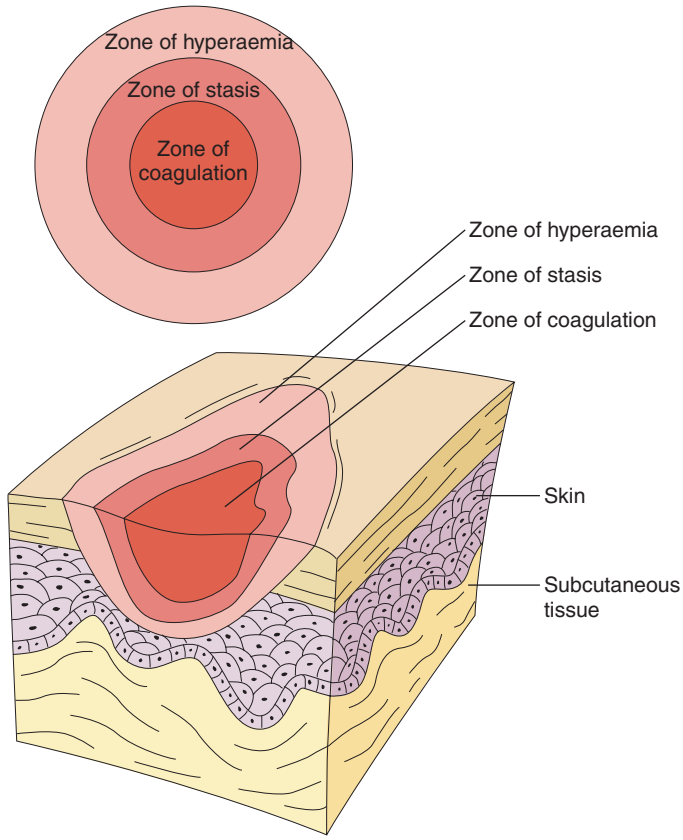


FIGURE 16.8 ■ The Jackson zones of burn injury (Jackson, 1950)

Source: Adapted from D. M. Jackson (1950). The diagnosis of the depth of burning. *British Journal of Surgery*, *40*(164), 588–596.

Integumentary system

The loss of skin in burn injuries interrupts normal skin functions and its protective mechanisms (see Chapter 14). Key mechanisms lost in burn injuries include the prevention of evaporative water loss, protection against bacteria and the maintenance of body warmth.

Heat transfer to skin is a complex phenomenon. If the microcirculation of the skin remains intact during burning, it cools and protects the deeper portions of the skin and cools the outer surface once the heat source is removed. When extensive burn injury occurs, the integrity of the microcirculation is lost and the burning process continues even after the heat source is removed.

JACKSON'S ZONES OF BURN INJURY Jackson (1950) proposed three concentric zones of burn injury. The zones are three dimensional and damage to the zone of stasis can lead to conversion to a deeper burn.

It is important to understand the pathophysiology of a burn in order to treat the person effectively (see Figure 16.8). Different causes of burns require different treatment.

- The outermost zone of hyperaemia affects only the epithelium; there is no skin loss. In this zone, tissue perfusion is increased, giving rise to the reddened erythema appearance. This zone usually heals within 7 days unless there is trauma to the area, infection or oedema, which can cause a conversion to a deeper burn.
- The medial zone of stasis is initially moist, red and blistered, and blanches on pressure. Tissue perfusion is decreased in this zone. It may recover or become pale and necrotic as a result of inadequate fluid resuscitation, infection, trauma, oedema or poor wound management.
- The inner zone of coagulation is the area of most damage. There can be no reversal of necrosis. Proteins are coagulated and the burn has a 'leathery' appearance (Bourdeaux & Manara, 2008; Singh et al., 2007).

The overall thickness of the dermis and epidermis varies considerably from one area of the body to another and is subject to the individual's age. Similar temperatures produce different depths of injury to different body parts. For example, in the adult, skin covering the medial aspect of the forearm is thinner and more easily damaged than the skin covering the back of the same person. Skin dissipates heat maximally in areas of greatest vascularisation. When heat absorption exceeds the rate of dissipation, cellular temperatures rise and skin tissue is destroyed.

The deep burn injury results in the formation of necrotic skin and damage to subcutaneous tissue. During the acute phase of the injury a hard crust (eschar) forms which covers the wound. The eschar is characteristically leathery and rigid. Removal of the eschar is required if healing is to be facilitated. In a partial-thickness and deep partial-thickness wound, slough (moist non-viable tissue) covers the wound surface, which also needs to be debrided to facilitate healing.

Hypovolaemic shock

Fluid and electrolyte shifts in burn injury result in the movement of large amounts of fluid from the intracellular and intravascular compartments into the interstitial spaces. This results in hypovolaemia and oedema of the burn area. It is this fluid shift that causes hypovolaemic shock, which is also referred to as 'burn shock' (see Figure 16.9). Inflammatory mediators and stress hormones are released and start a cascade of events that, if left untreated, can lead to multi-organ failure.

Shock is the inability of the body to adequately deliver oxygen and nutrients to the body and remove cellular waste. Symptoms of hypovolaemic shock are similar to those of shock following haemorrhage: decreased blood pressure, cardiac output, urine output and plasma volume, and an increase in pulse rate along with an increase in systemic vascular resistance leading to decreased peripheral blood flow. Haematocrit and haemoglobin are elevated despite adequate fluid resuscitation due to the haemoconcentration of intravascular fluid. Red blood cells are haemolysed as a result of the burn and inflammatory mediators are released after a major burn injury. After fluid balance is restored, haematocrit levels usually return to normal.

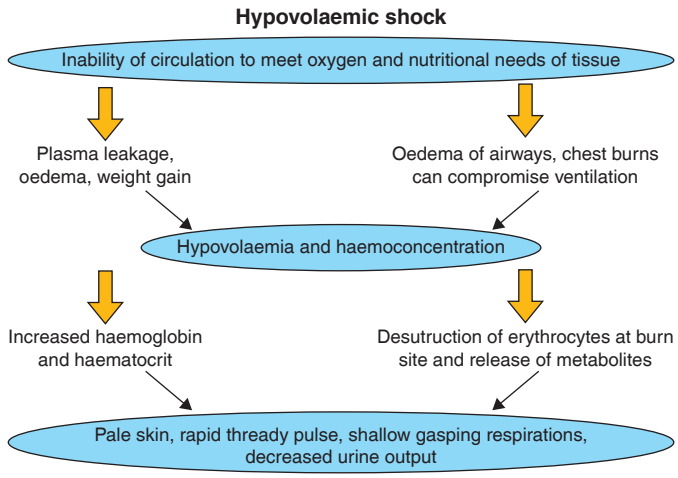

FIGURE 16.9 ■ Hypovolaemic shock algorithm

Source: Royal Perth Hospital.

Water, sodium and protein (albumin) leak through the less selectively permeable membranes of vessels to the interstitial spaces, causing oedema in non-burned tissue. There is also insensible fluid loss through the body surfaces that have been burned. Blisters and wound exudate are a result of this fluid shift. Potassium and sodium also move from the vessels and remain until the fluid shift resolves. Haemolysed red blood cells release potassium into the extracellular spaces (Knighton & Fong, 2008).

Towards the end of the resuscitative phase, as long as fluid replacement has been adequate, the membranes become selectively permeable again and leakage stops. Fluid is reabsorbed from the interstitial compartments into the intravascular compartment. The blood pressure rises as cardiac output increases and urinary output improves. This is usually around 24 hours post burn. This stage is known as the diuresis phase, with low specific gravity of urine. Potassium is slow to return to normal and hypokalaemia can occur, depending on the amount of potassium lost to the vascular space. Sodium can remain low due to sodium loss via the urine. The person is discouraged from drinking water and further depleting their sodium levels. During the diuresis phase the extra cardiac workload may predispose the older person or the person with cardiovascular disease to fluid volume overload. It is essential that the person is monitored and intravenous fluid is decreased and titrated to urine output and specific gravity.

Cardiovascular system

Major burns are manifested by widespread effects on the cardiovascular system. Increased vascular permeability and myocardial dysfunction as well as hypovolaemic shock, if left untreated, can result in a hyperdynamic/hypermetabolic state with an increased oxygen consumption. Improving cardiac output and oxygen delivery during the fluid resuscitation phase greatly improves the chances of survival (Jandziol & Hayes, 2008). Circumferential burns and oedema reduce blood flow to the extremities and if not treated can lead

to necrosis of a limb or digit. An escharotomy may be performed to a limb or the torso when there are circumferential burns. This should be done in consultation with the burns surgeon. Blood viscosity is initially increased due to cell destruction and fluid shifts within the body. Damage to skin structures results in microcirculation impairment.

CARDIAC RHYTHM ALTERATIONS Burns of more than 40% TBSA cause significant myocardial dysfunction, with a decrease in myocardial contractibility and cardiac output. These changes, which occur prior to a decrease in plasma volume, are believed to be due to the release of mediators, hormones and oxygen free radicals as a result of the burn and from ischaemic myocardial cells. Electrical burns often result in cardiac arrhythmias or cardiopulmonary arrest caused by heat damage to the myocardium or electrical interference with cardiac electrical activity (Jandziol & Hayes, 2008).

PERIPHERAL VASCULAR COMPROMISE Circumferential burns to the torso or extremities can result in **compartment syndrome** as a result of progressive development of arterial compression resulting in decreased blood supply to the area. Circulation to the extremities may be further impaired by oedema formation, inadequate fluid resuscitation and constrictive dressings or bandages. Limbs with circumferential burns should be elevated when not contraindicated and people with torso burns should be monitored for respiratory difficulties. Escharotomy may be required after consultation with the burn surgeon.

Respiratory system

Pulmonary damage may result from either direct inhalation injury or as part of the systemic response to the injury. The injury may range from mild respiratory inflammation to massive pulmonary failure, such as acute respiratory distress syndrome. Exposure to heat, toxic by-products of burned substances—for example, plastics—and smoke initiates the pathophysiological process associated with inhalation injury.

Inflammation occurs at localised sites within the airway and is manifested as hyperaemia. As a result, cells are destroyed and the bronchial cilia are rendered inactive. Because the mucociliary transport mechanism no longer functions, the person may develop bronchial congestion and infection.

Interstitial pulmonary oedema develops secondary to the escape of fluid from the pulmonary vasculature into the interstitial compartment of the lung tissue. Surfactant is inactivated, resulting in atelectasis and alveolar collapse. Sloughing of the damaged and dead lung tissue occasionally produces debris that may lead to complete airway obstruction.

Upper airway (above the level of the larynx) thermal injury results from the inhalation of hot gases, steam or vapours from chemicals dissolved in water. Generally, they occur when the person has been in an enclosed space. Inhalation injury is suspected when the person has singed facial, scalp or nasal hair. Physical findings include the presence of soot, charring, oedema, blisters and ulcerations along the mucosal lining of the oropharynx and larynx. The changes to tissue are the same as for thermal burn and severity is proportional to the length of exposure, type of chemical or temperature/pressure of steam. The resulting oedema in the airway may peak within 12 to 36 hours post injury (Bourdeaux & Manara, 2008).

Signs of increasing respiratory distress include hoarseness, laboured breathing and stridor. Inflammatory mediators cause oedema and respiratory obstruction can develop. The oedema will occur despite adequate fluid resuscitation measures. If there is also skin burn to the neck the swelling from this burn can further impede breathing.

The lower airway is protected very efficiently by laryngeal reflexes, so thermal injury below the larynx is not common and is usually only after exposure to extreme heat. However, when it does occur, it is typically associated with the inhalation of the products of combustion. Products containing sulfur, phosphorus or nitrogen, and compounds containing carbon, produce toxic by-products such as hydrogen chloride, hydrogen fluoride and ammonia. Acids and alkalis are released when these compounds come into contact with the moist respiratory mucosa, resulting in chemical burns. A classic finding is sputum containing soot or carbon particles which can damage alveoli (ANZBA, 2013; Bourdeaux & Manara, 2008).

Carbon monoxide, a common asphyxiate, is a colourless, tasteless, odourless gas that has a 200 times greater affinity for haemoglobin than does oxygen. It displaces oxygen to bind with haemoglobin, forming carboxyhaemoglobin. As a result, the decrease in arterial oxyhaemoglobin produces tissue hypoxia. Carbon monoxide impairs both oxygen delivery and cellular oxygen use. The clinical manifestations of carbon monoxide poisoning range from mild visual impairment to coma and death (see Table 16.6). Carbon monoxide poisoning should be suspected if the burn was in an enclosed space and the person is unconscious (Bourdeaux & Manara, 2008; Kealey, 2009).

Cyanide gas is released when plastics, polyurethane, nylon or silk are burned. The resultant production of cyanide gas affects cellular respiration. The brain and heart are most vulnerable to cyanide poisoning. Cyanide directly interferes with a cell's ability to utilise oxygen in metabolism. Cyanide poisoning should be suspected when the person shows signs of lactic acidosis regardless of adequate fluid resuscitation.

TABLE 16.6 Carbon monoxide intoxication

CARBOXYHAEMOGLOBIN (%)	SYMPTOMS
0–15	None (smokers, long-distance truck drivers)
15–20	Headache, confusion
20–40	Nausea, fatigue, disorientation
40–60	Hallucination, ataxia, syncope, convulsions, coma
> 60	Death

FAST FACTS

Manifestations of cyanide poisoning

- Headache
- Dizziness
- Seizures
- Tachycardia
- Fatal arrhythmias

Gastrointestinal system

Major burns cause a generalised response in the body that affects all organs, including the gastrointestinal tract. Blood flow to the gut is decreased as part of the effect of hypovolaemic shock. Translocation of gut bacteria due to the disruption of the mucosa increases the risk of sepsis in the person with burns. This process is believed to be one of the mechanisms causing systemic sepsis and multiple-organ dysfunction syndrome (Magnotti & Deitch, 2005).

Other effects include malnutrition, hypermetabolism and splanchnic hypoperfusion as a result of intravascular fluid loss. Early enteral feeding can influence some of the gastrointestinal problems, including prevention of paralytic ileus and stress gastritis. The hypermetabolic response can lead to a catabolic state, which further decreases wound healing and increases the risk of infection. Maintaining blood flow to the gut is vital in preventing multi-organ failure. Maintaining the body's haemodynamics through fluid resuscitation is imperative to support gut blood flow (Singh et al., 2007).

Stress ulcers, also known as **Curling's ulcers**, are acute ulcerations of the stomach or duodenum that may form following the burn injury. Abdominal pain, acidic gastric pH levels, haematemesis and malaena may indicate a gastric ulcer. However, this is a less common presentation in contemporary medicine with the advances in burn management and the implementation of fluid resuscitation, early enteral feeding and antacids (Colon, Schlegel & Chung, 2012).

Urinary system

During the early stages of the burn injury, renal blood flow and glomerular filtration rates are greatly reduced as a result of the decreased intravascular blood volume and the release of antidiuretic hormone by the posterior pituitary. Urine output decreases and serum creatinine and blood urea nitrogen increase.

Dark-brown concentrated urine may indicate myoglobinuria or haemoglobinuria, the result of underlying muscle damage or the release of large amounts of dead or damaged erythrocytes after a major burn injury, particularly following an electrical injury. When large amounts of these pigments are released, the liver cannot keep pace with conjugation and the pigments pass through the glomeruli. The pigments can occlude the renal tubules and cause renal failure, especially when dehydration, acidosis or shock is also present. Adequate fluid resuscitation aims to prevent renal tubule damage as well as renal failure. An indwelling catheter is inserted to enable accurate monitoring of urine output.

Immune system

Major burn injury can cause impairment of the immune system. The protection function of the skin is compromised, particularly in burns where there is a large TBSA. The amount of circulating immunoglobulin is decreased and the WBC function is also impaired. Part of the cascade of events that occurs following a major burn injury is the release of inflammatory cytokines. This release impedes the normal function of neutrophils, monocytes and lymphocytes. This series of events increases the person's risk of infection.

Metabolism

Major burns induce high energy expenditure, mediated by increased production of catecholamines, glucocorticoids and glycagon (Bonet, Marquez & Seron, 2011). The body's high demand for energy cannot be fully reversed despite adequate nutrition and medical management. Hyperglycaemia is also common, with evidence suggesting that pharmacological management of elevated blood glucose levels is required.

Two distinct phases characterise the body's metabolic response to the burn injury. The ebb phase is manifested by decreased oxygen consumption, fluid imbalance, shock and inadequate circulating volume. The gut function also slows down.

A second phase, the flow phase, occurs when adequate burn resuscitation has been accomplished and is dependent on adequate metabolic response mediated by adrenal cortical steroids.

This phase is characterised by increases in cellular activity and protein catabolism, lipolysis and gluconeogenesis. Hypermetabolism persists until after wound closure has been accomplished and may reappear if complications occur (Cochran, Jeschke & Collins, 2013).

CONSIDERATION FOR PRACTICE

An increased body temperature, without other manifestations of infection, is not indicative of infection in people with large burn wounds (in which the hypermetabolic response resets the core temperature to a higher level).

INTERPROFESSIONAL CARE

The burn team is composed of an interprofessional group of healthcare providers who together plan and implement the treatment of the burn-injured person during the acute and rehabilitative phases. The burn team consists of the nurse, physician and/or surgeon, physiotherapist, dietitian, occupational therapist, clinical psychologist and social worker. The team members meet regularly to discuss person progress and to determine collaboratively the most effective regimen of care and psychosocial support.

Phases of interprofessional care

As outlined earlier in this chapter, the clinical course of treatment for the burn person is divided into three phases, which overlap and begin on the day of the burn injury; they are the resuscitative phase, the acute wound healing phase and the rehabilitative phase.

Although these phases are useful predictors of the clinical needs of the burned person, it is important to recognise that the process of burn injury is dynamic and that the clinical phase is not clearly delineated. Assessment and management of the

burn-injured person are ongoing processes determined by the clinical picture; they last throughout the course of treatment. During each phase, different groups of nurses, medical practitioners and other healthcare specialists collaborate to manage the person's recovery.

Although many burn injuries are treated in local healthcare facilities, in many healthcare organisations throughout Australia there are guidelines for determining whether the person should be transported to a burns centre for interdisciplinary approaches to treatment and rehabilitation (see Box 16.3).

The resuscitative phase has already been discussed on previous pages. It includes pre-hospital care.

ACUTE WOUND HEALING PHASE The acute phase begins with the start of diuresis and has no defined end point as each person requires individual goal settings to determine progress. During this phase, wound care management, nutritional therapies and measures to control infectious processes are initiated. Excision and grafting of any wounds that require surgery is performed as soon as possible after injury. Enteral nutritional feeding to address kilojoule needs resulting from extensive energy expenditure are started in the resuscitative phase and continue through to discharge—and beyond, for some people. Measures to combat infection are implemented from the day of the burn injury and must continue until the wounds are healed.

Pain management constitutes a significant segment of the care plan throughout the clinical course of the burn-injured person. Adequate analgesia must be prescribed and given on a regular basis to maximise person comfort and to reduce the anxieties associated with wound debridement and intensive physiotherapy (Patterson, Tininenko & Ptacek, 2006).

REHABILITATIVE PHASE The rehabilitative phase begins on the day of the burn injury and ends when the person returns to the highest level of health and function they can achieve. During this phase, the primary focus is the biopsychosocial adjustment of the person, specifically the prevention of contractures and scars. The person's successful resumption of work, family and social roles is facilitated through physical, vocational, occupational and psychosocial rehabilitation. The person is taught to perform range-of-motion exercises to enhance mobility and support injured joints.

It is imperative to remember that while there have been three phases of interprofessional care identified, collaborative discharge planning commences on the day the person is admitted to the burns unit. No interprofessional team role is more important than another.

Fluid resuscitation formula

Fluid resuscitation is the administration of intravenous fluids to restore the circulating blood volume during the first 24 hours post burn injury. The ANZBA guidelines (2013) state that a burn injury of 20% TBSA and over results in a generalised sequestration of large amounts of fluid from the intravascular space to the interstitial spaces. Combined with oedema and insensible loss, plasma volume is depleted, resulting in intravascular hypovolaemia; left untreated, this can end in multi-organ failure.

Several formulas may be used to replace fluid loss. The ANZBA (2013) recommends the use of the Parkland (Baxter) formula (see Box 16.4).

Respiratory management

On admission to the emergency department, several baseline assessments of respiratory status must be obtained: chest x-ray study, arterial blood gases (ABGs), vital signs and carboxyhaemoglobin (COHb) levels, which should be ascertained from arterial blood. A portable breath analyser can be us d to detect carbon monoxide levels. It is important to remember that high oxygen concentrations have usually been administered in transit and so accurate levels of COHb are difficult to assess. Preparation for possible intubation should always be done in case of airway obstruction. The primary treatment plan is oriented towards preventing

BOX 16.4 Calculation of Parkland formula

Formula

2–4 mL Hartman's solution × kg (body weight) × %TBSA = total fluid requirements for first 24 hours after burn (commencing from time of injury)

Give:

½ (50%) total over first 8 hours

¼ (25%) total over next 8 hours

¼ (25%) total over next 8 hours (makes a total of a 24-hour period)

Example

For a 70-kg person with a 50% TBSA burn

4 mL x 70 kg x 50% TBSA burn = 14 000 mL

= 14 L in 24 h

50% of total in first 8 h = 7000 mL (875 mL/h)

25% of total in second 8 h = 3500 mL (436 mL/h)

25% of total in third 8 h = 3500 mL (436 mL/h)

- For adults the usual fluid maintenance of 2 L/24 hours will also be required (e.g. 2000 mL ÷ 24 hours = 83 mL/h).
- This requires a total of 436 mL + 83 mL = 519 mL/h over the first 8 hours.
- Fluid resuscitation commences as soon as possible following injury.

(Paediatric fluid maintenance requirements are determined subject to the child's weight.)

Enteral feeding volumes are taken into account when determining maintenance fluid volumes.

Formulas are guidelines. Fluid is administered at a rate to produce 0.5–1.0 mL/kg/h—that is, 30–50 mL of urine output per hour. In cases of an electrical burn, then urine output is maintained at 1–2 mL/kg/h.

Blood pressure and pulse rates should not be used in isolation to measure fluid resuscitation adequacy as an adult with a major burn is in a hypermetabolic state and will probably be tachycardic, anxious and in pain.

All formula guidelines are used as starting points and fluids are titrated according to the person's physical response. Hourly urine output is often used as one indicator of effective fluid replacement. Specific gravity of the hourly urine should be monitored.

atelectasis and maintaining alveolar oxygen exchange. The following interventions should be initiated:

- Maintain the head of the bed at 30 degrees or greater to maximise the person's ventilatory efforts (once cervical spine is cleared). Turn the person side to side every 2 hours to prevent hypostatic pneumonia.
- To keep airway passages clear, encourage the person to use incentive spirometry hourly and help them perform coughing and deep-breathing exercises regularly. Encourage expectoration of sputum. Monitor and document respiratory rate hourly depending on the person's condition. Measure oxygen saturation using pulse oximetry. In a person with high COHb levels the oxygen saturation will be inaccurate as no determination between oxygen and COHb can be made by the pulse oximeter.
- If respiratory status declines, prepare the person for intubation. Endotracheal or nasotracheal intubation may be used. If the person has suffered nasolabial burns, the endotracheal route may be preferred. Intubation is used for short-term ventilatory management. For long-term ventilatory management (i.e. greater than 3 weeks), a tracheostomy is performed.
- Humidified oxygen is administered to help prevent the drying of mucosa and tracheal secretions. Ambient air or oxygen flow is based on ABG results. The person may be placed on a face mask, steam collar, T-piece, mechanical ventilation with positive end-expiratory pressure, pressure-support ventilation or high-frequency jet ventilation. The person's room will be maintained at an ambient temperature at all times because hypothermia will delay wound healing, cause discomfort and affect consciousness. Breathing in warm air will assist the person to breathe comfortably. The goal of all therapies is to maintain adequate tissue oxygenation with the least amount of administered oxygen necessary.
- Medications to dilate constricted bronchial passages may be administered intravenously or by inhalation to control bronchospasms and wheezing. Mucolytic agents liquefy tenacious sputum and aid in expectoration.
- An arterial line may be inserted for continuous assessment of ABGs. Pulmonary artery pressure catheters may be inserted to measure pulmonary vascular resistance (PVR), pulmonary artery pressure (PAP), pulmonary artery wedge pressure (PAWP) and mixed venous oxygen saturation (SvO_2). The PVR and PAP rise in the presence of hypoxia. The SvO_2 is the average percentage of haemoglobin bound with oxygen in the venous blood and reflects overall tissue utilisation of oxygen. Pulse oximetry monitors arterial oxygen saturation levels. The person requiring this level of invasive monitoring may be in a critical care unit.
- Administer intravenous analgesia as ordered.

Intravenous analgesia is the preferred route of administration because of decreased gastric absorption. Intramuscular analgesia will not be absorbed from burned or oedematous areas and results in a build-up of analgesia in the tissues. In the diuresis phase the analgesia is then released and the person could receive too much analgesia at once. Adjunct medications such as anxiolytics should be used to help calm the person.

After stabilisation in the emergency department, the person is transferred to the critical care unit or a specialised burns unit.

Diagnosis

The following diagnostic tests are used to evaluate the person's progress and to modify intervention strategies. The monitoring process should depend on the extent and depth of the burn, the presence of inhalation burn, other injuries, co-morbidities and age.

- *Urinalysis* indicates the adequacy of renal perfusion and the person's nutritional status. In catabolic states, nitrogen is excreted in large amounts into the urine. Nitrogen balance is a measure for nutritional support required and should be done in conjunction with serum protein measurements. Inactivity causes muscle wasting and an increased nitrogen excretion. An indwelling catheter is inserted and should be maintained until the person is medically stable and able to use a urinal or bedpan. During the resuscitative phase, hourly specific gravity tests should be done as a clinical indicator of fluid replacement adequacy.

  Monitoring of urine output should continue until after the diuresis phase and in conjunction with hospital protocols. Loss of plasma protein and dehydration lead to proteinuria and elevated urine specific gravity. Glycosuria is a transient development following major burn injury; it can indicate a need to adjust the nutritional program.
- *Myoglobinuria*, which manifests as a dark-brown or wine-coloured urine, signals the development of acute tubular necrosis. It usually occurs following an electrical injury, and intravenous fluid should be maintained to assist in clearing the myoglobinuria.
- *The full blood count* is monitored regularly. Haematocrit is elevated secondary to haemoconcentration, haemolysis of RBCs and fluid shifts from the intravascular compartment. Haemoglobin is decreased secondary to haemolysis. Changes to leucocyte numbers occur in relation to the burn and further changes in response to medications or sepsis.
- *Serum electrolytes* are monitored regularly as clinically indicated during the resuscitation phase. They are a more accurate assessment of successful fluid resuscitation attempts than urine output. Frequency of tests should be done in accordance with the hospital policy. Sodium levels are decreased secondary to massive fluid shifts into the interstitium. Potassium levels initially are elevated during burn shock, as a result of cell lysis and fluid shifts into the extracellular space. Potassium levels decrease after burn shock resolves, as fluid shifts back to intracellular and intravascular compartments.
- *Renal function* test results are closely monitored. Blood urea nitrogen (BUN) is elevated secondary to dehydration and if the enteral feeding is high in protein. Creatinine is elevated in the presence of renal insufficiency. It is used as an indicator of rhabdomyolysis following electrical injury.
- *Total protein, albumin, transferrin, prealbumin, retinol binding protein, alpha-1-acid glycoprotein* and *C-reactive protein* indicate protein synthesis and nutritional status.

Because of the fluid shifts that occur during the early stages of the burn injury, they are more useful markers during the rehabilitative phase of care.

- *Creatine phosphokinase (CPK)* is elevated following an electrical burn, secondary to extensive muscle damage.
- *Serial ABGs* indicate the presence of hypoxia and acid–base disturbances and indicate the person's responses to changes in oxygen therapies. The burn-injured person may demonstrate elevated or lowered pH, decreased PCO_2 and PO_2, and low to normal bicarbonate levels. Their ABGs are a more accurate estimation of COHb as pulse oximetry cannot distinguish between oxygen and carbon monoxide.
- *Pulse oximetry* allows continuous assessment of oxygen saturation levels.
- *Serial chest x-ray studies* document changes within the first 24 to 48 hours that may reflect the presence of atelectasis, pulmonary oedema or acute respiratory distress syndrome (ARDS), also referred to as severe pulmonary congestion.
- *Serial 12-lead electrocardiograms (ECGs)* are necessary to monitor the development of arrhythmias, especially those associated with hypokalaemic and hyperkalaemic states.

Medications

PAIN CONTROL Burns are painful. In the resuscitative phase of care, intravenously administered narcotics are the best means of managing pain. Intravenous narcotics must be administered subject to hospital policies. Burn treatments can also produce high levels of anxiety, necessitating the use of anxiolytic agents such as midazolam and lorazepam (Montgomery, 2004). Anxiolytics are especially useful when administered 1 hour before wound care. During the acute phase, narcotics are administered around the clock on a regular basis to decrease pain that occurs at rest.

Patient-controlled analgesia (PCA) enhances the person's ability to cope with pain. The oral, subcutaneous or intramuscular route of administration should be avoided until haemodynamic stability and unimpaired tissue perfusion return. Some hospitals have access to specialty pain services and these should be involved to ensure the person receives the most appropriate analgesia to suit their needs. If the person has adequate analgesia at all times, they will be less anxious and more receptive to all care provided by occupational therapists, physiotherapists and nurses.

Alternative forms of pain and anxiety relief should be taught as an adjunct to pharmacological measures. Distraction, self-hypnosis, guided imagery and relaxation techniques are helpful adjuncts in managing pain and coping with loss. See Chapter 8 for a discussion of strategies for managing pain.

On admission it is important to ascertain medications, either prescribed or illicit, taken by the person prior to the burn injury, as these may further complicate the treatment regimen. Drugs that affect any of the major body systems or cause mood alterations will need to be factored into the treatment plan. As part of the early assessment, obtain and document blood levels of therapeutic pharmaceutical agents and mood-altering substances (Gamst-Jensen et al., 2014).

TETANUS PROPHYLAXIS If the person's immunisation status is in doubt, tetanus toxoid is administered intramuscularly early in the acute phase of care to prevent *Clostridium tetani* infection. A thorough health history should be taken to ensure the person has had the primary three doses of tetanus vaccination. If not, or the last booster was 20 years or more ago, then they may require immunoglobulin, not a booster.

ANTIMICROBIAL AGENTS Systemic infection is a leading cause of death in people with major burns. Gram-positive organisms such as *Staphylococcus* and *Streptococcus* colonise the burn surface during the first week post burn; gram-negative enteric organisms become more common with longer periods of hospitalisation. Prophylactic systemic antibiotics are not used in controlling burn wound flora because there may be poor delivery to the burn due to decreased blood flow. To aid in the prevention of infection the person is washed in chlorhexidine liquid soap (Main, 2008). Topical antimicrobial therapy in the form of wound dressings is used to manage the wound bioburden. Of the many antimicrobial agents available, bacteriocidal silver-impregnated dressings are recommended—for example, nanocrystalline dressings or impregnated dressings may be used. Despite antimicrobial therapy, people with major burns have a greater risk of sepsis and septic shock. Systemic antibiotics are commenced when a definitive diagnosis of infection is made. A biopsy of the area may be taken to identify infective organisms. Surface swabbing for microbiology may not be accurate in determining the organism involved (World Union of Wound Healing Societies, 2008).

FAST FACTS

Local signs of burn wound infection

- Increased redness greater than 2 cm erythema around wound
- Increase in pain
- Increased sloughing of burn tissue
- Increased oedema
- Conversion of burn to a deeper burn
- Black or brown areas of discolouration

Systemic antimicrobial therapy is used on induction for surgery and may be administered postoperatively. The therapy is discontinued as soon as the person's haemodynamic status returns to normal, usually within the first 24 hours. In the long-term treatment of identified infectious processes, drug administration is limited to the least amount of time required to eradicate the infection.

Topical antimicrobial agents *Silver* Silver has a long history of use in wound care and is documented in use as early as the 19th century. It has a broad antibacterial activity. With the advent of antibiotics its use declined. It had a resurgence in the 1960s and again in current medicine, particularly in the use of burns. While there is a potential for resistance to silver in wounds, there has not been any definitive research to confirm resistance to silver-impregnated dressings (Vermeulen et al., 2009; Vlachou et al., 2007).

Silver sulfadiazine Silver sulfadiazine (Flamazine™) is a silver and sulfonamide cream and has been used since the 1960s as a topical antimicrobial for burns. Originally called SSD, the product no longer has the chlorhexidine component and the name has changed to reflect this. It has been shown to be effective against anaerobic and aerobic bacteria. The silver ion binds with the DNA of the bacteria. It is bactericidal and is easy to apply, and for some people it is soothing. However, it is contraindicated in instances of sensitivity to silver and sulfur drugs (Fuller, 2009). It is not sustained release and therefore requires daily dressing changes (Vermeulen et al., 2009).

Silver-impregnated dressings There is an increasing variety of silver-impregnated dressings and they all differ in the type and amount of silver they contain. In the management of burns, high-dose, sustained-release nanocrystalline silver formulations (Acticoat®) are preferred. Nanocrystalline silver dressings are bactericidal and have been shown to be effective against anaerobic and aerobic bacteria. Nanocrystalline silver dressings can leave a temporary blue staining of the skin. They are applied moistened with sterile water (not saline). Water compresses are then placed over the dressing and they are secured with a roller bandage or tubular stretch bandage.

Research shows that the most effective topical agents are those that act against the major pathogens responsible for causing burn wound infection, achieve levels of concentration sufficient to decrease microbial colonisation, are rapidly excreted or metabolised, are non-toxic and are easy to use (Fong & Wood, 2006).

Role of the nurse

The role of the nurse in the care of the burn-injured person encompasses all aspects of general nursing care and, in particular, wound management, during which the nurse will focus on the following:

- administration of analgesia prior to treatment
- adherence to hospital protocol regarding wound cleansing and wound treatments
- ongoing assessment of the wound and healing status
- education for the person and their family to promote optimal wound healing outcomes.

HEALTH EDUCATION FOR THE PERSON AND FAMILY

- Discuss procedure with the burned person and strategies for maximising comfort at dressing changes.
- Advise the person to take analgesia prior to each dressing and on a regular basis to maintain comfort.
- Educate the person about the importance of physiotherapy and performing given range-of-motion exercises while wounds are healing.
- Educate the person about the importance of good nutrition—in particular, protein and carbohydrates to aid healing.

Role of the surgeon

The goal of any wound closure surgery is to provide the best possible cosmetic and functional outcome for the burned person. The current practice of early excision and grafting has improved the outcome for burns and has decreased mortality. Surgery is done once the person is cardiovascularly stable and after the resuscitation period. Not all wounds require the same surgical intervention. A small burn may be excised and directly closed, requiring only suture line care. Surgical management of burn injuries includes escharotomy, debridement of non-viable tissue and harvesting of autologous (person's own) split skin grafts (SSGs). Full-thickness skin grafts (FTGs) are used on functional areas if skin is available. The FTGs contract less than SSGs and in some of the deeper burns a tissue flap may be required to repair the defect.

Surgeons are mindful of the scar left by the donor site and will select an area of low exposure and good colour match when possible. The scalp may be used when there is little skin available for harvesting as it heals quickly and hair regrowth covers the donor site. The development of the dermal regeneration template Integra® has allowed earlier debridement of large areas of full-thickness eschar. Cultured epithelial autografts (CEAs) are also used by some surgeons when there is limited skin available for harvesting or to improve the meshed appearance of the scar from a meshed graft (Sood et al., 2015).

ESCHAROTOMY

When the burn eschar forms circumferentially around the torso or extremities, it acts as a tourniquet, impairing circulation. Left unchecked, the affected body part becomes gangrenous.

To prevent circumferential constriction of the torso or extremity, an **escharotomy** is performed by the physician with a scalpel or by electrocautery (see Figure 16.10). A sterile surgical incision is made longitudinally along the extremity or the trunk to release taut skin and allow for expansion caused by oedema formation. In the first 24 hours following the procedure, the incision should be gently packed with a calcium alginate dressing and covered with a nanocrystalline silver compress. After 24 hours, the site may be treated with a direct application of a topical bactericidal agent. See Box 16.5 for nursing implications for care of the person undergoing escharotomy.

SURGICAL DEBRIDEMENT

Surgical debridement is conducted when there are full-thickness burns, extensive necrosis, infection or prior to skin grafting. Other methods of debridement are outlined in Chapter 15. The surgical technique is dictated by the depth of burn. The wound is excised to the

BOX 16.5 Nursing implications for circumferential wound management

Care of the escharotomy wound

- Assess the extremity for reduced or absence of blood flow:
  a. Assess the extremity hourly for warmth, colour, sensation and capillary refill.
  b. Observe for evidence of numbness or tingling.
  c. Elevate the limb unless contraindicated.
  d. When dressing the escharotomy wound or limb with circumferential burns, leave fingertips and toes exposed for assessment purposes.
  e. Any applied bandages should not be tight.
- For circumferential burn wounds of the torso, assess for evidence of respiratory distress: elevate head of bed at least 30 degrees unless contraindicated.
- For circumferential burn wounds of the neck, assess for evidence of respiratory distress. Prepare the person for prophylactic intubation.
- Pack the escharotomy wound with calcium alginate dressings and dress the open wound with topical bactericidal silver dressing as ordered.

level of fascia (**fascial excision**) in full-thickness skin injury or sequential removal of thin slices of the burn wound to the level of viable tissue (tangential excision) is undertaken in partial-thickness skin injury. Because fascial excision sacrifices potentially viable fat and lymphatic tissue, its use is reserved for people with extensive or full-thickness burns. The most common technique used is electrocautery with cutting and coagulating current capabilities. Tangential excision is performed with the use of a dermatome. Shallow burns and some of moderate depth bleed briskly after one slice. If bleeding does not occur, the procedure is repeated until a viable bed of dermis or subcutaneous fat is reached. Following surgical debridement, haemostasis is vital to facilitate the repair of the wound surface. The debrided wound can be closed using traditional skin grafts in isolation or in association with tissue-engineered solutions. Once the wound has been dressed the person is returned to the burns unit and appropriately positioned and splinted, subject to the location of the injury and donor sites.

TYPES OF SKIN GRAFTS Autograft is the surgical removal of skin from one site on the individual (known as the donor site) and relocated to another site on the same individual. The donor site is allowed to heal by secondary intention.

Cultured epithelial autograft (CEA) Cultured epithelial **autografting** is a removal of autologous keratinocytes from a skin biopsy of approximately 2 cm from an unburned site on the person's body. The biopsy should be taken within 24 hours of the burn. The separated keratinocytes are then placed in a medium containing epidermal growth factor. Originally the technique involved placing the cells in a medium where, over a 5- to 7-day period, they expand to 50 to 70 times the size of the initial biopsies. The cells are again separated out and placed in a new culture medium for continued growth. With this technique, enough skin can be grown over a period of 3 to 4 weeks to cover an entire human body. The cells may be prepared as sheets attached to petroleum gauze backing, or in a suspension that is applied to the burn wound site. Problems with infection and lack of attachment have occurred. These problems have been reduced by using cells harvested at the time of the operation, and immediately applying them to the wound. The skin cells undergo no laboratory expansion and adhere directly to the wound bed. Using this more recent technique, the skin biopsy is placed in a ReCell® kit, separated and placed in a culture medium for growth. The cells are ready to use within 15–20 minutes. The CEA results in a smooth finish but is prone to shearing and blistering as cell layers are 10–15 cells thick (Knighton & Fong, 2008; Wood et al., 2012).

Homograft, or **allograft**, is a temporary skin substitute and has some advantages when wound coverage is needed and for the body to behave as if it has skin. Human skin that has been harvested from cadavers is stored in a 'skin bank' until required. The development of methods to achieve prolonged storage of frozen, viable skin has increased the use of this dressing; however, its short supply, infection risk and expense still pose problems. It is manufactured as strips cut to the pattern of the burn and applied using sterile technique. Under normal circumstances, a homograft is rejected within 14 to 21 days following application.

Heterograft, or **xenograft**, is another kind of temporary wound coverage. Only heterograft from porcine dermis is available. Although fresh porcine heterograft is available at some centres, frozen heterograft is much more commonly used. Once applied, heterograft appears to undergo early softening and lysis from enzymatic action from the wound. As a result, frequent changes of the heterograft dressing are necessary. Because of the high infection rates associated with this dressing, silver-nitrate-treated porcine heterograft has been developed to retard microbial growth. Temporary skin coverage does not vascularise but the underlying wound bed may epithelialise. Amniotic membranes are also used, particularly for face burns, but they do not reduce healing times (Lee et al., 2012).

Bioengineered tissue substitutes The multiple problems associated with the use of allograft and heterograft have driven the development of synthetic materials and composite material biological dressings. One such material is Biobrane®, a composite material consisting of nylon mesh bonded to silicone coated with bovine collagen, which has proved successful in the temporary coverage of partial- and full-thickness burns. Whereas Biobrane® adheres well to moderately clean wounds, it cannot adhere to grossly contaminated wounds. Biobrane® dressing is supplied in various sizes and is cut to fit the wound site and secured with staples or tape or skin closure strips (e.g. Steri-Strips®). It spontaneously separates from the wound when the underlying tissue heals (Pham et al., 2007).

If dermal thickness is lost, as in deep partial-thickness or full-thickness burns, several products can serve as a dermal replacement. Integra® is a synthetic dermal substitute made of bovine collagen and shark glycosaminoglycans, and Alloderm®

is human cadaver allograft dermis processed such that it is non-immunogenic. These products are placed in the wound, and split-thickness autografts are then placed over the dermal replacement. These products are used to provide wound coverage, reduce pain and facilitate healing.

Dermal regeneration template (Integra®) Dermal regeneration template provides both dermal and epidermal characteristics. This is a manufactured template that, when placed on to a viable wound bed following debridement of full-thickness or deep partial-thickness burns, forms a matrix resembling dermis. It is of greatest use when autografting is not a possibility and is also used in scar revision. It has two layers and is secured with staples. The dermal layer is biodegradable and causes the body to regenerate a new dermal layer. The silicone layer stays intact for 3 weeks and then is removed and autologous grafting is done. This is a two-stage process. Integra® becomes infected easily, resulting in a non-viable product that must be removed immediately. Because of this, meticulous nursing care of Integra®-covered wounds is required in order to prevent infection and loss of graft. Integra® is dressed daily with a silver-impregnated dressing (e.g. Acticoat®) in some hospitals while the silicone layer is separating. The silicone layer is removed prior to grafting. In some cases, cultured epithelial autograft (CEA) or ReCell® (in conjunction with split skin grafts) will be used after the silicone layer is removed. Nursing care is specific for this template and shearing must be prevented, particularly in the first week post application (Chester & Papini, 2004; Pham et al., 2007).

Split skin grafts Skin grafts can be split thickness (SSGs)—thin, intermediate or thick. They all contain epidermis and variable depths of dermis. Thin SSGs contract within the first few months. They contain no skin appendages, and vascularisation occurs readily; while thick SSGs have less contraction and usually contain some hair follicles.

The SSG can be laid in sheet form or meshed to allow for a greater area to be covered. These grafts leave a 'meshed' scar pattern (see Figure 16.11) and in some instances surgeons will use cultured epithelial autograft (CEA) or ReCell® to reduce the meshed look. Initially the graft is supplied by nutrients from the wound bed: the phase of imbibition. The graft will not take if the wound bed is insufficiently debrided, or slough, haematoma or excess exudate are present. Dressings must prevent shearing of the graft. Next, neovascularisation takes place; during this phase, blood vessels connect with capillaries in the graft. This is followed by the maturation phase when collagen forms between wound bed and graft. This last phase can take months to complete.

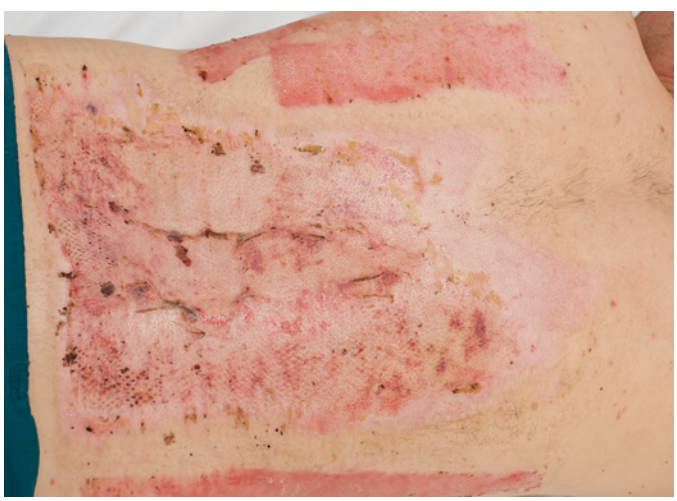

FIGURE 16.11 ■ Split skin graft on a back

Full-thickness skin grafts Full-thickness skin grafts (FTGs) involve removal of the whole epidermis and the dermis. The thickness of the FTG depends on the thickness at the donor site from where it is harvested. The graft is sutured to the recipient wound bed. Care must be taken to ensure the graft is in contact with wound bed or 'graft take' will not occur. Sometimes a 'tie over' dressing will be sutured over the top of the FTG to maintain the contact with the wound bed. The tie over is usually removed at the time of dressing change on about day 5 postoperatively or on the surgeon's instructions.

GRAFT CARE Grafts can be managed open with graft care attended to 1- to 4-hourly, depending on the surgeon's preferences or, more commonly, sealed under a bulky dressing for the first few days. The aim of graft care is to remove haematomas or exudate from beneath the graft to facilitate adherence. Small blisters are slit and exudate is expressed. Any wrinkles are flattened and edges prevented from rolling. Grafts can also be covered with paraffin gauze or silicone meshed dressings, which are then covered with a fluffed gauze filler to reduce any dead space in the wound defect and secured with a bandage system. This dressing is usually left sealed for at least 48 hours then removed. Ongoing burn wound management regimens are subject to the graft appearance. Grafts may also be sealed for up to 5 days with a negative pressure dressing.

DONOR SITE CARE A thin layer of donor skin is taken from the person with the use of a dermatome. Each surgical team has its preferred procedures for caring for donor sites and a range of dressings are used. Calcium alginate dressings are frequently used as they provide haemostatic and absorbent features. Donor sites generally take 2 weeks to re-epithelialise, and dressings are applied until healing.

FLAPS This procedure involves using a portion of skin with its intrinsic structures to repair a defect that is too extensive for an SSG or FTG. Flaps leave a scar at the point of injury, as well as the donor site scar. In burns, some flaps become non-viable due to decreased blood flow. There are many types of flaps; the surgeon decides which one to use depending on the defect and where it is located on the body.

Burn wound management

The outcomes of care for the person with a major burn depend in part on the prevention and treatment of infection. The goals of burn wound management are as follows (Honari, 2004):

- alleviate pain
- control microbial colonisation and prevent burn wound infection

- prevent burn wound conversion to a deeper burn
- achieve burn wound coverage as early as possible
- promote function of healing skin
- preserve function of the body part.

Burn wound management decisions are delayed until primary survey and lifesaving measures have been established. After first aid, burn wound management involves washing and covering the burn with a clean sheet for transfer. Care decisions are dependent on assessment of the depth and appearance of the wound and the dressing products available for the healthcare professional to use. Various dressing products suitable for burn wounds are discussed later in the chapter.

DEBRIDING THE BURN WOUND Burned tissue releases chemical mediators that stimulate phagocytosis in an attempt to digest necrotic tissue. Necrotic tissue that remains despite phagocytic action slows healing and prolongs inflammation. **Debridement** is the process of removing all loose tissue, wound debris and eschar (dead tissue) from the wound. The methods of debridement commonly employed in burn care are surgical (see above), mechanical (irrigation), and conservative sharp wound debridement (removal of loose non-viable tissue without pain or bleeding). Dressings that hydrate the wound will promote autolytic debridement.

During showering, non-viable tissue and slough can be removed while washing the burned area. Showers also promote a feeling of wellness for the person (Betts, 2003; Main, 2008). The person should be encouraged to do as much of the showering themselves as possible as this promotes independence and is good physical therapy. It may reduce the anticipation anxiety that arises when someone else is washing their burns. Hydrotherapy (in an immersion tank, a shower or on a spray table) is also used to cleanse the burn injury using a mild, non-perfumed, antimicrobial soap, to remove dead skin and separate eschar. The solution is then rinsed off with warm saline or tap water (Fernandez, Griffith & Ussia, 2006).

Body hair (except for eyebrows) may be shaved within the burn and to within 2.5 cm of the wound edges. This prevents debris building up around hair follicles, increasing the risk of infection. Shaving also allows for better washing of the burn and adherence of any dressing products. The edges of blisters or eschar are trimmed with sharp scissors. The wound is then covered with a topical antimicrobial agent according to hospital policy.

DRESSING THE BURN WOUND Once the burn wound has been cleaned and debrided, it will require a dressing. Moist wound healing principles and hospital policy on topical antimicrobials should be adhered to. Covering the burn helps to reduce the risk of infection and decreases pain.

All fingers and toes are wrapped separately. Dressings are held in place with roller bandages, retention tapes or tubular net. All care is taken not to restrict range of movement or circulation and to encourage person independence with activities of daily living.

TOPICAL NEGATIVE PRESSURE DEVICES Topical negative pressure devices consist of a foam or gauze dressing that is cut or folded to the wound shape and used to fill any defects. An occlusive, adhesive dressing seals the wound and tubing connects the dressing with the pump. Negative pressure systems reduce wound oedema, remove exudate and promote granulation and epithelialisation (DeSanti, 2005).

Role of the physiotherapist

Physiotherapists are primarily concerned with ensuring the respiratory system is not compromised after a burn injury. Lung compromise may impede oxygen delivery to the wound, slow wound healing and increase the risk of wound infection. To further facilitate oxygen transfer during the acute burn period, physiotherapists will focus on the reduction of oedema in order to improve the speed of wound healing and prevent burn conversion. Therapists recognise that impaired wound healing may lead to the development of hypertrophic scar, which may contribute to contractures after a burn injury. To prevent such long-term complications and assist with oedema reduction, people should be encouraged to exercise their burn-injured and non-burn-injured areas. As soon as possible following admission, the physiotherapist should prescribe and display active and self-assisted passive range-of-movement (ROM) exercises. The physiotherapist will perform passive ROM exercises for the person who is unable to do them independently. Ideally, an active exercise program is initiated and reinforced by the multidisciplinary team members. The program should involve a warm up and simple functional tasks, as well as specific exercises. Early ambulation is also part of the plan of care to reduce the risk of respiratory and circulatory complications. It is imperative that the person receives regular multimodal analgesia and pressure bandage support to facilitate these activities (van Baar et al., 2006).

Burned people must be maintained in positions that prevent or reduce the risk of contractures. Because flexion is the natural resting position of joints and extremities, early physiotherapy includes maintaining and correcting anti-deformity positions. Splints immobilise body parts and may have a role to play in preventing contractures of the joints, particularly if the person is unconscious in the critical care unit. Splints, if required, should be applied soon after the injury and removed according to schedules established by the therapist.

Physiotherapists facilitate postoperative recovery of the burned patient to prevent long-term loss of movement. The person should be encouraged to move and walk normally unless contraindicated following surgery. It is better that the person continues to move while the wounds are healing, rather than leaving it until their wounds are healed (Falder et al., 2009). Postoperative movement changes depending on the surgery type and specialist's preferences.

Role of the occupational therapist

Occupational therapists who work with individuals who have sustained a burn injury have two core areas of focus: function and scar management. These two areas are closely entwined, as a deficit in one area usually goes 'hand-in-hand' with the other, and vice versa.

The International Classification of Functioning, Disability and Health (ICF) represents the *functional impact* of illness

and injury. It defines function and disability in terms of the whole person rather than by illness or injury and looks beyond the medical to include other aspects of disability. It specifically addresses body structure and function, the activities people engage in, the interests they have and the environmental and personal factors that affect those experiences. This framework has a very useful application to the person who has sustained a burn injury as return to function must include the physical, psychological, relational and social impacts of the injury.

The return to functional independence is a journey that starts the day after injury. The contractile properties of the healing burn dictate early mobilisation to avoid scar contracture and this is achieved both through specific exercise programs and through the early resumption of self-care tasks (showering, dressing, feeding and hand function). The occupational therapist will design a functional retraining program which graduates the resumption of these tasks to enable the individual to experience success and gradually improve in independence. Standardised assessments may be used to measure a person's ability to personally care for themselves, but also include return to work, return to leisure and the resumption of social and relational roles (Murgatroyd & Karimi, 2015).

One of the greatest long-term impacts of a burn injury is the subsequent scarring. If healing is delayed beyond 21 days post injury, evidence suggests that this will result in an adverse scar outcome (Deitch et al., 1983), as will an injury that has required surgical intervention. Hypertrophic scarring is an aberrant form of the normal processes of wound healing but is commonly associated with burn injury (Aarabi, Longaker & Gurtner, 2007) and is defined as red, raised, firm and itchy. It carries the very real risk of joint contracture which has the potential to severely impact function, as well as being aesthetically unacceptable (Gabriel, 2011).

Since the 1970s, compression therapy has been the main form of treatment for hypertrophic scarring (Atiyeh, 2007). This compression therapy is primarily delivered through the form of tight-fitting elastic garments (pressure garments). Compression should be commenced as soon as the healing skin is able to tolerate the pressure (Bloeman et al., 2009) and withstand the shearing forces of donning and removing the garment. Occupational therapists 'prescribe' the most appropriate pressure garment for the patient, selecting from a range of ready-to-wear and custom-made garments, and taking into account the patient's individual needs and lifestyle. Pressure garments are to be worn 23 hours a day (Berman et al., 2008) for a period of up to 18 months.

A number of other modalities that are employed to assure a positive scar outcome include:

- daily scar massage—undertaken in conjunction with the application of moisturisers. Massage therapy aims to discourage the formation of fibrotic tissue and to realign the collagen fibres (Edwards, 2011)
- contact media—silicone products (gel sheets, gels 'in a tube', putty) and hydrocolloid dressings which are used in conjunction with compression therapy to improve hydration in the scar, reduce pain and itch, reduce vascularity and scar height, and improve pliability
- splinting—contracting scars may need either dynamic splinting (splints with moving components to apply a pull against the scar) or static splints to be worn at night to maintain an anti-contracture position.

As the occupational therapist is concerned with both function and scar, there are two areas of the body that require additional specialist input. These areas, the hands and the face, carry the risk of significant psychosocial impact given their visibility and significant potential impact on independence and function. Specialised programs include splinting exercise and a range of scar management techniques unique to these areas; most notably, transparent face masks (Parry et al., 2013; Serghiou, Holmes & McCauley, 2004).

Like many in the burns team, the intervention of the occupational therapist is prolonged. It starts at day 1 and accompanies the patient through the acute phase of burn injury, the stages of scar maturation and reintegration to life, work, independence and community.

Role of the dietitian

The role of the dietitian is to optimise the nutritional status of the burned person. Goals may include assisting the patient to maintain weight within 5% to 10% of pre-injury weight, prescription of an enteral feed that meets estimated nutritional needs, coordination of a diet that meets the patient's nutritional and individual needs, prevention of signs and symptoms of micronutrient deficiency, and minimisation of the risk of complications such as hyperglycaemia, hyponatraemia and hypertriglyceridaemia.

THE METABOLIC RESPONSE

The person with a major burn (> 15% to 20% TBSA in adults and > 10% TBSA in children) is in a hypermetabolic and catabolic state. Resting energy expenditure after severe burn injury can be elevated to twice normal levels (Shields et al., 2013). The mediators of the hypermetabolism include elevated levels of catecholamines, glucocorticoids and glucagon (Bonet et al., 2011). The extent of a person's hypermetabolism is directly proportionate to the size of the burn injury (Rousseau et al., 2013).

Recent advances in medical and nursing care have blunted hypermetabolic response to burn injury; however, it cannot be fully reversed.

NUTRITION SUPPORT

Careful nutrition assessment, planning, intervention and monitoring is required in order to ensure burns patients meet nutritional requirements. Adult patients with < 20% TBSA burns and paediatric patients with < 10% TBSA burns may be able to maintain nutritional status via a high-energy/high-protein diet and oral nutritional supplementation.

Early initiation of enteral nutrition improves outcomes in adult patients with > 20% TBSA burns (Kovacic-Vicic, Radman & Kovacic, 2013). Current recommendations suggest commencement of enteral nutrition (within 24–48 hours) for all adults with > 20% TBSA burns and children with > 10% TBSA burns (ANZBA, 2014). Early enteral feeding is

promoted to offset hypermetabolism, improve nitrogen balance, decrease infection, maintain intestinal barrier function, prevent bacterial translocation and decrease length of hospital stay. As nasogastric feeding is usually well tolerated by people with burns, post-pyloric feeding is rarely required. People on enteral feeds are also encouraged to eat and drink, if possible. Total parenteral nutrition (TPN) is appropriate only for those patients who have prolonged intolerance to enteral feeds and who are unable to attain adequate protein and calorie intake with enteral nutrition (Cochran et al., 2013). Examples where TPN may be instigated include pancreatitis, bowel obstruction, paralytic ileus or intestinal perforation.

MONITORING AND EVALUATION As a patient's burn injury heals, they are usually able to tolerate larger amounts of oral diet and nutritional supplements. Patients with major burns will usually progress from complete nutrition via enteral feeds to overnight feeds, and then enteral feeding will cease. The decision as to when to progress the patient is made by the team. Considerations include adequacy of oral intake, consumption of oral nutritional supplements and healing stage of the wounds. Nutrition-related monitoring may include food-intake charts, weekly weights, biochemical indices (renal function, liver function, Mg, PO_4^{3-}, BSL), maintenance of muscle stores (e.g. handgrip strength), bowels and fluid balance.

DISCHARGE PLANNING Hypermetabolism related to a major burn can persist for up to 2 years after the injury (Rodriguez et al., 2011). Patients with major burns should receive education prior to discharge about the importance of weight maintenance, adequate protein and following a general healthy diet. Evidence is scant about the long-term requirement for vitamins and minerals of burns patients. A daily multivitamin/multimineral supplement until wound healing is demonstrated may be useful to optimise vitamin and mineral intake.

Nursing care

Health promotion

Although treatments have improved significantly during the past several decades, prevention remains the primary goal. The nursing profession is currently well positioned to collaborate with other disciplines to develop initiatives to reduce the number of burn injuries. For example, as advocates, nurses can alert political leaders to the need to pass legislation aimed at reducing the incidence of burns. Appropriate legislative themes might centre on safety in the workplace (e.g. requirements for smoke alarms and sprinkler systems), on the highways (e.g. regulations regarding the transportation of flammable liquids) and in the home (e.g. requirements for safety devices for water heaters and wood-burning stoves and for self-extinguishing cigarettes). As educators, nurses can develop teaching plans for families and communities to heighten awareness of the problem. As researchers, nurses can investigate conditions leading to burn injury and suggest methods to reduce its prevalence. Working together with healthcare policy makers and community leaders, nurses can join the effort to lower the number of annual burn cases.

Nursing diagnoses and interventions

A major burn affects virtually every body system, as well as social, cultural, economic, psychological and spiritual wellbeing. Acute care is combined with ongoing rehabilitation that continues post discharge. Many nursing diagnoses are appropriate for the person with a major burn injury; they include *Impaired skin integrity*, *Deficient fluid volume*, *Acute pain*, *Risk of infection*, *Impaired physical mobility*, *Imbalanced nutrition: less than body requirements* and *Powerlessness*. The nursing care within a multidisciplinary team has been discussed with regard to the first six of these nursing diagnoses and the concept of *Powerlessness* is discussed below.

NURSING CARE PLAN A person with a major burn

Craig Howard is a 35-year-old coal miner from Central Queensland. Craig was driving home after a late shift when his 4-wheel drive veered off the road, rolled and caught on fire. He was freed from his vehicle by a passing motorist, who in turn summoned help and called police. The passing motorist stayed with Craig until the aerial rescue team arrived and transported him to the nearest metropolitan hospital emergency department. The hospital has a burns unit. Mr Howard's wife, Mary, and twin daughters, Jessica and Jane, aged 10, were notified of the accident by police.

ASSESSMENT

On his admission to the emergency department, Craig was diagnosed with deep partial-thickness and full-thickness burns of the anterior chest, and circumferential full-thickness burns of the arms and hands. An initial quick assessment based on the rule of nines estimates the extent of his burn injury at 36% of TBSA. His vital signs were as follows: T 35.6°C, P 140, R 40 and BP 98/60. At the scene, the paramedics inserted two large-bore cannulae and started the rapid infusion of Hartmann's solution. Craig is receiving 100% humidified oxygen via a face mask. Initial ABGs are: pH 7.49, PO_2 60 mmHg, PCO_2 32 mmHg and bicarbonate 22 mEq/L. Lung sounds indicate inspiratory and expiratory wheezing, and a persistent cough reveals sooty sputum production. An indwelling catheter was inserted into his bladder and initially drained a moderate amount of dark, concentrated urine. A nasogastric tube was inserted. Craig is alert and oriented and complains of severe pain associated with the burn injuries. The burns unit is notified and Craig is transferred there.

NURSING CARE PLAN A person with a major burn (continued)

Craig's condition is serious. There are several nursing diagnoses that could be developed, as noted below.

DIAGNOSIS

- *Impaired skin integrity* related to major burns injury.
- *Acute pain* related to major burns injury.
- Potential for *Infection* related to *Impaired skin integrity.*
- *Deficient fluid volume* related to major burns injury.
- *Impaired physical mobility* related to major burns injury.
- Potential for pressure injuries related to *Impaired physical mobility.*
- Potential for *Imbalanced nutrition* related to excess body requirements associated with burns injury.

PLANNING

- Ensure room is set up prior to the person's arrival, i.e. assemble all equipment required to weigh the person, shower and dress the person, administer IV fluids and nasogastric fluids, measure and test urine, correct documentation, analgesia ordered.
- Ensure all staff are aware a major burn is being admitted and that an appropriate staff member is allocated to this person.
- Warm the room.
- Prepare for possible prophylactic nasotracheal or endotracheal intubation to maintain airway patency.
- Prepare the person and family when they arrive with an explanation of protocols and procedures. This may help reduce anxiety and help with compliance.

Expected outcomes

- The person maintains an effective airway and vital signs are within normal limits. The person has clear breath sounds, and no evidence of cyanosis. Mental status is within normal limits.
- The person does not suffer from hypothermia as evidenced by warm peripheries, conscious level and vital signs.
- The person demonstrates adequate fluid volume by maintaining appropriate urine output and urea and electrolytes and other laboratory findings within normal limits.
- The person demonstrates understanding of instructions and orientation to person, time and place through conversation and compliance with requests and treatment.

IMPLEMENTATION

- *Maintain effective airway clearance,* as there is potential for increased lung congestion secondary to smoke inhalation and torso burns.
- *Maintain adequate fluid volume*, as abnormal fluid loss is possible secondary to burn injury.
- *Monitor for adequate tissue perfusion* (peripheral), as peripheral constriction secondary to circumferential burn wounds of the arms is a possibility.
- Weigh the person.
- Once cervical spine injury has been cleared, elevate head of bed to improve lung expansion and ventilation.
- Administer humidified 100% oxygen at prescribed amount.
- Educate the person on the importance of deep breathing and sitting upright to improve his breathing.
- Monitor for expectoration of sooty sputum, stridor, increase in wheezing.
- Elevate both arms on one or two pillows to reduce swelling.
- Perform neurovascular observations ½–1 hourly depending on neurovascular status and hospital protocol—that is, colour, warmth, movement, sensation and capillary refill.
- Remove dressings from fingertips to enable neurovascular observations to be done.
- Administer intravenous analgesia as ordered for pain.
- Observe for any signs of respiratory distress or decrease in respiratory status.
  - Observations to be performed ½–1 hourly depending on the person's condition and hospital protocol—that is, respiratory rate, blood pressure and pulse. Temperature 1 hourly as the person is hypothermic on admission. Oxygen saturations should be monitored continuously.
- Explain to the person all procedures and protocols to help reduce anxiety and encourage compliance with treatment. This may need to be done on more than one occasion.
- Initiate fluid resuscitation therapy using the Parkland (Baxter) formula to calculate intravenous fluid rate for the first 24 hours post burn. Review original calculations based on real weight, not estimated weight, and ensure fluid resuscitation time is from time of injury.
- Insert nasogastric tube and commence enteral feeding as instructed. Discourage the person from drinking water.
- Measure urine output 1-hourly and record specific gravity hourly.
- Document all observations, input and output accurately.
- Arrange for blood tests to be taken according to hospital burn resuscitation protocol and ensure the results are reviewed.
- Craig maintained his respiratory status and did not require intubation. He was continued on humidified oxygen sitting in an upright position in bed or chair with his arms elevated.
- Hourly urine outputs indicate adequate fluid resuscitation. Urine output has been maintained at 50 mL/h and is a straw colour; specific gravity is 1020. Blood pressure has increased to 100/64. He has remained tachycardic at 100, and his respiratory rate on humidified oxygen is 28. His temperature is now 37°C.
- To improve tissue perfusion of both arms, the physician has performed bilateral escharotomies and the wounds are packed with alginate and covered in a silver antimicrobial dressing, such as Acticoat®. Colour, warmth, movement, sensation and capillary return have improved, indicating escharotomies have been successful.

EVALUATION

- Craig Howard demonstrated a patent airway, as evidenced by clear breath sounds; absence of cyanosis; and vital signs, chest x-ray findings and ABGs within normal limits.

(continued)

NURSING CARE PLAN A person with a major burn (continued)

- Adequate fluid volume and electrolyte balance demonstrated, as evidenced by urine output, vital signs, mental status and laboratory findings within normal limits.
- Adequate tissue perfusion demonstrated, as evidenced by palpable pulses, warm extremities, normal capillary refill and absence of paraesthesia.

CRITICAL THINKING IN THE NURSING PROCESS

1. Explain the rationale for the immediate insertion of an indwelling catheter and nasogastric tube.
2. An escharotomy was performed on both arms. Why was this procedure necessary in Craig Howard's case?
3. What is the rationale supporting the intravenous administration of narcotics to control Craig's pain?
4. Explain the sequence of events that led to a fluid and electrolyte shift during the first 24 to 48 hours after Craig sustained his injury.

REFLECTION ON THE NURSING PROCESS

1. Outline what you have learned from this case study that you will apply to your future practice.
2. Which communication and person-centred education strategies would you use when caring for people with major burns such as Craig's?

CONSIDERATION FOR PRACTICE

An increased body temperature, without other manifestations of infection, is not indicative of infection in people with large burn wounds (in which the hypermetabolic response resets the core temperature to a higher level).

CONSIDERATION FOR PRACTICE

Assess all people, but especially the older person, for indications of pressure injury formation under a splint.

CONSIDERATION FOR PRACTICE

Narcotics are always administered intravenously, rather than orally, subcutaneously or intramuscularly in the resuscitative or acute phase of a burn due to decreased circulation and absorption of medications.

Powerlessness

Usually, the person with a major burn injury endures a lengthy hospital stay involving many treatments and care protocols that are beyond their control. During the early stages, much of the care regimen involves pain. Further, the foreign environment of the burns unit makes it difficult for the people to relate to the immediate surroundings. The person's body image is often altered, depending on the extent and location of the burn injury.

- Involve the person in their own care. Encourage independence with activities of daily living. Encourage the person to participate in showering and toilet and physiotherapy. Encourage the person to verbalise their feelings. *Powerlessness derives from the belief that one is unable to influence the outcome of a situation.*
- Keep needed items within reach, such as call bell, urinal, water pitcher and tissues, *to reinforce the person's feelings of control.*
- Encourage the person to express feelings. *The nurse can help the person cope by therapeutically listening, displaying a caring presence, clarifying misconceptions and providing positive feedback.*

NURSING CARE OF THE OLDER PERSON Burns in the older person

Older people are at greater risk of burns of all degrees of severity. Most burns are accidental, the result of slower reaction times, decreased mobility, visual deficits, a decreased sense of smell, forgetfulness and impaired sensation. Many older people are burned by stoves, hot water, hot food, irons, cookware and heating pads. Older people with cognitive impairments or dementia may start fires by leaving cooking foods unattended.

The care of older people with burns often presents unique challenges. They may delay seeking treatment, thus increasing the risk of infection and burn wound conversion. Their care may be complicated by the presence of other chronic illnesses. They may live alone and have no one to care for them during rehabilitation. Even small burns have the potential to become serious in older people.

Burn prevention strategies for older adults are as follows:

- Check the smoke detector battery once a month.
- Wear close-fitting clothing when cooking.
- Use a cooking timer with a loud alarm.
- Never lay anything over a heating device.
- Install anti-scald devices in bathroom plumbing.
- Encourage no smoking in the house.

- Involve the person in setting realistic goals to suit their level of recovery, but also encouraging them to aim for improvement, not stasis, in rehabilitation. *Rehabilitation starts the day the person is admitted, not when healed. Small incremental gains are easier to achieve and allow for frequent positive reinforcement.*

Community-based care

Education for the person with burns and their family is an important component of all phases of burn care. As treatment progresses, the nurse encourages family members to assume more responsibility in providing care. From admission to discharge, the nurse teaches the person and family to assess all findings, implement therapies and evaluate progress. The following topics should be addressed when preparing the person and family for home care:

- The long-term goals of rehabilitation care, which are to prevent soft tissue deformity, protect skin grafts, maintain physiological function, manage scars and return the person to an optimal level of independence.
- Avoiding exposure to people with colds or infections, and following aseptic techniques meticulously when caring for the wound.
- The need for progressive physical activity.
- How to apply splints, pressure support garments and other assistive devices.
- Dietary requirements with required kilojoules.
- Alternative pain control therapies, such as guided imagery, relaxation techniques and diversional activities.
- Care of the graft and donor sites.
- Referral for social service, clergy, and/or psychiatric services as appropriate.

TRANSLATIONTO PRACTICE Evidence-based practice: a person with a major burn

People with major burn injuries are at risk of pressure injuries due to deficient fluid volume, inadequate nutrition, pain and immobility. Healthy, intact skin can experience damage from friction and shearing forces, posing a second area of risk of pressure injuries.

In an investigation of pressure injury prevention in burned people (Gordon et al., 2004), a multidisciplinary team of burn care specialists reviewed and evaluated the current evidence of practice for preventing pressure injuries. Pressure injuries result from continuous, unrelieved pressure that causes reduced blood flow to vulnerable areas of the skin, resulting in tissue damage. The results of the study confirmed that contributing factors to the development of pressure injuries in people with burn injuries include inadequate dietary intake, malnutrition, decreased albumin levels, moisture and incontinence, reduced sensation, prolonged immobility, increased age and altered level of consciousness.

IMPLICATIONS FOR NURSING

Nurses and all members of the burn team assume an integral role in preventing pressure injuries. To prevent pressure injuries, nurses must constantly monitor the person with major burn injuries for signs of skin damage and conduct regular and frequent skin inspections. Chapter 15 discusses interventions for pressure injury prevention, assessment and management.

CRITICAL THINKING IN PERSON-CENTRED CARE

1. The person's head must be elevated to 30 degrees when nasogastric tube feedings are implemented. What strategies would you recommend to prevent inhalation of nasogastric feeds?
2. How could splints that are being used to prevent contractures be modified as the person's amount and extent of oedema fluctuates?
3. Develop a teaching plan for instructing nursing assistants on how to move, position and transfer people in a burns centre unit. Include in the teaching plan the proper technique for cleansing unburned skin.

CHAPTER HIGHLIGHTS

- Four types of burn injuries are thermal, chemical, electrical and radiation. The depth of the burn injury determines whether it is classified as a superficial, partial-thickness or full-thickness burn.
- The Wallace (1951) rule of nines, age-dependent burn graphs and the palmar surface assessment are all used to estimate the extent of a burn by assigning percentages to different parts of the body.
- Major burns involve multi-organ pathophysiological alterations. Most critical is the fluid shift from the intracellular and intravascular compartments into the interstitium, resulting in a type of hypovolaemic shock called burn shock. Other pathological processes include an impaired immune system, disturbed functions of the skin, inhalation injury, gastrointestinal ulcerations and ileus, renal failure and hypermetabolism.
- Interprofessional care focuses on managing the person during the resuscitative, acute and rehabilitative phases. To counter the effects of burn shock, fluid resuscitation using guidelines such as the Parkland (Baxter) formula are initiated to replace fluid and electrolyte losses.
- Additional management for the person with major burns includes preventing atelectasis, maintaining respiratory function, controlling pain, preventing infection and Curling's ulcer, promoting nutrition and providing wound care.
- Extensive eschar of an extremity or the torso, called circumferential wounds, can potentially occlude arterial flow or decrease respiratory function. An escharotomy is used to release tension, preventing additional complications.
- Surgical management of burn wounds includes debridement and skin grafting. Biological and biosynthetic dressings provide temporary covering and prepare the wound for permanent autografts.
- Continual psychological support of the person and family is essential throughout convalescence and rehabilitation.

CONCEPT CHECK

1 During the resuscitative phase of burn management, what diagnostic test result should the nurse expect to find?
1 increased haematocrit
2 increased serum albumin
3 decreased serum potassium
4 decreased blood urea nitrogen (BUN)

2 A person is admitted with severe burns to the face and chest. The injured skin is dry and leathery, with no pain sensations present. The nurse recognises that this burn is classified as:
1 superficial
2 superficial partial-thickness
3 deep partial-thickness
4 full-thickness

3 Which of the following people is at greatest risk of developing burn shock?
1 a 21 year old with 90% superficial burn from a tanning bed
2 a 30 year old with 10% TBSA from a gasoline explosion
3 a 39 year old with radiation burns following treatment for cancer
4 a 48 year old with >50% TBSA from a high-voltage electrical accident

4 A person with full-thickness burns over 50% of the body arrives in the emergency department. The person weighs 70 kg. Using the Parkland (Baxter) formula, calculate the amount of fluid replacement that the nurse should deliver in the first 8 hours.
1 3500 mL
2 7000 mL
3 10 500 mL
4 14 000 mL

5 For a person with a major burn, which of the following evaluation criteria indicate that fluid resuscitation is effective during the first 24 hours of care?
1 urine output of 30 to 50 mL/h
2 central venous pressure of 18
3 heart rate of 130 beats per minute
4 blood pressure 96/70

6 A person has deep partial-thickness burns to the entire left arm and left side of the back. What finding should be reported to the physician immediately?
1 fluid-filled vesicles on the left arm
2 pain in the left arm
3 blanching when pressure is applied to the left hand
4 decreased left radial pulse

7 A person received deep partial-thickness burns to the anterior trunk, perineum, and left arm anterior and posterior. Using the Wallace (1951) rule of nines, what is the percentage of total body surface area (TBSA) that was burned?
1 18%
2 28%
3 36%
4 40%

8 Which of the following topics should be included in a presentation on burn prevention at a senior citizens centre? (Select all that apply.)
1 Wear close-fitting clothing when cooking.
2 Use a solar-powered night light.
3 Check smoke detectors annually.
4 Install anti-scald devices in bathroom plumbing.
5 Have a neighbour routinely check for the odour of gas.

9 A person has possible carbon monoxide poisoning secondary to smoke inhalation. What manifestation should the nurse expect to find in a person with a 15% carbon monoxide level?
1 dark red skin colour
2 drowsiness
3 dizziness
4 hypotension

UNIT 4 BUILDING CLINICAL COMPETENCE

Responses to altered integumentary structure and function

CLINICAL SCENARIO

You have been assigned to work with the following four people for the 0700 shift on a medical–surgical unit. Significant data obtained during report are as follows:

- Mr Johnson is a 46 year old who is hospitalised for surgery to release contractures at his elbows which resulted from a flash burn from a grill fire 3 years ago. He is scheduled for surgery at 0800 and needs vital signs, preoperative medication and the preoperative checklist completed.
- Mrs Carter is a 35 year old who was hospitalised 2 days ago with cellulitis in the right calf. Vital signs are T 38°C, P 80, R 20, BP 116/76. She is complaining of a headache and pain in the right calf. She was last medicated for pain at 0300.
- Mr Jenkins is an 86 year old with herpes zoster. He was admitted 4 days ago with lesions on his left neck and trunk. Vital signs are T 37.2°C, P 88, R 26, BP 158/90. He is complaining of burning pain across his back and is requesting a nurse to check his back for new lesions.
- Mr Ugandi is a 34-year-old Indigenous Australian male who has AIDS. He was transferred from the burn critical care unit to the medical–surgical unit at 0600 after being treated for toxic epidermal necrolysis for the past month. He is ready to begin discharge teaching.

Critical thinking questions

1 In what order would you visit these people after report?

1.
2.
3.
4.

2 What top two priority nursing diagnoses would you choose for each of the people presented above? Can you explain, if asked, the rationale for your choices?

	Priority Nursing Diagnosis #1	Priority Nursing Diagnosis #2
Mr Johnson		
Mrs Carter		
Mr Jenkins		
Mr Ugandi		

3 Mr Johnson received partial-thickness and full-thickness flash burns on both anterior and posterior arms and his anterior trunk from the grill fire. Using the rule of nines, what is the percentage of total body surface (TBSA) burned? _____%

4 Morphine sulfate is the drug of choice for pain. Which manifestation requires immediate nursing intervention following morphine administration?

1. vomiting once after medication is administered
2. respiratory rate below 8 breaths per minute
3. blood pressure of 110/70 after a baseline blood pressure of 120/80
4. peripheral pulse of 68 after a baseline pulse of 78

5 A diet high in protein and iron may help prevent pressure injuries on the person who is on prolonged bed rest. Which foods should the nurse encourage the person to eat to help prevent pressure injuries?

1. eggs and chicken
2. broccoli and oranges
3. oatmeal and bananas
4. wholegrain bread and kidney beans

6 Mr Jenkins is being discharged to home. Which statement does the nurse need to teach Mr Jenkins about herpes zoster on discharge?

1. 'Continue taking the antiviral medication to cure the herpes zoster.'
2. 'You can attend church functions because herpes zoster is not contagious.'
3. 'Use narcotic pain medications only for severe pain so you do not become addicted to the medication.'
4. 'Wear cotton clothing and keep room temperatures cool to decrease the pain and itching from the herpes zoster lesions.'

7 Mrs Carter was admitted with cellulitis in the right calf. Which manifestations would the nurse assess on admission?

1. redness, oedema, and pain in the right calf
2. purulent drainage, pale skin, and pain in right calf
3. rash, redness, and swelling in right calf
4. itching, rash, and pain in right calf

8 The nurse applies mafenide acetate (Sulfamylon®) to Mr Ugandi's open skin wounds caused by toxic epidermal necrolysis. Which hypersensitivity reactions would require the nurse to discontinue the drug?

1. tachycardia and tachypnoea
2. nausea and vomiting
3. facial oedema and pruritus
4. diarrhoea and candidiasis

9 Which serum laboratory values are decreased with inadequate nutritional intake, such as in a person with severe burns? (Select all that apply.)

1. protein
2. potassium
3. iron
4. full blood cell count
5. glucose
6. calcium

10 When a person is admitted to the burns unit for treatment of severe burns, it is most important for the nurse to monitor the person for:

1. acute pain
2. nausea and vomiting
3. hypothermia
4. fluid and electrolyte imbalance

11 Which of these people is most at risk of skin breakdown leading to pressure injuries?

1. a 70 year old who had a stroke with left-sided paralysis
2. a quadriplegic admitted to the hospital with pneumonia

3. a 56 year old on dialysis three times a week
4. an 84 year old in traction for a hip fracture

12 Health teaching for skin cancer includes which interventions? (Select all that apply.)

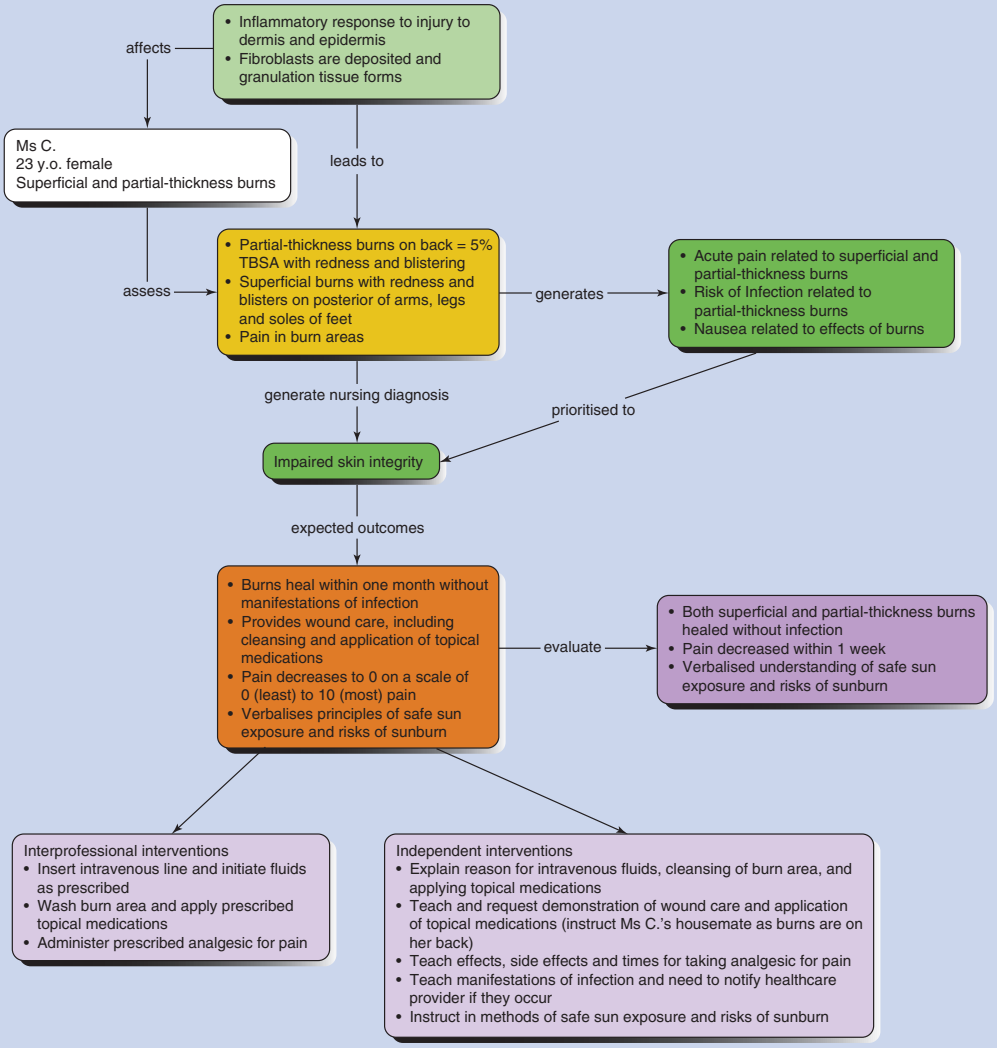
1. Wear long-sleeved shirts and a wide-brimmed hat in the sun.
2. Apply sunscreen once a day.
3. Avoid tanning booths or prolonged exposure to the sun.
4. Minimise exposure to the sun between 1 pm and 4 pm.
5. Apply sunscreen before and after swimming.

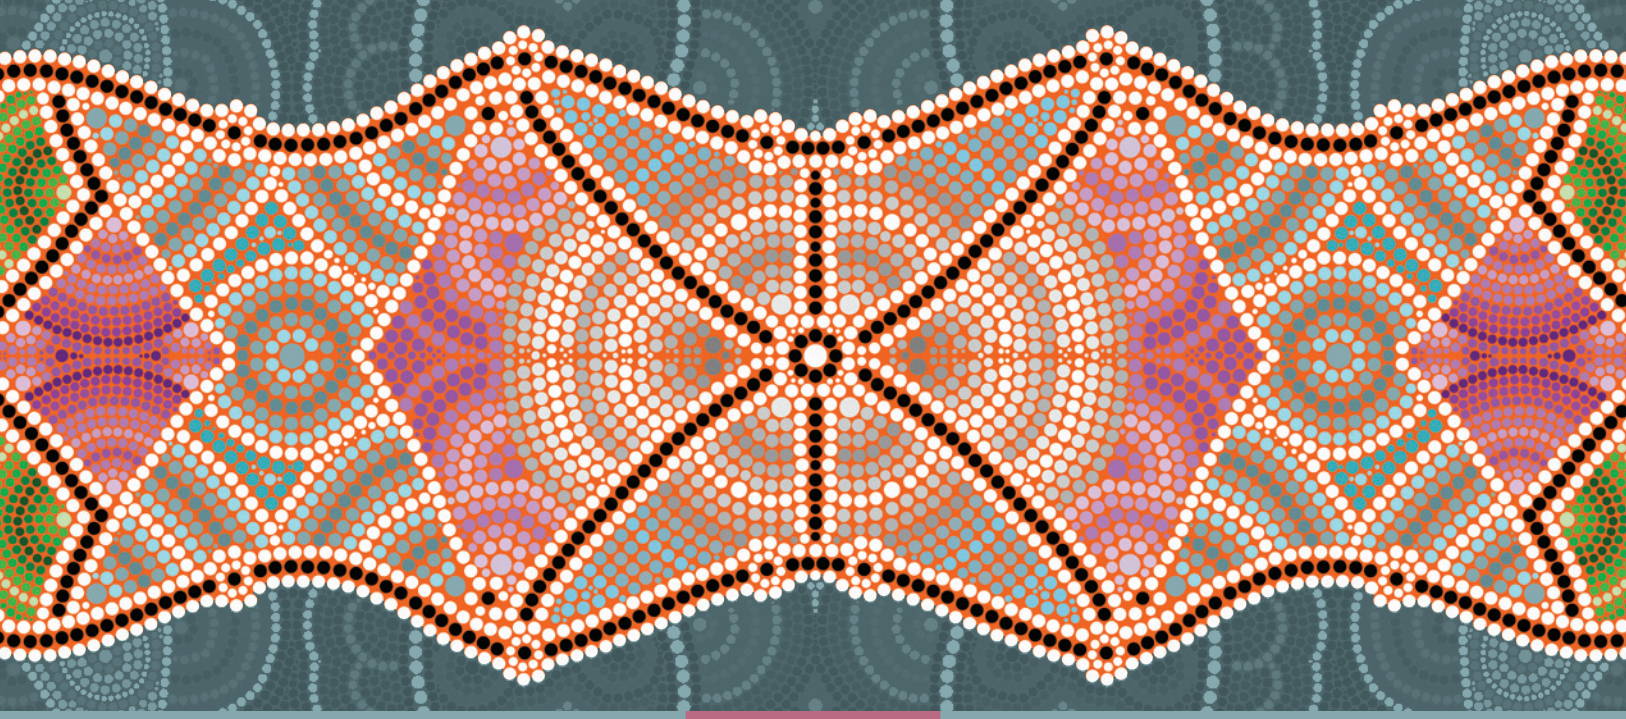
CASE STUDY

Ms Rachel Chelen is a 23 year old who is admitted to the medical–surgical unit for observation and treatment after being exposed to the sun for a prolonged period of time. On admission, Ms Chelen stated she fell asleep lying on her stomach while sunbathing at the beach. Her vital signs are T 39°C, P 94, R 26, BP 116/76. Her height is 167 cm and weight is 87 kg. Assessment findings are that her back is red and slightly oedematous with an area approximately 6 cm by 3 cm between the scapula that is beginning to develop blisters. The backs of her arms and legs, and soles of her feet are red and slightly oedematous. She is complaining of pain on her back, arms, legs and feet. She stated that she feels chilled, is nauseated and has a headache. Blood is drawn for a full blood count and electrolytes for baseline assessment. IV therapy is instituted to maintain hydration. The burn areas are washed with soap and water and an antibiotic ointment is applied. A mild analgesic is administered as ordered. Ms Chelen is covered to prevent further chilling and to prevent burned areas being exposed to air.

She is diagnosed with superficial and superficial partial-thickness burns. Using the rule of nines, the partial-thickness burn on her back is classified as approximately 5% total body surface area. The superficial burns over the rest of the reddened areas are not classified. Superficial burns involve the epidermis layer of the skin. Superficial partial-thickness burns involve the entire dermis and the papillae of the dermis. The pathophysiological effects of the superficial and partial-thickness burns are the result of exposure to the sun for a prolonged time. Inflammation occurs in response to tissue injury. Platelets aggregate at the burn injury site, fibrin is deposited, and a thrombus is formed. The thrombus, along with vasoconstriction, walls off the burn injury site. Then vasodilation occurs with increased capillary permeability, which leads to redness and oedema. Injury to the dermis results in a moist, glistening appearance as blisters form. The burned area will blanch on pressure. There is pain in response to touch and temperature changes. The burned area should heal within 14 to 21 days with minimal or no scarring, but may have pigment changes. Manifestations of superficial and superficial partial-thickness burns are skin redness, blister formation, local pain, headache, chills, nausea and vomiting. Complications of superficial and superficial partial-thickness burns are infection, hypothermia, dehydration and fluid and electrolyte imbalances.

Due to the severity of tissue injury from the burns, the priority nursing diagnosis of *Impaired skin integrity* is appropriate for guiding nursing care.





UNIT 5

RESPONSES TO ALTERED ENDOCRINE FUNCTION

CHAPTER 17

A PERSON-CENTRED APPROACH TO ASSESSING THE ENDOCRINE SYSTEM

NICOLE KNOX

KEY TERMS

LEARNING OUTCOMES

- Describe the anatomy and physiology of the endocrine glands.
- Explain the functions of the hormones secreted by the endocrine glands.
- Identify specific topics to consider during a health history interview of the person with health problems involving endocrine function, incorporating an understanding of age-related changes in assessment findings.
- Explain the nursing implications for a range of diagnostic tests associated with the endocrine glands.

CLINICAL COMPETENCIES

- Conduct and document a health history for the person who has or is at risk of alterations in the structure or function of the endocrine glands.
- Monitor the results of diagnostic tests and report abnormal findings.
- Conduct and document a physical assessment of the structure of the thyroid gland and the effects of altered endocrine function on other body structures and functions.

EQUIPMENT NEEDED

- Reflex hammer
- Safety pin, cotton ball, containers with hot and cold water, tuning fork
- Blood pressure cuff
- Stethoscope

The endocrine system plays an integral part in the regulation of the body's internal environment. Through hormones secreted by its glands, the endocrine system regulates such varied functions as growth, reproduction, metabolism, fluid and electrolyte balance, and gender differentiation. It also helps the body adapt to constant alterations in the internal and external environment.

ANATOMY, PHYSIOLOGY AND FUNCTIONS OF THE ENDOCRINE SYSTEM

The major endocrine organs are the pituitary gland, thyroid gland, parathyroid glands, adrenal glands, pancreas and gonads (reproductive glands). The locations of these glands are illustrated in Figure 17.1. Table 17.1 summarises the functions of the endocrine organs and their hormones. Specific information about the ovaries and testes is found in Chapters 46 to 48.

PITUITARY GLAND

The pituitary gland (hypophysis) is located in the skull beneath the hypothalamus of the brain (see Figure 17.2). It often is called the 'master gland' because its hormones regulate many body functions. The pituitary gland has two parts: the anterior pituitary (or adenohypophysis) and the posterior pituitary (or neurohypophysis). The anterior pituitary is glandular tissue, whereas the posterior pituitary is actually an extension of the hypothalamus.

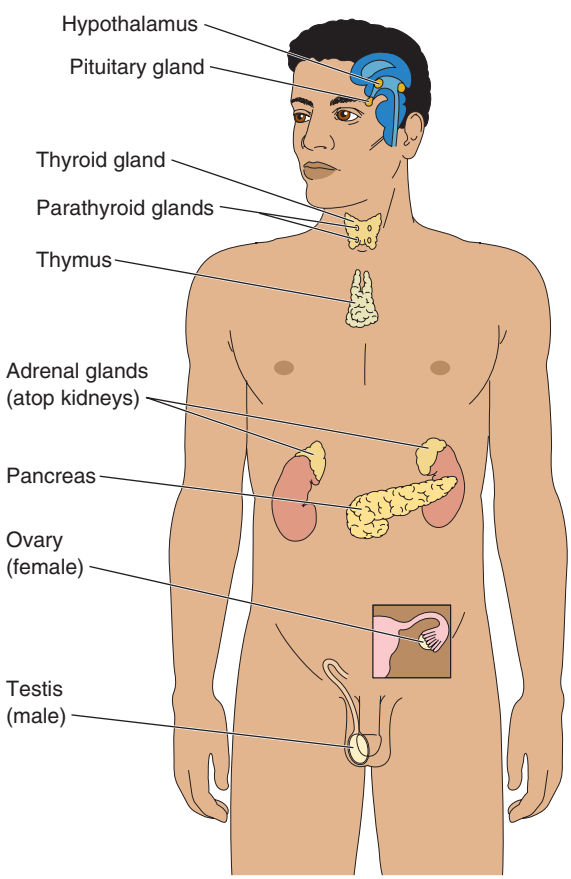


FIGURE 17.1 ■ Location of the major endocrine glands

Anterior pituitary

The anterior pituitary has several types of endocrine cells and secretes at least six major hormones (see Figure 17.3).

- Somatotropic cells secrete growth hormone (GH) (also called *somatotropin*). GH stimulates growth of the body by signalling cells to increase protein production and by stimulating the epiphyseal plates of the long bones.
- Lactotropic cells secrete prolactin (PRL). Prolactin stimulates the production of breast milk.
- Thyrotropic cells secrete thyroid-stimulating hormone (TSH). TSH stimulates the synthesis and release of thyroid hormones from the thyroid gland.
- Corticotropic cells secrete adrenocorticotropic hormone (ACTH). ACTH stimulates release of hormones, especially glucocorticoids, from the adrenal cortex.
- Gonadotropic cells secrete the gonadotropin hormones, follicle-stimulating hormone (FSH) and luteinising hormone (LH). These hormones stimulate the ovaries and testes (the gonads). In women, FSH stimulates the development of ovarian follicles and induces the secretion of oestrogenic female sex hormones. Increasing levels of LH work together with FSH to lead to ovulation and the formation of the corpus luteum from an ovarian follicle. In men, FSH is involved in the development and maturation of sperm. LH in men is called the interstitial cell-stimulating hormone (ICSH), which stimulates the interstitial cells of the testes to produce male sex hormones.

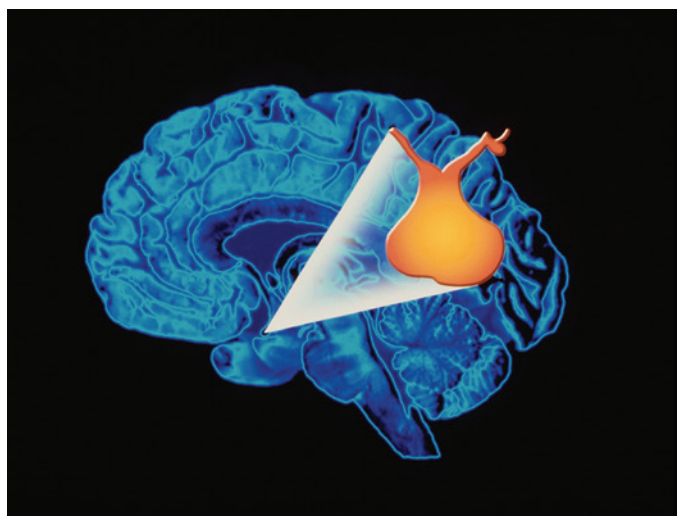

FIGURE 17.2 ■ Location of the pituitary gland

Source: Alfred Pasieka/Science Source.

TABLE 17.1 Organs, hormones, functions and feedback mechanisms of the endocrine system

ENDOCRINE ORGAN	HORMONE SECRETED	TARGET ORGAN AND FEEDBACK MECHANISM
Thyroid gland	Thyroid hormone (TH): thyroxine (T_4) is the major hormone secreted by the thyroid gland. It is converted to triiodothyronine (T_3) at the target tissues.	Maintains metabolic rate and the growth and development of all tissues. T_3 and T_4 are secreted in response to thyroid-stimulating hormone (TSH).
	Calcitonin	Maintains serum calcium levels by decreasing bone resorption and decreasing resorption of calcium in the kidneys whenever levels of plasma calcium are elevated. Works together with parathyroid gland to regulate calcium levels.
Parathyroid gland	Parathyroid hormone (PTH)	Maintains serum calcium levels by stimulating bone resorption and formation and by stimulating kidney resorption of calcium in response to falling levels of plasma calcium.
Adrenal cortex	Mineralocorticoids (e.g. aldosterone)	Promotes renal tubule reabsorption of sodium and water and excretion of potassium in response to elevated levels of potassium and low levels of sodium, thereby increasing blood pressure and circulating blood volume.
	Glucocorticoids (e.g. cortisol)	Help to regulate metabolism of carbohydrates, fats and proteins. Activate anti-inflammatory responses to stressors. Low cortisol levels stimulate hypothalamic secretion of corticotropin-releasing hormone (CRH), which stimulates the anterior pituitary gland to release ACTH, which in turn stimulates the adrenal cortex to secrete cortisol.
	Gonadocorticoids (androgens and small amounts of oestrogen and progesterone)	The quantity of sex hormones produced here is minimal and the mechanism is not well understood.
Adrenal medulla	Catecholamines (adrenaline and noradrenaline)	Secreted in response to physical or psychological stress; catecholamines stimulate the heart, constrict blood vessels, inhibit visceral muscles, dilate bronchioles, increase respiration and metabolism, and promote hyperglycaemia.
Anterior pituitary (adenohypophysis)	Growth hormone (GH)	Promotes growth of body tissues by enhancing protein synthesis and promoting use of fat for energy and thus conserving glucose. Release is stimulated by growth-hormone-releasing hormone (GHRH) in response to low GH levels, hypoglycaemia, increased amino acids, low fatty acids and stress.

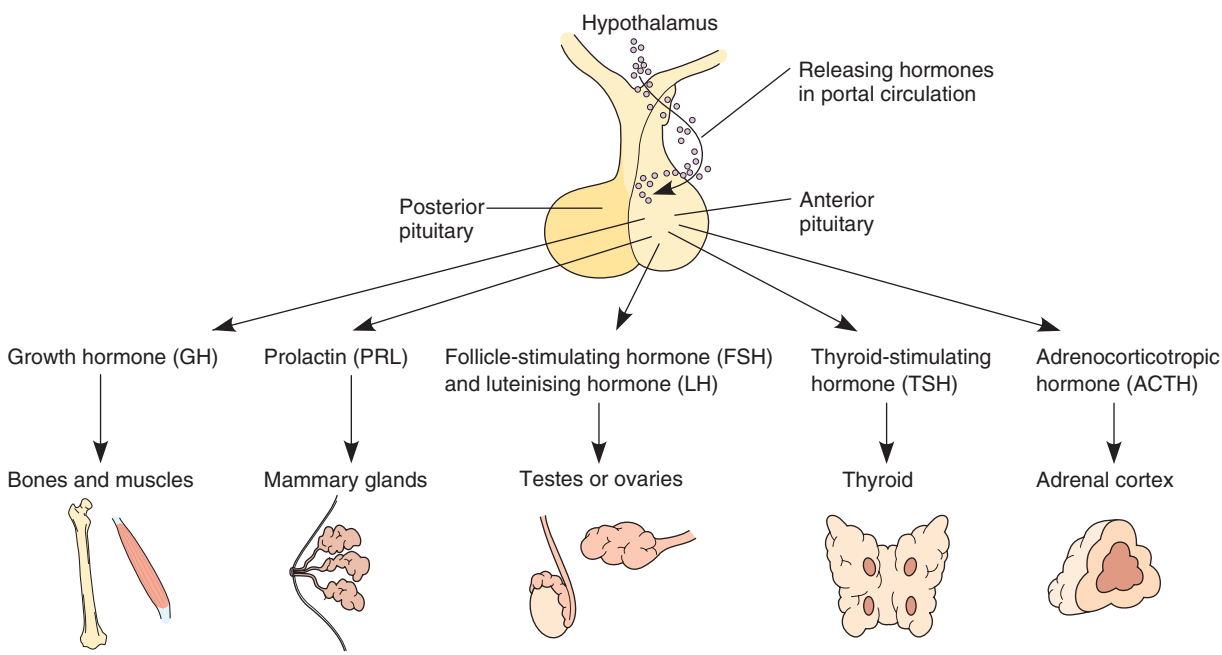

FIGURE 17.3 ■ Actions of the major hormones of the anterior pituitary

Posterior pituitary

The posterior pituitary is made of nervous tissue. Its primary function is to store and release antidiuretic hormone (ADH) and oxytocin, produced in the hypothalamus.

- ADH, also called *vasopressin*, decreases urine production by causing the renal tubules to reabsorb water from the urine and return it to the circulating blood volume.
- Oxytocin induces contraction of the smooth muscles in the reproductive organs. In women, oxytocin stimulates the myometrium of the uterus to contract during labour. It also induces milk ejection from the breasts.

THYROID GLAND

The **thyroid gland** (see Figure 17.4) is anterior to the upper part of the trachea and just inferior to the larynx. This butterfly-shaped gland has two lobes connected by a structure called the isthmus.

The glandular tissue consists of follicles filled with a jelly-like colloid substance called thyroglobin, a glycoprotein–iodine complex. Cells within the follicles secrete thyroid hormone (TH), a general name for two similar hormones: thyroxine (T_4) and triiodothyronine (T_3). The primary role of thyroid hormones in adults is to increase metabolism. TH secretion is initiated by the release of TSH by the pituitary gland and is dependent on an adequate supply of iodine.

The thyroid gland also secretes calcitonin, a hormone that decreases excessive levels of calcium in the blood by slowing the calcium-releasing activity of bone cells, serves as a marker for sepsis and is believed to be a mediator of inflammatory responses. However, when the thyroid gland is totally removed and thyroid hormone is replaced, calcium homeostasis and bone density remain relatively unchanged without replacing calcitonin.

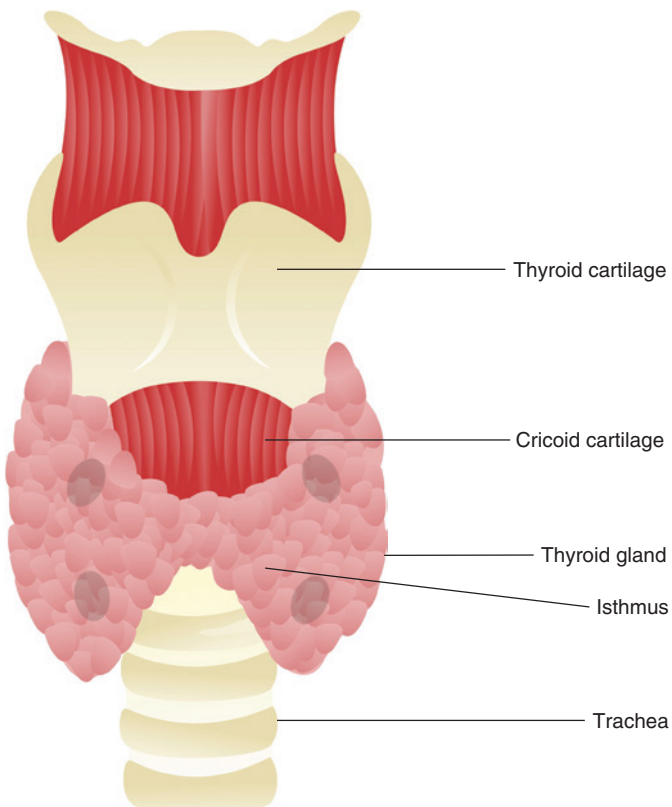

FIGURE 17.4 ■ The thyroid gland

Source: Zuzanae/Shutterstock.

Parathyroid glands

The parathyroid glands (usually four to six in number) are embedded on the posterior surface of the lobes of the thyroid gland. They secrete parathyroid hormone (PTH), or *parathormone*. When serum calcium levels fall, PTH secretion increases. PTH also controls phosphate metabolism. It acts primarily by increasing renal excretion of phosphate in the urine, by decreasing the excretion of calcium and increasing bone reabsorption to cause the release of calcium from bones. Normal levels of vitamin D are necessary for PTH to exert these effects on bone and the kidneys.

ADRENAL GLANDS

The two adrenal glands are pyramid-shaped organs that sit on top of the kidneys (see Figure 17.5). Each gland consists of two parts, which are distinct organs: an inner medulla and an outer cortex.

The adrenal medulla produces two hormones (also called catecholamines): adrenaline (epinephrine) and noradrenaline (norepinephrine). These hormones are similar to substances released by the sympathetic nervous system and thus are not essential to life. Adrenaline increases blood glucose levels and stimulates the release of ACTH from the pituitary; ACTH in turn stimulates the adrenal cortex to release glucocorticoids. Adrenaline also increases the rate and force of cardiac contractions; constricts blood vessels in the skin, mucous membranes and kidneys; and dilates blood vessels in the skeletal muscles, coronary arteries and pulmonary arteries. Noradrenaline increases both heart rate and the force of cardiac contractions. In addition it causes vasoconstriction of blood vessels throughout the body.

The adrenal cortex secretes several hormones, all corticosteroids. They are classified into two groups: mineralocorticoids and glucocorticoids.

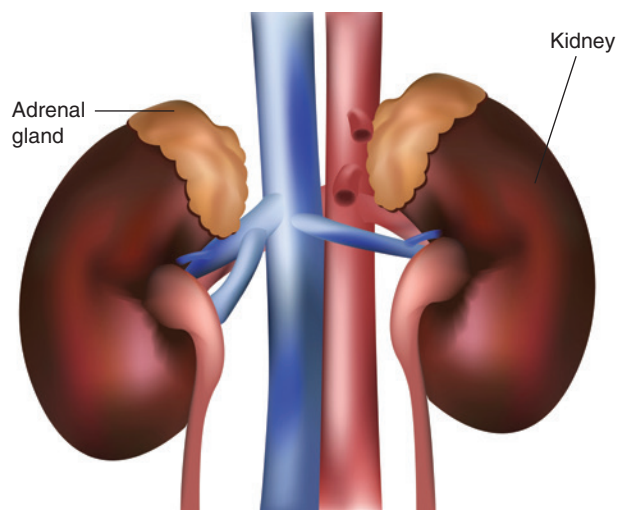

FIGURE 17.5 ■ Location of the adrenal glands

Source: Zuzanae/Shutterstock.

An enzyme named renin primarily controls the release of mineralocorticoids. When a decrease in blood pressure or sodium is detected, specialised kidney cells release renin to act on a substance called angiotensinogen, manufactured by the liver. Renin modifies angiotensinogen to form angiotensin I which is converted to angiotensin II by the angiotensin-converting enzyme. This stimulates the release of aldosterone from the adrenal cortex, which prompts the distal tubules of the kidneys to release increased amounts of water and sodium back into the circulating blood volume to increase blood pressure. This system (the renin–angiotensin–aldosterone system (RAAS)) is illustrated in Chapter 9 with the discussion of body fluid regulation.

The glucocorticoids include cortisol and cortisone. These hormones affect carbohydrate metabolism by regulating glucose use in body tissues, mobilising fatty acids from fatty tissue and shifting the source of energy for muscle cells from glucose to fatty acids. Glucocorticoids are released in times of stress. An excess of glucocorticoids in the body depresses the inflammatory response and inhibits the effectiveness of the immune system.

PANCREAS

The pancreas, located behind the stomach between the spleen and the duodenum, is both an endocrine gland (producing hormones) and an exocrine gland (producing digestive enzymes). The digestive enzymes produced by the pancreas are discussed in Chapter 20. The content in this chapter focuses on pancreatic hormones.

The endocrine cells of the pancreas produce hormones that regulate carbohydrate metabolism. They are clustered in bodies called pancreatic islets (or islets of Langerhans) scattered throughout the gland. Pancreatic islets have at least four different cell types:

1. Alpha cells produce glucagon, which decreases glucose oxidation and promotes an increase in the blood glucose levels by signalling the liver to release glucose from glycogen stores.
2. Beta cells produce insulin, which facilitates the uptake and use of glucose by cells and prevents an excessive breakdown of glycogen in the liver and muscle; thus, insulin decreases blood glucose levels. Insulin also facilitates lipid formation, inhibits the breakdown and mobilisation of stored fat and helps amino acids move into cells to promote protein synthesis. In general, the actions of glucagon and insulin oppose one another, helping to maintain a stable blood glucose level.
3. Delta cells secrete somatostatin, which inhibits the secretion of glucagon and insulin by the alpha and beta cells.
4. F cells secrete pancreatic polypeptide, which is believed to inhibit the exocrine activity of the pancreas.

GONADS

The gonads are the testes in men and the ovaries in women. These organs are the primary source of steroid sex hormones in the body. The hormones of the gonads are important in regulating body growth and promoting the onset of puberty.

In men, androgens (primarily testosterone) produced by the testes maintain reproductive functioning and secondary sex characteristics. Androgens also promote the production of sperm. In women, the ovaries secrete oestrogens and progesterone to maintain reproductive functioning and secondary sex characteristics. Progesterone also promotes the growth of the lining of the uterus to prepare for implantation of a fertilised ovum.

AN OVERVIEW OF HORMONES

Hormones are chemical messengers secreted by the endocrine organs and transported throughout the body, where they exert their action on specific cells called target cells. Hormones do not cause reactions directly, but rather regulate tissue responses. They may produce either generalised effects or local effects.

Hormones are transported from endocrine gland cells to target cells in the body in one of four ways:

1. Endocrine glands release most hormones, such as TH and insulin, into the bloodstream. Some hormones require a protein carrier.
2. Neurons release some hormones, such as adrenaline, into the bloodstream. This is called the neuroendocrine route.
3. The hypothalamus releases its hormones directly to target cells in the posterior pituitary by nerve cell extension.
4. With the paracrine method, released messengers diffuse through the interstitial fluid. This method of transport involves a number of hormonal peptides that are released throughout various organs and cells and act locally. An example is endorphins, which act to relieve pain.

Hormones that are released into the bloodstream circulate as either free, unbound molecules or as hormones attached to transport carriers. Hormone receptors are complex molecular structures, located on or inside target cells. They act by binding to specific receptor sites located on the surfaces of the target cells. These receptors recognise a specific hormone and translate the message into a cellular response. The receptor sites are structured so that they respond only to a specific hormone; for example, receptors in the thyroid gland are responsive to TSH but not to LH. Drugs that compete with a hormone for binding with transport carrier molecules increase hormone action by increasing the availability of the free, unbound hormone. Hormone levels are controlled by the pituitary gland and by feedback mechanisms. Although most feedback mechanisms are negative, a few are positive. Negative feedback is controlled in much the same way that the thermostat in an air conditioner regulates temperature. Sensors in the endocrine system detect changes in hormone levels and adjust the level of hormone secretion to maintain normal body levels. When the sensors detect a decrease in hormone levels, they begin actions to cause an increase in hormone levels; when hormone levels rise above normal, the sensors cause a decrease in hormone production and release. For example, when the hypothalamus or anterior

pituitary gland senses increased blood levels of TH, it releases hormones, causing a reduction in the secretion of TSH, which in turn prompts a decrease in the output of TH by the thyroid gland (see Figure 17.6).

In positive feedback mechanisms, increasing levels of one hormone cause another gland to release a hormone. For example, the increased production of oestradiol (a female ovarian hormone) during the follicular stage of the menstrual cycle in turn stimulates increased FSH production by the anterior pituitary gland. Oestradiol levels continue to increase until the ovarian follicle disappears, eliminating the source of the stimulation for FSH, which then decreases.

Stimuli for hormone release may also be classified as hormonal, humoral or neural (see Figure 17.7). In hormonal release, hypothalamic hormones stimulate the anterior pituitary to release hormones. Fluctuations in the serum level of these hormones in turn prompt other endocrine glands to release hormones. In humoral release, fluctuations in the serum levels of certain ions and nutrients stimulate specific endocrine glands to release hormones to bring these levels back to normal. In neural release, nerve fibres stimulate the release of hormones.

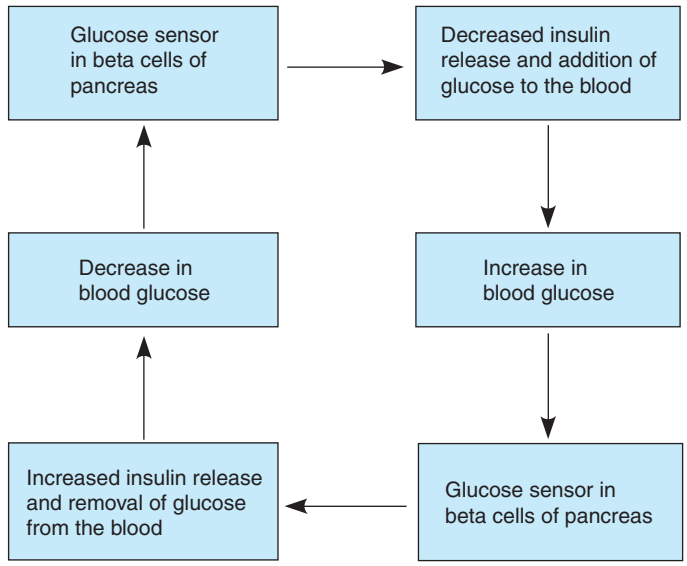

FIGURE 17.6 ■ Negative feedback

ASSESSING ENDOCRINE FUNCTION

The function of the endocrine glands is assessed by findings from a health assessment interview to collect subjective data, a physical assessment to collect objective data and diagnostic tests. Hormones affect all body tissues and organs and manifestations of dysfunction are often non-specific, making assessment of endocrine function sometimes more difficult than assessment of other body systems.

Health assessment interview

A health assessment interview to determine problems with the endocrine system may be part of a health screening or total health assessment, or it may focus on a chief complaint (such as increased urination or changes in energy levels). If the person has a problem with endocrine function, the nurse analyses its onset, characteristics and course, severity, precipitating and relieving

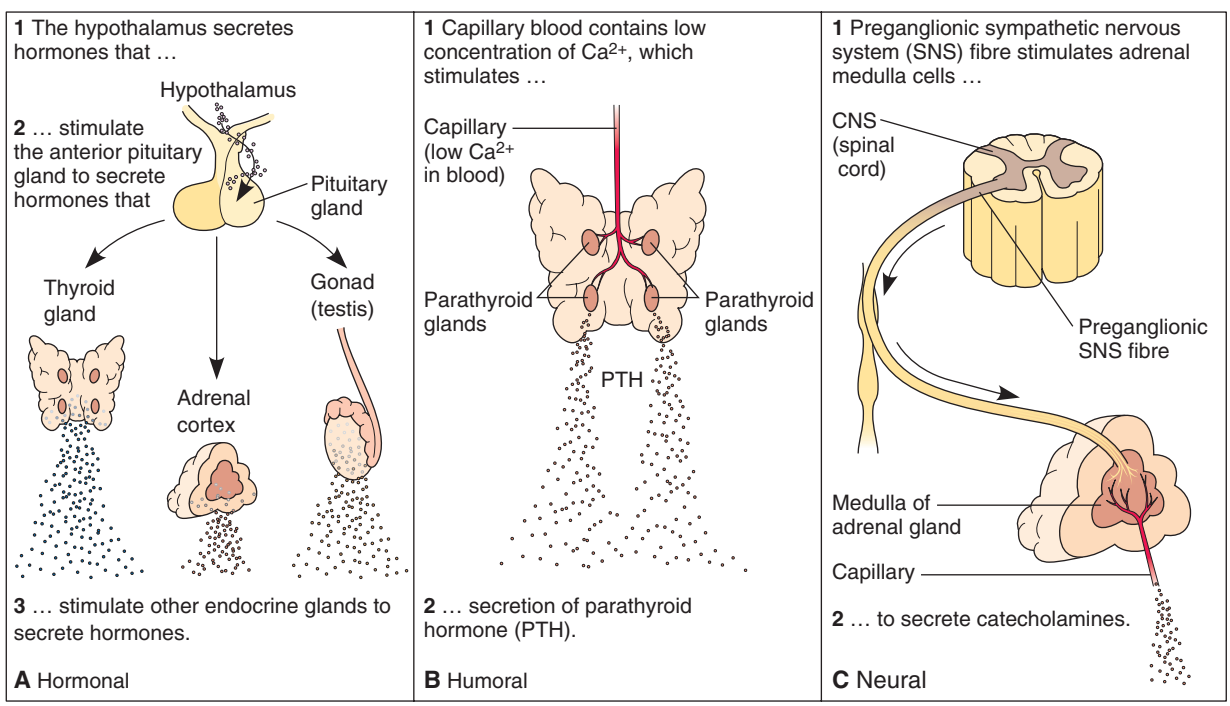

FIGURE 17.7 ■ Examples of three mechanisms of hormone release: *A*, hormonal; *B*, humoral; *C*, neural

factors, and any associated symptoms, noting the timing and circumstances. For example, the nurse may ask the person:

- Describe the swelling you noticed in the front of your neck. When did it begin? Have you noticed any changes in your energy level?
- When did you first notice that your hands and feet were getting larger?
- Have you noticed that your appetite has increased even though you have lost weight?

The health history includes information about the person's medical history, family history and social history. Ask the person about any changes in normal growth and development, as well as in height and weight. Changes in the size of extremities can often be detected by asking whether the person has had to have rings enlarged or buy increasingly larger shoes. Enlargement of the neck may be identified by asking whether the person has difficulty finding shirts or blouses with a collar that fits. Also explore changes such as difficulty swallowing; increased or decreased thirst, appetite and/or urination; visual changes; sleep disturbances; altered patterns of hair distribution (such as increased facial hair in women); changes in menstruation; changes in memory or ability to concentrate; and changes in hair and skin texture. Ask the person about any blow to the head, as well as previous hospitalisations, chemotherapy, radiation (especially to the neck) and the use of medications (especially hormones or steroids).

The nurse also asks about the person's occupational and social history. Include questions about the person's satisfaction with occupation, personal relationships and lifestyle. Other areas of assessment include the person's usual means of coping; use of alcohol, smoking or drugs; diet (including weight gain or loss); and exercise and sleep patterns. Although the person may not recognise changes in behaviour, family members may be able to provide important information.

Interview questions categorised by functional health patterns are listed below.

FUNCTIONAL HEALTH PATTERN INTERVIEW Endocrine system

FUNCTIONAL HEALTH PATTERN	INTERVIEW QUESTIONS AND LEADING STATEMENTS
Health perception–Health management	■ Describe your overall state of health, rating it on a scale of 1 to 10 with 10 being the best health you have had. ■ Describe any problems you have had with an endocrine gland (pituitary, thyroid, parathyroid, adrenal, pancreas, ovaries, testes). ■ If you had a problem with any of these glands, how was it treated (medications, surgery, diet, hormone replacement)? ■ Has any relative experienced any problems with an endocrine gland (pituitary, thyroid, parathyroid, adrenal, pancreas, ovaries, testes)? ■ Do you smoke, drink alcohol, and/or use recreational drugs? If so, how much and what kind? ■ Have you ever been tested for high or low blood sugar?
Nutritional–Metabolic	■ Describe what you eat and how much (and what type of) fluid you drink in a 24-hour period. ■ Do you take any nutritional supplements, herbs or vitamins? ■ Have you noticed any change in your hunger or thirst? ■ Has your weight changed? If so, by how many kilograms and over what time period? ■ Have you noticed any change in your energy level? If so, explain. ■ Have you noticed any change in your ability to tolerate heat or cold? ■ Have you noticed any difficulty swallowing? Explain. ■ Have you noticed any changes in the texture of your skin? If so, what were they?
Elimination	■ Have you noticed any change in urine colour, odour or amount or in the frequency of urination? If so, describe it. ■ Have you ever had kidney stones? If so, how were they treated? ■ Has there been a change in your bowel elimination (such as diarrhoea or constipation)? If so, explain the change.

FUNCTIONAL HEALTH PATTERN	INTERVIEW QUESTIONS AND LEADING STATEMENTS
Activity–Exercise	■ Describe your physical activities in a usual day. ■ Has your energy level increased or decreased? Explain. ■ Do some activities make you very tired? Explain how you feel.
Sleep–Rest	■ How many hours of sleep do you get each night? ■ Do you feel nervous and unable to rest? ■ Do you sweat at night?
Cognitive–Perceptual	■ Have you noticed any problem with your memory? ■ Do you feel restless, anxious or confused? ■ Have you noticed any change in your voice? ■ Have you noticed any change in the colour or condition of your skin and hair (colour, dryness, oiliness, bruises)? ■ Have you had any headaches, memory loss, changes in sensation, depression? If so, describe them. ■ Have you noticed any change in your vision? If so, describe them. ■ Have you had any heart palpitations? ■ Have you had any abdominal pain? What is it like and where is it located? ■ Have you had any pain or stiffness in your muscles and joints?
Self-perception–Self-concept	■ How does this condition make you feel about yourself? ■ How do you feel about taking medications?
Role–Relationships	■ How does this condition affect your relationships with others? ■ Does anyone in your family have an endocrine disorder? If so, when did it begin and how does it affect them? What family member is affected and at what age did it begin?
Stress tolerance	■ Does stress seem to make your condition worse? Explain. ■ Has this condition created stress for you? ■ Describe what you do when you feel stressed.
Value–Belief	■ Tell me how specific relationships or activities help you cope with this condition. ■ Describe specific cultural beliefs or practices that affect how you care for and feel about this condition. ■ Are there any specific treatments that you would not use to treat this condition?

Physical assessment

Physical assessment of the endocrine system may be performed as part of a total health assessment or it may be a focused assessment of the person with known or suspected problems with endocrine function. Sample documentation of an assessment of the thyroid gland is included in the accompanying box.

The only endocrine organ that can be palpated is the thyroid gland; however, other assessments that provide information about endocrine problems include inspection of the skin, hair, nails, facial appearance, reflexes and musculoskeletal system. Measuring and monitoring trends in height and weight and vital signs also provide clues to altered endocrine system function.

SAMPLE DOCUMENTATION
Assessment of the thyroid gland

A 37-year-old female presents at a community clinic with complaints of 'always feeling so hot', 'always hungry but losing weight' and 'can't sleep at night—too jittery'. Weight 53 kg (loss of 6 kg in last 3 months). BP 90/78, P 96. Skin very warm and moist. Anterior neck has diffuse enlargement. Thyroid gland enlarged bilaterally on palpation. Referral made to endocrine clinic for further evaluation.

The person may sit during the examination. A reflex hammer is used to test deep tendon reflexes. Prior to the examination, the nurse collects the necessary equipment and explains the

TABLE 17.2 Age-related endocrine changes

AGE-RELATED CHANGE	SIGNIFICANCE
Pituitary: ↓ production of ACTH, TSH, FSH	• Decreased secretion of glucocorticoids, 17-ketosteroids, progesterone, androgen and oestrogen (and thus lower levels on diagnostic tests)
Thyroid: ↑ in fibrosis and nodularity, ↓ in gland activity	• Lower basal metabolic rate • Increased incidence of hypothyroidism • Palpable nodules on palpation
Adrenal medulla: ↑ secretion and level of noradrenaline, increased plasma noradrenaline level, however ↓ beta-adrenergic response to noradrenaline	• Decreased response to beta-adrenergic and receptor blockers medications • May contribute to increased incidence of hypertension
Pancreas: calcification of blood vessels and distension and dilation of pancreatic ducts	• Decreased production of lipase with reduced fat absorption and digestion, leading to intolerance of fatty foods and indigestion • Decreased absorption of fat-soluble vitamins
Pancreas: delayed and decreased insulin release; believed accompanied by decreased sensitivity to circulating insulin	• Decreased ability to metabolise glucose with higher and more prolonged blood glucose levels may contribute to increased incidence of type 2 diabetes mellitus with ageing (however, higher than normal blood glucose levels are not unusual in non-diabetic older adults)

techniques to the person to decrease anxiety. Additional techniques for assessing hypocalcaemic tetany, a complication of endocrine disorders or surgery, are included in the examination sequence. Normal age-related changes in assessment findings are described in Table 17.2.

Diagnostic tests

The results of diagnostic tests of the endocrine system are used to support the diagnosis of a specific disease, to provide information to identify or modify the appropriate medication or therapy used to treat the disease, and to help nurses monitor the person's response to treatment and nursing care interventions. Diagnostic tests to assess the structure and function of the glands of the endocrine system are described in the box below and are summarised in the bulleted list that follows. Please note: normal reference values for all serum/urine tests vary slightly from laboratory to laboratory due to specific test kits used in each laboratory. More information is included in the discussion of specific disorders in Chapters 18 and 19.

- As a result of the many hormones produced by the pituitary gland and the number of target organs for those hormones, many direct and indirect diagnostic tests are used to determine pituitary function. The diagnostic tests described in this chapter include those of growth hormone (GH), somatomedin C, and causes of polyuria and pituitary tumours.
- Although a substantial number of diagnostic tests are used to identify and monitor thyroid function, the most accurate is TSH. Other tests of thyroid structure and function include thyroxine, triiodothyronine, thyroid antibodies, radioactive iodine uptake and thyroid scan.
- Diagnostic tests of the parathyroid hormone, which regulates serum calcium and phosphate levels, include PTH and serum calcium.
- Diagnostic tests for the adrenal glands assess the glucocorticoids, mineralocorticoids and androgens through both blood and 24-hour urine studies. The tests are of cortisol, aldosterone, ACTH, 17-ketosteroids and CT of the abdomen to identify adrenal gland tumours.
- Diagnostic tests of the pancreas are performed primarily to identify, confirm and monitor glucose levels in the person with diabetes mellitus. Those described are the oral glucose tolerance test (OGTT), fasting plasma glucose (FPG), glycosylated haemoglobin (HbA1c) and CT of the abdomen to identify pancreatic tumours or cysts.

Regardless of the type of diagnostic test, the nurse is responsible for explaining the procedure and any special preparation needed, for assessing for medication use that may affect the outcome of the tests, for supporting the person during the examination as necessary, for documenting the procedures as appropriate and for monitoring the results of the tests.

DIAGNOSTIC TESTS The endocrine system

PITUITARY TESTS

NAME OF TEST Growth hormone (GH), Human growth hormone (hGH)

PURPOSE AND DESCRIPTION In this blood test, GH levels (affected by food, stress and activity) are measured to identify GH deficiency (dwarfism) or GH excess (gigantism, acromegaly).

Normal value:
Men: < 5 μg/L
Women: < 10 μg/L

RELATED NURSING CARE Inform the person not to eat or drink 8–10 hours prior to having blood taken. Have the person sit down for 30 to 60 minutes before blood is taken.

DIAGNOSTIC TESTS The endocrine system (continued)

NAME OF TEST IGF-1 (Somatomedin C or Insulin-like growth factor)

PURPOSE AND DESCRIPTION The results of this blood test are used to identify diseases or conditions caused by hyper/hyposecretion of growth hormone and to evaluate the function of the pituitary gland.

Normal value:
Adult: 42–110 ng/mL
Results vary by age for children

RELATED NURSING CARE None; overnight fasting is preferred but not necessary.

NAME OF TEST Water deprivation test (Anti-diuretic hormone stimulation)

PURPOSE AND DESCRIPTION This combination blood and urine test is used to identify causes of polyuria (increased urine output), including central diabetes insipidus (DI), neurogenic diabetes insipidus, syndrome of inappropriate antidiuretic hormone (SIADH) and psychogenic polydipsia. ADH or vasopressin is given intramuscularly (IM) or subcutaneously (SC). In people without pathology, there is no change in urine and plasma osmolality. Urine osmolality increases in central diabetes insipidus and decreases in nephrogenic diabetes insipidus.

RELATED NURSING CARE The recommended fluid restriction prior to this test is dependent on the person's current urine output. Inform the person that the test will take up to 8 hours. Every hour for ordered length of test: assess weight, take postural BP (lying and standing measures separated by 2 minutes), assess urine for volume and specific gravity, and send samples of urine to the lab for osmolality. Blood samples for osmolality are taken when urine osmolality shows an increase of less than 30 mOsm/kg for 3 consecutive hours. Vasopressin is administered and urine osmolality is measured 30 to 60 minutes later.

Following the test the person needs to be rehydrated with oral fluids and have vital signs monitored.

NAME OF TEST Magnetic resonance imaging (MRI)

PURPOSE AND DESCRIPTION This radiographic study is done to identify tumours of the hypothalamus or pituitary gland.

RELATED NURSING CARE Inform the person of need to lie still during the examination. Remove any metallic objects (such as hair clips, jewellery) and assess for any metallic implants (such as pacemakers, body piercings, shrapnel). If present, the test is not performed due to the danger caused by the magnetic field from the machine.

THYROID TESTS

NAME OF TEST Thyroid-stimulating hormone (TSH)

PURPOSE AND DESCRIPTION In this blood test, TSH and T_4 levels are measured to differentiate pituitary from thyroid causes of hypothyroidism. A decreased T_4 level and a normal or increased TSH level can indicate a thyroid disorder. A decreased T_4 level and a decreased TSH level can indicate a pituitary disorder.

Normal value:
0.5–4.5 mIU/L

RELATED NURSING CARE Inform the person to avoid shellfish for several days prior to the test. Evaluate medications: TSH value may be increased by aspirin, steroids, dopamine and heparin; and decreased by lithium and potassium iodide.

NAME OF TEST Thyroxine (Free T_4)

PURPOSE AND DESCRIPTION This blood test is done to determine thyroid function and aid in the diagnosis of hyperthyroidism and hypothyroidism.

Normal value:
Adult: 10–36 pmol/L

RELATED NURSING CARE Assess medications: value may be decreased by cortisone, chlorpromazine (Largactil), phenytoin (Dilantin), heparin, lithium, sulfonamides (Serpasil), testosterone and propranolol (Inderal). Values may be increased by aspirin, iodine, oral contraceptives and oestrogens.

NAME OF TEST Triiodothyronine (Total T_3)

PURPOSE AND DESCRIPTION This blood test is used to diagnose hyperthyroidism and to compare T_3 with T_4 for diagnosis of thyroid disorder. It is useful in monitoring the effectiveness of thyroid replacement and suppressive therapy.

Normal value:
Adult 20–50 years: 1.2–3.4 mmol/L
Adult >50 years: 0.6–2.8 mmol/L

RELATED NURSING CARE Evaluate medications: value can be decreased by propylthiouracil, lithium, phenytoin (Dilantin), propranolol (Inderal), large doses of aspirin, steroids and sulfonamides. Value can be increased by oestrogens, progestins, oral contraceptives, T_3 and methadone; it will also be increased during pregnancy.

(continued)

DIAGNOSTIC TESTS The endocrine system (continued)

NAME OF TEST Triiodothyronine resin uptake (T_3RU)

PURPOSE AND DESCRIPTION This blood test is an indirect measure of free thyroxine (T_4). The person's blood is mixed with radioactive T_3 and synthetic resin, and the radioactive T_3 will bind with available thyroid-binding globulin sites. The unbound radioactive T_3 is added to resin for T_3 uptake. In hyperthyroidism there are few binding sites left; more T_3 is taken up by the resin and a high T_3 resin uptake results. The opposite occurs in hypothyroidism.

Normal value:
24–34% uptake

RELATED NURSING CARE No special preparation is needed.

NAME OF TEST Thyroid antibodies (TA)

PURPOSE AND DESCRIPTION A blood test used to identify thyroid immune disease (Graves' disease, chronic thyroiditis, Hashimoto's thyroiditis).

Normal values:
Antithyroglobulin: negative to titre <1:20
Antimicrosomal: negative to titre <1:100

RELATED NURSING CARE Assess for family history of thyroid disease and ask about recent viral infection (which could trigger autoimmune disease).

NAME OF TEST Radioactive iodine uptake (Radioimmunoassay or RIA)

PURPOSE AND DESCRIPTION This test provides a direct measure of thyroid activity and is useful in evaluating the activity of solitary thyroid nodules. Based on the rationale that the thyroid gland takes up iodine in any form, radioactive iodine is given orally or intravenously and the thyroid gland uptake is measured with a scanner at several hourly intervals and at 24 hours.

Normal value for uptake:
2–4 hours: 3–19%
24 hours: 11–30%

RELATED NURSING CARE The person should not eat or drink for 6 to 8 hours before the test, but can have food 1 hour after the oral dose is given. Advise the person not to take supplemental iodine several weeks before the test. Thyroid medications and amiodarone interfere with the test.

NAME OF TEST Thyroid scan

PURPOSE AND DESCRIPTION This radiological study evaluates thyroid nodules. Radioactive isotopes are given orally or intravenously and a scanner is passed over the thyroid to make a graphic record of the radiation emitted. A normal thyroid scan has a homogeneous pattern of radiation with symmetric lobes. Benign lesions appear as warm spots (take up more radiation); malignant tumours appear as cold spots (less radiation taken up).

RELATED NURSING CARE No special preparation is needed.

PARATHYROID TESTS

NAME OF TEST Parathyroid hormone (PTH)

PURPOSE AND DESCRIPTION A blood test done to identify hypoparathyroidism or hyperparathyroidism; also used to monitor response to PTH therapy.

Normal value:
Intact PTH: 10–65 ng/L
C-terminal PTH: 50–330 ng/L
N-terminal PTH: 8–24 ng/L

RELATED NURSING CARE Advise the person not to eat or drink for 8 hours before the test.

NAME OF TEST Calcium (Ca)

PURPOSE AND DESCRIPTION This blood test is used to check for serum calcium excess or deficit in parathyroid and bone disorders, and to monitor calcium levels.

Normal value:
2.3–2.8 mmol/L

RELATED NURSING CARE Assess for manifestations of tetany, including positive Chvostek's and Trousseau's signs, if hypocalcaemia is present.

ADRENAL TESTS

NAME OF TEST Cortisol

PURPOSE AND DESCRIPTION A blood test is done to measure amount of total cortisol in the serum and evaluate adrenal cortex function. It is decreased in Addison's disease and hypothyroidism; increased in Cushing's syndrome and hyperthyroidism.

Normal value:
8 am–10 am: 138–635 nmol
4 pm–6 pm: 83–359 nmol

A 24-hour urine test may be conducted to measure free (unbound) cortisol.

Normal value:
<276 nmol/24 hours

DIAGNOSTIC TESTS The endocrine system (continued)

RELATED NURSING CARE Bloods are usually taken at 0800 hours and again at 1600 hours. The results are compared with the 1600 hour level and should be between one- and two-thirds the level of the 0800 hour blood level. Evaluate medications: cortisol is decreased by androgens and phenytoin (Dilantin), and increased by oral contraceptives, oestrogen, cortisone and spironolactone (Aldactone).

Instruct the person how to save urine for a 24-hour period, to eat a low-sodium diet before the test and to avoid stressful situations and physical activity for at least 24 hours prior to the test. You do not need to measure each urine specimen. Ensure the urine specimen is kept on ice or refrigerated. Assess medications; values may be increased by spironolactone (Aldactone), hydrocortisone and oral contraceptives.

NAME OF TEST Aldosterone

PURPOSE AND DESCRIPTION This blood test is done to identify hyperaldosteronism and to compare blood and urine levels with other lab data to evaluate overhydration with increased sodium and adrenal malfunction.

Normal value:
Men: 0.17–0.61 nmol/L
Women: 0.14–0.80 nmol/L

A 24-hour urine test is considered a more reliable measure of aldosterone than a random aldosterone test.

Normal value:
6–72 nmol/L/24 hours

RELATED NURSING CARE Usually the person must sit upright for a period of 2 hours prior to the test. The person should be instructed to follow a diet with normal levels of sodium for 2 weeks prior to the test. Assess diet and lab results: levels are increased by hyponatraemia, hyperkalaemia and a low-salt diet. Assess medications: values are increased by diuretics, hydralazine (Apresoline), nitroprusside and oral contraceptives. Values are decreased by propanolol (Inderal), ACE inhibitors and licorice.

NAME OF TEST Adrenocorticotropic hormone (ACTH)

PURPOSE AND DESCRIPTION This blood test is done to determine if a decreased plasma level of cortisol is due to adrenal cortex hypofunction or pituitary hypofunction.

Normal value:
7 am–10 am: <18 pmol/L
4 pm: <11 pmol/L

RELATED NURSING CARE Advise the person that food and fluids may be restricted and to eat a low-carbohydrate diet for 24 hours prior to the test. Assess medications: ACTH values may be increased by metyrapone, vasopressin and insulin; and decreased by steroids, oestrogen amphetamines and alcohol.

NAME OF TEST ACTH stimulation

PURPOSE AND DESCRIPTION Performed to check for pituitary hypofunction. The drug metyrapone (Metopirone) is given to block the production of cortisol, thus causing an increased ACTH secretion.

If the ACTH level does not increase, the problem is pituitary insufficiency.

RELATED NURSING CARE Assess medications as for ACTH test.

NAME OF TEST ACTH suppression

PURPOSE AND DESCRIPTION Performed to check the origin of the condition. The drug dexamethasone (Dexmethsone) is given to suppress ACTH production. If an extremely high dose is needed, the cause is of pituitary origin; if the plasma cortisol continues to be high with ACTH suppression, the cause could be adrenal cortex hyperfunction (Cushing's syndrome). Normally, the plasma cortisol level should double in 1 hour.

RELATED NURSING CARE Advise the person to avoid caffeinated drinks and chocolates; no other food or fluid restriction is needed. Assess medications: false positives may be caused by phenytoin, barbiturates, meprobamate and carbamazepine. If dexamethasone causes gastric irritation, milk or antacids may be required.

NAME OF TEST 17-Ketosteroids

PURPOSE AND DESCRIPTION This 24-hour urine test is done to measure metabolites in urine and evaluate adrenal cortex function.

Normal value:
Men: 20–70 µmol in 24 hours
Women: 20–60 µmol in 24 hours

RELATED NURSING CARE Teach the person how to save urine. (Urine must contain a preservative and be refrigerated.) Assess medications and refer to information about the test. Levels are affected by a variety of medications; if possible, these should be discontinued for 48 hours before the test. Women cannot have the test while menstruating because blood can cause a false positive finding.

(continued)

DIAGNOSTIC TESTS The endocrine system (continued)

NAME OF TEST Computed tomography (CT) of the abdomen

PURPOSE AND DESCRIPTION This radiological study is used to assess for tumours (including size and metastasis).

RELATED NURSING CARE Determine if contrast medium will be used; if so, assess the person for an allergy to iodine (shellfish).

PANCREATIC ENDOCRINE TESTS

NAME OF TEST Fasting plasma glucose (FPG)

PURPOSE AND DESCRIPTION This blood test is used to identify or confirm a diagnosis of type 2 diabetes. It is also used to monitor treatment of diabetes mellitus. A finding of 7.0 mmol/L or above is now considered to be consistent with a diagnosis of type 2 diabetes. When looking to diagnose a person with type 2 diabetes, an oral glucose tolerance test should also be performed when a person has received a FPG result of 5.5–6.9 mmol/L. Additionally, diagnosis needs to be confirmed by two positive FPG levels on separate days.

Value:
Normoglycaemia: <6.1 mmol/L
Impaired glucose tolerance: 6.1–7 mmol/L
Diabetes: >7 mmol/L
(World Health Organization & International Diabetes Federation, 2006).

RELATED NURSING CARE Advise the person not to eat or drink anything other than water for at least 8 hours before the test. Do not administer insulin or oral hypoglycaemic medications until blood specimen is taken. Assess medications: FPG may be increased by cortisone, diuretics, ACTH, levodopa, anaesthetics and phenytoin (Dilantin).

NAME OF TEST Oral glucose tolerance test (OGTT or GTT)

PURPOSE AND DESCRIPTION Performed to diagnose diabetes mellitus if prior fasting plasma glucose findings are increased or inconsistent. It is also commonly used to diagnose gestational diabetes.

NURSING IMPLICATIONS The tests will not be done if the person's FPG is consistently high (>11 mmol/L). The person drinks a solution of 75 to 100 g of glucose, and samples of blood and urine are taken immediately and at 30, 60 and 120 minutes (or it may extend from 3 to 4 hours).

Reference values:

Time	Serum glucose level
Fasting	3.9–6.1 mmol/L
0.5 hour	<11.1 mmol/L
1 hour	<11.1 mmol/L
2 hours	<7.8 mmol/L
3 hours	Fasting level

RELATED NURSING CARE Advise the person that food, fluids (except water) and smoking are not allowed during the test or 12 hours prior to the test. Advise the person they must not exercise during the test. Assess medications: drugs that may increase OGTT levels are steroids, oral contraceptives, oestrogens, thiazide diuretics and salicylates. Explain to the person that they may feel weak and may perspire during the test and that they should report these symptoms to the nurse. Although they usually are transitory, these symptoms may be manifestations of hyperinsulinism.

NAME OF TEST Glycated haemoglobin (HbA1c)

PURPOSE AND DESCRIPTION This blood test is used to measure the effectiveness of treatment of diabetes mellitus. The results represent an average blood glucose level during a 2- to 3-month period; an elevated level indicates uncontrolled diabetes mellitus and increased risk of complications. It is not currently recommended for diagnosis of diabetes.

Good diabetic control: 2.5–5.9% of total haemoglobin

RELATED NURSING CARE Monitor findings: decreased levels can be caused by anaemias, long-term blood loss and chronic renal failure. Increased levels may result from hyperglycaemia, alcohol ingestion, pregnancy, haemodialysis and prolonged cortisone intake.

Genetic considerations

When conducting a health assessment interview and physical assessment, it is important for the nurse to consider genetic influences on the health of the adult. During the health assessment interview, ask about endocrine disorders in immediate family members, including the family member's age of onset and gender. Ask the person about a family history of such diseases as diabetes mellitus, diabetes insipidus, thyroid disorders, growth problems, hypertension and obesity. Ask women about problems with pregnancy, menstruation and/or menopause.

During the physical assessment, assess for any manifestations that might indicate a genetic disorder (see box below). If data indicate genetic risk factors or alterations, ask about genetic testing and refer for appropriate genetic counselling and evaluation. Chapter 7 provides further information about genetics in medical–surgical nursing.

GENETIC CONSIDERATIONS
Endocrine system

- Type 1 and type 2 diabetes mellitus are classified as multifactorial inheritance disorders because both genetic and environmental factors are necessary for onset of the disorder.
- Pendred syndrome is an inherited disorder in which people have hereditary deafness and a thyroid goitre.
- Hashimoto's disease (chronic thyroiditis) is believed to have a genetic component.
- Multiple endocrine neoplasia is a group of rare diseases caused by genetic defects leading to hyperplasia and hyperfunction of two or more components of the endocrine system (especially the parathyroid, pancreas and pituitary glands).

ENDOCRINE ASSESSMENTS

Technique/normal findings	Abnormal findings
Skin assessment	
Inspect skin colour. *Skin colour should be even and appropriate to the person's age and race.*	■ Hyperpigmentation may be seen in peoples with Addison's disease or Cushing's syndrome. ■ Hypopigmentation may be seen in people with diabetes mellitus, hyperthyroidism or hypothyroidism. ■ A yellowish cast to the person's skin might indicate hypothyroidism. ■ Purple striae over the abdomen and bruising may be present in the person with Cushing's syndrome.
Palpate the skin, assessing texture, moisture and the presence of lesions. *Skin should be appropriate to the person's race, smooth, warm, dry and intact without abnormal lesions.*	■ Rough, dry skin is often seen in people with hypothyroidism, whereas smooth and flushed skin can be a sign of hyperthyroidism. ■ Lesions (such as ulcerations) on the person's lower extremities might indicate diabetes mellitus.
Nails and hair assessment	
Assess texture, distribution and condition of nails and hair. *Hair should be of normal texture, appropriately distributed for gender; nail surfaces should have even colour with smooth surfaces.*	■ Increased pigmentation of the nails is often seen in people with Addison's disease. ■ Dry, thick, brittle nails and hair may be apparent in people with hypothyroidism; thin, brittle nails and thin, soft hair may be apparent in people with hyperthyroidism. ■ Hirsutism (excessive facial, chest or abdominal hair) may be seen in people with Cushing's syndrome.
Facial assessment	
Inspect the symmetry and form of the face. *Face should be bilaterally symmetrical.*	■ Variations of form and structure may indicate growth abnormalities such as **acromegaly** (continued growth of bone from growth hormone hypersecretion).
Inspect position of eyes. *Eyes should be equal in position on both sides of the face. Eyelids should close over eyes.*	■ **Exophthalmos** (protruding eyes) may be seen in people with hyperthyroidism.

ENDOCRINE ASSESSMENTS (continued)

Technique/normal findings	Abnormal findings
Thyroid gland assessment	
Palpate the thyroid gland for size and consistency. Stand behind the person and place your fingers on either side of the trachea below the thyroid cartilage (see Figure 17.8). Ask the person to tilt their head to the right. Now ask the person to swallow. As the person swallows, displace the left lobe while palpating the right lobe. Repeat to palpate the left lobe. *Thyroid gland is not usually palpable. If it is, lobes should feel smooth, rubbery and free of nodules.*	■ The thyroid may be enlarged in people with Graves' disease or a **goitre** (enlarged thyroid gland). ■ Multiple nodules may be seen in metabolic disorders, whereas the presence of only one nodule may indicate a cyst or a benign or malignant tumour. ■ One enlarged nodule suggests malignancy.
Motor function assessment	
Assess the deep tendon reflexes. Deep tendon reflexes are assessed with the reflex hammer and include the biceps reflex, brachioradialis reflex, triceps reflex, patellar reflex and Achilles reflex. *Normal values range from 1+ (present, but decreased) to 2+ (normal) to 3+ (increased). See Chapter 40 for guidelines and illustrations of deep tendon reflex assessment.*	■ Increased reflexes may be seen in people with hyperthyroidism; decreased reflexes may be seen in people with hypothyroidism.
Sensory function assessment	
Test the person's sensitivity to pain, temperature, vibration, light touch and stereognosis (the ability to identify an object merely by touch). Compare symmetrical areas on both sides of the body and compare the distal to the proximal regions of the extremities. Ask the person to close their eyes. *Sensory function should be bilaterally intact.* ■ To test pain, use the blunt and sharp ends of a new safety pin. Discard the pin after use. ■ To test temperature, use cups or other containers of cold and hot water. ■ To test vibration, use a tuning fork over one of the person's finger or toe joints. ■ To test light touch, use a cotton tip. ■ To test stereognosis, place in the person's hand a simple, familiar object, such as a rubber band, cotton ball or button. Ask the person to identify the object.	■ Peripheral neuropathy and paresthesias (altered sensations) may occur in people with diabetes, hypothyroidism or acromegaly.
Musculoskeletal assessment	
Inspect the size and proportions of the person's body structure. *Size and proportion of body structures should be bilaterally equal.*	■ Extremely short stature may indicate **dwarfism**, which is caused by insufficient growth hormone. ■ Extremely large bones may indicate acromegaly, which is caused by excessive growth hormone.

FIGURE 17.8 ■ Palpating the thyroid gland from behind the person

Technique/normal findings	Abnormal findings
Assessing for hypocalcaemic tetany	
Assess for **Trousseau's sign** (a test for hypocalcaemia) with resulting tetany (tonic muscle spasms) by inflating a blood pressure cuff above the antecubital space to a point greater than systolic blood pressure for 2–5 minutes. Trousseau's sign is discussed in relation to hypocalcaemia in Chapter 9. *A normal finding would be no carpal spasm in response to compression of the arm by the blood pressure cuff.*	■ Decreased calcium levels cause the persons hand and fingers to contract (**carpal spasm**).
Assess for **Chvostek's sign** (a test for hypocalcaemia) by tapping your finger in front of the person's ear at the angle of the jaw. A positive Chvostek's sign causes facial grimacing due to repeated contractions of the facial muscle. Chvostek's sign is discussed and illustrated in relation to hypocalcaemia in Chapter 9. *A normal finding would be no facial grimacing in response to tapping the person's face in front of the ear.*	■ Decreased calcium levels cause the person's lateral facial muscles to contract.

CONCEPT CHECK

1 What physiological response is expected if the pituitary gland produces an increased amount of ADH?
1 increased output of urine
2 decreased output of urine
3 increased facial hair growth in women
4 decreased production of testosterone

2 What assessment might be made to identify low calcium levels?
1 Save urine to measure 17-ketosteroids.
2 Palpate turgor of skin.
3 Conduct a Trousseau's sign test.
4 Observe colour of skin.

3 Excessive amounts of glucocorticoids, produced by the adrenal cortex, result in what pathophysiological health problem?
1 inhibited immune response
2 increased response to glucagon
3 delayed onset of puberty
4 decreased metabolic rate

4 When conducting a health history focused on the endocrine system, which of the following questions should be included?
1 'When did you first notice the pain in your abdomen?'
2 'Do your children have problems with urination?'
3 'Have you noticed a change in your thirst?'
4 'How did you get this scar on your leg?'

5 What assessments are made when palpating the thyroid gland?
1 oedema and movement
2 size and consistency
3 character and texture
4 pain and pulse rate

6 How many times does a FPG test showing an elevated level need to be performed to confirm a diagnosis of diabetes?
1 once only
2 twice, once in the morning and then in the afternoon
3 never, a glycated haemoglobin test is more accurate
4 twice, on two separate days

7 Which of the following tests is the most accurate indicator of thyroid function?
1 GH
2 FPG
3 aldosterone
4 TSH

8 Which is the only endocrine organ that can be palpated during physical assessment?
1 pancreas
2 liver
3 thyroid
4 pituitary

9 You are caring for a person with newly diagnosed hyperthyroidism. What might you find in an assessment?
1 increased thick hair growth
2 exophthalmos
3 decreased reflexes
4 rough, dry skin

10 What endocrine disorder might be assessed by testing deep tendon reflexes?
1 Cushing's syndrome
2 acromegaly
3 tetany
4 hyperthyroidism

CHAPTER 18

NURSING CARE OF PEOPLE WITH ENDOCRINE DISORDERS

SANDRA CAMPBELL-CROFTS

LEARNING OUTCOMES

- Compare and contrast the manifestations of disorders that result from hyper- and hypofunction of the thyroid gland.
- Describe the pathophysiology, manifestations and nursing care of the person with hyper- and hypofunction of the parathyroid glands.
- Discuss common disorders of the adrenal glands, incorporating pathophysiology, manifestations and associated nursing care.
- Compare and contrast common disorders of the pituitary gland and the resulting manifestations.

CLINICAL COMPETENCIES

- Assess the functional health status of people with endocrine disorders, and monitor, document and report abnormal manifestations.
- Use evidence-based research to provide appropriate teaching for self-medicating with thyroid hormone.
- Determine priority nursing diagnoses, based on assessed data, to select and implement individualised nursing interventions for people with endocrine disorders.
- Provide education to ensure the person knows that hormone replacement is for life and how to take medications efficiently and effectively.
- Monitor respiratory function after a thyroidectomy.
- Monitor for latent tetany following parathyroid removal—planned or inadvertent.
- Anticipate and recognise the effects of adrenal hormones.
- Revise the plan of care as needed to provide effective interventions to promote, maintain or restore functional health status to the person with endocrine disorders.

KEY TERMS

The thyroid, parathyroid, adrenal and pituitary glands are part of the endocrine system. Disorders of the structure and function of these glands alter normal hormone levels and the way body tissues use those hormones. When hormone production increases or decreases, people experience alterations in health.

People with disorders of the endocrine glands discussed in this chapter require nursing care for multiple problems. Nursing care is directed towards meeting physiological needs, providing education and ensuring psychological support for the person and family. A holistic approach to the complex needs of people with these endocrine disorders is an essential component of nursing care.

DISORDERS OF THE THYROID GLAND

The thyroid uses iodine to secrete thyroid hormone (TH). TH is of vital importance for both the development and the maintenance of brain function and other major organ systems (Warner & Mittag, 2012).

Thyroid disorders—both hyperthyroidism and hypothyroidism—are among the most common endocrine disorders. Thyroid disease is the second most common endocrine condition in women of childbearing age (Medenica et al., 2015). In Australia, thyroid diseases affect about 850 000 people (7.5% of women and 1.5% of men) and the prevalence of these conditions rises with age. Fortunately, thyroid conditions respond well to treatment (Thyroid Australia, 2011a).

PEOPLE WITH HYPERTHYROIDISM

Hyperthyroidism or **thyrotoxicosis** is a disorder caused by excessive functional activity of the thyroid gland. Because the primary effect of TH is to increase metabolism and protein synthesis, hyperthyroidism is characterised by increased basal metabolism, weight loss despite an increased food intake and alterations of the autonomic nervous system. The increase in metabolic rate and the alterations in cardiac output include sinus tachycardia and increased peripheral blood flow, oxygen consumption and body temperature (Molina, 2009; Porth & Matfin, 2009).

Elevated TH levels also increase carbohydrate, protein and lipid metabolism. Lipids are depleted and glucose tolerance decreases (Wang, 2013).

Pathophysiology and manifestations

Hyperthyroidism results from many different factors, including autoimmune thyroid stimulation as in Graves' disease (Segni et al., 2014); excess secretion of thyroid-stimulating hormone (TSH) by the pituitary gland; thyroiditis; non-malignant neoplasms such as toxic multinodular goitre; and an excessive intake of thyroid medications. The most common aetiologies of hyperthyroidism in Australia are Graves' disease and toxic multinodular goitre.

The person with hyperthyroidism typically has an increased appetite, yet loses weight, and may have increased bowel motility without diarrhoea. Additional manifestations related to hypermetabolism include increased nervousness or irritability, heat intolerance, insomnia, palpitations and increased sweating. There is an increased risk of fractures (Blum et al., 2015). The skin is smooth and warm, hair may become fine and hair loss in the scalp, eyebrow, axillary or pubic areas of the body is common. Emotional lability is also common. The 'Multisystem effects of hyperthyroidism' are shown opposite.

Graves' disease

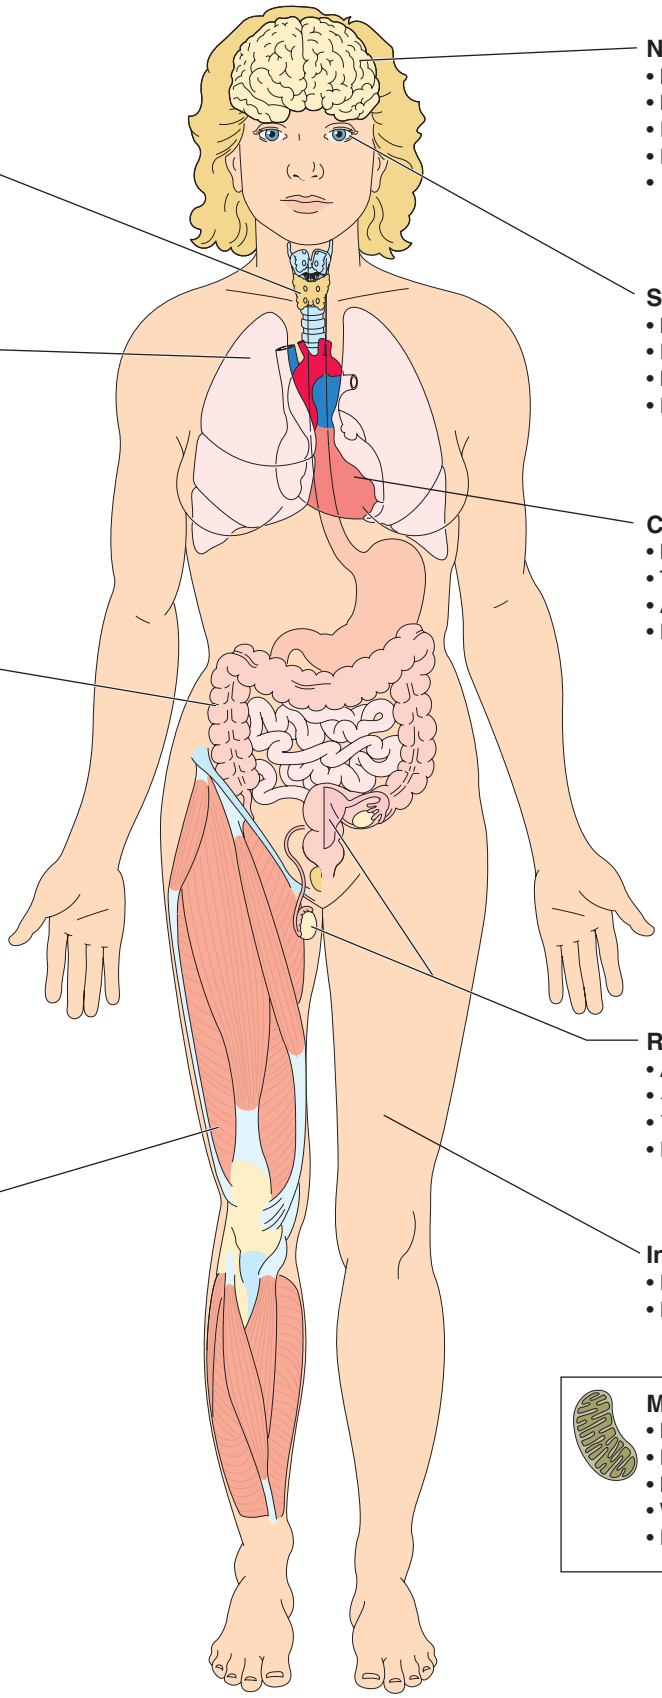
Graves' disease is the most common cause of hyperthyroidism and one of the most common autoimmune disorders in Australia, affecting 0.5% of the population (Campbell & Doogue, 2012). It is caused by a defect in immunoregulation in genetically predisposed individuals, leading to thyroid hyperplasia and an increased production of thyroid-stimulating hormone receptor antibodies (Campbell & Doogue, 2012). It is sometimes associated with the presence of other autoimmune disorders such as polyglandular autoimmune syndrome (PGA), myasthenia gravis and pernicious anaemia (Porth & Matfin, 2009; Pouye et al., 2014).

Graves' disease is seen five times more often in women than in men and occurs most frequently between the ages of 20 and 40. It is seen worldwide, with the incidence often correlated with the amount of iodine in the diet. Increased iodine intake (such as from radiocontrast dyes used in diagnostic tests, ingestion of supplement iodine tablets or medications such as amiodarone that contains 39% iodine by weight) have been associated with this disorder. Smoking, psychological stress and the postpartum period are also associated with Graves' disease.

People with Graves' disease have an enlarged diffuse thyroid gland (**goitre**) and manifestations of hyperthyroidism (as shown in Table 18.1). Goitre may be present as a consequence of both iodine deficiency and excess, and is evident in both hyperthyroidism and hypothyroidism (Zimmermann & Boelaert, 2015).

The common ophthalmopathy of Graves' disease is manifested as proptosis and visual dysfunction. **Proptosis** (forward displacement) of the eyeball occurs in about one-third of cases (Porth & Matfin, 2009). The forward protrusion (**exophthalmos**) results from an accumulation of inflammation by-products in the retro-orbital tissues. Often the sclera is visible above the iris. The upper lids are often retracted and the person has a characteristic unblinking stare (see Figure 18.1). In some cases proptosis may involve only one eye. Due to stretching or compression of the optic nerve, the person may experience blurred vision, diplopia, eye pain, lacrimation and photophobia. The inability to close the eyelids completely over the protruding eyeballs increases the risk of corneal dryness, irritation, infection and ulceration. Infiltration of the muscles that move the eye and of the optic nerve leads to

MULTISYSTEM EFFECTS OF HYPERTHYROIDISM



Endocrine
- Goitre

Respiratory
- Dyspnoea

Gastrointestinal
- Nausea
- Vomiting
- Diarrhoea
- Abdominal pain

Musculoskeletal
- Muscle wasting
- Weakness
- Fatigue

Neurological
- Hand and eye tremors
- Nervousness
- Insomnia
- Emotional lability
- ↑ reflexes

Sensory
- Blurred vision
- Photophobia
- Lacrimation
- Exophthalmos (Graves' disease)

Cardiovascular
- Hypertension
- Tachycardia
- Arrhythmias
- Palpitations

Reproductive
- Amenorrhoea (female)
- ↓ fertility (female)
- ↑ libido (male)
- Impotence (male)

Integumentary
- Fine, thin hair
- Flushed, moist skin

Metabolic processes
- Hyperthermia
- Diaphoresis
- Hunger
- Weight loss
- Fluid volume deficit

TABLE 18.1 Laboratory findings in hyperthyroidism

TEST	NORMAL VALUES	FINDINGS
Serum TA	≤ 1:10 titre	Increased
Serum TSH (sensitive assay)	0.27–4.2 mU/L	Decreased in primary hyperthyroidism
Serum T_4	Total 12–22 pmol/L	Increased
Serum T_3	Free 3–7.8 pmol/L	Increased
T_3 uptake (T_3RU)	25% to 35%	Increased
Thyroid suppression		Increased RAI uptake and T_4 levels

mU: microunits; pmol: picomoles.

paralysis and vision loss. The treatment of Graves' disease generally does not reverse these changes in the eyes.

A rare characteristic dermopathy of Graves' disease is **pretibial myxoedema** which occurs in 1% to 2% of people. Plaques and nodules develop bilaterally over the shins and dorsal surface of the feet. These plaques are oedematous, erythematous and sometimes hyperpigmented. Like the ophthalmopathy, the skin changes often persist despite successful treatment (Fatourechi, 2005).

Other manifestations include anaemia, vomiting, jaundice, fatigue, difficulty sleeping, hand tremors, increased bowel movements and changes in menstruation ranging from decreased flow to amenorrhoea. Twenty per cent of older people may present with atrial fibrillation, angina or congestive heart failure as a result of pulmonary hypertension.

Toxic multinodular goitre

Toxic multinodular goitre (see Figure 18.2) is a non-malignant tumour characterised by small, discrete, independently functioning nodules in the thyroid gland that secrete excessive amounts of TH. The aetiology includes a suspected genetic mutation of follicle cells as well as a deficiency of iodine (Zimmermann & Boelaert, 2015). People with this type of hyperthyroidism are usually women in their sixties or seventies who have had goitre for a number of years.

Excess TSH stimulation

Overproduction of TSH by the pituitary usually stimulates the thyroid gland to produce excess TH. The elevation in TSH

FIGURE 18.1 ■ Exophthalmos in a person with Graves' disease. The disorder causes oedema of fat deposits behind the eyes and inflammation of the extraocular muscles. The accumulating pressure forces the eyes outward from their orbits

Source: © Medical-On-Line/Alamy.

FIGURE 18.2 ■ Toxic multinodular goitre. The formation and growth of numerous nodules in the thyroid gland cause the characteristic massive enlargement of the neck

Source: Marka/Custom Medical Stock Photo.

secretion often results from a pituitary adenoma. This secondary form of hyperthyroidism is rare.

Subacute thyroiditis

Subacute thyroiditis (inflammation of the thyroid gland) is most often the result of a viral infection of the thyroid gland such as influenza or mumps. The symptoms of subacute thyroiditis are those of inflammation and the effects of increased TH. Subacute thyroiditis may become chronic, resulting in a hypothyroid state as repeated infections destroy gland tissue. See the discussion of Hashimoto's thyroiditis later in this chapter.

Thyroid crisis

Thyroid crisis (also called **thyroid storm**) is an extreme state of hyperthyroidism that is rare today because of improved diagnosis and treatment (Carroll & Matfin, 2010). Those affected usually have had untreated hyperthyroidism (most often Graves' disease) or have been receiving therapy but have experienced an acute stressor, such as an infection, trauma, myocardial infarction, diabetic ketoacidosis (DKA) or manipulation of the thyroid gland during surgery. Newer biological agents such as interleukin-2 and interferon alpha have been reported to induce thyroid storm (Carroll & Matfin, 2010). Thyroid crisis is a life-threatening condition.

The rapid increase in metabolic rate results in manifestations including hyperthermia, with body temperatures ranging from 39°C to 41°C; tachycardia; systolic hypertension; and gastrointestinal symptoms (abdominal pain, vomiting and increased bowel motions). Agitation, restlessness and tremors are common, progressing to confusion, psychosis, delirium and seizures. The mortality rate is high. Rapid treatment of thyroid crisis is essential to preserve life. Intensive care treatment includes cooling without aspirin (which increases free TH) or inducing shivering; replacing fluids, glucose and electrolytes; relieving respiratory distress via mechanical ventilation; stabilising cardiovascular function; and reducing TH synthesis and secretion.

INTERPROFESSIONAL CARE

Treatment of hyperthyroidism focuses on reducing the production of TH, thus establishing a **euthyroid** (normal thyroid) state, and preventing or treating complications. Depending on the person's age and physical status, oral antithyroid medications, radioactive iodine therapy or surgery may be used.

Diagnosis

Hyperthyroidism is diagnosed according to the manifestations of the specific disorders causing excessive TH and by diagnostic test results. Elevated levels of TH (both T_3 and T_4) and increased radioactive iodine (RAI) uptake are diagnostic criteria of hyperthyroidism. Laboratory findings in hyperthyroidism were shown earlier in Table 18.1.

The following diagnostic tests may be ordered:

- *TSH receptor antibodies*. This is useful to establish the diagnosis of Graves' disease, especially when a radionuclide thyroid scan is not able to be performed, as in pregnancy or lactation. Thyroid peroxidase and thyroglobulin autoantibodies may be useful in the diagnosis of subacute thyroiditis or autoimmune chronic lymphocytic thyroiditis.
- *TSH test (sensitive assay)*. Serum TSH levels are measured and compared with thyroxine (T_4) levels to differentiate pituitary from thyroid dysfunction. The best indicator of primary hyperthyroidism (such as in Graves' disease) is suppression of TSH below 0.27 mU/L. When the sensitive TSH is not suppressed, the hyperthyroidism is caused by a TSH-secreting pituitary tumour.
- *T_4 test, total*. Serum tetraiodothyronine (thyroxine) levels are measured to determine TH concentration and to test thyroid gland function. Levels are elevated in hyperthyroidism and acute thyroiditis.
- *T_3 test, free*. Serum triiodothyronine (T_3) is the active form of TH. T_3 is measured by radioimmunoassay (T_3RIA), which measures bound and free forms of this hormone. T_3 levels may be elevated in hyperthyroidism and thyroiditis. T_3 decreases in acute illness and starvation and is affected by medications such as amiodarone, propranolol and steroids (Molina, 2009).
- *T_3 uptake test*. T_3 uptake (T_3RU) is measured by an in vitro test in which the person's blood is mixed with radioactive T_3; the results are elevated in hyperthyroidism and in metastatic neoplasms.
- *RAI uptake test*. A radioactive iodine uptake test (thyroid scan) measures the absorption of ^{131}I or ^{123}I by the thyroid gland. A calculated dose of radioactive iodine is given orally or intravenously and the thyroid is then scanned (often after 24 hours). The distribution of radioactivity in the gland is recorded (increased uptake of radioactive iodine is seen in Graves' disease). In addition, the scan reveals the size and shape of the gland.
- *Thyroid suppression test*. RAI and T_4 levels are measured first. The person then takes TH for 7 to 10 days, after which the tests are repeated. Failure of hormone therapy to suppress RAI and T_4 indicates hyperthyroidism.
- *Fine needle biopsy*. Any suspicious enlargement of the thyroid gland should undergo biopsy with expert cytological examination.

Medications

Hyperthyroidism can be treated by administering antithyroid medications that reduce TH production. See 'Medication administration' box below.

Radioactive iodine therapy

Because the thyroid gland takes up iodine in any form, radioactive iodine (^{131}I) concentrates in the thyroid gland and damages or destroys thyroid cells so that they produce less TH. The person is placed on a low-iodine diet for up to six weeks prior to therapy to facilitate uptake (Ngyuen et al., 2015).

Results typically occur in 6 to 8 weeks. In most instances, the person is not hospitalised during treatment and does not require radiation precautions. Women of childbearing age should delay becoming pregnant for 6 months and men should allow 4 months for sperm turnover production. RAI has recently been shown to worsen the ophthalmopathy associated with Graves' disease (Hershman, 2013).

MEDICATION ADMINISTRATION Hyperthyroidism

IODINE SOURCES

Strong iodine solution (sodium iodide (^{131}I) solution BP)

The Wolff–Chaikoff effect has demonstrated that large doses of iodine for a short term inhibit TH synthesis and release (Carroll & Matfin, 2010).

Nursing responsibilities

- Assess for hypersensitivity to iodine before giving medication; for example, ask the person about allergies to shellfish.
- Dilute liquid iodine sources in water or orange juice to disguise bitter taste.
- Monitor for increased bleeding tendencies if the person is also taking anticoagulants; iodine increases their effect.

Health education for the person and family

- Administer at least 1 hour after antithyroid medications.
- The maximum effect of iodine in large doses usually occurs in 10 to 15 days.
- Long-term iodine therapy is not effective in controlling hyperthyroidism.

ANTITHYROID DRUGS

Carbimazole (Neo-Mercazole; Carbimazole Aristo)
(Propylthiouracil or PTU)

Antithyroid drugs, also known as thionamide medications, inhibit the incorporation of iodine into thyroglobulin, thus lowering TH production. They do not affect already formed hormones; therefore, several weeks may elapse before the person experiences therapeutic effects. Carbimazole is converted to methimazole in the body. This oral medication is given in divided doses according to the severity of the hyperthyroidism, from 15 mg/day up to 60 mg/day in severe cases. Once symptoms are controlled the dosage can be tapered to a long-term maintenance dose. Due to the high risk of foetal gastrointestinal defects, carbimazole is contraindicated during the first trimester of pregnancy (Campbell & Doogue, 2012).

Propylthiouracil is taken in divided doses three or four times daily until the person is euthyroid. Propylthiouracil is the preferred medication in the first trimester of pregnancy (Campbell & Doogue, 2012).

Nursing responsibilities

- Monitor for side effects: life-threatening agranulocytosis evidenced by reduced neutrophil count and fever, hypothyroidism, pruritus rash, periorbital oedema, anorexia or vomiting, loss of taste, menstrual irregularities.
- Severe hepatocellular injury occurs with propylthiouracil in 0.1% of patients. Monitor for evidence of jaundice.
- Administer drugs at the same time each day with meals to maintain stable blood levels.
- Monitor for symptoms of hypothyroidism: fatigue, weight gain, bradycardia.

Health education for the person and family

- Watch for unusual bleeding, redness, swelling, nausea, loss of taste or epigastric pain.
- If you are also taking warfarin for atrial fibrillation, report any signs of bleeding.
- It may take up to 12 weeks before you experience the full effects of the drugs. Take the medication regularly and exactly as prescribed. Do not discontinue abruptly.

Because the amount of gland destroyed is not readily controllable, the person may become hypothyroid and require lifelong TH replacement. Adverse reactions include radiation thyroiditis and cardiac instability due to liberation of stored thyroid hormone in the gland (Campbell & Doogue, 2012), sialadenitis (inflammation of the salivary gland) and xerostomia (dry mouth) (Charalambous, Frangos & Talias, 2014).

Surgery

Surgery is recommended when other treatments are not effective in young individuals, people with large or suspicious nodules, obstructive symptoms when the pressure on the oesophagus or trachea causes breathing or swallowing problems, for rapid resolution of symptoms. A *subtotal thyroidectomy* is usually performed. This procedure leaves enough of the gland in place to produce an adequate amount of TH. A total **thyroidectomy** is performed to treat thyroid cancer; the person then requires lifelong hormone replacement (Quérat et al., 2015).

Before surgery, the person should be in as nearly a euthyroid state as possible. Antithyroid drugs may be given to reduce hormone levels and iodine preparations to decrease the vascularity and size of the gland, which also reduces the risk of haemorrhage during and after surgery. Postoperative complications include laryngeal nerve palsy or hypocalcaemia due to removal of or damage to the parathyroid glands (Quérat et al., 2015).

Nursing care of the person having a subtotal thyroidectomy is discussed in the box below.

Nursing care

Health promotion

Although hyperthyroidism is not preventable, it is vital to teach the importance of regular healthcare provider visits and maintaining regular medication intake.

Assessment

The following data are collected through the health history and physical examination (see Chapter 17). Further focused assessments are described with nursing interventions.

NURSING CARE OF THE PERSON Having a subtotal thyroidectomy

PREOPERATIVE CARE

- Administer ordered antithyroid medications and iodine preparations and monitor their effects. *Antithyroid drugs are given before surgery to promote a euthyroid state. Iodine preparations are given before surgery to decrease vascularity of the gland, thereby decreasing the risk of haemorrhage.*
- Teach the person preoperatively to support the neck by placing both hands behind the neck when sitting up in bed, while moving about and while coughing. *Placing the hands behind the neck postoperatively provides support for the suture line.*
- Answer questions and allow time for the person to verbalise concerns. Because the incision is made at the base of the throat, people (especially women) are often concerned about their appearance after surgery. *Explain that the scar will eventually be only a thin line and that jewellery or scarves may be used to cover the scar.*
- Teach the person to expect hoarseness due to generalised swelling at the suture line. *This is expected to diminish with healing and is not caused by laryngeal nerve damage.*

POSTOPERATIVE CARE

- Perform focused assessments to monitor for complications: maintain patent airway and observe for respiratory distress. Assess respiratory rate, rhythm, depth and effort. Maintain humidification as ordered. Assist the person with deep breathing and coughing. Have suction equipment, oxygen and a tracheostomy set available for immediate use. *Respiratory distress may result from haemorrhage and oedema, which may compress the trachea; from tetany and laryngeal spasms resulting from removal or damage to the parathyroid glands; and from damage to the laryngeal nerve, causing spasms of the vocal cords. Stridor is heard in acute obstructions. This is a high-pitched, squeaky sound and is a sign of airway obstruction.*
- *Haemorrhage*. Assess dressing (if present) and the area under the person's neck and shoulders for drainage. Check volume drains. Monitor blood pressure and pulse as well as other signs and symptoms of hypovolaemic shock. Assess tightness of dressing (if present). *The vascularity of the gland increases the risk of haemorrhage. The location of the incision and the position of the person may cause the drainage to run back and under the person's neck. The danger of haemorrhage is greatest in the first 12 to 24 hours after surgery.*
- Provide comfort measures: administer analgesia as ordered and monitor their effectiveness; place the person in a semi-Fowler's position after recovery from anaesthesia; support head and neck with pillows. *Analgesic medications reduce acute pain and physical stress during the postoperative period. Positioning the person in a semi-Fowler's position and supporting the head and neck decreases strain on the suture line.*
  a. *Laryngeal nerve damage*. Assess for the ability to speak aloud, noting quality and tone of voice. *The location of the laryngeal nerve increases the risk of damage during thyroid surgery. Although hoarseness may be due to oedema or the endotracheal tube used during surgery and will subside, permanent hoarseness or loss of vocal volume is a potential danger.*
  b. *Tetany*. Assess for signs of latent tetany due to decreased circulating calcium levels, including tingling of toes, fingers and lips; muscular twitches; positive Trousseau's sign (carpal spasm elicited by compression of the upper arm (King, Hawley & Weller, 2008). Keep calcium gluconate or calcium chloride available for immediate intravenous use. *The parathyroid glands are located in and near the thyroid gland; surgery of the thyroid gland may injure or remove parathyroid glands, resulting in hypocalcaemia and tetany. Tetany may occur up to 7 days after a thyroidectomy.*

- *Health history:* other medical conditions, family history of thyroid disease, when symptoms began, severity of symptoms, intake of iodine or thyroid medications, menstrual history, changes in weight, bowel elimination.
- *Physical assessment:* muscle strength, tremors, vital signs, cardiovascular and peripheral vascular systems, integument, size of thyroid, presence of bruit over thyroid, eyes and vision.

Nursing diagnoses and interventions

In planning and implementing nursing care for the person with hyperthyroidism, the nurse considers the person's responses to the systemic effects of the disorder. Although each person may have different needs, nursing diagnoses discussed in this section focus on the most common problems: cardiovascular problems, visual deficits, altered nutrition and body image disturbance. See the accompanying 'Nursing care plan' below.

CONSIDERATION FOR PRACTICE

Teach the person to cover or tape the eyelids shut at night if they do not close and to sleep with the head of the bed elevated.

Risk of decreased cardiac output

Excess TH directly affects the heart, resulting in increased rate and stroke volume. Increases in the metabolic demands and oxygen requirements of peripheral tissues increase the demands on the heart, and systolic hypertension, angina, arrhythmias or cardiac failure may occur. The person often has shortness of breath and is easily fatigued. The risk of complications is greater in people with pre-existing cardiovascular disorders.

- Monitor blood pressure, pulse rate and rhythm, respiratory rate, oxygenation and breath sounds. Assess for peripheral oedema, jugular vein distension and increased activity intolerance. *Increased TH increases heart rate, stroke volume and tissue demand for oxygen, causing stress on*

the heart. This may result in hypertension, arrhythmias, tachycardia and congestive heart failure.

- Suggest keeping the environment as cool and free of distraction as possible. Decrease stress by explaining interventions, providing reassurance and teaching relaxation procedures. *A physically comfortable and psychologically calm environment can reduce stimuli and stressors. Stress increases circulating catecholamines, which further increase cardiac workload.*

Disturbed visual perception related to exophthalmos

- Monitor visual acuity, photophobia, integrity of the cornea and lid closure. *The cornea is at risk of dryness, injury,*

NURSING CARE PLAN A person with Graves' disease

Mrs Juanita Martin is a 33-year-old mother of four small children. She is a second-year student completing the requirements for an associate degree in childcare. For the past 3 months, Juanita has been constantly hungry and has eaten more than usual, but she has still lost 6.8 kg. She has multiple bowel movements each day and often feels nauseated. Her hands shake, she can feel her heart beating rapidly and she finds herself laughing or crying for no apparent reason.

Mrs Martin makes an appointment with her family physician. The nurse at the office completes a health history and physical assessment. When asked how she has been feeling, Mrs Martin replies, 'Well, I don't know what's wrong with me—but I keep losing weight and I cry at the drop of a hat. I am also just so hot all the time and I've never had that problem before. I hope I find out what's wrong and it's nothing serious.'

ASSESSMENT

The health history indicates that although her appetite has increased, Mrs Martin has lost 6.8 kg. She states that she has had increased bowel movements, nausea, palpitations, heat intolerance and mood changes. Physical assessment findings include the following: T 38.3°C, P 110, R 24 and BP 162/86. Her skin is moist and warm, her hair thin and fine. She has visible tremors in her hands. Her eyeballs protrude and she is unable to close her eyelids completely. Her thyroid is enlarged and palpable. Diagnostic tests reveal the following abnormal results: Free T_3, 18 pmol/L (normal range: 3–7.8 pmol/L), Total T_4, 30 pmol/L (normal range: 12–22 pmol/L). A thyroid scan demonstrates an enlarged thyroid with increased iodine uptake. The medical diagnosis of Graves' disease is made and Mrs Martin is commenced on the antithyroid medication propylthiouracil, 150 mg orally every 8 hours.

DIAGNOSES

- *Risk of imbalanced nutrition: less than body requirements* related to hyperthyroid state and increased metabolism as evidenced by weight loss of 6.8 kg with present weight 10% less than normal for her height.
- *Increased bowel movements* related to increased food intake and peristalsis as evidenced by more than four loose stools per day.
- *Risk of disturbed visual perception* and/or *Risk of eye infection* related to an inability to close the eyelids completely.
- *Anxiety* related to a lack of knowledge about disease process.

PLANNING

- Request that she keep a record of weekly weight.
- Discuss adopting a high-kilojoule diet. Identify food likes and dislikes, before instituting a plan to increase food intake.
- Request that she keep a stool chart, noting the time, type and precipitating factors for stools. Teach comfort measures for irritated anal area (clean washcloth and soap, no irritating ointment).
- Teach how to apply eye drops (artificial tears).
- Explain the need to elevate the head of the bed to 45 degrees at night and tape eye shields over eyes before sleep.
- Teach about Graves' disease, the medication's effects and side effects, and the need for continued medical care.

Expected outcomes

- Gain at least 0.45 kg every 2 weeks.
- Regain normal bowel elimination patterns.
- Maintain normal vision (with no evidence of corneal damage and/or infection) and verbalise measures to protect her eyes.
- Verbalise medical treatment and self-care needs.
- Verbalise a decrease in anxiety.

IMPLEMENTATION

- Mrs Martin will adopt a high-kilojoule diet and increase the food intake.
- Maintain a weekly record of her weight.
- Maintain a stool chart and adopt measures for anal comfort and hygiene.
- Regular application of eye drops and/or lubrication.
- Maintain head elevation and use of eye shields at night.
- Give Mrs Martin contacts for support or if she has any queries or concerns.

EVALUATION

By her next visit, Mrs Martin has gained 0.45 kg and has discussed her dietary needs with the nurse and her husband. She is having fewer bowel motions per day. She has safely applied the eyedrops and states that she uses the eye shields and elevates the head of her bed at night. The office nurse reviews the written and verbal information about Graves' disease and the medication prescribed. Mrs Martin verbalises her understanding, stating, 'I'll always take my medicine—I never want to feel like that again!' She also says that she feels much less anxious now that she understands what has happened.

CRITICAL THINKING IN THE NURSING PROCESS

1. What is the pathophysiological basis for Mrs Martin's abnormal vital signs?
2. What is the rationale for having the person with exophthalmos elevate the head of the bed at night?

REFLECTION ON THE NURSING PROCESS

1. Can you think of at least three other strategies that you would add to the plan of education for Mrs Martin and her family? Write the corresponding Expected outcomes and Implementation for your strategies.
2. Design an educational strategy to help teach Mrs Martin about her nutritional requirements.

conjunctivitis and corneal infections. Injury and infection of the cornea can result in further loss of visual acuity.

- Teach measures for protecting the eye from injury and maintaining visual acuity:
  - Use tinted glasses or shields as protection.
  - Use artificial tears to moisten the eyes.
  - Use cool, moist compresses to relieve irritation.
  - Cover and tape eyelids with an eye shield at night if they do not completely close.
  - Elevate the head of the bed to 45 degrees to promote periorbital fluid decrease.
  - Promptly report any pain or changes in vision.
  - Encourage the person to quit smoking which exacerbates exophthalmos.

Imbalanced nutrition: less than body requirements related to gastrointestinal hypermotility

The hypermetabolic state that occurs in hyperthyroidism causes gastrointestinal hypermotility. Although the person may have an increased appetite and eat more than usual, weight loss continues.

- Ask the person to weigh themselves weekly and keep a record of results. *The inability to meet metabolic demands results in loss of body weight. Regular monitoring detects continued weight loss.*
- In collaboration with a dietitian, teach the person the need for a diet high in carbohydrates and protein and including between-meal snacks. Six small meals a day may be more desirable than three large meals. Energy intake may need to be increased to 16 700 kilojoules/day if weight loss exceeds 10% to 17% for height and frame. *Increased nutrients as part of a well-balanced diet are necessary to meet metabolic demands. People are often better able to increase food intake by eating frequent, small meals. A 0.45 kg weight gain requires approximately 14 650 extra kilojoules.*
- Monitor nutritional status through results of laboratory data. Serum albumin, transferrin and total lymphocyte counts are commonly lower than normal in nutritional deficits. *A negative nitrogen balance signifies a catabolic state in which protein is lost and metabolic demands are not being met.*

Potential for disturbed body image related to physical changes common in hyperthyroidism

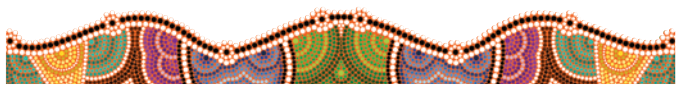
Physical changes common in hyperthyroidism include exophthalmos, goitre, tremors, hair loss, increased perspiration, loss of strength, fatigue, weight loss and changes in reproductive and sexual function (amenorrhoea in women, impotence in men and increased libido in both men and women). In addition, the person often has mood changes and insomnia and is constantly nervous and anxious. There may even be periods of psychosis. These changes are frightening not only for the person but also for family members.

- Establish a trusting relationship; encourage the person to verbalise feelings about self and to ask questions about the illness and treatment. Provide reliable information and clarify misconceptions. *Establishing trust facilitates open sharing of feelings and perceptions.*

Community-based care

People with hyperthyroidism primarily provide self-care at home. Teaching is individualised to meet the person's needs. Address the following topics:

- The person taking oral medications must understand the need for lifelong treatment.
- The person who has a thyroidectomy requires information about postoperative wound care.
- The person having radioactive iodine therapy needs to know the symptoms of hypothyroidism.
- Depending on the age of the person and the support systems available, referral to community healthcare agencies may be necessary.
- In addition, suggest the following online resources:
  - Thyroid Australia: www.thyroid.org.au
  - Australian Thyroid Foundation Limited: www.thyroid foundation.com.au
  - Thyroid Federation International: www.thyroid-fed.org.



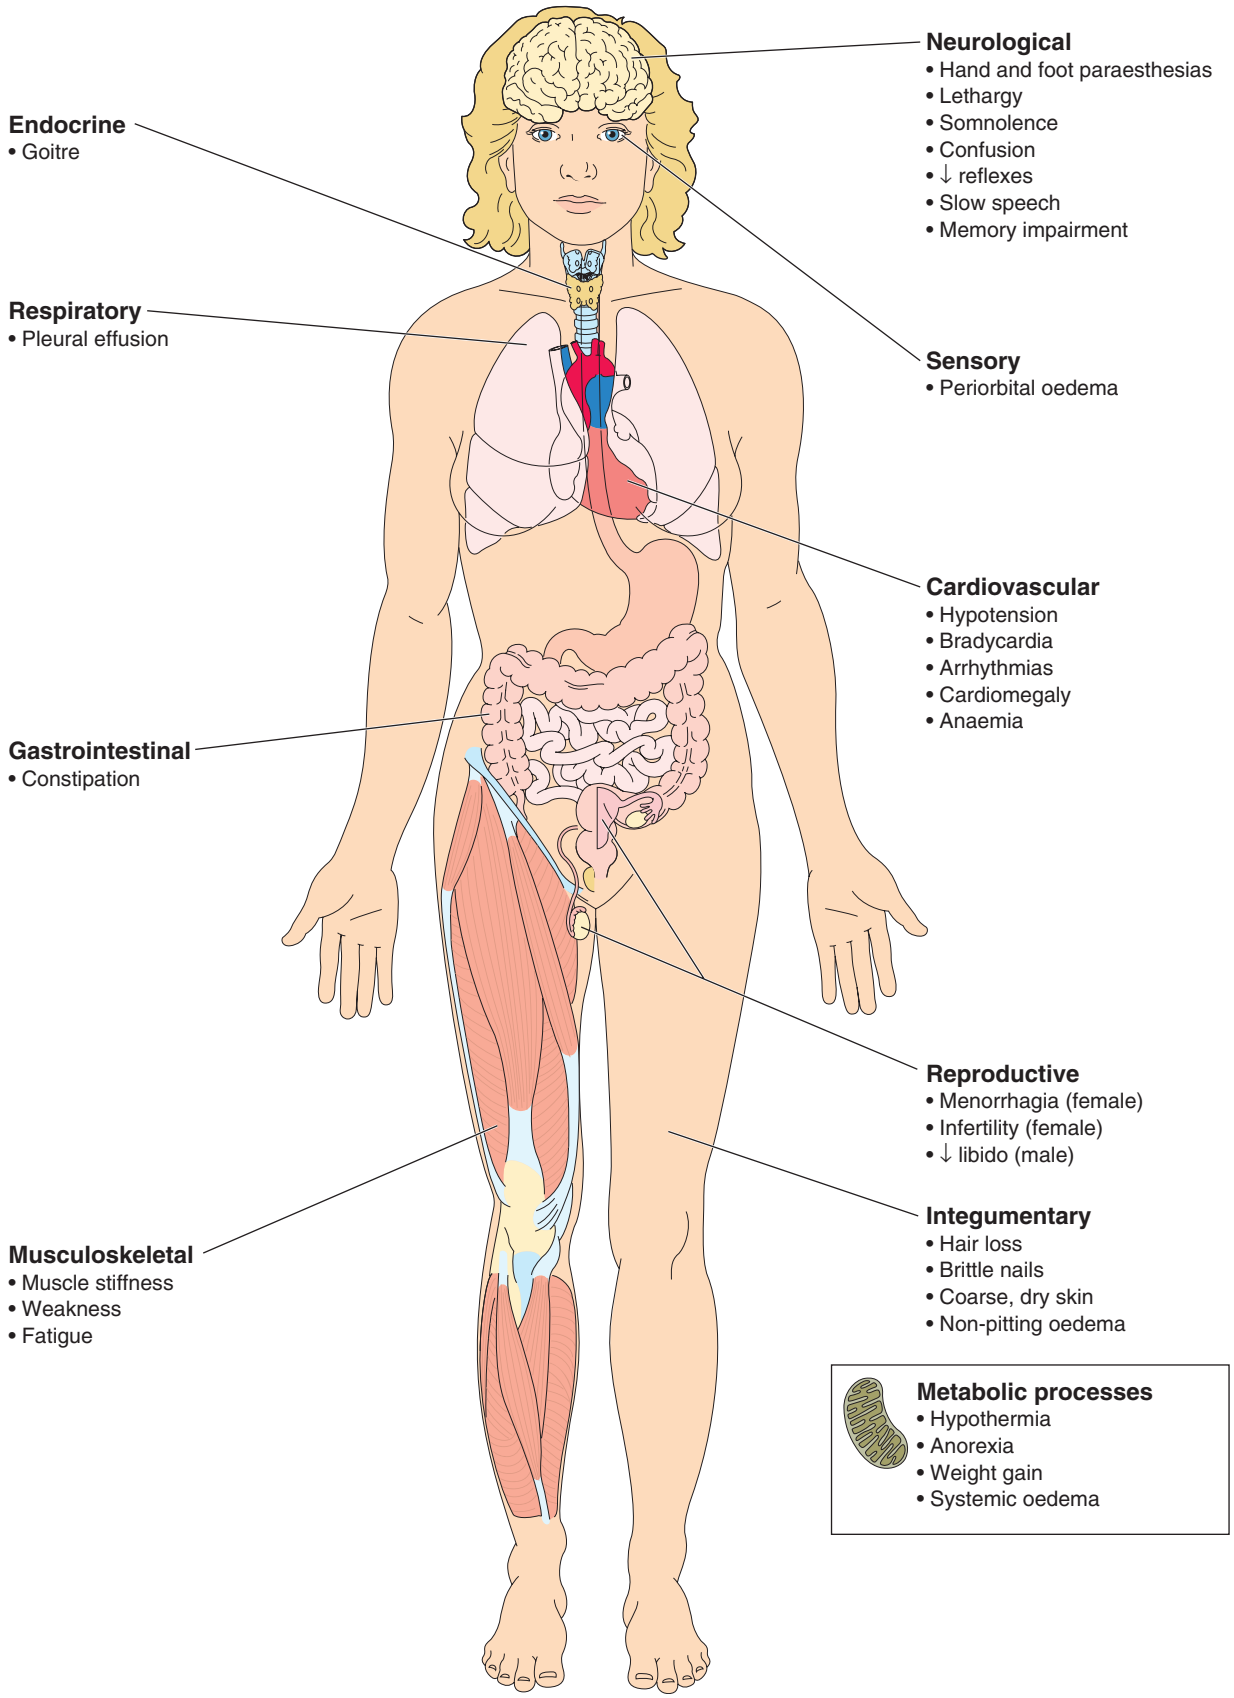
THE PERSON WITH HYPOTHYROIDISM

Hypothyroidism is a disorder that results when the thyroid gland produces an insufficient amount of TH. Because a decrease in TH levels decreases metabolic rate and heat production, hypothyroidism affects all body systems (see 'Multisystem effects of hypothyroidism' below). Hypothyroidism is most common in women between ages 30 and 60; the incidence rises with age. It is also associated with an increase in morbidity and mortality due to cardiovascular involvement (McQuade et al., 2011). Careful evaluation of symptoms is important in the older adult because manifestations of hypothyroidism are often thought to be the result of ageing instead of a pathological process.

Hypothyroidism occurs in about 5% of the adult population; most present with mild thyroid failure, characterised by raised serum TSH but normal free thyroxine or T_4. Worldwide, the most common cause of hypothyroidism is iodine deficiency. However, in Australia the most common cause of hypothyroidism is autoimmune chronic lymphocytic thyroiditis characterised by raised levels of thyroid peroxidase antibody, also known as Hashimoto's thyroiditis (Akamizu, Amino & DeGroot, 2013; Thyroid Australia, 2011b).

The hypothyroid state in adults is sometimes called **myxoedema**. The term reflects the characteristic accumulation of non-pitting oedema in the connective tissues throughout the body. The face of a person with myxoedema appears puffy, the tongue is enlarged, and the voice is hoarse and husky (So, MacIsaac & Grossman, 2012). Proteinaceous fluid can also accumulate within body cavities. The most common sites are the pericardial, pleural and peritoneal cavities. The reported incidence of pericardial effusion in newly diagnosed mild hypothyroid patients is 3%, increasing to 80% in myxoedema (Motabar et al., 2011).

MULTISYSTEM EFFECTS OF HYPOTHYROIDISM



Pathophysiology and manifestations

Hypothyroidism may be either primary or secondary. Primary hypothyroidism, which is more common, may be caused by congenital defects in the gland, loss of thyroid tissue following treatment for hyperthyroidism with surgery or radiation, antithyroid medications, thyroiditis or endemic iodine deficiency. Secondary hypothyroidism may result from pituitary TSH deficiency or peripheral resistance to thyroid hormones. Hypothyroidism has a slow onset, with manifestations occurring over months or even years. With treatment, the mental and physical symptoms rapidly reverse.

When TH production decreases, the thyroid gland enlarges in a compensatory attempt to produce more hormones. The goitre that results is usually a simple diffuse or non-toxic form. People living in certain areas of the world where the soil is deficient in iodine are more prone to become hypothyroid and develop simple goitre. (Iodine deficiency is discussed below.) The geriatric person has a decrease in T_4 production of approximately 30%, but serum levels are usually maintained because of the age-related decrease in T_4 degradation (Weissel, 2006).

The person with hypothyroidism characteristically has manifestations of goitre, fluid retention and oedema, decreased appetite, weight gain, constipation, dry skin, dyspnoea, pallor, hoarseness and muscle stiffness. Many also have a decreased sense of taste and smell, menstrual disorders, anaemia and cardiac enlargement. The pulse is typically bradycardic (Warner & Mittag, 2012). Deficient amounts of TH cause abnormalities in lipid metabolism, with elevated serum cholesterol and triglyceride levels. As a result, the person is at increased risk of atherosclerosis and cardiac disorders. Decreased renal blood flow and glomerular filtration rate reduce the kidneys' ability to excrete water, which may cause hyponatraemia. Sleep apnoea is more common in people with hypothyroidism. A severe state of hypothyroidism is called *myxoedema coma.*

Iodine deficiency

Iodine deficiency may result from certain goitrogenic drugs (which block TH synthesis); lithium carbonate, used to treat bipolar disorders; and antithyroid drugs. Lack of iodine can cause hypothyroidism and goitre, but this is rare in developed countries. It can also have a devastating effect on the development of the foetus and newborn child (Medenica et al., 2015). Insufficient iodine and thus TH during gestation and early childhood is known as the iodine deficiency disorder of congenital hypothyroidism, or cretinism.

In the last few years there has been an increase in iodine deficiency in Australia. This deficiency has been due to changes in milk sterilisation processes, which no longer use iodides, and less consumption of iodised salt due to concerns about salt intake in general (Brand-Miller, 2008). Around 150 Gk mug (millionths of a gram, or micrograms) of dietary iodine is needed each day to produce adequate levels of thyroid hormones. Seafoods such as oysters are particularly rich in iodine (Thyroid Australia, 2011a). Pregnant and breastfeeding women need to include an oral iodine supplement so that they are taking 250 μg in total per day of iodine (World Health Organization (WHO), 2007).

Hashimoto's thyroiditis

Hashimoto's thyroiditis is the most common cause of goitre and primary hypothyroidism in Australia. In this autoimmune disorder, antibodies develop that destroy thyroid tissue. Functional thyroid tissue is replaced with fibrous tissue and TH levels decrease. In addition, decreasing levels of TH in the early stages of the disorder prompt the gland to enlarge to compensate, causing goitre. However, as the disease progresses, the thyroid gland becomes smaller. This disorder is more common in women and has a familial link.

Myxoedema coma

Myxoedema coma is a life-threatening complication of long-standing, untreated primary hypothyroidism usually triggered by an acute infection, the administration of thyroid-hormone-reducing medications or trauma. Five per cent occur as a result of hypothalamic or pituitary causes. It is characterised by severe metabolic disorders (hyponatraemia, hypoglycaemia and lactic acidosis), hypothermia (usually below 32.2°C), cardiovascular complications (hypotension, bradycardia, cardiac tamponade), and altered mental state such as confusion and coma (due to cerebral oedema, hypoxia and hypercarbia). Seizures may precede coma in 25% of people (Gupta, 2013).

The treatment of myxoedema coma addresses the precipitating factors and manifestations and involves maintaining a patent airway; maintaining fluid, electrolyte and acid–base balance; maintaining cardiovascular status; increasing body temperature; and increasing TH levels with intravenous thyroxine and corticosteroids. Despite aggressive treatment the mortality rate for myxoedema coma remains up to 60% (Gupta, 2013).

INTERPROFESSIONAL CARE

The treatment of the person with hypothyroidism focuses on diagnosis, prevention or treatment of complications, and replacement of the deficient TH. With early and continued treatment, both appearance and mental function return to normal.

Diagnosis

Hypothyroidism is diagnosed by the clinical manifestations and by a decrease in TH, especially T_4 (see Table 18.2). TSH concentration often is increased, because the negative hormonal feedback from TH is lost. The same laboratory and diagnostic tests used to diagnose hyperthyroidism are also used to diagnose hypothyroidism, with opposite results in most cases.

Medications

Hypothyroidism is treated with medications that replace TH. Thyroxine, T_4 (Levothyroxine) is the preferred therapy, 1.6 μg/kg lean body weight daily (The Thyroid Society for Education and Research cited by Thyroid Australia, 2012). Medications commonly used to treat hypothyroidism and their nursing implications are shown in the 'Medication administration' box below. In the geriatric person, an age-related decrease in serum albumin and renal excretion can increase the amount of available drug and cause an exaggerated pharmacological effect. Therefore, the older person may require less thyroid medication than a younger person.

TABLE 18.2 Laboratory findings in hypothyroidism

TEST	NORMAL VALUES	FINDINGS
Serum TA	≤ 1:10 titre	Normal
Serum TSH	0.27—4.2 mU/L	Increased in primary hypothyroidism Decreased, secondary hypothyroidism
Serum T_4	Total 12–22 pmol/L	Decreased
Serum T_3	Free 3–7.8 pmol/L	Decreased
T_3 uptake (T_3RU)	25–35 %	Decreased
Thyroid suppression		No change in RAI uptake or T_4 levels

mU: microunits; pmol: picomoles.

Surgery

If the hypothyroid person has goitre large enough to cause respiratory difficulties or dysphagia, a subtotal thyroidectomy may be performed (see the 'Nursing care of the person' box on p. 535).

Nursing care

Health promotion

One of the most critical factors in preventing hypothyroidism is education of the public about the necessity of an adequate dietary intake of iodine. Since 2006, the mandatory fortification of bread with iodised salt has redressed the prevalence of hypothyroidism in Australia.

Assessment

Collect data through the health history and physical examination (see Chapter 17). Further focused assessments are described with nursing interventions below. When assessing the older person, be aware of normal changes with ageing, outlined in the box below.

- *Health history:* pituitary diseases, when symptoms began, severity of symptoms, treatment of hyperthyroidism with medications or radioactive iodine, thyroid surgery, treatment of head or neck cancer with radiation, diet, use of iodised salt, bowel elimination, respiratory difficulties.
- *Physical assessment:* muscle strength, deep tendon reflexes, vital signs, cardiovascular and peripheral vascular systems, integument, palpation of thyroid gland, weight.

MEDICATION ADMINISTRATION Hypothyroidism

THYROID PREPARATIONS

Thyroxine sodium (T_4) (Oroxine, Eutroxsig)
Liothyronine sodium (T_3) (Tertroxin)

Replacement oral thyroxine is the preferred therapy for hypothyroidism. A dose of 1.6 µg per kg body weight daily is the average required in adults. The dose is adjusted in cases of hypopituitarism and adrenal insufficiency due to risk of adrenal crisis if glucocorticoid replacement is not given simultaneously. The presence of cardiovascular disorders also requires a dose adjustment due to the risk of worsening ischaemic symptoms and arrythmias. In diabetes, the dose of insulin or hypoglycaemic drugs may need to be adjusted. Combined thyroxine (T_4) and liothyronine (T_3) therapy is being promoted for a small subset of people whose symptoms persist despite apparently adequate thyroxine therapy (McDermott, 2012).

Specific responsibilities include:

- Give first thing in the morning on an empty stomach with water, at least 30 to 60 minutes before breakfast and 3 to 4 hours before taking other medications.
- Be aware of interactions with vitamins, minerals and other herbal extracts.
- Thyroid preparations potentiate the effect of anticoagulant drugs. If taking an anticoagulant, monitor for bruising, bleeding gums and blood in the urine.
- Thyroid medications potentiate the effect of digitalis; monitor for signs of digitalis toxicity.
- Monitor for symptoms of coronary insufficiency: chest pain, dyspnoea and tachycardia.
- During dose adjustment, take pulse before administering drug. Report pulse > 100.

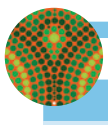
HEALTH EDUCATION OF THE PERSON AND FAMILY

- Opened and unopened packets of Oroxine and Eutroxsig tablets should remain both refrigerated and in their original foil packaging until administration.
- Do not substitute brands of drugs or use generic equivalents.
- These medications are lifelong therapy.
- Take thyroid preparation each morning to decrease the possibility of insomnia.
- Report symptoms of excess thyroid hormone: excess weight loss, palpitations, leg cramps, nervousness or insomnia.
- Thyroid preparations increase the risk of iodine toxicity. Do not use iodised salt or over-the-counter drugs containing iodine.
- If you are also taking an anticoagulant, report any signs of bleeding.
- Report any changes in menstrual periods.
- Closely monitor blood pressure and pulse (older people).
- Avoid excessive intake of raw goitrogenic foods that are known to inhibit TH utilisation, such as turnips, cabbage, carrots, spinach and peaches. The heat in cooking partially destroys the goitrogenic enzymes.

NURSING CARE OF THE OLDER ADULT Variations in assessment findings—hypothyroidism

NORMAL CHANGES WITH AGEING

- The thyroid gland undergoes some degree of atrophy, fibrosis and nodule formation.
- Hair growth decreases.
- Nails are often thick, brittle and yellow.
- Facial skin sags and bones become more prominent.
- Deep tendon reflexes decrease.
- Response to questions may be slower.



TRANSLATION TO PRACTICE Evidence-based practice: thyroid nodules, benign or malignant? Common causes and a simple approach to diagnosis and management in the clinical setting

Thyroid nodules are common with up to 50% of adults having nodules visible on ultrasound. About 5% of thyroid nodules are malignant (Mackenzie & Mortimer, (2004).

Thyroid nodules are more common in the older person, women, people with iodine deficiency and those who have had prior exposure to radiation. Significant symptoms, if present, may include dysphagia due to impingement of the goitre on the oesophagus, shortness of breath due to tracheal impingement and, less commonly, hoarseness of the voice due to possible laryngeal nerve compression (Brennan & French, 2007). Other suspicious features for malignant nodules include people younger than 20 years old or older than 70 years, male, nodule size more than 4 cm, rapid growth or family history. Pain may or may not be present.

IMPLICATIONS FOR NURSING

Clinical assessment of the person and recognising abnormal thyroid signs and symptoms is within the scope of nursing. Clinical assessment of the thyroid gland includes *Inspection* for scars, goitre, movement when swallowing, prominent veins; *Palpation* by (i) positioning the person and examining from behind with the neck slightly flexed to relax sternomastoid muscles—feeling each lobe and the isthmus of the gland for characteristics of goitre or nodules and examining cervical lymph nodes, and (ii) in front of the person examining characteristics of the nodules and position of the trachea which may be displaced; *Percussion* over the manubrium, dullness may indicate goitre, although CT scan is a more common procedure; *Auscultation* as bruit may occur in Graves' disease. *The Pemberton sign* is used to evaluate venous obstruction from goitres. Ask the person to raise the arms as high as possible and wait a few moments; signs of venous congestion such as redness of the face and breathlessness occur from retrosternal extension of the thyroid gland into the thorax (De Filippis et al., 2014). Also look for signs of hyper- or hypothyroidism.

CRITICAL THINKING IN PERSON-CENTRED CARE

1. What is the prevalence of malignant thyroid nodules and who has a higher risk of having them?
2. Most people with thyroid nodules do not have any significant symptoms. But, if present, which symptoms are important to notice and what do they indicate?
3. Which clinical assessments need to be attended when examining the thyroid gland of a person with suspected nodules? Which instructions would be given to a person when assessing for the Pemberton sign?
4. Outline what have you learned from the article that you will apply to your nursing practice.

Nursing diagnoses and interventions

In planning and implementing care for people with hypothyroidism, the nurse needs to take into account that the disorder affects all organ systems. Although many nursing diagnoses might be valid, this section focuses on person problems with cardiovascular function, elimination and skin integrity. See the accompanying 'Nursing care plan' below.

Decreased cardiac output related to decreased stroke volume, bradycardia and possible pericardial effusion

A TH deficiency causes a reduction in heart rate and stroke volume, resulting in decreased cardiac output. There may also be pericardial effusion and coronary artery disease may be present, further compromising cardiac function.

- Monitor blood pressure, heart rate and rhythm, respiratory rate and lung sounds. *Monopolysaccharide deposits in the pericardial sac causing pericardial effusion decreases the intensity of heart sounds and can cause a variety of ECG changes. Pleural effusions are associated with dyspnoea* (McCance & Huether, 2009).
- Administer supplemental oxygen as ordered. *Reduced cardiac output results in less oxygen to the tissues.*
- Avoid cool temperatures, increase room temperature if necessary, use additional bed covers and avoid drafts. *Chilling increases metabolic rate and puts increased stress on the heart.*
- Explain the need to alternate activity with rest periods. Ask people to report any breathing difficulties, chest pain, heart palpitations or dizziness. *Activity increases demands on the heart and should be balanced with rest. Symptoms of cardiac stress include dyspnoea, chest pain, palpitations and dizziness.*

Constipation

The hypothyroid person is likely to have a reduced appetite and decreased food intake, a diminished activity level because of muscle aches and weakness, reduced water absorption and reduced peristalsis to the point that faecal impaction may occur.

NURSING CARE PLAN A person with hypothyroidism

Jane Lee is a 60-year-old retired nurse living with her husband and daughter on a farm that has been in her Chinese family for four generations. Mrs Lee has gained 4.5 kg in the past few months, even though she is rarely hungry and eats much less than normal. She is always tired and weak—so tired that she has not even been able to help with the chores on the farm or do housework. She is concerned about her appearance and the way she sounds when she talks. Her face is puffy and her tongue always feels thick. Mr Lee convinces his wife to make an appointment at a health centre in a nearby town.

ASSESSMENT

Brian Henning, Nurse Practitioner (NP), completes the health assessment for Mrs Lee at the health centre. He finds that she now weighs 68 kg, an increase of 4.5 kg over her weight at her last visit 6 months earlier. Mrs Lee states that she always feels cold, tired and weak. She also states that she is constipated, has difficulty remembering things and looks different. Physical assessment findings include a palpable and bilaterally enlarged thyroid; dry, yellowish skin; non-pitting oedema of the face and lower legs; and slow, slurred speech. Diagnostic tests revealed the following abnormal findings: Free T_3, 1 pmol/L (normal range: 3–7.8 pmol/L); Total T_4, 8 pmol/L (normal range: 12–22 pmol/L); TSH increased. The medical diagnosis of hypothyroidism is made and Mrs Lee is started on levothyroxine 0.05 mg daily.

DIAGNOSES

- *Constipation* related to decreased peristalsis, as evidenced by hard, formed stools every 4 days.
- *Impaired verbal communication* related to changes in speech patterns and enlarged tongue.
- *Low self-esteem* related to changes in physical appearance and activity intolerance.

PLANNING

- Teach to increase fluids, bulk and fibre in the diet to help regain a normal bowel elimination pattern of a soft, formed stool every other day.
- Take medication as prescribed and do not expect immediate reversal of symptoms affecting speech. It may take some time but need to continue with the treatment. Store medication as required by manufacturer.
- Plan activities around rest periods. Encourage husband and daughter to help with house cleaning and cooking.

Expected outcomes

- Regain normal bowel elimination patterns, having a soft, formed stool at least every other day.
- Experience improvement in verbal communication.
- Regain positive self-esteem as medication reduces physical changes and fatigue.

IMPLEMENTATION

- Mrs Lee will start consuming a diet with bulk and fibre as well as increase her fluid intake immediately.
- She will start and continue to take the prescribed medications and understand that it may take some time for some for the symptoms to improve.
- Mrs Lee will be resting and taking naps when required.
- She will seek appropriate advice from a healthcare practitioner if there are any issues or concerns.

EVALUATION

On return to the health centre 2 months later, Mrs Lee reports that she is no longer constipated and that she has increased her fluid intake and eats oatmeal every day. She no longer feels cold, is regaining her normal energy, and even feels well enough to plant her garden. Her speech is clear and easy to understand. As she leaves the examining room, Mrs Lee says: 'It's hard to believe that I have changed so much—now I look and feel like the "old" me!'.

CRITICAL THINKING IN THE NURSING PROCESS

1. Which physical changes that normally occur with ageing are similar to the manifestations of hypothyroidism?
2. The person taking oral thyroid medications may become hyperthyroid. List the manifestations you would include in a teaching plan to signal this condition.

REFLECTION ON THE NURSING PROCESS

1. Which points have you learned from the case study that you will implement in your future nursing practice?
2. How will you plan an appropriate diet for Mrs Lee, taking into consideration her Chinese background as well as her likes and dislikes? Reflect on other people with different ethnic backgrounds in Australia.

- Encourage a free fluid intake. If kilojoule intake is restricted, ensure that liquids have no or low kilojoules. Sufficient fluid intake assists stool consistency.
- Discuss ways to maintain a high-fibre diet. Diets high in fibre and fluid produce soft stools. *Fibre that is not digested absorbs water, which adds bulk to the stool and assists in the movement of faecal material through the intestines.*
- Encourage activity as tolerated. *Activity influences bowel elimination by improving muscle tone and stimulating peristalsis.*

CONSIDERATION FOR PRACTICE

High-fibre foods include lentils, chickpeas and sweet potatoes, apples with skin, grain breads, bran cereals, prunes, broccoli, porridge, popcorn and peas (Brand-Miller, Foster-Powell & McMillan-Price, 2006; Cancer Council NSW, 2015).

Risk of impaired skin integrity related to oedema, dry and rough skin

The person with hypothyroidism is at risk of impaired skin integrity related to the accumulation of fluid in the interstitial spaces and to dry, rough skin. Decreased peripheral circulation,

decreased activity levels and slow wound healing further increase the risk. These interventions are outlined for the older person who is hospitalised for surgery or severe hypothyroidism.

- Monitor skin surfaces for redness or lesions, especially if the person's activity is greatly reduced. Use a pressure injury risk assessment scale to identify people at risk. *Hypothyroidism causes dry, rough, oedematous skin conditions that increase the risk of skin breakdown.*
- Provide or teach the immobile person measures to promote optimal circulation:
  - Use a turning schedule if the person is on bed rest, or teach the person to change position every 2 hours.
  - Limit the time for sitting in one position; shift weight or lift the body using arm rests every 20 to 30 minutes.
  - Use pillows, pads or sheepskin or foam cushions for bed and/or chair.
- Teach and implement a schedule of range-of-motion exercises. *Prolonged pressure, especially in people with oedema and circulatory impairment, can occlude capillaries and cause hypoxic tissue damage.*
- Provide or teach the person measures to maintain skin integrity:
  - Take baths only as necessary; use warm (not hot) water.
  - Use gentle motions when washing and drying skin.
  - Use alcohol-free skin oils and lotions.

  Dry skin and oedema increase the risk of skin breakdown. Hot water, rough massage and alcohol-based preparations may increase skin dryness, further impairing the body's ability to maintain skin integrity.

CONSIDERATION FOR PRACTICE

When moving, positioning or transporting, lift the person up in bed to prevent tissue damage from shearing forces.

Community-based care

People with hypothyroidism require lifelong care, primarily at home. Address the following topics:

- the need to take medications for the rest of their life
- the need for regular periodic dosage reassessments (e.g. every 6 months)
- if the person is older or does not have a support system, advise about helpful community resources.

THE PERSON WITH CANCER OF THE THYROID

The Australian Institute of Health and Welfare (AIHW, 2014) reported that the incidence of thyroid cancer increased by 281% between 1982 and 2014. In 2014, 1890 Australian women and 630 Australian men were diagnosed with thyroid cancer. Thyroid cancer in Australian females is the third most common cancer after breast and melanoma of the skin.

Risk factors associated with thyroid cancer are age, usually affecting people over the age of 35; gender, females having approximately three times the incidence of thyroid cancer than males; diet, either chronic iodine deficiency or chronically high iodine intake; history of thyroid disease; ionising radiation exposure; and family history and ethnicity, with a higher incidence in first-degree relatives (AIHW, 2014; Brennan & French, 2007). Thyroid cancer is more aggressive in men than in women (Gesing et al., 2012).

There are several types of thyroid cancer:

- Papillary thyroid carcinoma (PTC) is the most common thyroid malignancy. The risk is higher in those with a history of nodular goitre (Smith et al., 2013). The average age of diagnosis is 42, with 70% of cases occurring in women. Recently, Cinamon, Levy and Marom (2015) suggested that primary hyperparathyroidism is a possible risk factor for the development of PTC.

  PTC is the least aggressive type, but does metastasise to the local and regional lymph nodes and lungs. The mortality rate of PTC is usually higher in the elderly.
- Follicular thyroid carcinoma (FTC) is the second most common thyroid malignancy and may be associated with iodine deficiency. The average age of diagnosis is 50, with 75% of cases occurring in women. This form is more aggressive, with potential for vascular invasion and spread to lung and bone (Nguyen et al., 2015).

The diagnosis is made by measuring thyroid hormones, performing thyroid scans and fine-needle biopsy. The usual treatment is subtotal or total thyroidectomy. TSH suppression therapy with levothyroxine may be conducted prior to surgery. Radioactive iodine therapy (^{131}I) and chemotherapy are additional therapeutic options. The 5-year survival rate, if the tumour has not metastasised, is 95% for males and 97% for females (AIHW, 2014). Nursing care for the person with cancer is discussed in Chapter 13.

DISORDERS OF THE PARATHYROID GLANDS

Disorders of the parathyroid glands—hyperparathyroidism and hypoparathyroidism—are not as common as those of the thyroid gland. Hypercalcaemia and hypocalcaemia (the primary results of alterations in parathyroid function) are discussed in Chapter 9.

THE PERSON WITH HYPERPARATHYROIDISM

Hyperparathyroidism results from an increase in the secretion of parathyroid hormone (PTH), which regulates normal serum levels of calcium and phosphate. The four parathyroid

glands which secrete PTH are located on the thyroid gland. The two upper parathyroid glands are located on the posterior aspect of the upper thyroid lobes and the two lower parathyroid glands are located in the lower thyroid lobes. Two per cent of people have parathyroid glands situated within the thyroid gland (Sung, 2015).

Pathophysiology and manifestations

Hyperparathyroidism occurs more often in older adults and is three times more common in women. The disorder itself is not common. The three types of hyperparathyroidism are as follows:

1. Primary hyperparathyroidism occurs when there is hyperplasia or an adenoma in one or more of the parathyroid glands, resulting in the unregulated overproduction of parathyroid hormone. The coexistence of thyroid nodules and primary hyperparathyroidism has been reported to range between 12% and 52% (Cinamon et al., 2015). This disorder interrupts the normal regulatory mechanism between serum calcium levels and PTH secretion and increases the absorption of calcium through the gastrointestinal tract.
2. Secondary hyperparathyroidism is a compensatory response by the parathyroid glands to chronic hyperphosphataemia and hypocalcaemia. It is characterised by an increased secretion of PTH. Secondary hyperparathyroidism is found in people with early chronic kidney disease and vitamin D deficiency.
3. Tertiary hyperparathyroidism results from hyperplasia of the parathyroid glands and a loss of response to serum calcium levels. This disorder is most often seen in people with long-standing chronic kidney disease. Due to routine blood analysis of calcium, many people with hyperparathyroidism are identified prior to the development of symptoms. When symptoms occur, they are related to hypercalcaemia and various musculoskeletal, renal and gastrointestinal manifestations. Bone resorption results in pathological fractures, while elevated calcium levels alter neural and muscular activity, leading to muscle weakness and atrophy. Proximal renal tubule function is altered and metabolic acidosis, renal calculi formation and polyuria occur.

Manifestations of the effect of hypercalcaemia on the gastrointestinal tract include abdominal pain, constipation, anorexia and peptic ulcer formation. Hypercalcaemia also affects the cardiovascular system, causing arrhythmias, hypertension and increased sensitivity to cardiotonic glycosides (e.g. digitalis preparations). The manifestations of hyperparathyroidism are summarised in the accompanying box.

INTERPROFESSIONAL CARE

Hyperparathyroidism is diagnosed by excluding all other possible causes of hypercalcaemia; by at least a 6-month history of symptoms; and by laboratory analysis of levels of serum calcium and PTH. Sestamibi nuclear medicine scanning, which is extensively used in cardiac imaging, is also useful as sestamibi accumulates in parathyroid adenomas. Bone mineral density is used to determine the extent, if any, of bone resorption.

Treatment of hyperparathyroidism focuses on decreasing the elevated serum calcium levels. People with mild hypercalcaemia are urged to drink fluids and keep active to prevent dehydration and reduce the risk of kidney stones. They should avoid prolonged immobilisation, thiazide diuretics, large doses of vitamins A and D, antacids containing calcium and calcium supplements. Gastrointestinal illness with vomiting and diarrhoea can cause serum calcium levels to rise. Severe hypercalcaemia requires hospitalisation and intensive treatment with intravenous saline. Medications to inhibit bone resorption and reduce hypercalcaemia or calcimimetic medications such as cinacalcet (Sensipar) are the mainstay of secondary hyperparathyroidism. Calcitonin, a hormone produced by the thyroid gland, helps regulate calcium levels in the body by inhibiting bone resorption and increasing calcium excretion by the kidney (Lehne, 2012). Biphosphinates such as alendronate can be considered for those with symptomatic primary hyperparathyroidism who are unable to undergo surgery. Laser thermal ablation or radiofrequency ablation are other alternative therapies (Sung, 2015).

MANIFESTATIONS Hyperparathyroidism

MUSCULOSKELETAL SYSTEM
- Bone pain (back, joints and shins)
- Pathological fractures
- Muscle weakness
- Muscle atrophy

RENAL EFFECTS
- Renal calculi
- Polyuria
- Polydipsia

GASTROINTESTINAL SYSTEM
- Abdominal pain
- Peptic ulcers
- Pancreatitis
- Insulin resistance
- Nausea
- Constipation

CARDIOVASCULAR SYSTEM
- Arrhythmias
- Hypertension
- Deposition of calcium and phosphate in arterial walls

CENTRAL NERVOUS SYSTEM
- Paraesthesias
- Depression
- Confusion
- Psychosis

METABOLIC EFFECTS
- Acidosis
- Weight loss
- Fatigue

Surgical removal of the parathyroid glands affected by hyperplasia or adenoma treats all forms of hyperparathyroidism. The preoperative and postoperative nursing care is essentially the same as that for the person having a thyroidectomy (see above). In some cases autotransplantation of one parathyroid to the forearm may assist in controlling postoperative calcium homeostasis.

Nursing care

Nursing care of the person with hypercalcaemia is discussed in Chapter 9.

THE PERSON WITH HYPOPARATHYROIDISM

Hypoparathyroidism results from abnormally low PTH levels. The most common cause is inadvertent damage to or removal of the parathyroid glands during thyroidectomy.

Pathophysiology and manifestations

Due to reduced PTH, the ability to resorb calcium from the bone, and to regulate calcium reabsorption from the renal tubules, is impaired. Reabsorption of phosphate is increased in the renal tubules, causing hyperphosphataemia (McCance & Huether, 2009). The low calcium levels cause changes in neuromuscular activity, affecting peripheral motor and sensory nerves.

The neuromuscular manifestations that result from hypocalcaemia include numbness and tingling around the mouth and in the fingertips, muscle spasms of the hands and feet, convulsions and laryngeal spasms. Tetany, a continuous spasm of muscles, is the primary symptom of hypocalcaemia. In severe cases of tetany, death may occur. Assessments for tetany include Trousseau's sign (see Chapters 9 and 17). The manifestations of hypoparathyroidism are summarised in the box opposite.

MANIFESTATIONS Hypoparathyroidism

MUSCULOSKELETAL SYSTEM
- Muscle spasms
- Facial grimacing
- Carpopedal spasms
- Tetany or convulsions

INTEGUMENTARY SYSTEM
- Brittle nails
- Hair loss
- Dry, scaly skin

GASTROINTESTINAL SYSTEM
- Abdominal cramps
- Malabsorption

CARDIOVASCULAR SYSTEM
- Arrhythmias

CENTRAL NERVOUS SYSTEM
- Paraesthesias (lips, hands, feet)
- Mood disorders (irritability, depression, anxiety)
- Hyperactive reflexes
- Psychosis
- Increased intracranial pressure

INTERPROFESSIONAL CARE

Hypoparathyroidism is diagnosed by low serum calcium levels and high phosphorous levels in the absence of renal failure, an absorption disorder or a nutritional disorder.

Treatment of hypoparathyroidism focuses on increasing calcium levels. Intravenous calcium gluconate is given immediately to reduce tetany. Long-term therapy includes supplemental calcium, increased dietary calcium and vitamin D therapy.

Nursing care

Nursing care for the person with hypocalcaemia is discussed in Chapter 9.

DISORDERS OF THE ADRENAL GLANDS

Disorders of the adrenal cortex or adrenal medulla result in changes in the production of adrenocorticotropic hormone (ACTH). Hormones of the adrenal cortex are essential to life and maintain homeostasis in response to stressors. Disorders of the adrenal cortex result in complex physical, psychological and metabolic alterations. The disorders that occur are hyperfunction and hypofunction of the adrenal cortex and hyperfunction of the adrenal medulla.

THE PERSON WITH HYPERCORTISOLISM (CUSHING'S SYNDROME)

Cushing's syndrome is a chronic pathological disorder in which hyperfunction of the adrenal cortex produces symptoms associated with excessive amounts of circulating cortisol or ACTH (see Figure 18.3). Cushing's syndrome is more

FIGURE 18.3 ■ Among the manifestations of Cushing's syndrome are central obesity; fat deposits around the upper back (*A*), face (*B*) and clavicle; hirsutism; dilation of capillaries; and purple or red striae (due to weight gain)

Sources: A, Wellcome Image Library; *B*, Custom Medical Stock.

common in women, with the average age of onset between 30 and 50 years. However, the disorder may occur at any age, especially as the result of pharmacological therapy. People who take steroids (such as prednisone) for long periods of time are at increased risk of developing the disorder.

Pathophysiology

The most common aetiologies of Cushing's syndrome are as follows:

- The pituitary form, with ACTH hypersecretion by a tumour of the pituitary (called *Cushing's disease*). This is caused by a pituitary adenoma, with persistent but disorderly and random overproduction of ACTH (Lau, Rutledge & Aghi, 2015).
- The ectopic form, caused by ACTH-secreting tumours (usually of the lung or pancreas).
- The adrenal form, resulting from excessive cortisol secretion by a benign or malignant adrenal tumour. The excess secretion suppresses pituitary ACTH production, resulting in atrophy of the uninvolved adrenal cortex. Thirty-two per cent of Cushing's disease is due to excessive autonomous secretion of cortisol by the adrenal glands (McPhee, Papadakis & Tierney, 2008; National Endocrine and Metabolic Diseases Information Service, 2012).
- Iatrogenic Cushing's syndrome, resulting from long-term therapy with potent pharmacological glucocorticoid preparations (steroids).

Manifestations

Excess cortisol results in a redistribution of body fat deposits in the abdominal region (central obesity), fat pads under the clavicle, a 'buffalo hump' over the upper back and a round 'moon' face. Changes in protein metabolism cause peripheral muscle weakness and wasting. Glucocorticoid excess inhibits fibroblasts, resulting in loss of collagen and connective tissue. Thinning of the skin, abdominal striae (reddish purple 'stretch marks'), easy bruising, poor wound healing and frequent skin infections result. Glucose metabolism is altered and type 2 diabetes mellitus may occur. Changes in calcium absorption result in osteoporosis, compression fractures of the vertebrae, fractures of the ribs and renal calculi. Hypokalaemia and hypertension occur as potassium is lost and sodium is retained. Inhibited immune responses increase the risk of infection and increased gastric acid secretion increases the risk of peptic ulcers. Emotional changes range from depression to overt psychosis. In women, increasing androgen levels cause hirsutism (excessive facial hair in particular), acne, menstrual irregularities and infertility. Men could suffer impotence (Lau et al., 2015). The manifestations and effects of Cushing's syndrome are grouped by body system in the box opposite.

If the person undergoes a bilateral adrenalectomy as a treatment for Cushing's syndrome, an acute deficit of cortisol (Addisonian crisis) may result.

INTERPROFESSIONAL CARE

The treatment of Cushing's syndrome includes medications, radiation therapy or surgery, depending on the aetiological origin of the disorder.

Diagnostic tests

Cushing's syndrome is diagnosed through a variety of diagnostic tests. Findings are shown in Table 18.3 and in the following bulleted summary.

- *Plasma cortisol levels* are measured. If Cushing's disease is present, test results show a loss of the normal diurnal variations of higher levels in the morning and lower levels in the afternoon.
- *Plasma ACTH levels* are measured to determine the aetiology of the syndrome. Normally, plasma ACTH levels are

MANIFESTATIONS Cushing's syndrome

MUSCULOSKELETAL SYSTEM
- Weakness
- Osteoporosis
- Peripheral muscle weakness and wasting

INTEGUMENTARY SYSTEM
- Thin, easily bruised skin ('tissue paper' skin)
- Skin infections
- Poor wound healing
- Ecchymosis
- Purple striae (around thighs, breasts, abdomen)
- Hirsutism

CENTRAL NERVOUS SYSTEM
- Emotional lability
- Psychoses

GASTROINTESTINAL SYSTEM
- Peptic ulcers

CARDIOVASCULAR SYSTEM
- Hypertension

RENAL EFFECTS
- Renal calculi
- Polyuria
- Polydipsia
- Glycosuria

METABOLIC EFFECTS
- Hypokalaemia
- Hypernatraemia
- Type 2 diabetes mellitus
- Truncal obesity
- Buffalo hump

REPRODUCTIVE SYSTEM
- Oligomenorrhoea or amenorrhoea
- Impotence
- Decreased libido

highest from 7 am to 10 am and lowest from 7 pm to 10 pm. In secondary Cushing's syndrome, ACTH is elevated; in primary Cushing's syndrome, ACTH is decreased.

- *24-hour urine tests* (17-ketosteroids (17-KS) and 17-hydroxy-corticosteroids) are conducted to measure free cortisol and androgens; these hormones are increased in Cushing's syndrome. Because synthesis and circulation of adrenal hormones are diurnal and episodic, 24-hour urine collections more correctly reflect total hormone than serum levels drawn intermittently.
- *Serum potassium, calcium and glucose levels* are measured to identify electrolyte imbalances.
- *ACTH suppression test* may be conducted to identify the cause of the disorder. A synthetic cortisol (dexamethasone) is given to suppress the production of ACTH and plasma cortisol levels are measured. If an extremely high dose of cortisol is necessary to suppress ACTH, the primary disorder is adrenal cortex hyperplasia. If there is an abnormal release of cortisol after a low-dose suppression test, an adrenal tumour that produces cortisol, a body tumour or a pituitary tumour that produces ACTH is suspected (Stewart & Krone, 2011).

Medications

Cushing's syndrome that results from a pituitary tumour is treated by medications as an adjunct to surgery or radiation. Medical therapies are classified according to their site of action: at the pituitary gland by inhibiting ACTH secretion, at the adrenal gland by inhibiting steroidogenesis or at the target tissue by blocking the glucocorticoid receptor. Examples of some commonly prescribed drugs follow:

- Cabergoline used to suppress lactation or Parkinson's disease is a potent, long-acting dopamine-2 (D2) receptor agonist. Identification of dopamine (D2) receptors in corticotroph tumours has led to clinical trials of cabergoline in Cushing's disease.
- Metyrapone directly suppresses activity of the adrenal cortex and decreases peripheral metabolism of corticosteroids by inhibition of steroidogensis enzyme 11β-hydroxylase. Aminoglutethimide or ketoconazole (or both) inhibit cortisol synthesis by the adrenal cortex and may be administered to people with ectopic ACTH-secreting tumours that cannot be surgically removed. There is growing literature that shows ketoconazole, a well-known antifungal, may benefit by extra-adrenal actions through antagonist activity against glucocorticoid receptors.
- Pituitary adenomas contain receptors for somatostatin (growth hormone release inhibiting factor). Pasireotide diaspartate is an analogue of somatostatin which binds to these receptors. This inhibits the secretion of ACTH.

TABLE 18.3 Laboratory findings in Cushing's syndrome

	TEST	NORMAL VALUES	FINDINGS
Serum	Cortisol	am: 82–960 nmol/L	Increased
		pm: 30–550 nmol/L or ≤ 50% of morning peak	
	Blood urea nitrogen	5–25 mg/Dl	Normal
	Sodium	137–146 mmol/L	Increased
	Potassium	3.5–5.0 mmol/L	Increased
	Glucose (serum)	3.0–8.0 mmol/L	Increased
Urine	17-Ketosteroids	Male: 35–76 mmol/day	Increased
		Female: 21–55 mmol/day

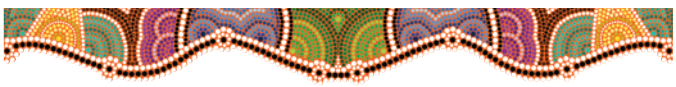
Surgery

When Cushing's syndrome is caused by an adrenal cortex tumour, an adrenalectomy may be performed to remove the tumour. Only one adrenal gland is usually involved; however, if an ACTH-producing ectopic tumour is involved, a bilateral adrenalectomy is performed. Lifelong hormone replacement is necessary if both adrenal glands are removed. Nursing care of the person having an adrenalectomy is discussed below.

Surgical removal of the pituitary gland (hypophysectomy) is indicated when Cushing's disease is the result of a pituitary disorder. The gland is removed either by a trans-sphenoidal route or by a craniotomy. Immediate cure rates for neurosurgical resection are between 65% and 90% (Lau et al., 2015). Nursing care for the person having cranial surgery is discussed in Chapter 41.



Nursing care

Health promotion

Stress the risk of developing Cushing's syndrome for people taking long-term steroids. The risk of adrenal crisis resulting from the abrupt discontinuation of steroid medications is an essential component of teaching. For a review of glucocorticoid administration, see Chapter 11.

Assessment

Collect the following data through the health history and physical examination (see Chapter 17). Further focused assessments are described with nursing interventions below.

- *Health history:* history of pituitary, adrenal, pancreatic or pulmonary tumour; frequent infections; gastrointestinal bleeding; stress fractures; pain, changes in weight distribution; change in height; fatigue; weakness; change in appearance; bruising; skin infections; menstrual history; sexual function.
- *Physical assessment:* vital signs, behaviour, appearance, fat distribution, face, skin, hair quantity and distribution, muscle size and strength, gait.

Nursing diagnoses and interventions

The nurse caring for the person with Cushing's syndrome must take a holistic approach to plan and implement interventions for a wide variety of responses, including problems related to fluid and electrolyte balance, injury, infection and body image. For additional information about people with alterations in fluid and electrolyte balance, see Chapter 9. See accompanying 'Nursing care plan' below.

Fluid volume excess

The excess cortisol secretion associated with Cushing's syndrome results in sodium and water reabsorption, causing fluid volume excess (Porth & Matfin, 2009). The person will have weight gain, oedema and hypertension.

- Ask the person to weigh themself at the same time each day and maintain a record of results. Body weight is an accurate indicator of fluid status. *One litre of fluid retention corresponds to about 1 kg of body weight.*
- Monitor blood pressure, rate and rhythm of pulse, respiratory rate and lung sounds. Assess for peripheral oedema and jugular vein distension. *Extracellular fluid volume excess resulting from sodium and water retention is manifested by hypertension and a pounding, rapid pulse. There may also be crackles and wheezes on lung auscultation, dependent oedema and venous distension.*
- Teach the person and family the reasons for the importance of limiting fluids as ordered. *Restricting fluid can help decrease the risk of fluid volume excess. Involving the person and family in the plan of care and teaching the rationale for interventions helps to achieve goals and minimise anxiety.*

NURSING CARE OF THE PERSON Having a laparoscopic adrenalectomy

PREOPERATIVE CARE

- Request a dietary consultation to discuss with the person a diet high in vitamins and proteins. If hypokalaemia exists, include foods high in potassium. *Glucocorticoid excess increases catabolism. Vitamins and proteins are necessary for tissue repair and wound healing following surgery.*
- Use careful medical and surgical asepsis when providing care and treatments. *Cortisol excess increases the risk of infection.*
- Monitor the results of laboratory tests of electrolytes and glucose levels. *Electrolyte and glucose imbalances must be corrected before the person has surgery.*
- Teach the person to turn, cough and perform deep-breathing exercises. *Although they are important for all surgical people, these activities are even more important for the person who is at risk of infection. Having the person practise and demonstrate the activities increases postoperative compliance.*

POSTOPERATIVE CARE

- Take and record vital signs, measure intake and output, and monitor electrolytes regularly, especially potassium during the first 48 hours after surgery. *Removal of an adrenal gland, especially a bilateral adrenalectomy, results in adrenal insufficiency. Addisonian crisis and hypovolaemic shock may occur. Cortisol is often given on the day of surgery and in the postoperative period to replace inadequate hormone levels. Intravenous fluids are also administered.*
- Assess body temperature, WBC levels and wound drainage. Change dressings using sterile technique. *Impaired wound healing increases the risk of infection in people with adrenal disorders. Use aseptic technique to decrease this risk.*
- Monitor for pain and administer analgesia as ordered. *Sufficient pain relief assists in early ambulation and reduced length of stay.*

NURSING CARE PLAN A person with Cushing's syndrome

Sara Domico is a 30-year-old solicitor living in a major metropolitan area. She has never been married and she shares her life with her cat, Beau, and her parents, who live nearby. Her doctor recently diagnosed Ms Domico as having Cushing's syndrome and admits her for surgery for an adrenal cortex tumour (adrenalectomy). She has been having increased muscle weakness, so much so that she has difficulty climbing the one set of stairs to her apartment. She has also had difficulty sleeping, irregular menstrual periods and hypertension.

ASSESSMENT

When Ms Domico arrives at the hospital the morning of surgery, she is admitted by the ward nurse, Ann Sprengel, Registered Nurse (RN), Clinical Nurse Specialist (CNS). Ann completes a physical assessment that includes abnormal findings of thin lower extremities, an enlarged abdomen, purple striae over the abdomen and buttocks, a round face and obvious facial hair. Ms Domico's blood pressure is 160/96. She tells Ann that she is always tired and that sometimes it 'just wears me out to walk from the bedroom to the kitchen'. Diagnostic tests conducted prior to admission reveal the following abnormal findings (all except cortisol levels are corrected before surgery):

Glucose: 16 mmol/L (normal range: 3.0–7.0 mmol/L)
Sodium: 152 mmol/L (normal range: 137–146 mmol/L)
Potassium: 3.2 mmol/L (normal range: 3.5–5.0 mmol/L)
Calcium: 2.10 mmol/L (normal range: 2.10–2.60 mmol/L)
Cortisol: 1150 nmol/L (normal for am: 82–960 nmol/L)

(South-Western Sydney Local Health District (SWSLHD) Liverpool Hospital Pathology Department, 2012).

DIAGNOSES

- *Fluid volume excess* related to sodium retention causing oedema and hypertension.
- *Risk of injury* related to generalised fatigue and weakness.
- *Risk of infection* related to impaired immune response and oedema.
- *Disturbed body image* related to physical changes secondary to Cushing's syndrome.

PLANNING

- Organise pre- and post-surgery education for Ms Domico involving an educator, specialist nurse, dietitian and other relevant allied health professionals.
- Develop a plan of pre-op care and recovery post surgery.
- Discuss the importance of monitoring and informing staff about intake and output of fluids as well as maintaining a record.
- Discuss about risks and risk prevention while hospitalised.
- Develop a written schedule of rest and activity periods.

Expected outcomes

- Regain a normal body fluid balance.
- Remain free of injury.
- Remain free of infection.
- Verbalise an understanding of the physical effects of the disease process and have realistic expectations of desired changes in appearance.

IMPLEMENTATION

- Weigh each morning, using the same scale.
- Maintain an accurate record of intake and output.
- Ensure adequate lighting in the room and wear glasses and shoes when getting out of bed.
- If possible, provide a private room and restrict visitors at this time after consulting with the person.
- Use strict medical and surgical asepsis when providing care.
- Provide time for discussion of the disease and treatment; encourage verbalisation of feelings and identify successful coping mechanisms used in the past.
- Encourage turning, coughing and deep breathing, and/or incentive spirometry every 2–4 hours.

EVALUATION

Ms Domico states that she is 'ready to have surgery and start feeling better'. She has not fallen or injured herself and she has remained free of infection. Although oedema is still present, she has lost 3.6 kg and her blood pressure has decreased. Ms Domico has openly discussed her concerns about the way she looks and feels; she understands that symptoms will improve following surgery. She has strong religious beliefs and family support, both of which provide strength and help her cope with the effects of the disorder and the need for any further treatment.

CRITICAL THINKING IN THE NURSING PROCESS

1. When Ms Domico was admitted to the hospital, several of her test results were abnormal. Describe the pathophysiological reason for those results.
2. List the assessments that nurses can make to determine body fluid balance.
3. Develop a plan of care for this person for the nursing diagnosis of *Fatigue*.

REFLECTION ON THE NURSING PROCESS

1. What have you learned from this scenario that you will utilise in your future nursing practice?
2. Develop a plan of education to Ms Domico during her recovery from surgery and plan for her discharge home, taking into consideration her social status such as her profession, living arrangements, infection risk from her pet, etc.

Risk of injury related to decreased bone density

The person with Cushing's syndrome is at risk of injury from several causes. Excess cortisol causes increased absorption of calcium and demineralisation of bones, resulting in an increased risk of pathological fractures, particularly in the vertebra and ribs (Arduc et al., 2014). Muscle weakness and fatigue are common, increasing the potential for accidental falls.

- Teach the person and family to maintain a safe environment:
  - Keep unnecessary clutter and equipment out of the way and off the floor.
  - Ensure adequate lighting, especially at night.
  - Encourage the use of assistive devices for ambulation or to ask for help if needed.
  - If the person wears corrective lenses, be sure they are available and clean.

- Encourage the use of non-slippery slippers or shoes.
- Consider wearing hip protectors when ambulant.
- Monitor for signs of fatigue (increased pulse and respirations); plan rest periods.

  A well-lit environment free of clutter decreases the risk of falls and injury. Sensory and motor deficits increase the risk of falls; corrective lenses, assistive devices and non-slippery footwear can decrease this risk. Hip protectors, although bulky, reduce the risk of hip fractures. Rest relieves fatigue. To reduce energy expenditure, include alternating periods of rest and activity in daily schedules.

Risk of infection

Elevated cortisol levels impair the immune response, increasing the risk of infection. Increased cortisol also affects protein synthesis, causing delayed wound healing, and inhibits collagen formation, which results in epidermal atrophy, further inhibiting resistance to infection. In addition, impaired blood flow to oedematous tissue results in altered cellular nutrition, which increases the potential for infection. The following interventions are outlined for the person with Cushing's syndrome who is hospitalised:

- Place in a private room, if possible and limit visitors. *The person must avoid exposure to environmental infection.*
- Monitor vital signs and verbalisations of subjective manifestations (for example, the person's response to 'How do you feel?') every 4 hours. *Increased body temperature and pulse are systemic indicators of infection; however, because Cushing's syndrome impairs the normal inflammatory response, the usual indicators of inflammation such as fever may not be present.*
- Pat skin dry gently after bathing. *Rough drying with towels increase risk of skin tears and skin infections.*
- Use principles of medical and sterile asepsis when conducting procedures or providing wound care. *Impaired skin and tissues make aseptic techniques even more necessary to decrease the risk of infection. Intact, clean and dry skin is the first line of defence against infection.*
- If wounds are present, assess the colour, odour and consistency of wound drainage and look for increased pain in and around the wound. Use a wound chart to keep a record of the wound progress.
- Teach the importance of increasing oral intake of protein and vitamins C and A. *Protein, vitamin C and vitamin A are necessary for collagen formation; collagen helps support and repair body tissues.*

CONSIDERATION FOR PRACTICE

A generalised feeling of malaise may be the primary manifestation of infection.

Disturbed body image

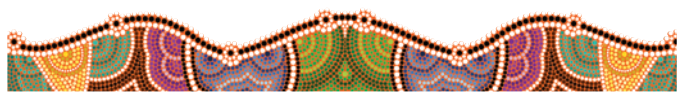
The person with Cushing's syndrome has obvious physical changes in appearance. The abnormal fat distribution, moon face, buffalo hump, thin skin, striae, acne and facial hair (in women) all contribute to disruptions in the way people with this disorder perceive themselves.

- Encourage people to express feelings and to ask questions about the disorder and its treatment. *The loss of one's normal body image may prompt feelings of hopelessness, powerlessness, anger and depression. Understanding the disease and adapting to changes from that disease are the first steps in regaining control of one's own body.*
- Discuss strengths and previous coping strategies. Enlist the support of family or significant others in reaffirming the person's worth. *Disturbances in body image are often accompanied by low self-esteem. Self-esteem derives from one's perception of competence and from appraisals of others.*
- Discuss signs of progress in controlling symptoms; for example, decreased facial oedema or increased activity tolerance. *Many physical changes from cortisol excess disappear with treatment. Clearly communicate this fact, because the person may believe changes are permanent.*

Community-based care

The person with Cushing's syndrome requires education about specific self-care responsibilities at home. Address the following topics:

- Safety measures to prevent falls if fatigue, weakness and osteoporosis are present.
- Taking medications as prescribed, with information about side effects. People often require medications for the rest of their lives and dosage changes are highly likely.
- Having regular health assessments.
- Wearing a MedicAlert® bracelet indicating the person has Cushing's syndrome.
- Helping the older person with referrals to social services or community health services because of the complexity of the treatment and care required.
- Providing helpful resources:
  - Australian Pituitary Foundation Ltd. Tel. 1300 331 807. www.pituitary.asn.au
  - The Endocrine Society of Australia. Tel. (02) 9256 5405. www.endocrinesociety.org.au.



THE PERSON WITH CHRONIC ADRENOCORTICAL INSUFFICIENCY (ADDISON'S DISEASE)

Addison's disease is a rare endocrine disorder that in Australia affects about 4 to 11 people per 100 000. In children, boys have an incidence of 75%; in adults, women constitute 70% of all cases (O'Connell & Siafarikas, 2010). The disease is characterised by low serum cortisol levels which manifest by weight loss, muscle weakness, fatigue, low blood pressure and sometimes darkening of the skin in both exposed and unexposed parts of the body (Australian Addison's Disease Association, 2006).

Pathophysiology

There are many possible causes of Addison's disease:

- Autoimmune destruction of the adrenals. This is the most common cause in the Western world, accounting for about 70% to 80% of all cases (O'Connell & Siafarikas, 2010). It may occur alone or as part of a polyglandular autoimmune syndrome (PGA). Type 2 PGA in adults is often associated with autoimmune thyroid disease, type 1 diabetes, systemic lupus erythematosus, primary ovarian or testicular failure, and pernicious anaemia (Godswill & Odigie, 2014).
- It is also seen in people who are taking anticoagulants, have had major trauma or sepsis, or are having open-heart surgery. Such people may have bilateral adrenal haemorrhage.
- Adrenoleukodystrophy, an X-linked disorder characterised by an accumulation of very-long-chain fatty acids in the adrenal cortex, testes, brain and spinal cord.
- ACTH deficit, resulting from pituitary tumours, pituitary surgery or irradiation, and the use of exogenous steroids.
- People who are abruptly withdrawn from long-term, high-dose steroid therapy. Other people at risk are those with tuberculosis or acquired immune deficiency syndrome (AIDS); the pathogens responsible for either disease can infiltrate and destroy adrenal tissue.

Adrenocortical destruction initially causes a decrease in adrenal glucocorticoid reserves. Basal glucocorticoid secretion is normal, but does not increase in response to stress and surgery. As the destruction of the adrenal cortex continues, even basal secretion of glucocorticoids and mineralocorticoids is deficient. Decreasing plasma cortisol reduces the feedback inhibition of pituitary ACTH and plasma ACTH rises.

Secondary adrenocortical insufficiency occurs when either large doses or prolonged therapy with glucocorticoids are given for their anti-inflammatory and immunosuppressive effects to treat autoimmune diseases such as arthritis and asthma. If the steroid medications are suddenly discontinued, the hypothalamus and pituitary cannot respond normally to the reduced level of circulating glucocorticoids. The person may develop manifestations of chronic adrenocortical insufficiency or, if subjected to stress, adrenal (Addisonian) crisis (McPhee et al., 2008).

Manifestations

The onset of Addison's disease is slow in most cases; the person experiences symptoms after about 90% of the function of the gland is lost. The primary manifestations are the result of elevated ACTH levels and decreased aldosterone and cortisol. Aldosterone deficiency affects the ability of the distal tubules of the nephron to conserve sodium. Sodium is lost, potassium is retained, extracellular fluid is depleted and the blood volume is decreased. Due to sodium loss, the person may have a craving for salt. Postural hypotension and syncope are common and hypovolaemic shock may occur. Hyponatraemia causes dizziness, confusion and neuromuscular irritability. Hyperkalaemia causes cardiac arrhythmias.

Cortisol insufficiency also causes decreased hepatic gluconeogenesis with hypoglycaemia. The person tolerates stress poorly and experiences lethargy, weakness, anorexia, nausea, vomiting and diarrhoea. The increased ACTH levels stimulate hyperpigmentation. In Caucasian people, the skin looks deeply suntanned or bronzed in both exposed and unexposed areas (Godswill & Odigie, 2014).

Addisonian crisis

Addisonian or **adrenal crisis** is a life-threatening response to acute adrenal insufficiency and occurs in about 25% of people (Australian Addison's Disease Association, 2006). Triggers include surgery, acute systemic illness, trauma or abrupt withdrawal of long-term corticosteroid therapy. The disorder is chronic after the acute episode resolves.

This response can occur in any person with Addison's disease; however, it is most commonly precipitated by major stressors, especially if the disease is poorly controlled.

The person with Addisonian crisis may have any of the manifestations of Addison's disease, but the primary symptoms develop rapidly: a high fever; weakness; severe, penetrating pain in the abdomen, lower back and legs; severe vomiting; diarrhoea; hypotension; and circulatory collapse, shock, seizures and coma.

MANIFESTATIONS Addison's disease

INTEGUMENTARY SYSTEM
- Delayed wound healing
- Hyperpigmentation

CARDIOVASCULAR SYSTEM
- Postural hypotension
- Arrhythmias
- Tachycardia

CENTRAL NERVOUS SYSTEM
- Lethargy
- Tremors
- Emotional lability
- Confusion

MUSCULOSKELETAL SYSTEM
- Weakness
- Muscle wasting
- Joint pain
- Muscle pain

GASTROINTESTINAL SYSTEM
- Anorexia
- Nausea and vomiting
- Diarrhoea

REPRODUCTIVE SYSTEM
- Menstrual changes

METABOLIC EFFECTS
- Hyperkalaemia
- Hyponatraemia
- Hypoglycaemia

Treatment of adrenal crisis is emergency resuscitation, restoring and maintaining circulating fluid, intravenous hydrocortisone, management of hypoglycaemia, and identification and treatment of precipitating factors. Admission to an intensive care unit may be necessary in most cases (O'Connell & Siafarikas, 2010).

INTERPROFESSIONAL CARE

The person with Addison's disease requires early diagnosis and treatment. Medical treatment includes cortisol replacement therapy.

Diagnostic tests

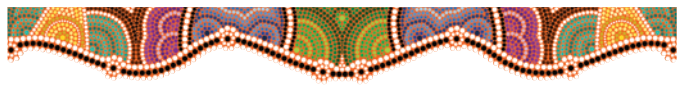
Addison's disease is diagnosed through findings of decreased levels of cortisol, aldosterone and urinary 17-KS. Dehydration may result in increased haematocrit and blood urea nitrogen (BUN). Blood glucose levels are decreased and potassium is increased. A list of laboratory findings in Addison's disease is shown in Table 18.4. The following diagnostic tests are used:

- *serum cortisol levels*, which are decreased
- *blood glucose levels*, which are decreased
- *serum sodium levels*, which are decreased
- *serum potassium levels*, which are increased
- *BUN levels*, which are increased
- *urinary 17-hydroxycorticoids* and *17-KS levels*, which are decreased
- *plasma ACTH levels*, which are increased in primary adrenal insufficiency but decreased in secondary adrenal insufficiency
- *possibly ACTH stimulation test* (cortisol levels rise with pituitary deficiency but do not rise in primary adrenal insufficiency)
- *CT scans* of the head, which identify any intracranial lesion impinging on the pituitary gland.

Medications

Treatment of Addison's disease involves replacing the hormones that the adrenal glands are not making. Cortisol is replaced orally with oral hydrocortisone. If aldosterone is also deficient, it is replaced with oral doses of a mineralocorticoid, fludrocortisone acetate (Florinef), which is taken once a day. Aldosterone replacement therapy is usually accompanied with an increased salt intake. The doses of each of these medications are adjusted to meet the needs of individuals. During an Addisonian crisis, low blood pressure, low blood sugar and high levels of potassium can be life threatening. Standard therapy involves intravenous injections of hydrocortisone, saline (salt water) and dextrose (sugar). When the person can take fluids and medications by mouth, the amount of hydrocortisone is decreased until a maintenance dose is achieved.

Nursing implications in cortisol replacement are given in the following 'Medication administration' box.



Nursing care

Health promotion

Health promotion interventions for the person with or at risk of Addison's disease focus on careful assessments during anticoagulant therapy, open-heart surgery and trauma treatment. If the disease is present, teaching to prevent or treat an Addisonian crisis is essential.

Assessment

Collect the following data through the health history and physical examination (see Chapter 17). Further focused assessments described with nursing interventions follow.

- *Health history:* weight loss, changes in skin colour, nausea and vomiting, anorexia, diarrhoea, abdominal pain, weakness, amenorrhoea, changes in sexual desire, confusion and stress intolerance.
- *Physical assessment:* height and weight, vital signs, skin, hair quality and distribution, muscle size and strength.

Nursing diagnoses and interventions

The person with Addison's disease requires nursing care for a wide variety of responses to the decrease in cortisol levels. Nursing diagnoses discussed in this section are directed towards problems with fluid and electrolyte balance and compliance with lifelong self-care. See the accompanying 'Nursing care plan' below.

TABLE 18.4 Laboratory findings in Addison's disease

	TEST	NORMAL VALUES	FINDINGS
Serum	Cortisol	am: 82–960 nmol/L pm: 30–550 nmol/L or ≤ 50% of morning peak	Decreased
	Blood urea nitrogen	5–25 mg/dL	Increased
	Sodium	137–146 mmol/L	Decreased
	Potassium	3.5–5.0 mmol/L	Increased
	Glucose (serum)	3.0–8.0 mmol/L	Decreased
Urine	17-Ketosteroids	Male: 35–76 mmol/day Female: 21–55 mmmol/L	Low/absent

Deficient fluid volume related to water and sodium loss

Fluid volume deficit in the person with Addison's disease results from loss of water and sodium, as well as from vomiting and diarrhoea. Extracellular fluid volume deficit, decreased cardiac output, hypotension and hypovolaemic shock may occur, especially in crisis situations. Interventions for this diagnosis are outlined for the person who is hospitalised.

- Monitor intake and output and assess for signs of dehydration: dry mucous membranes; thirst; poor skin turgor; sunken eyes; scanty or low, dark urine; increased urine specific gravity; weight loss; and increased haemoconcentration (increased haematocrit and BUN). *Glucocorticoid and mineralocorticoid depletion causes fluid volume deficit. Fluid volume deficit may reach crisis levels if undetected, causing altered tissue perfusion and hypovolaemic shock.*
- Monitor cardiovascular status: take and record vital signs, assess character of pulses, monitor potassium levels and electrocardiogram (ECG). *Fluid volume deficit may lead to hypotension and a rapid, weak or thready pulse. As aldosterone levels fall, renal excretion of potassium decreases and causes hyperkalaemia.*
- Weigh the person daily at the same time and in the same clothing. *Dehydration is manifested by weight loss.*
- Encourage an oral fluid intake of 3000 mL per day and an increased salt intake. Cortisol deficiency increases fluid loss, leading to extracellular fluid volume depletion. Oral fluid replacement is necessary to balance this loss. *An increase in dietary sodium can decrease the hyponatraemia characteristic of adrenal insufficiency.*
- Teach to sit and stand slowly and provide assistance as necessary. *Extracellular fluid volume deficit causes orthostatic hypotension, dizziness and possible loss of consciousness. These manifestations increase the risk of injury from falls.*

MEDICATION ADMINISTRATION Addison's disease

CORTISOL REPLACEMENTS

Cortisone acetate (Cortate, Cortef)
Hydrocortisone (Hysone, Solu-Cortef, Hydrocortisone sodium succinat)
Fludrocortisone acetate (Florinef)
Dexamethasone (Dexmethsone, Celestone chronodose, DBL Dexamethasone sodium phosphate injections, Betamethasone acetate sodium phosphate)
Prednisone (Sone, Predsone)
Prednisolone (Solone, Predsolone, Rediprep oral liquid, Panafcortelone, Panafcort, Predmix oral liquid)
Methylprednisolone (Medrol, Solu-Medrol)

(Australian trade names of medications, Australian Prescriber 2015)

NURSING ALERT

Prednisolone and prednisone are equivalent in potency; dexamethasone is four to five times more potent.

Adrenocorticosteroids are used for replacement therapy in acute and chronic adrenal insufficiency. These drugs have anti-inflammatory and immunosuppressant effects. They also facilitate coping with stress.

When these drugs are administered in small doses for replacement therapy, side effects are uncommon. Large doses or prolonged therapy may cause a Cushing's-like syndrome, with atrophy of the adrenal cortex. Older people, especially postmenopausal women, are more prone to develop hypertension and osteoporosis when undergoing glucocorticoid therapy. These drugs are used with caution in children and the older adult and are not usually administered to pregnant women.

Nursing responsibilities

- Establish baseline data, including mental status, neurological function, vital signs and weight.
- Identify medications that might interact with corticosteroids: hypoglycaemic medications, cardiac glycosides, oral contraceptives, anticoagulants, NSAIDs.
- Document and report increased blood pressure, oedema or weight gain, bleeding or bruising, weakness or manifestations of Cushing's syndrome.
- Administer oral forms of the drug with food to minimise its ulcerogenic effect.
- Monitor electrolyte levels for hypernatraemia and hypokalaemia.
- Monitor capillary blood glucose for hyperglycaemia in the diabetic person.

Health education for the person and family

- Take medications with food or milk and report any gastric distress or dark stools (malaena).
- Most people need to take the medications for the rest of their lives.
- Consume a diet that is low in potassium and higher in sodium and protein.
- Weigh yourself each day at the same time and report any consistent weight gain, which indicates fluid retention.
- Use safety measures in the home to prevent falls and injuries.
- Corticosteroids may impair the effectiveness of oral contraceptives.
- Take the medication regularly and continuously.
- Obtain and carry a MedicAlert® bracelet that says 'Adrenal insufficiency—takes hydrocortisone'.
- Monitor for increased stressors (infection, dental work, personal crisis) and increase the dose as indicated by the doctor.
- Anticoagulant drugs or insulin may decrease the effectiveness of corticosteroids.
- Report signs of dizziness on sitting or standing, nausea and vomiting, pain, thirst, feelings of anxiety, malaise, infections to your doctor.

NURSING CARE PLAN A person with Addison's disease

A 51-year-old unemployed salesman, Mr Don Sardoff, is brought to the emergency department by his wife, Ellen, at 8 am. Mrs Sardoff tells the emergency nurse that her husband has not been feeling well for the last week, but that when he got up this morning he was so weak he couldn't dress himself and didn't know where he was. Mrs Sardoff also tells the nurse that her husband has been taking a cortisone drug for treatment of his rheumatoid arthritis for the past 2 years, but stopped taking the medication as she notes, 'We didn't have the money to buy it this month.'

ASSESSMENT

On admission to the emergency room, Mr Sardoff is dehydrated, with dry oral mucous membranes and tongue, poor skin turgor and sunken eyes. His blood pressure is 94/44 and his pulse is rapid and weak. He is lethargic, dizzy and disoriented of time and place. Diagnostic tests reveal the following abnormal findings at 8:30 am:

- ECG: widening QRS complex and increased PR interval
- Sodium: 129 mmol/L (normal range: 137–146 mmol/L)
- Glucose: 2.9 mmol/L (normal range: 3.0–8.0 mmol/L)
- Potassium: 5.3 mmol/L (normal range: 3.5–5 mmol/L)
- Cortisol: 71 nmol/L (normal for am: 82–960 nmol/L)

The medical orders for Mr Sardoff include intravenous administration of 4% dextrose in 1/5 normal saline at 250 mL/h and hydrocortisone (Solu-Cortef) 200 mg. After the fluids and medication are initiated, Mr Sardoff is admitted to the hospital.

DIAGNOSES

- *Deficient fluid volume* related to hypovolaemia secondary to adrenal insufficiency.
- *Ineffective peripheral tissue perfusion* related to fluid volume deficit.
- *Anxiety* related to lack of knowledge about the effects and treatment of adrenal insufficiency.

PLANNING

- Discuss a diet that is high in sodium, low in potassium and has an increased fluid intake (3000 mL per day). Discuss the types of fluids desired and the best times for intake of increased fluids.
- Discuss and determine the need for and amount of intravenous therapy if the oral intake is not sufficient to restore circulating volume.
- Provide verbal and written instructions and encourage verbal feedback about the causes and effects of the disease, the effects of medications and the effects of not taking long-term cortisone drugs or abruptly stopping this medication.

Expected outcomes

- Regain normal fluid balance.
- Regain normal peripheral perfusion with blood pressure within normal range.
- Verbalise knowledge of the causes and effects of adrenal insufficiency.

IMPLEMENTATION

- Monitor intake and output closely.
- Take and record weight at the same time daily.
- Monitor blood pressure, pulses and skin turgor every 2 hours until stable, then four times a day.
- Monitor electrolytes and report abnormal results.
- Assist during activity to prevent falls.
- Ensure steroid medication is taken regularly or if the medication is to stop, to reduce the dosage in small doses over an extended period of time.

EVALUATION

Following treatment for acute adrenal insufficiency, Mr Sardoff is no longer dehydrated and his blood pressure has returned to his normal reading of 132/88. He is alert and oriented and anxious to learn to care for himself at home. After dietary instructions and teaching for self-care that included his wife, Mr Sardoff verbalises an understanding of his illness and the need to take his medication carefully and accurately.

CRITICAL THINKING IN THE NURSING PROCESS

1. Adrenal insufficiency is often diagnosed only when the person becomes seriously ill in response to a stressor. Explain why this statement is or is not true.
2. Describe the physical assessments that are found in the severely dehydrated person.
3. Outline a teaching plan for Mr Sardoff with foods for a high-sodium, low-potassium diet.

REFLECTION ON THE NURSING PROCESS

1. Outline what have you learned from this case study and how you are going to apply this new knowledge to your future practice.
2. Find out and discuss the financial cost of medications to treat adrenal insufficiency in Australia. What assistance is available to cover the cost of medications and/or treatment?

CONSIDERATION FOR PRACTICE

Hyperkalaemia causes changes in cardiac muscle function, which are reflected in ECG changes.

Community-based care

The person with Addison's disease provides self-care at home. One of the most important components of caring for the person with Addison's disease is teaching both the person and family to provide care. Family stability, an awareness of the serious nature of the disease and the effectiveness of treatment all promote compliance. The length of treatment and the side effects of medications, however, can discourage compliance. In addition to the information in the teaching topics included with nursing diagnoses and interventions, include the following topics:

- the importance of continuing healthcare
- referral to social worker, if appropriate
- referral to community agencies for continued education and support
- helpful resource:
  - Australian Addison's Disease Association Inc. Tel: (02) 6652 4761. www.addisons.org.au

THE PERSON WITH PHEOCHROMOCYTOMA

Pheochromocytomas are tumours of the adrenal medulla. These tumours produce catecholamines (adrenaline or noradrenaline) that stimulate the sympathetic nervous system. A pheochromocytoma tends to have sudden releases of hormones, which cause a sudden 'attack' or onset of symptoms. Symptoms may include hypertension, severe headaches, palpitations, excessive truncal sweating, cold and clammy skin, nausea and vomiting, blurry vision, dyspnoea, severe anxiety or panic attacks. These symptoms may last for a few seconds to several hours (Pheochromocytoma and Paraganglioma Research Support Organization (PRESSOR), 2006). Attacks are often precipitated by physical, emotional or environmental stimuli. Although pheochromocytomas are rare, with an annual incidence of about 10 per million, 10% can be malignant (PRESSOR, 2006).

A pheochromocytoma is diagnosed by increased catecholamine levels in the blood or urine, x-ray studies and surgical exploration. Because catecholamine secretion is episodic, a 24-hour urine test is a better surveillance method than serum catecholamines (Dugdale, Zieve & Black, 2013). Surgical removal of the tumour(s) by adrenalectomy is the treatment of choice.

DISORDERS OF THE PITUITARY GLAND

The pituitary gland produces hormones that affect multiple body systems through regulation of endocrine function. Target tissues include the thyroid, adrenal cortex, ovary, uterus, mammary glands, testes and kidneys. Disorders result from an excess or deficiency of one or more of the pituitary hormones due to a pathological condition within the gland itself or to hypothalamic dysfunction.

Although disorders of the pituitary cause diverse and serious problems, they are not as common as disorders of other endocrine glands. Hyperpituitarism and hypopituitarism are discussed in this section.

THE PERSON WITH DISORDERS OF THE ANTERIOR PITUITARY GLAND

The most common cause of hyperpituitarism is a benign adenoma. The manifestations result from pressure on the optic nerve causing visual changes or an excess of growth hormone (GH), prolactin (PRL), ACTH or TSH. Typically, 70% to 90% of the anterior pituitary is damaged before clinical manifestations develop (Porth & Matfin, 2009).

Conditions causing hypopituitarism include pituitary tumours, surgical removal of the pituitary gland, radiation and pituitary infarction, infection or trauma.

Pathophysiology and manifestations

Growth hormone (also called somatotropin) is produced by cells in the anterior pituitary throughout life. GH is necessary for growth and also contributes to metabolic regulation. GH stimulates all aspects of cartilage growth and one of its major effects is to stimulate the growth of the epiphyseal cartilage plates of the long bones. In addition, other body tissues respond to the metabolic effect of GH with increases in bone width and the growth of visceral and endocrine organs, skeletal and cardiac muscle, skin and connective tissue. Gigantism and acromegaly (discussed next) result from overstimulation of GH. Growth retardation and short stature result from deficient production of GH.

Hypersecretion of PRL affects reproductive and sexual function. Women may have irregular or absent menses, difficulty becoming pregnant and decreased libido. Men may be impotent and have decreased libido. PRL deficiency postpartum causes a failure to lactate.

An excess secretion of ACTH overstimulates the adrenal cortex, which in turn increases secretion of adrenal hormones. The result is Cushing's syndrome. Deficiencies of TSH are uncommon, but cause hypothyroidism.

Gigantism

Gigantism occurs when GH hypersecretion begins before puberty and the closure of the epiphyseal plates. The person becomes abnormally tall, often exceeding 213 cm in height, but body proportions are relatively normal.

Acromegaly

Acromegaly, which literally means 'enlarged extremities', occurs when sustained GH hypersecretion begins during adulthood, most commonly because of pituitary tumours. As a result of constant stimulation, bone and connective tissue continue to grow. The forehead enlarges, the maxilla lengthens, the tongue enlarges and the voice deepens (see Figure 18.4).

Other manifestations include peripheral nerve damage from entrapment of nerves causing pin and needles in the hands, swelling of hands and feet, joint pains, headache, gaps between the teeth, barrel chest, thick and oily skin and strong body odour, hair overgrow, snoring or drooling while asleep, hyperhidrosis (heavy sweating), hypertension, congestive heart failure due to cardiomegaly and visual disturbances. Impaired glucose tolerance and diabetes may also occur. Arthralgia develops secondary to the bone and connective tissue growth and may be relieved by treatment that halts excessive GH production.

INTERPROFESSIONAL CARE

Acromegaly is treated by surgical removal or irradiation of the pituitary tumour. A transsphenoidal or transfrontal surgical procedure is most commonly used. Octreotide (Sandostatin) suppresses the anterior pituitary gland and decreases GH levels. Gastrointestinal side effects are common. About 25% of people develop gallstones (Lehne, 2012).

FIGURE 18.4 ■ In acromegaly progressive alterations in facial appearance include enlargement of the cheekbones and jaw, along with thickening of soft-tissue structures such as the nose, lips, cheeks and the flesh above the brows

Nursing care

People with anterior pituitary disorders require interventions to help in coping with physical and emotional changes, as well as to prevent complications involving other organs and functions of the endocrine system. Nursing care for the person having cranial surgery is discussed in Chapter 41.

THE PERSON WITH DISORDERS OF THE POSTERIOR PITUITARY GLAND

Disorders of the posterior pituitary are related primarily to excessive or deficient antidiuretic hormone (ADH) secretion. The disorders discussed here are the syndrome of inappropriate ADH secretion and diabetes insipidus.

Pathophysiology and manifestations

Antidiuretic hormone is secreted in response to serum osmolality, which is monitored by osmoreceptors in the hypothalamus. When a condition of hyperosmolarity occurs, ADH secretion increases and renal water is reabsorbed. Hypo-osmolality causes the suppression of ADH and renal water excretion increases.

Syndrome of inappropriate ADH secretion

The **syndrome of inappropriate ADH secretion (SIADH)** is characterised by high levels of ADH in the absence of serum hypo-osmolality. This disorder is most often caused by the ectopic production of ADH by malignant tumours. A transient form may follow a head injury, pituitary surgery or the use of medications such as barbiturates, anaesthetics or diuretics.

Manifestations of SIADH occur as a result of excess water in relation to sodium in the extracellular fluid (Ellison & Berl, 2007). Blood volume expands, but the plasma is diluted. Aldosterone is suppressed and, as a result, renal excretion of sodium increases. Water moves from the hypotonic plasma and the interstitial spaces into the cells.

Manifestations of SIADH (see Chapter 9, Table 9.6) are usually non-specific but are related to hyponatraemia and water intoxication. Brain cells swell, causing neurological symptoms including headache, changes in mental status or personality, lethargy and irritability. Weight gain results from the retention of fluid (Pillai, Unnikrishnan & Pavithran, 2011). Usually no oedema is present because water is distributed between the intracellular and extracellular spaces.

Treatment addresses the low serum sodium and intracellular swelling. Nursing care involves teaching the person about restricting fluids to 500 to 1000 mL/day. Fluid restriction continues for 3 to 10 days until the source of excessive ADH secretion is addressed. Demeclocycline (Declomycin) is a tetracycline antibiotic with the unique property of creating excessive urine flow. It is used as a treatment for SIADH (Lehne, 2012). In severe or chronic cases, hypertonic saline, loop diuretics with increased salt intake, urea or mannitol may also be utilised to prevent circulatory overload (Thomas & Batuman, 2012).

Diabetes insipidus

Diabetes insipidus is the result of ADH insufficiency. The two types are as follows:

1. *Neurogenic diabetes insipidus* can either result from a disruption of the hypothalamus and pituitary gland (as from trauma, irradiation or cranial surgery) or be idiopathic.
2. *Nephrogenic diabetes insipidus* is a disorder in which the renal tubules are not sensitive to ADH. This may be congenital in origin or the result of renal failure.

A deficit of ADH causes excretion of large amounts of dilute urine (polyuria), in some instances as much as 12 L/day. The person has extreme thirst and drinks large volumes of water (polydipsia). If unable to replace the water loss, the person becomes dehydrated and hypernatraemic. Even though hyperosmolarity is present, the urine is diluted and has a low specific gravity.

If this disorder is caused by cerebral injury, symptoms commonly appear 3 to 6 days after the initial injury and last for 7 to 10 days. If the increased intracranial pressure is relieved, symptoms of diabetes insipidus usually disappear. However, diabetes insipidus may also be a chronic illness requiring lifelong treatment and care. See Table 18.5 for a comparison of posterior pituitary gland disorders.

INTERPROFESSIONAL CARE

SIADH is treated by correcting underlying causes, treating the hyponatraemia with intravenous hypertonic saline and restricting oral fluid intake to less than 800 mL/day.

Diabetes insipidus is also treated by correcting underlying causes, if possible. Other medical interventions include administering intravenous hypotonic fluids, increasing oral fluids and

TABLE 18.5 Comparison of posterior pituitary gland disorders

SIADH	DIABETES INSIPIDUS
Excessive ADH	Deficient ADH
Fluid volume excess	Fluid volume deficit
Restrict fluid intake	Encourage fluid intake
Demeclocycline (Declomycin) (oral agent) causes excessive urination	Desmopressin (DDAVP) (nasal spray) causes increased water reabsorption

replacing ADH hormone. Desmopressin acetate, administered intranasally, orally or parenterally, is the treatment of choice (McPhee et al., 2008).

Nursing care

Nursing care for the person with SIADH and diabetes insipidus focuses on the person's problems with fluid and electrolyte balance, as discussed in Chapter 9.

CHAPTER HIGHLIGHTS

- Hormones regulate growth, development and metabolism. Homeostasis is dependent on a balanced level of each type of hormone. Hormones not only affect organ function; they also interact and, when excesses or deficits occur, signs and symptoms are manifested.
- The pituitary gland, in conjunction with the hypothalamus, is the master gland of the body. Fifteen hormones and regulatory factors are synthesised in the anterior pituitary and hypothalamus; many are trophic hormones that stimulate the release of other hormones.
- Thyroid disorders are the most common endocrine disorders. Occurring mainly among women, these diseases change body image and impose challenges to energy levels, creating fatigue and exhaustion.
- Diagnostic tests and therapies are available to identify and treat thyroid disorders. Surgery, radiation therapy and medications support good quality of life, but the medications must be used throughout the lifetime.
- The parathyroid glands, which are located on thyroid tissues, provide parathyroid hormones that are essential for the maintenance of serum calcium, which is vital for cardiac function, bone stability, nerve conduction and muscle contraction.
- The adrenal glands regulate energy and fluid balance through corticosteroids and mineralocorticoids. Cushing's and Addison's diseases are polar opposites and treatment eliminates the signs and symptoms of one and creates the manifestations of the other. People with these disorders require education until they fully grasp the significance of the condition and the importance of adhering to the treatment plan.

CONCEPT CHECK

1 Graves' disease, the most common cause of hyperthyroidism, is categorised as what type of disorder?
1 autoimmune
2 infectious
3 allergic
4 genetic

2 What principle supports the treatment of hyperthyroidism with radioactive iodine?
1 Radioactive iodine reduces the vascularity of the thyroid gland.
2 Doses of radioactive iodine are too small to be hazardous to other body parts.
3 The thyroid gland takes up iodine in any form.
4 Irradiation of the thyroid gland decreases the risk of hypothyroidism.

3 You assess a person with newly diagnosed hypothyroidism as having an enlarged thyroid gland (goitre). What physiological process causes this enlargement?
1 an excess of TH stimulates thyroid follicles
2 an increased dietary iodine intake
3 a compensatory effort to produce more TH
4 tissue hypertrophy in response to increased TH

4 Mrs Jonah has taken cortisone for her rheumatoid arthritis for several years. What endocrine disorder is she most at risk of developing?
1 hyperthyroidism
2 hypothyroidism
3 acromegaly
4 Cushing's syndrome

5 Which statement illustrates that the person with Addison's disease understands your teaching?
1 'I will be sure to stop taking my medications when I have an infection.'
2 'I have purchased an emergency kit and keep it with me all the time.'
3 'I know I should never alter my dose of medications.'
4 'I wonder why I look suntanned all the time.'

6 Signs and symptoms of hyponatraemia found in SIADH include:
1 weight loss
2 irritability
3 hyperkalaemia
4 constipation

7 A home health nurse is caring for a person with hyperparathyroidism and osteoporosis. Which nursing diagnosis has priority with this person?
1 *Risk of fear*
2 *Risk of injury*
3 *Risk of isolation*
4 *Risk of chronic low self-esteem*

8 A nurse is monitoring a person for signs of hypocalcaemia. Which of the following is a sign of hypocalcaemia?
1 oliguria
2 positive Trousseau sign
3 diminished bowel sounds
4 hyperactive deep tendon reflexes

9 A person with increased ACTH levels and Addison's disease is likely to manifest:
1 tremor
2 hair loss
3 gingival hyperplasia
4 dermal hyperpigmentation

10 People treated with glucocorticoids are at risk of Addisonian crisis due to:
1 rapid withdrawal of glucocorticoids
2 excessive ACTH
3 sodium retention
4 hypokalaemia

CHAPTER 19

NURSING CARE OF PEOPLE WITH DIABETES MELLITUS

TRACY PARRISH

KEY TERMS

dawn phenomenon 581
diabetes mellitus (DM) 561
diabetic ketoacidosis (DKA) 581
diabetic nephropathy 588
diabetic neuropathies 588
diabetic retinopathy 587
endogenous insulin 564
exogenous insulin 564
gluconeogenesis 562
glucosuria 564
glycogenolysis 562
hyperglycaemia 563
hyperosmolar hyperglycaemic state (HHS) 581
hypoglycaemia 586
insulin 562
insulin reaction 586
ketonuria 567
ketosis 563
lipoatrophy 575
lipodystrophy 575
microalbuminuria 588
polydipsia 564
polyphagia 564
polyuria 564
Somogyi phenomenon 581
type 1 DM 561
type 2 DM 561

LEARNING OUTCOMES

- Discuss the chronic disease diabetes mellitus, identifying the prevalence and incidence of the disease in Australia.
- Explain the pathophysiology, risk factors, manifestations and complications of type 1 and type 2 diabetes mellitus.
- Discuss the nursing implications for insulin and oral hypoglycaemic agents used to treat people with diabetes mellitus.
- Compare and contrast the manifestations and interprofessional care of hyperglycaemia, hypoglycaemia, diabetic ketoacidosis and hyperosmolar hyperglycaemic state.
- Identify and explain the chronic complications associated with the disease diabetes mellitus.

CLINICAL COMPETENCIES

- Assess blood glucose levels and patterns of hyperglycaemia and hypoglycaemia in people with diabetes mellitus.
- Recognise the importance of early diagnosis and control of blood glucose to prevent complications.
- Determine priority nursing diagnoses, based on assessed data, to select and implement individualised nursing interventions for people with type 1 and type 2 diabetes mellitus.
- Administer oral and injectable medications used to treat type 1 and type 2 diabetes mellitus knowledgeably and safely.
- Provide skilled care to people with diabetic ketoacidosis and hyperosmolar hyperglycaemic states.
- Integrate interprofessional care into care of people with type 1 and type 2 diabetes mellitus, especially foot and eye care.
- Provide appropriate teaching to facilitate blood glucose monitoring, administration of oral and injectable hypoglycaemic medications, diabetic diet, appropriate exercise and foot care.
- Revise plan of care as needed to provide effective interventions to promote, maintain or restore normal glucose levels.
- Teach the relationship of hygiene, neuropathy and impaired microcirculation to infection; teach the principles and procedures of effective foot care.
- Assess the person's ability to read markings on syringes and to identify correct insulin and hypoglycaemics.
- Relate insulin (endogenous and exogenous), dietary intake and exercise to control of blood glucose.

DIABETES MELLITUS

Diabetes mellitus (DM) is a common chronic disease of adults requiring continuing medical supervision and self-care education. However, depending on the type of diabetes and the age of the person, needs and nursing care may vary greatly. Consider the following examples:

- Cheryl Draheim is a 45-year-old school teacher. She developed diabetes at age 34 after a car accident caused severe pancreatic injuries. Cheryl has always been very careful about taking her insulin, following her diet and exercising regularly. However, she is beginning to notice that her vision is getting worse and that she is having increasing pain in her legs, especially after standing for long periods of time.
- Tom Chang is 53 years old. Early in his forties, Tom was diagnosed with type 2 diabetes. Although he was taught about the disease and the importance of taking his oral medications, following his diet plan and getting exercise, he rarely did more than take the medication. Five years ago, he was hospitalised for hyperglycaemia and started taking insulin. Last year Tom had a stroke, leaving him unable to walk. He has now been admitted to the hospital for treatment of gangrene of the big toe on his left foot.
- Grace Staples is an independent 82-year-old woman who lives alone and happily takes care of her two cats. She is slightly overweight. Last year, during Grace's annual eye examination, eye changes typical for diabetes were found. She was referred to her family doctor, who diagnosed type 2 diabetes and started her on oral medications. Grace sticks to her diet, walks a kilometre every day and plans to live to be 100.

As illustrated in these examples, diabetes mellitus is not a single disorder but a group of chronic disorders of the endocrine pancreas, all categorised under a broad diagnostic label. The condition is characterised by inappropriate hyperglycaemia caused by a relative or absolute deficiency of insulin or by a cellular resistance to the action of insulin. Of the several classifications of diabetes, this chapter will focus on the two main types: type 1 and type 2. **Type 1 DM** is the result of pancreatic islet cell destruction and a total deficit of circulating insulin; **type 2 DM** results from insulin resistance with a defect in compensatory insulin secretion.

Diabetes mellitus has been recognised as a disease for centuries. *Diabetes* derives from a Greek word meaning 'to siphon', referring to the increased output of urine. *Mellitus* derives from a Latin word meaning 'sweet'. The two words together identify the disease as an outpouring of sweet urine. It was not until 1921 that techniques were developed for extracting insulin from pancreatic tissue and for measuring blood glucose. At the same time, researchers discovered that insulin, when injected, produces a dramatic drop in blood glucose. This meant that diabetes was no longer a terminal illness because hyperglycaemia could be controlled. Since that time, oral hypoglycaemic drugs, human insulin products, insulin pumps, home blood glucose monitoring and transplantation of the pancreas or of pancreatic islet or beta cells have advanced the treatment and care of people with diabetes.

People with DM face lifelong changes in lifestyle and health status. Nursing care is provided in many settings for the diagnosis and care of the disease and treatment of complications. A major role of the nurse is that of educator in both hospital and community settings.

INCIDENCE AND PREVALENCE

The prevalence of diabetes is increasing worldwide. Between 2011 and 2012, 4.2%—an estimated 999 000 Australians—were diagnosed with diabetes. Of these, around 119 000 people (11.9%) had type 1 and 848 000 (84.9%) had type 2 diabetes. Approximately 23 400 people were diagnosed with unknown type of diabetes. This rate has risen from 1.5% in 1989 (Australian Institute of Health and Welfare (AIHW), 2011). In relation to total Australian health costs, the 4.2% of people who have diagnosed diabetes account for 12% of total health costs. Type 2 diabetes costs Australia $3 billion a year. The cost of diabetes to the community for a person with no complications is $9625 a year, whereas for a person with complications, the cost to the community is $15 850 (AIHW, 2011; Baker IDI Heart and Diabetes Institute, 2006; Vision Australia Foundation, 2009.)

Globally, 171 million people had diabetes in the year 2000, with an estimated rise to 366 million by the year 2030 (World Health Organization (WHO), 2012).

Statistics (Australian Bureau of Statistics (ABS), 2011) reveal that diabetes is the sixth-highest cause of death by disease in Australia. People with diabetes are twice as likely to have cardiovascular disease as well as earlier onset of cardiovascular conditions. Between 2007 and 2008, diabetic people aged less than 45 years were five times as likely to have high cholesterol and 15 times as likely to have hypertension compared with people without diabetes. Furthermore they were more than twice as likely to have mental or behavioural problems as the general population (ABS, 2011).

According to the AIHW (2011), between 2007 and 2008, 4.3% of people born overseas living in Australia had diabetes compared with 4% of people born in Australia for the same period, which shows a similar incidence between these two groups.

OVERVIEW OF ENDOCRINE PANCREATIC HORMONES AND GLUCOSE HOMEOSTASIS

Hormones

The endocrine pancreas produces hormones necessary for the metabolism and cellular utilisation of carbohydrates, proteins and fats. The cells that produce these hormones are clustered in

groups of cells called the islets of Langerhans or pancreatic islets. These islets have three different types of cells:

1. Alpha cells produce the hormone *glucagon*, which stimulates the breakdown of glycogen in the liver, the formation of carbohydrates in the liver, and the breakdown of lipids in both the liver and adipose tissue. The primary function of glucagon is to decrease glucose oxidation and to increase blood glucose levels. Through **glycogenolysis** (the breakdown of liver glycogen) and **gluconeogenesis** (the formation of glucose from fats and proteins), glucagon prevents blood glucose from decreasing below a certain level when the body is fasting or in between meals. The action of glucagon is initiated in most people when blood glucose falls below about 3.9 mmol/L.
2. Beta cells secrete the hormone **insulin**, which facilitates the movement of glucose across cell membranes into cells, decreasing blood glucose levels. Insulin prevents the excessive breakdown of glycogen in the liver and in muscle, facilitates lipid formation while inhibiting the breakdown of stored fats and helps move amino acids into cells for protein synthesis. After secretion by the beta cells, insulin enters the portal circulation, travels directly to the liver and is then released into the general circulation. Circulating insulin is rapidly bound to receptor sites on peripheral tissues (especially muscle and fat cells) or is destroyed by the liver or kidneys. Insulin release is regulated by blood glucose; it increases when blood glucose levels increase and it decreases when blood glucose levels decrease. When a person eats food, insulin levels begin to rise in minutes, peak in 30 to 60 minutes and return to baseline in 2 to 3 hours.
3. Delta cells produce *somatostatin*, which is believed to be a neurotransmitter that inhibits the production of both glucagon and insulin.

Blood glucose homeostasis

All body tissues and organs require a constant supply of glucose; however, not all tissues require insulin for glucose uptake. The brain, liver, intestines and renal tubules do not require insulin to transfer glucose into their cells. Skeletal muscle, cardiac muscle and adipose tissue do require insulin for glucose movement into the cells.

Normal blood glucose is maintained in healthy people primarily through the actions of insulin and glucagon. Increased blood glucose levels, amino acids and fatty acids stimulate pancreatic beta cells to produce insulin. As cells of cardiac muscle, skeletal muscle and adipose tissue take up glucose, plasma levels of nutrients decrease, suppressing the stimulus to produce insulin. If blood glucose falls, glucagon is released to raise hepatic glucose output, raising glucose levels. Adrenaline, growth hormone, thyroxine and glucocorticoids (often referred to as glucose counter-regulatory hormones) also stimulate an increase in glucose in times of hypoglycaemia, stress, growth or increased metabolic demand. The regulation of blood glucose levels by insulin and glucagon is illustrated in Figure 19.1.

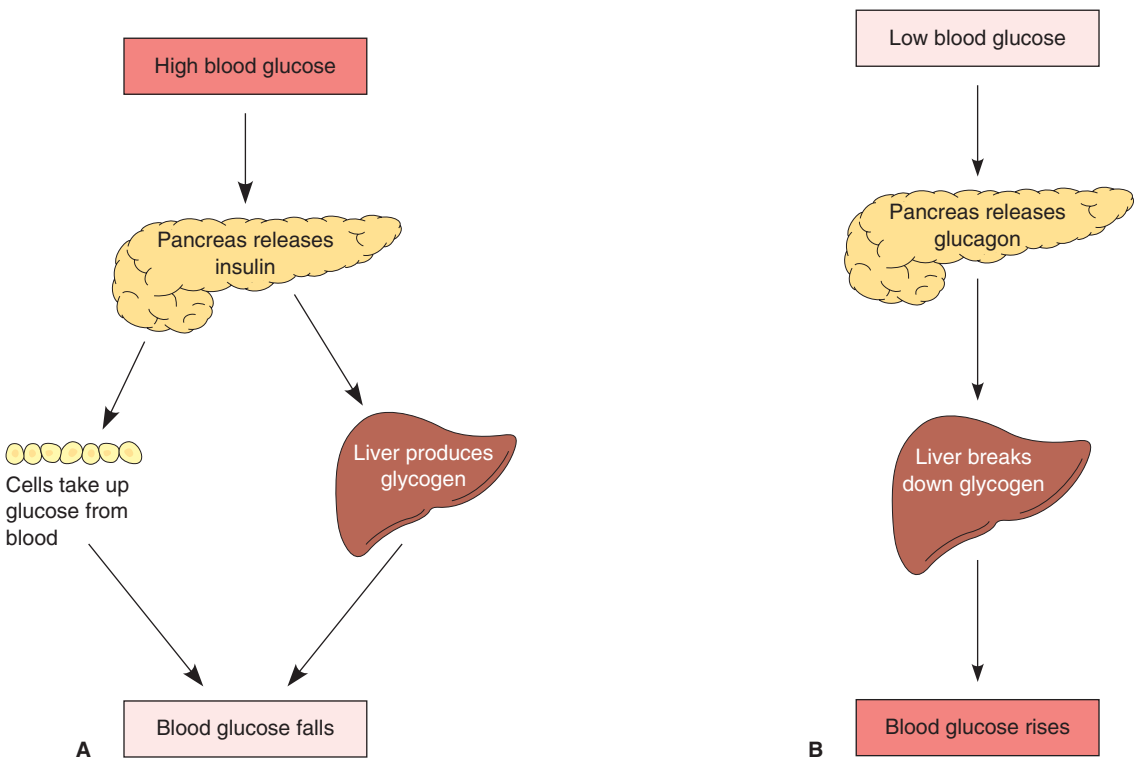

FIGURE 19.1 ■ Regulation (homeostasis) of blood glucose levels by insulin and glucagon. *A*, High blood glucose is lowered by insulin release. *B*, Low blood glucose is raised by glucagon release

PATHOPHYSIOLOGY OF DIABETES

DM is a group of metabolic diseases characterised by hyperglycaemia resulting from defects in the secretion of insulin, the action of insulin or both. There are four main types of DM. Type 1 diabetes (10–15% of all diagnosed cases) was formerly called juvenile-onset diabetes or insulin-dependent diabetes mellitus (IDDM). Type 2 diabetes (85–90% of diagnosed cases) was formerly labelled non-insulin-dependent diabetes mellitus (NIDDM) or adult-onset diabetes. The other main types are gestational diabetes (3–8% of all pregnancies); women who have had gestational diabetes are at increased risk of developing type 2 diabetes (Australian Diabetes Council, 2012). A new category called 'impaired fasting glucose' has been introduced. This category is analogous to 'impaired glucose tolerance' in indicating a metabolic stage between normal glucose homeostasis and diabetes. These states are risk factors for the development of diabetes and cardiovascular disease. Impaired fasting glucose is defined by a fasting glucose concentration of between 6.1 and 6.9 mmol/L (diabetesvic.org.au). The classification and characteristics of the types of diabetes are described in Table 19.1.

Type 1 diabetes

Type 1 diabetes most often occurs in childhood and adolescence, but it may occur at any age, even in the eighties and nineties. This disorder is characterised by **hyperglycaemia** (elevated blood glucose levels), a breakdown of body fats and proteins, and the development of **ketosis** (an accumulation of ketone bodies produced during the oxidation of fatty acids). Type 1 DM is the result of the destruction of the beta cells of the islets of Langerhans in the pancreas, the only cells in the body that make insulin. When beta cells are destroyed, insulin

TABLE 19.1 Classification and characteristics of diabetes

	CLASSIFICATION	CHARACTERISTICS
Type 1 diabetes	Immune mediated	Beta cells are destroyed, usually leading to absolute insulin deficiency. Markers to the immune destruction of the beta cells include islet cell autoantibodies (ICAs) and insulin autoantibodies (IAAs). The rate of beta-cell destruction is variable, usually more rapid in infants and children and slower in adults. Destruction of the beta cells has genetic predispositions and is also related to environmental factors as yet undefined.
	Idiopathic	Has no known aetiological causes. Need for insulin may be intermittent.
Type 2 diabetes	—	May range from predominantly insulin resistance with relative insulin deficiency to a predominantly secretory defect with insulin resistance. There is no immune destruction of beta cells. Initially, and in some cases for the entire life, insulin is not necessary. Most people with this form are obese or have an increased amount of abdominal fat. Risks for development include increasing age, obesity and a sedentary lifestyle. Occurs more frequently in women who have had gestational diabetes and in people with lipid disorders or hypertension. There is a strong genetic predisposition.
Other specific types	Genetic defects of beta cells	Hyperglycaemia occurs at an early age (usually before age 25). This type is referred to as maturity-onset diabetes of the young (MODY).
	Genetic defects in insulin action	Are genetically determined. Dysfunctions may range from hyperinsulinaemia to severe diabetes.
	Diseases of the exocrine pancreas	Acquired processes causing diabetes include pancreatitis, trauma, infection, pancreatectomy and pancreatic cancer. Severe forms of cystic fibrosis and haemochromatosis may also damage beta cells and impair insulin secretion.
	Endocrine disorders	Excess amount of hormones (e.g. growth hormone, cortisol, glucagon and adrenaline) impair insulin secretion, resulting in diabetes in people with Cushing's syndrome, acromegaly and pheochromocytoma.
	Drug- or chemical-induced	Many drugs impair insulin secretion, precipitating diabetes in people with predisposing insulin resistance. Examples are nicotinic acid, glucocorticoids, thyroid hormone, thiazides and Dilantin.
	Infections	Certain viruses may cause beta-cell destruction, including congenital measles, cytomegalovirus, adenovirus and mumps.
Gestational diabetes mellitus (GDM)	—	Any degree of glucose intolerance with onset or first recognition during pregnancy.
Impaired fasting glucose/impaired glucose tolerance	Metabolic stage between normal glucose homeostasis and diabetes	These states are risk factors for the development of diabetes and cardiovascular disease. Impaired fasting glucose is defined by a fasting glucose concentration of between 6.1 and 6.9 mmol/L (Australian Diabetes Council, 2013).

is no longer produced. Although type 1 DM may be classified as either an autoimmune or idiopathic disorder, 90% of the cases are immune mediated. The disorder begins with insulinitis, a chronic inflammatory process that occurs in response to the autoimmune destruction of islet cells. This process slowly destroys beta-cell production of insulin, with the onset of hyperglycaemia occurring when 80–90% of beta-cell function is lost. This process usually occurs over a long preclinical period. It is believed that both alpha-cell and beta-cell functions are abnormal, with a lack of insulin and a relative excess of glucagon resulting in hyperglycaemia.

Risk factors

Genetic predisposition plays a role in the development of type 1 DM. Although the risk in the general population ranges from 1:400 to 1:1000, the child of a person with diabetes has a 1:20 to 1:50 risk. Genetic markers that determine immune responses—specifically, DR3 and DR4 antigens on chromosome 6 of the human leucocyte antigen (HLA) system—have been found in 95% of people diagnosed with type 1 DM. (HLAs are cell surface proteins, controlled by genes on chromosome 6.) Although the presence of these markers does not guarantee that the person will develop type 1 DM, they do indicate increased susceptibility (Porth & Matfin, 2009).

Environmental factors are believed to trigger the development of type 1 DM. The trigger can be a viral infection (mumps, rubella or coxsackievirus B4) or a chemical toxin, such as those found in smoked and cured meats. As a result of exposure to the virus or chemical, an abnormal autoimmune response occurs in which antibodies respond to normal islet beta cells as though they were foreign substances, destroying them. The manifestations of type 1 DM appear when approximately 90% of the beta cells are destroyed. However, manifestations may appear at any time during the loss of beta cells if an acute illness or stress increases the demand for insulin beyond the reserves of the damaged cells. The actual cause and exact sequence are not completely understood, but research continues to identify the genetic markers of this disorder and to investigate ways of altering the immune response to prevent or cure type 1 DM.

Manifestations

The manifestations of type 1 DM are the result of a lack of insulin to transport glucose across the cell membrane into the cells (see Figure 19.2).

Glucose molecules accumulate in the circulating blood, resulting in hyperglycaemia. Hyperglycaemia causes serum hyperosmolarity, drawing water from the intracellular spaces into the general circulation. The increased blood volume increases renal blood flow and the hyperglycaemia acts as an osmotic diuretic. The resulting osmotic diuresis increases urine output. This condition is called **polyuria**. When the blood glucose level exceeds the renal threshold for glucose—usually about 10 mmol/L—glucose is excreted in the urine, a condition called **glucosuria**. The decrease in intracellular volume and the increased urinary output cause dehydration. The mouth becomes dry and thirst sensors are activated, causing the person to drink increased amounts of fluid (**polydipsia**).

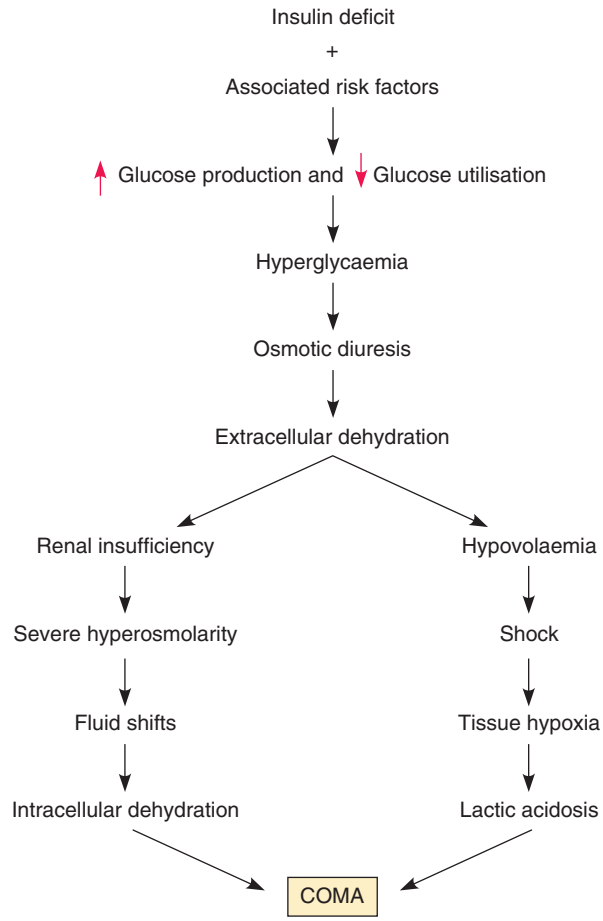

FIGURE 19.2 ■ Pathophysiological results of type 1 DM

Because glucose cannot enter the cell without insulin, energy production decreases. This decrease in energy stimulates hunger and the person eats more food (**polyphagia**). Despite increased food intake, the person loses weight as the body loses water and breaks down proteins and fats in an attempt to restore energy sources. Malaise and fatigue accompany the decrease in energy. Blurred vision is also common, resulting from osmotic effects that cause swelling of the lenses of the eyes.

Thus, the classic manifestations are polyuria, polydipsia and polyphagia, accompanied by weight loss, malaise and fatigue. Depending on the degree of insulin lack, the manifestations vary from slight to severe. People with type 1 DM require **exogenous insulin** to maintain life.

Type 2 diabetes

Type 2 DM is a condition of fasting hyperglycaemia that occurs despite the availability of **endogenous insulin**. Type 2 DM can occur at any age, but it is usually seen in middle-aged and older people. Heredity plays a role in its transmission. The level of insulin produced varies in type 2 DM and despite its availability, its function is impaired by insulin resistance. Insulin resistance forces the pancreas to work harder and produce more insulin, but when demand exceeds supply, DM results (Diabetes

Australia, Victoria, 2012; Saudek & Margolis, 2005). Whatever the cause, there is sufficient insulin production to prevent the breakdown of fats with resultant ketosis; thus, type 2 DM is characterised as a non-ketotic form of diabetes. However, the amount of insulin available is not sufficient to lower blood glucose levels through the uptake of glucose by muscle and fat cells. A major factor in the development of type 2 DM is cellular resistance to the effect of insulin. This resistance is increased by obesity, inactivity, illnesses, medications and increasing age. In obesity, insulin has a decreased ability to influence glucose metabolism and uptake by the liver, skeletal muscles and adipose tissue. Although the exact reason for this is not clear, it is known that weight loss and exercise may improve the mechanism responsible for insulin receptor binding or post-receptor activity (McCance & Huether, 2009). Hyperglycaemia increases gradually and may exist over time before diagnosis. According to the International Diabetes Federation (2009), diabetes remains seriously under-reported due to many people not being aware they have diabetes type 2. Many people do not seek help until they have developed complications, usually many years after diabetes has begun (Shaw, 2012). Treatment usually begins with prescriptions for weight loss and increased activity. If these changes can be sustained, no further treatment will be necessary for many individuals. Hypoglycaemic medications are begun when lifestyle changes are insufficient. Often, a combination of insulin and hypoglycaemic medication is used to achieve the best glycaemic control in the person with type 2 DM.

Risk factors

The main risk factors for type 2 DM are as follows:

- History of diabetes in parents or siblings. Although there is no identified HLA linkage, the children of a person with type 2 DM have a 15% chance of developing type 2 DM and a 30% risk of developing glucose intolerance (the inability to metabolise carbohydrate normally).
- Obesity, defined as being at least 20% over desired body weight or having a body mass index of at least 27 kg/m^2. Obesity, especially of the upper body, decreases the number of available insulin receptor sites in cells of skeletal muscles and adipose tissues, a process called *peripheral insulin resistance*. In addition, obesity impairs the ability of the beta cells to release insulin in response to increasing glucose levels.
- Physical inactivity.
- Race/ethnicity (see the 'Focus on cultural diversity' box below).
- In women, a history of gestational DM, polycystic ovary syndrome or delivering a baby weighing more than 4.1 kg.
- Hypertension ($\geq$ 130/85 in adults), HDL cholesterol of $\geq$ 0.9 mmol/L, and/or a triglyceride level of $\geq$ 2.8 mmol/L.
- Metabolic syndrome is a connection between obesity and the development of diabetes mellitus, and is thought to link cardiovascular disease with insulin resistance (Craft et al., 2011). Hypertension, abdominal obesity, dyslipidaemia, elevated C-reactive protein and fasting blood glucose greater than 6.1 mmol/L increase the risk of DM, coronary heart disease and stroke (Diabetes Australia, 2012; Porth & Matfin 2009).

Manifestations

The person with type 2 DM experiences a slow onset of manifestations and is often unaware of the disease until seeking healthcare for some other problem. The hyperglycaemia in type 2 is usually not as severe as in type 1, but similar symptoms occur, especially polyuria and polydipsia. Polyphagia is not often seen and weight loss is uncommon. Other manifestations are also the result of hyperglycaemia: blurred vision,

FOCUS ON CULTURAL DIVERSITY Diabetes in Indigenous Australians

Type 2 diabetes represents a serious public health problem for Indigenous Australians, occurring at a much higher rate than in the non-Indigenous population, and with a much earlier age of onset of the disease and its micro- and macrovascular complications. It is likely that diabetes is an important contributor to the considerably higher circulatory disease mortality rate among Indigenous Australians at young ages (9–10 times higher in Indigenous men aged 25–44 years and 12–13 times higher in Indigenous women aged 35–54 years). Thus, diabetes imposes significant financial and human costs on Australian society, which are disproportionately borne by Indigenous individuals, families and communities.

Indigenous Australians have the fourth-highest rate of type 2 diabetes (non-insulin-dependent diabetes mellitus, or NIDDM) in the world.

For the period 2003–2007, Indigenous Australians were seven times more likely than non-Indigenous Australians to have diabetes recorded as the cause of death on their death certificate (AIHW, 2011). The incidence of gestational diabetes (diabetes in pregnancy) is also two to three times higher among Indigenous Australian women than in the general Australian population.

As reported in the *National Aboriginal and Torres Strait Islander Health Survey 2004–2005*, 29 874, or 6.3% of, Indigenous Australians self-reported diabetes (ABS, 2012; AIHW, 2011). Craig et al. (2007) highlighted that data analysed from the Australasian Paediatric Endocrine Group NSW Diabetes Register in 2007 showed that type 2 diabetes accounts for 11% of new diabetes cases among 10–18 year olds. The incidence of diabetes in Indigenous children is about six times higher than that in non-Indigenous children (O'Dea, Rowley & Brown, 2007).

For Torres Strait Islanders, there were significant increases in body mass index (BMI)—the major risk factor—between 1999 and 2005 and a very high 5-year incidence of diabetes (O'Dea et al., 2007).

fatigue, paraesthesia and skin infections. If available insulin decreases, especially in times of physical or emotional stress, the person with type 2 DM may develop diabetic ketoacidosis (DKA), but this occurrence is uncommon.

Diabetes in the older adult

Although most older adults with diabetes have type 2 DM, the improved survival rates for people with diabetes have resulted in an increased number of older adults with type 1. The picture is complicated by the fact that blood glucose levels increase with age, beginning in the fifties. For this reason, it is more difficult to diagnose diabetes in the older adult; conversely, the older adult may be mistakenly diagnosed with the disease simply for exhibiting essentially normal age-related changes in glucose. The relationship between normal increases in glucose levels and the presence of diabetes is not yet understood.

The normal physiological changes of ageing may mask manifestations of the onset of diabetes. Signs can be dismissed and be considered as part of 'getting older' (Diabetes Australia, 2012). Signs and symptoms of diabetes in elders may not include the classic symptoms of polyuria and thirst. Conditions such as orthostatic hypotension, periodontal disease, infections, stroke, gastric hypotony, impotence, neuropathy, confusion, lethargy, gradual weight gain, leg cramps and glaucoma should be considered potential indicators of diabetes (Diabetes Australia, 2012) and may also increase the potential for complications from the disease or its treatment. Table 19.2 presents common problems in the older adult that make the diagnosis and management of diabetes more difficult. The older adult with diabetes also has a longer recovery period after surgery or serious illness, often requiring insulin to maintain blood glucose levels. The benefits and risks of treatment to maintain glycaemic control, as well as blood pressure and lipid management, must be carefully balanced.

INTERPROFESSIONAL CARE

Diagnosis

Diagnostic tests are conducted for screening purposes to diagnose diabetes, and ongoing laboratory tests are conducted to evaluate the effectiveness of diabetic management. Definitions of normal blood glucose levels vary in clinical practice, depending on the laboratory that performs the assay.

TABLE 19.2 Implications for nursing care of the older adult with diabetes

HEALTH PROBLEM/ COMPLICATION	IMPLICATIONS FOR NURSING CARE
Urinary incontinence	Polyuria, a classic manifestation of diabetes, often is ignored. This problem also often leads to social isolation.
Increased thirst	Polydipsia, a classic manifestation of diabetes, often is ignored. This further increases the risk of dehydration and electrolyte imbalances.
Decreased hunger and weight loss	Polyphagia, a classic manifestation of diabetes, often is ignored. The ageing process, medications, depression or lack of socialisation may decrease hunger. Weight loss may be gradual and go unnoticed.
Fatigue	Fatigue is a common symptom of diabetes but may be blamed on increased age.
Hypoglycaemia	The older adult may have either very mild manifestations or none at all. As a result, hypoglycaemia is often ignored until it causes serious effects.
Peripheral neuropathy	Manifestations may be thought to be due to arthritis, and over-the-counter drugs often are used to self-medicate. The risk of falls increases, as does the risk of gangrene and amputation.
Peripheral vascular disease	May go undetected if the person does not get enough exercise to cause claudication. May also impair abilities to climb stairs and walk.
Diabetic retinopathy	May be undetected if the person has cataracts. The diabetic person also has an increased incidence of cataracts and glaucoma. Deficits in vision threaten independence, mobility and social interactions. Yellowing of the lens with age makes it difficult to read coloured test strips; numerical meters are preferable. Filling insulin syringes may be impossible for the person with macular degeneration or other causes of visual loss.
Hypertension	Treatment with diuretics may further impair glucose tolerance and result in electrolyte imbalances.
Arthritis	Older adults may believe the pain from arthritis to be more important than the diabetes management. Also, depression from chronic pain as well as inactivity and loss of appetite may interfere with diabetes self-care.
Parkinson's disease	The tremors and rigidity of this disease make self-care involving fine and gross motor skills difficult or impossible.
Medications	Older adults commonly take more than one type of medication and are at increased risk of problems relating to drug interactions.

Sources: Adapted from D. Haire-Joshu (ed.), *Management of diabetes mellitus: Perspectives of care across the lifespan* (2nd ed.), pp. 755–830. St Louis, MO: Mosby; *Gerontological nursing* (6th ed.) by C. Eliopoulos (2005). Philadelphia: Lippincott Williams & Wilkins.

DIAGNOSTIC SCREENING According to the Australian Diabetes Society (ADS) (Twigg et al., 2007) and the National Health and Medical Research Council (NHMRC, 2009), diabetes mellitus is diagnosed if any of the following criteria are satisfied:

1. Symptoms of diabetes (polyuria, polydipsia, unexplained weight loss) and random plasma glucose ≥ 11.1 mmol/L.
2. Fasting plasma glucose ≥ 7.0 mmol/L.
3. Oral glucose tolerance test: 75 g glucose, 2-hour plasma glucose result ≥ 11.1 mmol/L.

In the absence of unequivocal symptoms, or if the glucose level is borderline, diagnosis by criterion 1 or 2 should be confirmed by repeat testing on a separate day.

Impaired glucose tolerance is diagnosed if a plasma glucose result 2 hours after a 75 g glucose load is between 7.8 and 11.0 mmol/L (inclusive).

Impaired fasting glucose is diagnosed if a fasting plasma glucose result is between 6.1 and 6.9 mmol/L (inclusive).

With regard to testing:

- People must fast for at least 8 hours to apply the fasting criteria.
- The criteria apply to people who are otherwise well at the time of diagnosis. Physiological stress from infection, trauma or other illness, or the effect of some drugs, may cause false positive results. In general, the criteria should be applied to ambulant outpatients only.
- Samples for plasma glucose should be separated from red cells as soon as possible after collection. When there may be a delay greater than 1 hour prior to centrifugation, samples must be collected into fluoride-oxalate tubes (grey-top). Even with these tubes a fall in plasma glucose of 0.1–0.2 mmol/L may occur.
- The criteria apply to venous plasma samples. Capillary or whole blood samples may require alternative decision points depending on the analysis method used.
- Haemoglobin A1c and home blood glucose meters are not appropriate methods for the diagnosis of diabetes.
- Fasting plasma glucose less than 5.5 mmol/L indicates a low probability of diabetes.

Who should be tested? Testing should be performed on anyone with symptoms suggestive of diabetes. Additionally, fasting plasma glucose should be performed as a screening test every 5 years in asymptomatic people from the following groups:

- people who are obese, hypertensive or have a first-degree relative with type 2 diabetes (screen from age 50)
- everyone with impaired glucose tolerance or cardiovascular disease
- women with a history of gestational diabetes or with polycystic ovary disease and obesity (screen from time of diagnosis)
- Indigenous Australians and other high-risk groups, including people from the Pacific Islands and the Indian subcontinent, and people of Chinese origin (screen from age 35)
- everyone over 65.

Interpretation of screening test If the fasting plasma glucose is:

- < 5.5 mmol/L—diabetes is unlikely; offer lifestyle advice and re-test in 5 years
- 5.5–6.9 mmol/L—diabetes is uncertain; glucose tolerance testing or more frequent fasting glucose indicated
- ≥ 7.0 mmol/L—diabetes likely; confirm with repeat fasting glucose on a separate occasion.

(Health Options Australia, 2012)

DIAGNOSTIC TESTS TO MONITOR DIABETES MANAGEMENT The following diagnostic tests may be used to monitor diabetes management:

- *Fasting plasma glucose (FPG).* This test is often ordered, especially if the person is experiencing symptoms of hypoglycaemia or hyperglycaemia. In most people, the normal range is 3.9 to 6.1 mmol/L.
- *Glycated haemoglobin (c) (HbA1c or A1c).* This test determines the average blood glucose level over approximately the previous 2 to 3 months. When glucose is elevated or control of glucose is erratic, glucose attaches to the haemoglobin molecule and remains attached for the life of the haemoglobin, which is about 120 days. The American Diabetes Association (2006) and Diabetes Australia (2008) recommend that HbA1c or A1c be performed at the initial assessment and then every 3 to 6 months. The goal for most people with diabetes is an HbA1c of ≤ 7%, although this may need to be adjusted according to individuals.
- *Urine glucose and ketone levels.* These are not as accurate in monitoring changes in blood glucose as blood levels. The presence of glucose in the urine indicates hyperglycaemia. Most people have a renal threshold for glucose of 10 mmol/L; that is, when the blood glucose exceeds 10 mmol/L, glucose is not reabsorbed by the kidney and spills over into the urine. This number varies highly, however. **Ketonuria** (the presence of ketones in the urine) occurs with the breakdown of fats and is an indicator of DKA; however, fat breakdown and ketonuria also occur in states of less-than-normal nutrition.
- *Urine test* for the presence of protein as albumin (*albuminuria*). If albuminuria is present, a 24-hour urine test for creatinine clearance is used to detect the early onset of nephropathy.
- *Serum cholesterol and triglyceride levels.* These are indicators of atherosclerosis and an increased risk of cardiovascular impairments. People with diabetes in general have similar rates of HDL or 'good' cholesterol to the general population but, on average, people with diabetes have higher levels of triglycerides and LDL or 'bad' cholesterol. Diabetes affects the balance between HDL and LDL in a number of ways (Diabetes Australia, 2008).
- *Serum electrolytes.* Levels are measured in people who have DKA or hyperosmolar hyperglycaemic state (HHS) to determine imbalances.

MONITORING BLOOD GLUCOSE There are two ways of monitoring blood glucose levels: self-blood glucose and serum HbA1c level. Self-blood glucose monitoring is a valuable tool for the person with diabetes and for the carer. It enables self-management and alerts carers and health professionals to possible issues and the need to change management. Self-blood glucose monitoring is a simple procedure which gives a result

within seconds. In Australia there are several types of blood glucose meters available for this purpose The HbA1c test is a serum blood test that shows an average blood glucose level over 10 to 12 weeks. (See 'Diagnostic tests to monitor diabetes management', above.)

URINE TESTING FOR KETONES AND GLUCOSE Urine testing is recommended to monitor hyperglycaemia and ketoacidosis in people with type 1 DM who have unexplained hyperglycaemia during illness or pregnancy. Ketones may be detected through urine testing and reflect the presence of DKA. (See 'Procedure 19.1: Testing urine for ketones and glucose'.)

Following is the equipment needed for self-blood glucose monitoring:

- Lancet device and lancets to perform a finger prick for obtaining a drop of blood.
- Test strips.
- A blood glucose meter appropriate for the person's individual needs. The manufacturer's instructions for use and maintenance of the meter must be followed carefully.
- Information on blood glucose monitoring and different blood glucose monitoring devices available in Australia can be found on the websites of Diabetes Australia (www.diabetesaustralia.com.au) or the Australian Diabetes Council (now Diabetes NSW, www.diabetesnsw.com.au).

The Australian Diabetes Educators Association (ADEA) (2010) in a position statement gives recommendations for the reliable and accurate use of blood glucose meters within the healthcare setting and in self-management of diabetes.

HAEMATOCRIT People with higher haematocrit values will usually test falsely low in blood glucose and people with lower haematocrit will test falsely high. Anaemia and sickle cell anaemia are two conditions that can affect haematocrit values.

OTHER SUBSTANCES Overdoses of many medications will cause inaccurate results. Meters and supplies vary in sensitivity to medications. Uric acid (a natural substance in the body that can be more concentrated in some people with diabetes), glutathione (an antioxidant also called *GSH*), ascorbic acid (vitamin C) and a variation in haematocrit are known to interfere (Ginsberg, 2009). Check the package insert for each meter to find what substances might affect its testing accuracy. Furthermore, strips sometimes give inaccurate readings if they have not been stored properly; therefore, it is relevant that the maintenance and storage of blood glucose testing equipment is followed as per instructions (Ginsberg, 2009).

USE OF CORRECT SUPPLIES AND SAMPLE VOLUME Be sure the test strips are compatible with the glucose meter and that they are not outdated and have not been exposed to air and humidity, which can alter strip sensitivity. Insufficient amounts of blood on the testing strip cause inaccurate results. Although a meter may indicate a sufficient amount of blood on the test strip, it is best to observe that the receptacle is full of capillary blood. Other possible reasons for inaccurate reading are wrong positioning of the strip in the meter, dirty hands prior to doing the test, a dirty meter, incorrect calibration, the meter is too cold or too hot, or it has a low or flat battery (Diabetes Australia, 2012).

Pharmacological treatment of diabetes mellitus

The pharmacological treatment for diabetes mellitus depends on the type of diabetes. People with type 1 DM must have insulin; those with type 2 DM are usually able to control glucose levels with an oral hypoglycaemic medication, but they may require insulin if control is inadequate.

INSULIN The person with type 1 DM requires a lifelong exogenous source of the insulin hormone to maintain life. Insulin is not a cure for diabetes; rather, it is a means of controlling hyperglycaemia. Insulin is also necessary in other situations, such as these:

- people with diabetes who are unable to control glucose levels with oral antidiabetic drugs and/or diet. Introduced when beta-cell function declines, insulin maintains glycaemic control and prevents complications (Diabetes Australia, 2012; Funnell, Kruger & Spencer, 2004)
- people with diabetes who are experiencing physical stress (such as an infection or surgery) or who are taking corticosteroids
- women with gestational diabetes who are unable to control glucose with diet
- people with DKA or HHS
- people who are receiving high-kilojoule tube feedings or parenteral nutrition.

Sources of insulin Preparations of insulin are derived from animal (pork pancreas) or synthesised in the laboratory from either an alteration of pork insulin or recombinant DNA technology, using strains of *Escherichia coli* to form a biosynthetic human insulin. Insulin analogues have been developed by modifying the amino acid sequence of the insulin molecule. Although different types are prescribed on an individualised basis, it is standard practice to prescribe human insulin.

PROCEDURE 19.1 Testing urine for ketones and glucose

TO TEST THE URINE FOR KETONES AND/OR GLUCOSE

1 Collect a small amount of urine.
2 Apply this to the test strip by dipping the strip in the urine sample.
3 Read desired test result at the specified time, by comparing the colour change on the test strip with the standard colour range for your brand of test strip. The reference colour chart is usually printed on the container.

Insulin preparations Insulin is classified according to how long it works in the body. There are five different types of insulin, ranging from short to long acting. Some insulins are clear in appearance, while others are cloudy.

Often people need varying amounts of both short- and longer-acting insulin. However, everyone is different and will respond differently to the insulin they take in the management of diabetes.

Types of insulin The five types of insulin are:

1. ultra-short-acting analogues
2. short-acting insulin
3. intermediate-acting insulin
4. long-acting analogue insulin
5. mixed insulin.

Ultra-short-acting analogue insulin Rapid-onset fast-acting insulin has a clear appearance. Its onset of work is within 5 to 10 minutes. Peak effect is 1 to 3 hours and its duration is 5 hours. When people use this type of insulin, they must eat immediately after they inject.

Ultra-short-acting analogue insulin types currently available in Australia are:

- NovoRapid (insulin aspart)
- Humalog (insulin lispro)
- Apidra (insulin glulisine).

Short-acting insulin Short-acting insulins always look clear. The onset is 30 minutes. Peak effect is 2.5 to 5 hours and duration is 8 hours. Short-acting insulin types currently available include:

- Actrapid (insulin neutral, regular)
- Humulin R (insulin neutral, regular).

Intermediate-acting insulin Intermediate-acting insulins appear cloudy. They have either protamine or zinc added to delay their action. These insulins need to be shaken before every use and do not need to be injected with a meal. The onset of work is 1.5 hours. Peak action is 4 to 12 hours. The duration is 12 to 16 up to 24 hours.

Intermediate-acting insulins currently available include:

- Protaphane (isophane)
- Humulin NPH (isophane NPH).

Long-acting analogue insulin Long-acting analogue insulins have a clear appearvvance and do not need to be injected with a meal. They have no pronounced peak action, which means the insulin is released into the bloodstream at a relatively constant rate. One injection can last 24 hours.

Long-acting analogue insulins available in Australia are:

- Levemir (insulin determir)
- Lanctus (insulin glargine).

Mixed insulin Mixed insulin always looks cloudy. It contains a pre-mixed combination of either a rapid-onset fast-acting or a short-acting insulin and intermediate-acting insulin. This makes it easier because two types of insulin can be given in one injection. If the insulin is '30/70', then it contains 30% of quick-acting and 70% of intermediate-acting insulin; '50/50' means 50% of each. Before injecting mixed or other cloudy insulin, the person must gently roll the vial or pen between the palms of their hands and/or rock it slowly to make sure the different strengths of insulin are evenly distributed.

The mixed insulins currently available include:

With ultra-short-acting insulin

- Humalog Mix 25 (25% insulin lispro, 75% lispro protamine suspension)
- Humalog Mix 50 (50% insulin lispro, 50% lispro protamine suspension)
- NovoMix 30 (30% insulin aspart, 70% aspart protamine suspension)

With rapid-acting insulin

- Humulin 30/70 (30% insulin neutral regular, 70% isophane)

Other mixed insulins

- Mixtard 30/70 (30% insulin neutral regular, 70% isophane)
- Mixtard 50/50 (50% insulin neutral regular, 50% isophane).

(Diabetes Australia, Victoria, 2012)

Insulin regimens The appropriate insulin dosage is individualised by achieving a balance between insulin, diet and exercise. While in the past there has been a tendency to try to minimise the number of injections per day, for most people with diabetes two or more injections each day are required, often a mixture of rapid-acting and intermediate-acting insulins. Increasingly more children and teenagers are being treated with multiple daily injections or insulin pumps. This is to try to more closely match the body's insulin needs, similar to the way the pancreas works in people without diabetes. Many children now start on multiple injections; or if started on two injections per day, soon evolve to three or four injections per day (Diabetes Australia, 2007). Timing of the injections depends on blood glucose levels, food consumption, exercise and types of insulin used. The objective is to avoid daytime hypoglycaemia while achieving adequate blood glucose control overnight.

Box 19.1 shows how a combination regimen of insulin three times per day and four times per day is intended to work.

Insulin administration Nursing implications for administering insulin are outlined in the 'Medication administration' box below and further discussion follows in the chapter. The considerations for administering insulin include routes of administration, syringe and needle selection, preparing the injection, sites of injection, mixing insulins and insulin regimens.

Routes of administration Only regular insulin is given by both subcutaneous and intravenous routes; all others are given only subcutaneously. If the intravenous route is not available, regular insulin may also be administered intramuscularly in an emergency situation.

Insulin injection devices There are many different devices available to inject insulin. The main choices include insulin syringes, insulin delivery pens and insulin pumps.

Insulin syringes. It is important to note that only syringes are to be used with insulin vials. Syringes available in Australia are 30 unit (0.3 mL), 50 unit (0.5 mL) and 100 unit (1.0 mL); the size of syringe will depend on the insulin dose. Needles on the syringes are available in different lengths and the syringes

BOX 19.1 Insulin regimens

Three times daily insulin injections

The diagram below shows how a combination is intended to work.

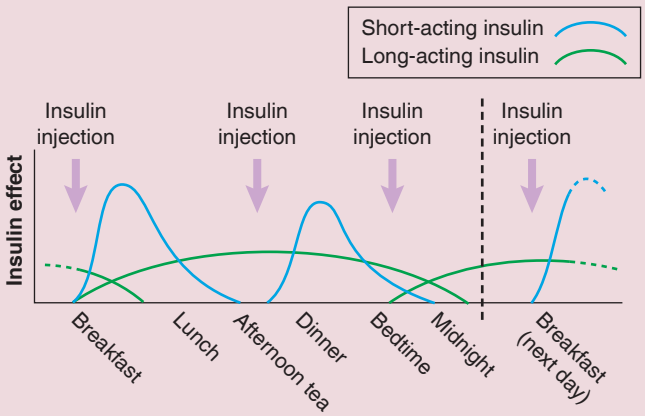

Figure showing an example of a 3 times per day injection pattern with injections at breakfast, afternoon tea and bed

In this routine people have:

- Before breakfast: rapid- or short-acting insulin (meal bolus) plus long-acting insulin (basal insulin)
- Before afternoon tea: rapid- or short-acting insulin (meal bolus)
- Before bed: long-acting insulin (basal insulin).

Four times daily injections (basal-bolus)

The diagram below shows how a combination is intended to work.

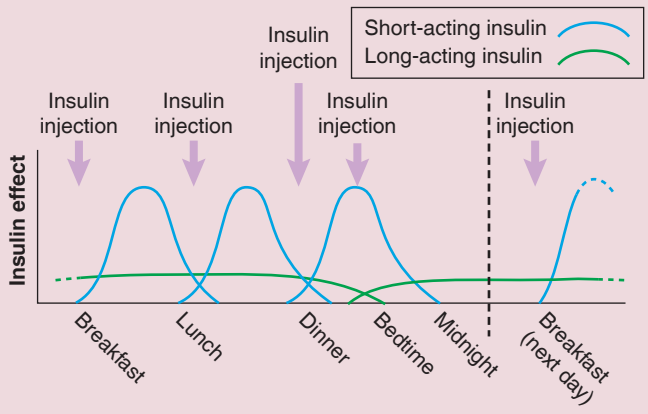

Figure showing a basal-bolus or MDI injection pattern

This routine is often referred to as a basal-bolus injection plan or multiple daily injections (MDI). Commonly about 40–50% of the insulin is given as long-acting insulin and the rest is divided up in the rapid- or short-acting doses. This offers very good flexibility for insulin adjustment and, when part of a comprehensive diabetes management plan, has been shown to have advantages for diabetes control. It is the most common starting insulin plan for older children, adolescents and adults. It is also commonly used in younger children, although they will need assistance with injections, particularly at school.

Source: G. R. Ambler & F. J. Cameron (eds) (2010). *Caring for diabetes in children and adolescents* (3rd ed.), pp. 24–25.

are one use only. Syringes are free for people registered with the National Diabetes Service Scheme (NDSS).

Insulin delivery devices. Many people find pen devices easier and more convenient than syringes. Pen devices come in all shapes and sizes and they can be durable (an insulin cartridge that fits into the pen is inserted and replaced when it is finished) or disposable (the pen device is prefilled with insulin and the whole device is disposed of when finished).

Pen needles vary in length and thickness. The higher the number, the finer the needle. It is recommended that the pen needle be changed with each injection. In Australia, pen needles are free for people registered with the NDSS.

Insulin pumps. The insulin pump is a small programmable device which holds a reservoir of insulin. The pump is programmed to deliver insulin into the body through thin plastic tubing known as the infusion set or giving set. It is worn outside the body in a pouch, on the belt or bra. The infusion set has a fine needle or flexible cannula that is inserted just below the skin (usually on the abdomen) where it stays in place for 2 to 3 days. Only short- or rapid-acting insulin can be used in the pump. Whenever food is eaten, the pump is manually programmed to deliver an amount of insulin into the body, similar to the way the pancreas does in people without diabetes. Between meals, a small and steady rate of insulin is delivered. The insulin pump isn't suitable for everyone. Its use must be discussed first with the diabetes healthcare team.

Storage of insulin Unopened insulin vials or pen cartridges should be kept on their side in the refrigerator (between 2ºC and 8ºC) and away from the freezer or freezing coils. Once opened, insulin should be kept below either 25ºC or 30ºC and thrown away after 30 days, even if there is some insulin left. Always check the expiry date and appearance of insulin before use. Insulin is destroyed when it has been exposed to direct sunlight, heat or allowed to freeze. In these cases, it should not be used.

Disposal of used syringes Used syringes, pen needles and lancets must be disposed of in a sharps container that meets the Australian safety standards, is puncture proof and has a secure lid. These containers are usually yellow in colour and are

MEDICATION ADMINISTRATION Insulin

NURSING RESPONSIBILITIES

- Discard vials of insulin 30 days after opening or where expiration date has passed.
- Refrigerate, but do not freeze, extra insulin vials not currently in use.
- Store insulin in a cool place and avoid exposure to temperature extremes or sunlight.
- Store compatible mixtures of insulin for no longer than 1 month at room temperature or 3 months at 2°C to 8°C.
- Discard any vials with discolouration, clumping, granules or solid deposits on the sides.
- If breakfast is delayed, also delay the administration of rapid-acting insulin.
- Monitor and maintain a record of blood glucose readings 30 minutes before each meal and bedtime (or as prescribed).
- Monitor food intake and notify the doctor if food is not being consumed.
- Monitor electrolytes (especially potassium), blood urea nitrogen (BUN) levels and creatinine.
- Observe injection sites for manifestations of hypersensitivity, lipodystrophy and lipoatrophy.
- If symptoms of hypoglycaemia occur, confirm by testing blood glucose level and administer an oral source of a fast-acting carbohydrate, such as juice, milk or crackers. Hypoglycaemic symptoms may vary but commonly include feelings of shakiness, hunger and/or nervousness, accompanied by sweating, tachycardia or palpitations.
- If symptoms of hyperglycaemia occur, confirm by testing blood glucose level and notify the doctor immediately.

HEALTH EDUCATION FOR THE PERSON AND FAMILY

- Self-administration of insulin, with a return demonstration (see Boxes 19.2, 19.3 and 19.4).
- Follow instructions for mixing insulins (refer to Box 19.8 later in the chapter).
- Always keep an extra vial of insulin available.
- Always have a vial of regular insulin available for emergencies.
- Be aware of the signs of hypersensitivity responses, hypoglycaemia and hyperglycaemia.
- Keep sweets or a sugar source available at all times to treat hypoglycaemia, if it occurs. Eat within 15 minutes of injecting rapid-acting insulins.
- Vision may be blurred during the first 6 to 8 weeks of insulin therapy; this is the result of fluid changes in the eye and should clear up in 8 weeks.
- Avoid alcoholic beverages, which may cause hypoglycaemia.
- Follow these guidelines for sick days:
  a. Never omit insulin.
  b. Always monitor blood glucose and/or urine ketones at least every 2 to 4 hours.
  c. Always drink plenty of fluids; try to drink at least one glass of water or other kilojoule-free, caffeine-free liquid each hour.
  d. Get as much rest as possible.
  e. Contact the doctor if there is persistent fever, vomiting, shortness of breath, severe pain in the abdomen, dehydration, loss of vision, chest pain, persistent diarrhoea, blood glucose levels above 14 mmol/L or ketones in the urine.
- Establish a plan for rotating injection sites and observe closely for changes in tissues, such as hardness, dimpling or sunken areas.

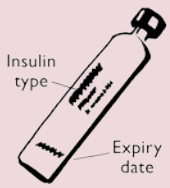
available through pharmacies, councils and Diabetes Australia. Procedures to dispose of sharps containers vary between the states and territories. For information, contact Diabetes Australia in the relevant state or the state government department of health or the local council. These are also excellent sources of information about where to get help with insulin (see Box 19.5).

Sliding-scale insulin Hospitalised people with type 1 and type 2 diabetes require intense blood glucose monitoring and frequent adjustments that are responsive to glycaemic changes secondary to the admitting condition and its treatment, including surgery (Deno & Schaper, 2011). Those with type 2 diabetes cannot manage with oral medications during hospitalisation because of the risk of hypoglycaemia from not eating and the slow response of these medications to correct hyperglycaemia. Hyperglycaemia is a serious and costly healthcare problem in hospitalised people today and is linked to increased morbidity, mortality and length of hospital stay. Hyperglycaemia is even seen in non-diabetic hospitalised people. Diabetic people with home insulin should be treated with an insulin regimen in hospital irrespective whether they have type 1 or type 2 diabetes. It is vital that blood glucose levels are stable prior to elective surgery and ideally people dependent on insulin should be placed first on the morning list of surgery. Following the hospital protocol for medication administration is important in preventing hypoglycaemia or hyperglycaemia. If the person is undergoing major surgery, or hyperglycaemia develops, an insulin–glucose infusion should be commenced. Clinical practice guidelines for the management of perioperative diabetes recommend target blood glucose levels of 5 to 10 mmol/L postoperatively. Clear written instruction regarding medication management should be given preoperatively and again on discharge to prevent complications (Australian Diabetes Council, 2012).

Maintaining normal blood glucose during hospitalisation decreases the risk of postoperative infections and shortens hospital stays. Healing is impaired when haemoglobin is glycosylated (HbA1c); glycosylated haemoglobin has increased affinity for oxygen, putting tissues at risk of ischemia (McCance &

BOX 19.2 How to draw up a mixed dose of insulin from penfill cartridges

1. Wash hands.



2. Check you have the correct insulin types. You will be drawing up the rapid- or short-acting insulin first.

3. If your long-acting insulin is 'cloudy' insulin (e.g. Protaphane, Humulin NPH), mix by tipping the cartridge up and down 10 to 20 times. *Do not shake the cartridge* as this damages the insulin. Clear insulin does not need to be mixed.

4. Open a new syringe. Make sure there is no air in the syringe by first pushing the plunger right down. Insert the needle into the cartridge of rapid- or short-acting insulin (e.g. Actrapid, Humulin R). Pull back the plunger of the syringe to draw up the dose required plus an extra 2 units, which allows you room to get rid of any air bubbles. The rubber stopper in the cartridge will gradually move down as you draw out the insulin and equalise the pressure.

5. Remove the syringe from the bottle, hold it vertically and push the plunger gently to get rid of any air bubbles and any extra insulin to obtain the correct dose. It may help to tap the side of the syringe to remove all air bubbles.

6. Insert the needle into the cartridge of long-acting insulin (e.g. Protaphane, Humulin NPH) and turn it upside down. Pull back the plunger to obtain the correct dose. If you draw back too much, you will have to discard the whole syringe and start again. *Do not push any insulin into the cartridge.*

7. Now you are ready to inject the insulin.

Source: G. R. Ambler & F. J. Cameron (eds) (2010). *Caring for diabetes in children and adolescents* (3rd ed.), p. 30. © Children's Diabetes Services. Reproduced with permission.

Huether, 2009). Further, diabetes leads to small-vessel disease, which impairs circulation and oxygenation of tissue for healing.

Intravenous insulin infusions are preferable for maintaining normal blood glucose during hospitalisation, although their use is dependent on frequent blood glucose monitoring and intensive nursing care. Supplements of regular insulin following sliding-scale prescriptions (relative to monitored blood glucose levels) are ineffective management protocols, risking both hyperglycaemia and hypoglycaemia. These supplements treat hyperglycaemia after it has occurred rather than preventing it. When medical conditions lead to observable periods of hyperglycaemia outside the ICU, it is preferable to provide basal subcutaneous insulin such as insulin glargine or short-acting insulin Actrapid and mealtime

BOX 19.3 Giving insulin with a syringe

To give an injection with a syringe:

1. Draw up insulin as described in Box 19.2.
2. Take a small pinch of skin with the index finger and thumb. The pinch needs to be at least to the depth of the needle. This is especially important in lean people, otherwise the injection may go too deep into the muscle layer and hurt more and the insulin will act differently.
3. Insert the needle straight into the pinched up skin (i.e. at 90 degrees) to its full length and push the plunger slowly all the way down to push in the insulin. In very lean individuals, injecting at a 45-degree angle to the skin may be necessary to avoid the injection going too deep.
4. Leave the needle in for about 5–10 seconds, then gradually let go of the skin and pull out the needle.
5. Dispose of the syringe in an approved sharps container.

Source: G. R. Ambler & F. J. Cameron (eds) (2010). *Caring for diabetes in children and adolescents* (3rd ed.), p. 31. © Children's Diabetes Services. Reproduced with permission.

supplements with rapid-onset fast-acting insulin or aspart insulin. Correctional doses can be added to the mealtime doses to keep serum glucose below 10.0 mmol/L (Diabetes Australia, Victoria, 2008).

Principles of insulin adjustment It is useful to think of three main types of insulin adjustments and to think of them in this order:

1. *Long-term adjustments.* These are changes to regular doses based on patterns in blood glucose readings over several days or longer. This may occur:
   - when coming out of a honeymoon phase
   - as the young person with type 1 diabetes grows, and especially when they have their growth spurt with puberty or reach the end of puberty
   - when there is a general change in activity levels.
2. *Thinking-ahead adjustments.* These are temporary changes to some doses based on what is going to happen that day. Examples of this are:
   - reducing a dose or doses for sporting activity
   - reducing an evening dose of insulin after a very active day to avoid delayed hypoglycaemia
   - adjusting a dose to plan for eating more or less at a meal.
3. *Fix-up adjustments.* This is adjusting a dose or giving an extra dose to 'fix up' a blood glucose reading that is unexpectedly high or low. For example:
   - reducing a short-acting insulin dose after hypoglycaemia near to injection time
   - giving a little extra short-acting insulin when the blood glucose level is found to be high before a meal
   - adjusting for sick days.

BOX 19.4 Giving insulin with a pen

1. Wash hands.
2. Check that you have the correct insulin pen (have your pens clearly marked) and that there is enough insulin remaining in the cartridge for the current injection. It is preferable to use a new needle for each injection.
3. If giving a cloudy long-acting or mixed insulin, be sure to mix the insulin well by inverting the pen 10 to 20 times. The cartridge contains a glass ball which mixes the insulin. Do not shake the pen as this will damage the insulin. Clear insulins do not need to be mixed.
4. Prime the pen (get rid of any air bubbles). Dial up a 2- to 4-unit dose and, holding the pen vertically, inject into the air to expel air bubbles (air shot) and to prime the pen. The pen is primed if drops of insulin without bubbles are coming from the needle. If not, keep repeating this procedure until a bubble-free stream of insulin is achieved with the air shot.
5. Dial up the required dose.
6. Select the injection site.
7. Steady the skin by taking a small pinch of skin with the index finger and thumb at the chosen site. The pinch needs to be at least to the depth of the needle. This is especially important in lean people, otherwise the injection may go too deep into the muscle layer and hurt more and the insulin will act differently. People who are not lean may not need to do a pinch, especially if using short needles (4, 5 or 6 mm), but only use a no-pinch technique if advised by your diabetes team.
8. Insert the needle straight into the pinched-up skin (i.e. at 90 degrees) to its full depth and push the pen button slowly all the way down to push in the insulin. In very lean individuals, injecting at a 45-degree angle to the skin may be necessary to avoid the injection going too deep.
9. Leave the needle in for 5–10 seconds, then gradually let go of the skin and pull out the needle.
10. Remove the needle from the pen after injection and dispose of in an approved sharps container.

BOX 19.5 Where to get help with insulin

- Local doctor or general practitioner (GP)
- Diabetes educator
- An accredited practising dietitian (contact the Dietitians Association of Australia)
- Diabetes specialist
- Diabetes Australia Infoline: Tel. 1300 136 588

BOX 19.6 Guidelines for insulin adjustment

- How you adjust insulin will depend on the types of insulin being used and the number of injections each day:
- Insulin doses often need adjustment. General principles are:
  - Pattern adjustment: look for patterns that indicate a need to adjust usual insulin doses because of high or low glucose levels at certain times over a few days or longer periods.
  - Look at this regularly.
  - Day-to-day adjustment (flexible daily adjustment): if you are using a flexible system, think about whether you need to adjust a dose or doses now or today to take into account a variation in carbohydrate intake or activity. Many people on multiple daily injections make these flexible decisions on a daily basis with their pre-meal injections.
  - Corrections: think about the need for a correction adjustment, especially for correcting a blood glucose level that is too high now.
- If hypoglycaemia is occurring frequently, don't delay adjustments.
- Seek help from your diabetes educator or doctor if you are not sure what to do or your adjustments are not working.
- Pump users also need to adjust insulin, but details are different.

Source: G. R. Ambler & F. J. Cameron (eds) (2010). *Caring for diabetes in children and adolescents* (3rd ed.), p. 115. © Children's Diabetes Services. Reproduced with permission.

More detail on these three types of adjustment is given in the following sections. General points include:

- Insulin adjustments are generally based on the recognition of blood glucose patterns over several days, so enough blood glucose readings need to be done to allow this.
- At times of instability or illness it is necessary to do extra blood glucose readings to guide adjustment.
- Cautious adjustments in steps are made in insulin doses until blood glucose levels in the target range are reached.
- Unexplained hypoglycaemia requires thinking about insulin doses without delay, and adjustment without waiting for a pattern to emerge may be justified.
- When adjusting, it is usually unwise to make changes to insulin doses every day, or to change too many doses at once, since this can lead to more instability and confusion.
- Frequent dose changes may be necessary when insulin needs are changing rapidly, in which case your diabetes educator or doctor should be aware and able to help.
- People on insulin are advised to adjust their dose in approximately 10% increments and observe the effects over several days before further changes.
- Half-unit increments can be made in people with small doses of insulin (< 5 units).
- People on insulin pumps need to determine if changes need to be made to the basal or the bolus dose from their monitoring; increments of 5% to 10% are appropriate.
- Rapid changes may be necessary in severe hypoglycaemia. (Australasian Paediatric Endocrine Group for the Department of Health and Ageing, 2005).
- Some children need variations in dose on a day-to-day basis to adjust for activity and exercise. See Box 19.6.
- Insulin adjustment also requires a knowledge of the types of insulin the child is on, particularly when they start to work and how long they work for.

  See Box 19.6 for guidelines for insulin adjustment.

Preparing the injection The vial of insulin in use may be kept at room temperature for up to 4 weeks. Stored vials should be kept in the refrigerator and brought to room temperature prior to administration.

Regular insulin does not require mixing. If the solution is cloudy or discoloured, the vial should be discarded. The other types of insulin must be mixed to disperse the particles evenly throughout the solution. Mix the vial by gently rolling it between the hands; vigorous shaking causes bubble formation and frothing, which makes the dose inaccurate. It is critical that no air bubbles remain in the prepared dose, because even a small bubble can displace several units of insulin.

Sites of injection Although in theory any area of the body with subcutaneous tissue can be used for injections of insulin, certain sites are recommended (see Figure 19.3). The rate of absorption and peak of action of insulin differ according to the site. The site that allows the most rapid absorption is the abdomen, followed by the deltoid muscle, then the thigh and then the hip. Because of the rapid absorption, the abdomen is the recommended site. See Box 19.7 for techniques to minimise painful injections.

When administering insulin, aspiration to check for blood is not necessary. Do not massage the site after administering the injection, because this may interfere with absorption; pressure, however, may be applied for about 1 minute. Rotation of injection sites is recommended for people using pork insulin; rotation within sites is recommended for people using human or purified pork insulin. The distance between consecutive injections should be about 2.5 cm (avoiding the area within a 5 cm radius from the umbilicus). Insulin should not be injected into an area to be exercised (such as the thigh before a vigorous walk) or to which heat will be applied;

BOX 19.7 Techniques to minimise painful injections

- Inject insulin that is at room temperature.
- Make sure no air bubbles remain in the syringe before the injection.
- Although the use of alcohol to clean the skin prior to the insulin injection is not recommended for people who use insulin long term, if there is a need for its use due to a possible contamination risk in the skin then wait until alcohol on the skin completely dries before the injection.
- Relax muscles in the injection area.
- Penetrate the skin with the needle quickly.
- Don't change the direction of the needle during insertion or withdrawal.
- Don't reuse needles. Always use a new needle with each injection.

Sources: Adapted from Hirsch, L., Gibney, M., Albanese, J. et al. (2010). Comparative glycemic control, safety and patient ratings for a new 4 mm x 32G insulin pen needle in adults with diabetes. *Current Medical Research and Opinion*, *26*(6), 1531–1541.

exercise or heat may increase the rate of absorption and cause a more rapid onset and peak of action.

Lipodystrophy **Lipodystrophy** (hypertrophy of subcutaneous tissue) or **lipoatrophy** (atrophy of subcutaneous tissue) may result if the same injection sites are used repeatedly, especially with pork and beef insulins. The tissues become hardened and have an orange-peel appearance. The use of refrigerated insulin may trigger the development of tissue atrophy or hypertrophy.

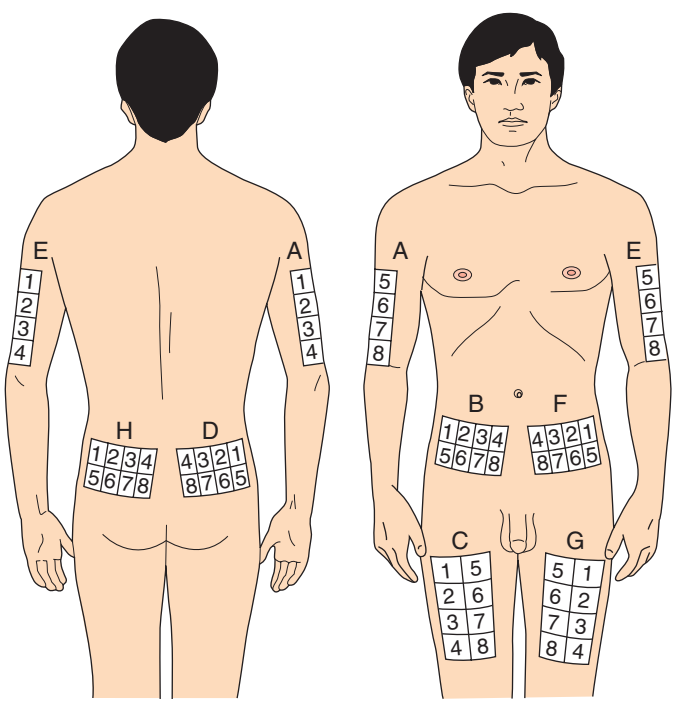

FIGURE 19.3 ■ Sites for insulin injections

These problems rarely occur with the use of human insulins. Lipodystrophy and lipoatrophy alter insulin absorption, delaying its onset or retaining the insulin in the tissue for a period of time instead of allowing it to be absorbed into the body. Lipodystrophy usually resolves if the area is unused for a minimum of 6 months.

Mixing insulins When a person with diabetes requires more than one type of insulin, mixing is recommended to avoid administering two injections per dose. Two different concentrations are administered, because a single dose of intermediate-acting or long-acting insulin rarely provides adequate control of blood glucose levels. The procedure for mixing insulins is described in Box 19.8. Following are some general guidelines:

- Commercially mixed insulins are recommended if the insulin ratio is appropriate for the requirements of the person.
- Regular insulin may be mixed with all types of insulin except long-acting insulin or glargine; it may be injected immediately after mixing or stored for future use.
- Intermediate-acting insulin such as Protophane, Humulin NPH, Hypurin Isophane (bovine or porcine) may be mixed only with regular or short-acting insulin.
- Do not mix human and animal insulins.
- Always withdraw regular insulin first to avoid contaminating the regular insulin with intermediate-acting insulin.

Hypersensitivity responses When injected, insulin may cause local and systemic hypersensitivity responses. Manifestations of local reactions are a hardening and reddening of the area that develops over several hours. Local reactions result from a contaminant in the insulin and are more likely to occur when less purified insulin products are used.

Systemic reactions occur rapidly and are characterised by widespread, red, intensely pruritic welts. Respiratory difficulty may occur if the respiratory system is involved. Systemic responses are due to an allergy to the insulin itself and are most common with beef insulin (not commonly used in Australia). The person can be desensitised by administering small doses of purified pork or human insulin, followed by progressively larger doses.

HYPOGLYCAEMIC AGENTS

Hypoglycaemic agents are used to treat people with type 2 DM. Nursing implications for this category of drugs are discussed in the 'Medication administration' box below. These medications lower blood sugar by stimulating or increasing insulin secretion, preventing breakdown of glycogen to glucose by the liver and increasing peripheral uptake of glucose by making cells less resistant to insulin. Peripheral uptake refers to uptake by muscles and fat in the arms and legs, rather than in the trunk. Some hypoglycaemics keep blood sugar low by blocking absorption of carbohydrates in the intestines. A new hypoglycaemic agent that is not insulin but is only available as an injectable is exenatide (Byetta), the first synthetic analogue of the incretin hormone glucagon-like peptide 1 (GLP-1). Exenatide is an 'incretin mimetic' which increases glucose-dependent insulin secretion, suppresses inappropriate glucagon secretion, delays gastric emptying and reduces appetite. It is approved for use in

BOX 19.8 Mixing insulins: 10 units of regular or short-acting and 20 units of NPH or intermediate-acting insulin

1. Wash hands.
2. Inspect regular insulin for clarity.
3. Gently rotate NPH insulin to mix well.
4. Wipe off the top of both vials with an alcohol pad.
5. Draw 20 units of air into the syringe and inject air into the NPH vial (Figure A). Withdraw needle.
6. Draw 10 units of air into the syringe and inject air into the regular vial (Figure B).
7. Invert the vial and withdraw 10 units of regular insulin (Figure C). Withdraw the needle.
8. Insert the needle into the NPH vial and carefully withdraw 20 units of NPH insulin (Figure D).
9. Administer the insulin.
10. Wash hands and properly dispose of the syringe.

D Withdrawing NPH insulin

Australia as an adjunctive therapy to improve glycaemic control in people with type 2 diabetes mellitus who are taking metformin, a sulfonylurea, or a combination of metformin and a sulfonylurea, but are not achieving adequate glycaemic control (National Prescribing Service (NPS), 2010).

ASPIRIN THERAPY People with diabetes are up to four times more likely to die from cardiovascular disease. It is recommended by the Royal Australian College of General Practitioners (RACGP) that a once-daily dose of 81 to 325 mg of enteric-coated aspirin be given to reduce atherosclerosis in people with vascular disease or increased cardiovascular risk factors.

Recent concerns have been raised by several experts in Australia with regard to the use of aspirin in people with diabetes for primary prevention of cardiovascular disease. They say that current guidelines for aspirin as primary prevention in these people have been extrapolated from evidence showing efficacy in secondary prevention of CVD events. There is still no clinical trial evidence to support the routine use of aspirin in primary prevention for people with diabetes. Diabetes Australia, which endorses the RACGP recommendations, does not have a position on the use of aspirin as primary prevention (*Medical Observer*, 2012; Song, Gray & Tesfaye, 2009; *The Lancet*, 2009).

Nutrition

The management of diabetes requires a careful balance between the intake of nutrients, the expenditure of energy and the dose and timing of insulin or oral antidiabetic agents. Although everyone has the same need for basic nutrition, the person with diabetes must eat a more structured diet to prevent hyperglycaemias. The goals for dietary management for adults with diabetes as recommended by the Heart and Diabetes Institute of Australia (2009a) are outlined in Box 19.9.

CARBOHYDRATES AND THE GLYCAEMIC INDEX All carbohydrate foods break down to glucose during digestion. Glucose enters the bloodstream, raising the blood glucose level which reaches a peak 30 to 60 minutes later (CSIRO & Baker IDI Heart and Diabetes Institute, 2012). As carbohydrate provides the body with fuel for energy, it should be a part of all diabetic meals and snacks. The quantity and types of carbohydrate-rich foods will affect blood glucose level. A very high carbohydrate intake may raise the blood glucose levels too high. Foods with carbohydrates include bread, legumes, biscuits, rice, fruit, cakes, pasta, milk and yoghurt, sugar, grains, cereals and starchy vegetables such as potato, sweet potato and corn.

MEDICATION ADMINISTRATION Oral hypoglycaemic agents available in Australia

There are six classes of oral medications available in Australia to treat type 2 diabetes. They are prescribed alone or in combination.

1. Sulfonylureas
2. Meglitinides
3. Biguanides
4. Alpha-glucosidase inhibitors
5. Thiazolidinediones (glitazones)
6. Dipeptidyl peptidase 4 (DPP4) inhibitors

SULFONYLUREAS

Glimepiride (Amaryl, Aylide, Diapride, Dimirel, Glimepiride Sandoz)
Glipizide (Minidiab, Melizide)
Gliclazide ER (Diamicron MR, Glyade MR, Oziclide MR)
Glicazide (Glyade, Mellihexal, Nidem, GenRx Gliclazide)
Glibenclamide (Daonil, Glimel)

Sulfonylureas act by stimulating the pancreatic cells to secrete more insulin and by increasing the sensitivity of peripheral tissues to insulin. The most common side effect is hypoglycaemia, therefore it is important that the person eat regular meals while on this medication. A person should only be taking one type of sulfonylurea medication. These drugs are often suspended during hospitalisation. Other side effects that may be seen with these medications are weight gain, stomach upset, jaundice and possibly rash (but is rare) (Diabetes Australia, Victoria, 2012; MIMS Online Australia, 2012).

MEGLITINIDES

Repaglinide (Novonorm)

These drugs lower blood glucose levels by stimulating release of insulin from the pancreatic islet cells. They produce a greater decrease in postprandial glucose (2 hours after starting a meal) and have a decreased risk of hypoglycaemia (Diabetes Australia, Victoria, 2012; MIMS Online Australia, 2012).

BIGUANIDES

Metformin (Glucophage, Diabex, Diaformin, Formet, Metforbell, Glucohexal, Glucomet, Genrx metformin, Genepharm metformin)
Metformin ER (Diabex XR, Diaformin XR, Metex XR)

Metformin is usually prescribed first for people with diabetes type 2. Biguanides decrease the overproduction of glucose by the liver, slow absorption of glucose in the small intestine and make the body more sensitive to insulin. These should be taken with meals, may help with weight loss and have side effects including diarrhoea, nausea and metallic taste. If renal insufficiency develops, metformin must be discontinued. Because of an increased risk of metformin-induced lactic acidosis, metformin is usually suspended during hospitalisation. It should be discontinued temporarily before and after using contrast media for diagnostic imaging and anaesthesia (Diabetes Australia, Victoria, 2012; MIMS Online Australia, 2012).

ALPHA-GLUCOSIDASE INHIBITORS

Acarbose (Glucobay)

These agents inhibit the enzyme alpha-glucosidase, found in the brush-border cells that line the small intestine, which breaks down more complex carbohydrates into sugars. Because alpha-glucosidase inhibitors inhibit the breakdown and subsequent absorption of carbohydrates (dextrins, maltose, sucrose and starch) from the gut following meals, the impact of these drugs is on post-prandial hyperglycaemia. They should not be taken in pregnancy, breastfeeding, inflammatory bowel disease or malabsorption syndrome. Possible side effects are flatulence, bloating and diarrhoea (Complete Medication Services Consultant Pharmacists (CMS), 2006; Diabetes Australia, Victoria, 2012; MIMS Online Australia, 2012).

THIAZOLIDINEDIONES (GLITAZONES)

Rosiglitazone (Avandia)
Pioglitazone (Actos)

This class of drugs acts by sensitising peripheral tissue to insulin, by enhancing insulin activity in both muscle and fat cells and, to a lesser extent, by inhibiting hepatic glucose production. Pioglitazone may also help by reducing cholesterol and triglyceride levels. They do not need to be taken with meals. Weight gain may occur due to fluid retention and increased fat tissue. People with heart failure or liver disease should avoid this medication. Liver function should be monitored regularly while on glitazones. Increased risk of small fractures in the arms, hands and feet have been reported in women taking this medication (Diabetes Australia, Victoria, 2012).

DIPEPTIDYL PEPTIDASE 4 (DDP-4) INHIBITORS

Sitagliptin (Januvia)
Vildagliptin (Galvus)
Saxagliptin (Onglyza)
Linagliptin (Trajenta)

DDP-4 inhibitors reduce glucose levels by inhibiting the enzyme DDP-4 and therefore prolonging the action of the incretin hormones. These hormones work by reducing glucose levels after meals by stimulating insulin production by the pancreas and by reducing the secretion of glucagon which will decrease the release of glucose from the liver. Tablets need to be taken at the same time each day. People may develop headaches and nausea and have an increased risk of getting a cold. These drugs are not to be taken by pregnant or breastfeeding women and people under 18 years old. Caution is to be taken when people have renal impairment, and DDP-4 inhibitors are not recommended for people with liver failure (Diabetes Australia, Victoria, 2012).

COMBINATIONS

Metformin/Glibenclamide (Glucovance)
Metformin/Rosiglitazone (Avandamet)
Sitagliptin/Metformin (Janumet)
Vidagliptin/Metformin (Galvumet)

These medications provide the action of two classes of medications in only one tablet in order to achieve desirable glucose control (Diabetes Australia, Victoria, 2012).

Nursing responsibilities

- Assess people taking oral hypoglycaemic agents closely for the first 7 days to determine therapeutic response.
- Follow their medication(s) instructions strictly.

(continued)

MEDICATION ADMINISTRATION Oral hypoglycaemic agents available in Australia (continued)

- Teach the person the importance of maintaining a prescribed diet and exercise program.
- Monitor for hypoglycaemia if the person is also taking non-steroidal anti-inflammatory agents (NSAIDs), sulfonamide antibiotics, ranitidine, cimetidine or beta-blockers; these drugs intensify the action of sulfonylureas.
- Monitor for hyperglycaemia if the person is also taking calcium channel blockers, oral contraceptives, glucocorticoids, phenothiazines or thiazide diuretics; these drugs decrease the hypoglycaemic responses to sulfonylureas.
- Do not administer these drugs to pregnant or lactating women.
- Assess for side effects.
- If the person is to have a thyroid test, determine whether a sulfonylurea has been taken; sulfonylureas interfere with the uptake of radioactive iodine.
- Monitor for hypoglycaemia with concurrent administration of an oral antidiabetic agent and insulin.

Health education for the person and family

- Maintain prescribed diet and exercise regimen.
- You may need insulin if you have surgery, trauma, fever or infection.
- Follow instructions to monitor blood glucose.
- Report illness or side effects to the healthcare provider.
- Undergo periodic laboratory evaluations as prescribed by your healthcare provider.
- Avoid alcohol intake, which may cause a reaction involving flushing, palpitations and nausea.
- The medication interferes with the effectiveness of oral contraceptives; other birth control measures may be required.
- Mild symptoms of hyperglycaemia may appear if a different agent is begun.
- Take medications as prescribed—for example, once a day at the same time each day.

What does GI mean? The glycaemic index (GI) is a guide to how a carbohydrate food may affect the blood glucose level. A low GI food breaks down to glucose more slowly and causes a slower rise in the blood glucose levels compared to a high GI food. Low GI carbohydrate foods should be chosen for a healthy diet. At least one low GI food should be included in each meal (see Table 19.3).

FIBRE A healthy meal plan contains foods high in dietary fibre. There are two types of fibre—soluble and insoluble. Eating soluble fibre helps to lower blood glucose and cholesterol levels. Insoluble fibre is good for a healthy digestive system. A variety of plant foods to get plenty of insoluble and soluble fibre should be included in the diet. The aim is to eat at least 30 g of fibre each day. Many of the low GI foods listed in Table 19.3 are also good sources of fibre.

SUGAR Small amounts of sugar can be included as part of a healthy meal—for example, 1–2 teaspoons of sugar added to porridge, or a teaspoon of jam or honey on multigrain toast. Savoury foods containing sugar, such as baked beans and tomato sauce, can also be eaten.

Foods which contain large amounts of sugar, such as soft drinks, regular jelly and confectionery, should be avoided. Some artificially sweetened foods are suitable, but some may be high in fat.

FATS Although blood glucose levels are directly affected by carbohydrate, eating too much fat is also a problem. Fats provide energy and some vitamins, so a small amount is essential. However, too much leads to carrying excess body weight, which increases insulin resistance. There are different types of fats in food and some are worse than others. Saturated fat and trans fat increase the risk of heart disease by increasing blood cholesterol levels.

Saturated fat is found in animal products (e.g. butter, full-cream milk, cheese and yoghurt, fatty meats, processed meats, cream, lard), palm oil (often used in commercial snacks and baked products such as biscuits and pastries), takeaway foods and chips, and coconut oil, including coconut cream and milk.

Trans fat is found in a variety of foods manufactured with vegetable oils, such as biscuits, pastries and some margarines.

Ways to reduce saturated and trans fat intake are to eat less fried foods, pies, processed meats, chips, chocolate, biscuits and pastries, limit butter, lard, cream and sour cream, choose lean meat and trim any fat off meat before cooking, remove chicken skin, use low-fat dairy products, and use monounsaturated and polyunsaturated oils and margarine spreads. These foods are still high in kilojoules; the amount should be minimised if weight control or weight loss is desired.

Monounsaturated fat is found in oils such as olive, canola, sunflower and peanut oil; in margarines made from monounsaturated vegetable oils such as olive or canola oil; in nuts such as peanuts, almonds and cashews; and in avocados and olives.

Polyunsaturated fat also helps to improve cholesterol levels. Polyunsaturated fat is found in oils such as sunflower, safflower and soybean oil, in margarines made from polyunsaturated vegetable oils such as sunflower or grapeseed oil, and in walnuts and fish.

Omega-3 fats (a type of polyunsaturated fat) improve heart health and have other health benefits. Eat fish (fresh or canned) at least twice a week to increase the intake of omega-3 fats. Fish such as salmon, gemfish and blue grenadier are good sources of omega-3 fats.

Plant sterols are added to some foods, including margarine spreads such as Flora Proactiv™ and Meadow Lea Logicol™. These help to reduce cholesterol levels. The use of these products should be discussed with the health

BOX 19.9 Goals for dietary management for adults with diabetes

- Control blood glucose levels.
- Control weight.
- Improve cholesterol levels.
- Reduce the risk of heart disease.
- Improve general health and wellbeing.

Dietary guidelines for Australian adults suggest:

- enjoying a wide variety of nutritious foods
- eating plenty of vegetables, legumes and fruits
- eating plenty of cereals (including breads, rice, pasta and noodles), preferably wholegrain
- including lean meat, fish, poultry and/or alternatives
- including milks, yoghurts, cheeses and/or alternatives—reduced-fat varieties should be chosen, where possible
- drinking plenty of water and taking care to:
  - limit saturated fat and moderate total fat intake
  - choose foods low in salt
  - limit alcohol intake if the person chooses to drink
  - consume only moderate amounts of sugars and foods containing added sugars
  - eat regularly during the day and spread food over breakfast, lunch and dinner.

Diabetics should aim to eat the following each day:

- 5 serves vegetables
- 2 serves fruit
- 5 serves grains, breads and cereals
- 2–3 serves low-fat dairy products
- 1 serve lean meat, chicken or fish, or a meat alternative such as lentils, beans or tofu.

People with higher energy needs may require more serves. A dietitian can offer guidance on the quantity of food that the person may need.

TABLE 19.3 Foods with a low GI

Breads	Multigrain breads, pumpernickel, fruit and grains, Bakers Delight low GI™
Breakfast cereals	High-fibre breakfast cereals such as rolled oats, untoasted muesli, All-Bran™, Guardian™
Pasta and noodles	Wheat pasta Most noodles, such as rice vermicelli, soba noodles, mung bean noodles
Rice	Long-grain rice such as Doongara and Basmati; wild, moolgiri low GI, brown, black and red rice
Grains	Quinoa, barley, buckwheat, semolina and bulgur
Fruits	Fresh, dried and canned fruit, such as apples, pears, oranges, grapes, grapefruit, peaches, plums, kiwi fruit and bananas
Starchy vegetables	Sweet potato (orange), yam, corn, Carisma™ and Nicola potato *Note:* Most coloured vegetables are low in carbohydrate and have little effect on blood glucose levels, e.g. salad, greens and orange
Legumes and pulses	All types (canned or dried) such as kidney beans, mixed beans, chick peas, lentils and baked beans
Milk and yoghurt	Low-fat milk and yoghurt, soy milk and yoghurt, and almond milk

Source: Heart and Diabetes Institute of Australia (2015). *Carbohydrates and Glycaemic Index (GI).* Retrieved from http://admin.bakeridi.edu.au/Assets/Files/Carbs%20&%20Glycaemic%20Fact%20SHEET.pdf.

professional, as quantities are important and they are not suitable for everyone.

When used in small quantities, both monounsaturated fat and polyunsaturated fat can help to improve blood cholesterol levels. Monounsaturated fat can help improve cholesterol levels if it is used in place of saturated fat.

Cholesterol in food Cholesterol is found in foods such as eggs, offal (e.g. kidneys, liver and brain) and seafood. Although cholesterol in food can increase the blood cholesterol level, it is more important to limit foods high in saturated fat or trans fat.

PROTEIN Protein is used by the body for growth and repair and is found in foods such as meat, fish, eggs and dairy products. The body's requirements for protein are met by 2–3 serves of dairy foods and 1 serve of meat or fish each day. A higher protein intake is not necessary and many foods high in protein are also high in saturated fat (e.g. dairy foods, meat) so eating more protein may also increase saturated fat intake.

SALT A high salt (sodium) intake contributes to high blood pressure in some people. Reducing the amount of salt that is consumed may help reduce blood pressure.

ALCOHOL Alcohol is high in energy and therefore can contribute to weight gain. If taking insulin or medications for diabetes, alcohol may increase the risk of hypoglycaemia. To reduce the risk of hypoglycaemia, alcohol should not be consumed without having a meal or snack containing carbohydrate.

It is recommended that people with diabetes limit alcohol to no more than 2 standard drinks a day. One standard drink equals: 285 mL beer, 425 mL light beer (less than 3% alcohol), 100 mL wine, 60 mL fortified wine, 30 mL spirit (Diabetes Australia, Victoria, 2012).

SWEETENERS The diet plan for people with diabetes restricts the amount of refined sugars. As a result, many people use non-nutritive sweeteners and foods or drinks made with non-sweeteners. Commercially produced non-nutritive sweeteners are approved for use by the FDA. Although questions have been raised about the safety of these substances in laboratory animal studies, they are considered safe for use by humans.

Included in this category of sweeteners are saccharin (Sweet & Low), aspartame or neotame (Nutrasweet®, Equal®), sucralose (Splenda®) and acesulfame potassium. The non-nutritive sweeteners have negligent amounts of or no kilojoules, do not produce dental caries and produce very little or no changes in blood glucose levels.

People with diabetes also use nutritive sweeteners, including fructose, sorbitol and xylitol. The kilojoule content of these substances is similar to that of table sugar (sucrose), but they cause less elevation in blood glucose. They are often included in foods labelled as 'sugar free'. Sorbitol may cause flatulence and diarrhoea.

Researchers are continuing to study the safety and effectiveness of the sweeteners. When teaching people about diet, the nurse should include information about the kilojoule content of sweeteners and the meaning of such phrases as *sugar free* and *dietetic* on labels (Diabetes Australia, 2012; Heart and Diabetes Institute of Australia, 2009a).

MEAL PLANNING Several different systems for meal planning are available to the person with diabetes. These systems include a consistent-carbohydrate diabetes meal plan, exchange lists, point systems, food groups, carbohydrate counting and kilojoule counting. No matter what system is used, however, it must take into account the person's individualised eating habits, diet history, food values and special needs. Altering foods and meal patterns is often one of the most difficult parts of diabetes management; careful consideration of individualised preferences enhances compliance with the diet. Although dietitians provide nutrition information and advice, nurses must know what is prescribed and be able to reinforce teaching and answer questions.

For information on diabetes and healthy eating, go to the Better Health Channel site at www.betterhealth.vic.gov.au/bhcv2/bhcarticles.nsf/pages/Diabetes_and_healthy_eating.

Diet plan for type 1 diabetes Diet and insulin prescription must be integrated for optimal energy metabolism and the prevention of hyperglycaemia or hypoglycaemia. The goals of the diet plan are to achieve optimal glucose and lipid levels, improve overall health and maintain reasonable body weight. To meet these goals, the following strategies must be implemented:

- Glucose regulation requires correlating eating patterns with insulin onset and peak of action.
- Meals, snacks and insulin regimens should be based on the person's lifestyle.
- Meal planning depends on the specific insulin regimen prescribed.
- Snacks are an important consideration in relation to the amount and timing of exercise.
- The diet plan must consider the availability of foods, based on occupational, financial, religious and ethnic constraints.
- Self-monitoring of blood glucose levels helps the person make adjustments for planned and unplanned changes in routines.

Diet plan for type 2 diabetes The goals of the diet plan are to improve blood glucose levels, improve overall health, prevent or delay complications, and attain or maintain reasonable body weight. Because the majority of these people are overweight, weight loss is important and facilitates achieving the other goals.

There are no specific guidelines for the type 2 diet, but in addition to decreasing kilojoules, it is recommended that the person consume three meals of equal size, evenly spaced approximately 4 to 5 hours apart, with one or two snacks. The person with type 2 DM should also decrease fat intake. If the exchange list is difficult to use, kilojoule counting or designing the diet by grams of fat may be more useful.

Sick-day management When the person with diabetes is sick or has surgery, blood glucose levels increase, even though food intake decreases. The person often mistakenly alters or omits the insulin dose, causing further problems. The guidelines for dietary management during illness focus on preventing dehydration and providing nutrition for promoting recovery. In general, sick-day management includes the following:

- monitoring blood glucose at least four times a day throughout an illness
- testing urine for ketones if blood glucose is greater than 13 mmol/L
- continuing to take the usual insulin dose or oral hypoglycaemic agent
- sipping 150 to 250 mL of fluid each hour
- substituting easily digested liquids or soft foods if solid foods are not tolerated (the substituted liquids and foods should be carbohydrate equivalents—e.g. ½ cup sweetened gelatine, ½ cup fruit juice, 1 ice block, ¼ cup sherbet and ½ cup regular soft drink)
- calling the healthcare provider if the person is unable to eat for more than 24 hours or if vomiting and diarrhoea last for more than 6 hours.

Diet plan for the older adult The majority of older adults have type 2 DM and should follow the general guidelines for that diet plan. However, special considerations for the older adult are important if the diet plan is to be followed, including:

- dietary likes and dislikes
- who prepares the meals
- age-related changes in taste perception
- dental health
- transportation to buy foods
- available income.

Other factors to consider in planning the diet for the older adult include the age-related decline in kilojoule requirements, decline in physical activity due to age and/or chronic illnesses, and the onset or progression of other chronic illnesses. The older adult who is overweight should reduce kilojoule intake to ensure weight loss; but at the same time, careful monitoring for malnutrition is necessary. It is possible for the older adult to revert to normal glucose tolerance if ideal body weight is regained.

Exercise

The third component of diabetes management is a regular exercise program. The benefits of exercise are the same for everyone, with or without diabetes: improved physical fitness,

improved emotional state, weight control and improved work capacity. In people with diabetes, exercise increases the uptake of glucose by muscle cells, potentially reducing the need for insulin. Exercise also decreases cholesterol and triglycerides, reducing the risk of cardiovascular disorders. People with diabetes should consult their primary healthcare provider before beginning or changing an exercise program.

The ability to maintain an exercise program is affected by many different factors, including fatigue and glucose levels. It is as important to assess the person's usual lifestyle before establishing an exercise program as it is before planning a diet. Factors to consider include the person's usual exercise habits, living environment and community programs. The exercise that the person enjoys most is probably the one that they will continue with throughout life. People with diabetes should determine the best type of exercise for their individual needs and follow the recommendations and advice of their health care provider, diabetes educator and other professionals when engaging in any exercise program. Considerations include using proper footwear, inspecting the feet daily and after exercise, avoiding exercise in extreme heat or cold, and eating a snack prior to strenuous exercise to prevent hypoglycaemia (Diabetes Australia, 2012; Better Health Channel, 2013).

ACUTE COMPLICATIONS OF DIABETES

The person with DM, regardless of type, is at increased risk of complications involving many different body systems. Alterations in blood glucose levels, alterations in the cardiovascular system, neuropathies, and an increased susceptibility to infection and periodontal disease are common. In addition, the interaction of several complications can cause problems of the feet. The 'Multisystem effects of diabetes mellitus' illustration on the next page shows the progression from cardinal signs to acute and late complications for the person with diabetes. A discussion of each of these complications follows; related interprofessional care and nursing care are discussed later in the chapter.

Acute complications: alterations in blood glucose levels

The following discussion provides additional information about hyperglycaemia and hypoglycaemia. Table 19.4 compares DKA, HHS and hypoglycaemia.

Hyperglycaemia

The main problems resulting from hyperglycaemia in the person with diabetes are DKA and HHS. Two other problems are the dawn phenomenon and the Somogyi phenomenon.

The **dawn phenomenon** is a rise in blood glucose between 4 am and 8 am that is not a response to hypoglycaemia. It is believed to be due to an increase in counter-regulatory hormones such as growth hormone, cortisol and catecholamines which work against the action of insulin and cause morning hyperglycaemia (WebMD, 2012). The **Somogyi phenomenon** is a combination of hypoglycaemia during the night with a rebound morning rise in blood glucose to hyperglycaemic levels. The hyperglycaemia stimulates the counter-regulatory hormones, which stimulate gluconeogenesis and glycogenolysis and also inhibit peripheral glucose use. This may cause insulin resistance for 12 to 48 hours (McCance & Huether, 2009).

DIABETIC KETOACIDOSIS As the pathophysiology of untreated type 1 DM continues, the insulin deficit causes fat stores to break down, resulting in continued hyperglycaemia and mobilisation of fatty acids with a subsequent ketosis. **Diabetic ketoacidosis (DKA)** develops when there is an absolute deficiency of insulin and an increase in the insulin counter-regulatory hormones. Glucose production by the liver increases, peripheral glucose use decreases, fat mobilisation increases and ketogenesis (ketone formation) is stimulated. Increased glucagon levels activate the gluconeogenic and ketogenic pathways in the liver. In the presence of insulin deficiency, hepatic overproduction of beta-hydroxybutyrate and acetoacetic acids (ketone bodies) causes increased ketone concentrations and an increased release of free fatty acids. As a result of a loss of bicarbonate (which occurs when the ketone is formed), bicarbonate buffering does not occur and a metabolic acidosis occurs, called DKA. Depression of the central nervous system from the accumulation of ketones and the resulting acidosis may cause coma and death if left untreated (Porth & Matfin, 2009). See Figure 19.4.

DKA also may occur in a person with diagnosed diabetes when energy requirements increase during physical or emotional stress. Stress states initiate the release of gluconeogenic hormones, resulting in the formation of carbohydrates from protein or fat. The person who is sick, has an infection, or decreases or omits their insulin doses is at a greatly increased risk of developing DKA.

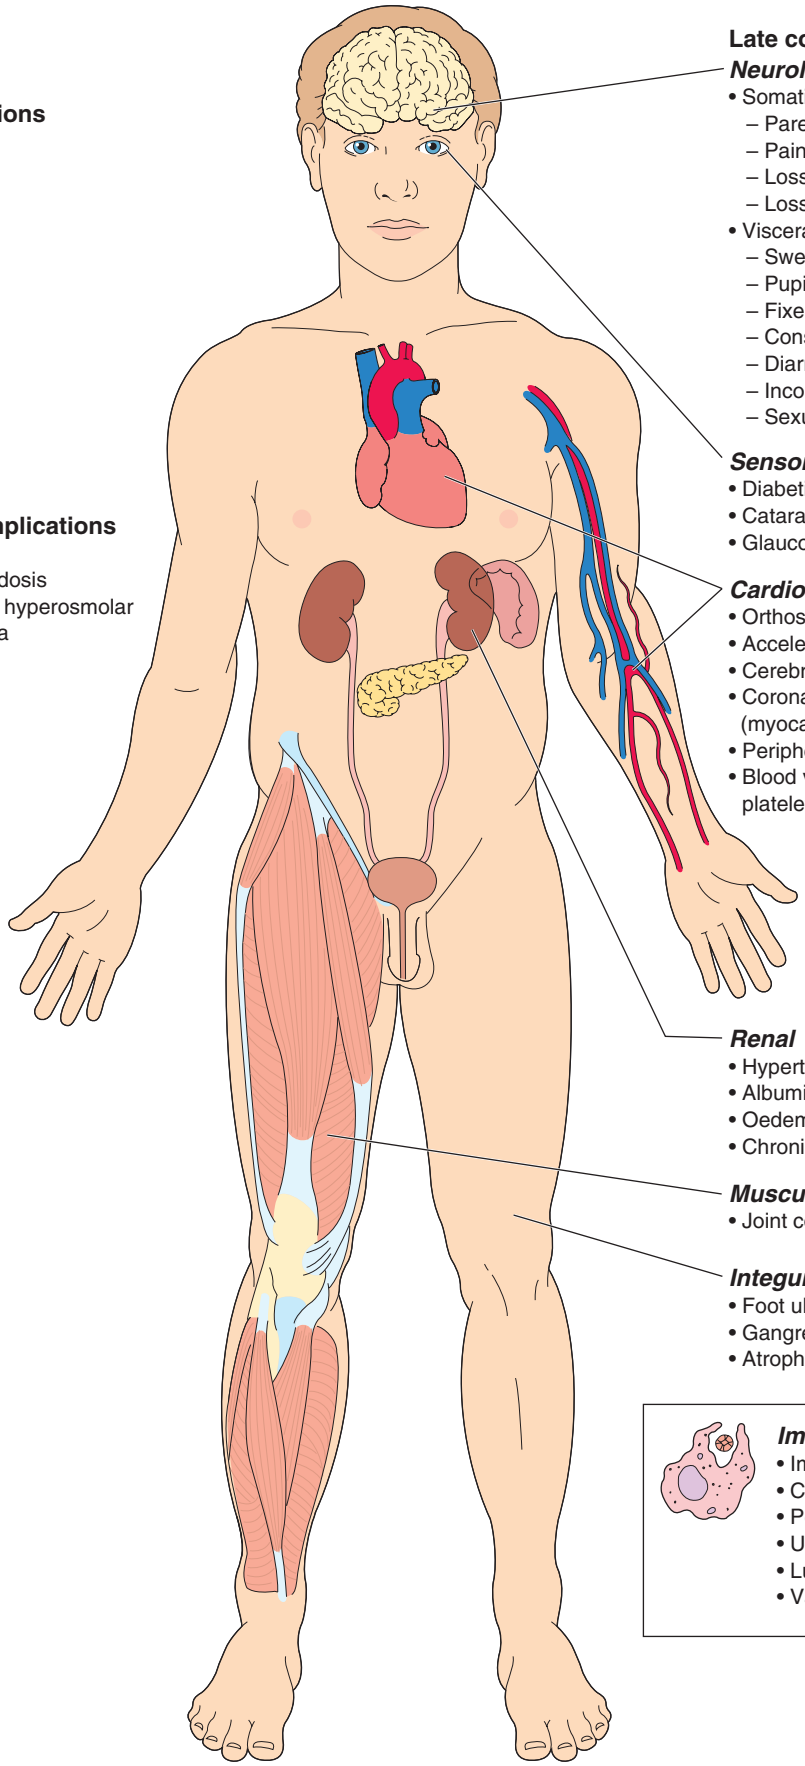
DKA involves four metabolic problems:

1. hyperosmolarity from hyperglycaemia and dehydration
2. metabolic acidosis from an accumulation of ketoacids
3. extracellular volume depletion from osmotic diuresis
4. electrolyte imbalances (such as loss of potassium and sodium) from osmotic diuresis.

Manifestations of DKA result from severe dehydration and acidosis.

HYPEROSMOLAR HYPERGLYCAEMIC STATE (HHS) The metabolic problem called **hyperosmolar hyperglycaemic state (HHS)** occurs in people who have type 2 DM. HHS is characterised by a plasma osmolarity of 340 mmol/kg or greater (the normal range is 280 to 300 mmol/kg (South-Western Sydney Local Health District (SWSLHD), 2012), greatly elevated blood glucose levels (over 33.3 mmol/L and often 55.5 to 111 mmol/L) and altered levels of consciousness. HHS is a serious, life-threatening medical emergency and has a higher mortality rate than DKA. Mortality is high not only because the metabolic changes are serious but also because people with diabetes are usually older and have other medical problems that either cause or are caused by HHS. The precipitating factors associated with

MULTISYSTEM EFFECTS OF DIABETES MELLITUS



Early manifestations
- Type 1 DM
  - Polyuria
  - Polydipsia
  - Polyphagia
  - Weight loss
  - Glycosuria
  - Fatigue
- Type 2 DM
  - Polyuria
  - Polydipsia
  - Blurred vision

Progressive complications
- Hyperglycaemia
  - Diabetic ketoacidosis
  - Hyperglycaemic hyperosmolar non-ketotic coma
- Hypoglycaemia

Late complications

Neurological
- Somatic neuropathies
  - Paresthaesias
  - Pain
  - Loss of cutaneous sensation
  - Loss of fine motor control
- Visceral neuropathies
  - Sweating dysfunction
  - Pupillary constriction
  - Fixed heart rate
  - Constipation
  - Diarrhoea
  - Incomplete bladder emptying
  - Sexual dysfunction

Sensory
- Diabetic retinopathy
- Cataracts
- Glaucoma

Cardiovascular
- Orthostatic hypotension
- Accelerated atherosclerosis
- Cerebrovascular disease (stroke)
- Coronary artery disease (myocardial infarction)
- Peripheral vascular disease
- Blood viscosity and platelet disorders

Renal
- Hypertension
- Albuminuria
- Oedema
- Chronic renal failure

Musculoskeletal
- Joint contractures

Integumentary
- Foot ulcers
- Gangrene of the feet
- Atrophic changes

Immune system
- Impaired healing
- Chronic skin infections
- Periodontal disease
- Urinary tract infections
- Lung infections
- Vaginitis

TABLE 19.4 DKA, HHS and hypoglycaemia comparison

		DKA	HHS	HYPOGLYCAEMIA
Diabetes type		Primary type 1	Type 2	Both
Onset		Slow	Slow	Rapid
Cause		↓ Insulin	↓ Insulin	↑ Insulin
		Infection	Older age	Omitted meal/snack
				Error in insulin dose
Risk factors		Surgery	Surgery	Surgery
		Trauma	Trauma	Trauma
		Illness	Illness	Illness
		Omitted insulin	Dehydration	Exercise
		Stress	Medications	Medications
			Dialysis	Lipodystrophy
			Hyperalimentation	Renal failure
				Alcohol intake
Assessments	Skin	Flushed; dry; warm	Flushed; dry; warm	Pallor; moist; cool
	Perspiration	None	None	Profuse
	Thirst	Increased	Increased	Normal
	Breath	Fruity	Normal	Normal
	Vital signs	BP ↓	BP ↓	BP ↓
		P ↑	P ↑	P ↑
		R Kussmaul's	R normal	R normal
	Mental status	Confused	Lethargic	Anxious; restless
	Thirst	Increased	Increased	Normal
	Fluid intake	Increased	Increased	Normal
	Gastrointestinal effects	Nausea/vomiting; abdominal pain	Nausea/vomiting; abdominal pain	Hunger
	Fluid loss	Moderate	Profound	Normal
	Level of consciousness	Decreasing	Decreasing	Decreasing
	Energy level	Weak	Weak	Fatigue
	Other	Weight loss	Weight loss	Headache
		Blurred vision	Malaise	Altered vision
			Extreme thirst	Mood changes
			Seizures	Seizures
Laboratory findings	Blood glucose	> 16.7 mmol/L	> 33.3 mmol/L	< 2.8 mmol/L
	Plasma ketones	Increased	Normal	Normal
	Urine glucose	Increased	Increased	Normal
	Urine ketones	Increased	Normal	Normal
	Serum potassium	Abnormal	Abnormal	Normal
	Serum sodium	Abnormal	Abnormal	Normal
	Serum chloride	Abnormal	Abnormal	Normal
	Plasma pH	< 7.3	Normal	Normal
	Osmolality	> 340 mmol/kg	> 340 mmol/kg	Normal
Treatment		Insulin	Insulin	Glucagon
		Treatment	Intravenous fluids	Rapid-acting carbohydrate
		Intravenous fluids Electrolytes	Electrolytes	Intravenous solution of 50% glucose

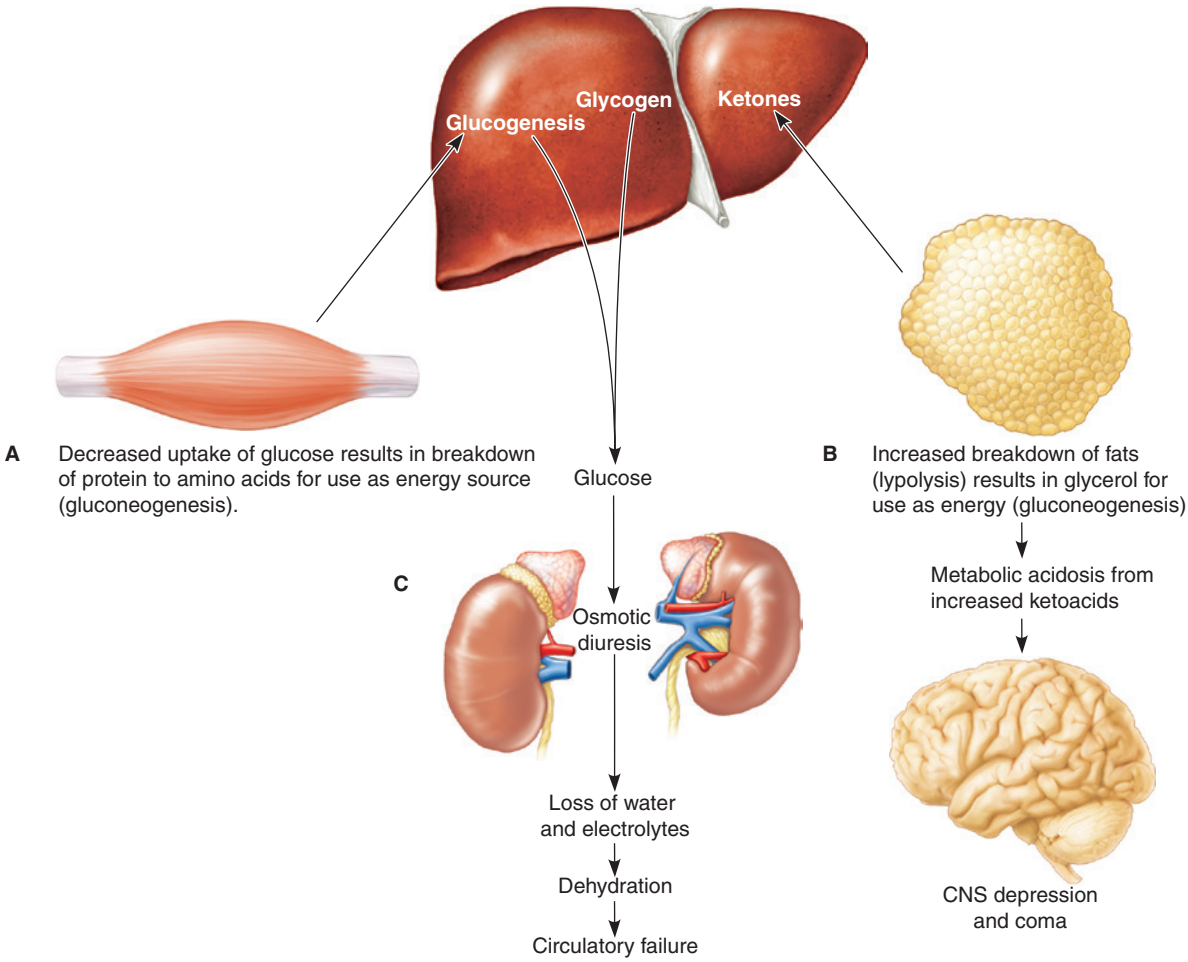


FIGURE 19.4 ■ In type I diabetes mellitus, without adequate insulin, muscle (*A*) and fat (*B*) cells are metabolised to provide sources of energy. Amino acids from skeletal muscle are converted to glucose in the liver; glycerol from fat cells is converted to glucose and fatty acids (ketoacids) which cause CNS depression and coma. Increased glucose (*C*) causes osmotic diuresis, leading to dehydration and decreased circulatory volume. These processes create the symptoms of diabetic ketoacidosis (DKA). The symptoms can be reversed with intravenous insulin to lower blood glucose. Blood pressure is raised to prevent circulatory failure by administering intravenous fluids; electrolytes are monitored and corrected

HHS include infection, therapeutic agents, therapeutic procedures, acute and chronic illness (see Box 19.10). The most common precipitating factor is infection. The manifestations of this disorder may be slow to appear, with onset ranging from 24 hours to 2 weeks. The manifestations are initiated by hyperglycaemia, which causes increased urine output. With increased output, plasma volume decreases and glomerular filtration rate drops. As a result, glucose is retained and water is lost. Glucose and sodium accumulate in the blood and increase serum osmolarity.

Serum hyperosmolarity results in severe dehydration, reducing intracellular water in all tissues, including the brain. The person has dry skin and mucous membranes, extreme thirst and altered levels of consciousness (progressing from lethargy to coma). Neurological deficits may include hyperthermia, motor and sensory impairment, positive Babinski's sign and seizures. *Metabolic acidosis is not part of the pathology; despite elevated blood glucose, sufficient insulin is present to prevent metabolism of fats with the resulting fatty acids and ketones of DKA.* Treatment is directed towards correcting fluid and electrolyte imbalances, lowering blood glucose levels with insulin and treating underlying conditions.

INTERPROFESSIONAL CARE

Treatment of hyperglycaemia

DKA

DKA requires immediate medical attention. Admission to the hospital is appropriate when the person has blood glucose of greater than 14 mmol/L, a decreasing pH and ketones in the urine. Priority management include assessment and management of the person's airway, breathing and circulation. Consider intubation and ventilation if required, administer oxygen if the person is hypoxic and insert a nasogastric tube if the person has low level of consciousness and is vomiting. Early

BOX 19.10 Factors associated with hyperosmolar hyperglycaemic state

Therapeutic agents
- Glucocorticoids
- Diuretics
- Beta-adrenergic blocking agents
- Immunosuppressants
- Chlorpromazine
- Diazoxide

Acute illness
- Infection
- Gangrene
- Urinary infection
- Burns
- Gastrointestinal bleeding
- Myocardial infarction
- Pancreatitis
- Stroke

Therapeutic procedures
- Peritoneal dialysis
- Haemodialysis
- Hyperosmolar alimentation (oral or parenteral)
- Surgery

Chronic illness
- Renal disease
- Cardiac disease
- Hypertension
- Previous stroke
- Alcoholism

assessment and correction of dehydration is essential. In the first 12 hours of treatment, adults usually require 8 to 10 L of intravenous fluid to replace losses from polyuria and vomiting (Lehne, 2012; Oakes & Cole, 2007). The initial fluid replacement may be accomplished by administering 0.9% saline solution at a rate of 500 to 1000 mL/h. After 2 to 3 hours (or when blood pressure and perfusion is returning to normal), the administration of 0.45% saline at 200 to 500 mL/h may continue for several more hours. When the blood glucose levels reach 14 to 16 mmol/L, dextrose is added to prevent rapid decreases in glucose; hypoglycaemia could result in fatal cerebral oedema.

Regular insulin is used in the management of DKA and may be given by various routes, depending on the severity of the condition. Mild ketosis may be treated with subcutaneous insulin, whereas severe ketosis requires intravenous insulin infusion. Nursing responsibilities for the person receiving intravenous insulin are described in the 'Medication administration' box below.

The electrolyte imbalance of primary concern is depletion of body stores of potassium. Initially, serum potassium levels may be normal, but they decrease during treatment. In DKA (and from rehydration), the body loses potassium from increased urinary output, acidosis, catabolic state and vomiting or diarrhoea. Potassium replacement is begun early in the course of treatment, usually by adding potassium to the rehydration fluids. Replacement is essential for preventing cardiac arrhythmias secondary to hypokalaemia. Cardiac rhythms and potassium levels must be monitored every 2 to 4 hours or more often, according to the severity of the person's condition. Often continuous cardiac monitoring is necessary.

HHS

HHS is a serious, life-threatening metabolic condition. The person admitted to the critical care unit for treatment typically manifests blood glucose levels over 40 mmol/L, increased serum osmolarity and altered levels of consciousness or seizures. Treatment is similar to that of DKA: correcting fluid and electrolyte imbalances and providing insulin to lower hyperglycaemia. In general, treatment modalities include the following:
- establishing and maintaining adequate ventilation
- correcting hypovolaemic shock with adequate intravenous fluids
- instituting nasogastric suction or gastric drainage if comatose to prevent aspiration
- maintaining fluid volume with intravenous isotonic or colloid solutions
- administering potassium intravenously to replace losses
- administering insulin to reduce blood glucose, usually discontinuing administration when blood glucose levels reach 14 mmol/L. (Because ketosis is not present, there is no need to continue insulin, as with DKA.)

MEDICATION ADMINISTRATION Intravenous insulin

GENERAL GUIDELINES

- Regular insulin may be given undiluted directly into the vein or through a Y-tube or three-way stopcock.
- Insulin infusion is usually diluted in 0.9% saline.

Nursing responsibilities

- Monitor blood glucose levels hourly.
- Infuse the insulin solution separately from the hydration solution.
- Flush or prime the intravenous tubing with 50 mL of insulin mixed with normal (0.9%) saline solution to saturate binding sites on the tubing before administering the insulin to the person; this step increases the amount of insulin delivered over the first few hours.
- Do not discontinue the intravenous infusion until subcutaneous administration of insulin is resumed.
- Monitor for manifestations of hypoglycaemia.
- Ensure that glucagon and/or dextrose 50% is readily available as an antidote for insulin overdose (also known as severe hypoglycaemia).
- Follow strict guidelines and protocols in relation to the administration, maintenance and titration of intravenous insulin infusions.

Hypoglycaemia

Hypoglycaemia (low blood glucose levels) is common in people with type 1 DM and occasionally occurs in people with type 2 DM who are treated with oral hypoglycaemic agents. This condition is often called insulin shock, **insulin reaction** or 'the lows' in people with type 1 DM. Hypoglycaemia results primarily from a mismatch between insulin intake (e.g. an error in insulin dose), physical activity and carbohydrate availability (e.g. omitting a meal). The intake of alcohol and drugs such as chloramphenicol (Chloromycetin), warfarin (Coumadin), monoamine oxidase inhibitors, probenecid (Benemid), salicylates and sulfonamides can also cause hypoglycaemia.

The manifestations of hypoglycaemia (see box below) result from a compensatory autonomic nervous system (ANS) response coupled with an impaired cerebral function due to a decrease in glucose available for use by the brain. The manifestations vary, particularly in older adults. The onset is sudden and blood glucose is usually less than 2.5 to 3.3 mmol/L. Severe hypoglycaemia may cause death.

People who have had type 1 DM for 4 or 5 years fail to secrete glucagon in response to a decrease in blood glucose. They then depend on adrenaline to serve as a counter-regulatory response to hypoglycaemia. However, this compensatory response can become absent or blunted. The person then develops a syndrome called *hypoglycaemia unawareness*. The person does not experience symptoms of hypoglycaemia even though it is present. Because treatment is not initiated in the absence of symptoms, the person is likely to have episodes of severe hypoglycaemia.

INTERPROFESSIONAL CARE

Treatment of hypoglycaemia

MILD HYPOGLYCAEMIA When mild hypoglycaemia occurs, immediate treatment is necessary. People experiencing hypoglycaemia should take about 15 g of a rapid-acting or simple sugar. This amount of sugar is found, for example, in three glucose tablets, ½ cup of fruit juice or a regular soft drink, 250 mL of skim milk, five Life Savers® sweets, three large marshmallows or 3 teaspoons of sugar or honey. Sugar should not be added to fruit juice. Adding sugar to the fruit sugar already in the juice could cause a rapid rise in blood glucose, with persistent hyperglycaemia.

People with diabetes should have some source of carbohydrate readily available at all times so that hypoglycaemic symptoms can be quickly reversed. A meal, including complex carbohydrates, should be consumed immediately so that hypoglycaemia does not re-occur. If hypoglycaemia occurs more than two or three times a week, the diabetes management plan should be adjusted.

SEVERE HYPOGLYCAEMIA People with diabetes who have severe hypoglycaemia are often hospitalised. The criteria for hospitalisation are one or more of the following:

- Blood glucose is less than 3.0 mmol/L and the prompt treatment of hypoglycaemia has not resulted in recovery of sensorium.
- The person has coma, seizures or altered behaviour.
- The hypoglycaemia has been treated, but a responsible adult cannot be with the person for the following 12 hours.
- The hypoglycaemia was caused by a sulfonylurea drug.

If the person is conscious and alert, 10 to 15 g of an oral carbohydrate may be given. If the person has altered levels of consciousness, parenteral glucose or glucagon is administered.

Glucose is administered intravenously as a 25–50% solution, usually at a rate of 10 mL over 1 minute by intravenous push or bolus, as the most rapid method of increasing blood glucose levels (Diabetes Australia, 2012).

Glucagon is an antihypoglycaemic agent that raises blood glucose by promoting the conversion of hepatic glycogen to glucose. It is used in severe insulin-induced hypoglycaemia and may be given in the recommended dose of 1 mg by the subcutaneous, intramuscular or intravenous routes. Glucagon has a short period of action; an oral (if the person is conscious) or intravenous carbohydrate should be administered following the glucagon to prevent a recurrence of hypoglycaemia. If the person has been unconscious, glucagon may cause vomiting when consciousness returns.

MANIFESTATIONS Hypoglycaemia

MANIFESTATIONS CAUSED BY RESPONSES OF THE AUTONOMIC NERVOUS SYSTEM

- Hunger
- Shakiness
- Nausea
- Irritability
- Anxiety
- Rapid pulse
- Pale, cool skin
- Hypotension
- Sweating

MANIFESTATIONS CAUSED BY IMPAIRED CEREBRAL FUNCTION

- Strange or unusual feelings
- Slurred speech
- Headache
- Blurred vision
- Decreasing levels of consciousness
- Difficulty in thinking
- Inability to concentrate
- Seizures
- Change in emotional behaviour
- Coma

Chronic complications

Alterations in the cardiovascular system

The macrocirculation (large blood vessels) in people with diabetes undergoes changes due to atherosclerosis; abnormalities in platelets, red blood cells and clotting factors; and changes in arterial walls. It has been established that atherosclerosis (clogging and hardening of the blood vessels) has an increased incidence and earlier age of onset in people with diabetes (although the reason is unknown). Other risk factors that contribute to the development of macrovascular disease of diabetes are hypertension, hyperlipidaemia, cigarette smoking and obesity. Alterations in the vascular system increase the risk of the long-term complications of coronary artery disease, cerebral vascular disease and peripheral vascular disease.

Alterations in the microcirculation in the person with diabetes involve structural defects in the basement membrane of smaller blood vessels and capillaries. (The basement membrane is the structure that supports and serves as the boundary around the space occupied by epithelial cells.) These defects cause the capillary basement membrane to thicken, eventually resulting in decreased tissue perfusion. Changes in basement membranes are believed to be due to one or more of the following: the presence of increased amounts of sorbitol (a substance formed as an intermediate step in the conversion of glucose to fructose), the formation of abnormal glycoproteins, or problems in the release of oxygen from haemoglobin (Porth & Matfin, 2009). The effects of alterations in the microcirculation affect all body tissues but are seen primarily in the eyes and the kidneys.

Coronary artery disease

Coronary artery disease is a major risk factor in the development of myocardial infarction in people with diabetes, especially in the middle to older adult with type 2 DM. Coronary artery disease is the most common cause of death for people with diabetes in Australia (ABS, 2015). Indigenous people have a higher incidence of death due to diabetes mellitus and ischaemic heart disease than non-Indigenous Australians (ABS, 2012). People with diabetes who have myocardial infarction are more prone to develop congestive heart failure as a complication of the infarction and are also less likely to survive in the period immediately following the infarction. (Myocardial infarction is discussed in Chapter 29.)

Hypertension

Hypertension (blood pressure ≥ 140/90 mmHg) is a common complication of DM. It affects 20–60% of all people with diabetes and is a major risk factor for cardiovascular disease and microvascular complications such as retinopathy and nephropathy. Hypertension may be reduced by weight loss, exercise, and decreasing sodium intake and alcohol consumption. If these methods are not effective, treatment with antihypertensive medications is necessary.

Stroke (cerebrovascular accident)

People with diabetes, especially older adults with type 2 DM, are 2 to 6 times more likely to have a stroke. Atherosclerosis of the cerebral vessels develops at an earlier age and is more extensive in people with diabetes due to high glucose levels over time leading to increased fat deposits in the blood vessel walls (Porth & Matfin, 2009; National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK) and National Institutes of Health (NIH), 2011). Around 75% of people with diabetes will die from cardiovascular disease or stroke (Diabetes NSW, 2015).

The manifestations of impaired cerebral circulation are often similar to those of hypoglycaemia or HHS: blurred vision, slurred speech, weakness and dizziness. People with these manifestations have potentially life-threatening health problems and require constant medical attention.

Peripheral vascular disease

Peripheral vascular disease of the lower extremities accompanies both types of DM, but the incidence is greater in people with type 2 DM. Atherosclerosis of vessels in the legs of people with diabetes begins at an earlier age, advances more rapidly and is equally common in both men and women. Impaired peripheral vascular circulation leads to peripheral vascular insufficiency with intermittent claudication (pain) in the lower legs and ulcerations of the feet. Occlusion and thrombosis of large vessels and small arteries and arterioles, as well as alterations in neurological function and infection, result in gangrene (necrosis or the death of tissue). Gangrene from diabetes is the most common cause of non-traumatic amputations of the lower leg. In people with diabetes, dry gangrene is most common, manifested by cold, dry, shrivelled and black tissues of the toes and feet. The gangrene usually begins in the toes and moves proximally into the foot.

Diabetic retinopathy

Diabetic retinopathy is the name for the changes in the retina that occur in the person with diabetes. The retinal capillary structure undergoes alterations in blood flow, leading to retinal ischaemia and a breakdown in the blood–retinal barrier. Retinopathy is a major long-term complication of diabetes. It affects about 1 in 4 people with diabetes (Vision Australia Foundation, 2009). The development of retinopathy is strongly related to the length of time diabetes has been present and the degree of blood glucose control. Regular eye checks and treatment can help prevent retinopathy.

Retinopathy has three stages:

- *Stage I:* non-proliferative retinopathy. Dilated veins, microaneurysms, oedema of the macula and the presence of exudates characterise this stage.
- *Stage II:* pre-proliferative retinopathy. Retinal ischaemia causes infarcts of the nerve fibre layer, with characteristic 'cotton wool' patches on the retina. Shunts form between occluded and patent vessels.
- *Stage III:* proliferative retinopathy. As fibrous tissue and new vessels form in the retina or optic disc, traction on the vitreous humor may cause haemorrhage or retinal detachment.

After 20 years of diabetes, almost all people with type 1 DM and more than 60% of people with type 2 DM will have some degree of retinopathy, in most cases without vision loss (Wong et al., 2006). If exudate, oedema, haemorrhage or ischaemia

occurs near the fovea, the person experiences visual impairment at any stage. In addition, the person with diabetes is at increased risk of developing cataracts (opacity of the lens) as a result of increased glucose levels within the lens itself. Screening for retinopathy is important, as laser photocoagulation surgery has proven beneficial in preventing loss of vision. Indigenous Australians have an increased incidence and rate of new cases of diabetes-associated retinopathy; therefore, this population needs appropriate resources allocated and to be closely monitored and treated (Landers, Henderson & Craig, 2012).

Diabetic nephropathy

Diabetic nephropathy is a disease of the kidneys characterised by the presence of albumin in the urine, hypertension, oedema and progressive renal insufficiency. Diabetes is the fastest-growing cause of kidney failure. It is the leading cause of end-stage renal disease (ESRD). About 30% of people with diabetes will develop kidney disease (International Diabetes Federation, 2009).

Despite research, the exact pathological origin of diabetic nephropathy is unknown; it has been established, however, that thickening of the basement membrane of the glomeruli eventually impairs renal function. It has been suggested that an increased intracellular concentration of glucose supports the formation of abnormal glycoproteins in the basement membrane and mesangium. The accumulation of these large proteins stimulates glomerulosclerosis (fibrosis of the glomerular tissue). Glomerulosclerosis thickens the basement membrane and simultaneously makes it functionally leaky, allowing large molecules such as protein to be lost in the urine. *Kimmelstiel–Wilson syndrome* is a type of glomerulosclerosis found only in people with diabetes. In advanced nephropathy, tubular atrophy occurs and end-stage renal disease results. (Renal failure is discussed in Chapter 27.)

The first indication of nephropathy is **microalbuminuria**, a low but abnormal level of albumin in the urine. Without specific interventions, people with type 1 DM with sustained microalbuminuria will develop overt nephropathy, accompanied by hypertension, over a period of 10 to 15 years. People with type 2 DM often have microalbuminuria and overt nephropathy shortly after diagnosis, because the diabetes has often been present but undiagnosed for many years. Because the hypertension accelerates the progress of diabetic nephropathy, aggressive antihypertensive management should be instituted. Management includes control of hypertension with angiotensin-converting-enzyme (ACE) inhibitors such as captopril (Capoten), weight loss, reduced salt intake and exercise.

Alterations in the peripheral and autonomic nervous systems

Peripheral and visceral neuropathies are disorders of the peripheral nerves and the autonomic nervous system. In people with diabetes, these disorders are often called **diabetic neuropathies**. The aetiology of diabetic neuropathies involves: (1) a thickening of the walls of the blood vessels that supply nerves, causing a decrease in nutrients; (2) demyelinisation of the Schwann cells that surround and insulate nerves, slowing nerve conduction; and (3) the formation and accumulation of sorbitol within the Schwann cells, impairing nerve conduction. The manifestations depend on the locations of the lesions.

PERIPHERAL NEUROPATHIES

The peripheral neuropathies (also called *somatic neuropathies*) include polyneuropathies and mononeuropathies. *Polyneuropathies*, the most common type of neuropathy associated with diabetes, are bilateral sensory disorders. The manifestations appear first in the toes and feet and progress upward. The fingers and hands may also be involved, but usually only in the later stages of diabetes. The manifestations of polyneuropathy depend on the nerve fibres involved.

The person with polyneuropathy commonly has distal paraesthesias (a subjective feeling of a change in sensation, such as numbness or tingling); pain described as aching, burning or shooting; and feelings of cold feet. Other manifestations may include impaired sensations of pain, temperature, light touch, two-point discrimination and vibration. There is no specific treatment for polyneuropathy.

Mononeuropathies are isolated peripheral neuropathies that affect a single nerve. Depending on the nerve involved, manifestations may include the following:

- palsy of the third cranial (oculomotor) nerve, with headache, eye pain and an inability to move the eye up, down or medially
- radiculopathy, with pain over a dermatome and loss of cutaneous sensation, most often located in the chest
- diabetic femoral neuropathy, with motor and sensory deficits (pain, weakness, areflexia) in the anterior thigh and medial calf
- entrapment or compression of the medial nerve at the wrist, resulting in carpal tunnel syndrome, with pain and weakness of the hand; the ulnar nerve at the elbow, with weakness and loss of sensation over the palmar surface of the fourth and fifth fingers; and the peroneal nerve at the head of the fibula, with foot drop.

VISCERAL NEUROPATHIES

The visceral neuropathies (also called autonomic neuropathies) cause various manifestations, depending on the area of the ANS involved. These neuropathies may include the following:

- Sweating dysfunction, with an absence of sweating (*anhydrosis*) on the hands and feet and increased sweating on the face or trunk.
- Abnormal pupillary function, most commonly seen as constricted pupils that dilate slowly in the dark.
- Cardiovascular dysfunction, resulting in such abnormalities as a fixed cardiac rate that does not change with exercise, postural hypotension, and a failure to increase cardiac output or vascular tone with exercise.
- Gastrointestinal dysfunction, with changes in upper gastrointestinal motility (*gastroparesis*) resulting in dysphagia, anorexia, heartburn, nausea and vomiting, and altered blood glucose control. Constipation is one of the most common gastrointestinal symptoms associated with diabetes, possibly a result of hypomotility of the bowel. Diabetic diarrhoea is not as common, but it does occur and is often

associated with faecal incontinence during sleep due to a defect in internal sphincter function.
- Genitourinary dysfunction, resulting in changes in bladder function and sexual function. Bladder function changes include an inability to empty the bladder completely, loss of sensation of bladder fullness and an increased risk of urinary tract infections. Sexual dysfunctions in men include ejaculatory changes and impotence. Sexual dysfunctions in women include changes in arousal patterns, vaginal lubrication and orgasm. Alterations in sexual function in people with diabetes are the result of both neurological and vascular changes.

Mood alterations

People with DM, both type 1 and type 2, endure the chronic strains of living with complex self-care and are at a somewhat increased risk of depression, which can negatively affect management of DM. Treating depression has been associated with better control of serum glucose, so screening for depression is an important part of assessing the individual's ability to manage the disease. Diabetes Australia (2012) reports the risk of depression more than doubles in people with diabetes. Nurses can assist depressed people by correcting misconceptions about depression, identifying individual strengths in managing diabetes, acknowledging negative feelings that may be expressed and suggesting problem-solving behaviours to better manage the disease.

Increased susceptibility to infection

The person with diabetes has an increased risk of developing infections. A combination of vascular insufficiency, neuropathies and systemic and local immunological dysfunction as well as hyperglycaemia and altered neutrophil function are believed to play a role in higher infection risks in people with diabetes (Porth & Matfin, 2009; Weintrob & Sexton, 2012).

The person with diabetes may have sensory deficits resulting in inattention to trauma and vascular deficits that decrease circulation to the injured area; as a result, the normal inflammatory response is diminished and healing is slowed. Nephrosclerosis and inadequate bladder emptying with retention of urine predispose the person with diabetes to pyelonephritis and urinary tract infections. Bacterial and fungal infections of the skin, nails and mucous membranes are common. Tuberculosis is more prevalent in people with diabetes than in the general population. Hospitalised people with a blood glucose value greater than 12 mmol/L have higher infection rates (AIHW, 2008).

Periodontal disease

Although periodontal disease does not occur more often in people with diabetes, it does progress more rapidly, especially if the diabetes is poorly controlled. It is believed to be caused by microangiopathy, with changes in vascularisation of the gums. As a result, gingivitis (inflammation of the gums) and periodontitis (inflammation of the bone underlying the gums) occur.

Complications involving the feet

The high incidence of both amputations and problems with the feet in people with diabetes is the result of angiopathy, neuropathy and infection. People with diabetes are at high risk of amputation of a lower extremity, with increased risk in those who have had DM for more than 10 years, are male, have poor glucose control or have cardiovascular, retinal or renal complications.

MANIFESTATIONS Peripheral vascular disease

- Loss of hair on lower leg, feet and toes
- Atrophic skin changes: shininess and thinning
- Cold feet
- Feet and ankles darker than leg
- Dependent rubor, blanching on elevation
- Thick toenails
- Diminished or absent pulses
- Nocturnal pain
- Pain at rest, relieved by standing or walking
- Intermittent claudication
- Patchy areas of gangrene on feet and toes

Vascular changes in the lower extremities of the person with diabetes result in arteriosclerosis. Diabetes-induced arteriosclerosis tends to occur at an earlier age, occurs equally in men and women, is usually bilateral and progresses more rapidly. The blood vessels most often affected are located below the knee. Blockages form in the large, medium and small arteries of the lower legs and feet. Multiple occlusions with decreased blood flow result in the manifestations of peripheral vascular disease (see the accompanying box). Peripheral vascular disease is discussed in Chapters 28 and 31.

Diabetic neuropathy of the foot produces multiple problems. Because the sense of touch and perception of pain are absent, the person with diabetes may have some type of foot trauma without being aware of it. The person thus is at increased risk of trauma to tissues of the feet, leading to ulcer development. Infections commonly occur in traumatised or ulcerated tissue (see Figure 19.5).

Despite the many potential sources of foot trauma in the person with diabetes, the most common are cracks and fissures caused by dry skin or infections such as athlete's foot, blisters caused by improperly fitting shoes, pressure from stockings or shoes, ingrown toenails and direct trauma (cuts, bruises or burns). It is important to remember that the person with diabetic neuropathy who has lost the perception of pain may not be aware that these injuries have occurred. In addition, when a part of the body loses sensation, the person tends to dissociate from or ignore the part, so that an injury may go unattended for days or weeks. The injury may even be forgotten entirely.

Foot lesions usually begin as a superficial skin ulcer. In time, the ulcer extends deeper into muscles and bone, leading to abscess or osteomyelitis. Gangrene can develop on one or more toes; if untreated, the whole foot eventually becomes gangrenous. (Care of the feet, an essential part of health education for the person and family, is discussed later in the chapter.)

Nursing care

The responses of the person with diabetes to the illness are often complex and individual, involving multiple body systems. Assessments, planning and implementation differ for the person with newly diagnosed diabetes, the person with long-term diabetes and the person with acute complications of diabetes. The plan of care and content of teaching also differ according to the type of diabetes, the person's age and culture, and their intellectual, psychological and social resources. However, nursing care often focuses on teaching the person to manage the illness. The 'Translation to practice' box below describes a study of quality of life in people with diabetes.

Health promotion

Health promotion activities primarily focus on preventing the complications of diabetes. Prevention of the disease has not been determined, although it is recommended that all people should prevent or decrease excess weight, follow a sensible and well-balanced diet, and maintain a regular physical exercise program. Blood glucose screening at 1–3-year intervals beginning at age 45 is recommended for those in the high-risk groups. These same activities, when combined with medications and self-monitoring, are also beneficial in reducing the onset of complications.

Assessment

The following data are collected through the health history and physical examination (see Chapter 17). Further focused assessments are described with nursing interventions in the following text. When assessing the older person, be aware of normal ageing changes in all body systems that may alter interpretation of findings.

- *Health history:* family history of diabetes; history of hypertension or other cardiovascular problems; history of any change in vision (e.g. blurring) or speech, dizziness, numbness or tingling in hands or feet; pain when walking; frequent voiding; change in weight, appetite, infections and healing; problems with gastrointestinal function or urination; or altered sexual function.
- *Physical assessment:* height/weight ratio, vital signs, visual acuity, cranial nerves, sensory ability (touch, hot/cold, vibration) of extremities, peripheral pulses, skin and mucous membranes (hair loss, appearance, lesions, rash, itching, vaginal discharge).

Nursing diagnoses and interventions

Although many different nursing diagnoses are appropriate for the person with diabetes, those discussed in this section address problems with skin integrity, infection, injury, sexuality, coping and health maintenance. The goals of care are to maintain function, prevent complications and teach self-management. See the accompanying 'Nursing care plan' for more information.

Risk of impaired skin integrity related to diabetic neuropathies

The person with diabetes is at increased risk of altered skin integrity as a result of decreased or absent sensation from neuropathies, decreased tissue perfusion from cardiovascular complications and infection. Impaired skin and tissue integrity, with resultant gangrene, is especially common in the feet and lower extremities.

Conduct baseline and ongoing assessments of the feet, including:

- musculoskeletal assessment that includes foot and ankle joint range of motion, bone abnormalities (bunions, hammer toes, overlapping digits), gait patterns, use of assistive devices for walking and abnormal wear patterns on shoes
- neurological assessment that includes sensations of touch and position, pain and temperature
- vascular examination that includes assessment of lower extremity pulses, capillary refill, colour and temperature of skin, lesions and oedema
- hydration status, including dryness or excessive perspiration
- lesions, fissures between toes, corns, calluses, plantar warts, ingrown or overgrown toenails, redness over pressure points, blisters, cellulitis or gangrene.

People with diabetes are at significant risk of lower-extremity gangrene. Peripheral neuropathies may result in alterations in the perception of pain, loss of deep tendon reflexes, loss of cutaneous pressure and position sensation, foot drop, changes in the shape of the foot and changes in bones and joints. Peripheral vascular disease may cause intermittent claudication, absent pulses, delayed venous filling on

TRANSLATION TO PRACTICE Evidence-based practice: diabetes: a national health priority

Diabetes is endemic in Australia and this chronic condition creates challenges for the individual, carers and healthcare providers. For the sufferers of diabetes and their families, the condition poses significant emotional, psychological and financial stress (Colagiuri et al., 2009). For the healthcare system, the significance is in the rising costs of treatment and the challenge of prevention of type 2 diabetes mellitus in particular. Sufferers of type 1 diabetes mellitus are generally young people who need support and education to transition to management of the condition as adults.

The consensus among experts is that patient education is pivotal to ensuring effective management of the condition and reducing healthcare costs (Callister, 2011; Colagiuri et al., 2009). The aim is to reduce the stressors to the individual and their carers, and to reduce the cost of healthcare services to both the sufferers of diabetes and the wider Australian community.

The Australian federal government has classified diabetes mellitus, in particular type 2 diabetes mellitus (which constitutes 85% of diagnosed cases), as a national health priority because of its significant impact on the health status and health economy of Australia (AIHW, 2011; Colagiuri, et al., 2009).

The *National Evidenced Based Guideline for Patient Education in Type 2 Diabetes* and the *National Evidence-based Clinical Care Guidelines for Type 1 Diabetes in Children, Adolescents and Adults* are evidence-based tools for healthcare providers in Australia to create a uniform support network for persons with diabetes and their carers.

Literature reviewed in these guidelines agree that the individual's active participation in goal setting and decision making is paramount to the success of management of diabetes and reducing complications which in turn would reduce the burden of cost to the healthcare system (Colagiuri et al., 2009). Dijkstra et al. (2006), Ragucci et al. (2005), Smart et al. (2009) and Wolfe et al. (2004) (as cited in Colagiuri et al., 2009) are examples of studies that identified the input of professionals such as pharmacists and dietitians to discuss medication management and lifestyle changes as a cost-effective method of delivery of information to the patient. The focus for type 1 diabetes mellitus patients was to support psychological and behaviour states of young children and adults in order to improve knowledge and self-management skills so as to transition to adulthood with less stress (Callister, 2011).

Diabetes is a multifaceted condition that requires a multidisciplinary approach to support the individual and carers. The nurse's involvement is to advocate for and support the individual in the management of diabetes. The role of the nurse is also pivotal to the prevention of type 2 diabetes.

IMPLICATIONS FOR NURSING

All teaching plans should be individualised and developed in collaboration with the person. Nurses often focus on diabetes management and control, especially compliance with prescribed regimens. Although people are sometimes termed 'non-compliant', this term conveys judgment about dependence. A focus on individualised education based on assessment of individual needs facilitates higher levels of compliance and improved self-care. It is important also to understand that self-control behaviours can change with variations in life and the disease itself, and that each person with diabetes responds uniquely to situations and interventions. Respecting and valuing what a person has learned from living with diabetes is critical to providing effective care.

CRITICAL THINKING IN PERSON-CENTRED CARE

1. You are caring for two people with diabetes who are receiving home care for complications of long-term diabetes. One person follows the medical regimen faithfully; the other adapts it to his own schedule and needs. What differences can you identify in your own reaction to these two different people? How would these reactions affect your relationship with the people?
2. Imagine you have just been diagnosed with type 1 diabetes. Make a list of the questions you would have and the areas that would cause you the most difficulty in complying with your medical care.
3. How would you respond if the person tells you, 'Sometimes I eat whatever I want to for several days.'? What do you think this behaviour indicates?

elevation, dependent rubor and gangrene. Injuries, lesions and changes in skin hydration potentiate infections, delayed healing and tissue loss in the person with diabetes mellitus.

- Teach foot hygiene. Wash the feet daily with lukewarm water and mild hand soap; pat dry and dry well between the toes. Apply a very thin coat of lubricating cream if dryness is present (but not between the toes). *Proper hygiene decreases the chance of infection. Temperature receptors may be impaired, so the water should always be tested before use.*

CONSIDERATION FOR PRACTICE

Teach the person with diabetes to always test the water temperature in the shower or bath before stepping in.

- Discuss the importance of not smoking if the person smokes. *Nicotine in tobacco causes vasoconstriction, further decreasing the blood supply to the feet.*
- Discuss the importance of maintaining blood glucose levels through prescribed diet, medication and exercise. *Hyperglycaemia promotes the growth of microorganisms.*
- Conduct foot care teaching sessions as often as necessary (see the box below). Include information about proper shoe fit and composition, avoiding clothing or activities that decrease circulation to the feet, foot inspections, care of toenails and the importance of obtaining medical care for lesions. If the person has visual deficits, is obese or cannot reach the feet, teach the caregiver how to inspect and care for the feet. Feet should be inspected daily. *Foot care is a*

NURSING CARE PLAN A person with type 1 diabetes

Jim Meligrito, aged 24, is a third-year nursing student at a large university. Mr Meligrito also works 20 hours a week as an on-campus security guard. His working hours are 8 pm to midnight, 5 nights a week. He lives with his father, who is also a student. Neither of the two men likes to cook and they usually eat 'whatever is handy'. Mr Meligrito has smoked 8 to 10 cigarettes a day for 5 years. He was diagnosed with type 1 diabetes mellitus at age 12. Although his insulin dosage has varied, he currently takes a total of 52 units of insulin each day, 8 units of Humalog (insulin lispro) three times per day, before each meal, and 28 units of Lanctus (glargine insulin) at different times in the evenings or before bed. He monitors his blood glucose about three times a week. He feels that he is too busy for a regular exercise program and that he gets enough exercise at work and in weekend sports activities. He has not seen a healthcare provider for over a year.

One day during a 6-hour clinical laboratory in paediatrics, Mr Meligrito notices that he is urinating frequently, is thirsty and has blurred vision. He is also very tired but blames all his symptoms on drinking a couple of beers and having had only 4 hours' sleep the night before while studying for an examination, and the stress he has been under lately from his studies and work. When he remembers that he had forgotten to take his insulin that morning, he realises he must have hyperglycaemia but decides that he will be all right until he gets home in the afternoon. Around noon, he begins having abdominal pain, feels weak, has a rapid pulse and vomits. When he reports his physical symptoms to his clinical facilitator, she sends him immediately to the hospital emergency department, accompanied by another student.

ASSESSMENT

As soon as Mr Meligrito arrives at the emergency room, his blood glucose level is measured at 17.0 mmol/L. Urine samples and additional blood samples are sent to the laboratory for analysis. Blood glucose is 18.3 mmol/L, urine shows the presence of ketones, electrolytes are normal and pH is 7.1. His vital signs are as follows: T 37.2°C, P 140, R 28 and BP 102/52. An intravenous infusion of 1000 mL normal (0.9%) saline with 40 mmol of KCl is started at a rate of 400 mL/h. Intravenous regular insulin at 5 units/h (diluted in 0.9% saline) is begun. Hourly blood glucose monitoring is initiated. Mr Meligrito is nauseated and lethargic but remains oriented. Five hours later, he has a blood glucose level of 9.0 mmol/L and his pulse and blood pressure are normal. Now there are no ketones in the urine, his vital signs, including his glucose level, are within normal parameters and he has no signs of metabolic acidosis. He is discharged from the hospital after seeing the hospital's diabetes nurse educator. When he meets with the diabetes educator, he says that he no longer feels in control of the diabetes or his future goal to become an anaesthetic nurse.

DIAGNOSES

- *Powerlessness* related to a perceived lack of control of his diabetes due to present demands on time.
- *Deficient or poor knowledge* of self-management of diabetes.
- *Risk of ineffective role performance* related to uncertainty about capacity to achieve desired role as a registered nurse.

PLANNING

- Mutually establish specific and individualised short-term and long-term goals for self-management to control blood glucose.
- Assess his level of knowledge and establish his needs to develop a program of education in different aspects of diabetes.
- Determine the need and plan referrals to appropriate support health allies such as dietitian, educator, psychologist, counsellor, etc.

Expected outcomes

- Identify those aspects of diabetes that can be controlled and participate in making decisions about self-managing care.
- Demonstrate an understanding of diabetes self-management through planned medication, diet, exercise and blood glucose self-monitoring activities.
- Explore and clarify Mr Meligrito's perceptions of his role as a student nurse, verbalising his ability to meet his expectations.

IMPLEMENTATION

- Provide opportunities to express his feelings about himself and his illness.
- Explore perceptions of his own ability to control his illness and his future, and clarify these perceptions by providing information about resources and support groups.
- Facilitate decision-making abilities in self-managing his prescribed treatment regimen.
- Provide positive reinforcement for increasing involvement in self-care activities.
- Provide relevant learning activities about insulin administration, dietary management, exercise, self-monitoring of blood glucose and healthy lifestyle.

EVALUATION

After taking an active part in the weekly educational meetings for 2 months, Mr Meligrito has greatly enhanced his understanding of and compliance with self-management of his diabetes. He states that he finally understands how insulin, food and exercise affect his body, having previously thought they were 'just things I should do when I wanted to'. He decides to perform self-management activities 1 week at a time, rather than think too far into (and thereby feel overwhelmed by) the future. Both son and father have developed a workable meal schedule and weekly grocery list and they have begun eating breakfast and dinner together. Jim and a friend have arranged to walk 5 to 10 km three times a week on a hiking trail. To gain a sense of control over his illness, he has also worked out a schedule that allows time for university, work, healthcare and himself.

CRITICAL THINKING IN THE NURSING PROCESS

1 What is the pathophysiological basis for the changes in temperature, pulse, respirations and blood pressure that

(continued)

occurred on Mr Meligrito's admission to the hospital emergency department?
2 How can poor self-management of diabetes increase the risk of long-term complications?
3 Is powerlessness a common response to a chronic illness? Why or why not?
4 Consider that you are teaching Mr Meligrito and another person, Mr McDaniel (aged 75, newly diagnosed with type 2 DM). What components of your teaching plan would be the same and what components would be different?

REFLECTION ON THE NURSING PROCESS

1 List the aspects that you have learned from this scenario that you will apply to your future clinical practice when caring for a person with poorly controlled diabetes.
2 Detail how you would approach and communicate with a person who has poor management of their diabetes in order to provide advice and education.

priority in diabetes management to prevent serious problems. Many people with diabetes are unaware of lesions or injury until infection and compromised circulation are far advanced. The hows and whys of each component must be included in teaching. A variety of methods may be used, including demonstration, return demonstration, audiovisual aids and written lists. If the person is wearing shoes and socks, ask them to remove them to practise foot care effectively.

Risk of infection

The person with diabetes is at increased risk of infection; this is believed to be due to vascular insufficiency that limits the inflammatory response, neurological abnormalities that limit the awareness of trauma and a predisposition to bacterial and fungal infections.

- Use and teach meticulous handwashing. *Handwashing is the single most effective method for preventing the spread of infection.*
- Monitor for manifestations of infection: increased temperature, pain, malaise, swelling, redness, discharge, cough. *Early diagnosis and treatment of infections can control their severity and decrease complications.*
- Discuss the importance of skin care. Keep the skin clean and dry, using lukewarm water and mild soap. *People with diabetes are more prone to develop furuncles and carbuncles; the infection often increases the need for insulin.*

MEETING INDIVIDUALISED NEEDS Foot care teaching session

Buying and wearing shoes and stockings

- Shoes that allow 1 to 2 cm of toe room are best; there should be room for toes to spread out and wiggle. The lining and inside stitching should be smooth and the insole soft. The sole should be flexible and cushion the foot. The heel should fit snugly and the arch support should give good support.
- Do not wear open-toed shoes, sandals, high heels or thongs; they increase the risk of trauma.
- Buy shoes late in the afternoon, when feet are at their largest; always buy shoes that feel comfortable and do not need to be 'broken in'.
- Shoes made of natural fibres (leather, canvas) allow perspiration to escape.
- Check the shoes before each wearing for foreign objects, wrinkled insoles and cracks that might cause lesions.
- Stockings made of wool or cotton allow perspiration to dry.
- Do not wear garters, knee stockings or pantyhose; they may interfere with circulation.
- Wear insulated boots in the winter.

Inspecting the feet

- Check the feet daily for red areas, cuts, blisters, corns, calluses or cracks in the skin. Check between the toes for cracks or reddened areas.
- Check the skin of the feet for dry or damp areas.
- Use a mirror to check each sole and the back of each heel.
- If you are unable to inspect the feet daily, be sure that someone else does so.

Care of toenails

- Cut the toenails after washing, when they are softer and easier to trim.
- Cut the nails straight across with a nail clipper and smooth edges and corners with an emery board.
- Do not use razor blades to trim the toenails.
- If you are unable to see well or to reach the feet easily, have someone else trim the nails. If the nails are very thick or ingrown, if the toes overlap or if circulation is poor, get professional care from a podiatrist.

General information

- Never go barefoot. Wear slippers when leaving the bed during the night.
- Do not use commercial corn medicines or pads, chemicals (such as boric acid, iodine or hydrogen peroxide) or over-the-counter cortisone medications on the feet.
- Do not put heating pads, hot water bottles or ice packs on the feet. If the feet become cold at night, wear socks or use extra blankets.
- Do not allow the feet to become sunburned.
- Do not put tape on the feet.
- Do not sit with the legs crossed at the knees or ankles.

Clean, intact skin and mucous membranes are the first line of defence against infection.

- Teach dental health measures:
  - Obtain a dental examination every 4 to 6 months.
  - Maintain careful oral hygiene, which includes brushing the teeth with a soft toothbrush and fluoridated toothpaste at least twice a day and flossing as recommended.
  - Be aware of the symptoms requiring dental care: bad breath; unpleasant taste in the mouth; bleeding, red or sore gums; and tooth pain.
  - If dental surgery is necessary, monitor for need to make adjustments in insulin. All people with diabetes need to be taught proper oral hygiene, and about the risk of periodontal disease and the importance of obtaining dental care for symptoms of oral or dental problems.
- Teach women with diabetes the symptoms and preventive measures for vaginitis caused by *Candida albicans*. The symptoms are an odourless, white or yellow cheese-like discharge and itching. Sexual transmission is unlikely, but discomfort may cause the person to avoid sexual activity. *Diabetes is a predisposing factor for* Candida albicans *vaginitis, the most common form of vaginitis. Poor personal hygiene and wearing clothing that keeps the vaginal area warm and moist increase the risk of vaginitis. The infection may spread to the urinary tract, resulting in urinary tract infections; preventing and treating vaginitis decrease this risk.*

CONSIDERATION FOR PRACTICE

Teach women with DM to take preventive measures by maintaining good personal hygiene, wiping front to back after voiding, wearing cotton underwear, avoiding tight jeans and nylon pantyhose, and avoiding douching.

Risk of injury related to neuropathies, visual deficit, hyperglycaemia

The person with diabetes is at risk of injury from multiple factors. Neuropathies may alter sensation, gait and muscle control. Cataracts or retinopathy may cause visual deficits. Hyperglycaemia often causes osmotic changes in the lenses of the eye, resulting in blurred vision. In addition, changes in blood glucose alter levels of consciousness and may cause seizures. The impaired mobility, sensory deficits and neurological effects of complications of diabetes increase the risk of accidents, burns, falls and trauma.

- Assess for the presence of contributing or causative factors that increase the risk of injury: blurred vision, cataracts, decreased adaptation to the dark, decreased tactile sensitivity, hypoglycaemia, hyperglycaemia, hypovolaemia, joint immobility, unstable gait. *A knowledge base is necessary to develop an individualised plan of care. The risk of injury increases with the number of factors identified.*
- Reduce environmental hazards in the healthcare facility and teach the person about safety in the home and in the community.

IN THE HEALTHCARE FACILITY

- Orient the person to new surroundings on admission.
- Keep the bed at the lowest level.
- Keep the floors free of objects.
- Use a night-light.
- Check the temperature of the bath or shower water before the person uses it.
- Instruct the person to wear shoes or slippers when out of bed.
- Monitor blood glucose levels regularly.
- Monitor for side effects of prescribed medications, such as dizziness or drowsiness.

IN THE HOME AND COMMUNITY

- Use a night-light, preferably one with a soft, no-glare bulb.
- Turn the head away when switching on a bright light.
- Avoid directly looking into headlights when driving at night.
- Test the temperature of the bath or shower water before use.
- Conduct a daily foot inspection.
- Wear shoes and slippers with non-skid soles.
- Do not use throw rugs.
- Install hand grips in the tub and shower and next to the toilet.
- Wear a seat belt when driving or riding in a car.

Strange environments and the presence of hazardous environmental factors increase the risk of falls or other accidents. Glare is often responsible for falls in people with visual deficits. The nurse can reduce factors that increase the risk of injury by implementing care and teaching safe practices during the activities of daily life.

- Monitor for and teach the person and family to recognise and seek care for the manifestations of DKA in the person with type 1 DM: hyperglycaemia, thirst, headaches, nausea and vomiting, increased urine output, ketonuria, dehydration and decreasing level of consciousness. *Blood glucose levels increase if the insulin need is unmet or insufficiently met; the cellular use of fats for fuel results in ketosis. Osmotic diuresis increases urinary output, resulting in thirst and dehydration.*

CONSIDERATION FOR PRACTICE

Make frequent assessments to monitor for symptoms of HHS in the older adult who has had major surgery.

- Monitor for and teach the person and family to recognise and seek care for the manifestations of HHS in the person with type 2 DM: extreme hyperglycaemia, increased urinary output, thirst, dehydration, hypotension, seizures and decreasing level of consciousness. *HHS is a life-threatening condition requiring recognition and treatment.*
- Monitor for and teach the person and family to recognise and treat the manifestations of hypoglycaemia: low blood glucose, anxiety, headache, uncoordinated movements, sweating, rapid pulse, drowsiness and visual changes. Teach the person and family to carry some form of rapid-acting sugar source at all times. *Severe hypoglycaemia causes a decrease in the level of consciousness. The decrease in blood glucose most often results from too much insulin, too little food or too much exercise.*

- Recommend that the person wear a MedicAlert® bracelet or necklace identifying self as a person with diabetes. *In case of sudden, severe illness or accident, a medical alert bracelet can allow immediate medical attention for diabetes to be instituted.*

Risk of sexual dysfunction related to peripheral neuropathy

Sexuality is a complex and inseparable part of every person. It involves not only physical sexual activities but also a person's self-perception as male or female, roles and relationships, and attractiveness and desirability. Changes in sexual function and in sexuality have been identified in both men and women with diabetes.

Alterations in erectile ability occur in approximately 50% of all men with diabetes. The incidence of impotence increases with the duration of the diabetes and is often associated with peripheral neuropathy. Libido is usually unaffected, even when impotence is present.

CONSIDERATION FOR PRACTICE

Sexual function is a private matter and people rarely share concerns unless the nurse initiates the discussion.

Women with diabetes also have alterations in sexual function, although the reason is less clear. The problems reported by women involve decreased desire and decreased vaginal lubrication. Women with diabetes are also at increased risk of vaginitis and may avoid sexual intercourse in order to avoid pain.

- Include a sexual history as a part of the initial and ongoing assessment of the person with diabetes. A specific history form may be used that addresses sexual development, personal and family values, current sexual practices and concerns, and changes desired. Ask a non-threatening, open-ended question to elicit information, such as: 'Tell me about your experience with sexual function since you have been diagnosed with diabetes.' *Obtaining accurate information to assess the sexual health of a person is necessary before counselling can begin or referrals can be made.*
- Provide information about the actual and potential physical effects of diabetes on sexual function. Include the effect of poor control of blood glucose on sexual function as part of any teaching plan. *People benefit from basic information about male and female anatomy and the sexual response cycle and how diabetes can affect this part of the body. Changes in blood glucose levels not only may cause changes in desire and physical response but also may alter sexual responses as a result of depression, anxiety and fatigue.*
- Provide counselling or make referrals as appropriate. The nurse is responsible for knowing about sexuality and sexual health throughout the lifespan and provides information based on knowledge of the effects of illness and treatment on sexual function. For example, men who are impotent may regain the ability to have sexual intercourse through penile implants, suction apparatus, the use of sildenafil citrate (Viagra) or injections of medications (such as yohimbine, an alpha-2 adrenergic blocker) that increase vascular blood flow into the corpus of the penis. Women with decreased vaginal lubrication can decrease painful intercourse by using vaginal lubricants (such as K-Y Jelly) or oestrogen creams.

  The nurse may make specific suggestions to facilitate positive sexual functioning, referring the person to the appropriate healthcare provider as necessary for intensive therapy.

Risk of ineffective coping related to the chronicity of diabetes

Coping is the process of responding to internal or environmental stressors or potential stressors. When coping responses are ineffective, the stressors exceed the individual's available resources for responding. The person diagnosed with diabetes is faced with lifelong changes in many parts of their life. Diet, exercise habits and medications must be integrated into the person's lifestyle and be carefully controlled. Daily injections may be a reality. Fear of potential complications and of negative effects on the future is common.

If the person is unable to cope successfully with these changes, emotional stress can interfere with glycaemic control. In addition, unsuccessful coping often results in non-compliance with prescribed treatment modalities, further impairing glycaemic control and increasing the potential for acute and chronic complications.

- Assess the person's psychosocial resources, including emotional resources, support resources, lifestyle and communication skills. *Chronic illness affects all dimensions of a person's life, as well as the lives of family members and significant others. A comprehensive assessment of strengths and weaknesses is the first step in developing an individualised plan of care to facilitate coping.*
- Explore with the person and family the effects (actual and perceived) of the diagnosis and treatment of diabetes on finances, occupation, energy levels and relationships. *Common frustrations associated with diabetes are the disease itself, the treatment modalities and the healthcare system. Effective coping involves maintaining a healthy self-concept and satisfying relationships, emotional balance and handling emotional stress.*
- Teach constructive problem-solving techniques. *Problem-focused behaviours include setting attainable and realistic goals, learning about all aspects of the problem, learning new procedures or skills that increase self-esteem and reaching out to others for support.*
- Provide information about support groups and resources, such as suppliers of products, journals, books and cookbooks for people with diabetes. *Sharing with others who have similar problems provides opportunities for mutual support and problem solving. Using available resources improves the ability to cope.*

Community-based care

Teaching the person and family to self-manage diabetes is a nursing responsibility. Even if a formal teaching plan is developed and implemented by advanced practice nurses, all nurses must be able to reinforce knowledge and answer questions. Teaching is necessary for both the person who is newly diagnosed and for the person who has had diabetes for years. In fact, the latter may need almost as much teaching as the newly diagnosed person. Products for diabetes care, especially insulins, have changed dramatically and knowledge about risk reduction to prevent complications has increased.

For the hospitalised person with diabetes, teaching should begin on admission. Prior to designing the teaching plan, the nurse makes an initial assessment of the person's and family's knowledge and learning needs, outlining past diabetes management practices and identifying physical, emotional and sociocultural needs. Educational level, preferred learning methods and style, life experiences and support systems are also assessed. According to Shrivastava, Shrivastava and Ramasava (2013), individuals who have been diagnosed with diabetes were shown to make a dramatic impact on the progression and development of their disease by being autonomous in their own care.

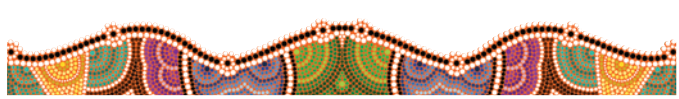
It is important that the nurse and person mutually establish goals based on the assessment data. It is equally important that family members understand that the responsibility for daily management lies with the person and that the primary role of the family is supportive. The person is the one who has the disease and who each day must take medications or inject insulin, test blood or urine, calculate and balance foods, exercise, adjust medications, inspect the body for injury and determine whether and when medical assistance is needed. However, family members require the same knowledge so that they can provide emotional support as well as physical care if necessary.

The following should be included in teaching the person and family about care at home.

- Information about normal metabolism, diabetes mellitus and how diabetes changes metabolism.
- Diet plan: how diet helps keep blood glucose in normal range; number of kilojoules required and why; amount of carbohydrates, meats and fats allowed, and why; and how to calculate the diet, integrating personal food preferences.
- Exercise: how it helps lower blood glucose; the importance of a regular program; types of exercise; integrating personal exercise preferences; how to handle increased activity.
- Self-monitoring of blood glucose: how to perform the tests accurately, how to care for equipment, what to do for high or low blood glucose.
- Medications:
  - Insulin: type, dosage, mixing instructions (if necessary), times of onset and peak actions, how to get and care for equipment, how to give injections, where to give injections.
  - Insulin: oral agents: type, dosage, side effects, interaction with other drugs.
- Manifestations of acute complications of hypoglycaemia and hyperglycaemia; what to do when they occur.
- Hygiene: skin care, dental care, foot care.
- Sick days: what to do about food, fluids and medications.
- Helpful resources:
  - Diabetes Australia: www.diabetesaustralia.com.au
  - Juvenile Diabetes Research Foundation Australia: www.jdrf.org.au
  - Koori Diabetes Services: www.archi.net.au/resources/chronic/disease/koori-diabetes
  - AIHW Diabetes, Australian Facts: www.aihw.gov.au/publication-detail/?id=6442468075
  - International Diabetes Federation: www.idf.org

Teaching may have to be adapted to the special needs of the older adult. Because 40% of all people with diabetes are over the age of 65, considering the special needs of this population is essential. Uncontrolled diabetes in the older adult increases the potential for functional loss, social disengagement and increased morbidity and mortality. Education for self-care allows the older adult to be more actively involved in their diabetes management and decreases the potential for acute and long-term complications from the disease. Considerations for teaching the older adult with diabetes include the following:

- Changes in diet may be difficult to implement for many reasons. Favourite foods are difficult to give up. Balanced meals at regular intervals may not have been part of the person's lifestyle. Purchasing, storing and preparing foods may be a problem. Dentures may not fit well. Changes in taste sensation often cause the person to increase the use of salt and sugar.
- Exercise of any type may not have been part of the activities of daily living. Exercise must be individualised for any physical limitations imposed by other chronic illnesses, such as arthritis, Parkinson's disease, chronic respiratory diseases and/or cardiovascular diseases.
- The diagnosis of a chronic illness threatens independence and self-worth. After years of taking care of self, the older adult with diabetes may now have to depend on others for help in meeting self-care needs. This in turn often leads to withdrawal from social interactions with others.
- Money to purchase medications and supplies often must be taken out of a fixed income.
- Visual deficits make insulin administration difficult or impossible. Visual deficits also interfere with blood glucose monitoring, food preparation, exercises and foot care.



CHAPTER HIGHLIGHTS

- The incidence of type 2 DM is increasing in epidemic proportions in all racial and ethnic groups globally.
- About 1 million Australians are diagnosed with diabetes and it is estimated that one person is diagnosed every 7 minutes.
- Type 2 diabetes represents a serious public health problem for Indigenous Australians, occurring at a much higher rate than in the non-Indigenous population. Aboriginal and Torres Strait Islander people have the fourth-highest rate of type 2 diabetes in the world.
- Type 2 DM has a hereditary link and is characterised by obesity and sedentary lifestyles. Unlike type 1 DM, in which the onset is often sudden, the development of symptoms that bring people to their healthcare providers for evaluation is slow; it is estimated that 50% of newly diagnosed type 2 DM people have already developed complications secondary to hyperglycaemia.
- Tighter, more intensive glycaemic control is increasingly the focus of care for hospitalised people with hyperglycaemia. Correcting hyperglycaemia is considered a benefit to diabetics and non-diabetics alike.
- New products for people with DM include insulins, non-insulin hypoglycaemics, insulin delivery devices such as pens and pumps, and blood glucose and ketone monitoring devices. Nurses must be familiar with these products and help people with diabetes become proficient in their use.
- Motivation for self-care by the person with diabetes continues to be a challenge because treatment commonly includes lifestyle changes. Through education and support, people can achieve control of DM and avoid complications.

CONCEPT CHECK

1 Increased susceptibility to the development of type 1 diabetes is indicated by which of the following?
1. genetic markers that determine immune response
2. persistent obesity throughout the adolescent years
3. delivery of a baby that weighs less than 2.7 kg
4. excessive amounts of plasma glucagon

2 Diabetic ketoacidosis is the result of which pathological process?
1. An excess amount of insulin drives all glucose into the cells.
2. A decreased amount of glucagon causes low protein levels.
3. A deficit of insulin causes fat stores to be used as an energy source.
4. An increase occurs in the breakdown of glucose molecules with hypoglycaemia.

3 Which of the following people would be most at risk of the development of type 2 DM?
1. young adult who is a professional basketball player
2. middle-aged man who maintains normal weight
3. middle-aged woman who is the sole caretaker of her parents
4. woman over age 70 who is overweight and sedentary

4 You are assigned a person who has a nursing diagnosis of *peripheral neurovascular dysfunction* involving both feet. Which of the following assessments would support this diagnosis?
1. normal sensation to touch
2. loss of normal reflexes
3. states, 'I can't feel my feet any more.'
4. states, 'I have been having chest pain.'

5 Which of the following statements would indicate the person understands teaching about foot care at home?
1. 'I will walk barefooted as long as I am in the house.'
2. 'I always buy my shoes as soon as the stores open.'
3. 'I will check my feet for cuts and bruises every night.'
4. 'If I get a blister, I just put alcohol on it and bandage it.'

6 Lantus insulin, a long-acting insulin, has a unique insulin characteristic that increases the risk of administration error. The nurse understands that this long-acting insulin is:
1. combined with glucose to raise energy levels
2. subject to being inactivated by light
3. a clear solution like regular insulin, unlike intermediate and long-acting insulins
4. activated by vigorous agitation

7 The nurse is preparing an insulin infusion for a person in diabetic ketoacidosis (DKA). She is careful to select the only type of insulin that can be administered intravenously, which is:
1. Lantus
2. Actrapid
3. regular
4. Humalog

8 Glycosylated haemoglobin (HbA1c) is useful for evaluating the degree of blood glucose control the person with diabetes has been maintaining for the previous 2 to 3 months. The American Diabetes Association recommended goal for HbA1c in the general population with diabetes is:
1. > 10%
2. > 8%
3. < 7%
4. < 3%

9 Subcutaneous injections of insulin can be made in several locations in the body. The nurse teaches the person that the most predictable absorption occurs in the:
1. hip
2. thigh
3. deltoid
4. abdomen

UNIT 5 BUILDING CLINICAL COMPETENCE
Responses to altered endocrine function

CLINICAL SCENARIO

In the afternoon shift you are looking after two people that have been admitted to your ward earlier in the day:

- Mrs Kelly Ly is a 47-year-old Vietnamese woman who has limited English. She is accompanied by her husband and her son who is helping with English translation when necessary. Mrs Ly has been admitted from the emergency department with increased confusion, agitation, nausea and vomiting, tachycardia, hypertension and weight loss. She has a history of Graves' disease, diagnosed 2 years ago on her arrival to Australia from Vietnam. On your assessment her observations are T 38.9°C, P 119, R 30, BP 171/83. Her blood glucose level is 3.7 mmol/L. She is anxious, agitated, her hands are shaking and she is complaining of abdominal pain and wanting to vomit. Her son told you that she is 'not herself' and she is 'confused'.
- Colin is 17 years old. He has had diabetes type 1 since he was 10 years old. He was transferred from the High Dependency Unit this morning. He is recovering from diabetic ketoacidosis (DKA) after falling ill with a severe chest infection. His vital signs are T 37.1°C, P 85, R14, BP 112/55. His blood sugar level is 7.9 mmol/L 2 hours after lunch. Colin says that he is feeling better but still coughing. He has two cannulaes for intravenous antibiotics. You performed a urinalysis that showed glucose + and ketones trace. Colin still has an indwelling catheter (IDC) and asks you when he can have it removed.

Critical thinking questions

1 After your assessment and above findings, which person needs your immediate attention? Provide the rationale for your decision.

2 What do you think is occurring for Mrs Ly? Explain the signs and symptoms that she is showing and relate them to her diagnosis of Graves' disease.

3 Mrs Ly may be showing other significant signs and symptoms of hyperthyroidism. List them according to body systems.

4 What are the main nursing diagnoses for Mrs Ly? List your immediate actions.

5 Mrs Ly is very likely to be experiencing a thyroid crisis, which is a medical emergency. Thyroid crisis or thyroid storm can be defined as:

1. extreme hypothyroidism
2. excess production of parathyroid hormone (PTH)
3. low production of thyroid hormone (TH)
4. excess production of TH

6 Mrs Ly has been experiencing difficulty fully closing her eyelids for a few months. What is the possible cause for this?

1. goitre
2. pretibial myxoedema
3. proptosis
4. amenorrhoea

7 Mrs Ly has recovered with medication management and discharge planning is in progress as she may be discharged home tomorrow. Develop a discharge plan, taking into consideration her ethnic background and limited English. Include in your plan some education in relation to follow-up care, management and prevention of complications in Graves' disease.

8 Colin is upset because he feels that he has always done the best to manage his diabetes and he still got DKA. Explain DKA to Colin and how it occurred when he got the chest infection.

9 The doctor has told Colin that he would like to leave the IDC in until there are no ketones present in the urine and this is likely to occur soon. What is the reason for ketones to be present in Colin's urine?

1. Ketones are the product of glucose breakdown that is excreted in the urine.
2. They are the product of fat breakdown excreted in the urine.
3. Polyuria causes dehydration that leads to ketones in the urine.
4. It is normal to have presence of ketones in the urine when there is glucose as well.

10 Colin presented to the hospital with a sugar level of 30 mmol/L. He was rehydrated, electrolyles were replaced and he was commenced on insulin and then dextrose intravenously. Why is it essential to reduce the blood sugar level slowly and gradually at that stage of DKA?

11 Colin's glycosylated haemoglodin or HbA1c come back at 9%. Explain glycosylated haemoglobin and what this result means.

12 If Colin gets an episode of hypoglycaemia with a glucose level of 2.7 mmol/L, which signs and symptoms might he experience?

1. bradycardia, nausea, vomiting
2. polyuria, polydipsia, polyphagea
3. diarrhoea, nausea, thirst
4. hypotension, tachycardia, profuse sweating

13 Colin is preparing for dinner and needs to have his Humalog injection. When does he need to take his insulin?

1. 30 minutes before he starts eating
2. immediately after he finishes his meal
3. immediately before he starts eating
4. 1 hour before his meal

CASE STUDY

Mr Lewis is a 70-year-old Aboriginal male who was admitted with health problems of increased urination, increased thirst, fatigue, blurred vision and numbness in his feet. He states that he retired 9 months ago after 45 years as a construction worker. He now leads a sedentary lifestyle and doesn't have as much energy as he used to have. He has gained 14 kg since retirement. Upon assessment,

Mr Lewis weighs 116 kg and is 180.5 cm tall. Vital signs are T 37°C, P 88, R 20 and BP 150/90. Decreased pulses are palpated in dorsal pedalis and posterior tibial pulses. Both feet are cool to touch with slow capillary refill in toes. The following laboratory studies are ordered to confirm the diagnosis of type 2 diabetes mellitus: plasma glucose concentration, fasting blood glucose and oral glucose tolerance test.

Type 2 diabetes mellitus is a disease of fasting hyperglycaemia despite the production of some insulin by the beta cells of the pancreas. The level of insulin production varies, affecting the amount available for cellular metabolism.

With increased age, sedentary lifestyle and obesity, cells become resistant to insulin. The uptake of glucose by muscle and fat cells is not sufficient to lower the blood glucose. In obesity, insulin has a decreased ability to influence glucose metabolism and affect the uptake of glucose by cells in the liver, skeletal muscles and adipose tissue, resulting in a high blood glucose level.

The manifestations of type 2 diabetes mellitus include polyuria, polydipsia, blurred vision, fatigue, paraesthesias and skin infections. In times of physical or emotional stress, the person may develop a hyperosmolar hyperglycaemic state (HHS). Complications of type 2 diabetes mellitus include coronary heart disease (myocardial infarction), hypertension, stroke, peripheral vascular disease (atherosclerosis, vascular insufficiency, amputations), end-stage renal disease (nephropathy) and blindness (retinopathy).

Based on Mr Lewis's manifestations and weight gain, a priority nursing diagnosis of *Imbalanced nutrition: more than body requirements* is appropriate for guiding nursing care for this person.

UNIT 6

RESPONSES TO ALTERED GASTROINTESTINAL FUNCTION

CHAPTER 20

A PERSON-CENTRED APPROACH TO ASSESSING THE GASTROINTESTINAL SYSTEM

NICOLE KNOX

KEY TERMS

LEARNING OUTCOMES

- Describe the sources of nutrients and their functions in the human body.
- Describe the anatomy, physiology and functions of the gastrointestinal system and accessory digestive organs.
- Discuss rationales for questions included in a health assessment interview of a person with nutritional and gastrointestinal disorders.
- Explain techniques used for assessing nutritional status and gastrointestinal function.

CLINICAL COMPETENCIES

- Conduct and document a health history for people who have or are at risk of alterations in nutrition and gastrointestinal function.
- Conduct and document a physical assessment of nutritional status and the gastrointestinal system.
- Monitor the results of diagnostic tests and report abnormal findings.

EQUIPMENT NEEDED

- Stethoscope
- Weight scale with height measuring attachment
- Tape measure
- Skinfold calipers
- Water-soluble lubricant
- Faecal occult blood test kit (FOBT)
- Disposable gloves

Nutrition is the sum total of the processes involved in the taking in and the utilisation of food substances by which growth, repair and maintenance of the body are accomplished. It involves ingestion, digestion, absorption/assimilation and elimination. Nutrients are stored by the body in various forms and drawn upon when the food intake is not sufficient.

The digestive organs responsible for these processes are the gastrointestinal tract (also called the alimentary canal) and the accessory digestive organs. The gastrointestinal tract consists of the mouth, pharynx, oesophagus, stomach, small intestine and large intestine. The accessory digestive organs include the liver, gallbladder and pancreas (see Figure 20.1). This chapter discusses the assessment of these organs.

NUTRIENTS

Nutrients are substances found in food and are used by the body to promote growth, maintenance and repair. The categories of nutrients are carbohydrates, proteins, fats, vitamins, minerals and water. Dietary guidelines for nutrients specific to Australians are summarised in Table 20.1.

Nutritional deficits are common in people who are obese. All treatments, including bariatric surgery (see Chapter 21), consist of lifelong dietary control, exercise and behaviour change. These procedures contribute to nutritional deficiencies by restricting food intake and/or limiting intestinal absorption. The most commonly described nutritional deficiencies include thiamine (B_1), B_{12}, folate (B_9), vitamin D, vitamin E and copper deficiencies (Becker, Balcer & Galetta, 2012). The incidence of neurological complications in this group of people is estimated at around 16% and includes encephalopathy, optic neuropathy, myelopathy and polyneuropathy. Risk factors for nutritional complications include vitamin non-adherence, protracted vomiting and excessive alcohol consumption.

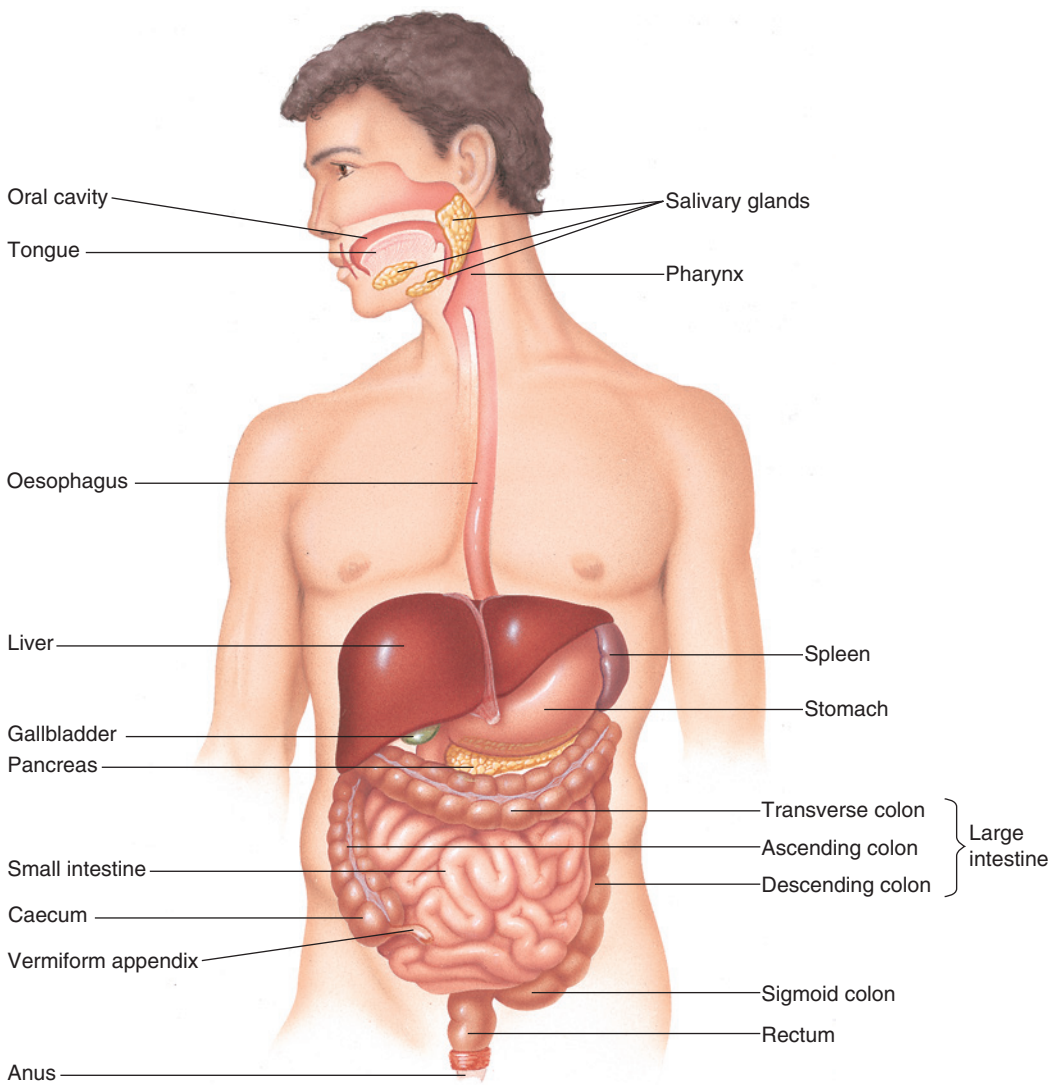

FIGURE 20.1 ■ Organs of the gastrointestinal tract and accessory digestive organs

TABLE 20.1 Dietary guidelines for Australians

FOR ADULTS	FOR CHILDREN AND ADOLESCENTS
Enjoy a wide variety of nutritious foods *Adults should be encouraged to:* • Eat mostly vegetables and legumes/beans • Include grain (cereal) foods, mostly wholegrain and/or high cereal fibre varieties (including breads, rice, pasta and noodles) • Include lean meat and poultry, fish, eggs, tofu, nuts and seeds, and legumes/beans • Include milks, yoghurts, cheeses and/or alternatives, mostly reduced fat • Include 2 servings of fruit per day • Drink plenty of water *and take care to:* • Limit foods with saturated fat and moderate total fat intake • Limit foods with added salt • Limit your alcohol intake if you choose to drink • Limit foods and drinks containing added sugars **Prevent weight gain: be physically active and eat according to your energy needs** **Care for your food: prepare and store it safely** **Encourage and support breastfeeding**	**Encourage and support breastfeeding** **Children and adolescents need sufficient nutritious foods to grow and develop normally** • Growth should be checked regularly for young children • Physical activity is important for all children and adolescents **Enjoy a wide variety of nutritious foods** *Children and adolescents should be encouraged to:* • Eat plenty of vegetables and legumes/beans • Eat moderate amounts of fruit (whole fruit is preferred to fruit juice) • Eat plenty of cereal foods, mostly wholegrain and/or high cereal fibre varieties (including breads, rice, pasta and noodles) • Include lean meats and poultry, fish, eggs, tofu, nuts and seeds, and legumes/beans • Include milks, yoghurts, cheese and/or alternatives. Reduced-fat milks are not suitable for young children under 2 years, because of their high energy needs, but reduced-fat varieties should be encouraged for older children and adolescents • Choose water as a drink. Alcohol is not recommended for children *and care should be taken to:* • Limit foods with saturated fat and moderate total fat intake. Low-fat diets are not suitable for infants • Limit foods high in salt • Limit foods and drinks containing added sugars **Care for your child's food: prepare and store it safely**

Source: Based on material provided by the National Health and Medical Research Council (NHMRC) (2013). *Eat for Health Educator Guide: Information for nutrition educators*, www.nhmrc.gov.au/_files_nhmrc/publications/attachments/n55b_educator_guide_140321.pdf. Used by permission of the Australian Government.

Carbohydrates

The primary sources of carbohydrates (which include sugars and starches) are plant foods. Monosaccharides and disaccharides come from milk, sugar cane, sugar beets, honey and fruits. Polysaccharide starch is found in grains, legumes and root vegetables. Following ingestion, digestion and metabolism, carbohydrates are converted primarily to glucose, the molecule body cells use to make adenosine triphosphate (ATP). Excess glucose in the healthy person is converted to glycogen or fat. Glycogen is stored in the liver and muscles; fat is stored as adipose tissue. Carbohydrate use by the body is shown in Figure 20.2A.

Regardless of the source, all carbohydrates supply 16.7 kilojoules (kJ) per gram. The recommended dietary intake is 125 to 175 g, most of which should be complex carbohydrates (such as fruits, starchy vegetables and whole grains). Excessive intake of carbohydrates over time can result in obesity, tooth decay and elevated plasma triglycerides. Over extended periods of time, carbohydrate deficiencies lead to tissue wasting from protein breakdown and metabolic acidosis from an excess of ketones as a by-product of fat breakdown.

Proteins

Proteins are classified as either complete or incomplete. Complete proteins are found in animal products such as eggs, milk, milk products and meat. They contain the greatest amount of amino acids and meet the body's amino acid requirements for tissue growth and maintenance. Incomplete proteins are found in legumes, nuts, grains, cereals and vegetables. These sources are low in or lack one or more of the amino acids essential for building complete proteins.

The body uses proteins to build many different structures, including skin keratin and the collagen and elastin in connective tissues and muscles. They also are used to make enzymes, haemoglobin, plasma proteins and some hormones. Protein use by the body is shown in Figure 20.2B.

Proteins provide 16.7 kJ per gram. The recommended dietary intake of protein is 64 g for men and 46 g for women. (This is higher for adults over 70 years of age.) Healthy people with adequate energy intake have an equal rate of protein synthesis and protein breakdown and loss, reflected as nitrogen balance. If the breakdown and loss of proteins exceed intake, a negative nitrogen balance results. This may be due to starvation, altered physical states (e.g. from injury or illness) and altered emotional states (such as depression or anxiety). A positive nitrogen balance, which results when protein intake exceeds breakdown, is normal during growth, tissue repair and pregnancy. Anabolic steroids affect the rate of protein use; for example, the adrenal corticosteroids are released in times of stress to increase protein breakdown and conversion of amino acids to glucose. Excessive intake of proteins may lead to obesity, whereas deficits cause weight loss and tissue wasting, oedema and anaemia.

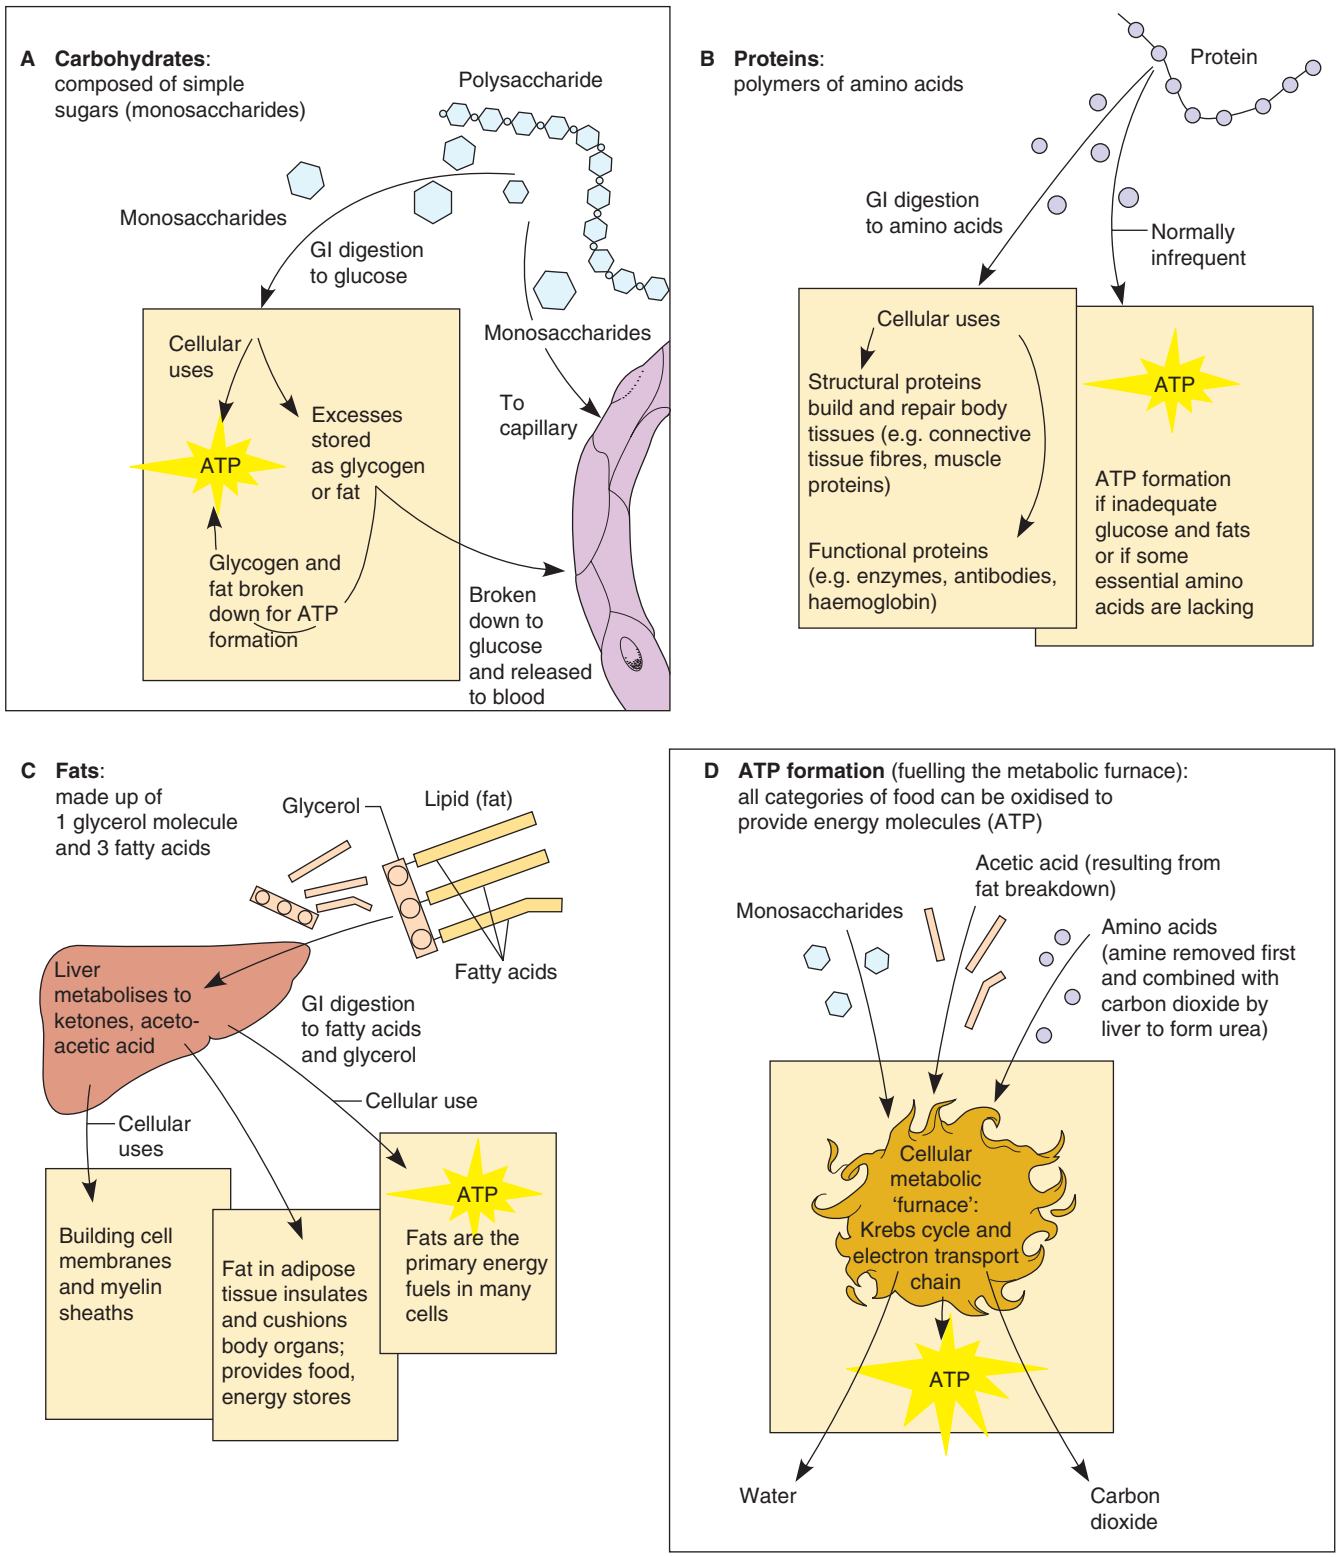

FIGURE 20.2 ■ A schematic overview of nutrient use by body cells, including *A*, carbohydrates; *B*, proteins; *C*, fats; and *D*, ATP formation

Fats (lipids)

Fats, or lipids, include phospholipids; steroids, such as cholesterol; and neutral fats, more commonly known as triglycerides. Neutral fats are the most abundant fats in the diet. They may be either saturated or unsaturated. Saturated fats are found in animal products (milk and meats) and in some plant products (such as coconut). Unsaturated fats are found in seeds, nuts and most vegetable oils. Sources of cholesterol include meats, milk products and egg yolks. Fat use by the body is shown in Figure 20.2C.

Fats supply 37.7 kJ per gram. When a person consumes more than the body requires, the excess is stored as adipose tissue, increasing the risk of obesity and heart disease. A deficit of fats may cause excessive weight loss and skin lesions.

Fats are a necessary part of the structure and function of the body. For example:

- Phospholipids are a part of all cell membranes.
- Triglycerides are the major energy source for hepatocytes and skeletal muscle cells.
- Dietary fats facilitate absorption of fat-soluble vitamins.
- Linoleic acid, an essential fatty acid, helps form prostaglandins, regulatory molecules that assist in smooth muscle contraction, maintenance of blood pressure and control of inflammatory responses.
- Cholesterol is the essential component of bile salts, steroid hormones and vitamin D.
- Adipose tissue serves as a protection around body organs, as a layer of insulation under the skin and as a concentrated source of fuel for cellular energy.

Vitamins

Vitamins are organic compounds that facilitate the body's use of carbohydrates, proteins and fats. All the vitamins except vitamins D and K must be ingested in foods or taken as supplements. Vitamin D is made by ultraviolet irradiation of cholesterol molecules in the skin and vitamin K is synthesised by bacteria in the intestine.

Vitamins are categorised as either fat soluble or water soluble. The fat-soluble vitamins (A, D, E and K) bind to ingested fats and are absorbed as the fats are absorbed. Water-soluble vitamins (the B complex and C) are absorbed with water in the gastrointestinal (GI) tract. (However, vitamin B_{12} must become attached to the intrinsic factor (a protein) to be absorbed.) Fat-soluble vitamins are stored in the body and excesses may cause toxicity; water-soluble vitamins in excess of body requirements are excreted in the urine.

The recommended dietary intake (RDI) or adequate intake (AI) and the source and function of vitamins, as stated by the National Health and Medical Research Council (NHMRC), are listed in Tables 20.2 and 20.3.

Minerals

Minerals work with other nutrients to maintain the structure and function of the body. An adequate supply of calcium, phosphorus, potassium, sulfur, sodium, chloride and magnesium—as well as other trace elements such as iron, iodine, copper and zinc—is necessary to health. Most minerals in the body are found in body fluids or are bound to organic compounds. The best sources of minerals are vegetables, legumes, milk and some meats. Dietary sources for the major minerals are discussed in Chapter 9. The recommended dietary intake for minerals is outlined in Table 20.4.

TABLE 20.2 Recommended dietary intake/adequate intake of fat-soluble vitamins

NAME	SOURCE	FUNCTION	MINIMUM RECOMMENDED DIEATRY INTAKE/ADEQUATE INTAKE (AI) (M = MEN, W = WOMEN)
Vitamin A (retinol)	• Fish liver oils • Egg yolk • Liver • Fortified milk • Margarine	Necessary for vision, integrity of skin and mucous membranes, cell membrane function and reproductive function	M = 900 mcg W = 700 mcg
Vitamin D	• The action of sunshine on cholesterol in the skin	Necessary for blood calcium homeostasis (in turn, necessary for blood clotting), bone formation and neuromuscular function	M and W = 5 mcg M and W 51–70 = 10 mcg M and W > 70 = 15 mcg
Vitamin E (as ∝-tocopherol)	• Vegetable oils • Margarine • Whole grains • Dark green leafy vegetables	As an antioxidant, helps prevent the oxidation of vitamins A and C in the intestines and decreases the oxidation of unsaturated fatty acids to facilitate cell membrane integrity	M = 10 mg W = 7 mg
Vitamin K	• Synthesised by coliform bacteria in the large intestine • Green, leafy vegetables • Cabbage • Cauliflower • Pork	Essential for the formation of clotting proteins in the liver	M = 70 mcg W = 60 mcg

TABLE 20.3 Recommended dietary intake of water-soluble vitamins

NAME	SOURCE	FUNCTION	MINIMUM RECOMMENDED DIETARY INTAKE/ ADEQUATE INTAKE (A1) (M = MEN, W = WOMEN)
Vitamin B_1 (thiamine)	• Lean meats • Liver • Eggs • Green leafy vegetables • Legumes • Whole grains	An essential coenzyme for carbohydrate metabolism and use; also for healthy function of nerves, muscles and the heart	M = 1.2 mg W = 1.1 mg
Vitamin B_2 (riboflavin)	• Liver • Egg white • Whole grains • Meat • Poultry • Fish • Milk	Involved in the catabolism and use of carbohydrates, fats and proteins; the use of other B vitamins; and is important for the production of adrenal hormones	M = 1.3 mg M > 70 years = 1.6 mg/day W = 1.1 mg W > 70 years = 1.3 mg/day
Vitamin B_6 (pyridoxine)	• Meat • Poultry • Fish • Potatoes • Tomatoes • Sweet potatoes • Spinach	Necessary for amino acid metabolism, and formation of antibodies and haemoglobin	M and W < age 51 = 1.3 M > age 51 = 1.7 mg W > age 51 = 1.5 mg
Vitamin B_{12} (cyanocobalamin)	• Liver • Meat • Poultry • Dairy foods (except butter) • Eggs	Essential for the production of nucleic acids and red blood cells in the bone marrow; also plays an important role in the use of folic acid and carbohydrates and in healthy function of the nervous system	M and W = 2.4 mcg
Vitamin C (ascorbic acid)	• Citrus fruits • Potatoes • Tomatoes • Green leafy vegetables	Acts as an antioxidant and vasoconstrictor; also serves in the formation of connective tissue, conversion of cholesterol to bile salts, iron absorption and use and conversion of folic acid to an active form	M and W = 45 mg
Vitamin B_3 (niacin; nicotinamide)	• Meat • Poultry • Fish • Liver • Peanuts • Green leafy vegetables	Plays an important role in the metabolism of carbohydrates and fats; inhibits cholesterol synthesis; important for integumentary, nervous and digestive system health; assists in the manufacture of reproductive hormones	M and W = 35 mg (as nicotinic acid)
Biotin (B_7)	• Liver • Eggs • Nuts • Legumes	Essential for the catabolism of fatty acids and carbohydrates and helps dispose of the waste products of protein catabolism	M = 30 mcg W = 25 mcg
Pantothenic acid (B_5)	• Meats • Whole grains • Egg yolk • Liver • Yeast • Legumes	Assists in the synthesis of steroids and of the haem in haemoglobin; is essential for the metabolism of carbohydrates and fats, and for the manufacture of reproductive hormones	M = 6 mg W = 4 mg
Folic acid (folate; B_9)	• Liver • Dark green vegetables • Lean beef • Eggs • Veal • Whole grains • Synthesised by bacteria in the intestine	The basis of a coenzyme necessary to the manufacture of nucleic acids and so is essential for the formation of red blood cells, growth and development, and nervous system health	M and W = 400 mcg

TABLE 20.4 Recommended dietary intake of minerals

NAME	MINIMUM RECOMMENDED DIETARY INTAKE/ADEQUATE INTAKE (A1) (M = MEN, W = WOMEN)	NAME	MINIMUM RECOMMENDED DIETARY INTAKE/ADEQUATE INTAKE (A1) (M = MEN, W = WOMEN)
Calcium	M and W = 1000 mg M > 70 and W > 51 = 1300 mg	Chromium	M = 35 mcg W = 25 mcg
Phosphorus	M and W = 1000 mg	Iodine	M and W = 150 mcg
Iron	M = 8 mg W = 18 mg W > 51 = 8 mg	Selenium	M = 70 mcg W = 60 mcg
Zinc	M = 14 mg W = 8 mg	Magnesium	M = 400–420 mg W = 310–320 mg
Manganese	M = 5.5 mg W = 5 mg	Copper	M = 1.7 mg W = 1.2 mg
Molybdenum	M and W = 45 mcg	Sodium	M and W = 460–920 mg

Dietary fibre

Food Standards Australia New Zealand (FSANZ) defines dietary fibre as:

> *that fraction of the edible parts of plants or their extracts, or synthetic analogues, that are resistant to the digestion and absorption in the small intestine, usually with complete or partial fermentation in the large intestine and promote one or more of the following beneficial physiological effects—(i) laxation; (ii) reduction in blood cholesterol; (iii) modulation of blood glucose.* (FSANZ, 2012, p. 2)

Adequate intake of dietary fibre has been linked to a reduction in the occurrence of several chronic diseases and is essential to maintain functioning of the GI tract. An adequate intake for women is 25 g/day and for men is 30 g/day.

ANATOMY, PHYSIOLOGY AND FUNCTIONS OF THE GASTROINTESTINAL SYSTEM

The gastrointestinal tract is a continuous hollow tube, extending from the mouth to the anus. Foods are placed in the mouth, then they are subjected to a variety of processes that move them and break them down into usable elements, and nutrients are absorbed from the lumen of the small intestine into the blood or lymph, while indigestible materials are eliminated. Bowel elimination is the end process in digestion. The digestive processes are as follows:

- ingestion of food
- movement of food and wastes
- secretion of mucus, water and enzymes
- mechanical digestion of food
- chemical digestion of food
- absorption of nutrients from digested food
- elimination of wastes.

The mouth

The mouth, also called the oral or buccal cavity, is lined with mucous membranes and is enclosed by the lips, cheeks, palate and tongue (see Figure 20.3).

The lips and cheeks are skeletal muscle covered externally by skin. Their function is to keep food in the mouth during chewing. The palate consists of two regions: the hard palate and the soft palate. The hard palate covers bone in the roof of the mouth and provides a hard surface against which the tongue forces food. The soft palate, extending from the hard palate and ending at the back of the mouth as a fold called the uvula, is primarily muscle. When food is swallowed, the soft palate rises as a reflex to close off the oropharynx.

The tongue, composed of skeletal muscle and connective tissue, is located in the floor of the mouth. It contains mucous and serous glands, taste buds and papillae. The tongue mixes food with saliva during chewing, forms the food into a mass (called a *bolus*) and initiates swallowing. Some papillae provide surface roughness to facilitate licking and moving food; other papillae house the taste buds.

Saliva moistens food so it can be made into a bolus, dissolves food chemicals so they can be tasted and provides enzymes (such as amylase) that begin the chemical breakdown of starches. Saliva is produced by salivary glands, most of which lie superior or inferior to the mouth and drain into it. The salivary glands include the parotid, the submaxillary and the sublingual glands.

The teeth chew (masticate) and grind food to break it down into smaller parts. As the food is masticated, it is mixed with saliva. Adults have 32 permanent teeth. The teeth are embedded in the gingiva (gums), with the crown of each tooth visible above the gingiva.

The pharynx

The pharynx consists of the oropharynx and the laryngopharynx (see Figure 20.3). Both structures provide passageways for food,

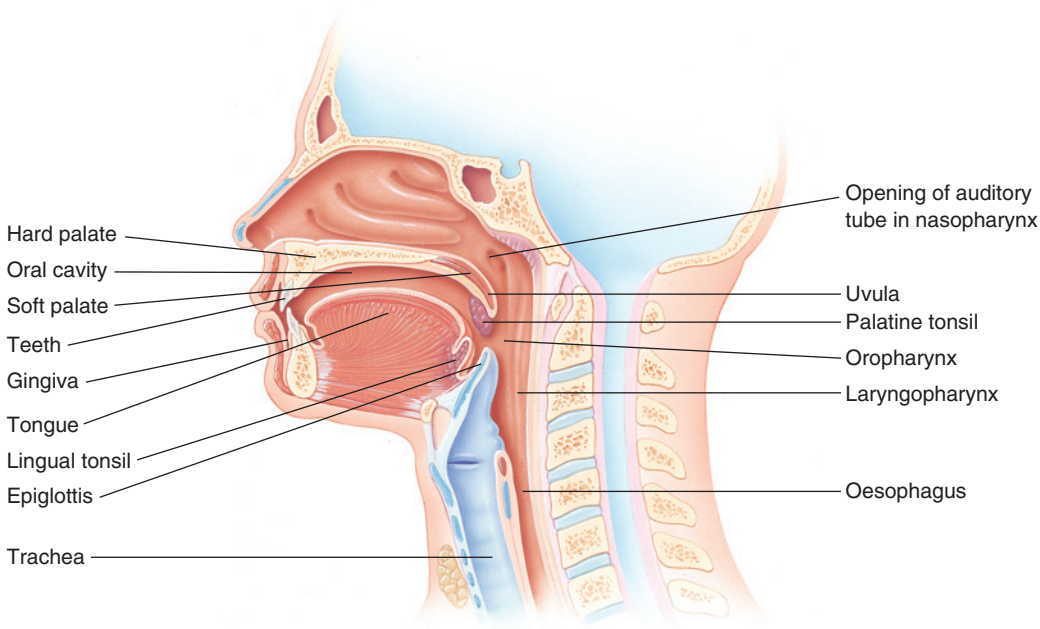

FIGURE 20.3 ■ Structures of the mouth, the pharynx and the oesophagus

fluids and air. The pharynx is made of skeletal muscles and is lined with mucous membranes. The skeletal muscles move food to the oesophagus via the pharynx through **peristalsis** (alternating waves of contraction and relaxation of involuntary muscle). The mucosa of the pharynx contains mucus-producing glands that provide fluid to facilitate the passage of the bolus of food as it is swallowed.

The oesophagus

The oesophagus, a muscular tube about 25 cm long, serves as a passageway for food from the pharynx to the stomach (see Figures 20.1 and 20.3). The epiglottis, a flap of cartilage over the top of the larynx, keeps food out of the larynx during swallowing. The oesophagus descends through the thorax and diaphragm, entering the stomach at the cardiac orifice. The gastro-oesophageal sphincter surrounds this opening. This sphincter, along with the diaphragm, keeps the orifice closed when food is not being swallowed.

For most of its length, the oesophagus is lined with stratified squamous epithelium; simple columnar epithelium lines the oesophagus where it joins the stomach. The mucosa and submucosa of the oesophagus lie in longitudinal folds when the oesophagus is empty.

The stomach

The stomach, located high on the left side of the abdominal cavity, is connected to the oesophagus at the upper end and to the small intestine at the lower end (see Figure 20.4). Normally about 25 cm long, the stomach is a distensible organ that can expand to hold up to 4 L of food and fluid. The concave surface of the stomach is called the lesser curvature; the convex surface is called the greater curvature. The stomach may be divided

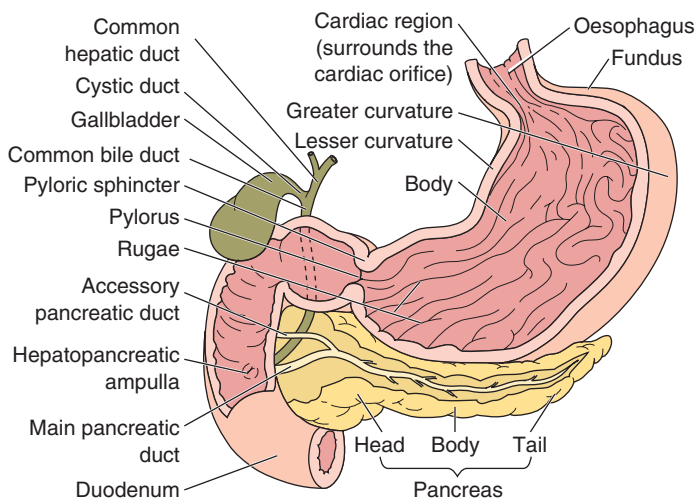

FIGURE 20.4 ■ The internal anatomical structures of the stomach, including the pancreatic, cystic and hepatic ducts, the pancreas and the gallbladder

into regions extending from the distal end of the oesophagus to the opening into the small intestine. These regions are the cardiac region, fundus, body and pylorus (see Figure 20.4). The pyloric sphincter controls emptying of the stomach into the duodenal portion of the small intestine. The stomach is a storage reservoir for food, continues the mechanical breakdown of food, begins the process of protein digestion and mixes the food with gastric juices into a thick fluid called chyme.

The stomach is lined with columnar epithelial, mucus-producing cells. Millions of openings in the lining lead to

gastric glands that can produce 4 to 5 L of gastric juice each day. The gastric glands contain a variety of secretory cells, including the following:

- Mucous cells produce alkaline mucus that clings to the lining of the stomach and protects it from being digested by gastric juice.
- Zymogenic cells produce pepsinogen (an inactive form of pepsin, a protein-digesting enzyme).
- Parietal cells secrete hydrochloric acid and intrinsic factor. Hydrochloric acid activates and increases the activity of protein-digesting cells and also is bactericidal. Intrinsic factor is necessary for the absorption of vitamin B_{12} in the small intestine.
- Enteroendocrine cells secrete gastrin, histamine, endorphins, serotonin and somatostatin. These hormones or hormone-like substances diffuse into the blood. Gastrin is important in regulating secretion and motility of the stomach.

The secretion of gastric juice is under both neural and endocrine control. Stimulation of the parasympathetic vagus nerve increases secretory activity; in contrast, stimulation of sympathetic nerves decreases secretions. The three phases of secretory activity are the cephalic phase, the gastric phase and the intestinal phase.

- The cephalic phase prepares for digestion and is triggered by the sight, odour, taste or thought of food. During this initial phase, motor impulses are transmitted via the vagus nerve to the stomach.
- The gastric phase begins when food enters the stomach. Stomach distension (stimulating stretch receptors) and chemical stimuli from partially digested proteins initiate this phase. Gastrin-secreting cells produce gastrin, which in turn stimulates the gastric glands (especially the parietal cells) to produce more gastric juice. Histamine also stimulates hydrochloric acid secretion.
- The intestinal phase is initiated when partially digested food begins to enter the small intestine, stimulating mucous cells of the intestine to release a hormone that promotes continued gastric secretion.

Mechanical digestion in the stomach is accomplished by peristaltic movements that churn and mix the food with the gastric juices to form chyme. Gastric motility is enhanced or retarded by the same factors that affect secretion—namely, distension and the effect of gastrin. After a person eats a well-balanced meal, the stomach empties completely in approximately 4 to 6 hours. Gastric emptying depends on the volume, chemical composition and osmotic pressure of the gastric contents. The stomach empties large volumes of liquid content more rapidly, while solids and fats slow gastric emptying.

The small intestine

The small intestine begins at the pyloric sphincter and ends at the ileocaecal junction at the entrance of the large intestine (see Figure 20.1). The small intestine is about 6 m long but only about 2.5 cm in diameter. This long tube hangs in coils in the abdominal cavity, suspended by the mesentery and surrounded by the large intestine. The small intestine has three regions: the duodenum, the jejunum and the ileum. The duodenum begins at the pyloric sphincter and extends around the head of the pancreas for about 25 cm. Both pancreatic enzymes and bile from the liver enter the small intestine at the duodenum. The jejunum, the middle region of the small intestine, extends for about 2.4 m. The ileum, the terminal end of the small intestine, is approximately 3.6 m long and meets the large intestine at the ileocaecal valve.

Food is chemically digested, and most of it is absorbed, as it moves through the small intestine. Circular folds (deep folds of the mucosa and submucosa layers), villi (finger-like projections of the mucosa cells) and microvilli (tiny projections of the mucosa cells) increase the surface area of the small intestine to enhance absorption of food. Although up to 10 L of food, liquids and secretions enter the GI tract each day, less than 1 L reaches the large intestine.

Enzymes in the small intestine break down carbohydrates, proteins, lipids and nucleic acids. Pancreatic amylase acts on starches, converting them to maltose, dextrins and oligosaccharides; the intestinal enzymes dextrinase, glucoamylase, maltase, sucrase and lactase further break down these products into monosaccharides. Pancreatic enzymes (trypsin and chymotrypsin) and intestinal enzymes continue to break down proteins into peptides. Pancreatic lipases digest lipids in the small intestine. Triglycerides enter as fat globules and are coated by bile salts and emulsified. Nucleic acids are hydrolysed by pancreatic enzymes and then broken apart by intestinal enzymes. Both pancreatic enzymes and bile are excreted into the duodenum in response to the secretion of secretin and cholecystokinin, hormones produced by the intestinal mucosa cells when chyme enters the small intestine.

Nutrients are absorbed through the mucosa of the intestinal villi into the blood or lymph by active transport, facilitated transport and passive diffusion. Almost all food products and water, as well as vitamins and most electrolytes, are absorbed in the small intestine, leaving only indigestible fibres, some water and bacteria to enter the large intestine.

The large intestine

The large intestine, or colon, begins at the ileocaecal valve and terminates at the anus (see Figure 20.5). It is about 1.5 m long. The large intestine frames the small intestine on three sides and

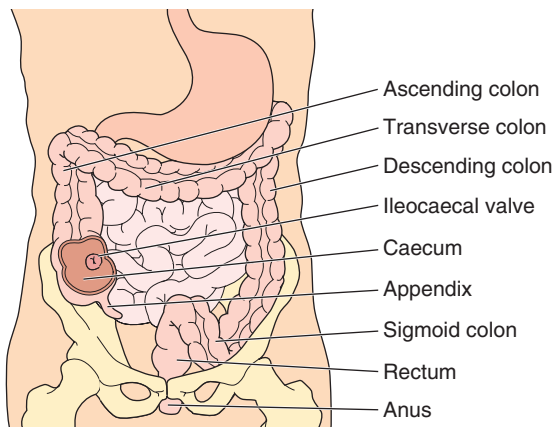

FIGURE 20.5 ■ Anatomy of the large intestine

includes the caecum, the appendix, the colon, the rectum and the anal canal.

The first section of the large intestine is the caecum. The appendix is attached to its surface as an extension. The appendix, a twisted structure in which bacteria can accumulate, may become inflamed.

The colon is divided into ascending, transverse and descending segments. The ascending colon extends along the right side of the abdomen to the hepatic flexure, where it makes a right-angled turn. The next segment, called the transverse colon, crosses the abdomen to the splenic flexure. At this juncture, the descending colon descends down the left side of the abdomen and ends at the S-shaped sigmoid colon. The sigmoid colon terminates at the rectum.

The rectum is a mucosa-lined tube approximately 12 cm in length (see Figure 20.6). The rectum has three transverse folds (valves of Houston) that retain faeces yet allow flatus to be passed through the anus. The rectum ends at the anal canal, which terminates at the anus.

The anus is a hairless opening at the end of the digestive system, from which bowel motions (stools) are passed. It has both an internal involuntary sphincter and an external voluntary sphincter. The sphincters are usually open only during defecation. The anorectal junction separates the rectum from the anal canal and may be the site of internal haemorrhoids (clusters of dilated veins in swollen anal tissue).

The major function of the large intestine is to eliminate indigestible food residue from the body. The large intestine absorbs water, salts and vitamins formed by the food residue and bacteria. The semiliquid chyme that passes through the ileocaecal valve is formed into faeces as it moves through the large intestine. Faeces are moved along the intestine by peristalsis**,** waves of alternating contraction and relaxation. Goblet cells lining the large intestine secrete mucus that facilitates the lubrication and passage of faeces.

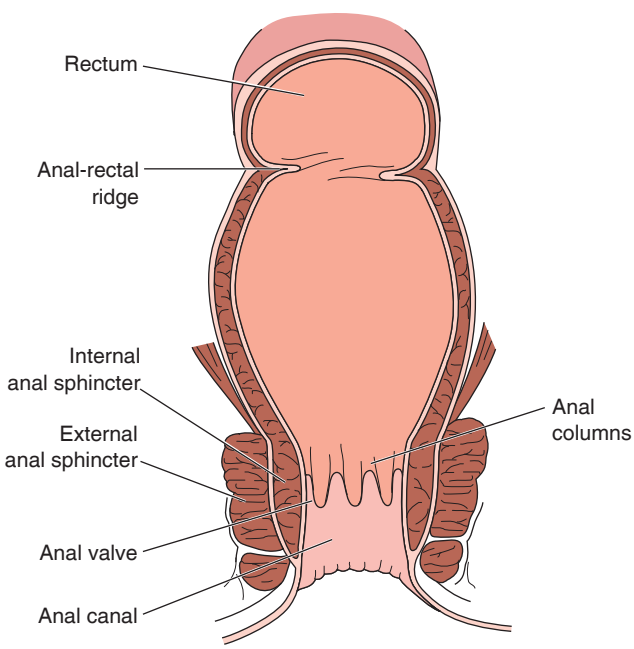

FIGURE 20.6 ■ Structure of the rectum and anus

The defecation reflex is initiated when faeces enter the rectum and stretch the rectal wall. This spinal cord reflex causes the walls of the sigmoid colon to contract and the anal sphincters to relax. This reflex can be suppressed by voluntary control of the external sphincter. Closing the glottis and contracting the diaphragm and abdominal muscles to increase intra-abdominal pressure (**Valsalva manoeuvre**) facilitate expulsion of faeces. Prolonged suppression of defecation can result in a weakened reflex that may in turn lead to **constipation** (infrequent and often uncomfortable passage of hard, dry stool). Frequent bouts of constipation may lead to external haemorrhoids at the area of the external haemorrhoidal plexus.

The accessory digestive organs

The liver, gallbladder and exocrine pancreas secrete substances necessary for the digestion of chyme. The liver produces bile, necessary for fat digestion and absorption, and stores it in the gallbladder. The liver also receives nutrients absorbed by the small intestine and metabolises or synthesises these nutrients so they are in a form that can be used by the cells of the body. The exocrine pancreas produces enzymes necessary for digestion of fats, proteins and carbohydrates.

The liver and gallbladder

The liver weighs about 1.4 kg in the average-size adult. It is located in the right side of the abdomen, inferior to the diaphragm and anterior to the stomach (see Figure 20.1). The liver has four lobes: right, left, caudate and quadrate. A mesenteric ligament separates the right and left lobes and suspends the liver from the diaphragm and anterior abdominal wall. The liver is encased in a fibroelastic capsule, called the Glisson capsule. This capsule contains blood vessels, lymphatics and nerves. When the liver is diseased or swollen, distension causes pain and the lymphatics may ooze fluid into the peritoneal cavity.

Liver tissue consists of units called lobules, which are composed of plates of hepatocytes (liver cells). A branch of the hepatic artery, a branch of the hepatic portal vein and a bile duct communicate with each lobule. Sinusoids, blood-filled spaces within the lobules, are lined with Kupffer cells. These phagocytic cells remove debris from the blood.

Bile production is the liver's primary digestive function. **Bile** is a greenish, watery solution containing bile salts, cholesterol, bilirubin, electrolytes, water and phospholipids. These substances are necessary to emulsify and promote the absorption of fats. Liver cells make from 700 to 1200 mL of bile daily. When bile is not needed for digestion, the sphincter of Oddi (located at the point at which bile enters the duodenum) is closed and the bile backs up the cystic duct into the gallbladder for storage.

Bile is concentrated and stored in the gallbladder, a small sac cupped in the inferior surface of the liver. When food containing fats enters the duodenum, hormones stimulate the gallbladder to secrete bile into the cystic duct. The cystic duct joins the hepatic duct to form the common bile duct, from which bile enters into the duodenum (see Figure 20.4).

The major digestive and metabolic functions of the liver are outlined in Box 20.1. These functions require a large amount of blood, with the liver receiving blood from both venous and arterial blood vessels. The hepatic artery, branching from the abdominal aorta, provides oxygenated blood at the rate of 400 to 500 mL/min. The hepatic portal vein delivers about 1000 to 1200 mL/min of deoxygenated blood to the liver from the inferior and superior mesenteric veins and the splenic vein.

The exocrine pancreas

The pancreas, a gland located between the stomach and small intestine, is the primary enzyme-producing organ of the digestive system. It is a triangular gland extending across the abdomen, with its tail next to the spleen and its head next to the duodenum (see Figure 20.4). The body and tail of the pancreas are retroperitoneal, lying behind the greater curvature of the stomach. The pancreas is actually two organs in one, having both exocrine and endocrine structures and functions. The exocrine portion of the pancreas, through secretory units called acini, secretes alkaline pancreatic juice containing many different enzymes. The acini, clusters of secretory cells surrounding ducts, drain into the pancreatic duct. The pancreatic duct joins with the common bile duct just before it enters the duodenum (so that pancreatic juice and bile from the liver enter the small intestine together). The pancreas also has endocrine functions, discussed in Chapter 17.

The pancreas produces from 1 to 1.5 L of pancreatic juice daily. Pancreatic juice is clear and has a high bicarbonate content. This alkaline fluid neutralises the acidic chyme as it enters the duodenum, optimising the pH for intestinal and pancreatic enzyme activity. The secretion of pancreatic juice is controlled by the vagus nerve and the intestinal hormones secretin and cholecystokinin. Pancreatic juice contains enzymes that aid in the digestion of all categories of foods: lipase promotes fat breakdown and absorption; amylase completes starch digestion; and trypsin, chymotrypsin and carboxypeptidase are responsible for half of all protein digestion. Nucleases break down nucleic acids.

BOX 20.1 Major digestive and metabolic functions of the liver

- Secretes bile.
- Stores fat-soluble vitamins (A, D, E and K).
- Metabolises bilirubin.
- Stores blood and releases blood into the general circulation during haemorrhage.
- Synthesises plasma proteins to maintain plasma oncotic pressure.
- Synthesises prothrombin, fibrinogen and factors I, II, VII, IX and X, which are necessary for blood clotting.
- Synthesises fats from carbohydrates and proteins to be either used for energy or stored as adipose tissue.
- Synthesises phospholipids and cholesterol necessary for the production of bile salts, steroid hormones and plasma membranes.
- Converts amino acids to carbohydrates through deamination.
- Releases glucose during times of hypoglycaemia.
- Takes up glucose during times of hyperglycaemia and stores it as glycogen or converts it to fat.
- Alters chemicals, foreign molecules and hormones to make them less toxic.
- Stores iron as ferritin, which is released as needed for the production of red blood cells.

METABOLISM

After nutrients (carbohydrates, fats and proteins) are ingested, digested, absorbed and transported across cell membranes, they must be metabolised to produce and provide energy to maintain life. **Metabolism** is the process of biochemical reactions occurring in the body's cells. Metabolic processes are either catabolic or anabolic. Catabolism involves the breakdown of complex structures into simpler forms—for example, the breakdown of carbohydrates to produce ATP, an energy molecule that fuels cellular activity. In the process of anabolism, simpler molecules combine to build more complex structures—for example, amino acids bond to form proteins.

The biochemical reactions of metabolism produce water, carbon dioxide and ATP (see Figure 20.2D). The energy value of foods is measured in calories or joules; in Australia the preferred unit of measure is kilojoules (kJ). One kilojoule is equivalent to 0.24 kilocalorie. A kilocalorie is defined as the amount of heat energy needed to raise the temperature of 1 kilogram (kg) of water 1 degree Celcius (1°C).

ASSESSING NUTRITIONAL STATUS AND GASTROINTESTINAL FUNCTION

Nutritional status and the function of the gastrointestinal system are assessed by findings from a health assessment interview to collect subjective data, a physical assessment to collect objective data and diagnostic tests. The obesity epidemic has put **bariatric care** in the forefront for all healthcare providers. Bariatric nurse specialists reveal that obese individuals are often the target of prejudice, bullying and ridicule, and that misunderstanding by the community, media and health professionals is common. People affected in this way are often reluctant to seek care or to follow medical advice. Person-centred care and collaboration with the affected person and their family is essential to positive long-term outcomes. Sensitive attention to health assessment interviews and physical assessment of overweight and obese people is required to identify those at risk of nutritional and neurological deficits and in need of specialist support.

See the box below for sample documentation of a nutritional status assessment.

Health assessment interview

A health assessment interview to determine problems with nutrition and GI function may be conducted during a health screening, may focus on a chief complaint (such as nausea or unexplained weight loss) or may be part of a total health assessment. People may feel embarrassed to talk about weight, digestion and bowel elimination patterns. Remember to request permission to conduct the interview. Due to the sensitive nature of many of the questions, ask about the presence of others during the assessment. To promote effective rapport, ask about less personal information first. It is important to identify whether the problem is acute (less than 3 months) or chronic (more than

SAMPLE DOCUMENTATION

Assessment of nutritional status

28/02/2016
NURS
1100 hrs

A 22-year-old female visiting her GP for a regular check-up. Height 165 cm; weight 58 kg. BMI: 24. MAC: 28 cm. Waist-to-hip ratio: 0.6. Skin is warm, moist and smooth without lesions other than well-healed scar on RLQ of abdomen from appendectomy, age 15. Oral mucosa and tongue pink and moist. No breath odour. All teeth present with evidence of dental care. Abdomen slightly concave when lying on back, bowel sounds present in all four quadrants, liver non-palpable, tympany over lower abdomen on percussion.——————— RN Brown

(S BROWN RN)

3 months). If there has been a change in the person's normal GI function lasting for 4 weeks or longer, ask if this is related to any change in their lifestyle. Questions could cover diet, fluids, medication (prescribed, complementary and over-the-counter medicines), personal stresses such as a change in job, recent foreign travel (especially if a person has diarrhoea) and surgery.

If the person has a health problem involving nutrition and GI function, analyse its onset, characteristics and course, severity, precipitating and relieving factors, and any associated symptoms, noting the timing and circumstances. For example, the nurse may ask the person:

- Have you had any episodes of indigestion, nausea, vomiting, diarrhoea or constipation? If so, describe the appearance of what was vomited or the stools and anything that makes these problems better or worse. How long have you had these problems?
- What do you usually eat and drink (include alcohol) during a 24-hour period? Has your dietary pattern changed recently? If so, please describe.
- Are you generally happy with your diet? If necessary, ask person to describe what they believe to be a 'healthy' diet.

Also consider red-flag symptoms for bowel cancer, such as blood mixed in with stools, an increase in mucus and wind, weight loss without dieting, feeling tired and a family history. For example, ask the person:

- Do you have cramping or abdominal pain? If so, please ask for a description of type frequency and quality.
- Have you ever had any bleeding from your rectum? If so please describe the amount and colour of the blood (for example, was it bright red or dark?).

When collecting information about the person's current health status, ask about any changes in weight, appetite and the ability to taste, chew or swallow. What is the person's perception of the role of nutrition in maintaining health? Who buys and prepares the food? What medications (prescribed, over-the-counter or complementary) is the person currently taking? Does the person take any vitamins, herbal supplements or other 'health food' items? Does the person consume alcohol or recreational drugs (how much, what type, how often)? If the person has experienced nausea or vomiting, ask whether the vomitus contains bright red blood, dark (old) blood, bile or faecal material. If the person is very thin or expresses concerns about body size incongruent with the ratio of height to weight, ask whether the person induces vomiting or uses laxatives to control weight. Ask whether the person has dental appliances, such as braces, bridges or dentures, and what self-care measures are used for them, as well as oral hygiene practices and frequency of dental visits.

CONSIDERATION FOR PRACTICE

Culture influences all aspects of one's life. It is a learned system of beliefs, values and rules that people use to guide their activities. Culture shapes behaviours, attitudes and beliefs about being fat, being thin, eating, food nutrition, activity and exercise. Culture provides the foundation for how you view your own body as well as someone else's body. The term 'fat' is influenced by culture. Body weight is looked at differently from one culture to another.

Ask the person to describe any heartburn, indigestion, abdominal discomfort or pain. Explore the location of the pain, the type of pain, the time it occurs, foods that aggravate or relieve it, and how it is relieved. Abdominal pain is often referred to other sites (see Chapter 8 for further information on pain assessment). For example, a person with a liver disorder may experience pain over the right shoulder (Kehr's sign). Epigastric (middle upper abdominal) pain is experienced in cases of acute gastritis, obstruction of the small intestine and acute pancreatitis. Pain in the right upper quadrant is associated with cholecystitis. Pain in the left upper quadrant may be related to a gastric ulcer. Sudden onset of lower abdominal cramping often occurs in obstruction of the colon. Left lower abdominal pain may be associated with diverticulitis. Rectal pain may occur with stool retention and/or haemorrhoids. Determine whether the person has had any lower abdominal pain or rectal pain, which may be associated with a distended colon filled with gas or fluid. Crampy, colicky pains occur with diarrhoea and/or constipation.

Ask about any medical conditions that may influence the person's bowel elimination pattern, such as stroke or spinal cord impairment, inflammatory gastrointestinal diseases, endocrine disorders, cancer and allergies. Note any recent travel to other countries. Information about the person's psychosocial history and cultural background is also important. Assess the person's lifestyle for any patterns of psychological stress and/or depression, which may alter bowel elimination. Depression may be associated with constipation, whereas **diarrhoea** (frequent passage of loose, watery stools) may occur in situations of high stress and anxiety. Explore the person's activities of daily living (ADLs), including exercise, sleep–rest patterns and dietary and fluid intake. Changes in ADLs can influence bowel elimination patterns. More women than men seek help for constipation, suggesting that hormonal changes may play a role. Ask about history of diarrhoea, constipation or bleeding from the rectum, and collect information about the use of medications, laxatives, suppositories or enemas. For example, anticholinergic drugs, antihistamines, tranquillisers or narcotics may cause constipation.

The health history should include questions about any prior surgeries or trauma of the GI tract. Explore the history (personal

FUNCTIONAL HEALTH PATTERN INTERVIEW — Nutritional status and gastrointestinal system

FUNCTIONAL HEALTH PATTERN	INTERVIEW QUESTIONS AND LEADING STATEMENTS
Health perception–Health management	■ Have you had any illness or surgery that affects your nutrition and gastrointestinal (GI) function? If so, how were these treated? ■ Describe your current problem; how long has it lasted; what have you done to treat it? ■ What medications do you take? Do you take antacids? If so, what do you use them for and how often do you take them? ■ Are you currently taking alternative or complementary medicines, such as herbs, homeopathics, traditional medicines? If so, what do you use them for and how often do you take them? ■ Do you have allergies to foods? What are they and how do you react? How do you manage them? ■ Do you have your own teeth? If not, please describe any gaps, replacement teeth/dentures. ■ Do you have tooth or gum problems or pain that interferes with your ability to eat? ■ When was your last dental examination? ■ Describe what you do each day to take care of your teeth.
Nutritional–Metabolic	■ Describe what you eat and how much (and type) of fluids you drink in a 24-hour period. ■ Describe dietary supplements, such as vitamins, minerals, tonics, herbs, that you currently are taking. ■ Have you noticed any change in your appetite recently? Explain. ■ What is your current weight? What do you feel your ideal weight would be? Have you had a recent gain or loss? Explain. ■ Describe your food likes and dislikes. ■ Do you have any of the following: indigestion, belching, nausea, vomiting, difficulty swallowing? If so, what causes this and how do you treat it? ■ Do you drink alcohol? If so, what type? Describe your average number of drinks each day. ■ Questions specific to the person's culture and ethnic group would be included in this functional health pattern area, such as what types of food are preferred or not eaten, what types of foods are never eaten together and what types of foods are eaten to remain healthy.
Elimination	■ What is the pattern of your bowel movements? Has it been affected by your condition/illness? ■ Ask women of reproductive age if their menstrual cycle affects their bowel movements. If so, how? ■ Do you use laxatives, suppositories, enemas or other substances to help the regularity of your bowel movements? Please describe. ■ Are your bowel movements affected by what you eat? Explain. ■ Have you noticed any change in the colour of your urine or bowel movements? Explain. ■ Have you ever used laxatives or made yourself vomit to control your weight? Explain.
Activity–Exercise	■ Describe your activities on a typical day. ■ What type of exercise do you get, and how often? ■ Do you smoke? If so, what and how many cigarettes per day? ■ Do you use recreational drugs? If so, what type, amount and how often?
Sleep–Rest	■ Do you wake up hungry during the night? ■ Does abdominal pain, cramping, nausea or diarrhoea ever interfere with your sleep? Explain.
Cognitive–Perceptual	■ Describe the amount and type of foods you should eat each day. ■ Rate your ability to taste and smell foods on a scale of 1 to 10 (with 10 being excellent). ■ Describe any pain you have had in your mouth, stomach or abdomen. What type of pain was it (dull, crampy, achy, burning)? What seems to cause it? What do you do to relieve it? ■ How do you prefer to receive your health information? Written, verbal, internet, mixture? Please explain. ■ Do you have any difficulties reading and understanding health information? If so, what or who helps you to understand and feel well informed?

FUNCTIONAL HEALTH PATTERN	INTERVIEW QUESTIONS AND LEADING STATEMENTS
Self-perception–Self-concept	■ How does this problem/condition make you feel about yourself? ■ Are you satisfied with your appearance in terms of weight? If not, why? ■ Have you tried gaining or losing weight? If so, what worked or didn't work for you?
Role–Relationships	■ How does this condition affect your relationships with others? ■ Who normally buys food and prepares your meals? ■ Do you eat with others regularly? If so, who? Where do you normally eat your meals?
Sexuality–Reproductive	■ Has this condition affected your usual sexual activities? Can you describe your concerns and what you do to manage? ■ Ask women of reproductive age if their menstrual cycle is affected by this condition? If so, please describe what happens, and how you manage it.
Coping–Stress tolerance	■ Have you experienced any type of stress that may have worsened this condition? ■ Has having this condition created stress for you? ■ Describe what you do when you feel stressed.
Value–Belief	■ Tell me how specific relationships or activities help you cope with this problem. ■ Do you have specific cultural beliefs or practices that affect how you care for and feel about this condition? Please describe. ■ Are there any specific treatments that you would not use to treat this condition? ■ Are your spiritual beliefs, needs or practices affected by this condition/illness? Please describe.

and family) of any medical condition that may affect the person's ingestion, digestion and/or metabolism (e.g. Crohn's disease, diabetes mellitus, irritable bowel syndrome, peptic ulcers or pancreatitis). Other areas significant to the assessment of nutritional status and the gastrointestinal system are food allergies (especially to milk, which is evidenced as lactose intolerance with abdominal cramping, excessive flatus and loose stools), and a family history that may provide clues to increased risk of health problems.

If the person has an **ostomy** (surgical opening into the bowel), ask about skin care problems, consistency of stool, foods that cause problems with diarrhoea or **flatus** (intestinal gas), the number of times that the person empties the appliance bag each day and irrigation habits. It is also important to explore the person's feelings about the appliance.

To obtain information about the person's nutritional status, ask about changes in weight, appetite, food preferences, fibre content, food intolerances (wheat or dairy products—possible intolerance), special or supplementary diets (may cause diarrhoea), spicy foods (often increase gut motility) and any cultural or ethnic influences on dietary intake. The person could complete a food diary before attending for a clinic or outpatient visit. Ask about regular fluid intake—for example, amount of coffee, diet drinks, sports drinks, excess alcohol; these may increase gut motility, giving a loose stool. Ask whether the person experiences nausea and vomiting; if so, determine any relation to food intake and ask the person to describe the character of the emesis. In addition, ask about indigestion, the use of antacids or other over-the-counter medications, herbal preparations and episodes of diarrhoea and its character. Also ask about the use of analgesic drugs prescribed or other drugs; for example, narcotics slow bowel motility and can lead to chronic constipation, and anti-inflammatory drugs can irritate the gut and bowel.

Explore any family history of colon cancer, colitis, gallbladder disease or malabsorption syndromes, such as lactose intolerance and coeliac sprue. Assess the person's risk factors for cancer, including age greater than 50; family member with colon cancer; history of endometrial, ovarian or breast cancer; and previous diagnoses of colon inflammation, polyps or cancer.

People with cognitive problems require careful assessment. For example, if a person is unable to retain information or change behaviour, there is little point in teaching anal exercises to improve the strength of the pelvic floor muscles as these are unlikely to be carried out. An assessment of cognitive function should include the person's ability to understand what is being explained, retain information and learn, change behaviour and carry out instructions at home.

In addition to other factors assessed in the health history, culture and ethnicity are important components of nutritional status and gastrointestinal health. Australia is culturally and ethnically diverse and, as such, numerous cultural food customs can be seen throughout the country. Nutritional diversity is common among cultural and ethnic groups, and questions should be included to identify specific customs, food likes and dislikes, and how foods are prepared and served. In some ethnic groups, for example, dietary substances are used to protect health, such as eating raw garlic or onions (Spector, 2012). In Indigenous Australian culture, food is often depicted in art and stories, highlighting how important food and the collecting and sharing of it are in this culture. In other cultures, dietary balance is believed to be necessary to keep the body in balance or harmony. It is therefore necessary for nurses to be mindful of specific culturally related nutritional values and practices and to ask questions to identify health-related concerns specific to individualised dietary intake. If English is not

the person's first language it is important to assess oral and written language fluency, ask which language they prefer to receive their health information in and use interpreters where necessary.

Interview questions categorised by functional health patterns are listed in the box above.

Physical assessment

Begin by explaining what will happen during the physical examination, and encourage the person to take deep, regular breaths to increase relaxation. If a rectal examination is included, explain that it may be uncomfortable may feel as though they might be about to have a bowel movement, and sometimes flatus (gas) is passed. Assure the person that this is normal. Ensure that the examination area is private and the person is draped properly to prevent unnecessary exposure. Remember to ask the person's permission to proceed with a physical examination.

Physical assessment of gastrointestinal and nutritional status may be performed as part of a total health assessment, as a focused assessment of people with known or suspected health problems, in combination with assessment of the urinary and reproductive systems (problems that may cause manifestations similar to those of the gastrointestinal system), or alone for people with known or suspected health problems. The techniques of inspection, auscultation, percussion and palpation are used. Palpation is the last method used in assessing the abdomen.

CONSIDERATION FOR PRACTICE

When assessing the abdomen, use palpation last, because pressure on the abdominal wall and contents may interfere with bowel sounds and cause pain, ending the examination.

Collect objective data by obtaining anthropometric measurements (height, weight, triceps skin folds and midarm circumference) and by examining the mouth and abdomen. Prior to the examination, collect all necessary equipment and explain techniques to the person to decrease anxiety. The person may be seated during assessment of the mouth, but is supine during the abdominal assessment. Older adults or those with limited mobility may need assistance with positioning.

Physical assessment of the integumentary system, nervous system, musculoskeletal system, cardiovascular system and respiratory system may also reflect the person's nutritional status. Table 20.5 summarises abnormal nutritional assessment findings related to these body systems. Normal age-related findings for the older adult are summarised in Table 20.6.

Diagnostic tests

The results of diagnostic tests of nutritional status and gastrointestinal function are used to support the diagnosis of a specific disease, to provide information to identify or modify the appropriate medication or therapy used to treat the disease and to help nurses monitor the person's responses to treatment and nursing care interventions. More information, including specific laboratory tests, is included in the discussion of disorders in Chapters 21, 22, 23 and 24.

Regardless of the type of diagnostic test, the nurse is responsible for explaining the procedure and any special preparation needed, for supporting the person during the examination as necessary, for documenting the procedure as appropriate and for monitoring the results of the test.

Genetic considerations

When conducting a health assessment interview and physical assessment, it is important for the nurse to consider genetic influences on the health of the adult. During the health assessment interview, ask about family members with known abnormalities of copper accumulation in the body, hypercholesteraemia, abnormal cholesterol or fat metabolism, obesity or cancer of the pancreas. During the physical assessment, assess for any manifestations that might indicate a genetic disorder (see the accompanying 'Genetic considerations' box). If data are found to indicate genetic risk factors or alterations, ask about genetic testing and refer for appropriate genetic counselling and evaluation. Chapter 7 provides further information about genetics in medical–surgical nursing.

TABLE 20.5 Assessment findings due to malnutrition

BODY SYSTEM	ASSESSMENT FINDINGS
Nails	Soft and spoon shaped in iron deficiency. Splinter haemorrhages in vitamin C deficiency.
Hair	Dry, dull and scarce in zinc, protein and linoleic acid deficiencies.
Skin	Flaky and dry in vitamin A, vitamin B and/or linoleic acid deficiency. Cracks and/or hyperpigmentation in niacin deficiency. Bruising in vitamin C or vitamin K deficiency.
Eyes	Eyes become dry and soft with decrease in vitamin A. Conjunctiva is pale with a decrease in iron and red with a decrease in riboflavin.
Nervous system	Reflexes are decreased and person may have peripheral neuropathies with thiamine deficiency. Person may be irritable and/or disoriented with thiamine deficiency.
Musculoskeletal system	Muscle wasting is seen with deficits in protein, carbohydrate and fat metabolism. Calf pain occurs with thiamine deficiency; joint pain may occur with vitamin C deficiency.
Cardiovascular system	Heart size and rate may increase with thiamine deficiency. Diastolic blood pressure may be increased with a high intake of fat. Lowered cardiac output and decreased blood pressure may occur with kilojoule deficiencies over a long time period.
Gastrointestinal system	Cheilosis (sores at corner of mouth) seen in vitamin-B-complex deficiencies, especially riboflavin. Stomatitis and spongy, bleeding gums may also be seen in malnutrition.

TABLE 20.6 Age-related gastrointestinal changes

AGE-RELATED CHANGE	SIGNIFICANCE
Teeth: ↑ number of root cavities and cavities around existing dental work; tooth enamel harder and more brittle; dentin is more fibrous; tooth cusps flatten; root pulp shrinks; ↑ loss of bone supporting teeth	Increase in periodontal disease and tooth loss Increase in fractures of teeth Increased incidence of dentures, caps, tooth implants
Gums: gingiva retracts	Increase in periodontal disease
Taste: less acute as tongue atrophies, especially for sweet sensations	Excessive seasoning of foods
Saliva: ↓ amount is produced (one-third of that produced in younger years)	Decreased ability to break down starches Swallowing may take longer
Oesophageal motility: ↓ intensity of propulsive waves and slower emptying time, weaker gag reflex	Discomfort when swallowing food Increased risk of aspiration
Stomach: mucosa atrophies, ↓ production of hydrochloric acid and pepsin leading to higher pH in stomach	Increase in incidence of gastric irritation
Liver: less efficient handling of cholesterol	Increased incidence of gallstones

DIAGNOSTIC TESTS Gastrointestinal disorders

OESOPHAGEAL AND STOMACH TESTS

NAME OF TEST Oesophageal acidity, Oesophageal manometry, Acid perfusion (Bernstein test)

PURPOSE AND DESCRIPTION Oesophageal acidity is measured to diagnose problems of the lower oesophageal sphincter and chronic reflux oesophagitis. A catheter with a pH electrode is inserted into the oesophagus through the mouth. The measurement may be one time, or over a 24-hour period.

Oesophageal manometry is done to measure oesophageal sphincter pressure and peristaltic contractions for diagnosis of oesophageal motility problems, such as achalasia. A manometric catheter with a pressure transducer is inserted into the oesophagus through the mouth and oesophageal pressure is measured before and after swallowing.

Acid perfusion (Bernstein test) tests are performed to distinguish between gastric acid reflux and cardiac involvement. A nasogastric tube is inserted through the nose into the oesophagus. A saline solution, followed by a hydrochloric acid (HCl) solution, is dripped into the catheter and the person is asked to indicate when pain occurs. Normal oesophageal pH is 5 to 6.

RELATED NURSING CARE Advise the person to be nil by mouth (NBM) and to avoid alcohol intake for 8–12 hours prior to the exam. Assess medications: results of the tests may be affected by antacids, anticholinergics and cimetidine-like drugs, which increase the pH, reducing acidity and causing false test results.

NAME OF TEST Barium swallow or Upper GI series (see Figure 20.7)

PURPOSE AND DESCRIPTION To diagnose oesophageal varices, inflammation, ulcerations, hiatal hernia, foreign bodies, polyps, diverticula and tumours of the oesophagus, stomach and duodenal bulb. These radiological studies are done by observing the movement of a contrast medium with a fluoroscope.

RELATED NURSING CARE Advise the person to be NBM and avoid smoking for 8–12 hours before the exam; person will drink 450–550 g of barium sulfate (a non-water-soluble chalky liquid) or meglumine diatrizoate (Gastrografin, a water-soluble liquid) before the exam. Withhold medications for 8 hours before the exam, according to the medical officer's directions. Following the exam, ensure the person eliminates the barium by giving laxatives and forcing fluids as appropriate.

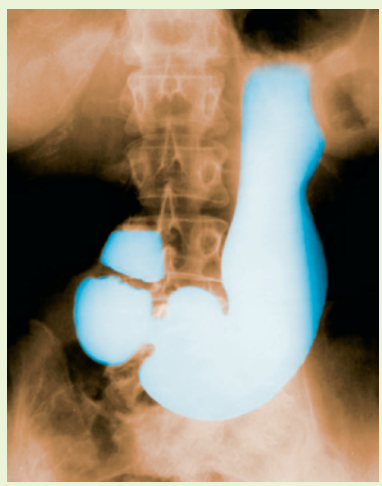

FIGURE 20.7 ■ A barium x-ray of a healthy stomach

Source: Biophoto Associates/Science Source.

(continued)

DIAGNOSTIC TESTS Gastrointestinal disorders (continued)

NAME OF TEST Barium enema

PURPOSE AND DESCRIPTION An x-ray examination of the lower gastrointestinal (GI) tract, it is used to diagnose inflammation, ulcerations, structural changes, diverticula and tumours of the lower GI and investigations of pain and anaemia. These radiological studies are done by observing the movement of a contrast medium, which is inserted through a tube in the rectum into the colon.

RELATED NURSING CARE Preparation for the test requires emptying of the large intestine. The nurse will advise the person to follow a clear fluid diet for 1–3 days prior to the examination. The day prior to the test the person will be required to take a combination of oral laxatives and an enema (an additional enema may be required on the day). Following the exam, the person will resume a normal diet. If the person has not eliminated the barium a laxative may be required.

NAME OF TEST Colonoscopy

PURPOSE AND DESCRIPTION An examination of the lower GI tract, used to diagnose cancer, inflammation, ulcerations, structural changes and investigations of pain, bowel changes and anaemia. The colonoscope is used to directly visualise the colon and rectum; a biopsy can be taken during the examination if an abnormal growth is visualised.

RELATED NURSING CARE Preparation for the test requires emptying of the large intestine. The nurse will advise the person to follow a clear fluid diet for 1–3 days prior to the examination. The day prior to the test the person will be required to take a combination of oral laxatives and an enema (an additional enema may be required on the day). Inform the person a light sedative is given during the exam. Following the exam, the person will resume a normal diet; inform the person flatus is quite common post procedure. The person will require someone to drive them home following the test due to the sedatives used during the examination.

NAME OF TEST Upper GI endoscopy (Oesophagogastroduodenoscopy (OGD))

PURPOSE AND DESCRIPTION To directly visualise mucous membrane lining of the oesophagus, stomach and duodenum. A flexible fibre-optic endoscope is used to visualise inflammations, ulcerations, tumours or varices; and video imaging may illustrate gastric motility. May also be combined with an ultrasound examination by attaching an ultrasound transducer to the endoscope.

RELATED NURSING CARE Schedule at least 2 days after barium swallow or upper gastrointestinal series. Ensure the informed consent is signed prior to premedication. Encourage questions and provide answers and support.

Keep the person NBM for 6–8 hours before the procedure. Remove dentures and eyewear. Follow routine preoperative checklist.

HEALTH EDUCATION FOR THE PERSON AND FAMILY

- Do not eat or drink anything for 6–8 hours before the procedure.
- The procedure is somewhat uncomfortable but requires only 20–30 minutes to complete.
- A local anaesthetic will be used in your throat and you will be given a sedative during the procedure.
- After the procedure, you will be allowed to eat and drink as soon as your gag reflex returns and you are able to swallow.
- You may experience mild bloating, belching or flatulence following the procedure.
- Contact your doctor immediately if you develop any of the following: difficulty swallowing; epigastric, substernal or shoulder pain; vomiting blood; black tarry stools; or fever.

NAME OF TEST Magnetic resonance imaging (MRI)

PURPOSE AND DESCRIPTION A scan that uses magnetic and radio waves to identify a source of gastric bleeding, tumours or cysts.

RELATED NURSING CARE Inform the person of need to lie still during the examination. Remove any metallic objects (such as hair clips, jewellery) and assess for any metallic implants (such as pacemakers, body piercings, shrapnel). If present, test is not performed due to the danger caused by the magnetic field from the machine. Explain the need to be NBM for at least 6 hours prior to the exam.

NAME OF TEST Gastroscopy

PURPOSE AND DESCRIPTION See Upper GI endoscopy.

RELATED NURSING CARE See Upper GI endoscopy.

DIAGNOSTIC TESTS Gastrointestinal disorders (continued)

NAME OF TEST Gastric analysis
Normal values:
Fasting: 1.0–5.0 mEq/L/per hour
Stimulation: 10–25 mEq/L/per hour

PURPOSE AND DESCRIPTION To evaluate gastric secretions and detect an increase or decrease of free hydrochloric acid. To conduct the gastric analysis, a nasogastric tube is inserted into the stomach and specimens are aspirated to evaluate gastric acidity. A stimulation gastric analysis may follow, with a gastric stimulant (such as Histalog or pentagastrin) administered and several gastric samples aspirated.

RELATED NURSING CARE Advise person to remain NBM with no smoking for 8–12 hours prior to the exam. Assess medications and fluid intake: anticholinergics, cholinergics, adrenergic blockers, antacids, steroids, alcohol and coffee can alter results. Remove loose dentures. Insert nasogastric tube. Aspirate gastric contents at 15- to 20-minute intervals as ordered.

NAME OF TEST Gastric emptying studies

PURPOSE AND DESCRIPTION To evaluate the ability of the stomach to empty liquids or solids. In this nuclear imaging study, the person is asked to eat a cooked egg containing Tc^{-99m} (solids) or to drink orange juice with Tc^{-99m} (liquids). Sequential images are recorded with a gamma camera every 2 minutes for up to an hour. Emptying should occur within 70–125 minutes.

RELATED NURSING CARE Explain to person that the substances contain only very small amounts of radioactivity and are not hazardous.

GALLBLADDER AND PANCREAS TESTS

NAME OF TEST Abdominal ultrasound, Hepatobiliary ultrasound, Gallbladder ultrasound

PURPOSE AND DESCRIPTION Abdominal ultrasound is used to detect abdominal tumours, cysts and ascites.

Hepatobiliary ultrasound is used to visualise the biliary ducts and to detect subphrenic abscesses, cysts, tumours and cirrhosis of the liver.

Gallbladder ultrasound is used to detect gallstones.

These non-invasive procedures record ultrasound waves as they are reflected off body structures. A conductive gel is applied to the skin and a transducer placed on the area.

RELATED NURSING CARE Advise the person to remain NBM for 8–12 hours prior to the test.

NAME OF TEST Cholecystography (oral) (GB Series)
If the gallbladder cannot be visualised with an oral contrast substance, an IV cholangiography may be ordered. *If the person is also having GI x-rays with barium, the GB tests should be done first, because barium would interfere with the test.*

PURPOSE AND DESCRIPTION To detect gallbladder stones, inflammation or tumours and obstruction of the cystic duct. The evening before the test, radiopaque tablets (e.g. iopanoic acid (Telepaque), sodium ipodate (Oragrafin), iodoalphionic acid (Priodax) or iodipamide meglumine (Cholografin)) are given; the following morning x-rays are taken. A high-fat meal may be given after the fasting x-rays are completed and further x-rays taken to determine how fast the GB expels the dye.

RELATED NURSING CARE Advise person to eat a fat-free diet 24 hours prior to the test. No food or fluids except sips of water should be taken 12 hours before the test. Assess person for allergy to iodine, seafood or x-ray dye (many contain iodine).

NAME OF TEST Cholangiography

- Percutaneous transhepatic cholangiogram (PTC)
- Surgical cholangiogram

PURPOSE AND DESCRIPTION A PTC is done to evaluate filling of the hepatic and biliary ducts. Using local anaesthesia, the liver and bile duct is entered with a long needle (using fluoroscopy), bile is withdrawn and a contrast medium is injected into the bile duct.

During a surgical cholangiogram with general anaesthesia, contrast medium is injected into the common bile duct to evaluate filling of the common bile duct.

RELATED NURSING CARE Assess person for allergy to iodine, seafood or x-ray dye (many contain iodine). Monitor for bile leakage or haemorrhage following the tests. Normal preoperative routine is required for the surgical procedure.

NAME OF TEST Magnetic resonance cholangiopancreatography (MRCP)

PURPOSE AND DESCRIPTION This non-invasive MRI study is done to evaluate the biliary and pancreatic ducts.

RELATED NURSING CARE Assess for metal implants or pregnancy. (Test will not be done if present.)

(continued)

DIAGNOSTIC TESTS Gastrointestinal disorders (continued)

NAME OF TEST Computed tomography (CT)

PURPOSE AND DESCRIPTION A non-invasive procedure, using radiofrequency waves and a magnetic field; used to evaluate disorders of the gallbladder, pancreas, biliary tract and liver.

RELATED NURSING CARE No special preparation is needed.

NAME OF TEST Endoscopic retrograde cholangiopancreatography (ERCP)

PURPOSE AND DESCRIPTION To directly visualise gastrointestinal structures and retrieve gallstones from the distal common bile duct, dilate structures and biopsy tumours. A fibre-optic endoscope is inserted (under fluoroscopy) through the mouth down the oesophagus, stomach and descending duodenum, and the common bile ducts and pancreatic ducts are cannulated. Contrast medium is injected into the ducts and structures are visualised.

RELATED NURSING CARE Advise the person to be NBM for 8 hours before the test. Following the test, assess vital signs and gag reflex and monitor for complications (such as pancreatitis).

NAME OF TEST Serum lipase

PURPOSE AND DESCRIPTION This blood test is used to measure the secretion of lipase by the pancreas.

Normal value: 0–160 Unit/L

RELATED NURSING CARE No special preparation is needed.

NAME OF TEST Serum amylase

PURPOSE AND DESCRIPTION This blood test is used to measure the secretion of amylase by the pancreas. It is used to diagnose acute pancreatitis, when amylase level peaks in 24 h and then drops to normal in 48 to 72 h.

Normal value: 0–130 Unit/L

RELATED NURSING CARE No special preparation is needed.

LIVER TESTS

NAME OF TEST Liver biopsy

PURPOSE AND DESCRIPTION To rule out metastatic cancer or to detect a cyst or cirrhosis of the liver. Using ultrasound, a biopsy needle is inserted into the liver and guided to the pathological site. See Figure 20.8.

RELATED NURSING CARE Related nursing care of the person having a liver biopsy is described below.

PREPARATION OF THE PERSON

- Review chart for signed consent form.
- Keep the person NBM as per policy, usually 4–6 hours pre-procedure.
- Assess and record baseline vital signs.
- Review prothrombin time (PT) and platelet count; administer vitamin K as ordered.
- Instruct to empty bladder immediately before the biopsy.
- Place in supine position on far right side of bed; turn head to left and extend right arm above head to improve access to the biopsy site.

HEALTH EDUCATION FOR THE PERSON AND FAMILY

- Discuss preparation for the biopsy and expected sensations during the procedure.
- Hold your breath following expiration during needle insertion to keep diaphragm and liver high and stabilised in the abdominal cavity.
- Obtaining the tissue sample usually requires only 10–15 seconds; there may be some pain or discomfort during this time.
- Direct pressure is applied to the site immediately after the needle is removed; you will be placed on your right side to maintain site pressure.
- You may develop pain in the right shoulder as the anaesthetic loses effect.
- You will be monitored for bleeding after the procedure.
- Food and fluids are withheld for 2 hours after the biopsy; you then can resume your usual diet.
- Avoid coughing, lifting or straining for 1–2 weeks.

Note: A wide variety of blood tests are used to diagnose and monitor liver disease. These are discussed in appropriate interprofessional care sections in Chapter 24.

DIAGNOSTIC TESTS Gastrointestinal disorders (continued)

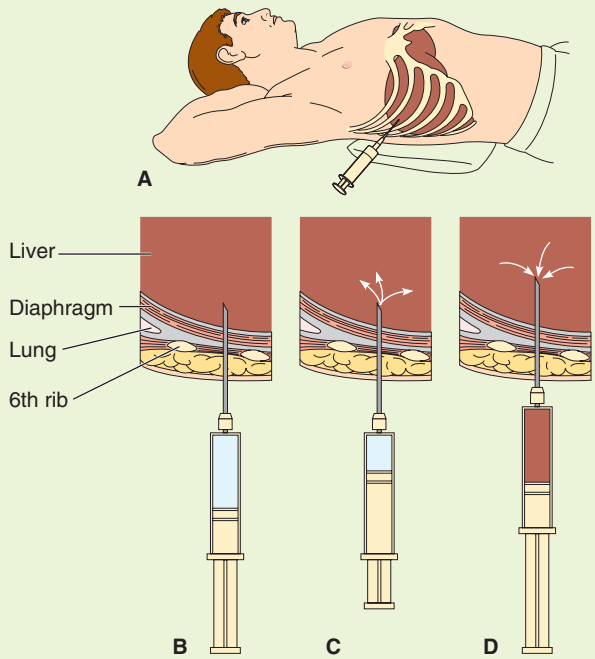

FIGURE 20.8 ■ Liver biopsy. *A*, The person exhales completely, and then holds their breath. This brings the liver and diaphragm to their highest position. *B*, The biopsy needle is inserted into the liver. *C*, Approximately 1 mL of saline is injected to clear the needle of blood and tissue. *D*, The needle is advanced and a tissue sample is aspirated. Pressure is applied to the site immediately after the needle is withdrawn. The specimen is sent to the laboratory for analysis

GENETIC CONSIDERATIONS Nutritional and gastrointestinal system

- Cleft lip and/or palate are influenced by genetic factors.
- An autosomal recessive disorder, Wilson's disease is an abnormality of copper transport, resulting in copper accumulation and toxicity to the liver and brain, resulting in neurological disease in adults.
- Colon cancer is one of the most common inherited cancer syndromes.
- Tangier disease is a disease of cholesterol transport, leading to characteristic orange tonsils, very low levels of high-density lipoprotein and an enlarged liver and spleen.
- Hypercholesterolaemia has a familial tendency.
- About 90% of human pancreatic cancers show a chromosome defect.
- Obesity is believed to result from a variety of factors, including genetics.
- Gaucher disease, more common in descendants of Jewish people from Eastern Europe, results in the lack of an enzyme to break down fats. Fats accumulate in the liver, spleen and bone marrow, causing pain, fatigue, jaundice, bone damage, anaemia and even death.
- Coeliac disease is a genetic, inherited disease responsible for the malabsorption of nutrients resulting in malnutrition. If people with coeliac disease eat certain types of proteins (glutens, found in wheat, barley, rye, and oats) an autoimmune response causes damage to the small intestine, so that nutrients are not absorbed.
- Due to a rapid change in diet, Indigenous Australians are prone to a group of conditions identified as 'insulin resistant syndrome' (also known as syndrome X). It includes renal disease, heart disease, obesity and type 2 diabetes (AIHW, n.d.).

NUTRITIONAL AND GASTROINTESTINAL ASSESSMENTS

Technique/normal findings	Abnormal findings

Anthropometric assessment

Weigh the person and measure the person's height. Compare the person's actual weight to ideal body weight (IBW) (see Table 20.7). *Weight should be appropriate to height as indicated on a standardised table.*

- A weight 10–20% less than ideal body weight indicates malnutrition.
- A weight 10% above ideal body weight is considered overweight.
- A weight 20% above ideal body weight is considered obese.

TABLE 20.7 Example of a height and weight table (IBW)

HEIGHT (CM)	HEIGHT (FT, IN)	WEIGHT (KG)	HEIGHT (CM)	HEIGHT (FT, IN)	WEIGHT (KG)
148	4'10"	44–55	173	5'8"	59–74
150	4'11"	45–56	175	5'9"	61–76
152	5'0"	46–58	178	5'10"	63–79
155	5'1"	48–60	180	5'11"	65–81
158	5'2"	50–62	183	6'0"	66–83
160	5'3"	51–64	185	6'1"	68–85
162	5'4"	52–66	188	6'2"	71–88
165	5'5"	54–68	190	6'3"	72–90
168	5'6"	66–71	193	6'4"	74–92
170	5'7"	58–72	196	6'5"	77–96

Calculate the person's percentage of ideal body weight (%IBW). Use the formula in Table 20.8 to determine the presence of obesity and/or malnutrition based on %IBW. *Ideal body weight should be within normal range.*

TABLE 20.8 Indications of nutritional status by body weight

%IBW	%UBW	NUTRITIONAL STATUS
> 120	—	Obese
110–120	—	Overweight
80–90	85–95	Mildly undernourished
70–79	75–84	Moderately undernourished
< 70	< 75	Severely undernourished

UBW = usual body weight

- Using %IBW may result in overlooking malnutrition in a very obese person.

Calculate the person's percentage of usual body weight (%UBW) to determine weight change, using this formula:

$$\frac{\text{Current weight}}{\text{Usual weight}} \times 100$$

Refer to Table 20.8 to determine nutritional status based on %UBW.

Measure body mass index (BMI). Determine BMI by using one of the following formulas. *BMI should be between 20 and 25.*

$$\frac{\text{Weight in kilograms}}{\text{Height in metres}^2} = \text{BMI}$$

$$\frac{\text{Weight in pounds} \times 705}{\text{Height in inches}^2} = \text{BMI}$$

- A BMI of 25–29.9 kg/m^2 indicates overweight.
- A BMI of 30 kg/m^2 and above indicates obesity.

Technique/normal findings	Abnormal findings
Measure triceps skinfold thickness (TSF). Find the midpoint between the person's olecranon and acromion processes. Grasp the skin and fat and pull it away from the muscle. Apply skinfold calipers for 3 seconds and record reading (see Figure 20.9). Repeat three times and average the three readings. Compare the person's reading with the standard values shown in Table 20.9. *TSF should be within normal range as compared to standard values.*	■ Triceps readings are 10% or more below standards in malnutrition and 10% or more above standards in obesity or overnutrition.

FIGURE 20.9 ■ Measuring TSF with calipers

Source: 3660 Group Inc./Getty Images.

TABLE 20.9 Values for anthropometric measurements

	STANDARD VALUE	
MEASUREMENT	MALE	FEMALE
Triceps skinfold thickness	12.5 mm	16.5 mm
Midarm circumference	29.3 cm	28.5 cm
Midarm muscle circumference	25.3 cm	23.2 cm

Measure midarm circumference (MAC). Find the midpoint between the person's olecranon and acromion processes. Wind tape measure around arm (see Figure 20.10). Compare the person's reading to the standard values shown in Table 20.9. *MAC should be within normal range as compared with standard values.*	■ MAC decreases with malnutrition and increases with obesity.

FIGURE 20.10 ■ Measuring MAC with a tape measure

Source: Bubbles Photolibrary/Alamy.

Calculate midarm muscle circumference (MAMC). Use the person's triceps skinfold measurement and midarm circumference readings to calculate the person's MAMC: $MAMC = MAC - (0.314 \times TSF)$ Compare the result to the standard values shown in Table 20.9. *MAMC should be within normal range as compared to standard values.*	■ In mild malnutrition, the MAMC is 90% of the standard; in moderate malnutrition, 60–90%. In severe malnutrition (muscle wasting), the MAMC is less than 60% of the standard.

Technique/normal findings	Abnormal findings
Determine waist-to-hip ratio. With the person standing, measure the waist and then measure the hips midway between the iliac crest and the greater trochanter. Use the formula below to calculate the waist-to-hip ratio. *Normal findings: females, waist ratio less than or equal to 0.80; males, waist ratio less than or equal to 1.0.*	■ Females with a ratio greater than 0.80 and males with a ratio greater than 0.9 have a greater risk of mortality from a cardiac-related death.

$$\frac{\text{Waist circumference}}{\text{Hip circumference}} = \text{waist-to-hip ratio}$$

Oral assessment

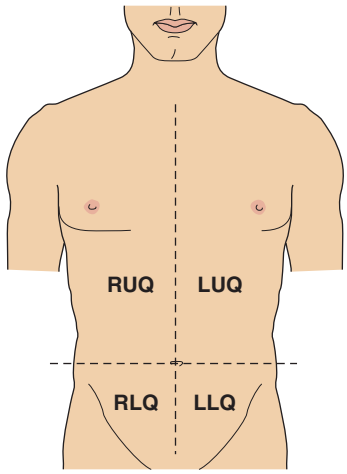
Inspect and palpate the lips. *Lips should be of normal colour for race without lesions.*	■ **Cheilosis** (painful lesions at corners of mouth) is seen with riboflavin and/or niacin deficiency. ■ Cold sores or clear vesicles with a red base are seen in herpes simplex 1.
Inspect and palpate the tongue. *Tongue should be pink, smooth and have good turgor.*	■ Atrophic smooth **glossitis** is characterised by a bright red tongue. It is seen in B_{12}, folic acid and iron deficiencies. ■ Vertical fissures are seen in dehydration. ■ A white or pale coated tongue during or after treatment with oral antibiotics can be caused by *Candida albicans* (the same pale fungus responsible for most vaginal yeast infections). ■ Black hairy tongue, also known as lingua villosa nigra, results from hyperkeratosis of the tongue. It may have different colours varying from white, yellow or brown to black depending upon the involved extrinsic factors (i.e. tobacco, coffee, tea, food or drugs) and intrinsic factors (i.e. chromogenic organisms in the normal flora).
Inspect and palpate the buccal mucosa. *Mucosa should be moist, without lesions and of appropriate colour.*	■ **Leucoplakia** (small white patches) may be a sign of a premalignant condition. ■ A reddened, dry, swollen mucosa may be seen in stomatitis. ■ Candidiases (white cheesy patches that bleed when scraped) may be seen in immunosuppressed people receiving antibiotics or chemotherapy, and in terminally ill people.
Inspect and palpate the teeth. *Teeth should be in a state of good hygiene without caries.*	■ Cavities and excessive plaque are seen with poor nutrition and/or poor oral hygiene.
Inspect and palpate the gums. *Gums should be of even colour without swelling.*	■ Swollen, red gums that bleed easily (**gingivitis**) are seen in periodontal disease, vitamin C deficiencies or with hormonal changes.
Inspect the throat and tonsils. *Tonsils (if present) should be of appropriate colour and size.*	■ In acute infections, tonsils are red and swollen and may have white spots.
Note the person's breath. *Breath should not have unusual or foul odours* (***halitosis***).	■ Sweet, fruity breath (like the smell of apples which are 'past their prime' or even downright rotten) is noted in diabetic ketoacidosis. A person on a high-protein diet can suffer from halitosis. ■ Acetone breath (smells like nail polish remover) may be a sign of uraemia or diabetes. ■ Foul breath may result from respiratory infections, postnasal drip, liver disease and anorexia. ■ Poor dental/oral health (e.g. untreated cavities, oral candidiasis and poor oral hygiene—inadequate brushing and flossing) may result in bad breath.

CONSIDERATION FOR PRACTICE
Always wear gloves when assessing the oral cavity.

Technique/normal findings	Abnormal findings

Abdominal assessment

The quadrants of the abdomen, with related internal structures, are illustrated in Figure 20.11. Box 20.2 provides guidelines for abdominal assessment.



Right Upper Quadrant
Liver and gallbladder
Pylorus
Duodenum
Head of pancreas
Right adrenal gland
Portion of right kidney
Hepatic flexure of colon
Portions of ascending and transverse colon

Left Upper Quadrant
Left lobe of liver
Spleen
Stomach
Body of pancreas
Left adrenal gland
Portion of left kidney
Splenic flexure of colon
Portions of transverse and descending colon

Midline
Aorta
Bladder
Uterus

◯ = Umbilicus

Right Lower Quadrant
Lower pole of right kidney
Caecum and appendix
Portion of ascending colon
Bladder (if distended)
Right ovary and salpinx
Right spermatic cord
Right ureter

Left Lower Quadrant
Lower pole of left kidney
Sigmoid colon
Portion of descending colon
Bladder (if distended)
Left ovary and salpinx
Uterus (if enlarged)
Left spermatic cord
Left ureter

FIGURE 20.11 ■ The four quadrants of the abdomen, with anatomical location of organs within each quadrant

BOX 20.2 Guidelines for assessing the abdomen

Ask the person to empty their bladder before beginning the examination. Assist the person to the dorsal recumbent (supine) position, with a small pillow under the head, a pillow under the knees (if desired) and the arms at the sides of the body. Warm the stethoscope before applying it to the person's skin. Ask the person to point to areas that are painful and explain that those areas will be examined last. Expose the abdomen from below the breasts to the pubic symphysis and drape the person's thoracic and genital areas. When you document your findings, specify the location by abdominal quadrant.

General guidelines for abdominal assessment are as follows:

1. Inspect the abdomen under a good light source that is shining across the abdomen. Sit at the right side of the person and note symmetry, distension, masses, visible peristalsis and respiratory movements. If masses are detected, ask the person to take a deep breath, which decreases the size of the abdominal cavity and makes any abnormality more visible.
2. Auscultate each quadrant of the abdomen, using the diaphragm of the stethoscope. Listen for bowel sounds, arterial bruits, venous hums and friction rubs.
3. Percuss several areas within each quadrant of the abdomen, using a systematic path (e.g. always begin in the lower left quadrant, then proceed to the lower right quadrant, upper right quadrant and upper left quadrant, respectively). The predominant percussion tones for the entire abdomen are tympany and dullness. Tympany is present over gas-filled intestines. Dullness is present over the liver, the spleen, an enlarged kidney or a full stomach. Percuss for fluid, gaseous distension and masses.
4. Palpate each quadrant of the abdomen for shape, position, mobility, size, consistency and tenderness of the major abdominal organs. Begin this part of the assessment with light palpation and increase the depth of palpation to elicit tenderness or better identify organ size and shape. Deep palpation should be conducted only by nurses with considerable experience. Remember to palpate areas of indicated tenderness last and to use gentle pressure. Palpation may be difficult or impossible if the person exhibits muscle guarding from pain or is ticklish. The gallbladder and the spleen are normally not palpable.

Technique/normal findings	Abnormal findings
Inspect abdominal contour, skin integrity, venous pattern and aortic pulsation. *Abdomen should be slightly concave or rounded with intact skin. There should not be distended veins or obvious aortic pulsations.*	■ Generalised abdominal distension may be seen in gas retention or obesity. ■ Lower abdominal distension is seen in bladder distension, pregnancy or ovarian mass. ■ General distension and an everted umbilicus are seen with ascites and/or tumours. ■ A scaphoid (sunken) abdomen is seen in malnutrition or when fat is replaced with muscle. ■ **Striae** (whitish silver), commonly called stretch marks, may result from rapid growth at puberty, during or after pregnancy, or significant weight gain. Striae may also occur as a result of abnormal collagen formation or a result of medications or chemicals that interfere with collagen formation. ■ Spider angiomas may be seen in liver disease. ■ Dilated veins are prominent in cirrhosis of the liver, ascites, portal hypertension or venocaval obstruction. ■ Pulsation is increased in aortic aneurysm.
Auscultate all four quadrants of the abdomen with the diaphragm of the stethoscope (see Figure 20.12). Begin in the lower right quadrant, where bowel sounds are almost always present. Normal bowel sounds (gurgling or clicking) occur every 5 to 15 seconds. *Listen for at least 5 minutes in each of the four quadrants to confirm the absence of bowel sounds.*	■ **Borborygmus** (hyperactive high-pitched, tinkling, rushing or growling bowel sounds) is heard in diarrhoea or at the onset of bowel obstruction. ■ Bowel sounds may be absent later in bowel obstruction, with an inflamed peritoneum and/or following surgery of the abdomen.
Auscultate the abdomen for vascular sounds with the bell of the stethoscope (see Figure 20.13). *No sounds (bruits, venous hum or friction rub) other than bowel sounds should be auscultated.*	■ **Bruits** (blowing sound due to restriction of blood flow through vessels) may be heard over constricted arteries. A bruit over the liver may be heard in hepatic carcinoma. ■ A venous hum (continuous medium-pitched sound) may be heard over a cirrhotic liver. ■ Friction rubs (rough grating sounds) may be heard over an inflamed liver or spleen.

FIGURE 20.12 ■ Auscultating the abdomen with the diaphragm of the stethoscope

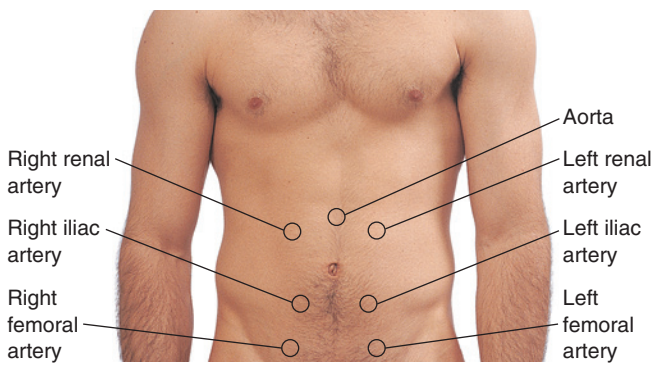


FIGURE 20.13 ■ Location of placement of the stethoscope for auscultation of arteries of the abdomen

Technique/normal findings	Abnormal findings
Percuss the abdomen in all four quadrants (see Figure 20.14). *Normally, tympany is heard over the stomach and gas-filled bowels.*	■ Dullness is heard when the bowel is displaced with fluid or tumours, or filled with a faecal mass.

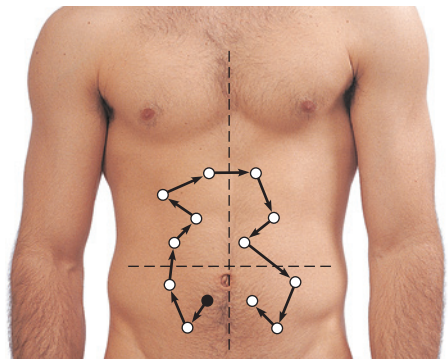

FIGURE 20.14 ■ Location of sites for systematic percussion of all four quadrants

Percuss the liver (see Box 20.3 for guidelines for liver percussion and palpation; see Figure 20.15 for landmarks). *The lower border of liver dullness is located at the costal margin to 1–2 cm below.*	■ In cirrhosis and/or hepatitis, the liver span is greater than 6–10 cm in the MCL and greater than 4–8 cm in the MSL.

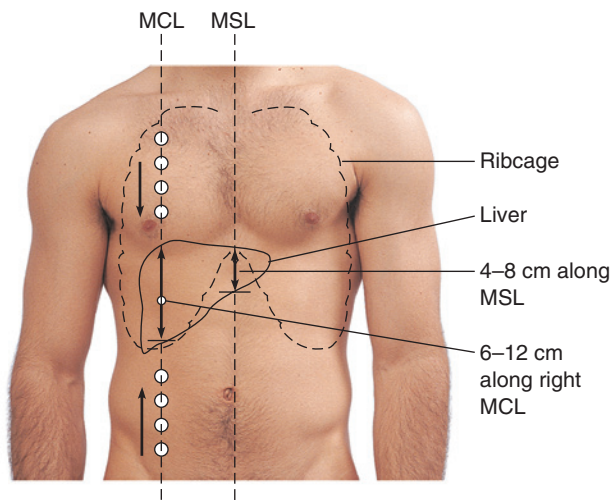

FIGURE 20.15 ■ Anatomical location of the liver, with the midclavicular line (MCL) and midsternal line (MSL) superimposed. The normal liver span is 6–12 cm at the MCL

BOX 20.3 Guidelines for percussing and palpating the liver

The size of the liver may be determined by percussion and palpation, as follows:

1. Percuss in the midclavicular line (MCL), beginning below the umbilicus (see Figure 20.15). Begin to percuss over a region of tympany and move upwards. The first dull percussion tone occurs at the lower border of the liver. Determine the upper liver border by beginning percussion over an area of lung resonance (in the MCL) and percussing downwards to the first dull tone, usually at the 5th to 7th interspace. Mark each of these locations and measure the distance from one mark to the other to determine liver size. The normal liver size is 6–12 cm at the MCL; however, men have larger livers than women.
2. Conduct bimanual palpation of the liver (see Figure 20.19) by placing your left hand under the person at the level of the 11th to 12th ribs and applying upward pressure. Place your right hand below the costal margin, ask the person to take a deep breath and palpate for the liver border. The liver is not normally palpable in a healthy adult, although it may be in very thin people.

Technique/normal findings	Abnormal findings
Percuss the spleen for dullness posterior to the midaxillary line at the level of the 6th to 11th rib (see Figure 20.16). *The spleen is percussed as an oval area of dullness approximately 7 cm wide near the left 10th rib and slightly posterior to the midaxillary line.*	■ A large area of dullness that extends to the left anterior axillary line on inspiration is associated with an enlarged spleen and may be related to trauma, infection or mononucleosis.

FIGURE 20.16 ■ Percussing the spleen

Percuss for shifting dullness (see Figure 20.17). *If ascites is not present, the borders between tympany and dullness remain relatively constant despite position changes.*	■ In a person with ascites, the level of dullness increases when the person turns to the side.

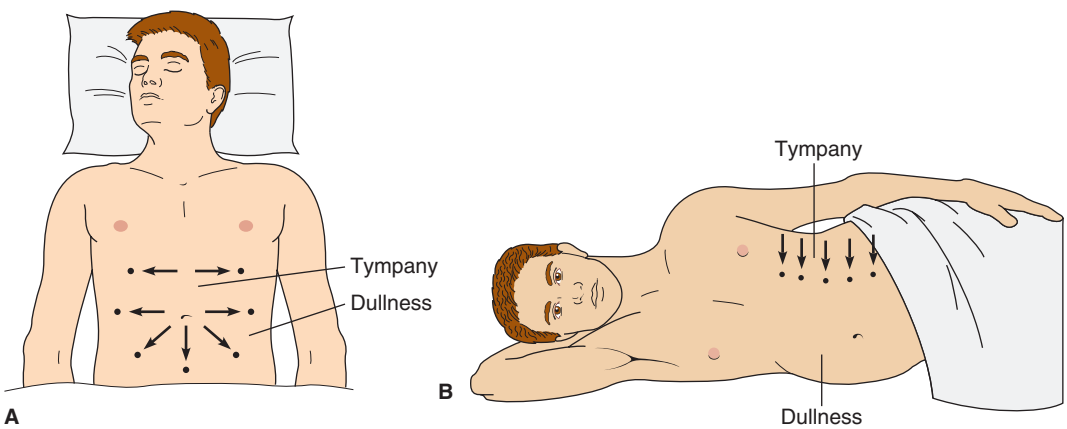

FIGURE 20.17 ■ Percussing for shifting dullness in ascites. *A*, Common percussion tones when the person is lying supine; *B*, changes in percussion tones (shifting dullness) when the person turns to the side

Palpate the abdomen in all four quadrants. *There should be no abdominal masses or pain on palpation.*	■ In cases of peritoneal inflammation, palpation causes abdominal pain and involuntary muscle spasms. ■ Abnormal masses include aortic aneurysms, neoplastic tumours of the colon or uterus, and a distended bladder or distended bowel due to obstruction. ■ A rigid, board-like abdomen may be palpated when the person has a perforated duodenal ulcer.

CONSIDERATION FOR PRACTICE

Never use deep palpation in a person who has had a pulsatile abdominal mass, renal transplant or polycystic kidneys, or is at risk of haemorrhage

Technique/normal findings	Abnormal findings
Use a circular motion to move the abdominal wall over underlying structures (see Figure 20.18). Feel for masses and note any tenderness or pain the person may have during this part of the exam. Palpate lightly at first (1.3–2 cm), then deeply (4–5 cm) with caution. If a mass is palpated, ask the person to raise the head and shoulders. A mass in the abdomen may become more prominent with this manoeuvre, as will a ventral abdominal wall hernia. If the mass is no longer palpable, it is deeper in the abdomen.	

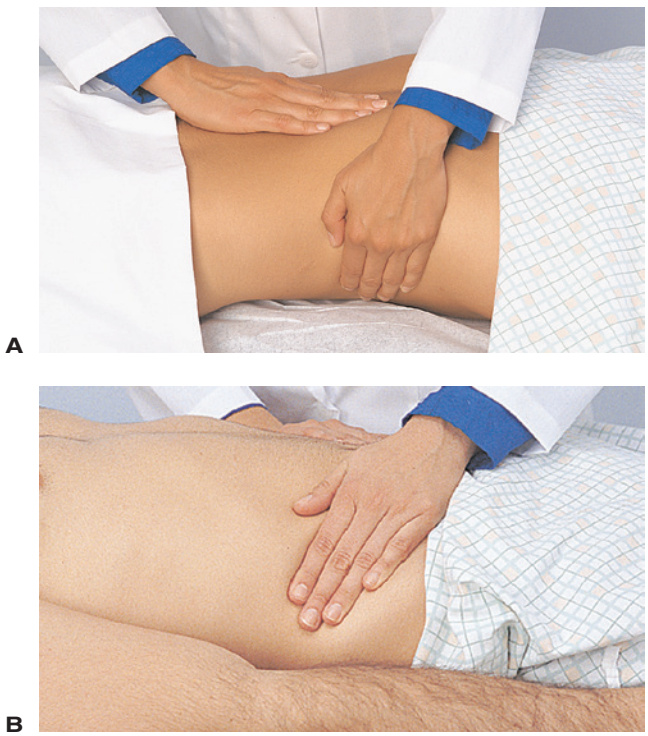

FIGURE 20.18 ■ Light to moderate palpation of the abdomen. *A*, In light palpation, the examiner, keeping the fingers approximated, gently depresses the abdominal wall about 1 cm to assess for large masses, slight tenderness and muscle guarding. *B*, The examiner performs moderate palpation by using the palm or the side of the hand to depress the abdominal wall to a slightly greater depth than in light palpation. This technique is useful for assessing abdominal organs that move with respiration (such as the liver and the spleen)

Palpate for rebound tenderness. Press the fingers into the abdomen slowly and release the pressure quickly. *Releasing pressure should not cause or increase pain.*	■ In peritoneal inflammation, pain occurs when the fingers are withdrawn. ■ Right upper quadrant pain occurs with acute cholecystitis. ■ Upper middle abdominal pain occurs with acute pancreatitis. ■ Right lower quadrant pain occurs with acute appendicitis. ■ Left lower quadrant pain is seen in acute diverticulitis.
Palpate the liver (see Figure 20.19). Note whether the person guards the abdomen or reports any sharp pain, especially on inspiration. *The abdomen should be non-tender and the liver is usually non-palpable.*	■ An enlarged liver with a smooth, tender edge may indicate hepatitis or venous congestion. ■ An enlarged, non-tender liver may be felt in a malignant condition. ■ The person with inflammation of the gallbladder feels sharp pain on inspiration and stops inspiring. This is called Murphy's sign.

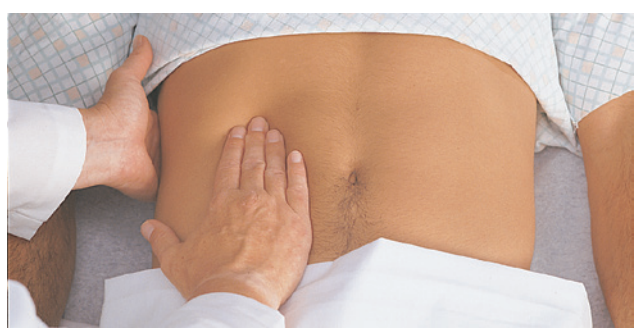

FIGURE 20.19 ■ Palpating the liver with the bimanual method

Inguinal area assessment

Inspect the inguinal area for bulges after asking the person to bear down. *The inguinal area is normally free of bulges.*	■ Bulges that appear in the inguinal area when the person bears down may indicate a **hernia** (a defect in the abdominal wall that allows abdominal contents to protrude outward).

Technique/normal findings	Abnormal findings
Palpate the inguinal area with a gloved hand. Ask the person to shift weight to the left to palpate the right inguinal area and vice versa. Place your right index finger upward into the inguinal area and ask the person to bear down or cough. *Bulging or masses are normally not palpable.*	■ A bulge or mass may indicate a hernia.

CONSIDERATION FOR PRACTICE

Nurses need to be culturally alert and competent when working with people with disorders of the bowel, bowel cancer and undergoing faecal testing. Ways of raising issues and talking about them will depend on a person's cultural worldview about health, bodies and elimination practices. Being well informed and engaging in ongoing cultural education, together with close collaboration with Indigenous or migrant health professionals, will assist nurses to provide relevant, timely and culturally safe care.

Perianal assessment (performed only by experienced nurses or under supervision)

Inspect the perianal area. Wearing gloves, spread the person's buttocks apart. Observe the area and ask the person to bear down as if trying to have a bowel movement. *The perianal area should be intact, without obvious lesions.*	■ Swollen, painful, longitudinal breaks in the anal area may appear in people with anal fissures. (These are caused by the passing of large, hard stools or by diarrhoea.) ■ Dilated anal veins appear with haemorrhoids. ■ A red mass may appear with prolapsed internal haemorrhoids. ■ Doughnut-shaped red tissue at the anal area may appear with a prolapsed rectum. ■ Movable, soft masses may be polyps.
If accredited to conduct a rectal examination, palpate the anus and rectum. Lubricate the gloved index finger and ask the person to bear down. Touch the tip of your finger to the person's anal opening. Flex the index finger and slowly insert it into the anus, pointing the finger towards the umbilicus (see Figure 20.20). Rotate the finger in both directions to palpate any lesions or masses. *There should be no masses in the anus or rectum.*	■ Hard, firm, irregular embedded masses may indicate carcinoma.

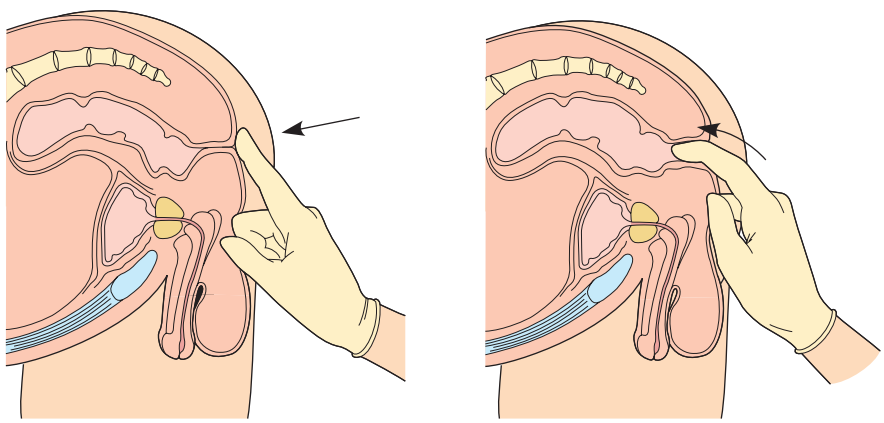

FIGURE 20.20 ■ Digital examination of *A*, the anus; and *B*, the rectum

Faecal assessment

Inspect the person's faeces. After palpating the rectum, withdraw your finger gently. Inspect any faeces on the glove. Note colour and/or presence of blood. Also use gloved fingers to note consistency. *Stool should be soft with no blood present, either on the stool or as occult blood.*	■ See Box 20.4 for information about stool characteristics.
Test the faeces for occult blood. Use a testing kit such as Occultest or Hemoccult II. *There should be no blood in the faeces.*	■ A positive occult blood test requires further testing for colon cancer or gastrointestinal bleeding due to peptic ulcers, ulcerative colitis or diverticulosis.
Note the odour of the faeces. *No distinctly foul odours should be present.*	■ Distinctly foul odours may be noted with stools containing blood, infections, parasites or extra fat, or in cases of colon cancer.

BOX 20.4 Assessing stool characteristics

Inspect faeces for colour, odour and consistency after the rectal exam or after defecation. Both hands are gloved.

Colour

- Blood *on* the stool results from bleeding from the sigmoid colon, anus or rectum. Blood *within* the stool indicates bleeding from the colon due to ulcerative colitis, diverticulosis or tumours. Black, tarry stools, called **melaena**, occur with upper gastrointestinal bleeding. Oral iron may turn stools black and mask melaena.
- Greyish or whitish stools can result from biliary tract obstruction due to lack of bile in stool.
- Greasy, frothy, yellow stools, called **steatorrhoea**, may appear with fat malabsorption.

Odour

- Distinct, foul odours may be noted with stools containing blood or extra fat, or in cases of colon cancer.
- Consistency:
  - Hard stools or long flat stools may result from a spastic colon or bowel obstruction due to a tumour or haemorrhoids. Hard stools may also result from dehydration or ingestion of oral iron.
  - Mucusy, slimy faeces may indicate inflammation and occur in irritable bowel syndrome.
  - Watery, diarrhoea stools appear with malabsorption problems, irritable bowel syndrome, emotional or psychological stress, ingestion of spoiled foods or lactose intolerance.

CONCEPT CHECK

1 A person you are caring for asks you what type of foods are complete proteins. What would be your best response?
1 none
2 eggs and milk
3 fruits and vegetables
4 butter and oils

2 Following minor surgery, a nurse would assess a person who is deficient in vitamin K for what possible complication?
1 infection
2 blood clotting
3 keloid formation
4 slow peristalsis

3 On monitoring a person's lab results, you notice a greatly elevated serum amylase level. What disease does this indicate?
1 cheilosis
2 gastric reflux
3 gallstones
4 acute pancreatitis

4 While assessing an older adult, you notice her teeth have obvious cavities and she has difficulty swallowing. She says, 'My mouth is so dry.' What health problem might result from these findings?
1 nutritional deficit
2 acute pain
3 altered elimination
4 risk of infection

5 What percussion sound would a nurse expect to hear when assessing the abdomen of a person with ascites?
1 inaudible bowel sounds
2 resonance
3 alternating amplitude
4 shifting dullness

6 A person asks you to tell her what internal haemorrhoids are. What would you say?
1 'They are part of the arteries of the body.'
2 'They are just bits of tissue that occur for no reason.'
3 'They are swollen veins in the anal canal.'
4 'They are part of the lymphatic system.'

7 Which of the following questions or statements would be appropriate for the person with an ostomy?
1 'Have you had any bleeding from your haemorrhoids?'
2 'Has your appetite changed lately?'
3 'Tell me about your family.'
4 'Describe the consistency of your stools.'

8 Why is removal of polyps from the colon during a colonoscopy important?
1 to identify genetic disorders
2 to prevent the development of cancer
3 to facilitate further examination of the bowel
4 to decrease future problems with constipation

9 What term is used to describe black, tarry stools?
1 occult blood
2 haematemesis
3 melaena
4 steatorrhoea

10 You are caring for a person the first day following bowel surgery. You do not hear bowel sounds during your initial assessment. What would you do?
1 Immediately call the doctor and report this abnormal finding.
2 Repeat the assessment in 30 minutes to ensure accuracy of findings.
3 Document the assessment as normal following abdominal surgery.
4 Ask another nurse to check your assessment before reporting it.

CHAPTER 21

NURSING CARE OF PEOPLE WITH NUTRITIONAL DISORDERS

SANDRA CAMPBELL-CROFTS

LEARNING OUTCOMES

- Describe the complications and interprofessional care associated with the nutritional disorder of obesity.
- Describe the pathophysiology, complications and interprofessional care associated with the eating disorder malnutrition.
- Compare and contrast the three nutritional eating disorders of anorexia nervosa, bulimia nervosa and binge-eating disorder.

CLINICAL COMPETENCIES

- Assess the functional health status of the person with nutritional disorders.
- Monitor nutritional status and responses to care; document and report abnormal or unexpected responses.
- Use assessment data to determine priority nursing diagnoses and select and implement nursing interventions.
- Administer medications and enteral and parenteral nutrition knowledgeably and safely.
- Integrate interprofessional care in the plan of care.
- Adapt cultural values and variations into the plan of care for the person with nutritional disorders.
- Plan and provide family teaching to restore, promote and maintain functional health status.
- Evaluate responses to care and use data to revise a plan of care as needed.

KEY TERMS

Obesity and malnutrition, the major nutritional disorders in the world today, affect many systems and organs. They often cause serious health problems, such as hypertension, cardiovascular disease, fluid and electrolyte imbalances, disability and even death.

A person with nutritional disorders requires complex, skilled nursing care. Developmental, sociocultural, psychological and physiological factors may play a role in these disorders: a holistic approach to nursing care is vital. Nursing care focuses on identifying causes, meeting nutritional and physiological needs, providing education and meeting the psychological needs of the person and their family. Before proceeding with the discussion of obesity and malnutrition, review the sections on metabolism and nutrients in Chapter 20.

THE PERSON WITH OBESITY

Obesity, an excess of adipose tissue, is one of the most common, preventable non-communicable health problems worldwide, with 1.6 billion adults classified as overweight and 400 million considered obese (World Health Organization, 2006). The contribution of obesity to a poor health-related quality of life is greater than alcohol abuse and similar to smoking, with 7% of the total burden of disease in Australia being attributed specifically to obesity (National Preventative Health Taskforce (NPHT), 2009).

Health-related problems associated with obesity are listed in Table 21.1.

While obesity is often defined by body weight, it is more accurately measured by the **body mass index (BMI)**, the international standard measurement of the amount of body fat or adipose tissue compared to height, and the waist-to-hip ratio. (See Box 21.1 to calculate BMI.) A BMI of 25 to 29.9 kg/m^2 is classified as *overweight but not obese*; class 1 obese is a BMI between 30 and 35 kg/m^2, class 2 obese is a BMI between 35 and 40 kg/m^2 and class 3 is a BMI greater than 40 (Australian Institute of Health & Welfare (AIHW), 2015). Class 3 obesity is also known as morbid obesity.

Incidence and prevalence

Australia ranks seventh among high-income countries for rates of obesity (National Health Performance Authority, 2013). According to the Australian Bureau of Statistics (ABS) (2012), in 2011–2012, 10.8 million Australian adults were estimated to be either overweight or obese and, of these, 4.7 million were estimated as being obese. The prevalence of overweight and obese Australian adults aged 18 years and over has continued to rise to over half the population, at 63.4% in 2011–2012. The prevalence of overweight and obese children aged 5–17 has stabilised at 25.3%. One challenge in obtaining accurate prevalence data is the tendency for people to underestimate their self-reported weight (Magnusson, 2010).

Table 21.2 shows estimations of overweight and obesity in Australia. It indicates that in 2011–2012 South Australia had the greatest percentage of Australian adults who were overweight but Queensland had the greatest percentage who were obese.

The ABS (2008) identified that adults with higher qualifications were less likely to be obese, while those in low-income households were more likely to be obese. Many overweight and obese individuals suffer from sarcopenic malnutrition (high fat mass, low muscle mass) due to the overconsumption of nutrient-poor high-fat diets.

The NPHT (2009) has reported that 11% of the burden of disease in Indigenous Australians can be attributed to overweight and obesity. Kondalsamy-Chennakesavan et al. (2008) found that Indigenous Australians have a lower BMI than Australians of European origin, but central fat deposition as measured by waist-to-hip-ratios was common in all Indigenous Australian communities.

TABLE 21.1 Health-related problems associated with obesity

BODY SYSTEM	OBESITY-RELATED PROBLEMS
Cardiovascular	Atherosclerosis, hypercholesterolaemia, dyslipidaemia Coronary artery disease Congestive cardiac failure Hypertension Stroke Varicosities Venous thrombosis, hypercoagulopathy, pulmonary embolism
Respiratory	Sleep disorders Asthma Sleep apnoea
Gastrointestinal	Gallbladder disease Diverticular disease Hiatal hernia Non-alcoholic fatty liver (steatohepatitis) Colorectal cancer Oesophageal cancer
Genitourinary	Cancer of the prostate Kidney cancer Obesity-induced glomerulopathy Stress incontinence
Musculoskeletal	Chronic lower back pain Muscle strains and sprains Osteoarthritis of hips and knees
Endocrine and reproductive	Metabolic syndrome Insulin sensitivity and/or resistance Diabetes mellitus, type 2 Pancreatic cancer Postmenopausal breast cancer Ovarian, uterine and endometrial cancers Amenorrhoea and infertility Complications of pregnancy, gestational diabetes mellitus Polycystic ovarian syndrome
Other	Depression Binge-eating disorder Postoperative complications, infection Obesity-related sarcopenia

TABLE 21.2 Estimations of overweight and obesity by Australian state or territory

STATE/TERRITORY	OVERWEIGHT	OBESE
South Australia	37%	30%
Western Australia	37%	28%
Tasmania	37%	28%
Australian Capital Territory	37%	25%
Victoria	35%	26%
New South Wales	35%	26%
Northern Territory	35%	27%
Queensland	30%	35%

Risk factors

Adipose tissue is created when energy consumption exceeds energy expenditure. Research has identified that adipose tissue is not a passive store of energy but plays a complex role in endocrine, metabolic and immune regulation which can contribute to the development of cancer, insulin resistance and type 2 diabetes mellitus (Booth, Magnuson & Fouts, 2015). Genotype technologies associated with the Human Genome Project have found specific genes related to the development of obesity, which has led to the view that some individuals are genetically predisposed to obesity (Locke et al., 2015).

Physical inactivity is probably the most important factor contributing to obesity. Inactive people may consume fewer kilojoules than active people but continue to gain weight due to a lack of energy expenditure. Contemporary cultural and environmental factors such as increased work and time pressures encourage the use of labour-saving devices and reliance on the car for transportation. Increased sedentary time spent watching television and using the computer also contribute to decreased energy expenditure (Dunstan et al., 2012). Environmental influences, such as an abundant and readily accessible food supply, fast-food restaurants, advertising and inappropriately stocked vending machines contribute to increased food intake. Magnusson (2010) has suggested that the imperative within the Australian food industry is the maintenance of profits through unhealthy purchasing patterns.

Sociocultural influences that contribute to obesity in Australia include the social appetite, which is the social, cultural, political, religious and economic contexts in which food is eaten. Examples are overeating at family meals, rewarding behaviour with food, religious and family gatherings that promote increased food intake, a tendency to eat meals away from home or eat takeaway meals from fast-food restaurants, and sedentary lifestyles (Germov & Williams, 2009). Economic pressures encourage low-income consumers towards higher-calorie energy-dense food options (Magnusson, 2010).

Low self-esteem may precipitate unhealthy eating behaviours such as seeking comfort foods (e.g. chocolate) and the resulting weight gain in turn may diminish self-image even further. A person may overeat as a result of anxiety, depression, guilt or boredom, or as a means of getting attention. Some experts characterise overeating as a food addiction and as a coping mechanism for stressful life events (Fraser, 2013).

Overview of normal physiology

All body activities require energy, including activities of daily living and those necessary to maintain cell and tissue function. **Nutrients** in food (or enteral or parenteral feedings) provide this energy and are the building blocks for growth and tissue repair. The body stores excess nutrients and energy (measured as kilojoules) to meet its needs when required nutrients are unavailable. More than 70% of the energy expended each day goes to maintaining the **basal metabolic rate (BMR)**, essentially the 'cost' (in kilojoules) of being alive. Physical activity accounts for only 5–10% of the energy spent daily.

Fat cells store excess energy as **triglycerides**, formed from dietary fats and carbohydrates. The body breaks down the triglycerides in fat cells when needed to provide energy (Porth & Matfin, 2009).

Pathophysiology

Obesity occurs when excess kilojoules are stored as fat. It can result from excess energy intake, decreased energy expenditure or a combination of both.

Appetite, which affects food intake, is regulated by the central nervous system and by emotional factors (Mayer, 2011). The hunger centre in the hypothalamus stimulates appetite in response to stimuli such as hypoglycaemia. As nutrient levels rise, the satiety centre (also in the hypothalamus) sends the message to stop eating. Gastrointestinal filling and hormonal factors also signal *satiety* (a sensation of fullness). Several hormones are involved in regulating obesity and body fat distribution including thyroid hormone, insulin, leptin (a peptide produced by adipocyte tissue that suppresses appetite and increases energy expenditure) and ghrelin (a peptide that originates within the lining of the stomach to induce hunger) (Klok, Jacobsdottir & Drent, 2007). The two main types of body fat distribution are central (visceral) obesity and peripheral (subcutaneous) obesity. Each type of body fat distribution is characterised by a different metabolic profile and degree of cardiovascular risk (Ibrahim, 2010).

Central (or visceral) **obesity** (apple shaped) is identified by a waist circumference greater than 80 cm in women and 94 cm in men or, alternatively, a waist-to-hip ratio of greater than 1 in men or 0.8 in women. (See Chapter 20 for a method to calculate the waist-to-hip ratio.) People with central body obesity tend to have more intra-abdominal fat within the mesentery and omentum which surrounds the abdominal organs, generate higher levels of circulating free fatty acids and have a greater uptake of glucose due to insulin resistance (Ibrahim, 2010). As a result, central obesity is associated with a greater risk of complications such as hypertension, abnormal blood lipid profile, heart disease, stroke and elevated insulin levels. Men tend to have more intra-abdominal fat than women, although women tend to develop a central fat distribution pattern after menopause due to oestrogen deficiency (Ibrahim, 2010).

Peripheral (or subcutaneous) **obesity** (pear shaped), in which the waist-to-hip ratio is less than 0.8, is more commonly seen in women. The risk of hyperinsulinaemia, abnormal lipids and heart disease is lower in people with peripheral obesity than in those with central obesity.

Complications of obesity

Obesity is a significant risk factor for cardiovascular disease, including hypertension, coronary heart disease (CHD) and heart failure. The prevalence of hypertension and hypercholestrolaemia in obese men and women is higher than in people with a BMI of less than 25 (Booth, Prevost & Gulliford, 2015). The increases in blood pressure seen with obesity increase the risk of CHD and stroke. Approximately 60% of obese individuals have **metabolic syndrome**, including three or more of the following: increased waist circumference; hypertension; elevated blood triglycerides and fasting blood glucose; and low HDL cholesterol (Ibrahim, 2010; McPhee, Papadakis & Tierney, 2008). The metabolic syndrome is an identified risk factor for atherosclerosis and CHD. Obesity-associated obstructive sleep apnoea also contributes to the risk of CHD and heart failure.

Obesity increases the risk of insulin resistance and type 2 diabetes mellitus. Both weight gain in adulthood and abdominal (central) obesity are positively correlated with the risk of developing insulin resistance and type 2 diabetes mellitus (Gallagher et al., 2009). Obesity affects reproductive function in both men and women. Androgen (male sex hormone) levels are reduced in obese men; menstrual irregularities and polycystic ovarian syndrome (PCOS) are more common in obese women. PCOS is an additional risk factor for hyperinsulinaemia and insulin resistance. Increased weight also increases the risk of developing gallstones in both men and women. The risk of developing several types of cancer, including colon, breast and endometrial, increases in obesity (AIHW, 2015). A link between obesity and chronic kidney disease has been attributed to the increased metabolic demands of the kidney, leading to higher glomerular capillary pressures with resultant glomerular hypertrophy (Singh & Kari, 2013). Increased weight places abnormal stress on joints, increasing the prevalence of joint pain and osteoarthritis, particularly in the weight-bearing joints of the knees and hips. Other health-related problems associated with obesity are listed in Table 21.1.

INTERPROFESSIONAL CARE

Because obesity has many contributing factors, its treatment is far more complex than just reducing the amount of food consumed. Most experts recommend an individualised program of moderate exercise, diet and behaviour modification designed to meet that person's specific capabilities and needs.

Diagnosis

Although body weight may be used to identify obesity, measures of body fat are more accurate. Males at ideal body weight have 10–20% body fat, whereas females at ideal body weight have 20–30% body fat.

BOX 21.1 Calculating body mass index (BMI)

BMI = weight (kg)/height^2 (m^2)
Normal = BMI 18.5–24.9 kg/m^2
Overweight = BMI 25–29.9 kg/m^2
Obese = BMI > 30 kg/m^2
Morbid obesity = BMI > 40 kg/m^2

- *Body mass index* is used to identify excess adipose tissue (National Health and Medical Research Council (NHMRC), 2013a). BMI is calculated by dividing the weight (in kilograms) by the height in metres squared (m^2) (see Box 21.1). BMI calculations may not as accurately reflect the extent of adipose tissue in people who are highly muscular (e.g. body builders) or in those who have lost muscle mass (e.g. older adults). Table 21.3 provides a tool for determining adult BMIs.
- *Anthropometry* includes measurements of height, weight, bone size and skinfold to estimate subcutaneous fat. See Chapter 20 for more information about anthropometric measurements.
- *Waist circumference* is an additional measurement to determine body fat distribution. The measurement is taken halfway between the last rib and the top of the iliac crest. Men with a waist measurement of 94 cm or greater and women with a waist measurement of 80 cm or greater have a higher risk of complications of obesity.

Other diagnostic tests may be done to help identify a physiological cause of obesity, as well as complications of obesity.

- *A thyroid profile*, including a total T_3 and T_3 uptake, free T_4 (FT_4) and total T_4, free thyroxine index (FTI) and thyroid-stimulating hormone (TSH), rules out thyroid disease (see Chapter 17).
- *Serum glucose* is measured to identify coexisting diabetes mellitus.
- A *lipid profile* is ordered; high-density lipoprotein (HDL) ('good cholesterol') levels may be reduced in obese people, whereas low-density lipoprotein (LDL) ('bad cholesterol') levels are elevated.
- An *electrocardiogram* (ECG) is performed to detect effects of obesity on the heart, such as rate or rhythm disruptions, myocardial infarction or ventricular hypertrophy.

Medications

When used in combination with diet and moderate exercise, medications can assist in promoting weight loss. Their long-term efficacy, however, is questionable; rebound weight gain following the cessation of drug use is common. In addition, tolerance, addiction and side effects may occur. These products are usually recommended only as an adjunct to therapy and only when the traditional therapies of diet and exercise have been unsuccessful.

Sibutramine hydrochloride (Reductil) is a prescription-only medication that acts on the CNS as an appetite suppressant. Orlistat (Xenical) inhibits fat absorption from the GI tract, leading to weight loss. It has the added benefit of lowering blood

TABLE 21.3 Body mass index table for BMIs

Height (cm)	Weight (kg)																	
200	11	13	14	15	16	18	19	20	21	23	24	25	26	28	29	30	31	33

glucose and cholesterol. See the 'Medication administration' box below for the nursing implications of these drugs.

Methylcellulose and other bulk-forming products may decrease appetite by producing a sensation of fullness. A person taking these products may experience flatulence or diarrhoea and may need to increase fluid intake to prevent constipation.

Treatments

Successful treatment of obesity (sustained achievement of normal body weight without adverse consequences) is rarely achieved. Treatment focuses on reducing the health risks associated with obesity by changing lifestyle in both eating and exercise habits. A combination of treatments including a reduction in sedentary behaviour and an increase in physical activity, dietary therapy, behaviour modification, pharmacology and, in some cases, surgery is required to achieve and maintain weight loss.

EXERCISE Exercise is a critical element in weight loss and maintenance. Physical activity improves physical fitness, decreases appetite, promotes self-esteem and increases the basal metabolic rate. An exercise or activity program should reflect the person's physical condition, interest, lifestyle and abilities (NHMRC, 2013b). Evaluation by a healthcare practitioner is important before beginning an exercise program. The practitioner instructs the person to progressively increase the duration and intensity of activity but to stop exercising and report symptoms if chest pain or shortness of breath occurs. A moderate aerobic exercise program of 30–40 minutes, 5 or more days a week promotes weight loss while reducing adipose tissue, increasing lean body mass and promoting long-term weight control. Table 21.4 presents examples of kilojoule use per hour for moderate physical activities.

TABLE 21.4 Kilojoule use per hour for moderate physical activities

TYPE OF EXERCISE	KILOJOULES/HOUR	TYPE OF EXERCISE	KILOJOULES/HOUR
Sleeping	230	Walking	1170
Eating	360	Table tennis	1210
Sewing	360	Gardening	1470
Knitting	360	Tennis	1470+
Sitting	360	Water aerobics	1670
Standing	420	Skating	1760+
Driving	460	Dancing, aerobic	1760+
Office work	590	Aerobics	1880+
Housework, moderate	670+	Bicycling, moderate	1880+
Golf, with trolley	750	Jogging	2090
Golf, without trolley	1000	Gardening, digging	2090
Gardening, planting	1050	Swimming, active	2090+
Dancing, ballroom	1090		

MEDICATION ADMINISTRATION Drugs to treat obesity

APPETITE SUPPRESSANTS

Sibutramine (Reductil)

Sibutramine reduces hunger and increases sensations of satiety by inhibiting the uptake of serotonin, noradrenaline and dopamine. The medication should be used in conjunction with a low-kilojoule, low-fat diet and regular moderate exercise.

Nursing responsibilities

- Assess for contraindications, such as pregnancy or lactation, use of other appetite suppressants, impaired liver or kidney function, history of CHD or alcohol abuse.
- Regularly monitor blood pressure and heart rate during treatment. Increases may indicate need to reduce dose or discontinue treatment.

Health education for the person and family

- Take as directed; do not exceed recommended dose. Do not take if you may be pregnant or are breastfeeding.
- Take your last dose no later than 4 pm to avoid insomnia.
- You may experience difficulty sleeping, nervousness or palpitations while taking this drug.
- Increase your fluid intake to reduce possible side effects of dry mouth and constipation.
- This drug does not replace diet and exercise for weight loss; continue to follow your prescribed regimen.

LIPASE INHIBITOR

Orlistat (Xenical)

Orlistat inhibits lipases necessary for the breakdown and absorption of fat, thus decreasing the absorption of dietary fat. Its action is primarily local, within the GI tract, with few systemic effects.

Nursing responsibilities

- Administer with meals or up to 1 hour following a meal.
- Provide a fat-soluble vitamin supplement (A, D, E and K) daily. Separate administration time from orlistat by at least 2 hours.

Health education for the person and family

- Take as directed; do not increase dose. You may skip a dose if you do not consume a meal containing fat.
- Use in conjunction with a low-kilojoule, low-fat diet.
- Common gastrointestinal side effects include oily or fatty stools, flatulence, oily discharge or frequent stools with difficulty controlling defecation. These side effects may diminish with time or increase if a meal high in fat is consumed.
- Notify your healthcare provider if you become pregnant while taking this medication.

NUTRITION The diet is planned to create a daily 2000 to 4000 kJ deficit off the recommended 8700 kJ/day currently recommended in Australia. Ideally, the diet should be low in kilojoules and fat, and contain adequate nutrients, minerals and fibre. The person should eat regular meals with small servings. A gradual, slow weight loss of no more than 0.5 kg per week is recommended. For most people, this means a diet of 4186 to 5020 kJ/day for women and 5020 to 6700 kJ/day for men. Fewer than 5020 kJ each day may lead to loss of lean tissue and nutritional deficiencies. 'Yo-yo' dieting (repeated cycles of weight loss and gain) may lead to a metabolic deficiency that makes subsequent weight loss efforts increasingly difficult. Therefore, it is critical that dieters take any weight loss effort seriously and include plans for long-term maintenance. The best approach is to modify dietary intake without severe restrictions, eating a well-balanced diet and developing improved eating habits.

Very-low-kilojoule diets (VLKDs), otherwise known as very-low-energy diets (VLEDs), are generally reserved for people who have a BMI greater than 30 (Sumithran & Proietto, 2008). This type of program requires meals to be replaced with nutritionally complete but protein-sparing and modified fat sachets of powder which are dissolved in a glass of water to create a 'milkshake'. Between 1674 and 3349 kJ/day is consumed. This type of weight loss regimen must be undertaken for any length of time under close medical supervision. Exercise, nutrition and behaviour modification counselling should accompany the diet (Snel et al., 2012). Adverse effects generally are minor, but could include fatigue, constipation, nausea and diarrhoea. Recently, the development of gallstones formation requiring cholecystectomy has been attributed to VLKDs (Gudzune et al., 2015).

BEHAVIOUR MODIFICATION People who wish to lose weight quickly readily accept dangerous regimens to achieve rapid weight loss. Behaviour modification is the critical component of a successful long-term weight loss management program. Strategies such as keeping food records of the type and amount of foods eaten, eliminating cues that precipitate eating such as television advertisements, and changing the type of food eaten and the speed of eating are often helpful.

Researchers have found that most overweight people are stimulated to eat by external and emotional cues, such as the proximity to food and the time of day. In contrast, hunger and satiety are the cues that regulate eating in adults of normal weight. Strategies to control food cues include keeping food out of view, controlling portion size, reducing or eliminating the habit of consuming snack foods, and eating only in designated areas. See Box 21.2 for a list of behavioural modification strategies.

Other behaviour modification approaches focus on helping a person examine factors that affect their eating behaviours (Magnusson, 2010). The goal is to empower the person who is stimulated to eat to choose other activities that are not related to food.

Weight loss services such as Weight Watchers, Jenny Craig Weight Loss Centres, SureSlim and Lite N' Easy promote weight loss success through coaching and peer support. Most organised programs require participants to pay a fee, which may improve compliance.

BOX 21.2 Behavioural modification strategies for the obese person

Controlling the environment

- Encourage participation in reading and analysing food labels so as to purchase nutritious low-kilojoule foods.
- Shop from a prepared list and on a full stomach.
- Keep all foods in the kitchen.
- Store all foods in the refrigerator or the cabinets in opaque containers.
- Prepare exact portions of food to eliminate leftovers.
- Limit portion size of foods.
- Ensure 2 serves of fresh fruit and 5 serves of vegetables are eaten each day (Department of Health and Ageing, 2008).
- Eat all foods in the same place; avoid eating in the kitchen or in the car.
- Avoid eating when watching television or reading.
- Reduce frequency of eating out at fast-food restaurants.

Controlling physiological responses to food

- Have set times for meals; avoid grazing behaviour.
- Eat slowly by taking small bites, allowing 20 minutes for a meal.
- Eat a salad or drink a hot beverage before a meal.
- Put eating utensils or food down between bites.
- Concentrate on the eating process; savour the food.
- Stop eating with the first feelings of fullness.

Controlling psychological responses to food

- Appreciate the aesthetic experience of eating.
- Use attractive dinnerware and prepare a formal setting for eating.
- Use small plates and cups to make servings of food look larger.
- Concentrate on conversations and socialisation during the meal.
- Use non-food rewards for meeting a goal.
- Acknowledge small successes and improvements in all behaviour.
- Substitute other activities for eating (e.g. reading, exercise, hobbies).

SURGERY Surgical treatment of obesity, otherwise known as *bariatric surgery* or *metabolic surgery*, is limited to **morbidly obese** people (BMI of over 40 kg/m^2 or 200% ideal body weight) who have a documented failure of non-surgical weight loss or those with a BMI over 35 kg/m^2 who have serious obesity-related health problems such as metabolic syndrome, type 2 diabetes mellitus, hypertension or heart disease (Korda et al., 2012). In addition, a person must be able to tolerate surgery and be free of addiction to alcohol or other drugs such as nicotine. The benefits of surgery include major weight loss, improved blood pressure, improved blood lipid profile, a remission of type 2 diabetes mellitus and reduced risk of sleep apnoea, angina and heart failure (Diabetes Australia, 2011). However, bariatric surgery is not without risk, and some people regain some of the lost weight over time. Surgical problems, such as a stretched pouch or separated stitches, may also affect the amount of weight loss). Although bariatric surgery procedures have been listed on the Australian Medicare Benefits Schedule (MBS) since 1992, Korda et al. (2012) found that this procedure is predominantly performed in private hospitals with significant out-of-hospital expenses, thereby exacerbating existing Australian health inequalities in obesity due to the socioeconomic gradient.

Bariatric surgery takes two forms: malabsorptive and restrictive. The most common procedures in Australia are all performed laprascopically: adjustable gastric banding; sleeve gastrectomy; and Roux-en-Y gastric bypass (Shannon, Gervasoni & Williams, 2013). In restrictive banding procedures such as adjustable gastric banding (AGB) (see Figure 21.1), a hollow band of silicone rubber is placed around the upper (proximal) portion of the stomach. The band is inflated with saline solution to create a small stomach pouch with a narrow passage through to the rest of the stomach which restricts the amount of food that can be consumed. The amount of band inflation can be adjusted using a port implanted under the skin. Sleeve gastrectomy is performed by resecting the stomach to the size of a tubular sleeve in the lesser curvature of the stomach (Rosenthal et al., 2012). The Roux-en-Y gastric bypass involves the stomach being made smaller, with the duodenum being bypassed to reduce absorptive capacity. This procedure was found to achieve a greater total weight loss and for up to 5 years but had a higher complication rate (Colquitt et al., 2014).

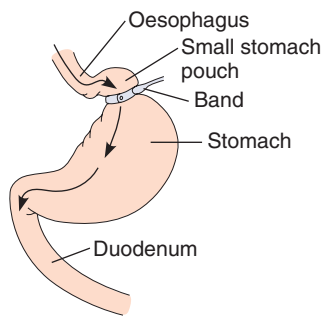

FIGURE 21.1 ■ Adjustable gastric banding

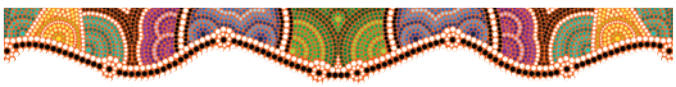
Few nutritional deficiencies are associated with restrictive bariatric procedures. Postprandial vomiting is a common postoperative complication (Shannon et al., 2013). The band may slip or break, necessitating a return to surgery.

Although the risk of postoperative complications is high, the mortality rate for bariatric procedures is low; possible postoperative complications include anastomosis leak with peritonitis, haemorrhage, abdominal wall hernia, gallstones, wound

infections, deep venous thrombosis, nutritional deficiencies and gastrointestinal symptoms (McPhee et al., 2008). In dumping syndrome, stomach contents move rapidly through the small intestine, drawing fluid into the intestine by osmosis. The person experiences nausea, bloating, abdominal pain, weakness, sweating and possibly syncope. See Chapter 22 for more information about dumping syndrome.

Nursing care for the person who has undergone bariatric surgery is substantially the same as for a person who has undergone a gastric resection. See Chapter 22 for more information about gastric resection and associated nursing care. People undergoing bariatric surgery have some additional nursing care needs related to the effects of the surgery on gastrointestinal function (see 'Meeting individualised needs', below).



Nursing care

Health promotion

Maintaining a healthy weight throughout the lifespan begins in childhood. Obese children and teenagers become obese adults. Promote healthy eating with education to reduce consumption of highly processed high-sugar, high-fat, high-salt foods and increase the exposure to low-processed nutrient-rich foods such as high-fibre whole grains, lean protein-rich meats, fresh fruits and a variety of vegetables (NHMRC, 2013b). The Health at Every Size (HAES) movement shifts the focus from weight loss to increasing health-promoting behaviours (Bacon & Aphramor, 2011). This healthy eating approach to health and thus weight loss has been supported by the Dietary Approaches to Stop Hypertension (DASH) diet which has been repeatedly demonstrated to protect against cardiovascular disease, stroke and heart failure (Salehi-Abargouei et al., 2013). The Healthy Living Pyramid (Nutrition Australia, 2015) provides visual guidance for appropriate food choices to maintain a healthy, well-balanced diet.

Adults commonly gain about 10 kg between early and middle adulthood. Encourage the person to reduce the number of kilojoules consumed as energy needs change.

Assessment

Collect the following data through the health history and physical examination (see Chapter 20):

- *Health history:* risk factors; current and usual weight; recent weight gains or losses; perception of weight and effect on health; usual diet and food intake; exercise/activity patterns; prior weight loss efforts and results; current medications; coexisting disorders such as cardiovascular disease and type 2 diabetes mellitus; tobacco use; family history of overweight and weight-related morbidity.
- *Physical examination:* vital signs; weight and height; anthropometric skinfold measurements; waist circumference; waist-to-hip ratio; BMI; inspect skin under the breasts and abdominal folds.

Nursing diagnoses and interventions

Nursing care for overweight and obese people is community based and holistic, focusing on both physiological and psychological responses to weight and appearance. See below for a nursing care plan for the person with obesity.

MEETING INDIVIDUALISED NEEDS Recommended diet following bariatric surgery

A person undergoing bariatric surgery to restrict stomach capacity and/or nutrient absorption has unique learning needs to prevent discomfort and nutritional complications after surgery:

- Ensure slow, progressive transitions in food texture from liquids to solid foods over the first 8 postoperative weeks. A restricted liquid diet is prescribed in the first 2 weeks of the postoperative period. Fruit juices and other concentrated sugars are avoided. *The person is at risk of developing dumping syndrome in the early postoperative period; simple carbohydrates increase the risk.*
- When clear liquids are tolerated, non-fat or low-fat milk is added to the diet. *Milk provides a protein source. Lactose-free or soy milk is recommended to reduce the risk of diarrhoea. People with a lactase deficiency may not be able to digest the natural lactose sugar in milk.*
- Pureed foods are introduced into the diet in approximately 1–2 weeks and the diet is advanced to include soft foods within about 2 months after surgery. *Gradual increases in food textures preserve the staple line and allow the restricted stomach to adapt.*
- Increasing fluid intake and maintaining protein intake are priorities during the healing process. *Fluid intake is necessary to maintain fluid balance and protein for nitrogen balance and tissue healing.*
- Instruct the person to eat regularly, consume smaller portions, cut food into small pieces, chew food well and eat slowly. *Failure to thoroughly chew food and eat slowly can lead to regurgitation, vomiting and abdominal discomfort.*
- Advise the person to take an adult multiple vitamin and mineral supplement after restrictive surgery. *Because the overall quantity of food consumed is reduced, the person may develop a micronutrient deficiency.*
- Advise the person to avoid sugar and concentrated sweets (fruit juice, sugar-containing beverages, honey) and to separate consumption of solid foods and liquids by at least 30 minutes. *Concentrated sugars can precipitate dumping syndrome.*

Source: Adapted from Shannon, Gervasoni & Williams (2013). The bariatric surgery patient: Nutrition considerations. *Australian Family Physician, 42*(8), 547–552.

CONSIDERATION FOR PRACTICE

Use of an inappropriate-sized sphygmomanometer is a common source of error in measuring blood pressure in obese people, resulting in a falsely high blood pressure. Choose a cuff on which the width of the bladder is 40% of the circumference of the arm and the length of the bladder is sufficient to cover at least 65% of the upper arm.

Activity intolerance

Obese people may experience excess fatigue, tachycardia and shortness of breath with activity due to the physiological effects of excess weight as well as a sedentary lifestyle. A medical evaluation may be needed before beginning an exercise program.

- Assess current activity level and tolerance of that activity. Assess vital signs. *This provides baseline information to plan an activity program and assess response to that activity.*
- After medical clearance, plan with the person a program of regular, gradually increasing exercise. Consider a consultation with an exercise physiologist. *An individualised exercise program promotes activities within that person's physical capabilities.*

Imbalanced nutrition: more than body requirements

Although many factors contribute to obesity, it always involves an imbalance of kilojoule consumption to energy expenditure.

- Encourage the person to identify the factors that contribute to excess food intake. *Identification of cues to eating helps the person eliminate or reduce these cues.*
- Establish realistic weight loss goals and exercise/activity objectives. *Small, reasonable goals, such as loss of 0.5 kg per week, increase the likelihood of success.*
- Encourage participation in reading and analysing food labels on processed and packaged foods. *Increased decision making encourages healthier food choices.*
- Assess knowledge and discuss well-balanced diet plans. Provide necessary teaching about the recommended inclusion of two fruit and five vegetable serves in the diet. *Knowledge empowers the person to participate and make appropriate food choices.*
- Discuss behaviour modification strategies, such as self-monitoring and environmental management. *Behaviour modification, diet and exercise are critical to promoting successful, long-term weight loss.*
- Monitor weight loss and blood pressure weekly with annual laboratory data, including blood glucose and lipid levels. *Continuing assessment is important not only to evaluate the safety of weight loss strategies, but also to reinforce positive benefits of weight loss.*

Ineffective therapeutic regimen management

Most overweight or obese people experience some difficulty integrating all the components of a weight loss program into a daily routine. For a weight loss and maintenance program to be successful, the overweight person must modify dietary intake in a world of daily temptations. There may be many obstacles to exercise, including a busy schedule, activity intolerance, impaired physical mobility, lack of equipment and the embarrassment of being fat.

- Discuss ability and willingness to incorporate changes into daily patterns of diet, exercise and lifestyle. *This provides data from which to set realistic goals with the person.*
- Beginning with gentle non-weight-bearing exercise such as swimming may encourage participation. Increase activity levels based on physical ability. *Exercise success increases likelihood of continuation.*
- Establish strategies for dealing with 'stress' eating or interruptions in the therapeutic regimen. *A sense of failure associated with overeating or lack of exercise can lead to further overeating. Identifying positive strategies to deal with these situations promotes self-acceptance and limits self-punishment through overeating.*

Chronic low self-esteem

Although many obese people may have accepted their weight and body appearance on some level, most overweight and obese individuals verbalise the experience of 'fat prejudice' or stigma in their family, workplace or community. Obese people may experience ridicule, prejudice and health problems attributed to being 'fat'. These experiences, coupled with day-to-day problems such as finding attractive clothing or a chair large enough to sit on can affect self-esteem. Many report that 'fat' jokes or comments contribute to a sense of negative self-worth.

- Encourage the person to verbalise the experience of being overweight and validate that experience. *This provides baseline data to use in developing individualised interventions to address self-esteem issues.*
- Set small goals with the person and offer positive feedback and encouragement. Small goals provide more opportunities for success. *Positive feedback and encouragement provide a comfortable environment in which to develop self-esteem.*
- Refer for counselling as appropriate. *Many people benefit from counselling for issues related to self-esteem.*

Community-based care

Weight reduction usually occurs in community-based settings. Weight loss and maintenance require a long-term commitment by the person, their family and supportive environmental systems that encourage healthy choices and lifestyles. Address the following topics with the person and their family:

- Small, subtle lifestyle modifications are more effective than dramatic diets. Fad diets promote rapid weight loss but often are not nutritionally sound or may be difficult to maintain for a lifetime (Magnusson, 2010).
- All household members should also consume a diet that is nutritionally sound. Encourage participation in analysing nutrient food labels prior to purchasing processed or packaged foods.

NURSING CARE PLAN A person with obesity

Sam Elliott, aged 57, has gained 20 kg since his retirement 2 years ago. The most active thing he does each day is 'pottering around the garden'. His diet includes apple juice, oatmeal porridge, 2 slices of white toast with strawberry jam and white coffee with 2 sugars for breakfast; 2 donuts or a blueberry muffin and coffee with friends mid-morning; a ham-and-cheese sandwich with a bag of potato chips and a soft drink for lunch; and cheese, biscuits and wine before a dinner of meat, potatoes, vegetables and dessert. He tells the nurse, 'I have never had to diet. I just don't know how to get this weight off.'

ASSESSMENT

Mr Elliott is 173 cm tall and weighs 91.2 kg. His BMI is 30.1 kg/m^2. His cholesterol is 6.14 mmol/L (normal < 5.13 mmol/L) with an HDL of 1.00 mmol/L (normal 1.5 mmol/L) and an LDL of 4.85 mmol/L (normal < 3.31 mmol/L). His BP is 138/90. His fasting blood glucose is normal at 5.0 mmol/L. His ECG shows normal sinus rhythm. He reports fatigue and shortness of breath with activity. His healthcare provider has advised a weight loss of 13 kg and a regular exercise program.

DIAGNOSES

- *Imbalanced nutrition* related to food intake in excess of nutritional energy requirements.
- *Risk of ineffective therapeutic regimen* related to knowledge deficit.
- *Activity intolerance* related to sedentary lifestyle evidenced by fatigue when attempting gentle exercise.

PLANNING

- Enter an agreement with Mr Elliott to meet once each week to assess progress.

Expected outcomes

- Lose 0.5 kg each week.
- Increase levels of moderate exercise up to walking 30 minutes for 5 days each week.
- Verbalise an understanding of the relationship between weight loss, weight control and exercise.
- Identify support systems for behaviour modification.
- Increase knowledge level of healthier food choices.

IMPLEMENTATION

- Assess weight and blood pressure each week
- Discuss current eating habits and strategies to reduce fat and kilojoule intake.
- Discuss cues such as boredom that promote eating. Identify strategies to eliminate or reduce eating cues.
- Teach to keep a food diary to examine and change eating habits.
- Discuss the role of regular exercise in weight loss and weight control. Instruct to maintain an exercise record to track the intensity and duration of activity.
- Discuss lifestyle and behaviour modification strategies to promote successful weight loss and control.

EVALUATION

Two weeks after changing his diet and beginning to exercise, Mr Elliott has lost 1 kg. He has maintained a food diary. He has identified boredom as a cue to eating. In light of that fact, he has started volunteering at the local hospital. He is walking for 30 minutes, 5 days a week. He plans to increase his activity periods to 45 minutes. He verbalises commitment to a lifelong plan of exercising and eating a high-fibre, low-fat diet. His BP has ranged from 132/76 to 136/84. He plans to have the employee health nurse at the hospital check his weight and BP each week and to join Weight Watchers for ongoing support.

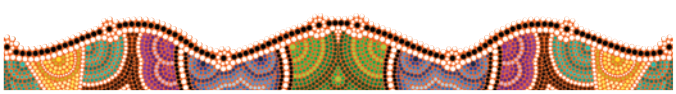
CRITICAL THINKING IN THE NURSING PROCESS

1. What are some possible pathophysiological bases for Mr Elliott's abnormal cholesterol, HDL and LDL levels?
2. Develop a teaching plan for a group of overweight men and women.
3. Identify potential barriers to losing weight and strategies to reduce or eliminate these barriers.

REFLECTION ON THE NURSING PROCESS

1. How achievable is a non-surgical weight loss intervention program over the long term?
2. What other nursing interventions would you consider utilising if Mr Elliott's weight loss does not meet the expected outcome?

- Set realistic goals to increase levels of incidental exercise.
- Establish realistic weight loss goals and a system of non-food rewards for achieving each goal.
- Identify an 'exercise buddy' or support system to promote continued physical activity.
- Expect occasional failures. Resume prescribed diet and exercise routine as soon as possible; the goal is long-term weight management.
- Community resources such as Weight Watchers or healthcare-based programs provide information, strategies and social support for successful weight management.



THE PERSON WITH MALNUTRITION

Malnutrition results from an inadequate intake of nutrients and can be defined as the state of being poorly nourished due to an imbalance in nutrition (Tuso & Beattie, 2015). There may be a lack of macronutrients (kilojoules, carbohydrates, proteins and fats) or micronutrients such as vitamins and/or minerals. Malnutrition is associated with a high burden of illness, depression of the immune system, poor wound healing, bone and muscle weakness, longer lengths of hospital stay with higher treatment costs and increased morbidity and mortality (van der Meij, Wijnhoven & Finlayson, 2015). Malnutrition may be caused by inadequate nutrient intake; impaired absorption and use of nutrients; or loss of nutrients due to diarrhoea, haemorrhage, renal failure or increased

metabolic needs due to an underlying illness (e.g. infection or physiological stressors such as cancer).

Protein energy malnutrition (PEM) is the state of decreased body pools of protein with or without fat depletion or a state of diminished functional capacity, caused at least partly by inadequate nutrient intake relative to nutrient demand and/or which is improved by nutritional repletion (Cant, 2011).

Incidence and prevalence

PEM is a widespread cause of disease and mortality throughout the world. It is endemic in African subtropical regions affected by global warming and famine (Sunyer & Grimalt, 2007). Groups at risk of malnutrition in Australia include children of Indigenous Australian heritage, culturally and linguistically diverse people, families with low socioeconomic status, older adults, the homeless and people undergoing complex medical treatments such as chemotherapy or dialysis. Even when food is plentiful, a person may be undernourished due to poor food choices. Food insecurity in Australia is a risk factor for malnutrition due to limited access, either financially or geographically, to healthy nutritious food. Malnutrition is associated with the anorexia of ageing due to decreased appetite or increased food insecurity (van der Meij et al., 2015). Malnutrition may be present on admission to hospital or may develop as a result of surgery or serious illness. Malnutrition increases both mortality and the incidence of complications in both medical and surgical situations.

See Box 21.3 for conditions commonly associated with malnutrition.

Risk factors

Risk factors for malnutrition include the following:

- age—older adults are at greater risk of malnutrition due to a variety of factors (see the 'Meeting individualised needs' box below)
- poverty, homelessness, inadequate food storage and preparation facilities
- functional health problems that limit mobility or vision
- history of rapid weight loss of more than 10% of usual weight over the last 6 months
- oral or gastrointestinal problems that affect food intake, digestion and absorption
- chronic pain or chronic diseases such as pulmonary, cardiovascular, renal and endocrine disorders, or cancer
- dementia, mental health disorders such as depression
- medications or treatments that affect appetite
- alcohol or drug addition
- acute problems such as infection, surgery or trauma
- dieting behaviours such as anorexia nervosa or bulimia
- inability to obtain food such as would occur in famine or disaster.

BOX 21.3 Conditions associated with malnutrition

- Acute respiratory failure
- Ageing
- AIDS
- Alcoholism
- Burns
- COPD
- Dementia
- Eating disorders
- Ear disease in Aboriginal and Torres Strait Islander children
- Gastrointestinal disorders
- Neurological disorders
- Renal disease
- Short bowel syndrome
- Surgery
- Trauma

Pathophysiology

Carbohydrates and fats in the diet are the body's primary energy sources. Approximately 15–25% of the body is fat, the body's energy reservoir. Fat-free mass includes muscles, bones, skin and organs which are metabolically active tissues. Proteins in the diet primarily are used to maintain these tissues. Glycogen and proteins in this lean body mass also act as energy stores.

When dietary intake of nutrients does not meet the body's energy needs, the body uses glycogen, body proteins and lipids (fats) to support metabolism. Neurones in the brain depend completely on a constant source of glucose for normal function; importantly, glucose is unable to be stored within the brain and needs to be delivered via the bloodstream.

In **starvation** (inadequate dietary intake), glycogen initially is used to provide energy. After the first 24 hours of starvation, gluconeogenesis (formation of new glucose from proteins) is the major source of energy. As starvation continues, the body breaks down fats into free fatty acids and ketones, which provide glucose for the brain. The size of all body compartments is reduced as body fats and muscle proteins are used to meet this glucose demand. As lean body mass is reduced, metabolically active tissue is lost and energy expenditure decreases.

The stress of acute illness or trauma produces a different response. The acute stress response produces a state of hypermetabolism and **catabolism** (cell and muscle breakdown). This hypermetabolic state increases energy expenditure and nutrient needs. If untreated, up to half of the body's protein stores can be used up within 3 weeks.

Many hospitalised people are malnourished (starved) on admission. Surgery or illness promotes a stress response, resulting in protein energy malnutrition. In PEM, both protein and kilojoules are deficient. The intake of adequate kilojoules but with a chronic reduction in protein intake is called *kwashiorkor*. When both proteins and kilojoules are insufficient to meet the body's needs, PEM is also known as *marasmus*.

Manifestations

Weight loss is the most apparent manifestation of malnutrition. The malnourished person may have a body weight of less than 90% of ideal. Body mass also is reduced (see Box 21.1), as is anthropometric skinfold thickness. Other manifestations include a wasted appearance, dry and brittle hair, and pale mucous membranes. Abdominal or bipedal peripheral oedema may be present. Older adults may present with general symptoms of frailty, falls, weakness, slow walking speed, reduced physical activity capacity, pressure ulcers, unintentional weight loss and exhaustion (Malafarina et al., 2012). Manifestations of specific nutrient deficiencies may be present (see accompanying box). See also the following 'Multisystem effects of malnutrition'.

MEETING INDIVIDUALISED NEEDS **Nutrition for the older adult**

Older adults are at greater risk of malnutrition. Body fat mass increases up to about 75 years of age, then begins to decrease. Age-related changes that contribute to malnutrition include a loss of appetite due to changes in taste and smell, a higher incidence of gastrointestinal disease such as dysphagia or delayed gastric emptying, poor oral health, loss of teeth or ill-fitting dentures, anorexia caused by medications, and functional limitations that contribute to food insecurity by impairing the ability to shop and cook. Psychosocial issues such as depression or dementia also contribute to the problem. Older adults living on fixed incomes may not be able to afford to purchase food. Lifestyle factors such as social isolation and loneliness contribute to the issue (van der Meij et al., 2015). Eating is a social event and older adults who eat alone may not eat as well as those who share meals with companions.

Conduct a thorough assessment to determine nutritional status. Assess psychological factors that influence eating habits, such as loneliness, isolation and depression. Note the person's general appearance and obtain a diet history, including information about foods and nutrients the person consumes and any recent weight losses or gain. Review laboratory values, including complete blood count, total protein, albumin and prealbumin.

Health education for the person and family

To maintain nutritional status, the older person should be advised to:

- Eat a well-balanced diet.
- Keep a food diary.
- Eat fresh 2 serves of fruit and 5 serves of vegetables each day.
- Consume soft foods if chewing difficulties are present.
- Increase consumption of micronutrient-dense dairy products if tolerated.
- Shop wisely to get the most value for money.
- Avoid high-fat, high-salt processed foods.
- Drink adequate fluids.
- Take regular gentle exercise to maintain muscle tone.
- Take body weight each week and contact local physician if weight has further decreased.
- Contact local organisations for the availability of congregate meals (e.g. at local senior centres) or home-delivered meals (e.g. Meals on Wheels).

Subcutaneous fat and muscle proteins are broken down in PEM, impairing mobility and increasing the risk of skin and tissue breakdown (pressure ulcers). A lack of physical activity results in further muscle loss known as sarcopenia. Protein synthesis is inhibited in PEM and wound healing is delayed. Serum albumin levels fall, leading to abdominal oedema, diarrhoea and impaired nutrient absorption. Cachexia is characterised by severe muscle loss with increased protein catabolism due to an underlying disease such as chronic kidney disease or cancer (Barker, Gout & Crowe 2011). Immune function is impaired in cachexia with an increased risk of infection. Cardiac output falls and the risk of postural hypotension increases.

INTERPROFESSIONAL CARE

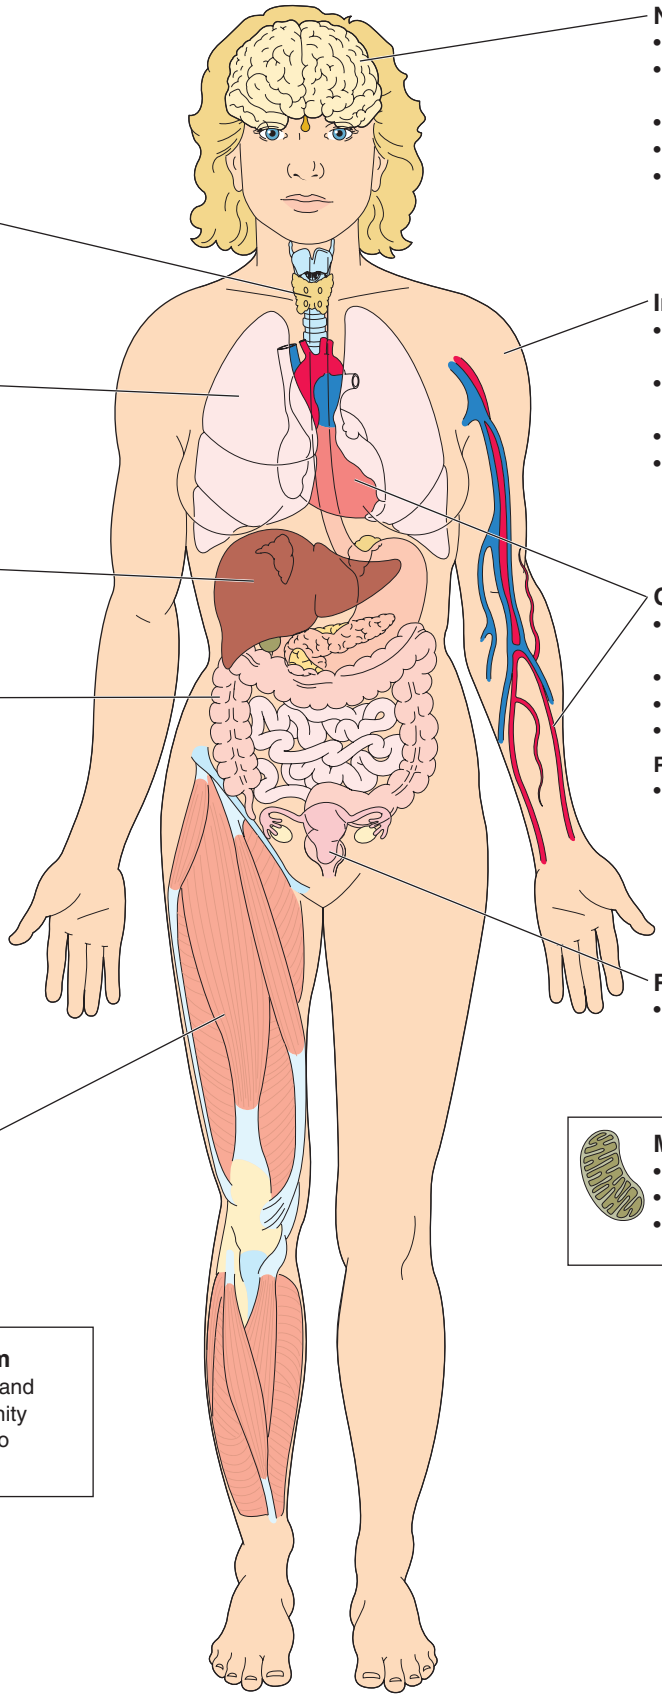
The goal of treatment for the malnourished person is to restore ideal body weight while replacing and restoring depleted nutrients and minerals. The person's age, severity of malnutrition and coexisting health problems help determine interventions. Treatment may include oral supplementation, tube feedings or parenteral nutrition.

Diagnosis

Nutrition screening tools such as those discussed in Box 21.4 can help identify a person at risk of malnutrition. Their use has been suggested as best practice guidelines for all acute hospital settings by the Dietitians Association of Australia. Barker et al. (2011) identified a number of validated screening and assessment tools for malnutrition. These include the Malnutrition Screening Tool (MST), the Malnutrition Universal Screening Tool (MUST), the Mini Nutrition Assessment (MNA), the Nutritional Risk Screening (NRS-2002), the four-item Short Nutrition Assessment Questionnaire (SNAQ) and the Subjective Global Assessment (SGA). As with obesity, the standard measurements to assess for malnutrition include diet history, height, weight, calculation of BMI and anthropometric skinfold measurements. A BMI of less than 18–20 kg/m^2 may indicate malnutrition. Other assessments include questioning on any history of unintentional weight loss and the severity of any illnesses that have impacted on oral food intake. The following laboratory studies also may be ordered:

- *Serum albumin* is reduced in PEM and may be below 32 g/L.
- *Prealbumin* (also known as transthyretin) should be measured for any person at risk of malnutrition and anyone with a serum albumin of less than 30 g/L. Prealbumin, which has a short (2-day) half life, is a better measure of nutritional status than albumin because it is sensitive to acute changes in nutritional status despite the presence of multiple-organ disease (Caccialanza et al., 2013). See Table 21.5 for normal prealbumin levels and the implications of reduced prealbumin levels.
- *Transferrin* is a protein that transports iron. It decreases in the presence of protein energy malnutrition.
- The *total lymphocyte count* is evaluated by multiplying the WBC by the percentage of lymphocytes. The total lymphocyte count is reduced in PEM.
- *Serum electrolytes* are measured. Potassium levels are low in severe malnutrition.

MULTISYSTEM EFFECTS OF MALNUTRITION



Neurological
- ↓ Cognition
- ↓ Consciousness (drowsiness, lethargy)
- Tremors
- Paraesthesias
- Impaired coordination

Endocrine
- ↓ Thyroid hormones
- ↓ Testosterone (male)
- ↓ Oestrogen (female)

Integumentary
- Hair: brittle, dull, dry, loss of colour
- Nails: fragile, brittle, spoon-shaped
- Petechiae
- Poor wound healing

Respiratory
- Respiratory rate
- Vital capacity

Hepatic
- Hepatomegaly
- ↓ Bile synthesis

Cardiovascular
- Arrythmias and conduction disturbances
- ↓ HR
- ↓ BP
- Enlarged heart

Potential complication
- Heart failure

Gastrointestinal

Oral/oesophageal:
- Cheilosis
- Glossitis
- Gingivitis

Stomach/intestines:
- Ascites
- Constipation
- Intestinal atrophy
- Steatorrhoea
- ↓ Gastric and pancreatic secretions

Potential complication
- Malabsorption syndrome

Reproductive
- Amenorrhoea

Musculoskeletal
- Muscle wasting
- Tenderness
- Impaired strength

Metabolic processes
- ↓ Weight
- ↓ Core body temperature
- Oedema

Immune system
- ↓ Cell-mediated and humoral immunity
- ↑ Susceptibility to infections

MANIFESTATIONS Specific nutrient deficiencies

DEFICIENCY	ASSESSMENT DATA	DEFICIENCY	ASSESSMENT DATA
Kilojoules	Weight loss	Dry beriberi	Polyneuritis, convulsions, confusion, apathy, muscle weakness, ataxia, nystagmus, sleeplessness, anxiety
Protein (marasmus*)	Weakness, listlessness Loss of subcutaneous fat Muscle wasting	Riboflavin (vitamin B_2)	Cheilosis (crusting and ulceration at the corner of the mouth), stomatitis Neuropathy, glossitis Normocytic anaemia
Protein (kwashiorkor†)	Thin or sparse hair Flaking skin Loss of cardiac muscle Hepatomegaly Peripheral oedema	Vitamin C (scurvy)	Swollen, bleeding gums Delayed wound healing Weakness, depression Easy bruising
Vitamin A	Night blindness Altered taste and smell Dry, scaling, rough skin Impaired immune function	Iron	Smooth tongue Listlessness, fatigue Dyspnoea Anaemia
Thiamine (vitamin B_1‡) Wet beriberi	Confusion, apathy Cardiomegaly, dyspnoea Muscle cramping and wasting Paraesthesias, neuropathy Ataxia		

* Marasmus is a physiological adaptation to severe protein energy malnutrition (PEM) which involves the gradual breakdown of fat and muscle to provide energy and amino acids for protein synthesis, essential for continued homeostasis (Badaloo et al., 2006).

† Kwashiorkor is a similar response to severe protein energy malnutrition (PEM) but is associated with more complex and pathological changes due to the inefficient mobilisation and utilisation of adipose tissues together with impaired muscle breakdown processes (Badaloo et al., 2006).

‡ Thiamine, vitamin B_1 is a water-soluble vitamin that is absorbed primarily in the jejunum. The thiamine deficiency disease known as beriberi can have neurological or cardiac manifestations. Beriberi may be seen in developed nations where the diet contains excessive carbohydrates as thiamine is a requirement of carbohydrate metabolism. Bariatric beriberi occurs from the rearrangement of the absorptive areas of the intestinal tract resulting in a decreased surface area of the jejunum (Frank, 2011). Diuretics may also contribute to beriberi due to the losses through the urinary system (Misumida, Hisashi Umeda & Iwase, 2014).

Medications

Malafarina et al. (2012) found that vitamin D demonstrated increased strength and was associated with fewer falls. Malnourished people generally require supplemental vitamins and minerals to restore essential micronutrients (Tuso & Beattie, 2015). A multivitamin and mineral supplement may be given or therapy may be tailored to correct specific deficiencies. See the 'Medication administration' box below for nursing implications of vitamin and mineral supplements.

TABLE 21.5 Normal and high-risk prealbumin levels

PREALBUMIN LEVEL	IMPLICATIONS	SUGGESTED INTERVENTIONS
150–360 mg/L	Within normal limits	None
100–150 mg/L	High risk of nutritional deficit	Monitor level biweekly
100–50 mg/L	Significant risk of malnutrition	Aggressive nutritional support (e.g. enteral feedings or parenteral nutrition)
≤ 50 mg/L	Malnourished	

Nutrition

Fluids and nutrients should be carefully reintroduced in severely malnourished people to prevent life-threatening refeeding syndrome (Redgrave et al., 2015). First, fluid and electrolyte imbalances are corrected, with particular attention paid to restoring normal potassium, phosphate, magnesium and calcium levels, as well as acid–base balance. Once fluid and electrolyte imbalances are corrected, oral protein and kilojoules are gradually reintroduced. Initial feedings are in limited amounts (100 mL) of liquid formula to prevent diarrhoea. Vitamin and mineral supplements at about twice the Nutrient Reference Values (NRVs) are provided along with refeeding. Lactose intolerance may develop in severely malnourished people; lactose-free dairy products or yoghurt may be tolerated better.

BOX 21.4 Nutrition screening tools

NUTRITION SCREENING TOOL	SUMMARY/USES	LIMITATIONS
Malnutrition Screening Tool (MST)	• Easy three-question tool which can be used by non-trained staff • Assesses recent weight and appetite losses • Useful in medical, surgical and oncology environments	• Further nutritional assessment is needed for those identified at severe risk of malnutrition
Mini Nutrition Assessment (MNA)	• Used in aged care environments • Has an abbreviated two-step questionnaire which identifies those at risk of malnutrition who then can be referred to the complete 18-step MNA	• Limited scope—developed for use in aged care
Nutritional Risk Screening (NRS-2002)	• Uses BMI, recent weight and appetite losses together with a subjective analysis of disease • Recommended by the European Society for Clinical Nutrition and Metabolism (ESPEN) for hospital use • Is useful in prompting the initiation of nutritional support	• Subjectivity of the tool • Does not allow for definitive diagnosis
The four-item Short Nutrition Assessment Questionnaire (SNAQ)	• Quick and easy screening tool • Developed to diagnose malnutrition in hospitalised people • Does not require calculation of BMI	• Further nutritional assessment is needed for those identified at severe risk of malnutrition

Source: Based on Barker, L. A., Gout, B. S. & Crowe, T. C. (2011). Hospital malnutrition: Prevalence, identification and impact on patients and the healthcare system. *International Journal of Environmental Research and Public Health*, *8*, 514–527.

Gradual refeeding is necessary to prevent electrolyte imbalances from developing as potassium, magnesium, phosphorus and glucose move into the cells. Heart failure may occur due to depressed cardiac function (Abed et al., 2014). Abnormalities in gastrointestinal function can lead to malabsorption and diarrhoea with refeeding. Food intake is gradually increased in increments of 1000 kJ twice a week until the person is able to consume about 10 000 kJ per day and is gaining 1.5–2.0 kg weekly. Commercially available nutritional supplements (such as Carnation Instant Breakfast, Ensure and Sustacal) may supplement protein and kilojoule intake.

ENTERAL NUTRITION

Enteral nutrition, or tube feeding, may be used to meet kilojoule and protein requirements in those unable to consume adequate food. The indication for tube feedings is when the lower gastrointestinal tract is still able to absorb nutrients, such as where there is difficulty swallowing, loss of gag reflex in victims of cerebrovascular accident, unresponsiveness, and oral or neck surgery (Curtis, 2013). Enteral nutrition is also indicated in the presence of severe trauma where the lower gastrointestinal tract is unaffected, anorexia or serious illness such as Crohn's disease, or malignancy. Tube feedings may provide part or all of the person's nutritional needs. Enteral nutrition is the preferable method of feeding when oral intake is not possible, as this method provides nutrients directly to the stomach and other digestive organs, reduces the incidence of enteric pathogens, promotes blood flow to the gastrointestinal tract and supports other functions of the GI tract such as the release of hormones and epidermal growth factors (Preiser et al., 2015). There is a growing trend in Australia to offer enteral nutrition in the home for long-term serious illnesses (Agency for Clinical Innovation Home Enteral Nutrition Network, 2012).

Enteral tube feeding is the delivery of a liquid, nutritionally complete formula through a soft, small-calibre tube such as a nasogastric tube into the stomach, or a nasoduodenal or nasojejunal tube into the small intestine (see Figure 21.2). Large-bore gastric (Salem sump) tubes can be used for the dual purposes of gastric decompression and feeding. Fine-bore gastric tubes are more comfortable for the person and cause less trauma and tissue irritation. Jejunal tubes are associated with much better absorption of feeds and a lower risk of regurgitation and subsequent aspiration compared to gastric tubes. A transgastric–jejunal feeding tube allows for simultaneous jejunal feeding and gastric decompression. Feeds can also be administered through a gastrostomy or jejunostomy tube. Percutaneous endoscopic gastrostomy (PEG) tubes are becoming the method of choice for

MEDICATION ADMINISTRATION Vitamin and mineral supplements

FAT-SOLUBLE VITAMINS

Vitamin A
Vitamin D
Vitamin E
Vitamin K

The fat-soluble vitamins are absorbed in the gastrointestinal tract. Vitamins A and D are stored in the liver. Fat-soluble vitamins A, D, E and K should be taken with food.

All fat-soluble vitamins may become toxic if taken in excess amounts.

Nursing responsibilities

- Monitor for manifestations of vitamin excess as well as for adverse effects from vitamin administration.
- Monitor carefully for hypersensitivity reactions during parenteral administration. Have emergency equipment available.
- Do not administer vitamin K intravenously due to increased risk of anaphylaxis.

Health education for the person and family

- Teach the importance of eating a well-balanced diet. If indicated, provide lists of foods high in specific vitamins.
- Caution that excessive intake of these vitamins may lead to vitamin toxicity.

WATER-SOLUBLE VITAMINS

Vitamin C (ascorbic acid)
Vitamin B complex:
Thiamine (B_1)
Riboflavin (B_2)
Niacin (nicotinic acid)
Pyridoxine hydrochloride (B_6)
Pantothenic acid
Biotin

If the diet is deficient in one vitamin, it is usually deficient in other vitamins as well; therefore, multivitamin preparations are often administered. Most of these water-soluble vitamins are well absorbed from the gastrointestinal tract.

Nursing responsibilities

- Monitor for responses to replacement therapy.
- Monitor for hypersensitivity reactions from parenteral administration. Have emergency equipment available.

Health education for the person and family

- Do not exceed the recommended daily allowances for the specific vitamin.

MINERALS

Copper
Manganese
Phosphorus
Chromium
Iodine
Iron
Selenium
Calcium
Zinc

Minerals are inorganic chemicals that are vital to a variety of physiological functions. Also called trace elements, these minerals are part of a balanced diet. Recommended daily intakes have not been established for all mineral substances. The dosage of prescribed minerals depends on the specific deficiency, route of administration and the person's general health.

Nursing responsibilities

- Monitor for manifestations of mineral imbalance.
- Prior to administration, dilute oral mineral preparations. Administer minerals with fruit juice to increase absorption.
- Prior to the administration of iodine, assess for history of hypersensitivity to iodine or seafood; if hypersensitive, notify the doctor.

Health education for the person and family

- Encourage the person to avoid exceeding the known recommended daily intake of the mineral.
- Instruct the person to take minerals on an empty stomach, which will increase their ability to be fully absorbed. Zinc can be taken with or after meals.

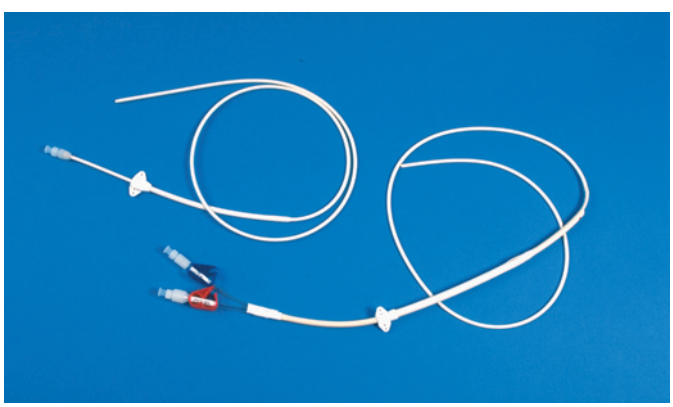


FIGURE 21.2 ■ A nasoduodenal tube and a jejunostomy tube

Source: Courtesy of Michal Heron/Pearson Education/PH College.

long-term enteral feeding regimens, palliative enteral nutrition for terminal malignancies of the upper gastrointestinal tract or for decompression of malignant obstructions (Mobily & Patel, 2015).

Tube placement must be checked by x-ray prior to initiating any fluids or feeds to confirm that the end of the tube is correctly placed within the stomach and not in the lungs (Curtis, 2013). Kim et al. (2012) report that ultrasonography is a low-radiation alternative for determining correct placement. However, if results are inconclusive, an x-ray is mandatory. Periodical aspiration of the tube and checking the pH of aspirated contents is necessary to verify continued correct placement. A pH of < 4 indicates the presence of gastric acid and confirms placement in the stomach; pH > 6 indicates the tube is in the jejunum. See Box 21.5 and the 'Translation to practice' box below.

Most tube feeding formulas provide 4 kJ/mL with approximately 14% of the kilojoules from protein, 60% from

FIGURE 21.3 ■ The nurse secures the feeding tube of a person receiving a continuous enteral feeding

carbohydrates and 25–30% from fat. Administering 1500 mL per day provides the recommended daily intake of all vitamins and minerals. Formulas that provide more kilojoules per millilitre, more grams of protein, added fibre or lower fat are also available (see Table 21.6). Commercial products provide instructions for initiating therapy. Enteral feedings should be started with small volumes of water then small volumes of feed to prevent diarrhoea, with the volume gradually increased to provide the required kilojoules for maintenance and healing. Formulas may be administered as a bolus feeding or as a continuous drip feeding regulated by a kangaroo feeding pump (see Figure 21.3).

Aspiration and diarrhoea are the most common complications of enteral feedings. Continuous infusion of the formula reduces the risk of aspiration. The risk also is reduced by placing the feeding tube in the jejunum rather than the stomach. To avoid aspiration, the nurse elevates the head of the bed at least 30 degrees during feeding and for at least 1 hour after feeding. Formulas that contain fibre can reduce the incidence of

BOX 21.5 Measures to verify feeding tube placement

After inserting the feeding tube and verifying appropriate placement through pH of the aspirate and an x-ray, mark the feeding tube position near the nose with an indelible marker. Prior to each feeding (or every 8 to 12 hours if continuous feedings are being administered), assess the abdomen and tube placement. Use the following steps to assess tube placement:

- Assess the abdomen for distension, bowel sounds and tenderness using the sequence of inspection, auscultation, percussion and palpation.
- Assess tube condition and placement by verifying that the indelible mark remains at the same position and that the feeding tube is securely fastened to the nose. Ask the person to open their mouth and inspect the position of the tube in the oropharynx. Do not administer a feeding if the person is having difficulty speaking or is coughing.
- Using a 60 mL syringe, inject 30 mL of air into the feeding tube, then aspirate a small amount of stomach contents and check the pH of the aspirate.

Reassess tube placement if the person vomits or retches, requires oropharyngeal suctioning, complains of discomfort or reflux into the mouth, or develops signs of respiratory distress (Curtis, 2013).

TRANSLATION TO PRACTICE Evidence-based practice: determining feeding tube placement

The auscultatory (air bolus) method of determining the location for feeding tubes on initial placement and prior to initiating feeding has previously been recommended in nursing textbooks. The premise was that injecting a small amount of air into the tube will produce a distinctive sound if the tube is correctly located, presumably in the stomach. Sounds produced by tubes located in the oesophagus, intestines and respiratory tract were presumed to be different enough to alert the nurse to the improper location. However, the auscultatory method for determining placement is not reliable because the rush of air can be heard irrespective of tube location (i.e. lung or stomach) (Metheny, Stewart & Mills, 2012). This is especially true for small-bore feeding tubes. Testing the pH level of aspirates from newly inserted feeding tubes and regularly during intermittent feedings can distinguish gastric from respiratory and intestinal placement. Based on the pH of a large number of samples of aspirates from feeding tubes, a pH of between 0 and 4 suggests gastric placement and a pH of 7 or greater indicates respiratory placement. As the tube advances through the stomach into the intestine, pH levels increase and the colour of the aspirate changes. If placement in the small intestine is required, a confirmatory x-ray should be taken. Metheny et al. (2012) recommend that routinely the pH method be used rather than the auscultatory method and that protocols be updated to reflect current information.

IMPLICATIONS FOR NURSING

With the advent of small-bore nasogastric and nasointestinal feeding tubes and the increasing use of gastrostomy and jejunostomy feeding tubes, more people are candidates to receive enteral feedings. Aspiration of contents with pH testing prior to x-ray confirmation is mandatory for determining tube placement.

CRITICAL THINKING IN PERSON-CENTRED CARE

1. Compare the normal pH of aspirates obtained from the respiratory tract, oesophagus, stomach, duodenum and jejunum.
2. Develop a teaching plan for the person being discharged with a gastrostomy or jejunostomy feeding tube.

TABLE 21.6 Selected enteral feeding formulas

FORMULA TYPE	CONTAINS	EXAMPLES
Complete—suitable for most people requiring enteral feedings	• 4 kJ/mL • Protein: ~ 14% total kJ • Fat: ~ 30% total kJ • Carbohydrate: ~ 60% total kJ • Recommended daily intake of all minerals and vitamins is 1500 mL/day	Compleat, Ensure, Isocal, Nutren, Isolan Sustacal, Resource
High-kilojoule complete—appropriate for those on a fluid restriction	As above; provides 6–8 kJ/mL	Ensure Plus, Sustacal HC, Comply, Nutren 1.5, Resource Plus, Isocal HCN, Magnacal, TwoCal HN
Complete lactose-free, high-residue—used to prevent/treat diarrhoea, constipation	As above; provides fibre	Jevity, Profibre, Nutren 1.0 with fibre, Fibrelan, Sustacal with fibre, Ultracal, Ensure with fibre, Fibresource, Accupep HPF, Reabfin, others
Disease-specific formulas:		
Renal failure	Essential amino acids	Amin-Aid, Travasorb Renal, Aminess
Respiratory failure	Fat: > 50% total kJ	Pulmocare, NutriVent
Liver failure with hepatic encephalopathy	High amounts of branched-chain amino acids	Hepatic-Acid II, Travasorb Hepatic

diarrhoea. Fluid and electrolyte status is monitored carefully and additional water is regularly administered as needed to provide fluid replacement and ensure tube patency.

PARENTERAL NUTRITION **Parenteral nutrition (PN)** is the intravenous administration of carbohydrates (high concentrations of dextrose), protein (amino acids), electrolytes, vitamins, minerals and fat emulsions. These hypertonic solutions usually are administered through a central vein, such as the subclavian or external jugular vein (see Figure 21.4). A peripherally inserted central catheter (PICC) line may be used for short-term total parenteral nutrition (TPN).

PN is initiated when a person's nutritional requirements cannot be met through diet, enteral feedings or peripheral vein infusions. A person who has undergone major surgery or trauma where the lower intestinal tract is non-functioning or who is seriously undernourished is often a candidate for PN. PN is used for both short- and long-term management of nutritional deficiencies. Many people are discharged to home with PN and monitored by home health nurses.

To begin therapy, the physician inserts the central venous catheter under aseptic conditions. The location of the catheter tip is confirmed by x-ray. A triple-lumen catheter is most commonly used. This type of catheter permits concomitant administration of medications, intralipids or blood through other lumens. Parenteral nutrition solutions are either purchased commercially or mixed in the pharmacy using sterile technique under a laminar-flow airhood. A commonly used solution includes 500 mL of 50% dextrose, 500 mL of an 8.5% amino acid solution, electrolytes, minerals and vitamins. The sterility of the solution is maintained and no medication, other than intralipids, is added to the solution after it is mixed or to the lumen through which the PN is being administered. Most hospitals have specific policies and procedures for changing the tubing and the dressing at the insertion site, as well as for hanging new containers. PN solutions are always administered with an infusion pump to ensure the correct rate of infusion.

The person receiving parenteral nutrition is at risk of mechanical, metabolic and infectious complications. Pneumothorax, haemothorax, brachial plexus injury and improper position are possible complications of central venous catheter insertion. Once in place, the catheter may dislodge, leak or break and become an embolus. Clots also may form within or around the catheter.

Fluid overload is a risk with parenteral nutrition, particularly in older adults. The high-glucose formulas can lead to osmotic diuresis or shifts of electrolytes—potassium and phosphorus in particular—into the cells, leading to hyperglycaemia, hypokalaemia or hypophosphataemia. Blood glucose and serum electrolyte levels are carefully monitored during treatment. In addition to electrolyte imbalances, acid–base disturbances may develop, as well as refeeding oedema or heart failure (Fletcher, 2013). Long-term use of parenteral nutrition can lead to gallstone formation and liver disease. Nutrient deficiencies may develop, including deficiencies of vitamins, iron and other minerals when parenteral nutrition is continued for three or more months (Fletcher, 2013).

Disruption of the skin barrier and administration of a solution high in glucose presents a risk of infection in a person receiving PN. Infection may be local, limited to the exit site or surrounding a tunnelled catheter, or may lead to sepsis. The person's temperature and other manifestations of infection must be carefully monitored. Meticulous sterile technique is used for catheter exit site care and container and tubing changes (Fletcher, 2013).

Nursing care

Health promotion

Aggressive nursing assessment and interventions can help prevent malnutrition associated with hospitalisation or long-term care. In hospitalised people, carefully monitor any food intake (Tuso & Beattie, 2015). Document the nutrition plan and report if nutrition intake does not meet with that plan. When the person is placed on nil by mouth (NBM) status for surgery or tests, ask the doctor to restore diet orders as soon as possible. If allowed, encourage family members to provide favourite or culturally appropriate foods to promote intake. In long-term care settings, promote socialisation during meals. Assess food likes and dislikes and provide foods the person is more likely to eat.

Assessment

Collect nutritional assessment data on admission and periodically (once or twice a week) during long-term institutionalisation.

- *Health history:* usual daily dietary pattern (type and amount of foods consumed); usual weight and recent changes; appetite and food tolerance; specific food likes and dislikes; specific cultural foods; difficulty swallowing; problems such as anorexia, nausea, diarrhoea or constipation; history of surgery and/or chronic diseases (e.g. chronic lung disease) and medications.
- *Physical examination:* height, weight, anthropometric skinfold thickness, BMI; vital signs; general appearance, evidence of muscle wasting, mobility; skin and mucous membranes; bowel sounds; laboratory studies. In children, the mid upper arm circumference (MUAC) has been recently endorsed by the World Health Organization as a validated method to assess malnutrition (Blackwell et al., 2015).

Use of a nutritional assessment tool can help identify a person (older adults in particular) at risk of malnutrition (see Box 21.4). Such tools assess food intake, mobility and BMI, as well as weight loss, psychological or physiological stress, and dementia or psychological conditions to determine the presence of or risk of malnutrition.

Nursing diagnoses and interventions

The complex effects of malnutrition on multiple body systems place the person at high risk of a number of other health issues. This section addresses problems with nutrition, infections, fluid volume and skin integrity. See below for a nursing care plan for the person with malnutrition.

NURSING CARE PLAN A person with malnutrition

Rose Chow is an 88-year-old widow who lives alone. She typically rises early and has a cup of tea before spending her morning pottering in her garden. She consumes her main meal of the day at lunch, which usually includes rice and some vegetables. For dinner, she generally eats a bowl of rice with 'whatever seems to be in the fridge'. She admits to having little interest in cooking or eating since her husband died 10 years ago, and her group of friends has been 'dying off too'.

ASSESSMENT

Mrs Chow weighs 43.1 kg and is 160 cm tall, with a BMI of 16.8.kg/m^2. She reports weighing 53.5 kg 5 years ago. Her triceps anthropometric skinfold thickness measurement is 11 mm. (Normal values for a female: >13 mm.) Her skin is pale and she appears thin and wasted. Her temperature is 36.1°C. Diagnostic test results include serum albumin 30 g/L (normal 38–50 g/L) and serum cholesterol 3.0 mmol/L (normal 3.5–5.4 mmol/L). A diagnosis of protein energy malnutrition is made and a 6280 kJ per day diet is recommended.

DIAGNOSES

- *Imbalanced nutrition* related to food intake less than nutritional energy requirements.
- *Risk of ineffective therapeutic regimen* related to knowledge deficit.
- *Risk of infection* related to protein energy malnutrition.
- *Impaired social interaction* related to widowhood and reduced social support group.

PLANNING

Plan to meet with Mrs Chow once each week to assess progress.

Expected outcomes

- Gain at least 0.5 kg per week.
- Verbalise understanding of nutritional requirements and identify strategies to incorporate requirements into daily diet after discharge.
- Remain infection-free, evidenced by normal vital signs.
- Identify strategies to increase social interaction, such as participating in senior citizens' lunches at local senior centre.

IMPLEMENTATION

- Weigh weekly at a consistent time of day.
- Refer to dietitian for evaluation of nutritional needs.
- Teach about nutritional requirements and plan an eating program that includes high-kilojoule, high-protein foods and supplements and reflects her food preferences.
- Encourage small, frequent meals.
- Encourage keeping a food intake diary.
- Teach strategies to reduce risks for infection.
- Provide information about communal meals available to seniors in the community and help Mrs Chow develop a plan to participate.

EVALUATION

One month later, Mrs Chow has gained 1.5 kg and reports feeling 'more energetic'. A friend is helping her shop to ensure that she purchases foods to maintain her protein, kilojoule and nutrient intake. She has begun attending senior lunches twice a week and is enjoying 'being around people again'. Although she still doesn't enjoy cooking like she used to, she is using prepared foods and supplements to maintain her nutrient intake.

CRITICAL THINKING IN THE NURSING PROCESS

1. What is the physiological basis for Mrs Chow's low albumin and cholesterol levels?
2. Mrs Chow asks, 'Can I get better by just taking more vitamins?' How will you respond?
3. Design a teaching plan for a person with protein energy malnutrition.

REFLECTION ON THE NURSING PROCESS

1. What role did culture have on Mrs Chow's risk of protein malnutrition?
2. What role did being an older person have on Mrs Chow's nutritional intake?

Imbalanced nutrition: less than body requirements

The nurse plays a critical role in the ongoing assessment of the malnourished person, while collaborating with the multidisciplinary team to provide nutritional therapies.

- If the person is able to eat, provide an environment and nursing measures that encourage eating. Eliminate foul odours, provide oral hygiene before and after meals, make meals appetising and offer frequent, small meals including preferred cultural foods. Consult with the nutrition support team to provide adequate protein, kilojoules, minerals and vitamins. *Oral hygiene and a pleasant environment make food more appetising. Small, frequent meals are generally more appealing and less overwhelming to a person with anorexia. Many require complicated nutritional therapy, such as enteral or parenteral therapy, to meet nutritional needs.*
- Provide a rest period before and after meals. *Eating requires energy and the malnourished person may have decreased physical strength and energy.*
- Assess knowledge and provide appropriate teaching. *Lack of knowledge often contributes to undernutrition. Education empowers the person to make healthy choices.*

Risk of infection

Malnourished people have a much higher risk of infection than well-nourished people. Malnutrition affects many components of the immune system, including the skin, mucous membranes, and lymph tissue and cells.

- Monitor temperature and assess for manifestations of infection every 4 hours. *Although the baseline temperature may be subnormal in malnourished people, any elevation from baseline may indicate infection. Manifestations of*

infection may include chills, malaise, erythema and leukocytosis. Early detection of infection may prevent complications.

- Maintain medical asepsis when providing care and surgical asepsis when carrying out procedures. *Handwashing is the best strategy to prevent the spread of pathogens. Sterile technique is required for procedures such as inserting central lines and changing dressings.*
- Teach the signs and symptoms of infection, good handwashing technique and factors that increase the risk of infection. *Knowledge empowers the person to participate in self-care, thus reducing exposure to infectious pathogens.*

Risk of fluid volume deficit

The person with malnutrition may also have a fluid volume deficit due to difficulty swallowing fluids. Administration of hyperosmolar nutritional solutions may lead to dehydration or electrolyte disturbances.

- Monitor oral mucous membranes, urine specific gravity, level of consciousness and laboratory findings every 4 to 8 hours. *Dry mucous membranes, increased urine specific gravity, decreased level of consciousness and electrolyte imbalances may indicate dehydration.*
- Weigh daily and monitor intake and output on fluid balance chart. *Daily weights and intake and output measurements help monitor fluid balance.*
- If allowed, offer preferred fluids frequently in small amounts, considering the person's preferences. *Frequent, small amounts of fluids are better tolerated and promote adequate intake.*

Risk of impaired skin integrity

Skin integrity depends on adequate nutrition. Loss of subcutaneous tissue and muscle increase the risk of pressure ulcers. In addition, healing is impaired in malnourished people.

- Assess skin every 4 hours. *Baseline and ongoing assessments allow prompt identification of early skin breakdown.*
- Turn and position at least every 2 hours. Encourage passive and active range-of-motion exercises. *These measures reduce pressure and promote oxygenation of cells.*
- Keep skin dry and clean and minimise shearing forces. Keep linen smooth, clean and dry. Provide therapeutic beds, air mattresses or pads. *These nursing measures promote comfort and reduce the risk of skin breakdown.*

Community-based care

A person with malnutrition may be cared for at home or in the hospital with oral diet, enteral or parenteral therapy. Each year, it is more common to see people managing tube feeding or TPN at home. Health education for the person and their family includes the following topics:

- Diet recommendations and use of nutritional supplements.
- Where to obtain recommended foods and nutritional supplements.
- If continuing enteral or parenteral nutrition, how to (1) prepare and/or handle solutions, (2) add them to either the feeding tube or central line, (3) manage infusion pumps, (4) care for the feeding tube or central catheter, (5) recognise and manage problems and complications, and (6) how and when to notify the healthcare provider of problems.

The person with an eating disorder

Eating disorders are characterised by severely disturbed eating behaviour and weight management. The three most common eating disorders in Australia are anorexia nervosa, bulimia nervosa and binge-eating disorder (BED). Eating disorders are increasing in Australia and are more common in affluent societies that are exposed to mass media advertising and plentiful food. Eating disorders are the third most common chronic illness in adolescents in Australia after obesity and asthma. Eating disorders occur equally in males and females before puberty but females are affected in increasing numbers during adolescence and young adulthood (Gonzales, Kohn & Clarke, 2007). It was estimated in 2012 that eating disorders affected nearly 1 million Australians. Premature death from physical causes and by suicide in young adults who suffer from an eating disorder is higher than in the general population (Eating Disorders Victoria, 2015).

The Diagnostic and Statistical Manual of Mental Disorders (DSM-5) advises that the diagnosis of **Anorexia nervosa** is characterised by: (1) the persistent restriction of oral energy intake leading to a significantly low BMI or BMI-for-age; (2) an intense fear of gaining weight or of becoming fat, or persistent ritualistic behaviour that interferes with weight gain despite having a lower than normal BMI; and (3) a disturbance in the way one's body weight or shape is experienced, undue influence of body shape and weight on self-evaluation, or a persistent lack of recognition of the seriousness of the low BMI (Eating Disorders Victoria, 2015). **Bulimia nervosa** is characterised by recurring episodes of binge eating followed by purge behaviours such as self-induced vomiting, use of laxatives or diuretics, fasting or excessive exercise at least twice a week for a period of greater than 3 months. A third eating disorder, **binge-eating disorder**, is believed to affect many more people than either anorexia or bulimia. Binge-eating disorder is characterised by recurrent episodes of binge eating—eating an excessive amount of food during a defined period of time and a sense of lack of control over eating during binge episodes (Eating Disorders Victoria, 2015).

Anorexia nervosa

Anorexia nervosa typically begins during puberty in an attempt to cope with a perceived stress (Gonzales et al., 2007). People with anorexia nervosa are usually high achievers who have a distorted body image and an irrational fear of gaining weight. Refusal to maintain body weight at or above a minimally normal level for height and body type is a common manifestation of anorexia nervosa. The person will maintain weight loss by restricted kilojoule intake, often accompanied by excessive exercise. Some may exhibit binge–purge behaviour. Although its cause is unknown, a number of risk factors, both biological and psychosocial, have been identified for anorexia nervosa.

LINKS TO NATIONAL PATIENT SAFETY STANDARDS

NSQHS Standard 8:
Preventing and Managing Pressure Injuries

'The intention of this Standard is to prevent patients from developing pressure injuries and effectively managing pressure injuries when they do occur.' (Australian Commission on Safety and Quality in Health Care, 2011, p. 54)

Implementing this standard is achieved through organisations establishing systems to assist with prevention and management of pressure injuries. Patients should be screened on admission and appropriate strategies put in place to prevent pressure injury. People with pressure injuries are managed using best practice guidelines and affective communication is undertaken between all individuals involved in a person's care.

Caring for an individual experiencing a nutritional disorder requires the consideration that there is an increased risk of developing a pressure injury. Constant vigilance and adherence to facility guidelines is required to minimise the risk of the development of pressure injuries.

Source: © Australian Commission on Safety and Quality in Health Care.

Abnormal levels of neurotransmitters and other hormones may play a role. Current research suggests genetic factors linked with environmental factors may influence the development of eating disorders (Eating Disorders Victoria, 2015). Women who develop anorexia nervosa tend to be obsessive and perfectionist and often feel inadequate or unable to maintain control in their lives. Family, social or occupational (e.g. a career in modelling, television or ballet) pressures contribute to maintain low body weight. People with anorexia often experience depression or anxiety.

The manifestations and complications of anorexia nervosa are listed in the box below.

MANIFESTATIONS AND COMPLICATIONS Eating disorders

DISORDER	MANIFESTATIONS	COMPLICATIONS
Anorexia nervosa	▪ Weight < 85% of normal; muscle wasting ▪ Fear of weight gain, refusal to eat ▪ Disturbed body image, excessive exercise ▪ Amenorrhoea (loss of menses) ▪ Skin and hair changes (fine hair—lanugo—over body) ▪ Hypotension, bradycardia ▪ Hypothermia ▪ Constipation ▪ Insomnia	▪ Electrolyte and acid–base disturbances ▪ Reduced cardiac muscle mass, low cardiac output, arrhythmias ▪ Anaemia ▪ Hypoglycaemia, elevated serum uric acid levels ▪ Osteoporosis ▪ Enlarged salivary glands ▪ Delayed gastric emptying ▪ Abnormal liver function
Bulimia nervosa	▪ Weight often normal; may be slightly overweight ▪ Binge–purge behaviour ▪ Oligomenorrhoea or amenorrhoea ▪ Lacerations of palate; callus on fingers or dorsum of hand	▪ Enlarged salivary glands ▪ Stomatitis, loss of dental enamel ▪ Fluid, electrolyte and acid–base imbalances ▪ Arrhythmias ▪ Oesophageal tears, stomach rupture

Binge-eating disorder	▪ Usually overweight or obese
	▪ Recurrent episodes of binge eating (2 or more days a week for 6 months)
	▪ Episodes characterised by:
	  ▪ Eating more rapidly than usual
	  ▪ Eating until uncomfortably full
	  ▪ Eating large amounts of food when not physically hungry
	  ▪ Eating alone due to embarrassment over quantity
	  ▪ Disgust, depression or guilt following a binge episode
	  ▪ Marked distress about binging behaviour
		▪ Type 2 diabetes mellitus
		▪ Hypertension, hyperlipidaemia
		▪ Coronary heart disease, heart failure
		▪ Gallbladder disease
		▪ Depression, social isolation

Bulimia nervosa

Bulimia nervosa is an eating disorder in which people binge on food and then, in an attempt to counteract this behaviour, take extreme measures such as making themselves vomit, taking laxatives or starving themselves (Hay et al., 2014). Bulimia nervosa develops in late adolescence or early adulthood, often following failed attempts to lose weight through dieting. Foods consumed during a binge often are high in kilojoules and fat. After binge eating, the person induces vomiting (usually by stimulating the gag reflex) or may take excessive quantities of laxatives or diuretics. In contrast to anorexia, the person's weight is often normal. Fluid and electrolyte balance, in contrast, may be severely disrupted by loss of fluid and gastrointestinal secretions. The complications of bulimia nervosa (see the box below) primarily result from the purging behaviour.

Binge-eating disorder

Binge-eating disorder (BED) was identified as a condition distinct from overeating in 1992 (Eating Disorders Victoria, 2015). While many of the characteristics of bulimia and binge-eating disorder are similar with feelings of guilt, disgust and depression, a person with BED usually binges in private and does not purge. BED commonly affects middle-aged adults and is slightly more common in women than in men. People with BED usually eat when not hungry and are overweight or obese, often morbidly obese. Psychosocial factors contribute: up to half of people with BED either are depressed or have experienced depression in the past. Alcohol abuse and impulsivity are common behavioural traits in a person with BED.

INTERPROFESSIONAL CARE

Eating disorders, anorexia nervosa in particular, are difficult to treat effectively. Because of the intense fear of weight gain and distorted body image, these people strongly resist increasing food intake. In all cases, a comprehensive treatment plan for eating disorders includes medical care and monitoring, psychosocial interventions and nutrition counselling (Gonzales et al., 2007).

Diagnosis

There is no specific diagnostic test for anorexia, bulimia or binge-eating disorder. Laboratory studies of a person with anorexia or bulimia may show anaemia and leucopenia, abnormal serum electrolyte levels and elevated blood urea nitrogen (BUN) and serum creatinine. In people with BED, the blood glucose and lipid levels may be elevated. The BMI is usually above the normal range and may identify the person as obese or morbidly obese.

A mental health evaluation is indicated for people with eating disorders to identify contributing factors and help direct treatment.

Treatment

A multidisciplinary approach that includes psychology, psychiatry, medicine, dietetics, family therapy and social work is used In Australia (Hay et al., 2014). The aims of treatment are to restore weight, reverse malnutrition and relieve the mental anguish associated with eating.

Treatment is usually as an outpatient but some may require hospitalisation, particularly if their weight is less than 75% of normal. Refeeding is gradually introduced to avoid complications such as heart failure. Oral intake is the preferred option in refeeding. Meals must be supervised and a firm but empathetic attitude conveyed about the importance of adequate food intake. Enteral or intravenous feeding may be required to supplement oral intake. Psychological treatment, initiated when malnutrition has been corrected and weight gain begun, focuses on providing emotional support and helping the person base their self-esteem on factors other than weight (e.g. personal relationships, satisfaction with achieving occupational goals) (Hay et al., 2014). Cognitive–behavioural therapy or psychotherapy may be used; families may be included in the treatment program. A selective serotonin reuptake inhibitor (SSRI) such as olanzapine (Zyprexa), quetiapine (Seroquel) or risperidone (Risperdal) may be prescribed to facilitate weight maintenance and reduce anxiety.

The goal of bulimia treatment is to reduce or eliminate binge eating and purging behaviour. A combination of nutritional counselling and therapy, psychosocial interventions and medications may be used. Nutritional counselling is directed at establishing a regular meal pattern and encouraging an appropriate amount of regular exercise. An SSRI may be of benefit. Cognitive–behavioural therapy also is used to treat bulimia, focusing on excessive concerns about weight, persistent dieting and binge–purge behaviours.

Treatment for those with BED focuses on establishing healthy eating patterns, psychosocial therapy (including cognitive–behavioural therapy and group counselling) to address underlying issues and management of obesity and its complications. A person with BED may also benefit from an SSRI or other antidepressant drug.

Nursing care

Nurses can be instrumental in identifying a person with an eating disorder and referring for treatment. It is particularly important to identify these disorders early to prevent adverse effects on growth and increase the success of treatment.

The nurse is an integral part of the eating disorders treatment team. *Imbalanced nutrition: less than body requirements* is a primary nursing diagnosis for a person with anorexia or

bulimia, and *Imbalanced nutrition: more than body requirements* is a priority nursing diagnosis for people with binge-eating disorder (BED). The following nursing diagnoses also should be considered:

- *Ineffective sexuality patterns* related to body image concerns.
- *Chronic low self-esteem* related to tendency to binge eat.
- *Disturbed body image* related to altered eating pattern.
- *Ineffective therapeutic regimen* related to knowledge deficit.

When planning and implementing care, consider the following nursing activities:

- Ensure a commitment from the person that they wish to alter their eating patterns.
- Regularly monitor weight each week using standard conditions. *Weight gain or loss provides information about the effectiveness of care, as well as the person's risk of complications.*
- Monitor food intake during meals, recording percentage of meal and snacks consumed. Maintain close observation for at least 1 hour following meals; do not allow the person to be alone in the bathroom. *Observing the person during and after meals helps prevent disposal of food and purging behaviour after eating. Recording actual food intake allows accurate calculation of kilojoule intake.*
- Serve balanced meals, including all nutrient groups. Increase serving size gradually. The person may find 'normal' food servings overwhelming, reducing the desire to eat. *Kilojoule intake is initially limited to prevent complications associated with refeeding, then gradually increased.*
- Administer a multivitamin and mineral supplement to replace losses.

Involvement of the family and social support persons is vital to success. Encourage family members to participate in teaching and nutritional counselling sessions. Discuss the value of family therapy to address issues that have contributed to the disorder. Emphasise the need to provide consistent messages of support for healthy eating habits. Discuss using rewards for food and kilojoule intake rather than weight gain. Provide referrals to a dietitian, nutritional support team, counselling and support groups for people with eating disorders.

CHAPTER HIGHLIGHTS

- Nutritional disorders are common, affecting people worldwide and contributing significantly to mortality and morbidity. While malnutrition is a serious problem in underdeveloped nations, obesity and its consequences are more prevalent in Australia and other industrialised societies.
- Obesity, defined as excess adipose tissue and a BMI greater than 30 kg/m^2, is linked with many disorders, including type 2 diabetes mellitus, coronary heart disease, gallbladder disease and osteoarthritis.
- Exercise and reduced kilojoule intake are the mainstays of obesity treatment. Drugs that suppress the appetite or interfere with fat absorption in the gut may be used to facilitate weight loss in a person with multiple risk factors for obesity complications or people who have had difficulty achieving weight loss through diet and exercise.
- Bariatric surgery is a viable treatment option for the morbidly obese. The primary types of bariatric surgery used in Australia are restrictive and malabsorptive procedures that limit stomach capacity and nutrient absorption.
- Nursing care for obese people focuses on health promotion, education and support of the prescribed treatment plan.
- In Australia, protein energy malnutrition is a common problem among the elderly and hospitalised people. Malnutrition increases the risk of complications and impairs healing. Early identification and prevention are the primary focuses of treatment; nurses can be instrumental in identifying at-risk people (e.g. the elderly, a person living alone, people on extended NBM status).
- Refeeding of malnourished people is a gradual process. Enteral feedings (oral or by feeding tube) are preferred whenever possible. Parenteral nutrition may be required when enteral feeding is not possible or not tolerated.
- Eating disorders, including anorexia nervosa, bulimia nervosa and binge-eating disorder, can be difficult to effectively treat and maintain in remission. While a person with anorexia typically is underweight and malnourished, resisting efforts to achieve a normal weight, a person with bulimia is more likely to be of normal weight and those with binge-eating disorder tend to be overweight or obese.
- Treatment for eating disorders is multifaceted, including physical care to restore electrolyte balance and treat complications, nutritional counselling and therapy, psychosocial therapy, family support and possibly medications.

CONCEPT CHECK

1 Of the following noted in a person's history, which does the nurse identify as risk factors for obesity?
   1 adopted at 2 months of age
   2 usual diet includes 'fast-food' meals twice a week
   3 does not engage in regular activity
   4 allergic to chocolate and strawberries

2 A person on a reduced-kilojoule diet asks the nurse what she can do to lose weight faster, because most weeks she loses no more than 0.2 kg. 'At this rate, it will take me years to get to my goal!'
1 'Let's re-evaluate your long-term goal. Perhaps it was set too low for you.'
2 'A kilogram of body fat equals 14 650 kJ. Let's re-evaluate your diet and exercise plan for kilojoule intake and expenditure.'
3 'Perhaps we should look into a diet supplement since you are unable to stick with your prescribed diet plan.'
4 'You sound frustrated. Would you like to take some time off from your diet and exercise plan?'

3 An expected finding in a person admitted with a diagnosis of protein energy malnutrition would be:
1 recent 5 kg weight loss
2 increased anthropometric skinfold thickness measurements
3 hyperactive bowel sounds
4 anxiety and agitation

4 Before administering an intermittent enteral feeding, the nurse confirms placement of the small-bore feeding tube in the stomach by:
1 instilling water and listening for the gastric gurgle
2 withdrawing the tube slightly, then reinserting it
3 aspirating gastric contents and checking for a pH of < 4
4 obtaining an x-ray of the chest and stomach

5 The nurse identifies which of the following as realistic goals for a person with anorexia nervosa?
1 will consume 100% of a 10 465 kJ diet
2 will gain 0.5 kg per week
3 will rest alone in room following meals
4 will participate in family counselling

6 The nurse identifies which nursing diagnosis as high priority for a person with a BMI of 30.4 kg/m^2 and a waist-to-hip ratio of 1.1?
1 *Health-seeking behaviours: weight loss*
2 *Risk of impaired cardiovascular tissue perfusion*
3 *Ineffective coping*
4 *Deficient knowledge regarding diet*

7 The nurse teaching a person about sibutramine (Reductil) includes which of the following instructions?
1 You may skip a dose of the drug if you skip a high-fat meal.
2 Do not consume alcohol while taking this drug.
3 Do not drive while taking this drug because the drug may increase sleepiness.
4 Increase your intake of water and other fluids while taking this drug.
5 Continue to follow your prescribed diet while taking this drug.

8 The nurse caring for a home-bound older adult who is losing 1 to 2 kg monthly plans for which of the following?
1 Meals on Wheels deliveries
2 ensure nutritional supplements
3 placement in a residential care facility
4 transportation to congregate senior meals
5 follow-up by primary care physician
6 referral for diagnostic studies

9 Which of the following is a high-priority nursing intervention to prevent malnutrition in the person undergoing surgery?
1 aggressive pain management
2 daily weighing
3 maintaining intravenous flow
4 requesting early restoration of oral intake

10 Three days after gastric bypass surgery, the person complains of increasing abdominal pain. Bowel sounds are absent; the abdomen is firm and very tender. The nurse should:
1 report findings to the surgeon
2 ambulate the person to promote peristalsis
3 chart assessment data and continue to monitor
4 evaluate the effectiveness of analgesia

CHAPTER 22

NURSING CARE OF PEOPLE WITH UPPER GASTROINTESTINAL DISORDERS

TRACY PARRISH

LEARNING OUTCOMES

- Describe the pathophysiology and complications associated with common disorders of the mouth.
- Discuss the pathophysiology, manifestations and nursing care of a person with a disorder of the oesophagus.
- Describe the pathophysiology, manifestations and complications associated with common disorders of the stomach and duodenum.

CLINICAL COMPETENCIES

- Assess the functional health status of people with upper gastrointestinal disorders.
- Monitor, document and, as needed, report manifestations of upper gastrointestinal disorders and their complications.
- Plan nursing care using evidence-based research.
- Determine priority nursing diagnoses and interventions based on assessed data.
- Administer medications and prescribed care knowledgeably and safely.
- Coordinate and integrate interprofessional care into the plan of care.
- Construct and revise individualised plans of care, considering the culture and values of the person.
- Plan and provide the person and family with teaching to promote, maintain and restore functional health.

KEY TERMS

The upper gastrointestinal (GI) tract includes the mouth, oesophagus, stomach and proximal small intestine. Food and fluids, ingested through the mouth, move through the oesophagus to the stomach. The stomach and upper intestinal tract (duodenum and jejunum) are responsible for the majority of food digestion. When an acute or chronic disease process interferes with the function of this portion of the GI tract, nutritional status can be affected and the person may experience symptoms that interfere with their lifestyle.

Nurses provide both acute care for the hospitalised person and education about the skills and knowledge needed to manage these conditions at home.

DISORDERS OF THE MOUTH

Inflammations, infections and neoplastic lesions of the mouth affect food ingestion and nutrition. Oral lesions may have a variety of causes, including infection, mechanical trauma, irritants such as alcohol, and hypersensitivity. Appropriate treatment of the disorder, any underlying factors and associated symptoms is essential.

THE PERSON WITH STOMATITIS

Stomatitis, inflammation of the oral mucosa, is a common disorder of the mouth. It may be caused by viral (herpes simplex) or fungal (*Candida albicans*) infections, mechanical trauma (e.g. cheek biting) or irritants such as tobacco or chemotherapeutic agents. Stomatitis is a common side effect of cancer treatment, occurring in 40% of people receiving standard dose chemotherapy and more than 85% of people receiving head and neck radiation (Caplinger, Royse & Martens, 2010).

Box 22.1 outlines risk factors for stomatitis.

FAST FACTS

- Specific chemotherapy treatments, high-dose and dose-dense chemotherapy protocols increase the risk of stomatitis.
- Repetitive radiation to the head and neck or radiation directly to the oral mucosa contributes to stomatitis.
- Adherence to an oral healthcare protocol can reduce the severity and duration of stomatitis.
- Healing time can take from 2–3 weeks unless there is a complicated infection or repeated doses of chemotherapy or radiation (Caplinger et al., 2010; Cheng, 2007; Harris et al., 2008).

Pathophysiology and manifestations

Radiotherapy and chemotherapy damage the DNA of basal epithelial cells, resulting in necrosis and death of some cells. This stimulates the release of inflammatory cytokines such as tumour necrosis factor alpha (TNF-α) and interleukins that further damage tissues, causing additional epithelial cells to die and greater injury to the mucosa. The injury to the mucosa is manifested in extremely painful lesions, which are portals for bacteria, viruses and fungi. This may lead to bacteraemia and sepsis; ultimately, however, healing of the mucosa will occur (Niscola et al., 2008).

The clinical manifestations of stomatitis vary according to its cause; however, the main symptom is pain. Pain may vary from a mild burning through to severe pain and may be associated with nausea, hypersalivation and infection (Niscola et al., 2008). Table 22.1 outlines common causes of stomatitis with their manifestations and treatment.

Stomatitis can lead to malnutrition, fluid and electrolyte imbalance, an increased risk of infection (especially for neutropenic patients), a reduction in quality of life and increased hospital stays.

BOX 22.1 Risk factors for stomatitis

- Age > 65 years
- Impaired immune status (HIV disease, cancer, diabetes)
- Chronic renal failure or heart failure
- Chemotherapy, radiation therapy, stem cell transplant
- Oxygen therapy, mouth breathing
- Medications (antibiotics, phenytoin, anticholinergics, corticosteroids)
- Poor oral hygiene, ill-fitting dentures
- Tobacco or alcohol use

INTERPROFESSIONAL CARE

Stomatitis is diagnosed by direct physical examination and, if indicated, cultures, smears and evaluation for systemic illness. Assessment tools such as the World Health Organization Mucositis Assessment Tool are available to assist with diagnosis.

Treatment addresses both the underlying cause and any coexisting illnesses. An undiagnosed oral lesion present for more than 1 week and which does not respond to therapy must be evaluated for malignancy.

Direct smears and cultures of lesions may be obtained to identify causative organisms. If systemic illness is suspected, a variety of diagnostic tests may be ordered to identify the underlying cause.

The best management for mucositis, the oral form of stomatitis, due to chemotherapy or radiation is prevention through education on oral care and diet. Oral care reduces the amount of microbial flora, and reduces pain and bleeding which assists in preventing infection. General treatment measures include providing meticulous oral hygiene four times a day with a soft toothbrush or sponge swab and flossing. Bland oral mouth rinses such as normal saline or water and sodium bicarbonate mixed

TABLE 22.1 Manifestations and treatment of common stomatitis conditions

TYPE	CAUSE	MANIFESTATIONS	TREATMENT
Cold sore, fever blister	Herpes simplex virus	• Initial burning at site • Clustered vesicular lesions on lip or oral mucosa	• Self-limiting • Aciclovir, valaciclovir to shorten course
Aphthous ulcer (canker sore, ulcerative stomatitis)	Unknown; may be type of herpes virus	• Well-circumscribed, shallow erosions with white or yellow centre encircled by red ring • Less than 1 cm in diameter • Painful	• Topical steroid ointment • Oral prednisone
Candidiasis (thrush)	*Candida albicans*	• Creamy white, curd-like patches • Red, erythematous mucosa	• Fluconazole (Diflucan) • Ketoconazole (Nizoral) • Clotrimazole pessaries • Nystatin mouth rinse
Necrotising ulcerative gingivitis (trench mouth, Vincent's infection)	Infection with spirochetes and bacilli or systemic infection	• Acute gingival inflammation and necrosis • Bleeding, halitosis • Fever • Cervical lymphadenopathy	• Correct any underlying disorders • Oral penicillin
Oral mucositis	Damage to epithelial cells and stem cells in the submucosa caused by chemotherapy or radiation therapy	• Erythema and inflammation of oral mucosa • Painful, irregularly shaped ulcerations, initially superficial, progressing to deep ulcers that may be confluent (overlapping with one another) • Pseudomembranes covering ulcers • Tissue necrosis with spontaneous bleeding, potential sepsis	• Regular oral hygiene with brushing and flossing • Sodium bicarbonate solution or normal saline mouth rinses after and between meals • Lignocaine viscous gel before meals for analgesia • Cryotherapy before, during and after chemotherapy administration

together can be used to loosen debris in the mouth, reduce the acidity of oral fluids, dilute accumulating mucus and discourage yeast colonisation. The person should be instructed to take a tablespoon of the rinse, swish it in their mouth for at least 30 seconds, and then expectorate (Harris et al., 2008; Munn, 2008).

Cryotherapy, the use of ice chips or ice-cold water for the prevention of oral mucositis, is also recommended for use in chemotherapy agents with a short half life. The person sucks on ice or holds ice-cold water in their mouth prior to, during and after rapid infusion of the chemotherapy agent. Cryotherapy is based on the theory that vasoconstriction decreases exposure of the oral mucous membranes to the chemotherapy agent (Harris et al., 2008; Weiner & Deeken, 2010).

Medications

Using a topical anaesthetic, such as 2% viscous lignocaine, diphenhydramine (Benadryl) solution or benzocaine spray or gel can promote comfort and the ability to consume oral food and fluids. Lignocaine solution is not swallowed, to avoid impairment of the swallowing mechanism. Orabase, a protective paste, may be applied to oral ulcers to promote comfort. Triamcinolone acetonide may be mixed in Orabase to reduce inflammation and promote healing. Sodium bicarbonate or normal saline mouthwashes may provide relief and promote cleansing, whereas alcohol-based mouthwashes may cause pain and burning and should be avoided.

Fungal infections often are treated with a nystatin oral suspension; the person 'swishes and swallows' the solution. Clotrimazole lozenges also treat oral fungal infections. If the infection does not resolve, oral antifungal medications such as fluconazole or ketoconazole may be used. Antifungals are usually continued for at least 3 days after symptoms disappear.

Herpetic lesions may be treated with topical or oral aciclovir of valaciclovir (Valtrex). Aciclovir ointment provides comfort and lubrication while limiting the spread of the virus. Aciclovir capsules reduce the severity of symptoms and the duration of the lesions.

Bacterial infections are treated with antibiotics based on cultures and smears. Oral penicillin is the treatment of choice if the person is not allergic and the cultured bacteria are sensitive. Nursing implications for selected drugs used to treat stomatitis are outlined below.

Nursing care

Health promotion

Nurses can help prevent stomatitis by identifying people at risk and suggesting measures to reduce the likelihood that stomatitis will develop. Educate and encourage all people to regularly perform mouth care, including teeth brushing and flossing. Written information sheets or posters that can be displayed in

MEDICATION ADMINISTRATION Drugs used to treat stomatitis

TOPICAL ORAL ANAESTHETICS

Viscous lignocaine
Triamcinolone acetonide (Kenalog in Orabase)

These drugs reduce the pain associated with mucous membrane lesions or stomatitis. They provide temporary relief of pain. Any oral lesion that persists longer than 1 week should be evaluated by an oral surgeon.

Nursing responsibilities

- Instruct the person to seek medical attention for any oral lesion that does not heal within 1 week.
- Monitor for local hypersensitivity reactions and discontinue use if they occur.

Health education for the person and family

- Apply every 1 to 2 hours as needed.
- Perform oral hygiene after meals and at bedtime.

TOPICAL ANTIFUNGAL AGENTS

Clotrimazole (Canestan)
Nystatin (Nilstat)

These products help in the topical treatment of candidiasis. Their effects are primarily local rather than systemic.

Nursing responsibilities

- Instruct the person to dissolve lozenges in the mouth.
- Instruct the person to rinse mouth with oral suspension for at least 2 minutes and expectorate or swallow as directed.
- These drugs are contraindicated in pregnancy.

Health education for the person and family

- Take medication as prescribed.
- Do not eat or drink 30 minutes after medication.
- Contact physician if symptoms worsen.
- Perform good oral hygiene after meals and at bedtime; remove dentures at bedtime.

ANTIVIRAL AGENTS

Aciclovir (Zovirax)
Valaciclovir (Valtrex)

Aciclovir and valaciclovir are useful in the treatment of oral herpes simplex virus. They help reduce the severity and frequency of infections. These antiviral agents interfere with the DNA synthesis of herpes simplex virus.

Nursing responsibilities

- Start therapy as soon as herpetic lesions are noted.
- Administer with food or on an empty stomach.

Health education for the person and family

- The virus remains latent and can recur during stressful events, fever, trauma, sunlight exposure and treatment with immunosuppressive drugs.
- Take the medication as ordered and contact the physician if symptoms worsen.

the person's bathroom outlining an oral care regimen, with symptoms that should be reported to clinicians, may promote compliance and reduce risk of oral mucositis occurring. Verify the person's understanding with return explanation and demonstration (Moore et al., 2009; Harris et al., 2008).

Encourage people with ill-fitting dentures or other dental prostheses (such as partial plates) to see a qualified dentist or dental prosthetist. Suggest people taking an extended course of antibiotic therapy or who have impaired immune function consume yoghurt containing live bacterial cultures unless contraindicated. Discuss dietary modifications, such as limiting consumption of highly spiced or acidic foods and avoiding very hot beverages. A high-protein diet and increased oral fluids will assist in mucous membrane regeneration. People undergoing chemotherapy or radiation therapy should avoid use of alcohol and tobacco because these substances further damage oral mucosa, increasing the risk of oral mucositis. Instead suggest the person chew or suck ice during chemotherapy sessions.

Assessment

Oral assessment is important not only for people who have been diagnosed with stomatitis but also for those with risk factors, manifestations or evidence of possible complications (e.g. recent weight loss).

- *Health history:* complaints of mouth pain, altered taste, dysphagia, lack of appetite, malaise; presence of dentures, regularity of dental care; current health status including chronic diseases; current medications; use of alcohol or tobacco.
- *Physical examination:* inspect lips, gums, teeth, interior cheeks, tongue and base of tongue, soft and hard palate; tonsils, oral pharynx and the amount of saliva. Observe and assess general health status including temperature and weight.
- *Diagnostic tests:* WBC, sedimentation rate, serum albumin.

Nursing diagnoses and interventions

Nursing care for the person with stomatitis or oral mucositis focuses not only on the oral inflammation, but also on any underlying systemic diseases, and the effects of the condition on the person's comfort and nutrition.

Impaired oral mucous membrane related to loss of integrity of oral mucous membrane

Regardless of cause, the pain and symptoms must be relieved to promote comfort as well as food and fluid intake.

- Assess and document oral mucous membranes and the character of any lesions every 4 to 8 hours. Baseline and ongoing assessment data provide the basis for evaluation. Teach the person or their caregiver to perform daily oral assessments in the outpatient setting and to report findings to clinicians as required (Harris et al., 2008).
- Assist with thorough mouth care after meals and at bedtime. Brush all tooth surfaces for at least 90 seconds twice daily with a soft toothbrush and floss at least once daily. Allow toothbrush to air dry before storing. If unable to tolerate a toothbrush, offer sponge swabs. Avoid using alcohol-based mouthwashes or lemon-glycerin swabs as

these may dry and irritate mucous membranes, causing pain and further tissue damage. Providing bland rinses such as sodium bicarbonate and normal saline after meals promotes comfort and reduces risk of infection (Maguire et al., 2013).
- Assess knowledge and teach about condition, mouth care and treatments. Instruct to avoid alcohol, tobacco and spicy or irritating foods. Knowledge promotes the person's participation in the plan of care and compliance. Alcohol, tobacco and hot, spicy or rough foods may injure the inflamed mucous membranes.

Risk of imbalanced nutrition (less than body requirements) related to oral pain

Oral lesions and pain may limit oral intake, which may in turn lead to nutritional deficits. Anorexia and general malaise may also contribute to decreased intake.
- Assess food intake as well as the person's ability to chew and swallow. Weigh daily. Provide appropriate assistive devices such as straws or feeding syringes. *Adequate nutrition is essential for healing. Daily weights allow monitoring of the adequacy of food intake. Assistive devices may allow food intake while avoiding irritation of ulcerations or lesions.*
- Encourage a high-kilojoule, high-protein diet considerate of food preferences. Offer soft, lukewarm or cool foods or liquids, such as milk shakes, nutritional supplements, iceblocks and puddings, frequently in small amounts. Obtain nutritional consultation. *Oral intake may be limited and enriched foods and liquids enhance nutrition. A nutritional consultation can help ensure an adequate diet and assist in meeting nutritional needs.*
- Provide analgesics for pain relief as needed. *Significant pain associated with stomatitis or oral mucositis can interfere with effective mouth care and food and fluid intake. Pain management is a vital part of nursing care.*

Community-based care

People with mild stomatitis generally provide self-care. While people with cancer-treatment-related oral mucositis may require more aggressive therapy, the person and caregivers are often able to manage the regimen in home or community-based settings. Include the following topics in teaching for home care:
- management of underlying health conditions and ongoing treatments such as chemotherapy
- the recommended diet and oral hygiene regimen, including foods and substances to avoid (e.g. alcohol, tobacco products)
- nutritional supplements to help meet nutritional requirements
- prescribed medication, its route, side effects, frequency of administration and signs and symptoms to report
- the importance of completing the full course of antibiotic, antiviral or antifungal treatment
- manifestations to report and the importance of follow-up care.

THE PERSON WITH ORAL CANCER

Oral cancer, malignancy of the oral mucosa, may develop on the lips, tongue, floor of the mouth or other oral tissues. It is uncommon, accounting for 2–3% of all malignancies and 0.5% of all deaths in Australia in 2006 (Australian Institute of Health and Welfare (AIHW), 2012; Kademani, 2007). It has, however, a high rate of morbidity and mortality. The incidence of this type of head and neck cancer is three times as high in men as in women, and it is seen more often in men over age 40 (AIHW, 2012). The stage of an oral cancer determines the prognosis, treatment and degree of disability. The primary risk factors for oral cancer are smoking, drinking alcohol and chewing tobacco. Human papillomavirus (HPV) has been associated in 14–22% of oropharyngeal tumours and increases the risk of oral cancer development 3- to 5-fold (Kademani, 2007). Marijuana use and occupational exposures to chemicals also may contribute to the risk of oral cancer.

Pathophysiology and manifestations

Oral cancer is usually a squamous cell carcinoma. Although a cancerous lesion can develop in any area of the mouth, the most common sites are the lower lip, tongue and floor of the mouth. Most early cancers present as inflamed areas with irregular, ill-defined borders. These lesions typically are not painful. More advanced cancers appear as deep ulcers that are fixed to deeper tissues. Early lesions involve the mucosa or submucosa, whereas more advanced tumours may invade and destroy underlying tissues, including muscles and bones of the face. Tumours frequently metastasise to regional lymph nodes. Other cancerous lesions, including lymphoma, malignant melanoma and Kaposi's sarcoma, may also develop in the mouth, although less frequently than squamous cell carcinoma.

The person may be asymptomatic with oral cancer in the early stages and detection is through routine screening or referral when symptoms develop. The earliest symptom of oral cancer is a painless oral ulceration or lesion (see Figure 22.1). Later symptoms vary and may include mass lesions, difficulty speaking, swallowing or chewing, loose teeth, earache, bleeding, swollen lymph nodes and sensory or motor nerve compromise (Kademani, 2007). See the accompanying box for other manifestations of oral cancer. Any oral lesion that does not heal or respond to treatment within 1 to 2 weeks should be evaluated for malignancy.

MANIFESTATIONS Oral cancer

- White patches (leucoplakia)
- Red patches (erythroplakia)
- Ulcers
- Masses
- Pigmented areas (brownish or black)
- Fissures
- Asymmetry of the head, face, jaws or neck

FIGURE 22.1 ■ Oral cancer

Source: © John Radcliffe Hospital/Science Source.

INTERPROFESSIONAL CARE

The first component of treatment is eliminating any causative factors such as chewing tobacco, smoking or drinking alcohol. Tumour staging then determines therapy. The TNM (tumour, nodes, metastasis) classification is used to stage oral cancer (see Box 22.2). A biopsy of the oral lesion allows direct visualisation of cells to determine the presence or absence of cancerous cells. Staging may require additional diagnostic studies such as computed tomography (CT) scans or magnetic resonance imaging (MRI).

Radiation and chemotherapy may be considered based on the person's age, tumour stage, general condition and preferences. Radiation therapy may be used preoperatively to 'shrink' the tumour or postoperatively to limit the risks of metastasis. Chemotherapy may be indicated depending on the stage of the tumour. See Chapter 13 for more information about radiation and chemotherapy to treat cancer.

Following the biopsy and staging of the tumour, surgery is generally indicated, although an advanced or extensive tumour may be considered unresectable. If the tumour involves surrounding tissues, the cosmetic effects of surgery are important considerations. The goal of surgery is removal of the lesion and potentially cancerous surrounding tissue or lymph nodes. Advanced carcinomas may require extensive excision or a *radical neck dissection*, a potentially disfiguring procedure in which the lymph nodes and muscles of the neck are removed. A tracheostomy is performed at the time of surgery. The tracheostomy may be temporary but is often permanent. See Chapter 34 for more information about caring for a person following radical neck dissection and a tracheostomy.

BOX 22.2 Oral cancer staging

Stage 0	Carcinoma in situ
Stage I	Tumour ≤ 2 cm; no regional node involvement
Stage II	Tumour > 2 cm to ≤ 4 cm; no regional node involvement
Stage III	Tumour ≤ 2 cm to > 4 cm; one involved lymph node
Stage IVA & B	Tumour may invade adjacent structures; one or more nodes involved
Stage IVC	Distant metastasis present

Nursing care

Health promotion

Reducing or eliminating tobacco use (smoking and smokeless tobacco) and excess alcohol consumption can significantly reduce the incidence of oral cancer. Teach children and adolescents about the dangers of using tobacco and alcohol. Emphasise the relationship between smokeless tobacco and oral cancer. Discuss strategies to deal with peer pressure to use tobacco and alcohol.

To promote early identification of and intervention for oral cancer, teach people about the risk factors for and manifestations of the disease. With the link between HPV and oral cancer (Kademani, 2007), promoting vaccination against HPV should also be considered.

Assessment

Early precancerous oral lesions are very treatable. Unfortunately, these lesions usually are painless, so diagnosis and treatment often is delayed. Assess the oral cavity of all people, particularly those with risk factors for oral cancer.

- *Health history:* complaints of oral lesions that fail to heal; use (current or past) of tobacco products or excess alcohol.
- *Physical examination:* inspect and palpate lips and oral mucosa (including tongue and floor of mouth under the tongue) for tumours or lesions. Lesions may appear as velvety red or white patches that do not scrape off or as ulcers or areas of necrosis.

Nursing diagnoses and interventions

The mouth allows food ingestion and the lips are integral to verbal and non-verbal expression. The head, mouth and lips are important to self-perception and body image. Nursing diagnoses discussed in this section consider such problems as airway clearance, nutrition, communication and body image. See the accompanying nursing care plan below.

Risk of ineffective airway clearance related to potential oral obstruction by the cancer

The location and the extent of an oral cancer and its excision may compromise the airway. Swelling of adjacent tissues, increased oral secretions or difficulty swallowing may contribute to respiratory distress. If extensive surgery is performed, a tracheostomy is usually performed to maintain airway patency.

CONSIDERATION FOR PRACTICE

In the initial postoperative period, assess airway patency and respiratory status at least hourly. A patent airway is vital to maintain respirations and oxygenation of tissues. Frequent assessment allows early identification of possible airway compromise.

- Unless contraindicated, place in high-Fowler's position, supporting arms. Assist the person to turn, cough and deep breathe at least every 2 to 4 hours. *High-Fowler's position promotes lung expansion. Turning, coughing and deep breathing help maintain a patent airway by preventing pooling of secretions.*
- Maintain adequate hydration (2000 to 3000 mL per day unless contraindicated) and humidity of inspired air. *Adequate hydration helps thin and loosen secretions.*

Risk of imbalanced nutrition (less than body requirements) related to inability to tolerate oral intake

Surgery affects oral food and fluid intake. Enteral feedings or total parenteral nutrition may be required. A gastrostomy tube usually is inserted during surgery to maintain nutrition. If an oral diet is permitted, anorexia or pain may affect intake.

NURSING CARE PLAN A person with oral cancer

Gavin Sandford, a married 44-year-old farmer, has two adult children. He and his wife grow and sell fruit and vegetables. Two months ago, Mr Sandford developed a sore on his tongue that would not heal. Mr Sandford tells his admission nurse, Sara Bucklin, 'The doctor says he will have to remove part of my tongue', and anxiously asks, 'Will I look the same? How will I be able to talk?'

ASSESSMENT

Mr Sandford's admission history reveals that he has been healthy, but has smoked two packets of cigarettes a day for more than 20 years and usually drinks two to four beers per day. He admits to being anxious and fearful of surgery and its outcomes. He says he quit smoking and drinking 2 weeks ago. The biopsy report is positive for squamous cell carcinoma of the tongue. Mr Sandford has no enlarged cervical nodes and says he has no bloody sputum or saliva, difficulty swallowing, chewing or talking. His weight is in the normal range for his height. A wide excision of the oral lesion is planned.

DIAGNOSES

- *Risk of ineffective airway clearance* related to oral surgery.
- *Risk of imbalanced nutrition (less than body requirements)* related to oral surgery.
- *Impaired verbal communication* related to excision of a portion of the tongue.
- *Disturbed body image* related to surgical excision of the tongue.

PLANNING

- Teach the importance of activity, turning, coughing and deep breathing prior to the surgery.
- Encourage Mrs Sandford to visit at mealtimes to assist with and encourage oral intake.
- Demonstrate and allow practising using magic slate and flash cards prior to surgery.
- Arrange for a dietician review prior to surgery to assess energy needs and plan appropriate enteral feeding.
- Discuss the grief process with Mr Sandford and his family and encourage expression of feelings.

Expected outcomes

- Maintain a patent airway and remain free of respiratory distress.
- Maintain a stable weight and level of hydration.
- Effectively communicate with staff and family using a magic slate and flash cards.
- Communicate an increased ability to accept changes in body image.

IMPLEMENTATION

- Assess airway patency and respiratory status every hour until stable.
- Maintain semi-Fowler's position, supporting arms. Encourage to turn, cough and deep breathe every 2 to 4 hours.
- Monitor daily weights.
- Assess response to enteral feedings.
- Allow adequate time for communication efforts using magic slate and flash cards where necessary.
- Keep buzzer in reach at all times and answer promptly. Alert all staff of inability to respond verbally.
- Provide emotional support and encourage self-care and participation in decision making.

EVALUATION

At the time of discharge, Mr Sandford has maintained his weight and has started on oral liquids, including supplements and enriched liquids. His airway has remained clear and he is effectively coughing and deep breathing. He has used the magic slate to communicate throughout his hospital stay. He is regaining use of his tongue and can speak a few words. Although initially distressed, he is communicating an increased ability to cope with loss of part of his tongue. He and his wife say they understand his discharge instructions, including diet, activity, follow-up care and signs and symptoms to report.

CRITICAL THINKING IN THE NURSING PROCESS

1. What measures can you, as a nurse, implement to reduce the incidence of oral cancer?
2. Plan a health education program for young men who smoke.

REFLECTION ON THE NURSING PROCESS

1. Outline what you have learned from this case study that you will apply to your future practice.
2. Mr Sandford's wife calls you 2 weeks after discharge. She tells you that he refuses to try to talk and is relying on his magic slate to communicate. Reflect on how you will respond.

- Weigh daily. Assess oral intake for adequacy of protein, kilojoules and nutrients. *Daily weights and nutritional assessments provide information about the adequacy of diet.*
- Offer soft, bland foods with supplements as indicated. Provide small, frequent feedings, making mealtimes pleasant. *Soft, bland foods may be better tolerated following oral surgery. Large meals may be overwhelming; small, frequent meals promote food and nutrient intake.*
- Provide enteral feedings per gastrostomy tube as ordered. Elevate the head of the bed 30 to 45 degrees. *Enteral feedings maintain nutritional status in the person who is unable to consume foods orally. Elevating the head of the bed reduces the risk of regurgitation and aspiration of gastric contents.*
- Assess for gastric residual volume per facility protocol for the type of feeding (intermittent or continuous). See the 'Translation to practice' box below. Notify the doctor of volumes greater than 200 mL or 50% of previous feeding if feeding is intermittent. *Excess residual volume may increase the risk of aspiration.*
- Consider a nutritional consultation to assess diet and plan appropriate supplements. *A registered dietitian can calculate energy requirements and develop an individualised diet plan to meet nutritional requirements.*

Impaired verbal communication

Oral surgery can interfere with communication. Effective communication is vital to postoperative recovery and prevention of complications.

- Before surgery, establish and practise a communication plan such as using a sketch pad or flash cards. *Practising communication techniques reduces fear and anxiety while promoting communication.*
- Provide ample time for communication efforts and do not answer for the person. Be alert for non-verbal communications. Use yes/no questions and simple phrases. *Providing adequate time allows the person opportunity to express ideas and thoughts. Non-verbal communication provides cues regarding comfort or other needs. Simple yes/no questions are easily answered non-verbally.*
- If indicated, refer to or consult with a speech therapist. *A speech therapist can help promote or restore effective communication.*

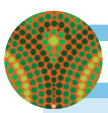
Disturbed body image

Radical surgery of the head or neck seriously affects body image. An altered speech pattern and any disfigurement affect the person's ability to feel attractive or effective in work or social roles. People may defer lifesaving surgery to postpone disfiguring interventions or therapies.

CONSIDERATION FOR PRACTICE

Provide buzzer by the bedside and respond promptly. Make all staff aware that the person cannot verbally respond. Non-verbal people rely on buzzers to summon help. Answering promptly reduces fear and anxiety and maintains safety.

- Assess coping style, self-perception and responses to altered appearance or function. *This information can be used to identify appropriate interventions and care.*
- Encourage verbalisation of feelings regarding perceived and actual changes. *Non-judgmental acceptance of feelings and fears helps establish trust.*



TRANSLATION TO PRACTICE Evidence-based practice for people with enteral feeding tubes

Practices and protocols for caring for enterally fed people and for assessing gastric residual volume have previously been inconsistent. Current recommendations include providing good oral hygiene, elevating the head of the bed 30–45 degrees, administering prokinetic agents such as metoclopramide where indicated, providing continuous feeds, administering the feeds directly to the small bowel via a gastrostomy tube and assessing gastric residual volumes regularly (Lord, 2012).

Gastric residual volumes have been used to determine aspiration risk; when the volume exceeds a predetermined level the tube feed is then withheld. Researchers have come to varying conclusions about the amount of residual volume that is considered safe and does not increase the risk of aspiration. Recent research advocates limits of 200–500 mL as saliva and gastric secretions need to be included in the volume as well as the tube feed (Lord, 2011). In addition, the withholding of enteral feed should be influenced by assessment of the person. Feelings of fullness, nausea, vomiting, abdominal discomfort or distension indicate when the enteral feed should be withheld (Lord, 2012).

IMPLICATIONS FOR NURSING

Gastric motility slows following surgery or trauma, in diabetes, sepsis or electrolyte imbalance, and with medications such as narcotic analgesics. Excessive gastric distension may increase the risk of aspiration of gastric contents; however, when enteral feeds are withheld unnecessarily, the nutritional status of the person is at risk. Impaired nutrition affects healing and recovery and may prolong the person's hospital stay. Therefore it is recommended that a clinical pathway or algorithm is developed which reflects current practice guidelines and is institution-specific to guide nurses with decision making regarding the withholding of feeds (Lord, 2011; 2012).

CRITICAL THINKING IN PERSON-CENTRED CARE

1. Which factors might influence the accuracy of residual volume measurements? Which measures can be taken to obtain accurate measurements?
2. What would be the effect of withholding one bolus feeding of 240 mL of a standard enteral formula? If this is repeated daily for a week, what is the cumulative effect?
3. One reason frequently cited for avoiding checking residual volume is the risk of plugging the feeding tube. Identify measures to prevent this potential problem.

- Provide emotional support, encourage self-care and provide decision-making opportunities. *Self-care promotes self-acceptance and independence. Giving choices empowers the person to participate in care.*

Community-based care

Discharge planning for the person with oral cancer depends on the type of treatment planned and surgery performed. Depending on the person's age, condition and availability of support systems, referral to community healthcare agencies may be an essential component of care. Visits from home health nurses can assist in meeting healthcare needs.

Discuss the following topics with the person and their family members or care providers:

- diagnosis and prescribed care
- monitoring for new lesions or recurrences
- diet, nutrition and activity
- pain management
- airway management, care of incision and signs and symptoms to report.

DISORDERS OF THE OESOPHAGUS

The oesophagus plays an essential role in the ingestion of food and liquids. Disorders of the oesophagus can be inflammatory, mechanical or cancerous. Because of its location and neighbouring organs, the symptoms of oesophageal disorders may mimic those of a variety of other illnesses.

FAST FACTS

- GORD affects up to 20% of people in Western countries
- Up to 10% of people are likely to experience heartburn weekly (Selby, 2010).

THE PERSON WITH GASTRO-OESOPHAGEAL REFLUX DISEASE

Gastro-oesophageal reflux is the backward flowing of gastric contents into the oesophagus. When this occurs, the person experiences heartburn. Many people with gastro-oesophageal reflux have few symptoms, while others develop inflammatory oesophagitis as a result of exposure to gastric juices. **Gastro-oesophageal reflux disease (GORD)** is a common gastrointestinal disorder.

Pathophysiology

Normally, the lower oesophageal sphincter remains closed except during swallowing. Reflux (backflow) of gastric contents into the oesophagus is prevented by pressure differences between the stomach and the lower oesophagus. The diaphragm, the lower oesophageal sphincter and the location of the gastro-oesophageal junction below the diaphragm help maintain this pressure difference (see Figure 22.2).

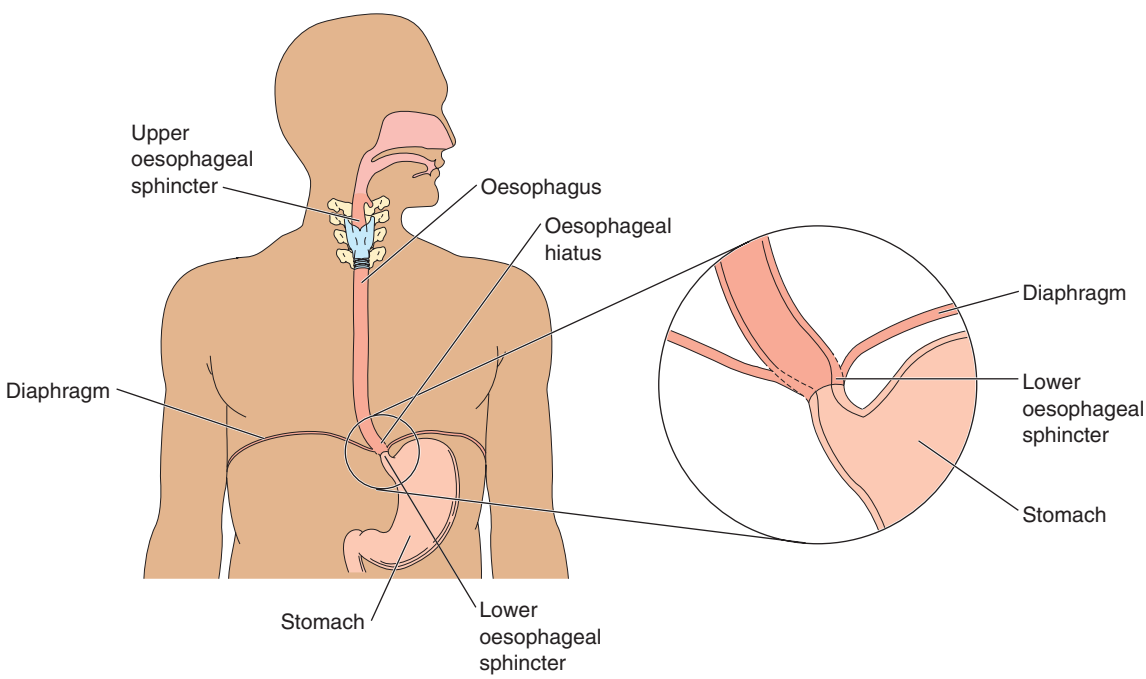


FIGURE 22.2 ■ The oesophagus. The inset shows a closer view of the lower oesophageal sphincter

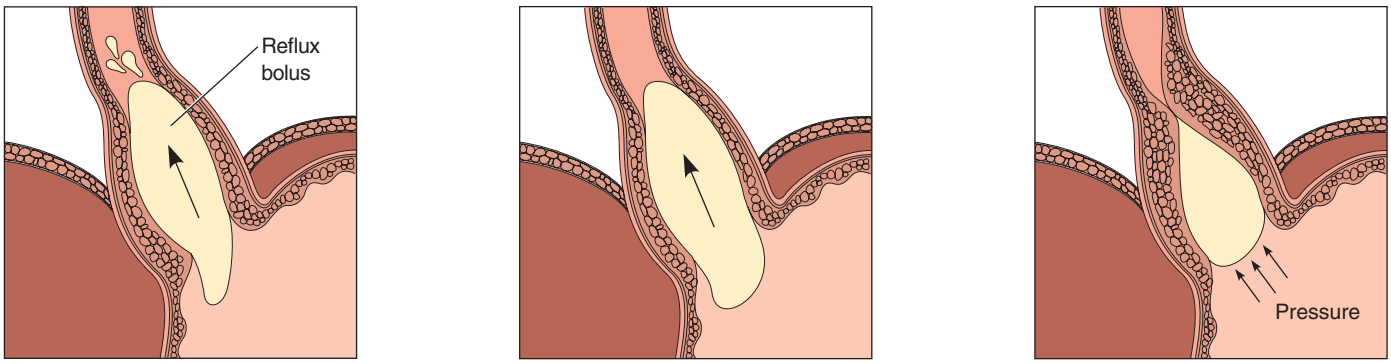

Transient lower oesophageal sphincter relaxation

Incompetent lower oesophageal sphincter

Increased intragastric pressure

FIGURE 22.3 ■ Mechanisms of gastro-oesophageal reflux

Gastro-oesophageal reflux may result from transient relaxation of the lower oesophageal sphincter, an incompetent lower oesophageal sphincter and/or increased pressure within the stomach (see Figure 22.3). Factors contributing to gastro-oesophageal reflux include increased gastric volume (e.g. after meals), positioning that allows gastric contents to remain close to the gastro-oesophageal junction (e.g. bending over, lying down) and increased gastric pressure (e.g. obesity, pregnancy or wearing tight clothing). A hiatal hernia may contribute to GORD.

Gastric juices contain acid, pepsin and bile, which are corrosive substances. Oesophageal peristalsis and bicarbonate in salivary secretions normally clear and neutralise gastric juices in the oesophagus. During sleep, however, and in people with impaired oesophageal peristalsis or salivation, the oesophageal mucosa is damaged by gastric juices, causing an inflammatory response. With prolonged exposure, oesophagitis develops. Superficial ulcers develop and the mucosa becomes red, friable and may bleed. If untreated, scarring and oesophageal stricture may develop.

Manifestations

GORD causes burning, retrosternal pain which may radiate to the jaw or other areas of the chest. These symptoms can be confused with cardiac pain and therefore thorough assessment, the person's history and investigations are necessary. Regurgitation, or reflux, also occurs in GORD causing gastric acid to enter into the throat leaving a metallic, bitter taste in the mouth. The gastric acid may also irritate the airways causing the person to develop a chronic cough, or exacerbation of their asthma or chronic obstructive pulmonary disease (Selby, 2010).

Complications of GORD include oesophagitis, oesophageal ulcer, peptic stricture, haemorrhage, Barrett's oesophagus and oesophageal cancer. Both symptoms and complications of GORD lead to significant lifestyle disruptions including sleep disturbance, impaired ability to concentrate and inability to undertake physical or social activities (Morcom, 2008).

INTERPROFESSIONAL CARE

Often the diagnosis of GORD is made by the history of symptoms and predisposing factors. Interprofessional care focuses on lifestyle changes, diet modification and, for more severe cases, drug therapy. Surgery is reserved for people who develop serious complications.

Diagnosis

Diagnostic tests that may be ordered for people with manifestations of GORD include:

- *Barium swallow* to evaluate the oesophagus, stomach and upper small intestine.
- *Upper endoscopy* to permit direct visualisation of the oesophagus. Tissue may be obtained for biopsy to establish the diagnosis and rule out malignancy. See Chapter 20 for nursing care of the person undergoing an upper endoscopy.
- *24-hour ambulatory pH monitoring* may be performed to establish the diagnosis of GORD. For this test, a small tube with a pH electrode is inserted through the nose into the oesophagus. The electrode is attached to a small box worn on the belt that records the data. The data are later analysed by computer.
- *Oesophageal manometry* measures pressures of the oesophageal sphincters and oesophageal peristalsis.

Medications

Antacids such as Mylanta relieve mild or moderate symptoms by neutralising stomach acid. Gaviscon, which forms a floating barrier between the gastric contents and the oesophageal mucosa when the person is upright, may also be used.

Omeprazole (Losec), lansoprazole (Zoton), pantoprazole (Somac) and esomeprazole (Nexium) are proton-pump inhibitors (PPIs) that reduce gastric secretions. PPIs are the first-line pharmacological treatment as they promote healing of erosive oesophagitis and also relieve symptoms (Morcom, 2008; Selby, 2010). An 8-week course of treatment is initially prescribed, although some people may require 3 to 6 months of therapy.

MEDICATION ADMINISTRATION Drugs used to treat GORD, gastritis and peptic ulcer disease

PROTON-PUMP INHIBITORS

Esomeprazole (Nexium)
Lansoprazole (Zoton)
Omeprazole (Losec)
Pantoprazole (Somac)
Rabeprazole (Aciphex)

Proton-pump inhibitors are the drugs of choice for GORD. PPIs inhibit the hydrogen-potassium-ATP pump, reducing gastric acid secretion. Initially, the PPI may be given twice a day, with the dose reduced to once daily (at bedtime) after 8 weeks.

Nursing responsibilities

- Administer before breakfast and at bedtime if ordered twice a day; at bedtime if once a day.
- Do not crush tablets.
- Monitor liver function tests for possible abnormal values, including increased AST, ALT, alkaline phosphatase and bilirubin levels.

Health education for the person and family

- Take the drug as ordered for the full course of therapy, even if symptoms are relieved.
- Do not crush, break or chew tablets.
- Avoid cigarette smoking, alcohol, aspirin and NSAIDs while taking this drug because these substances may interfere with healing.
- Report black tarry stools, diarrhoea or abdominal pain to your primary care provider.

H_2-RECEPTOR BLOCKERS

Cimetidine (Tagamet) **Ranitidine (Zantac)**
Famotidine (Pepcidine) **Nizatidine (Nizac)**

H_2-receptor blockers reduce acidity of gastric juices by blocking the ability of histamine to stimulate acid secretion by the gastric parietal cells. As a result, both the volume and concentration of hydrochloric acid in gastric juice are reduced. H_2-receptor blockers are given orally or intravenously. Both prescription and over-the-counter preparations are available.

Nursing responsibilities

- To ensure absorption, do not give an antacid within 1 hour before or after giving an H_2-receptor blocker.
- When administered intravenously, do not mix with other drugs. Administer in 20 to 100 mL of solution over 15 to 30 minutes. Rapid intravenous injection as a bolus may cause arrhythmias and hypotension.
- Monitor for interaction with such drugs as oral anticoagulants, beta-blockers, benzodiazepines, tricyclic antidepressants and others. H_2-receptor blockers may inhibit the metabolism of other drugs, increasing the risk of toxicity.

Health education for the person and family

- Take the drug as directed, even if pain and gastric discomfort are relieved early in the course of therapy.
- Take at bedtime if once-a-day dosing is ordered. If spaced through the day, take before meals. Avoid taking antacids for 1 hour before and 1 hour after taking this drug.
- To promote healing, avoid cigarette smoking (which increases gastric acid secretion) and gastric mucosal irritants such as alcohol, aspirin and NSAIDs.
- Long-term use of these drugs can lead to gynaecomastia (breast enlargement) and impotence in men, and breast tenderness in women. Discontinuing the drug will reverse these effects.
- Report possible adverse effects such as diarrhoea, confusion, rash, fatigue, malaise or bruising to your care provider.

ANTI-ULCER AGENT

Sucralfate (Carafate)

Sucralfate reacts with gastric acid to form a thick paste that adheres to damaged gastric mucosal tissue. It protects gastric mucosa and promotes healing through this local action.

Nursing responsibilities

- Administer on an empty stomach, 1 hour before meals and at bedtime.
- Do not crush tablets.
- Separate administration time from antacids by at least 30 minutes.

Health education for the person and family

- Take as directed, even after symptoms have been relieved.
- Do not crush or chew tablets; shake suspension well.
- Increase your intake of fluids and dietary fibre to prevent constipation.

ANTACIDS

Gavisco Gelusil Gastrogel Mylanta

Antacids buffer or neutralise gastric acid, usually acting locally. Antacids are used in GORD, gastritis and peptic ulcer disease to relieve pain and prevent further damage to oesophageal and gastric mucosa.

Nursing responsibilities

- Antacids interfere with the absorption of many drugs given orally; separate administration times by at least 2 hours.
- Monitor for constipation or diarrhoea resulting from antacid therapy. Notify the physician should either develop; a different antacid may be ordered.
- Although most antacids have little systemic effect, electrolyte imbalances can develop. Monitor serum electrolytes, particularly sodium, calcium and magnesium levels.

Health education for the person and family

- Take your antacid frequently as prescribed, 1 to 3 hours after meals and at bedtime. To be effective, the antacid must be in your stomach.
- Avoid taking an antacid for approximately 2 hours before and 1 hour after taking another medication.
- Shake suspensions well prior to administration.
- Chew tablets thoroughly and follow with a glass of water.
- Report worsening symptoms, diarrhoea or constipation to your primary care provider.

(continued)

MEDICATION ADMINISTRATION Drugs used to treat GORD, gastritis and peptic ulcer disease (continued)

- Continue taking the antacid for the duration prescribed. Although pain and discomfort often are relieved soon after treatment begins, healing takes 6 to 8 weeks.

PROKINETIC AGENT

Metoclopramide (Maxalon)

By acting on the central nervous system, metoclopramide stimulates upper gastrointestinal motility and gastric emptying. As a result, nausea, vomiting and symptoms of GORD are reduced.

Nursing implications

- Do not administer this drug to children or to people with possible gastrointestinal obstruction or bleeding, or a history of seizure disorders, pheochromocytoma or Parkinson's disease.
- Monitor for extrapyramidal side effects (e.g. difficulty speaking or swallowing, loss of balance, gait disruptions, twitching or twisting movements, weakness of arms or legs) or manifestations of tardive dyskinesia (uncontrolled rhythmic facial movement, lip smacking, tongue rolling). Report immediately.
- Give oral doses 30 minutes before meals and at bedtime.
- May be given by direct intravenous push over 1 to 2 minutes.

Health education for the person and family

- Take this drug as directed. If you miss a dose, take as soon as you remember unless it is close to the time for the next dose.
- Do not drive or engage in other activities that require alertness if this drug makes you drowsy.
- Avoid using alcohol or other CNS depressants while you are taking this drug.
- Immediately contact your healthcare provider if you develop involuntary movements of your eyes, face or limbs.

Histamine$_2$-receptor (H_2-receptor) blockers reduce gastric acid production and are effective in treating GORD symptoms. When treating GORD, H_2-receptor blockers are usually given twice a day or more frequently for a prolonged period of time. Cimetidine, ranitidine, famotidine and nizatidine are all approved by the Therapeutic Goods Administration (TGA) for the treatment of GORD.

A prokinetic agent, such as metoclopramide (Maxalon), may be ordered to enhance oesophageal clearance and gastric emptying. Metoclopramide is used to treat people with regurgitation, symptoms of indigestion and night-time symptoms. However, it is not recommended for long-time use due unfavourable side effects and only modest efficacy for symptom relief and healing (Morcom, 2008). See the 'Medication administration' box above for the nursing implications of drugs used to treat GORD.

Nutrition and lifestyle management

GORD is a chronic condition. Dietary and lifestyle changes are important to reduce symptoms and long-term effects of the disorder. Contributing factors to GORD include obesity, smoking, alcohol and certain foods, and therefore lifestyle interventions are an essential adjunct to pharmacological therapy for GORD (Morcom, 2008). Dietary modifications such as the avoidance of acidic or fatty foods, avoiding large meals and waiting 2 hours after dinner before going to bed may be beneficial; however, there is limited clinical evidence to support this (Morcom, 2008). Smoking cessation, alcohol avoidance, stress reduction, weight loss and elevating the head of the bed are recommended for symptom relief (Morcom, 2008; Selby, 2010).

Surgery

Surgery may be used for people who do not respond to pharmacological and lifestyle management. Antireflux surgeries increase pressure in the lower oesophagus, inhibiting gastric content reflux. Laparoscopic fundoplication, a procedure in which the gastric fundus is wrapped around the distal oesophagus, is the treatment of choice for GORD. An open surgical procedure known as Nissen fundoplication may also be done (see Figure 22.4). Other laparoscopic procedures to tighten the lower oesophageal sphincter may include use of an endoscopic suturing system or burning spots on the muscle surrounding the sphincter to create scar tissue. Surgery or ablation therapy also is recommended to reduce the risk of oesophageal cancer in people with persistent cell changes in the distal oesophagus.

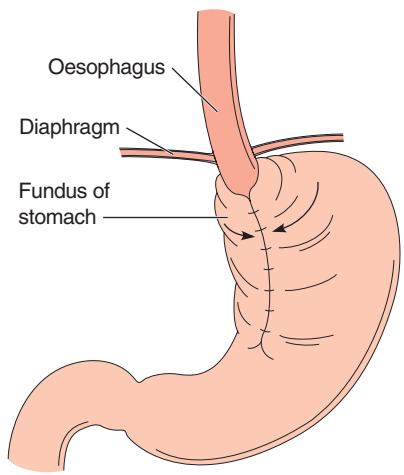

FIGURE 22.4 ■ Nissen fundoplication. The fundus of the stomach is wrapped around the lower oesophagus and the edges are sutured together

Nursing care

Assessment

Assessment data related to GORD include the following:

- *Health history:* manifestations such as frequent heartburn; intolerance of foods that are acidic, spicy or fatty; regurgitation of acidic gastric juice; increased symptoms when bending over, lying down or wearing tight clothing; difficulty swallowing.
- *Physical assessment:* epigastric tenderness, weight.

Nursing diagnoses and interventions

Relieving the discomfort associated with GORD is the priority of nursing care. Education focuses on preventing symptoms and long-term consequences of the disorder.

Pain related to reflux

The epigastric pain associated with GORD can be severe, interfering with rest and causing anxiety.

- Provide small, frequent meals. Restrict intake of fat, acidic foods, coffee and alcohol. *Limiting the size of meals reduces pressure in the stomach, reducing oesophageal reflux. Fatty, acidic foods, coffee and alcohol increase gastric acidity and interfere with gastric emptying, increasing the incidence of gastro-oesophageal reflux.*
- Instruct to stop smoking. Refer to a smoking cessation clinic or program as needed. *Cigarette smoking increases gastric acidity and interferes with healing of damaged mucosa.*
- Administer antacids, H_2-receptor blockers and PPIs as ordered. Instruct the person to continue therapy as prescribed, even after symptoms have been relieved. *These drugs neutralise or reduce gastric acid secretion, relieving symptoms and promoting healing.*
- Discuss the long-term nature of GORD and its management. *Lifestyle changes need to be continued after healing and symptom relief to manage the long-term effects of GORD.*

Community-based care

GORD is a lifelong condition best managed by the person. Teach the person and family about continuing management strategies which may be of benefit, including dietary changes, remaining upright after meals and avoiding eating for at least 3 hours before bedtime. Suggest elevating the head of the bed on 15 to 20 cm wooden blocks placed under the legs. Discuss the need for continued gastric acid reduction using antacids, H_2-receptor blockers or PPIs. All are effective to reduce the acidity of gastric juices. Antacids, the most cost-effective measure, require frequent doses to neutralise gastric acid. H_2-receptor blockers, also available over the counter, are a cost-effective management strategy that requires only twice-a-day dosing.

THE PERSON WITH A HIATAL HERNIA

A **hiatal hernia** occurs when part of the stomach protrudes through the oesophageal hiatus of the diaphragm into the thoracic cavity. Although hiatal hernia is thought to be a common problem, most affected individuals are asymptomatic. The incidence of hiatal hernia increases with age.

In a *sliding hiatal hernia*, the gastro-oesophageal junction and the fundus of the stomach slide upward through the oesophageal hiatus (see Figure 22.5A). Several factors may contribute to a sliding hiatal hernia, including weakened gastro-oesophageal diaphragmatic anchors, shortening of the oesophagus or increased intra-abdominal pressure. Small sliding hiatal hernias produce few symptoms.

In a *paraoesophageal hiatal hernia*, the junction between the oesophagus and stomach remains in its normal position below the diaphragm while a part of the stomach herniates through the oesophageal hiatus (see Figure 22.5B). A paraoesophageal hernia can become incarcerated (constricted) and strangulate, impairing blood flow to the herniated tissue. People with paraoesophageal hernia may develop gastritis or chronic or acute gastrointestinal bleeding. The manifestations of hiatal hernias are listed in the following box.

A barium swallow or an upper endoscopy may be done to diagnose hiatal hernia. Many people with hiatal hernia require no treatment. If symptoms are present, treatment measures such

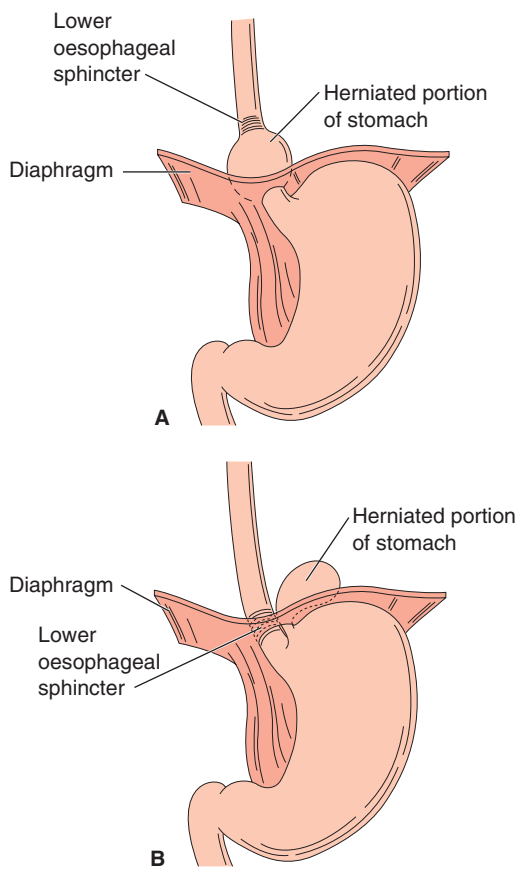

FIGURE 22.5 ■ Hiatal hernias. *A*, Sliding hiatal hernia. *B*, Paraoesophageal hiatal hernia

as those for people with GORD may be ordered. If medical management is ineffective or the hernia becomes incarcerated, surgery may be required. The most common surgical procedure is the Nissen fundoplication (see Figure 22.4). This surgery, which may be done laparoscopically, prevents the gastro-oesophageal junction from slipping into the thoracic cavity.

Nursing care for the person with a hiatal hernia is similar to that for the person with GORD. If surgery is performed, nursing care is similar to that for people undergoing gastric or thoracic surgery (see Chapter 3).

MANIFESTATIONS Hiatal hernia

- Reflux, heartburn
- Feeling of fullness
- Substernal chest pain
- Dysphagia
- Occult bleeding
- Belching, indigestion

THE PERSON WITH IMPAIRED OESOPHAGEAL MOTILITY

Disorders of oesophageal motility can cause **dysphagia** (difficult or painful swallowing) or chest pain. It is estimated that nearly 75% of people hospitalised with stroke experience dysphagia. Other neurological disorders such as Parkinson's disease, amyotrophic lateral sclerosis and Alzheimer's disease also can cause dysphagia.

Primary disorders of swallowing are less common. **Achalasia**, a disorder of unknown aetiology, is characterised by impaired peristalsis of the smooth muscle of the oesophagus and impaired relaxation of the lower oesophageal sphincter (LOS). The person experiences gradually increasing dysphagia with both solid foods and liquids. Fullness in the chest during meals, chest pain and night-time cough are additional manifestations. Other people may experience **diffuse oesophageal spasm** that causes non-peristaltic contraction of oesophageal smooth muscle. This disorder causes chest pain and/or dysphagia. The chest pain can be severe and usually occurs at rest.

Treatment of achalasia may include endoscopically guided injection of botulinum toxin into the lower oesophageal sphincter or balloon dilation of the LOS. Botulinum toxin injection lowers LOS pressure, but may need to be repeated every 6 to 9 months. Balloon dilation tears muscle fibres in the LOS, reducing its pressure (see Figure 22.6). A laparoscopic myotomy (incision into the circular muscle layer of the LOS) also reduces pressure and relieves symptoms.

THE PERSON WITH OESOPHAGEAL CANCER

Cancer of the oesophagus is a relatively uncommon malignancy in Australia. It does, however, have a high mortality rate, with a 5-year survival rate of only 15% (Edmondson & Schiech, 2008) primarily because symptoms often are not recognised until late in the course of the disease.

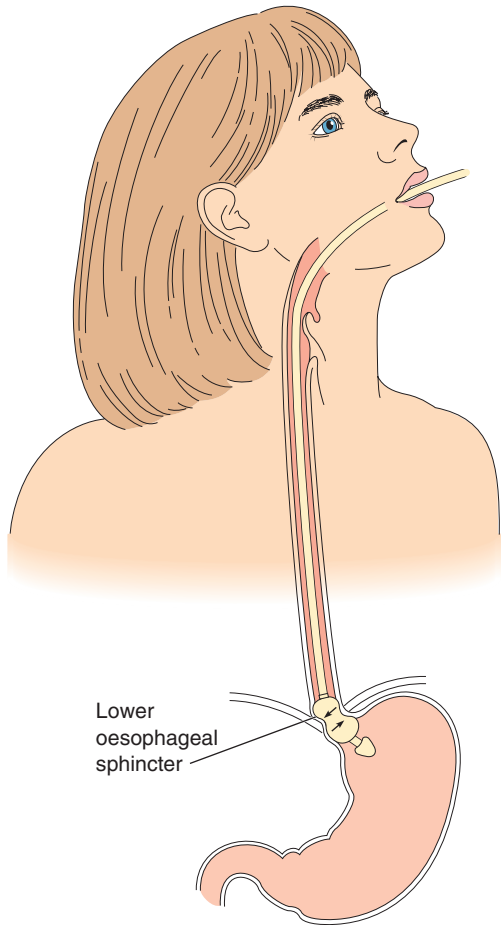

FIGURE 22.6 ■ Balloon dilation of the lower oesophageal sphincter

Pathophysiology

There are two types of oesophageal tumours: adenocarcinoma and squamous cell carcinoma. Cigarette smoking and chronic alcohol use are strong risk factors for squamous cell oesophageal tumours in Western countries. In Asian countries, chewing betel nuts and eating certain pickled vegetables are risk factors. There are investigations currently into the link between HPV and oesophageal cancer (Edmondson & Schiech, 2008).

Adenocarcinoma has been linked to obesity, GORD and Barrett's oesophagus. Combining any of these co-morbidities with tobacco use further increases the risk of oesophageal cancer developing (Edmondson & Schiech, 2008). Box 22.3 lists major identified risk factors for oesophageal cancer.

Only about 15% of oesophageal tumours develop in the upper portion of the oesophagus; about 35% develop in the mid portion. The lower third of the oesophagus is the most common site, accounting for about 50% of tumours. Adenocarcinomas tend to develop in dysplastic (abnormal) columnar epithelium in the distal oesophagus. They are commonly associated with Barrett's oesophagus, a possible complication of chronic GORD and achalasia.

The disease usually spreads to adjacent and supraclavicular lymph nodes, the liver, lungs and the pleura.

BOX 22.3 Risk factors for oesophageal cancer

- Excess alcohol consumption
- Cigarette smoking
- Ingested carcinogens such as nitrates and industrial chemicals
- Smoked opiates
- Physical mucosal damage (e.g. lye ingestion, radiation damage, chronic achalasia)
- Congenital disorders
- Chronic gastric reflux
- Obesity

Manifestations

Dysphagia is the most common symptom of oesophageal carcinoma, typically accompanied by weight loss (Pennathur et al., 2013). Other manifestations are listed in the following box.

Tracheoesophageal fistulas may develop as the disease progresses, leading to aspiration, pneumonia and shortness of breath. Paraneoplastic symptoms such as hypercalcaemia also may accompany advanced oesophageal cancer.

MANIFESTATIONS Oesophageal cancer

- Dysphagia
- Anaemia
- Unintentional weight loss
- GORD-like symptoms
- Regurgitation
- Anorexia
- Chest pain
- Persistent cough
- Hoarseness

INTERPROFESSIONAL CARE

Controlling dysphagia and maintaining nutritional status are essential goals of therapy for people with oesophageal cancer, regardless of the stage of the disease. Treatment may involve surgery, radiation therapy and/or chemotherapy.

Diagnosis

Diagnostic and staging procedures for oesophageal cancer may include endoscopy, bronchoscopy and scans to detect metastasis. The following diagnostic tests may be performed (see Chapter 20):

- *Barium swallow* to identify irregular mucosal patterns or narrowing of the lumen, which suggest oesophageal cancer.
- *Upper endoscopy* to allow direct visualisation of the tumour and obtain tissue for biopsy.
- *Chest x-ray, CT scans* or *MRI* to identify possible tumour metastases to other organs or tissues.
- *Full blood count (FBC)* may indicate anaemia due to chronic blood loss. *Serum albumin* levels may be low due to malnutrition and liver function tests (*ALT*, *alkaline phosphatase*, *AST* and *bilirubin*) are elevated if liver metastases are present.

Treatments

The treatment of oesophageal cancer depends on the stage of the disease, as well as factors such as the person's condition and preference.

People with early oesophageal cancer usually are treated with surgery alone. Surgery involves resection of the affected portion of the oesophagus (*oesophagectomy*) and possible anastomosis of the stomach to the remaining oesophagus. Mediastinal lymph nodes may be resected at the time of surgery. Oesophagectomy is not without risk; potential surgical complications include anastomosis leak, respiratory complications such as pneumonia or acute respiratory distress syndrome, gastric necrosis or bleeding, cardiac arrhythmias, and infection and sepsis. Postoperative recovery is usually in the intensive care unit (ICU) for 12 days before transfer to a surgical ward (Edmondson & Schiech, 2008; Viklund & Lagergren, 2007).

Other approaches to early oesophageal cancer include combined radiation and chemotherapy or radiation therapy or chemotherapy alone prior to surgical resection of the tumour. Although the prognosis of oesophageal cancer is poor, current evidence suggests significant benefit from preoperative chemotherapy or chemoradiotherapy prior to resection of local, operable cancer (Gebski et al., 2007). However, more research in this area is needed.

When the tumour is too advanced or if surgery is considered too risky, palliative measures such as brachytherapy, chemotherapy and oesophageal stenting may be considered (Edmondson & Schiech, 2008). Approximately 50% of people with oesophageal cancer are considered incurable at time of diagnosis, therefore palliative treatments focus on maintaining good quality of life through relief of dysphagia, providing nutritional support, administering pain relief and offering psychological support (Viklund & Lagergren, 2007).

Nursing care

Health promotion

Health promotion measures to reduce the risk and incidence of oesophageal cancer include educating people (especially young people) about the dangers of cigarette smoking and excess alcohol use. Refer to smoking cessation and alcohol treatment programs as indicated. Educate people with GORD about the relationship between chronic damage to the oesophagus due to reflux and oesophageal cancer and stress the importance of effective disease management.

Assessment

Early diagnosis and treatment of oesophageal cancer can make a difference in the person's prognosis. Collect the following assessment data related to oesophageal cancer:

- *Health history:* current symptoms such as chest pain, dysphagia, odynophagia (pain with swallowing), coughing or hoarseness; duration of symptoms; recent weight loss; smoking history; current and past patterns of alcohol consumption.
- *Physical examination:* weight; general health status; skin colour; supraclavicular and cervical lymph nodes for lymphadenopathy.

Nursing diagnoses and interventions

Disruption of the integrity and function of the oesophagus and the discomfort associated with swallowing in people with oesophageal cancer affect the person's ability to maintain adequate nutritional status and, potentially, a patent airway.

Risk of imbalanced nutrition (less than body requirements) related to dysphagia

The person diagnosed with oesophageal cancer may already suffer from some degree of malnutrition because of difficulty and pain with swallowing. Enteral nutrition via nasogastric feeding tube or gastrostomy tube or parenteral nutrition maintains nutritional status after surgery or if the tumour is inoperable and obstruction occurs. See Chapter 21 for nursing interventions related to enteral and parenteral feedings.

Risk of ineffective airway clearance due to surgery

After surgery for oesophageal cancer, the person is at high risk of aspiration and difficulty maintaining a patent airway due to disruption of the oesophagus and incision into the thoracic cavity.

- Assess mental and respiratory status (including rate, depth, breath sounds and oxygen saturation levels) at least every hour during the initial postoperative period. *Altered mental status increases the risk of aspiration. An increased respiratory rate, dyspnoea, diminished breath sounds or decreased oxygen saturation levels may indicate impaired airway clearance or possible aspiration pneumonia.*
- Provide aggressive pulmonary hygiene measures, including endotracheal suctioning and chest physiotherapy as indicated or ordered. Following extubation, encourage frequent coughing, deep breathing and use of the incentive spirometer. *Respiratory complications are a frequent complication of oesophagectomy. Aggressive nursing care helps mobilise secretions and prevent atelectasis and possible pneumonia.*
- If present, monitor chest tube function and drainage. Promptly report drainage that is bright red and excessive in amount (> 70 mL/h) or purulent. Maintain patency of chest tubes per unit protocol or physician's order. If a thoracic incision has been used, chest tubes are placed to promote lung reinflation. *Proper chest tube function is necessary to prevent pneumothorax and impaired lung inflation.*
- Monitor cardiopulmonary status and haemodynamic pressures. Administer intravenous fluids and fluid boluses as ordered. Fluid volume imbalances that compromise cardiopulmonary status may develop following oesophagectomy. *Maintaining adequate fluid intake and preventing fluid overload are important postoperatively. The person also is at risk of acute respiratory distress syndrome, a critical complication that can further compromise ventilation, gas exchange and circulation.*
- Do not move or manipulate the nasogastric tube. Maintain low gastric suction as ordered. *Manipulating or moving the nasogastric tube may disrupt suture lines, resulting in a leak into the mediastinum.*
- Verify enteral tube feeding placement by x-ray (see Chapter 21). Stop enteral feedings if feelings of fullness or nausea occur. Suction gastrointestinal contents as needed, positioning the person on the side. *Overdistension of the stomach or delayed gastric emptying may result in regurgitation of stomach contents. Nausea or a feeling of fullness may indicate stomach overdistension. Suctioning and positioning limit the risk of aspiration.*

Anticipatory grieving

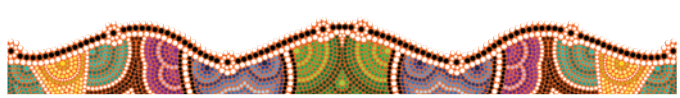
Upon a diagnosis of cancer, the person and family may experience a grief reaction. The pessimistic prognosis associated with oesophageal cancer and the disruptions in relationships may result in an intense sense of loss. Chapter 4 discusses care of the person experiencing grief and loss.

Community-based care

Most care for people with oesophageal cancer is provided in community-based and home settings. Include the following topics in person and family teaching for home care:

- planned treatment options, including the risks, benefits and potential adverse effects of each
- wound and follow-up care following surgery
- prevention and manifestations of complications such as wound or chest infection, anastomosis leak, deep vein thrombosis
- how to prepare, implement and care for tube feedings or home parenteral nutrition.

Based on the person's needs and prognosis, referral to a home health agency and/or hospice may be appropriate.



DISORDERS OF THE STOMACH AND DUODENUM

The stomach and upper small intestine (duodenum and jejunum) are responsible for the majority of food digestion. The major disorders that affect digestion are nausea and vomiting, gastritis, peptic ulcer disease and cancer of the stomach. Nursing roles in managing these disorders include both acute care for the hospitalised person and teaching to give the person the skills and knowledge to manage these conditions at home.

OVERVIEW OF NORMAL PHYSIOLOGY

Normally, the stomach is protected from the digestive substances it secretes—namely, hydrochloric acid and pepsin—by the **gastric mucosal barrier**. The gastric mucosal barrier includes:

- An impermeable hydrophobic lipid layer that covers the gastric epithelial cells. This lipid layer prevents diffusion of water-soluble molecules, but substances such as aspirin and alcohol can diffuse through it.
- Bicarbonate ions secreted in response to hydrochloric acid secretion by the parietal cells of the stomach. When bicarbonate (HCO_3^-) secretion is equal to hydrogen ion (H^+) secretion, the gastric mucosa remains intact. Prostaglandins, chemical messengers involved in the inflammatory response, support bicarbonate production and blood flow to the gastric mucosa.
- Mucous gel that protects the surface of the stomach lining from the damaging effects of pepsin and traps bicarbonate to neutralise hydrochloric acid. This gel also acts as a lubricant, preventing mechanical damage to the stomach lining from its contents.

When an acute or chronic irritant disrupts the mucosal barrier, or when disease alters the processes that maintain the barrier, the gastric mucosa becomes irritated and inflamed. Lipid-soluble substances such as aspirin and alcohol penetrate the gastric mucosal barrier, leading to irritation and possible inflammation. Bile acids also break down the lipids in the mucosal barrier, increasing the potential for irritation (Porth & Matfin, 2009). In addition, aspirin and other non-steroidal anti-inflammatory drugs (NSAIDs) inhibit prostaglandins. Aspirin and NSAIDs also alter the nature of gastric mucus, affecting its protective function.

THE PERSON WITH NAUSEA AND VOMITING

Nausea and vomiting are common gastrointestinal symptoms. **Nausea** is a subjective, unpleasant sensation of sickness or queasiness. It may or may not be accompanied by (and possibly relieved by) vomiting. **Vomiting** is the forceful expulsion of the contents of the upper gastrointestinal tract resulting from contraction of muscles in the gut and abdominal wall. Nausea and vomiting without abdominal pain are commonly associated with food poisoning, infectious gastroenteritis (discussed in Chapter 23), gallbladder disease or ingestion of toxins (such as drugs or alcohol). When associated with severe abdominal pain, they may indicate a serious disorder such as peritonitis, acute gastrointestinal obstruction or pancreatitis.

Pathophysiology

Nausea occurs when the vomiting centre in the medulla of the brain is stimulated. Distension of the duodenum is a common stimulus for nausea. The vomiting centre can be stimulated by input from several different sources:

- the gastrointestinal tract, produced by distension, irritation or infection
- the vestibular system of the ear
- higher central nervous system centres in response to certain sights, smells or emotional experiences
- chemoreceptors outside the blood–brain barrier that are stimulated by drugs, chemotherapeutic agents, toxins, systemic disorders and pregnancy
- disorders such as acute myocardial infarction and heart failure commonly produce nausea and vomiting, possibly due to direct stimulation of the vomiting centre by hypoxia
- increased intracranial pressure (e.g. due to intracranial bleeding or a tumour) produces vomiting that may or may not be accompanied by nausea.

Anorexia—loss of appetite—commonly precedes nausea, just as nausea frequently precedes vomiting. Vomiting, a response that requires coordinated movements of the thorax and abdominal wall, the gut, the pharynx and the muscles of the mouth and face, is coordinated by the brainstem. *Emesis* (or *vomitus*) is produced when inspiratory muscles of the thorax (including the diaphragm) and abdomen contract, increasing intrathoracic and intra-abdominal pressures. The gastro-oesophageal sphincter relaxes and the larynx moves upward to facilitate oral expulsion of gastric contents.

In addition to the subjective sensation of queasiness, nausea frequently is accompanied by autonomic nervous system manifestations such as pallor, sweating, tachycardia and increased salivation. Vomiting, which stimulates the vagus nerve and parasympathetic nervous system, may be accompanied by dizziness, light headedness, hypotension and bradycardia.

Potential complications of vomiting include dehydration, hypokalaemia, metabolic alkalosis (from loss of hydrochloric acid from the stomach), aspiration with resulting pneumonia and rupture or tears of the oesophagus (known as a Mallory–Weiss tear).

INTERPROFESSIONAL CARE

In most cases, nausea and vomiting are self-limited and require no treatment. If vomiting is severe or accompanied by other symptoms, acute care may be required to determine the underlying problem and prevent or treat complications such as dehydration.

Diagnostic tests may include serum electrolytes; pregnancy testing if indicated; liver, pancreatic and renal function studies; and imaging studies (x-ray of the abdomen, abdominal CT scan) to detect gastrointestinal obstruction. An upper endoscopy may be performed. (See Chapter 20 for nursing care of the person undergoing upper endoscopy.) CT scan or MRI of the head may be ordered if an intracranial problem is suspected as the cause. Specialised testing, such as gastrointestinal motility studies, may be indicated when other diagnostic studies are negative for an anatomical cause of nausea and vomiting.

Food is initially withheld, although clear liquids in small quantities are encouraged to prevent dehydration. Dry foods such as crackers may reduce nausea and promote comfort.

Medications

Unless vomiting is associated with pregnancy, anti-emetic medications may be prescribed to prevent or control nausea and vomiting. These drugs fall into several different classes and often are more effective when given in combination.

- Serotonin receptor antagonists are the most effective drugs available for people experiencing nausea and vomiting due to chemotherapy. They are effective when given only once or twice a day, an additional advantage. Drugs within this class include ondansetron (Zofran), granisetron (Kytril) and tropisetron (Navoban).
- Dopamine antagonists include the phenothiazines (e.g. prochlorperazine (Stemetil) and promethazine (Phenergan)), butyrophenones (haloperidol and droperidol) and other drugs such as metoclopramide (Maxalon). These drugs, while effective, can produce extrapyramidal symptoms, sedation and hypotension.
- Antihistamines such as betahistine (Serc) are primarily used to treat nausea and vomiting arising from vestibular centre stimuli (e.g. motion sickness).
- While corticosteroids are not approved as a class for treating nausea and vomiting, two drugs in this class, methylprednisolone (Solu-Medrol) and dexamethasone (Decadron), may be used in combination to treat vomiting associated with cancer treatment.
- Lorazepam (Ativan) is a benzodiazepine drug approved for use as an anti-emetic. It produces a degree of sedation, but can suppress anticipatory vomiting (e.g. before chemotherapy). It also helps control extrapyramidal symptoms associated with the phenothiazine anti-emetics (dopamine antagonists).

Nursing responsibilities and person education for anti-emetic drugs are outlined in the accompanying ‘Medication administration’ box.

Complementary and alternative medicine

Mind–body interventions such as biofeedback, guided imagery, music therapy and hypnosis may be effective for some people with nausea. Biofeedback uses machinery to translate physiological processes into audible or visible signals to teach the person to exert conscious control over those processes. In guided imagery, the person uses imagination to invoke specific images to modify physiological responses. Music therapy involves the person in creating or listening to music to affect physiological and psychological responses. In hypnosis, an altered mind state is induced to make the person receptive to suggestions.

Ginger, an aromatic root frequently used in cooking and also available in capsule form, may also be helpful in relieving nausea and vomiting, particularly when due to pregnancy and chemotherapy (Alparslan et al., 2012; Ozgoli, Goli & Simbar, 2009). Ginger can inhibit platelet aggregation and may increase the risk of bleeding in people taking antiplatelet or anticoagulant drugs (Lehne, 2012).

Nursing care

Assessment of the person is vital to help determine the cause of nausea and vomiting and to rule out underlying systemic disease or acute conditions that require immediate care (e.g. bowel obstruction). When the cause is known or no other acute symptoms are present, nursing interventions can promote comfort and prevent complications.

Nausea

An unpleasant sensation in the epigastric or abdominal region, nausea is a subjective sensation best described by the person.

- Monitor subjective complaints of nausea, vital signs, skin turgor and condition, and weight. Maintain accurate intake and output records. Monitor amount, colour and specific gravity of urine. *Nausea can cause aversion to food and fluids, leading to dehydration even when it is not accompanied by vomiting.*
- Administer anti-emetic medication as ordered, prior to meals and before treatments or procedures known to stimulate nausea. *Preventing nausea is particularly important for people receiving chemotherapy, to avoid the association between the treatment and nausea.*
- Instruct to deep breathe to voluntarily suppress the vomiting reflex. *Controlling vomiting helps prevent dehydration and other complications associated with prolonged or severe vomiting.*
- Instruct to consume small quantities of clear fluids and dry foods at separate times. *Separating the intake of dry foods and fluids helps reduce the nausea stimulus.*

MEDICATION ADMINISTRATION Drugs used to prevent and treat nausea and vomiting

SEROTONIN RECEPTOR ANTAGONISTS

Ondansetron (Zofran)
Granisetron (Kytril)
Tropisetron (Navoban)

The serotonin receptor antagonists suppress nausea and vomiting by blocking the effect of serotonin on vagal afferent nerves that stimulate the vomiting centre. Their primary uses are to prevent vomiting associated with chemotherapy, radiation therapy and surgery.

Nursing responsibilities

- Administer 30 to 60 minutes prior to chemotherapy or surgery as directed.
- May be given orally, sublingually (Ondansetron wafers) or intravenously (push or infusion; follow directions specific to the drug used).
- Monitor liver function and clotting studies; report abnormal levels to the physician.

Health education for the person and family

- Take this drug exactly as directed.
- This drug may be taken without regard to food intake.
- Headache is a common side effect of these drugs. Use paracetamol or another mild analgesic as directed by your physician.

DOPAMINE ANTAGONISTS

Prochlorperazine (Stemetil)
Promethazine (Phenergan)
Haloperidol (Haldol)
Droperidol (Dropletan)
Metoclopramide (Maxalon)

These drugs act by blocking dopamine receptors in the chemoreceptor trigger zone (CTZ). Their primary uses are to suppress nausea and vomiting associated with surgery, cancer chemotherapy and toxins. The major adverse effects associated with these drugs are sedation, hypotension and extrapyramidal reactions. Older adults are more sensitive to the effects of these drugs; a lower dose often is indicated.

Nursing responsibilities

- Administer orally or parenterally as ordered before surgery, or before meals and procedures known to produce nausea and vomiting.
- These drugs may interact with a number of other medications, often increasing their sedative and hypotensive effects.
- Administer with caution to older adults, closely monitoring for adverse effects such as confusion, agitation, changes in vital signs.
- Monitor for evidence of extrapyramidal symptoms, including tremor, restlessness, hyperactivity, anxiety, impaired coordination; notify doctor if symptoms develop.

Health education for the person and family

- Use the drug as ordered; do not increase your dose without consulting your primary care provider.
- These drugs may cause drowsiness. Avoid using other central nervous system (CNS) depressants such as alcohol while taking these drugs.
- Change positions from lying to sitting and sitting to standing slowly because these drugs can cause light headedness or dizziness.
- Promptly report changes in coordination, tremors, difficulty speaking or swallowing, or weakness to your physician.

ANTIHISTAMINES

Betahistane (Serc)

Antihistamines are primarily used to treat nausea and vomiting associated with motion sickness. They act by blocking histamine and acetylcholine (muscarinic) receptors in the neural pathway from the inner ear to the vomiting centre in the brainstem.

Nursing responsibilities

- Do not administer these drugs to people for whom anticholinergic drugs are contraindicated: people with narrow-angle glaucoma, urinary retention, bowel obstruction.
- May be administered orally, parenterally or rectally, depending on the preparation and the person's ability to tolerate oral preparations.
- Use with caution in people who are taking other CNS depressants or antihistamine preparations, tricyclic antidepressants or monoamine oxidase inhibitors.

Health education for the person and family

- These drugs frequently cause drowsiness. Use caution when operating machinery or performing tasks requiring mental alertness.
- Avoid using alcohol or other substances that cause drowsiness or sedation while taking these drugs.
- The medication may cause dry mouth. Sips of water, ice chips, boiled lollies and sugarless gum can be used for comfort.
- Use sunscreen and protective clothing to protect from sunburn while using these drugs.

THE PERSON WITH GASTROINTESTINAL BLEEDING

Because of its constant exposure to the environment, the gastrointestinal tract can be subjected to trauma and exposed to toxins, infection with pathogens such as *Helicobacter pylori* (*H. pylori*), inflammatory processes and insults such as ischaemia due to systemic diseases. While the mucosal lining of the GI tract is remarkably able to withstand these insults and heal rapidly, its rich supply of blood can result in significant bleeding when a vessel is eroded or abnormally distended (*varices*). Gastrointestinal haemorrhage is a relatively common cause of admission and complication of critical illnesses. It is a medical emergency requiring aggressive medical and nursing care.

Although bleeding and haemorrhage can occur anywhere in the GI tract, the upper portion of the tract is more commonly affected. The three primary disorders leading to upper

gastrointestinal (UGI) haemorrhage are erosive gastritis, peptic ulcer disease and oesophageal varices. Erosive gastritis and peptic ulcer disease are discussed in the following sections of this chapter; oesophageal varices, usually seen as a complication of cirrhosis of the liver, are discussed in Chapter 24.

FAST FACTS

- UGI bleeds are associated with increasing non-steroidal anti-inflammatory drug (NSAID) use.
- Approximately 64% are associated with *H. pylori* infection in people with peptic ulcer bleeding.
- UGI bleeding is twice as common in men as in women.
- Prevalence increases with age (Wilkins et al., 2012).

Pathophysiology

Blood in the GI tract has several effects. It is irritating to the stomach and typically leads to nausea and vomiting (**haematemesis**, vomiting blood). If the blood has been present in the stomach for a period of time and is partially digested, it may have a 'coffee-grounds' appearance, rather than presenting as bright red blood. The accumulation of blood in the GI tract stimulates peristalsis, leading to hyperactive bowel sounds and diarrhoea. Stools may be black and tarry (melaena) or frankly bloody (**haematochezia**); stool containing partially digested blood has a characteristic odour. With significant upper GI bleeding, digestion of blood proteins increases blood urea nitrogen (BUN) levels.

Physiological responses to an upper GI bleed depend on the rapidity and magnitude of the blood loss. GI bleeding resulting from erosion of a small vessel typically is slow and may not be identified until the person presents with manifestations of blood loss anaemia due to depletion of iron stores. (See Chapter 32 for further discussion of blood loss anaemia.) Although no visible blood may be present in the stool, **occult** (or hidden) **bleeding** may be detected by chemical means.

GI haemorrhage, with loss of a significant amount of blood within a few hours, rapidly depletes blood volume, producing manifestations of decreased cardiac output: tachycardia, hypotension, pallor and decreased urine output. Peripheral blood vessels constrict to maintain perfusion of vital organs. Unless the blood volume is restored, hypovolaemic shock progresses, leading to acidosis, renal failure, bowel infarction, acute coronary syndrome, coma and death. See Chapter 10 for more information about shock and its management.

INTERPROFESSIONAL CARE

The acuity of the bleed and the person's condition dictate the timing and extent of diagnostic testing and interventions. A person with a massive GI haemorrhage is admitted to the critical care unit and aggressively treated to stem bleeding, restore blood volume and stabilise the cardiovascular system. Identifying the cause of the bleeding is postponed in many cases until the person's condition has been stabilised.

When the bleeding is slow or chronic, diagnostic testing and treatment may be managed in a community-based setting.

Diagnosis

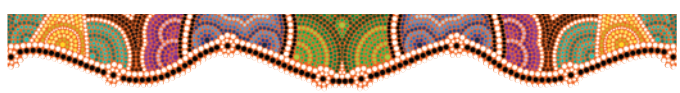
Diagnostic testing focuses on determining the extent and effects of the bleed, as well as its cause.

- A *full blood count (FBC) with haemoglobin and haematocrit* is obtained. In an acute bleed, the FBC, haemoglobin and haematocrit may not initially indicate the extent of blood loss because plasma is lost along with blood cells.
- *Blood type and crossmatch* are performed to prepare for transfusion as necessary.
- *Serum electrolytes, osmolality* and *BUN* are obtained to determine the effects of the blood loss and protein digestion on blood chemistries.
- *Liver function tests* and a *coagulation profile* may be obtained to help determine the cause of the bleeding.
- An *upper endoscopy* is performed as soon as possible to identify and, if possible, treat the source of bleeding. See Chapter 20 for nursing care of the person undergoing upper endoscopy.

Treatments

In acute GI haemorrhage, initial treatment focuses on stemming the bleeding, restoring cardiovascular stability and maintaining the person's airway. Intravenous fluids such as normal saline are administered through a large-bore intravenous catheter. Fresh whole blood, which contains clotting factors, is administered to restore blood volume and components in an acute haemorrhage. In less acute situations, packed red cells may be administered to restore the oxygen-carrying capacity of the blood. Intubation may be required to protect against aspiration of blood into the airways (Wilkins et al., 2012).

Haemostasis is achieved using upper endoscopy whenever possible. A sclerosing agent may be injected into the bleeding vessel or the vessel may be sealed using a heated probe, diathermy or laser. Rarely, emergency surgery is required to stop haemorrhage.



Nursing care

Health promotion

Preventing gastrointestinal bleeding is the most important step in reducing the mortality and morbidity associated with an acute GI haemorrhage. Identifying people at risk and instituting regular gastric pH monitoring and maintenance of drug therapy to reduce gastric acidity are important preventive measures. All critically ill people should be considered to be at risk of stress-related erosive gastritis.

Assessment

Assessment of the person experiencing an acute GI haemorrhage is very focused on the immediate crisis. The ability to obtain subjective information may be limited; however, it is important to identify possible contributing factors such as use of aspirin, NSAIDs, other platelet inhibitors or anticoagulant

medications, and the presence of any acute or chronic conditions that may contribute to bleeding (e.g. hypertension, a clotting disorder, peptic ulcer disease, excessive alcohol use, chronic hepatitis or cirrhosis of the liver). If possible, identify all current medications and their purpose, as well as any allergies to medications or other substances. If possible obtain any history of abdominal pain, black tarry stools, vomiting, dysphagia, rectal bleeding or chest pain (Wilkins et al., 2012).

Physical examination focuses on the effect of the bleeding on cardiovascular status. Obtain vital signs and orthostatic vital signs (an early sign of hypovolaemia). Place the acutely ill person on a cardiac monitor and obtain a rhythm strip. Obtain oxygen saturation level. Assess peripheral pulse strength, as well as colour, temperature and capillary refill of extremities. Evaluate mental status, including level of consciousness and orientation. An indwelling catheter may be inserted to evaluate urine output.

Nursing diagnoses and interventions

Nursing care priorities for the person with an acute GI bleed focus on restoring and maintaining an effective cardiac output and tissue perfusion, and on stopping the haemorrhage and preventing further bleeding.

Risk of decreased cardiac output related to haemorrhage

Significant amounts of blood may be lost in a very short time with an acute GI haemorrhage. Because some of the blood enters the bowel, it may be difficult to accurately estimate the amount of blood lost by measuring emesis, gastric suction return and blood expelled as faeces. As blood volume drops, venous return decreases. The heart rate increases to maintain the cardiac output, and peripheral blood vessels constrict to improve venous return and cardiac output.

- Frequently assess and document vital signs, including blood pressure, pulse rate and cardiac rhythm, respiratory rate and oxygen saturation levels. Obtain haemodynamic pressure measurements as ordered, reporting trends and changes. *The vital signs, oxygen saturation levels and haemodynamic pressure values provide indicators of the effectiveness of peripheral tissue perfusion, oxygenation and fluid replacement.*
- Monitor for and report changes in skin colour, temperature and moisture, or slow capillary refill. *Peripheral vasoconstriction and activation of the sympathetic nervous system typically cause pale, cool and moist or diaphoretic skin. Development of cyanosis or mottling indicates a further decrease in tissue perfusion and oxygenation.*
- Insert an indwelling urinary catheter and measure urine output hourly. Report an output of less than 30 mL for two consecutive hours. *A fall in urine output may indicate further reduction in cardiac output. As cardiac output falls, the kidneys become ischaemic and acute renal failure may develop.*
- Unless contraindicated, insert a nasogastric tube to assess for presence of blood or coffee ground material. *Acute blood in the stomach implies UGI bleeding is likely and predicts that the bleeding is caused by a high-risk lesion* (Wilkins et al., 2012).
- Maintain two peripheral intravenous lines with large-bore catheters or a central venous catheter for fluid and blood administration as ordered. Frequently monitor vital signs, respiratory status and haemodynamic pressure measurements, reporting changes in status. *Rapid administration of isotonic intravenous fluids, blood and blood products can lead to fluid overload and potential heart failure.*

Risk of impaired tissue integrity related to nasogastric tube insertion

- Maintain drainage and patency of nasogastric tube. Connect to low suction if ordered. *Blood is irritating to the GI tract, precipitating vomiting and stimulating peristalsis, leading to diarrhoea. In addition, digested blood can increase BUN levels, potentially leading to confusion and altered mental status.*
- Irrigate the nasogastric tube with room-temperature saline or tap water as ordered. Calculate intake and output, subtracting the amount of irrigant from gastric output. *Irrigation of the nasogastric tube helps remove irritating blood from the gut and produces a degree of vasoconstriction in stomach mucosa, slowing bleeding.*
- Prepare for upper endoscopy or surgery as planned. *Endoscopy or emergency surgery may be performed to repair the bleeding site or sclerose bleeding vessels.*
- Following an acute bleed and in people at risk of GI bleeding, monitor gastric pH as ordered and check vomitus and faeces for the presence of occult blood. Maintain infusions of drugs to reduce gastric acidity as ordered. *The person remains at risk of GI bleeding. Monitoring for occult blood helps identify slow bleeding or recurrent haemorrhage. Reducing the acidity of gastric secretions reduces irritation of the gastric mucosa, reducing the risk of bleeding.*

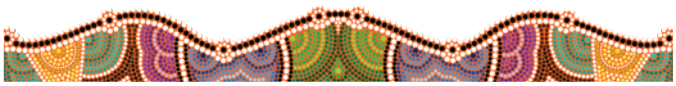
Community-based care

Following an acute GI haemorrhage, continuing care focuses on resolving the underlying disease process if possible and preventing future episodes of GI bleeding. If a bleeding gastric ulcer was identified, testing for *H. pylori* infection will be done and a treatment regimen prescribed to eradicate the infection. (See the section on peptic ulcer disease later in this chapter.) The person who experienced an episode of erosive stress gastritis will often be discharged with instructions to continue taking a gastric-acid-reducing medication and avoid known gastric irritants such as aspirin, NSAIDs and alcohol. The person with oesophageal varices due to cirrhosis or chronic hepatitis needs additional instructions (see Chapter 24).

People with minor or slow GI bleeding often are managed in the community. Provide teaching about the cause of the bleeding and measures to prevent future episodes. Provide verbal and written instructions for prescribed medications such as acid reducers and oral iron supplements. Discuss appropriate nutrition; while a special diet to ‘soothe the stomach’ rarely is

indicated, foods rich in iron may be recommended to treat the resulting anaemia.

Discuss indicators of GI bleeding to be reported to the doctor. If the source of bleeding has not been identified, provide instructions about prescribed follow-up diagnostic testing.



THE PERSON WITH GASTRITIS

Gastritis, inflammation of the stomach lining, results from irritation of the gastric mucosa. Gastritis is common and may be caused by a variety of factors. The most common form of gastritis, **acute gastritis**, is generally a benign, self-limiting disorder associated with the ingestion of gastric irritants such as aspirin, NSAIDs, alcohol, caffeine or foods contaminated with certain bacteria. Manifestations of acute gastritis may range from asymptomatic to mild heartburn to severe gastric distress, vomiting and bleeding with haematemesis (vomiting blood).

Chronic gastritis is a separate group of disorders characterised by progressive and irreversible changes in the gastric mucosa (Porth & Matfin, 2009). Chronic gastritis is more common in older adults, chronic alcoholics and cigarette smokers. When symptoms of chronic gastritis occur, they are often vague, ranging from a feeling of heaviness in the epigastric region after meals to gnawing, burning, ulcer-like epigastric pain unrelieved by antacids.

Pathophysiology

Acute gastritis

Acute gastritis is characterised by disruption of the mucosal barrier by a local irritant. This disruption allows hydrochloric acid and pepsin to come into contact with the gastric tissue, resulting in irritation, inflammation and superficial erosions. The gastric mucosa rapidly regenerates, generally making acute gastritis a self-limiting disorder, with resolution and healing occurring within several days.

The ingestion of aspirin or other NSAIDs, corticosteroids, alcohol and caffeine is commonly associated with the development of acute gastritis. Accidental or purposeful ingestion of a corrosive alkali (such as ammonia, disinfectant and other cleaning agents) or acid leads to severe inflammation and possible necrosis of the stomach. Gastric perforation, haemorrhage and peritonitis are possible results. Iatrogenic causes of acute gastritis include radiation therapy and administration of certain chemotherapeutic agents.

Erosive gastritis

A severe form of acute gastritis, **erosive** or **stress-induced gastritis** occurs as a complication of other life-threatening conditions such as shock, severe trauma, major surgery, sepsis, burns or head injury. When these erosions follow a major burn, they are called Curling's ulcers, after Thomas Curling, a British physician who first described them in 1842. When stress ulcers occur following head injury or CNS surgery, they are referred to as **Cushing's ulcers**, after Harvey Cushing, a US surgeon.

The primary mechanisms leading to erosive gastritis appear to be ischaemia of the gastric mucosa resulting from sympathetic vasoconstriction and tissue injury due to gastric acid. As a result, multiple superficial erosions of the gastric mucosa develop. Maintaining the gastric pH at greater than 3.5 and inhibiting gastric acid secretion with medications help prevent erosive gastritis.

MANIFESTATIONS The person with acute gastritis may have mild symptoms such as anorexia or mild epigastric discomfort relieved by belching or defecating. More severe manifestations include abdominal pain, nausea and vomiting. Gastric bleeding may occur, with haematemesis or melaena (black, tarry stools that contain blood). Erosive gastritis is not typically associated with pain. The initial symptom often is painless gastric bleeding occurring 2 or more days after the initial stressor. Bleeding typically is minimal, but can be massive. Corrosive gastritis can cause severe bleeding, signs of shock and an *acute abdomen* (severely painful, rigid, board-like abdomen) if perforation occurs. See the accompanying 'Manifestations' box.

Chronic gastritis

Unrelated to acute gastritis, chronic gastritis is a progressive disorder that begins with superficial inflammation and gradually leads to atrophy of gastric tissues. The initial stage is characterised by superficial changes in the gastric mucosa and a decrease in mucus. As the disease evolves, glands of the gastric mucosa are disrupted and destroyed. The inflammatory process involves deep portions of the mucosa, which thins and atrophies. There appear to be at least two different forms of chronic gastritis, classified as type A and type B.

Type A gastritis, the less common form of chronic gastritis, usually affects people of Northern European heritage. This type of gastritis is thought to have an autoimmune component. In type A or autoimmune gastritis, the body produces antibodies to parietal cells and to intrinsic factor. These antibodies destroy gastric mucosal cells, resulting in tissue atrophy and the loss of hydrochloric acid and pepsin secretion. Because intrinsic factor is required for the absorption of vitamin B_{12}, this immune response also results in pernicious anaemia. For further discussion of pernicious anaemia, see Chapter 32.

MANIFESTATIONS Acute and chronic gastritis

ACUTE GASTRITIS

Gastrointestinal
- Anorexia
- Nausea and vomiting
- Haematemesis
- Melaena
- Abdominal pain

Systemic
- Possible shock

CHRONIC GASTRITIS

Gastrointestinal
- Vague discomfort after eating; may be asymptomatic

Systemic
- Anaemia
- Fatigue

Type B gastritis is the more common form of chronic gastritis. Its incidence increases with age, reaching nearly 100% in people over the age of 70. Type B gastritis is caused by chronic infection of the gastric mucosa by *H. pylori*, a gram-negative spiral bacterium. *H. pylori* infection causes inflammation of the gastric mucosa, with infiltration by neutrophils and lymphocytes. The outermost layer of gastric mucosa thins and atrophies, providing a less effective barrier against the auto-digestive properties of hydrochloric acid and pepsin.

Infection with *H. pylori* also is associated with an increased risk of peptic ulcer disease. *H. pylori* infection significantly increases the risk of developing gastric cancer. See the sections that follow for more information about these disorders.

MANIFESTATIONS Chronic gastritis is often asymptomatic until atrophy is sufficiently advanced to interfere with digestion and gastric emptying. The person may complain of vague gastric distress, epigastric heaviness after meals or ulcer-like symptoms. These symptoms typically are not relieved by antacids. In addition, the person may experience fatigue and other symptoms of anaemia. If intrinsic factor is lacking, paraesthesias and other neurological manifestations of vitamin B_{12} deficiency may be present. See the 'Manifestations' box above.

INTERPROFESSIONAL CARE

Acute gastritis is usually diagnosed by the history and clinical presentation. In contrast, the vague symptoms of chronic gastritis may require more extensive diagnostic testing.

People with acute and chronic gastritis are generally managed in community settings. The person requires acute care only when nausea and vomiting are severe enough to interfere with their normal fluid and electrolyte balance and nutritional status. If haemorrhage results, surgical intervention may be required.

Diagnosis

Diagnostic tests that may be ordered for the person with gastritis include the following:

- *Haemoglobin, haematocrit* and *red blood cell (RBC) indices* are evaluated for evidence of anaemia. The person with gastritis may develop pernicious anaemia because of parietal cell destruction or iron-deficiency anaemia because of chronic blood loss.
- *Serum vitamin B_{12} levels* are measured to evaluate for possible pernicious anaemia. Normal values for vitamin B_{12} are 200 to 1000 pg/mL, with lower levels seen in older adults.
- *Upper endoscopy* may be done to inspect the gastric mucosa for changes, identify areas of bleeding and obtain tissue for biopsy. Bleeding sites may be treated with electro- or laser coagulation or injected with a sclerosing agent during the procedure. See the 'Diagnostic tests' box in Chapter 20 for preparation and teaching related to an upper endoscopy.

Medications

Drugs such as a PPI, H_2-receptor blocker or sucralfate may be ordered to prevent or treat acute stress gastritis. PPIs and H_2-receptor blockers reduce the amount or effects of hydrochloric acid on the gastric mucosa. Lansoprazole (Zoton), esomeprazole (Nexium) and omeprazole (Losec) are examples of PPIs. H_2-receptor blockers include cimetidine (Tagamet), ranitidine (Zantac), famotidine (Pepcid) and nizatidine (Nizac). These drugs also are available in non-prescription strength. Sucralfate (Carafate) works locally to prevent the damaging effects of acid and pepsin on gastric tissue. It does not neutralise or reduce acid secretion. Nursing implications for drugs commonly used in managing gastritis are included in the 'Medication administration' box on page 671.

The person with type B chronic gastritis may be treated to eradicate the *H. pylori* infection. This generally involves combination therapy consisting of two antibiotics (such as metronidazole and clarithromycin or a tetracycline) and a PPI. In some cases, eradication of the infection is not warranted and the person is treated symptomatically.

Treatments

In acute gastritis, gastrointestinal tract rest is provided by 6 to 12 hours of NBM status, then slow reintroduction of clear fluids (broth, tea, jelly, carbonated beverages), followed by ingestion of free fluids (creamy soups, puddings, milk) and finally a gradual reintroduction of solid food.

If nausea and vomiting threaten fluid and electrolyte balance, intravenous fluids and electrolytes are ordered.

Nursing care

Health promotion

Health promotion aims to educate the person about measures to prevent acute gastritis. Food contaminated with bacteria is a significant cause of acute gastritis. Discuss food safety measures such as fully cooking meats and egg products and promptly refrigerating foods after cooking to avoid bacterial growth. Stress that food contaminated with potential pathogens often looks, smells and tastes good, making it difficult to identify.

Teach people to abstain from eating or drinking anything during an acute episode of vomiting and then to reintroduce clear liquids gradually once vomiting has stopped (2 to 4 hours after the last episode of vomiting). Suggest using a sports drink to replace lost electrolytes and fluid. Instruct people to avoid milk and milk products until they easily tolerate clear liquids and solid foods such as dry toast or crackers.

Assessment

Assessment data to collect for people with acute or chronic gastritis include the following:

- *Health history:* current symptoms and their duration; relieving and aggravating factors; history of ingestion of toxins, contaminated food, alcohol, aspirin or NSAIDs; other medications.
- *Physical examination:* vital signs, including orthostatic vitals if indicated; peripheral pulses; general appearance; abdominal assessment, including appearance, bowel sounds and tenderness.

Nursing diagnoses and interventions

In planning and implementing nursing care for the person with acute or chronic gastritis, consider both the direct effects of the disorder on the gastrointestinal system and nutritional status, as well as its effects on lifestyle and psychosocial integrity. This section focuses on problems of fluid balance and nutrition.

Risk of fluid volume deficit related to gastrointestinal upset

Nausea, vomiting and abdominal distress are the primary manifestations of acute gastritis. The risk of fluid and electrolyte imbalance is high because of inadequate intake of food and fluids and abnormal losses of fluids and electrolytes with vomiting.

- Monitor and record vital signs at least every 2 hours until stable, then every 4 hours. Check for orthostatic hypotension.

CONSIDERATION FOR PRACTICE

Tachycardia, tachypnoea and hypotension, especially orthostatic hypotension, may indicate fluid volume deficit. Electrolyte or acid–base imbalances resulting from vomiting may cause cardiac arrhythmias or changes in respirations.

- Weigh daily. Monitor and record intake and output; record urine output every 1 to 4 hours as indicated. *Daily weights are an accurate indicator of fluid volume. Urine output of less than 30 mL per hour indicates decreased cardiac output and a need for prompt fluid replacement.*
- Monitor skin turgor, colour and condition and status of oral mucous membranes frequently. Provide skin and mouth care frequently. *Skin turgor and mucous membrane assessments indicate hydration status. Good skin and mouth care are necessary to maintain skin and mucous membrane integrity.*
- Monitor laboratory values for electrolytes and acid–base balance. Report significant changes or deviations from normal. *Electrolytes are lost through vomiting, increasing the risk of electrolyte and acid–base imbalances. These imbalances, in turn, affect multiple body systems.*
- Administer oral or parenteral fluids as ordered. *Oral fluids may be withheld until vomiting has ceased, then gradually reintroduced. Intravenous fluids restore or maintain hydration until adequate oral intake is resumed.*
- Administer anti-emetic and other drugs as ordered to relieve vomiting and facilitate oral feeding. Encourage fluids as soon as feasible. *The oral route is preferred for fluid and nutrient intake; medications may be used to allow earlier resumption of feeding.*

CONSIDERATION FOR PRACTICE

Ensure safety: place buzzer within reach, put up the side rails, instruct person to avoid getting up without assistance. Orthostatic hypotension may lead to syncope and to falls if the person attempts to get up without assistance.

Risk of imbalanced nutrition (less than body requirements) related to gastrointestinal upset

Manifestations of chronic gastritis may lead to reduced food intake and malnutrition. The person often associates these unpleasant sensations with eating and may gradually reduce food intake. Associated anorexia also contributes to poor food intake.

- Monitor and record food and fluid intake and any abnormal losses (such as vomiting). *Careful monitoring can help in developing a dietary plan to meet the energy needs of the person. Consultation with a dietitian may prove beneficial.*
- Monitor weight and laboratory studies such as serum albumin, haemoglobin and RBC indices. *Weights and laboratory values provide data regarding nutritional status and the effectiveness of interventions.*
- Arrange for dietary consultation to determine energy and nutrient needs and develop a dietary plan. Consider food preferences and tolerances in menu planning. *A diet high in protein, vitamins and minerals may be prescribed to meet the nutritional needs of the person with chronic gastritis. In addition, specific food intolerances may need to be considered. Planning to include preferred foods in the diet helps ensure consumption of the prescribed diet.*
- Provide nutritional supplements between meals or frequent small feedings as needed. *Many people with chronic gastritis tolerate small, frequent feedings better than three large meals per day.*
- Maintain tube feedings or parenteral nutrition as ordered. Refer to Chapter 21 for further information on enteral and parenteral feedings.

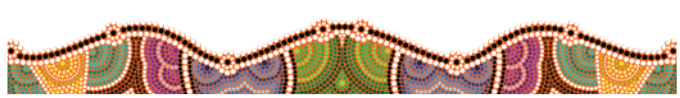
Community-based care

Because acute or chronic gastritis is usually managed in community-based settings, education is vital. For the person with acute gastritis, teaching focuses on managing acute symptoms, reintroducing fluids and solid foods, identifying indicators of possible complications (e.g. continued vomiting, signs of fluid and electrolyte imbalance) and preventing future episodes.

Provide the following information for people with chronic gastritis:

- maintaining optimal nutrition
- helpful dietary modifications
- using prescribed medications
- avoiding known gastric irritants, such as aspirin, NSAIDs, alcohol and cigarette smoking.

Referral to smoking cessation classes or programs to treat alcohol abuse may be necessary.



THE PERSON WITH PEPTIC ULCER DISEASE

Peptic ulcer disease (PUD), a break in the mucous lining of the gastrointestinal tract where it comes in contact with gastric juice, is a chronic health problem. In Australia, people presenting

to hospital with PUD are likely to be male and aged 60 or above (Halland et al., 2011). **Peptic ulcers** occur in any area of the gastrointestinal tract exposed to acid–pepsin secretions, including the oesophagus, stomach or duodenum. **Duodenal ulcers** usually develop between the ages of 60 and 69 and are more common in men than women. **Gastric ulcers** usually develop between the ages of 50 and 59 (Halland et al., 2011).

Risk factors

Chronic *H. pylori* infection and use of aspirin and NSAIDs are the major risk factors for PUD. Contributing risk factors are listed in Box 22.4. Overall, it is estimated that one in six people infected with *H. pylori* develops PUD. A strong familial pattern suggests a genetic factor in the development of PUD. Cigarette smoking is a significant risk factor, doubling the risk of PUD. Cigarette smoking inhibits the secretion of bicarbonate by the pancreas and possibly causes more rapid transit of gastric acid into the duodenum.

Pathophysiology

The innermost layer of the stomach wall, the gastric mucosa, consists of columnar epithelial cells supported by a middle layer of blood vessels and glands and a thin outer layer of smooth muscle. The mucosal barrier of the stomach, a thin coating of mucous gel and bicarbonate, protects the gastric mucosa. The mucosal barrier is maintained by bicarbonate secreted by the epithelial cells, by mucous gel production stimulated by prostaglandins and by an adequate blood supply to the mucosa.

An **ulcer**, or break in the gastrointestinal mucosa, develops when the mucosal barrier is unable to protect the mucosa from damage by hydrochloric acid and pepsin, the gastric digestive juices. See the accompanying 'Pathophysiology illustrated: Peptic ulcer disease'.

H. pylori infection, found in about 70% of people who have PUD, is unique in colonising the stomach. It is spread person to person (oral–oral or faecal–oral) and contributes to ulcer formation in several ways. The bacteria produce enzymes that reduce the efficacy of mucous gel in protecting the gastric mucosa. In addition, the host's inflammatory response to *H. pylori* contributes to gastric epithelial cell damage without producing immunity to the infection. Although the gastric mucosa is the usual site for *H. pylori* infection, this infection also contributes to duodenal ulcers. This is possibly related to increased gastric acid production associated with *H. pylori* infection.

NSAIDs contribute to PUD through both systemic and topical mechanisms. Prostaglandins are necessary for maintaining the gastric mucosal barrier. NSAIDs interrupt prostaglandin synthesis by disrupting the action of the enzyme cyclooxygenase (COX). The two forms of this enzyme are COX-1 and COX-2. The COX-1 enzyme is necessary to maintain the integrity of the gastric mucosa, but the anti-inflammatory effects of NSAIDs are due to their ability to inhibit the COX-2 enzyme. The COX-2-selective NSAIDs may be less damaging to the gastric mucosa because they have less effect on the COX-1 enzyme. In addition to their systemic effect, aspirin and many NSAIDs cross the lipid membranes of gastric epithelial cells, damaging the cells themselves.

The ulcers of PUD may affect the oesophagus, stomach or duodenum. They may be superficial or deep, affecting all layers of the mucosa (see 'Pathophysiology illustrated: Peptic ulcer disease'). Duodenal ulcers usually develop in the proximal portion of the duodenum, close to the pylorus (see Figure 22.7). They are sharply demarcated and usually less than 1 cm in diameter (see Figure 22.8). Gastric ulcers often are found on

BOX 22.4 Risk factors for peptic ulcer disease

- *H. pylori* infection
- Low socioeconomic status
- Crowded, unsanitary living conditions
- Unclean food or water
- Use of aspirin
- Advanced age
- History of PUD
- Concurrent use of other drugs such as glucocorticoids or NSAIDs
- Cigarette smoking
- Family history of PUD

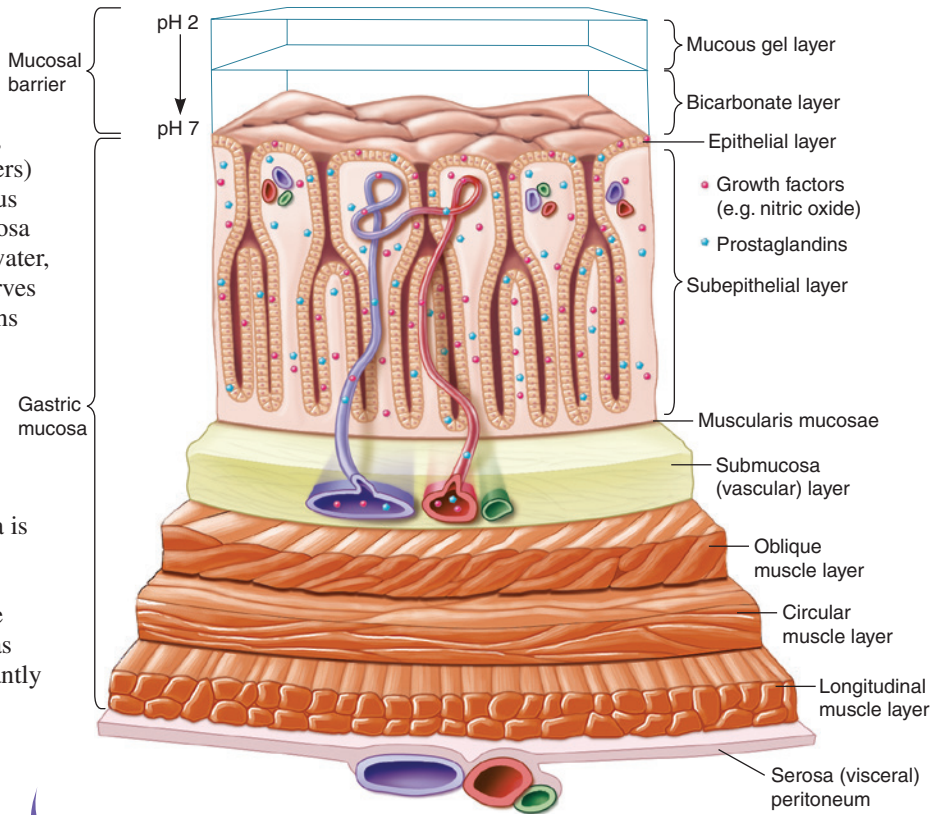
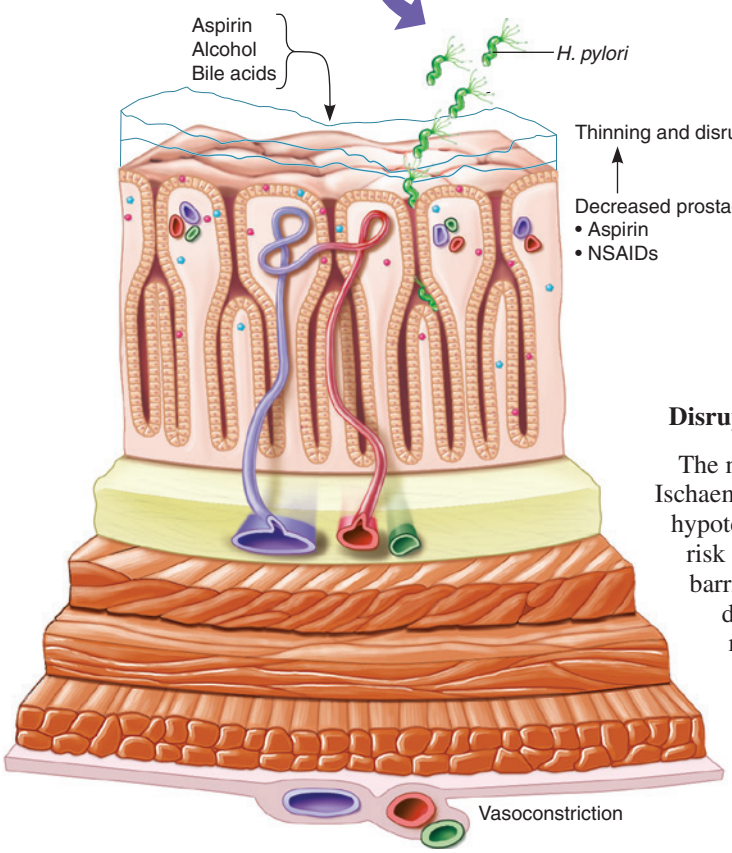
Peptic ulcer disease

Normal gastric mucosa

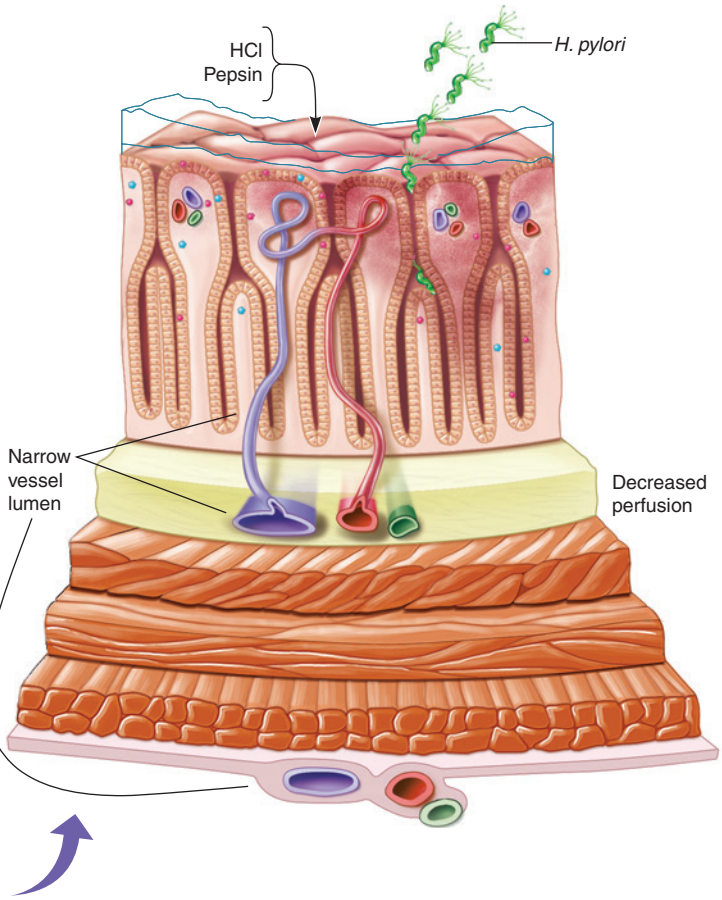
In the stomach and duodenum, the mucosal barrier protects the gastric mucosa (including the epithelial, vascular and smooth muscle layers) from damage. Specialised mucous cells throughout the gastric mucosa produce a mucus (a mixture of water, lipids and glycoproteins) that serves as a barrier to the diffusion of ions (such as hydrogen ion) and molecules (such as pepsin). A thin layer of bicarbonate, secreted by surface epithelial cells, forms between the mucous and cell membranes. Blood flow to the gastric mucosa is vital to maintain this barrier. Prostaglandins and nitric oxide stimulate mucus and bicarbonate production, helping maintain it as well. The mucosal barrier constantly bathes surfaces of the gastric epithelial lining.





Disruption of mucosal barrier

The mucosal barrier can be disrupted by a number of factors. Ischaemia of the gastric mucosa (e.g. due to haemorrhage, hypotension or shock) impairs mucus production, increasing the risk of damage to the mucosa. Aspirin disrupts the mucosal barrier and, along with other non-steroidal anti-inflammatory drugs, inhibits prostaglandins which are necessary to maintain mucous production. Alcohol and bile acids also damage the mucous barrier. *Helicobacter pylori*, a common pathogen to infect the gastric mucosa, disrupts the mucosal barrier.

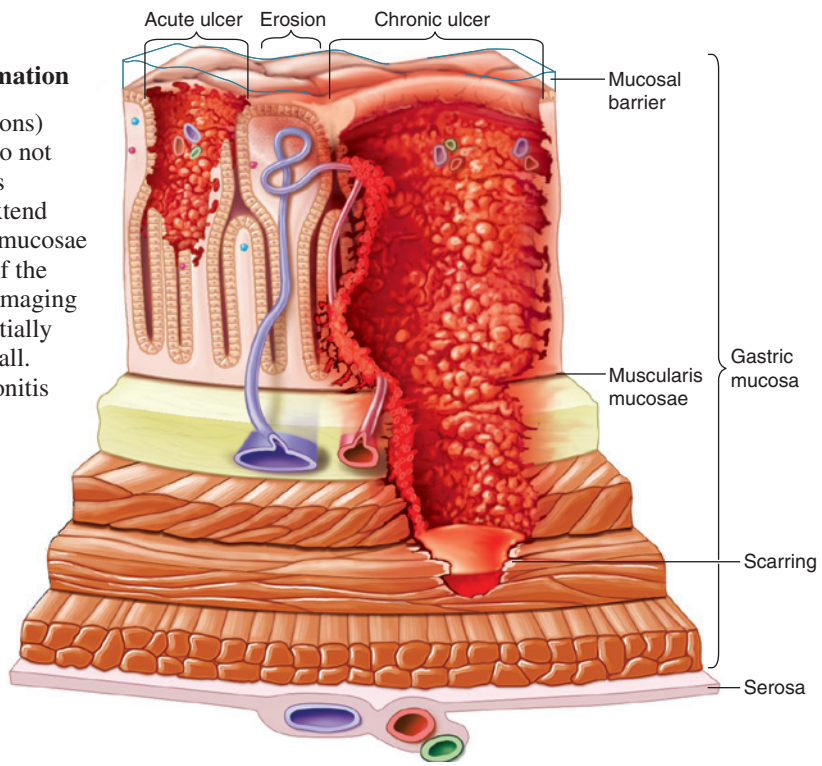


Inflammatory process

When the mucosal barrier is damaged, gastric acid and digestive juices disrupt the epithelial cell membranes, allowing acid to diffuse into cell walls. An acute inflammatory process results. Gastric epithelial cells migrate to the damaged area, a process known as restitution. Adequate blood flow and an alkaline environment are necessary for this repair process. Prostaglandins play an important role in epithelial repair. In the presence of *H. pylori* infection, excess acid production, inadequate blood flow, inhibition of prostaglandins, and other factors that are less clear, the inflammatory process further damages gastric and duodenal epithelial cells, leading to ulceration of the mucosa.

Erosion and ulcer formation

Superficial ulcers (erosions) erode the mucosa, but do not penetrate the muscularis mucosae. True ulcers extend through the muscularis mucosae and into deeper layers of the gastrointestinal wall, damaging blood vessels and potentially penetrating the entire wall. Haemorrhage and peritonitis are potential acute complications of peptic ulcers.



the lesser curvature and the area immediately proximal to the pylorus. Gastric ulcers are associated with an increased incidence of gastric cancer.

Peptic ulcer disease may be chronic, with spontaneous remissions and exacerbations. Exacerbations of the disease may be associated with trauma, infection or other physical or psychological stressors.

Manifestations

Pain is the classic symptom of peptic ulcer disease. The pain is typically described as gnawing, burning, aching or hunger-like and is experienced in the epigastric region, sometimes radiating to the back. The pain occurs when the stomach is empty (2 to 3 hours after meals and in the middle of the night) and is relieved by eating, with a classic 'pain–food–relief' pattern. The person may complain of heartburn or regurgitation and may vomit.

The presentation of peptic ulcer disease in the older adult is often less clear, with vague and poorly localised discomfort, perhaps chest pain or dysphagia, weight loss or anaemia. In the older adult, a complication of PUD, such as upper GI haemorrhage or perforation of the stomach or duodenum, may be the presenting symptom.

Complications

The complications associated with peptic ulcers include haemorrhage, obstruction and perforation. See the box below for the manifestations of these complications.

Among people with PUD, 10–20% experience **haemorrhage** as a result of ulceration and erosion into the blood vessels of the gastric mucosa. In the older adult, bleeding is the most frequent complication. When small blood vessels erode, blood loss may be slow and insidious, with occult blood in the stool the only initial sign. If bleeding continues, the person becomes anaemic and experiences symptoms of weakness, fatigue, dizziness and orthostatic hypotension. Erosion into a larger vessel can lead to sudden and severe bleeding with haematemesis, melaena or haematochezia (blood in the stool) and signs of hypovolaemic shock.

Gastric outlet obstruction may result from oedema surrounding the ulcer, smooth muscle spasm or scar tissue. Generally, obstruction is a gradual rather than an acute process. Symptoms include a feeling of epigastric fullness, accentuated ulcer symptoms and nausea. If the obstruction becomes complete, vomiting occurs. Hydrochloric acid, sodium and potassium are lost in vomitus, potentially leading to fluid and electrolyte imbalance and metabolic alkalosis.

The most lethal complication of PUD is **perforation** of the ulcer through the mucosal wall. When perforation occurs, gastric or duodenal contents enter the peritoneum, causing an inflammatory process and peritonitis. Chemical peritonitis from the hydrochloric acid, pepsin, bile and pancreatic fluid is immediate; bacterial peritonitis follows within 6 to 12 hours from gastric contaminants entering the normally sterile peritoneal cavity. When an ulcer perforates, the person has immediate, severe upper abdominal pain, radiating throughout the abdomen and possibly to the shoulder. The abdomen becomes rigid and board-like, with absent bowel sounds. Signs of shock may be present, including diaphoresis, tachycardia and rapid, shallow respirations. Classic symptoms of perforation may not be present in an older adult. The older adult may instead present with mental confusion and other non-specific symptoms. This atypical presentation can lead to delays in diagnosis and treatment, increasing the associated mortality rate.

MANIFESTATIONS PUD complications

HAEMORRHAGE
- Occult or obvious blood in the stool
- Haematemesis
- Fatigue
- Weakness, dizziness
- Orthostatic hypotension
- Hypovolaemic shock

OBSTRUCTION
- Sensations of epigastric fullness
- Nausea and vomiting
- Electrolyte imbalances
- Metabolic alkalosis

PERFORATION
- Severe upper abdominal pain, radiating to the shoulder
- Rigid, board-like abdomen
- Absence of bowel sounds
- Diaphoresis
- Tachycardia
- Rapid, shallow respirations
- Fever

Zollinger–Ellison syndrome

Zollinger–Ellison syndrome is peptic ulcer disease caused by a gastrinoma or gastrin-secreting tumour of the pancreas, stomach or intestines. Gastrinomas may be benign, although 50–70% are malignant tumours. Gastrin is a hormone that stimulates the secretion of pepsin and hydrochloric acid. The increased gastrin levels associated with these tumours result in hypersecretion of gastric acid, which in turn causes mucosal ulceration.

The peptic ulcers of Zollinger–Ellison syndrome may affect any portion of the stomach or duodenum, as well as the oesophagus or jejunum. Characteristic ulcer-like pain is common. The high levels of hydrochloric acid entering the duodenum may also cause diarrhoea and steatorrhoea (excess fat in the faeces) from impaired fat digestion and absorption. Complications of bleeding and perforation are often seen with Zollinger–Ellison syndrome. Fluid and electrolyte imbalances may also result from persistent diarrhoea, with resultant losses of potassium and sodium in particular.

INTERPROFESSIONAL CARE

Treatment for PUD focuses on eradicating *H. pylori* infection and treating or preventing ulcers related to the use of NSAIDs.

Diagnosis

- *CT scan* using oral contrast is commonly the diagnostic procedure chosen first; it is less costly and less invasive than endoscopy. Small or very superficial ulcers may be missed, however.
- *Upper endoscopy* allows visualisation of the oesophageal, gastric and duodenal mucosa and direct inspection of ulcers. Tissue also can be obtained for biopsy. Nursing care of the person undergoing an endoscopy is outlined in Chapter 20.
- Biopsy specimens obtained during an endoscopy can be tested for the presence of *H. pylori* using several different methods. In the *biopsy urease test*, the specimen is put into a gel containing urea. If *H. pylori* is present, the urease that it produces changes the colour of the gel, often within minutes. Biopsy specimen cells also can be microscopically examined or cultured for evidence of *H. pylori*. Although these tests are highly specific for *H. pylori* infection, their invasiveness, cost and lack of availability in some areas limits their usefulness.
- A non-invasive method of detecting *H. pylori* infection is the *urea breath test*. In this test, radiolabelled urea is given orally. The urease produced by *H. pylori* bacteria converts the urea to ammonia and radio-labelled carbon dioxide, which can then be measured as the person exhales.
- If Zollinger–Ellison syndrome is suspected, *gastric analysis* may be performed to evaluate gastric acid secretion. Stomach contents are aspirated through a nasogastric tube and analysed. In Zollinger–Ellison syndrome, gastric acid levels are very high.

Medications

The medications used to treat PUD include agents to eradicate *H. pylori*, drugs to decrease gastric acid content and agents that protect the mucosa. Nursing responsibilities related to selected drugs to treat GORD, gastritis and PUD are found in the 'Medication administration' box on pages 671–672.

Eradication of *H. pylori* is often difficult. Combination therapies that use two antibiotics with a proton-pump inhibitor (e.g. combinations of a PPI, clarithromycin and amoxicillin, or a PPI, a tetracycline and metronidazole) are necessary. With complete eradication of *H. pylori*, reinfection rates are less than 0.5% per year.

In people who have NSAID-induced ulcers, the NSAID in use should be discontinued if at all possible. If this is not possible, twice-daily PPIs enable ulcer healing.

Medications that decrease gastric acid content include PPIs and the H_2-receptor antagonists.

- Proton-pump inhibitors bind the acid-secreting enzyme (H^+, K^+ ATPase) that functions as the proton pump, disabling it for up to 24 hours. These drugs are very effective, resulting in more than 90% ulcer healing after 4 weeks. Compared with the H_2-receptor blockers, the PPIs provide faster pain relief and more rapid ulcer healing.
- Histamine$_2$-receptor blockers inhibit histamine binding to the receptors on the gastric parietal cells to reduce acid secretion. These drugs are very well tolerated and have few serious side effects; however, drug interactions can occur. These drugs must be continued for 8 weeks or longer for ulcer healing.

Agents that protect the mucosa include sucralfate, bismuth, antacids and prostaglandin analogues.

- Sucralfate binds to proteins in the ulcer base, forming a protective barrier against acid, bile and pepsin. Sucralfate also stimulates the secretion of mucus, bicarbonate and prostaglandin.
- Antacids stimulate gastric mucosal defences, thereby aiding in ulcer healing. They provide rapid relief of ulcer symptoms and are often used as needed to supplement other anti-ulcer medications. Antacids are inexpensive, but people often have difficulty with a regular regimen because the drugs must be taken frequently and may cause either constipation (from the aluminium-type antacids) or diarrhoea (from the magnesium-based antacids). Antacids also interfere with the absorption of iron, digoxin, some antibiotics and other drugs.
- Prostaglandin analogues (misoprostol) promote ulcer healing by stimulating mucus and bicarbonate secretions and by inhibiting acid secretion. Although not as effective as the other drugs discussed, misoprostol is used to prevent NSAID-induced ulcers.

Treatments

NUTRITION In addition to pharmacological treatment, people are encouraged to maintain good nutrition, consuming balanced meals at regular intervals. It is important to teach people that bland or restrictive diets are no longer necessary. Mild alcohol intake is not harmful. Smoking should be discouraged because it slows the rate of healing and increases the frequency of relapses.

SURGERY The identification of *H. pylori* as a cause of PUD and the availability of drugs to treat the infection and heal peptic ulcers has all but eliminated surgery as a treatment option for peptic ulcer disease. Older people, however, may have undergone gastric resection surgery for PUD and may have long-term complications related to the surgery. See the section on gastric cancer for more information about gastric surgery and its potential complications.

Treatment of complications

The person hospitalised with a complication of PUD, such as bleeding, gastrointestinal obstruction or perforation, and peritonitis, requires additional interventions to restore homeostasis.

In haemorrhage associated with PUD, initial interventions focus on restoring and maintaining circulation. Crystalloid solutions such as normal saline are administered intravenously to restore intravascular volume if signs of shock (tachycardia, hypotension, pallor, low urine output and anxiety) are present. Whole blood or packed red blood cells may be administered to restore haemoglobin and haematocrit levels. A nasogastric tube is inserted to prevent aspiration of vomited gastric contents.

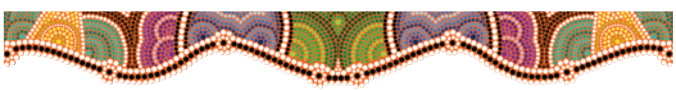
Endoscopy with direct injection of a clotting or sclerosing agent into the bleeding vessel may be performed. Laser photocoagulation, using light energy, or electrocoagulation, which uses electric current to generate heat, can also be done via endoscopy to seal bleeding vessels.

The person is kept NBM until bleeding is controlled. Proton-pump inhibitors are administered intravenously (e.g. 40 mg

of esomeprazole (Nexium) per intravenous push or admixture daily) to reduce the risk of rebleeding. Surgery may be necessary if medical measures are ineffective in controlling bleeding. Older adults who experience bleeding as a complication of PUD are more likely to rebleed or require surgery to control the haemorrhage. See page 695 for the nursing care of the person having gastric surgery.

Repeated inflammation, healing, scarring, oedema and muscle spasm can lead to gastric outlet (pyloric) obstruction. Initial treatment includes gastric decompression with nasogastric suction and administration of intravenous normal saline and potassium chloride to correct fluid and electrolyte imbalance. H_2-receptor blockers are given intravenously as well. Balloon dilation of the gastric outlet may be done via upper endoscopy. If these measures are unsuccessful in relieving obstruction, surgery may be required.

Gastric or duodenal perforation resulting in contamination of the peritoneum with gastrointestinal contents often requires immediate intervention to restore homeostasis and minimise peritonitis. Intravenous fluids maintain fluid and electrolyte balance. Nasogastric suction removes gastric contents and minimises peritoneal contamination. Placing the person in the Fowler's or semi-Fowler's position allows peritoneal contaminants to pool in the pelvis. Intravenous antibiotics aggressively treat bacterial infection from intestinal flora. Laparoscopic surgery or an open laparotomy may close the perforation.



Nursing care

Health promotion

Although it is difficult to predict which people will develop peptic ulcer disease, promote health by advising people to avoid risk factors such as excessive aspirin or NSAID use and cigarette smoking. In addition, encourage people to seek treatment for manifestations of GORD or chronic gastritis, both of which are also associated with *H. pylori* infection.

Assessment

Collect the following subjective and objective data when assessing the person with peptic ulcer disease:

- *Health history:* complaints of epigastric or left upper quadrant pain, heartburn or discomfort; its character, severity, timing and relationship to eating; measures used for relief; nausea or vomiting, presence of bright blood or 'coffee grounds' appearing material in vomitus; current medications, including use of aspirin or other NSAIDs; cigarette smoking and use of alcohol or other drugs.
- *Physical examination:* general appearance, including height and weight relationship; vital signs, including orthostatic measurements; abdominal examination, including shape and contour, bowel sounds and tenderness to palpation; presence of obvious or occult blood in vomitus and stool.

Nursing diagnoses and interventions

The priorities of nursing care for the person with peptic ulcer disease are reducing discomfort, maintaining nutritional status and preventing or rapidly identifying and intervening for potential complications. See the accompanying nursing care plan below.

Pain related to PUD

The pain of PUD is often predictable and preventable. Pain is typically experienced 2 to 4 hours after eating, as high levels of gastric acid and pepsin irritate the exposed mucosa. Measures to neutralise the acid, minimise its production or protect the mucosa often relieve this pain, minimising the need for analgesics.

- Assess pain, including location, type, severity, frequency and duration, and its relationship to food intake or other contributing factors.
- Administer PPIs, H_2-receptor antagonists, antacids or mucosal protective agents as ordered. Monitor for effectiveness and side effects or adverse reactions. *The pain associated with PUD is generally caused by the effect of gastric juices on exposed mucosal tissue. These medications reduce pain and promote healing by reducing acid production, neutralising the acid or providing a barrier for the damaged mucosa.*
- Teach relaxation, stress reduction and lifestyle management techniques. Refer for stress management counselling or classes as indicated. *Although there is no clear relationship between stress and PUD, measures to relieve stress and promote physical and emotional rest help to reduce the perception of pain and may reduce ulcer genesis.*

CONSIDERATION FOR PRACTICE

Avoid making assumptions about pain. Acute pain may indicate a complication, such as perforation (often heralded by sudden, severe epigastric pain and a rigid, board-like abdomen) or it may be totally unrelated to PUD (e.g. angina, gallbladder disease or pancreatitis).

Disturbed sleep pattern

Night-time ulcer pain, which typically occurs between 1 and 3 am, may disrupt the sleep cycle and result in inadequate rest. Anticipation of pain may lead to insomnia or other sleep disruptions.

- Stress the importance of taking medications as prescribed. *The bedtime dose of PPI or H_2-receptor blocker minimises hydrochloric acid production during the night, reducing night-time pain.*
- Instruct to limit food intake after the evening meal, eliminating any bedtime snack. *Eating before bed can stimulate the production of gastric acid and pepsin, increasing the likelihood of night-time pain.*
- Encourage the use of relaxation techniques and comfort measures such as soft music as needed to promote sleep. *Once the pain associated with PUD has been controlled, these measures help to reduce anxiety and re-establish a normal sleep pattern.*

NURSING CARE PLAN A person with peptic ulcer disease

Sean O'Donnell is a 47-year-old police officer who lives and works in a metropolitan area. Mr O'Donnell has had 'heartburn' and abdominal discomfort for years, but thought it went along with his job. Last year, after becoming weak, light headed and short of breath, he was found to be anaemic and was diagnosed as having a duodenal ulcer. He took omeprazole (Losec) and ferrous sulfate for 3 months before stopping both, saying he had 'never felt better in his life'. Mr O'Donnell has now been admitted to the hospital with active upper GI bleeding.

ASSESSMENT

Rachel Clark is Mr O'Donnell's admitting nurse. On initial assessment, Mr O'Donnell is alert and oriented, though very apprehensive about his condition. Skin pale and cool; BP 136/78, P 98; his abdomen is distended and tender with hyperactive bowel sounds; 200 mL bright red blood is obtained on nasogastric tube insertion. Haemoglobin 8.2 g/dL and haematocrit 23% on admission. Mr O'Donnell is taken to the endoscopy lab where his bleeding is controlled using laser photocoagulation. On his return to the ward, he receives two units of packed RBCs and intravenous fluids to restore blood volume. A 5-day course of high-dose oral omeprazole (40 mg bd) is ordered to prevent rebleeding and Mr O'Donnell is allowed to begin a clear fluid diet 24 hours after his endoscopy. Tissue biopsy obtained during endoscopy confirms the presence of *H. pylori* infection.

DIAGNOSES

- *Deficient fluid volume* related to acutely bleeding duodenal ulcer.
- *Risk of injury* related to acute blood loss.
- *Anxiety* related to threat to wellbeing.
- *Ineffective therapeutic regimen management* related to lack of knowledge regarding PUD and its treatment.

PLANNING

- Ensure buzzer is kept by bedside at all times.
- Discuss situation and provide information about all procedures and treatments. Encourage Mr O'Donnell to alert nursing staff immediately if he experiences any signs of blood loss such as dizziness or vomiting.
- Arrange for a pharmacist review to discuss current and planned treatment measures, the importance of completing the prescribed treatment to reduce the risk of further ulcer development and avoiding use of aspirin or NSAIDs in the future.

Expected outcomes

- Maintains normal blood pressure, pulse and urine output (> 30 mL/h).
- Remains free of injury.
- Seeks information to reduce anxiety.
- Identifies and uses coping strategies to manage anxiety.
- Describes prescribed therapeutic regimen.
- Verbalises ability to manage prescribed regimen.

IMPLEMENTATION

- Encourage Mr O'Donnell to ask for help when getting up or ambulating. Remind to rise slowly from lying to sitting and sitting to standing.
- Reassure about the effectiveness of treatment in reducing the risk of further bleeding.
- Discuss stress reduction techniques and refer for stress reduction counselling or workshops as indicated.

EVALUATION

Mr O'Donnell is discharged 48 hours after admission. He has had no further evidence of bleeding and has resumed a regular diet. His haemoglobin and haematocrit remain low and he has a prescription for ferrous sulfate. He will complete the prescribed high-dose omeprazole regimen at home and then begin treatment with omeprazole, amoxicillin and clarithromycin to eradicate the *H. pylori* infection detected during endoscopy. After 2 weeks of this regimen, he will continue taking omeprazole at bedtime for 4 to 8 weeks. He verbalises a good understanding of his treatment and of the importance of completing the entire regimen. Mr O'Donnell expresses concern about his ability to 'keep his cool on the inside' when under stress. Ms Clark, his Registered Nurse, gives him the names of several resources to help with stress management in case he wants help.

CRITICAL THINKING IN THE NURSING PROCESS

1. How does *H. pylori* infection contribute to the development of peptic ulcers?
2. Describe the physiological responses to fear and anxiety. Why is it important to alleviate fear and its physical consequences in people with PUD?
3. What suggestions can you make to help Mr O'Donnell manage his complex treatment regimen during the next 3 months?
4. Develop a teaching plan that includes stress reduction techniques Mr O'Donnell can use while carrying out his duties as a police officer.

REFLECTION ON THE NURSING PROCESS

1. Outline what you have learned from this case study that you will apply to your future practice.
2. Reflect on the lifestyle stressors involved in Mr O'Donnell's life. What strategies could he use to reduce stress while carrying out his duties as a police officer?

Imbalanced nutrition (less than body requirements) related to PUD

In an attempt to avoid discomfort, the person with PUD may gradually reduce food intake, sometimes jeopardising nutritional status. Anorexia and early satiety are additional problems associated with PUD.

- Assess current diet, including pattern of food intake, eating schedule and foods that precipitate pain or are being avoided in anticipation of pain. *The person may not realise the extent of self-imposed dietary limitations, especially if symptoms have persisted for an extended time. Assessment increases awareness and also helps to identify the adequacy of nutrient intake.*
- Refer to a dietitian for meal planning to minimise PUD symptoms and meet nutritional needs. Consider normal eating patterns and preferences in meal planning. *Although*

no specific diet is recommended for PUD, people should avoid foods that increase pain. Six small meals per day often help increase food tolerance and decrease postprandial discomfort.

- Monitor for complaints of anorexia, fullness, nausea and vomiting. *Adjust dietary intake or medication schedule as indicated. PUD and resultant scarring can lead to impaired gastric emptying, necessitating a treatment change.*

CONSIDERATION FOR PRACTICE

Advise the person to report increasing or persistent symptoms of anorexia, nausea and vomiting, or fullness to the healthcare provider.

- Monitor laboratory values for indications of anaemia or other nutritional deficits. Monitor for therapeutic and side effects of treatment measures such as oral iron replacement. Instruct the person taking oral iron replacement to avoid using an antacid within 1 to 2 hours of taking the iron preparation. *Anaemia can result from poor nutrient absorption or chronic blood loss in people with PUD. Oral iron supplements may cause GI distress, nausea and vomiting; if these side effects are intolerable, notify the physician for a possible change of therapy. Antacids bind with oral iron preparations, blocking absorption.*

Deficient fluid volume related to haemorrhage

Erosion of a blood vessel with resultant haemorrhage is a significant risk for the person with PUD. Acute bleeding can lead to hypovolaemia and fluid volume deficit, which can lead to a decrease in cardiac output and impaired tissue perfusion.

CONSIDERATION FOR PRACTICE

Monitor and record blood pressure and pulse every 15 to 30 minutes until stable. Monitor central venous pressure or pulmonary artery pressure as indicated. Insert an indwelling catheter and monitor urinary output hourly. Weigh daily. Continuous monitoring of cardiac output parameters is essential in people with an acute haemorrhage to identify possible shock and intervene at an early stage.

- Monitor stools and gastric drainage for overt and occult blood. Assess gastric drainage (vomitus or from a nasogastric tube) to estimate the amount and rapidity of haemorrhage. *Drainage is bright red with possible clots in acute haemorrhage; dark red or the colour of coffee grounds when blood has been in the stomach for a period of time. Haematochezia (stool containing red blood and clots) is present in acute haemorrhage; melaena (black, tarry stool) is an indicator of less acute bleeding. When small vessels are disrupted, bleeding may be slow and not overtly evident. With chronic or slow gastrointestinal bleeding, the risk of a fluid volume deficit is minimal; anaemia and activity intolerance are more likely.*
- Maintain intravenous therapy with fluid volume and electrolyte replacement solutions; administer whole blood or packed cells as ordered. *Both fluids and electrolytes are lost through vomiting, nasogastric drainage and diarrhoea in an episode of acute bleeding. To prevent shock, it is essential to maintain a blood volume and cardiac output sufficient to perfuse body tissues. Whole blood and packed cells replace both blood volume and red blood cells, providing additional oxygen-carrying capacity to meet cell needs.*
- Unless contraindicated insert a nasogastric tube and maintain its position and patency. Initially, measure and record gastric output every hour, then every 4 to 8 hours. *Nasogastric suction removes blood from the gastrointestinal tract, preventing vomiting and possible aspiration. Gastric output is replaced millilitre for millilitre with a balanced electrolyte solution to maintain homeostasis.*
- Monitor haemoglobin and haematocrit, serum electrolytes, BUN and creatinine values. Report abnormal findings. *Haemoglobin and haematocrit are lower than normal with acute or chronic GI bleeding. In acute haemorrhage, initial results may be within normal range because both cells and plasma are lost. Loss of fluids and electrolytes with gastric drainage and diarrhoea will alter normal levels. Digestion and absorption of blood in the GI tract may result in elevated BUN and creatinine levels.*
- Assess abdomen, including bowel sounds, distension, girth and tenderness every 4 hours and record findings. *Borborygmi or hyperactive bowel sounds with abdominal tenderness are common with acute GI bleeding. Increased distension, increasing abdominal girth, absent bowel sounds or extreme tenderness with a rigid, board-like abdomen may indicate perforation.*
- Maintain bed rest with the head of the bed elevated. Ensure safety. *Loss of blood volume may cause orthostatic hypotension with resultant syncope or dizziness upon standing.*

Community-based care

Peptic ulcer disease is managed in home and community-based settings; only its complications typically require treatment in an acute care setting. Provide the following information when preparing the person for home care:

- prescribed medication regimen, including desired and potential adverse effects
- importance of continuing therapy even when symptoms are relieved
- relationship between peptic ulcers and factors such as NSAID use and smoking. If indicated, refer to a smoking cessation clinic or program
- importance of avoiding aspirin and other NSAIDs; stress the necessity of reading the labels of over-the-counter medications for possible aspirin content
- manifestations of complications that should be reported to the local doctor, including increased abdominal pain or distension, vomiting, black or tarry stools, light headedness or fainting

- stress and lifestyle management techniques that may help prevent exacerbation. Refer to resources for stress management, such as classes, counselling and formal or informal groups.

THE PERSON WITH CANCER OF THE STOMACH

Worldwide, cancer of the stomach is the second most common cancer after skin cancer; but it is less common in Australia.

FAST FACTS

- The incidence of gastric cancer increases with age, with the most common ages of presentation being between 50 and 70 years.
- Men are affected twice as often as women.
- The incidence of gastric cancer is highest in the Republic of Korea followed by Japan, China and Eastern Europe (Ferlay et al., 2014).
- Five-year survival is poor, at approximately 26% (Cancer Australia, 2015).

Risk factors

H. pylori infection is a major risk factor for cancer of the distal portion of the stomach; from 35% to 89% of cases can be attributed to this infection. Other risk factors are a genetic predisposition, chronic gastritis, pernicious anaemia, gastric polyps and carcinogenic factors in the diet (such as smoked foods and nitrates). Achlorhydria, a lack of hydrochloric acid in the stomach, is a known risk factor. The risk of gastric cancer also is increased in people who have had a partial gastric resection. Socioeconomic factors are also linked with gastric cancer, including occupations that involve exposure to certain chemicals such as dust, asbestos, solvents and pesticides; smoking; and a diet poor in fruit and vegetables and lacking antioxidant mechanisms (Santibanez et al., 2012).

Pathophysiology

Adenocarcinoma, which involves the mucus-producing cells of the stomach, is the most common form of gastric cancer. These carcinomas may arise anywhere on the mucosal surface of the stomach but are most frequently found in the distal portion. Fifty to sixty per cent of gastric cancers occur in the antrum or pyloric region (Porth & Matfin, 2009). Gastric cancer begins as a localised lesion (in situ), then progresses to involve the mucosa or submucosa (early gastric carcinoma). Lesions may spread by direct extension to tissues surrounding the stomach—the liver, in particular. The lesion may ulcerate or appear as a polypoid (polyp-like) mass (see Figure 22.9). Lymph node involvement and metastasis occur early due to the rich blood and lymphatic supply to the stomach. Metastatic lesions are often found in the liver, lungs, ovaries and peritoneum.

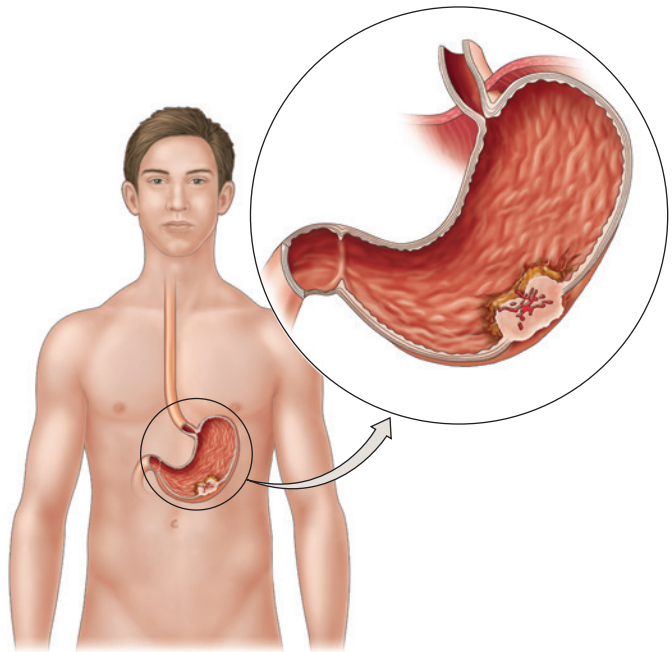


FIGURE 22.9 ■ Gastric cancer affecting the antrum of the stomach

Manifestations

Few symptoms are associated with gastric cancer. Unfortunately, the disease is often quite advanced and metastases are usually present at the time of diagnosis. Early symptoms are vague, including feelings of early satiety, anorexia, indigestion and possibly vomiting. The person may experience ulcer-like pain unrelieved by antacids, typically occurring after meals. As the disease progresses, weight loss occurs and the person may be **cachectic** (in very poor health and malnourished) at the time of diagnosis. An abdominal mass may be palpable and occult blood may be present in the stool, indicating gastrointestinal bleeding.

INTERPROFESSIONAL CARE

Diagnosis

Anaemia detected by a full blood count is often the first indication of gastric cancer. An upper GI x-ray with barium swallow is useful to identify lesions and ultrasound or CT scan may identify a mass. Upper endoscopy with visualisation and biopsy of the lesion provides the definitive diagnosis.

Surgery

When gastric cancer is identified prior to the development of metastasis, surgical removal of part or all of the stomach and regional lymph nodes is the treatment of choice. **Partial gastrectomy** involves removal of a portion of the stomach, usually the distal half to two-thirds. In partial gastrectomy, the surgeon constructs an anastomosis from the remainder of the stomach directly to the duodenum or to the proximal jejunum.

The **gastroduodenostomy**, or **Billroth I**, and the **gastrojejunostomy**, or **Billroth II**, are commonly used partial gastrectomy procedures (see Figures 22.10A and B).

A **total gastrectomy**, removal of the entire stomach, may be done for diffuse cancer that is spread throughout the gastric mucosa but limited to the stomach. In a total gastrectomy, the surgeon constructs an anastomosis from the oesophagus to the duodenum or jejunum. Total gastrectomy with **oesophagojejunostomy** is illustrated in Figure 22.10C.

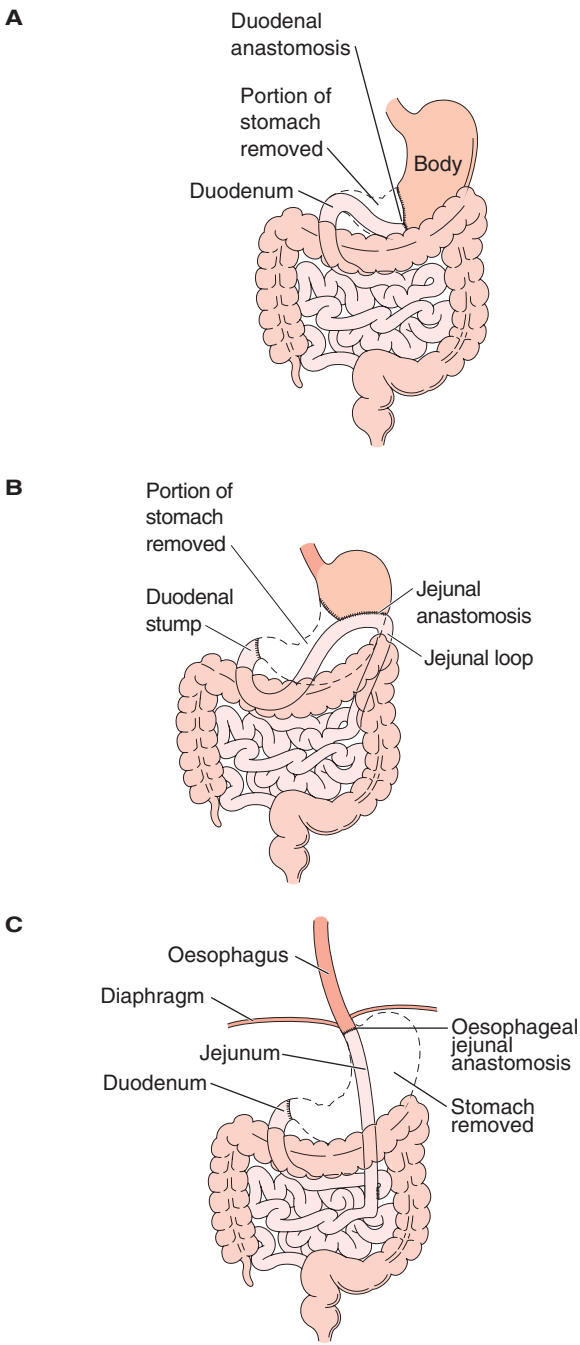

FIGURE 22.10 ■ Partial and total gastrectomy procedures. *A*, Partial gastrectomy with anastomosis to the duodenum. *B*, Partial gastrectomy with anastomosis to the jejunum. *C*, Total gastrectomy with anastomosis of the oesophagus to the jejunum

Nursing care of the person who has undergone gastric surgery is outlined in the following box.

Complications

Several long-term complications may develop following gastrectomy procedures. **Dumping syndrome** is the most common problem. It may follow a partial gastrectomy with duodenal or jejunal anastomosis. When the pylorus has been resected or bypassed, a hypertonic, undigested food bolus may rapidly enter the duodenum or jejunum. Water is pulled into the lumen of the intestine by the hyperosmolar character of the chyme, resulting in decreased blood volume and intestinal dilation. Peristalsis is stimulated and intestinal motility is increased.

Early symptoms of dumping syndrome occur within 5 to 30 minutes after eating. These symptoms result from intestinal dilation, peristaltic stimulation and hypovolaemia caused by undigested food in the proximal small intestine. Manifestations include nausea with possible vomiting, epigastric pain with cramping and borborygmi (loud, hyperactive bowel sounds), and diarrhoea. Systemic symptoms from the hypovolaemia and reflex sympathetic stimulation include tachycardia, orthostatic hypotension, dizziness, flushing and diaphoresis.

The entry of hyperosmolar chyme into the jejunum also causes a rapid rise in the blood glucose. This stimulates the release of an excessive amount of insulin, leading to hypoglycaemic symptoms 2 to 3 hours after the meal. The pathogenesis and clinical manifestations of dumping syndrome are represented in Figure 22.11. Dumping syndrome is typically self-limiting, lasting 6 to 12 months after surgery; however, a small percentage of people continue to experience long-term symptoms.

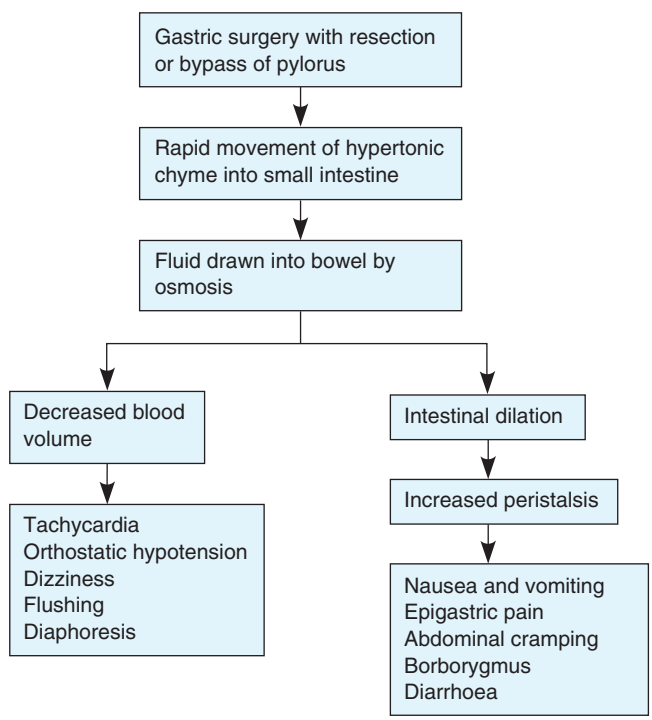

FIGURE 22.11 ■ The pathogenesis and manifestations of dumping syndrome

NURSING CARE OF THE PERSON having gastric surgery

PREOPERATIVE NURSING CARE

- See Chapter 3 for routine preoperative care and teaching.
- Insert a nasogastric tube if ordered preoperatively. *Although it is often inserted in the surgical suite just prior to surgery, the nasogastric tube may be placed preoperatively to remove secretions and empty stomach contents.*

POSTOPERATIVE NURSING CARE

- Provide routine care for the surgical person as outlined in Chapter 3.
- Assess position and patency of nasogastric tube, connecting it to low suction. Gently irrigate with sterile normal saline if tube becomes clogged. The nasogastric tube will be placed in surgery to avoid disruption of the gastric suture lines and should be well secured. If repositioning or tube replacement is needed, notify the surgeon. *Patency must be maintained to keep the stomach decompressed, reducing pressure on sutures.*
- Assess colour, amount and odour of gastric drainage, noting any changes in these parameters or the presence of clots or bright bleeding. Initial drainage is bright red. It becomes dark, then clear or greenish-yellow over the first 2 to 3 days. *A change in the colour, amount or odour may indicate a complication such as haemorrhage, intestinal obstruction or infection.*
- Maintain intravenous fluids while nasogastric suction is in place. *The person on nasogastric suction is not only unable to take oral food and fluids but also is losing electrolyte-rich fluid through the nasogastric tube. If replacement fluid and electrolytes are not maintained, the person is at risk of dehydration, imbalances of electrolytes and metabolic alkalosis.*
- Provide anti-ulcer and antibiotic therapy as ordered. *These medications may be ordered for the postoperative person, depending on the procedure performed. Antibiotic therapy is a common preventive measure for infection that may result from contamination of the abdominal cavity with gastric contents.*
- Monitor bowel sounds and abdominal distension. *Bowel sounds indicate resumption of peristalsis. Increasing distension may indicate third spacing, obstruction or infection.*
- Resume oral food and fluids as ordered. Initial feedings are clear fluids, progressing to free fluids and then frequent small feedings of regular foods. Monitor bowel sounds and for abdominal distension frequently during this period. *Oral feedings are reintroduced slowly to minimise trauma to the suture lines by possible gastric distension.*
- Encourage ambulation. *Ambulation stimulates peristalsis.*

HEALTH EDUCATION FOR THE PERSON AND FAMILY

- Begin discharge planning and teaching. Consult with a dietitian for diet instructions and menu planning; reinforce teaching. Teach the person about potential postoperative complications, such as abdominal abscess, dumping syndrome, postprandial hypoglycaemia or pernicious anaemia. Also, teach the person to recognise signs and symptoms and to take preventive measures. *The person's gastric capacity is reduced after partial gastrectomy, necessitating a corresponding reduction in meal size. Changes in gastric emptying and reduction in gastric secretions may change the person's tolerance for many foods, requiring slow reintroduction of these foods. Dumping syndrome, postprandial hypoglycaemia and pernicious anaemia are possible long-term complications of partial gastrectomy. For most people, dietary modifications can control both dumping syndrome and postprandial hypoglycaemia.*

Dumping syndrome is managed primarily by a dietary pattern that delays gastric emptying and allows smaller boluses of undigested food to enter the intestine. Meals should be small and more frequent. Liquids and solids are taken at separate times instead of together during a meal. The amount of proteins and fats in the diet is increased, because they exit the stomach more slowly than carbohydrates. Carbohydrates, especially simple sugars, are reduced. The person is instructed to rest in a recumbent or semirecumbent position for 30 to 60 minutes after meals. Anticholinergics, sedatives and antispasmodics may be prescribed.

Anaemia may be a chronic problem after a major gastric resection. Iron is absorbed primarily in the duodenum and proximal jejunum; rapid gastric emptying or a gastrojejunostomy may interfere with adequate absorption.

The cells of the stomach produce intrinsic factor, required for the absorption of vitamin B_{12}. Vitamin B_{12} deficiency leads to pernicious anaemia. Because of hepatic stores of vitamin B_{12}, symptoms of anaemia may not be seen for 1 to 2 years after surgery. Vitamin B_{12} levels are routinely monitored following extensive gastric resections.

Other nutritional problems seen following surgery include folic acid deficiency and decreased absorption of calcium and vitamin D. Poor absorption of nutrients, combined with the inability to eat large meals, puts the person at risk of weight loss in addition to the more specific nutrient deficiencies. Nearly 50% of people who have gastric surgery experience significant weight loss, primarily because of insufficient kilojoule intake. Factors contributing to insufficient intake of kilojoules include early satiety (feeling of fullness), decreased stomach size and altered emptying patterns.

Other therapies

Radiation or chemotherapy may be used to eliminate any lymphatic or metastatic spread. For the person with more advanced disease, treatment is palliative and may include surgery and chemotherapy. These people may require a gastrostomy or jejunostomy feeding tube (see Figure 22.12). See the following box for nursing care of the person with a gastrostomy or jejunostomy tube.

Because gastric cancer is generally advanced by the time of diagnosis, the prognosis is poor. The 5-year survival rate of all people treated for gastric carcinoma is 20%.

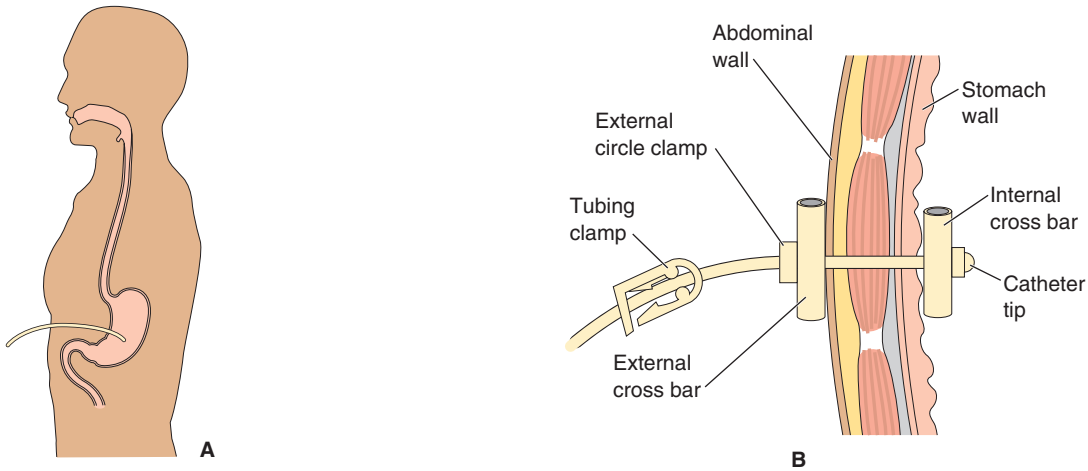

FIGURE 22.12 ■ Gastrostomy. *A*, Gastrostomy tube placement. *B*, The tube is fixed against both the abdominal and the stomach walls by cross bars

NURSING CARE OF THE PERSON with a gastrostomy or jejunostomy tube

People who have had extensive gastric surgery or who require long-term enteral feedings to maintain nutrition may have a gastrostomy or jejunostomy tube inserted.

PROCEDURE

Gastrostomy tubes are surgically placed in the stomach, with the stoma in the epigastric region of the abdomen (see Figure 22.12). Jejunostomy tubes are placed in the proximal jejunum. Immediately following the procedure, the tube may be connected to low suction or plugged. If the person has been receiving tube feedings, these may be reinitiated shortly after tube placement.

NURSING CARE

- Assess tube placement by aspirating stomach contents and checking pH of aspirate to determine gastric or intestinal placement. A pH of 5 or less indicates gastric placement; the pH is generally 7 or higher with intestinal placement. *Recent studies show auscultation to be ineffective in determining feeding tube placement. Measuring the pH of aspirate from the tube is more reliable as a means of determining tube placement.*
- Inspect the skin surrounding the insertion site for healing, redness, swelling and the presence of any drainage. If drainage is present, note the colour, amount, consistency and odour. *Changes in the insertion site, drainage or lack of healing may indicate an infection.*
- Assess the abdomen for distension, bowel sounds and tenderness *to evaluate functioning of the gastrointestinal tract.*
- Until the stoma is well healed, use sterile technique for dressing changes and site care. Clean technique is appropriate for use once healing is complete. *Sterile technique reduces the risk of wound contamination by pathogens that can lead to infection. Once healing has occurred, clean technique is acceptable because the gastrointestinal tract is not a sterile body cavity.*
- Wearing clean gloves, remove old dressing. Cleanse the site with saline or tap water and rinse as appropriate. A well-healed stoma may be cleansed in the shower with the tube clamped or plugged. Pat dry with 4 × 4 gauze pads and allow to air dry. Apply Stomahesive, karaya or other protective agents around tube as needed to protect the skin. *Gastric acid and other wound drainage is irritating to the skin. Meticulous care is important to maintain the integrity of the skin surrounding the stoma.*
- Re-dress the wound using a stoma dressing or folded 4 × 4 gauze pads. Do not cut gauze pads, because threads may enter the wound, causing irritation and increasing the risk of inflammation.
- Irrigate the tube with 30 to 50 mL of water and clean the tube inside and out as indicated or ordered. Soft gastric tubes may require cleaning of the inner lumen to maintain patency. *Tube feeding formulas may coat the inside of the gastrostomy tube and eventually cause it to become occluded. Regular irrigation with water as indicated maintains tube patency.*
- Provide mouth care or remind the person to do so. *When feedings are not being taken orally, the usual stimulus to do mouth care is lost. In addition, salivary fluids may not be as abundant and oral mucous membranes may become dry and cracked.*

HEALTH EDUCATION FOR THE PERSON AND FAMILY

- If indicated, teach the person and family how to care for the tube and feedings. *Refer to a home health agency or community nurse for support and reinforcement of learning. Gastrostomy tubes are often in place long term. When the person and family are able to assume care, independence and self-image are enhanced.*

Nursing care

Health promotion

Although the exact causes of gastric cancer are unknown, contributing factors such as *H. pylori* infection and consumption of foods preserved with nitrates have been identified. To reduce their risk of developing gastric cancer, encourage people with known *H. pylori* infection to complete the prescribed course of treatment and verify that it has eradicated the infection. With all people, discuss the relationship between gastric cancer and consumption of foods preserved with nitrates (such as bacon and other processed meats) and encourage limited consumption of these products.

Assessment

Assessment data related to gastric cancer include the following:

- *Health history:* manifestations such as anorexia, early satiety, indigestion or vomiting; epigastric pain after meals; recent unintentional weight loss.
- *Physical assessment:* general appearance, weight for height; abdominal distension or a palpable upper abdominal mass; occult blood in stool or vomitus.

Nursing diagnoses and interventions

Priorities of nursing care for the person with gastric cancer focus on the effects of the disease and its treatment on nutritional status and on the effects of a potentially fatal disease on the person and their family. See the accompanying nursing care plan for a person with gastric cancer.

Risk of imbalanced nutrition (less than body requirements) manifested by unintentional weight loss

The person with gastric cancer may be malnourished because of anorexia, early satiety and increased metabolic needs related to the tumour. Extensive gastric resection also makes it difficult to consume an adequate diet. Malnourishment, in turn, impairs healing and the person's ability to tolerate cancer treatment.

- Consult with dietitian for a complete nutrition assessment and diet planning. *The person is at risk of protein energy malnutrition, which impairs the ability to heal and recover from extensive surgery.*
- Weigh daily. Monitor laboratory values such as haemoglobin, haematocrit and serum albumin levels. *Daily weights are a valuable measurement of both fluid and nutritional status. Laboratory values provide further evidence of nutritional status.*
- Provide preferred foods; have family prepare meals when possible. Provide supplemental feedings between meals. *Small, frequent feedings and preferred foods encourage intake of nutrients.*

CONSIDERATION FOR PRACTICE

Assess ability to consume adequate nutrients. Nausea and feelings of early satiety may impair nutrient consumption, indicating a need to institute enteral or parenteral feedings.

- Arrange for visitors to be present during meals. Eating is a social function as well as a physiological one. *Companionship often improves food intake.*
- Administer pain and anti-emetic medications as needed before meals. *Pain and nausea suppress the appetite; relief promotes food intake.*

Anticipatory grieving

- Encourage family members to spend as much time as possible with the person. The family may feel helpless and ineffectual. *Supporting family members' presence can encourage this vital interaction.*
- Do not negate denial if present. *Denial is a coping mechanism that protects the person from hopelessness.*
- Allow the person to talk openly if desired about their condition and the prognosis. *Acceptance of the person's fears helps reduce anxiety and promote coping behaviours.*
- Actively listen to the person's and family's expressions of grieving. Avoid interrupting or offering meaningless words of consolation. *Being present and listening actively are often the most effective interventions for the grieving person.*

Community-based care

Although the person with gastric cancer may be hospitalised for surgery, most care is provided in the home and community-based settings such as hospice care. When preparing the person and family for home care, discuss the following topics:

- care of incision and feeding tube (if present) or central venous line
- maintaining nutrition and preventing complications of surgery such as dumping syndrome
- pain management
- provide referrals to home care agencies, hospice and cancer support groups as appropriate
- provide information about services available through the local branch of Cancer Council Australia.

NURSING CARE PLAN A person with gastric cancer

George Harvey is a 61-year-old lawyer who lives with his wife, Harriet. For the last 3 months, Mr Harvey has had increasing anorexia and difficulty eating. He has lost 4.5 kg. His doctor has diagnosed gastric cancer and Mr Harvey is admitted for a partial gastrectomy and gastrojejunostomy. The oncologist has recommended postoperative chemotherapy and radiation. Mr Harvey reports that the doctor told him 'that will give me the best chance for a cure'.

ASSESSMENT

On admission before surgery, Mr Harvey tells his nurse, Lauren Walsh, that he has eaten very little in the past few weeks. He asks, 'What will happen to my wife if something happens to me? I'm afraid this cancer will get me.' Mr Harvey weighs 67 kg and is 183 cm tall. He is pale and thin; his vital signs are BP 148/86, P 92, R 18 and T 36.5°C PO. A firm mass is palpable in the left epigastric region. The rest of his physical assessment data are within normal limits. Mr Harvey's haemoglobin is 12.8 g/dL, haematocrit is 39% and serum albumin level is 3.2 g/dL, indicating that he is mildly malnourished. All other preoperative laboratory and diagnostic studies are within normal limits.

DIAGNOSES

- *Risk of imbalanced nutrition (less than body requirements)* related to anorexia and difficulty eating.
- *Acute pain* related to surgical incision and manipulation of abdominal organs.
- *Risk of ineffective airway clearance related to upper abdominal surgery.*
- *Anticipatory grieving* related to recent diagnosis of cancer.

PLANNING

- Arrange for dietary education, including strategies to prevent dumping syndrome, prior to surgery.
- Encourage Mrs Harvey to visit at mealtimes to assist with and promote oral intake.
- Discuss the grief process and encourage verbalisation of feelings about diagnosis and perceived losses.
- Establish a schedule to cough, deep breathe and use breathing incentive every 2 to 4 hours and as needed. Demonstrate how to splint abdomen during coughing.
- Ensure buzzer is kept within reach at all times and encourage Mr Harvey to alert nursing staff promptly when he is experiencing pain.

Expected outcomes

- Maintain present weight during hospitalisation.
- Resume a high-kilojoule, high-protein diet by the time of discharge.
- Verbalise effective pain management, maintaining a reported pain level of 3 or less on a scale of 1 to 10.
- Maintain a patent airway and clear breath sounds.
- Verbalise feelings regarding diagnosis and participate in decision making.

IMPLEMENTATION

- Weigh daily.
- Maintain nasogastric tube placement, patency and suction as ordered.
- Maintain intravenous fluids and total parenteral nutrition as ordered until oral food intake is resumed.
- Maintain patient-controlled analgesia until able to take oral analgesics.
- Assess respiratory status, including rate, depth and breath sounds, every hour initially, then every 4 hours.
- Encourage participation in decision making.

EVALUATION

Mr Harvey's weight remained stable through his hospitalisation. On discharge he is taking a high-protein, high-kilojoule diet in six small feedings per day. He and his wife have reviewed his diet with the dietitian and are planning on using some dietary supplements at home to meet protein needs. He verbalises an understanding of measures to prevent dumping syndrome, including separating his intake of solid foods and liquids. Mr Harvey is using oral analgesics in the morning and at bedtime to control his pain. He and his wife have begun to discuss the meaning of his diagnosis. Mrs Harvey tells the discharge nurse, 'We are going to go to a support group called "Coping with cancer" when George is stronger.'

CRITICAL THINKING IN THE NURSING PROCESS

1. What is the rationale for maintaining nasogastric suction after gastrojejunostomy?
2. Develop a preoperative teaching plan for a person undergoing a partial gastrectomy.
3. Design interventions to ensure adequate nutrition for people with advanced gastric cancer.

REFLECTION ON THE NURSING PROCESS

1. Outline what you have learned from this case study that you will apply to your future practice.
2. Mr Harvey calls you just before the initial dose of chemotherapy and says, 'Everyone tells me that chemotherapy will cause vomiting and I don't think I can take being sick again.' Reflect on how you would respond.

CHAPTER HIGHLIGHTS

- Nausea and vomiting, common GI symptoms, may be indicative of disorders affecting many organ systems, including the GI tract, inner ear, CNS or heart. Complications such as dehydration, electrolyte imbalance and aspiration of gastric contents are primary concerns in treating nausea and vomiting.
- Stomatitis and oral mucositis are common disorders of the mouth, potentially having a significant effect on comfort and nutrition.
- Tobacco and alcohol use contribute to a number of upper GI disorders, including GORD, oral and oesophageal cancers, and peptic ulcer disease. Encourage all people to stop smoking or using smokeless tobacco and to reduce alcohol to moderate amounts, if at all, to reduce their risk of developing these disorders.
- Gastro-oesophageal reflux disease (GORD) is common. While it often is considered to be a benign condition, prolonged exposure of the lower oesophagus to gastric juices can lead to oesophagitis, haemorrhage and scarring.
- Both oesophageal and gastric cancer are often diagnosed late in the disease because their symptoms may be vague. Encourage people with complaints of dysphagia, a sensation of gastric fullness or heartburn to seek medical evaluation. Surgical resection of the cancerous portion of the oesophagus or stomach is the treatment of choice when the tumour is diagnosed early.
- Upper gastrointestinal bleeding can lead to significant blood loss and shock. Peptic ulcer disease accounts for the majority of UGI haemorrhage, although erosive gastritis and oesophageal varices also are common causes.
- Acute gastritis, often associated with aspirin or NSAID use, is generally benign and self-limited. Erosive gastritis, a complication of critical conditions such as shock, trauma, a major burn or head injury, can lead to unexpected gastric haemorrhage. Chronic gastritis is an unrelated disorder associated with *H. pylori* infection.
- *H. pylori* infection also is a major risk factor for peptic ulcer disease and gastric cancer. Effectively treating the infection can reduce or eliminate the risk of future exacerbations of PUD.
- An acute change in the nature of abdominal pain in a person with PUD, especially when accompanied by vomiting, guarding of the abdomen or a change in bowel sounds, could indicate an obstruction or perforation and release of gastric contents into the peritoneal cavity.

CONCEPT CHECK

1 The nurse assessing for oral cancer risk factors in a person with a persistent sore on his tongue asks about:
1. consumption of highly spiced food
2. thumb sucking or pacifier use as a child
3. regular use of dental floss
4. tobacco use in any form

2 The nurse teaching a person with gastro-oesophageal reflux disease includes which of the following instructions? (Select all that apply.)
1. This is a benign disease requiring no treatment.
2. Elevate the head of the bed.
3. Stop taking the prescribed proton-pump inhibitor once symptoms are relieved.
4. Peppermint and chocolate lollies can help relieve symptoms.
5. Avoid lying down for several hours after eating.

3 The nurse evaluates his teaching of a person with acute stress gastritis as effective when the person states that she will:
1. avoid using aspirin or NSAIDs for routine pain relief
2. consume only bland foods
3. return for yearly upper endoscopy exams
4. fully cook all meat, poultry and egg products

4 The nurse identifies which of the following nursing diagnoses as highest priority for the person admitted with peptic ulcer disease and possible perforation?
1. *Acute pain*
2. *Ineffective health maintenance*
3. *Nausea*
4. *Impaired gastrointestinal tissue integrity*

5 Following a partial gastrectomy for gastric cancer, the person complains of nausea, abdominal pain and cramping, and diarrhoea after eating. Recognising manifestations of dumping syndrome, the nurse recommends:
1. fasting for a period of 6 to 12 hours before meals
2. decreasing the protein content of meals
3. frequent small meals that contain solid foods or liquids, but not both
4. a diet rich in carbohydrates to maintain blood glucose levels

6 The nurse caring for a person with oesophageal cancer affecting the middle portion of the oesophagus would immediately report which of the following?
1. crackles in the base of the right lung
2. bright bleeding from the mouth
3. weight loss
4. difficulty swallowing solid foods

7 The physician has ordered omeprazole 20 mg twice daily, clarithromycin 500 mg twice daily and amoxicillin 1 g daily for a person with peptic ulcer disease. It is most important for the nurse to instruct the person to:
1. stop the drugs immediately and notify the physician if a rash, hives or itching develop
2. consume yoghurt daily while taking these drugs
3. take the drugs on an empty stomach, 1 hour before breakfast and at least 2 hours after dinner
4. take the drugs with a full glass of water

8 When planning care for a person with stomatitis, the nurse identifies which of the following as a priority intervention?
1. Assist to cleanse mouth with mouthwash following meals.
2. Allow the person to select appealing foods from a menu.
3. Provide viscous lignocaine to relieve mouth pain before meals.
4. Refer the person to a smoking cessation program.

9 The evening following a gastric resection, the nurse notes that there has been no drainage from the nasogastric tube for the past 3 hours. The nurse should:
1 chart the finding
2 reposition the nasogastric tube
3 gently irrigate the tube with normal saline
4 notify the surgeon

10 A person with a history of peptic ulcer disease suddenly begins to complain of severe abdominal pain. The nurse should: (Select all that apply.)
1 administer the prescribed proton-pump inhibitor
2 obtain an order for a narcotic analgesic
3 withhold oral food and fluids
4 place the person in Fowler's position
5 notify the physician

CHAPTER 23

NURSING CARE OF PEOPLE WITH BOWEL DISORDERS

ELSPETH HILLMAN

LEARNING OUTCOMES

- Explain the pathophysiology, manifestations, interprofessional and nursing care of people with disorders of intestinal motility.
- Explain the pathophysiology, complications and interprofessional care of people with acute inflammatory or infectious bowel disorders.
- Compare and contrast the pathophysiology, manifestations and complications of chronic inflammatory bowel disorders.
- Discuss the risk factors, pathophysiology and interprofessional care associated with neoplastic bowel disorders.
- Discuss the pathophysiology, manifestations and nursing care of people suffering from structural and obstructive bowel disorders.
- Describe the pathophysiology, manifestations and nursing care of a person suffering an anorectal disorder.

CLINICAL COMPETENCIES

- Assess the functional status of a person with bowel disorders and monitor, document and report abnormal manifestations.
- Use evidence-based research to prevent aspiration in critically ill individuals with enteral feedings and to make accurate assessments of faecal incontinence in older adults.
- Determine priority nursing diagnoses based on assessed data and select and implement individualised nursing interventions for a person with bowel disorders.
- Administer medications used in the management of bowel disorders knowledgeably and safely.
- Provide skilled care to a person following the formation of an ileostomy or colostomy, or perianal surgery.
- Integrate interprofessional care into care of a person with bowel disorders.
- Provide appropriate teaching to promote nutrition, prevent infectious and helminth infestations, encourage preventive screening for colon cancer and facilitate community-based care for healthcare needs resulting from bowel disorders.
- Revise plan of care when necessary to provide effective interventions promoting, maintaining or restoring functional health status to a person with a bowel disorder.

KEY TERMS

Disorders of intestinal absorption and bowel elimination do not only affect functional elimination status. Other functional health patterns affected include, but are not limited to, health perception–health management, nutritional–metabolic, activity–exercise, self-perception–self-concept and sexuality–reproductive. Bowel function is affected by inflammations, infections, tumours, obstructions or changes in bowel structure.

A person with an intestinal disorder often faces extensive diagnostic testing, surgery and permanent changes in their physical appearance and lifestyle. Nursing care is directed towards meeting the person's physiological needs, providing emotional support and assisting the person's adaption to lifestyle changes.

DISORDERS OF INTESTINAL MOTILITY

Few body functions respond as readily to internal and external influences as defecation. Factors directly affecting the gastrointestinal (GI) tract include food intake and bacterial population which affect the number and consistency of stools. Indirect factors also affect elimination. Consider the effects psychological stress or voluntary postponement of defecation have on elimination.

'Normal' bowel elimination patterns vary widely. For some people, two to three stools per day is their usual pattern, whereas for other people their usual pattern is three stools per week. It is important to evaluate each person's bowel elimination against their normal pattern.

THE PERSON WITH DIARRHOEA

Diarrhoea is an increase in the frequency, volume and fluid content of the stool. In diarrhoea, the water content of faeces is increased, usually due to either malabsorption or water secretion in the bowel. It is a clinical manifestation, rather than the primary disorder.

Diarrhoea may be acute or chronic. Acute diarrhoea (lasting less than a week) is usually due to an infectious agent. Chronic diarrhoea (persisting longer than 3 to 4 weeks) may be caused by inflammatory bowel disorders, malabsorption or endocrine disorders.

Pathophysiology

Approximately 1500 mL of digested material enters the large intestine daily. Normally, most of the water and some solutes are reabsorbed in the bowel, leaving approximately 200 mL of faeces to be eliminated.

Large-volume diarrhoea is characterised by both increased numbers and volume of stools caused by increased water content of the stool. This increased water content results from either osmotic or secretory processes. Water is pulled into the bowel lumen by osmosis when the faeces contain osmotically active molecules. Some stool softeners and laxatives work on this principle. When lactose in milk is not broken down and absorbed, the lactose molecules exert an osmotic pull, causing diarrhoea. The diarrhoea associated with cholera and *Escherichia coli* infection is caused by increased water secretion in the small and large intestines. Unabsorbed dietary fat, some laxatives and drugs cause secretory diarrhoea.

Small-volume diarrhoea, characterised by frequent small stools, is usually caused by inflammation or disease of the colon. Diseases affecting the intestinal mucosa—for example, inflammatory bowel disease—cause exudative diarrhoea. Mucosal inflammation causes plasma, serum proteins, blood and mucus to accumulate in the bowel, increasing faecal bulk and fluidity. An increased propulsion rate within the bowel decreases the amount of water normally absorbed from chyme, leading to diarrhoea. For this reason, laxatives increasing bowel motility and bowel resection or bypass can lead to diarrhoea.

Antibiotic-associated diarrhoea occurs as a result of disruption of normal intestinal flora by antibiotic therapy. Loss of normal flora affects digestion of food leading to diarrhoea, or allows an overgrowth of pathogens (e.g. *Clostridium difficile* (*C. difficile*)). The accompanying 'Translation to practice' box provides information about other causes of diarrhoea in hospitalised people.

Manifestations

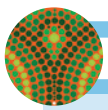
Clinical manifestations of diarrhoea depend on the cause, duration, severity and area of bowel affected, as well as a person's age and general health. Diarrhoea presents as several large, watery stools daily or very frequent small stools containing blood, mucus or exudates.

Complications

Diarrhoea can have devastating effects. Water and electrolytes are lost in diarrhoeal stools, leading to dehydration, particularly in the very young, older adults or debilitated individuals unable to respond to thirst. With severe diarrhoea, vascular collapse and hypovolaemic shock may occur. Potassium and magnesium are lost, potentially leading to hypokalaemia and hypomagnesaemia. The loss of bicarbonate in the stool can lead to metabolic acidosis. See Chapter 9 for further discussion of the effects of fluid and electrolyte imbalances.

INTERPROFESSIONAL CARE

Management of diarrhoea focuses on identifying and treating the underlying cause. Additionally, the diarrhoea itself needs to be treated, comfort promoted and complications prevented. A health history (including the onset and associated circumstances of the diarrhoea) and physical examination often provide enough information to identify its cause. However, precise diagnosis is only achieved with laboratory investigations.



TRANSLATIONTO PRACTICE Evidence-based practice: diarrhoea

People who have been hospitalised often have a number of risk factors for diarrhoea. *Clostridium difficile* is now recognised as the cause of a significant portion of treatment-related diarrhoea; it does not, however, account for all cases. Previous studies have demonstrated a relationship between diarrhoea and enteral tube feedings, medications containing sorbitol, lactose intolerance and other factors. A review by Chang and Huang (2013) looked at the risk of developing diarrhoea during enteral feeding. Findings illustrate the contributory effects of medications, severe illness, infection and and enteral tube feeding.

IMPLICATIONS FOR NURSING

People who are severely ill often require enteral tube feedings for nutritional support. Healing and immune function require adequate nutrition; other studies point to the beneficial effects of enteral nutrition for the majority of people. Discontinuing enteral feedings due to diarrhoea is not a desirable option. In some cases, changing the enteral feeding formula or adding probiotic (cultures of beneficial yeasts or bacteria) supplements may help normalise bowel function. Other options include antidiarrhoeal medications or soluble fibre supplements.

CRITICAL THINKING IN PERSON-CENTRED CARE

1. Administering medications containing sorbitol, a sugar that is not absorbed by the gut, is associated with an increased risk of developing diarrhoea among people who have been hospitalised. How does sorbitol increase the risk of diarrhoea? What would you do if you realised that a seriously ill person you are caring for was receiving enteral tube feeding and medications containing sorbitol?
2. The position of the feeding tube tip in the gut is also identified as a risk factor for diarrhoea associated with enteral tube feedings. Thinking about the functions of the stomach, pyloric valve, duodenum and jejunum, which type of tube (gastric, duodenal or jejunal) might carry the highest risk of diarrhoea? The lowest? What other enteral tube feeding risk factors are considered in tube placement?
3. A person is being discharged home with a gastrostomy tube and directions for enteral feedings. What teaching will you provide to the person and their family regarding tube care, feeding administration and bowel management?

Diagnosis

Diagnostic tests ordered to help identify the cause of diarrhoea may include a stool specimen analysis, culture and sensitivity. A sigmoidoscopy to visualise the bowel mucosa may be conducted. (See Chapter 20 for further information on diagnostic tests.) Tissue biopsy to identify chronic inflammatory processes, infection and other causes of diarrhoea may be obtained. Recently developed and improved diagnostic methods include enzyme immunoassays for faecal antigens and reverse transcriptase-polymerase chain reaction (RT-PCR) to identify some viruses (e.g. norovirus), and ELISA and the fluorescein-labelled antibody test to detect antigens or oocysts of some protozoa (e.g. *Giardia* and *Cryptosporidium*) (Lee & Bishop, 2013). Additionally, serum electrolytes, serum osmolality and arterial blood gases (ABGs) are collected to assess for adverse effects of diarrhoea. Increased serum osmolality indicates water loss and dehydration.

Medications

Antidiarrhoeal medications are used sparingly or not at all until the cause of diarrhoea is identified. In diarrhoea associated with botulism or bacillary dysentery, giving an antidiarrhoeal agent worsens or prolongs the infection by slowing toxin elimination from the bowel. Once the underlying cause for diarrhoea is established, specific medications, if appropriate, are ordered to treat the underlying cause. Antibiotics are used cautiously as these alter the bowel's normal bacterial population and may actually increase diarrhoea. A balanced electrolyte solution may be required to replace fluid and electrolyte losses. Intravenous or oral potassium preparations may also be prescribed.

Opium and some of its derivatives, anticholinergics, absorbents and demulcents are commonly used as antidiarrhoeal preparations. Specific preparations, their method of action and nursing implications for these medications are outlined in the following 'Medication administration' box.

Nutrition

Fluid and electrolyte replacement is of primary importance in managing a person with diarrhoea. If the person is tolerating oral fluids (i.e. the person is not experiencing nausea and vomiting), an oral glucose/balanced electrolyte solution provides the best fluid replacement. Several commercial preparations (e.g. Gastrolyte) are available, as are paediatric solutions which can be used for adults as well as children.

During acute diarrhoea, the person's diet should be modified to rest the bowel. During the first 24 hours, solid food should be withheld. After this time, frequent, small amounts of starchy foods can be added. Milk and milk products are added last, as these contain lactose which frequently aggravates the diarrhoea. Raw fruit and vegetables, fried foods, bran, wholegrain cereals, condiments, spices, coffee and alcoholic beverages are avoided during the recovery period as the bowel has difficulty processing these complex materials.

People with chronic diarrhoea may benefit by eliminating specific foods from their diet. Foods and non-food substances aggravating diarrhoea are outlined in Table 23.1. The diet should be high in kilojoules and nutritional value. Vitamin supplements may be necessary, particularly the fat-soluble vitamins (A, D, E, and K). Occasionally, people with severe chronic diarrhoea require parenteral nutrition (see Chapter 21).

TABLE 23.1 Foods aggravating chronic diarrhoea

FOODS	REASON
Milk, ice-cream, yoghurt, soft cheeses, cottage cheese	Contain lactose; not tolerated by people with lactase deficiency unable to digest lactose.
Apple juice, pear juice, grapes, honey, dates, nuts, figs, fruit-flavoured soft drinks	Contain fructose; when consumed in large quantities, fructose may not be totally absorbed, causing an osmotic pull of fluid into the bowel.
Table sugar	Contains sucrose; not tolerated by people with sucrase deficiency.
Sugarless gums and mints	May contain sorbitol or mannitol, sugars that are not absorbed causing an osmotic draw.
Antacids	Magnesium-containing antacids decrease bowel transit time and contain poorly absorbed salts exerting an osmotic draw.
Coffee, tea, cola drinks, over-the-counter analgesics containing codeine	Contain caffeine, decreasing bowel transit time.

MEDICATION ADMINISTRATION Antidiarrhoeal preparations

ABSORBENTS AND PROTECTANTS

Kaolin and pectin (Kaopectate, Donnagel-MB)
Polycarbophil (FigerNorm, Equalactin)

Absorbent preparations act locally in the intestines to bind substances that can cause diarrhoea. Absorbents are safe and are generally available over the counter, although their efficacy has not been proved.

Nursing responsibilities

- Assess for contraindications to antidiarrhoeal therapy, such as some infections or chronic inflammatory bowel disease, including ulcerative colitis.
- If fever is present, check with doctor before giving the medication.
- Administer these medications at least 1 hour before or 2 hours after other oral medications; these may interfere with the absorption of other medications.
- Observe the person's response to the medication. Constipation is a potential problem.

Health education for the person and family

- Take the recommended dosage at the onset of diarrhoea and after each loose stool.
- Do not take any of these preparations for more than 48 hours. If diarrhoea persists, notify the doctor.
- Do not give antidiarrhoeal medications to debilitated older adults without medical supervision.

ANTISECRETORY

Bismuth subsalicylate (Pepto-Bismol)

Bismuth subsalicylate, available without a prescription, has antisecretory, anti-inflammatory and antibacterial effects. It is widely used to control traveller's diarrhoea. Although it is generally safe at recommended doses, bismuth subsalicylate has potential toxic effects and interacts with medications such as aspirin and oral anticoagulants.

Nursing responsibilities

- Administer as ordered.
- Do not administer within 1 hour of other medications, as it may interfere with their absorption.
- Monitor for increased anticoagulant effect when given with warfarin or aspirin.

Health education for the person and family

- Chew bismuth subsalicylate tablets, rather than swallowing these whole, for maximal effectiveness.
- This medication may cause harmless darkening of your tongue and stools.
- If you are allergic to aspirin, use bismuth subsalicylate with caution. Do not use aspirin while you are taking this medication unless directed to do so by your doctor. Contact your doctor if diarrhoea persists for more than 2 days.

OPIUM AND OPIUM DERIVATIVES

Camphorated tincture of opium (Paregoric)
Tincture of opium (laudanum, opium tincture)
Difenoxin (Motofen)
Diphenoxylate (Lomotil, Lotrol, others)
Loperamide hydrochloride (Imodium)

Opium and its derivatives act on the central nervous system (CNS) decreasing the motility of the ileum and colon, slowing transit time and promoting more water absorption. These medications also decrease the sensation of a full rectum and increase anal sphincter tone.

Difenoxin, diphenoxylate and loperamide hydrochloride are synthetic opioids chemically related to pethidine (Bullock & Manias, 2014). However, they have minimal analgesic, euphoric or abuse-promoting effects and are in more common use today.

Nursing responsibilities

- Assess for contraindications to antidiarrhoeal or narcotic medications prior to giving these drugs.
- Administer paregoric undiluted with water.
- Do not administer difenoxin and diphenoxylate to a person receiving monoamine oxidase inhibitors (MAOIs); hypertensive crises may occur.
- Observe closely for increased effects of other CNS depressants, such as alcohol, narcotic analgesics or barbiturate sedatives.
- Observe for abdominal distension; toxic megacolon may occur if these medications are given to a person with ulcerative colitis.

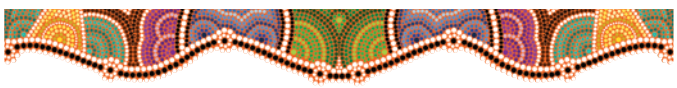
Health education for the person and family

- Take the medication as recommended at the onset of diarrhoea and after each loose stool.
- These medications may be habit forming; use for no more than 48 hours.
- Avoid using alcohol and over-the-counter cold preparations while taking these medications.
- These preparations may cause drowsiness; avoid driving or operating machinery while taking them.

Complementary and alternative therapies

Herbal or homeopathic therapies may be used to help relieve diarrhoea. People with lactose intolerance may use lactase enzymes tablets or drops when consuming milk products. Herbal treatments include a strong tea of black pepper, chamomile, coriander, rosemary, sandalwood or thyme. Ginger tea or capsules are helpful in reducing intestinal inflammation and decreasing the effects of food poisoning.

Probiotics, live microogranisms similar to those normally found in the gut, may be used to prevent or treat antibiotic-associated diarrhoea (Campbell, 2014; Reintam Blaser, Deane & Fruhwald, 2015). Probiotics are available as dietary supplements and food (e.g. yoghurt, yoghurt drinks). The person should consult a qualified medical or homeopathic practitioner when choosing to manage their diarrhoea with complementary and alternative therapies.



Nursing care

Health promotion

Prevention of diarrhoeal diseases essentially involves avoiding infectious agents (Lee & Bishop, 2013). Educating individuals and their families about the importance of handwashing is a primary measure to prevent and reduce the spread of infectious diseases, including those causing diarrhoea. Educating people about safe food handling techniques prevents bacterial contamination. Discuss measures to ensure safe drinking water. For people planning travel to remote areas or outside Australia, discuss the importance of avoiding the consumption of high-risk foods (especially raw foods) and beverages, and purification methods for drinking and cooking water.

Assessment

The nursing assessment helps identify the cause of the person's diarrhoea, as well as early signs of complications. Collect the following assessment data:

- *Health history:* duration and extent of diarrhoea; associated manifestations; dietary intake; recent visits to remote areas or overseas travel or contact with people recently returned from overseas; previous history of diarrhoea; chronic diseases; prescription and non-prescription medications including complementary supplements.
- *Physical examination:* vital signs (including orthostatic blood pressure); peripheral pulses and capillary refill; skin temperature, moisture and turgor; colour and moisture of mucous membranes; abdominal contour and girth; bowel sounds; stool for obvious or occult blood, pus, mucus or steatorrhoea (bulky, foul-smelling stool).

Nursing diagnoses and interventions

Nursing care of people with diarrhoea focuses on identifying the cause, relieving the clinical manifestations and preventing complications and spread of infection to others.

Diarrhoea

Nursing interventions for diarrhoea are provided to assist a person recover their normal elimination pattern without adverse consequences.

- Use standard precautions, including gloves and handwashing. *Standard precautions help prevent the spread of infection to others.*
- Monitor and record the frequency and characteristics of bowel movements *to provide a measure of the effectiveness of treatment.*
- Measure abdominal girth and auscultate bowel sounds every 8 hours as indicated. *Loud, rushing bowel sounds (borborygmi) indicate increased peristalsis and may be heard in a person with acute diarrhoea. Diminished or absent bowel sounds may indicate a complication of treatment, such as constipation or toxic megacolon.*
- Provide ready access to toilet, commode or bedpan. *The person may have little warning of the need to defecate. Easily accessed toileting facilities reduce the risk of soiling or injury.*
- Administer antimuscarinic medications as prescribed *to promote comfort by reducing colicky pain sometimes associated with diarrhoea.*
- Limit food intake if the diarrhoea is acute, reintroducing solid foods slowly, in small amounts, *allowing the bowel to rest and mucosa to heal in acute diarrhoea states.*

Risk of deficient fluid volume

The increased water content of diarrhoeal stool places the person at risk of fluid deficit.

- Record intake and output; weigh daily; assess skin turgor, mucous membranes and urine specific gravity every 8 hours. *These assessments are used to monitor fluid volume status.*

CONSIDERATION FOR PRACTICE

Assess skin turgor over the sternum of older adults. Loss of subcutaneous fat associated with ageing makes assessment of skin turgor on the arms or hands less reliable.

- Monitor vital signs, including orthostatic blood pressures. *A mild fluid volume deficit results in orthostatic hypotension. This is identified by a 10 mmHg or more drop in BP and increase of 10 beats per minute (bpm) in pulse when changing from a lying to a sitting position or from a sitting to a standing position.*

CONSIDERATION FOR PRACTICE

Remember to institute safety precautions when assisting a person with orthostatic hypotension to ambulate. *The decrease in blood pressure with position changes can cause light headedness and syncope.*

- Provide fluid and electrolyte replacement solutions as indicated. Ensure ready access to fluids; assist a debilitated person with fluid intake. Notify the doctor if the person is unable to tolerate oral fluids. *Oral fluids are encouraged as tolerated to prevent dehydration. Intravenous fluids are necessary when oral fluids are not tolerated. An intake of 3000 mL/day or more is often needed to replace fluid losses.*

Risk of impaired skin integrity

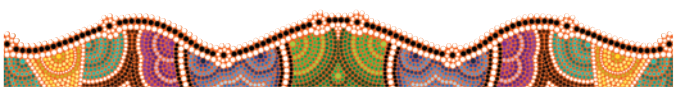
Decreased extracellular fluid volume and the irritating effects of diarrhoeal stool increase the risk of skin breakdown.

- Assist with cleaning the perianal area as needed. Use warm water, a gentle cleanser and soft cloths. *Cleansing removes irritating substances in the stool. Gentle cleansing helps maintain integrity of dehydrated skin.*
- Apply protective ointment to the perianal area. *Moisture-barrier ointments or creams protect the skin from excoriation and help prevent tissue breakdown.*

Community-based care

Acute and chronic diarrhoea generally are managed by the person at home. Teach the individual and their family members about the following topics:

- cause of diarrhoea (as directed by the diagnosis)
- importance of handwashing and hygiene measures
- importance of maintaining adequate fluid intake to replace lost water and electrolytes
- use of a balanced electrolyte solution (e.g. Gastrolyte) or a similar product (purchased) for electrolyte replacement
- recommendations to limit food intake during acute diarrhoea and resume food gradually with small meals of foods with a constipating effect: apple sauce, bananas, water crackers, rice and potatoes
- avoiding foods high in fibre, milk products and caffeine
- ways to maintain nutrition if chronic diarrhoea is a problem: frequent small meals, nutritional supplements, vitamin supplements
- precautions and limitations of antidiarrhoeal preparations
- importance of seeking medical intervention if diarrhoea continues or recurs.



THE PERSON WITH CONSTIPATION

Constipation is defined as the infrequent (less than two bowel movements weekly) or difficult passage of stools. Constipation affects older adults more frequently than younger people. A recent Australian study reported that constipation in community-dwelling older adults had a prevelance between 11% and 55% (Werth, Williams & Pont, 2015). Although faecal transit in the large intestine slows with ageing, the increased incidence of constipation is thought to relate more to impaired general health, increased medication use and decreased physical activity in the older adult than to being part of the ageing process.

Pathophysiology

Constipation may be a primary problem or a manifestation of another disease or condition. Acute constipation, a definite change in a person's bowel elimination pattern, is often caused by an organic process. A change in bowel patterns persisting or becoming more frequent or severe may be due to a tumour or other partial bowel obstruction. However, in chronic constipation functional causes impairing storage, transport and evacuation mechanisms impede the normal passage of stools. Common causes of constipation are listed in Table 23.2.

Psychogenic factors are the most frequent causes of chronic constipation. These factors include postponing defecation when the urge is felt and the perception of satisfaction with defecation. Some people use laxatives and enemas to stimulate a bowel movement when constipation is perceived. Overuse of these leads to intestinal problems, worsening constipation. *Cathartic colon* (impaired colonic motility and changes in bowel structure) mimics ulcerative colitis in that the normal pouchlike or saccular appearance of the colon is lost. *Melanosis coli* is a brownish-black discolouration of the colon mucosa. Both conditions may be caused by long-term laxative use.

Manifestations

Clinical manifestations of constipation include having bowel movements less often than the usual pattern, frequent flatus, abdominal discomfort, anorexia, straining to achieve bowel movement and the passage of hard, dry stools.

Faecal impaction may develop from significant constipation or long-term dependence on laxatives or enemas. Impaction occasionally results after barium administration for radiological exam. The impaction is felt as a rock-hard or putty-like mass of faeces in the rectum. Faecal impaction may

TABLE 23.2 Selected causes of constipation

FACTOR	RELATED CAUSE
Activity	Lack of exercise; bed rest
Dietary	Highly refined, low-fibre foods; inadequate fluid intake
Medications	Antacids containing aluminum or calcium salts; narcotic analgesics; anticholinergics; many antidepressants, tranquillisers and sedatives; antihypertensives, such as ganglionic blockers, calcium channel blockers, beta-adrenergic blockers, diuretics; iron supplements
Large bowel	Diverticular disease, inflammatory disease, tumour, obstruction; changes in rectal or anal structure or function
Psychogenic	Voluntary suppression of urge; perceived need to defecate on schedule; depression
Systemic	Advanced age; pregnancy; neurological conditions (trauma, multiple sclerosis, tumours, cerebrovascular accident, parkinsonism); endocrine and metabolic disorders (hypothyroidism, hypocalcaemia, uraemia, porphyria)
Other	Chronic laxative or enema use

result in abdominal cramping and a full sensation in the rectal area. Additionally, watery mucus or foul-smelling liquid stool may be passed around the impaction, causing the person to report diarrhoea.

INTERPROFESSIONAL CARE

Initial evaluation of constipation is based on the health history and physical examination. The abdomen may appear distended and bowel sounds may be reduced. If faecal impaction is present, digital examination of the rectum reveals a palpable, hard or putty-like faecal mass.

Simple or chronic constipation is treated with education (a daily bowel movement is not necessary for health), modification of diet and increasing fluid intake and exercise routines. If the problem is acute or does not resolve, further diagnostic examination is ordered.

Diagnosis

A barium enema is ordered to identify bowel structure, tumours or diverticula. If the problem is acute, a sigmoidoscopy or colonoscopy may be used for evaluation and biopsy. (See Chapter 20 for nursing implications of these tests.)

Medications

Laxatives—occasionally called aperients or purgative preparations—are used to promote stool evacuation. Laxatives are grouped in categories depending on their mechanism of action. These include osmotic laxatives (non-absorbable inorganic salts, polyethylene glycol, sugars and alcohol), stimulant laxatives, faecal softeners, lubricants and bulk-forming laxatives (Bullock & Manias, 2014). Laxatives are indicated for constipation resulting from poor bowel habits, opioid analgesia, medications with anticholinergic side effects and loss of intestinal muscle tone following surgery or bed rest or due to age. Laxatives are often used to reduce straining, reduce pain associated with anorectal disorders and before surgery or diagnostic procedures.

Stimulant laxatives and enemas interfere with normal bowel reflexes and are not recommended for regular use as these may lead to colon dilation and reduced peristalsis, requiring increased amounts. All laxatives are contraindicated if a person has an intestinal obstruction, undiagnosed abdominal pain, nausea or vomiting, paralytic ileus, suspected appendicitis, undiagnosed rectal bleeding, faecal impaction, rectal fissures, ulcerated haemorrhoids, Crohn's disease, ulcerative colitis or chronic inflammatory bowel disease. When the bowel is obstructed, laxatives may cause serious mechanical damage and perforate the bowel.

If a person is unable to consume enough dietary fibre to prevent constipation, the only appropriate laxatives safe for long-term use are bulking agents, such as psyllium seed (e.g. Metamucil), *Plantago ovata* seeds (ispaghula or psyllium husk—e.g. Fybogel) and sterculia and frangula (e.g. Normacol Plus). These agents act by increasing the bulk of the faeces and drawing water into the bowel, softening it. Some bulking agents (e.g. Fybogel and Normafibre) contain aspartame. Therefore, caution is needed if given to a person with phenylketonuria (Tiziani, 2013). Commonly prescribed laxatives are discussed in the 'Medication administration' box below.

Nutrition

Foods with high fibre content are recommended. Vegetable fibre is largely indigestible and unabsorbable, so it increases stool bulk. Fibre also helps draw water into the faecal mass, softening the stool and making defecation easier. Raw fruits and vegetables are good sources of dietary fibre, as is cereal bran. Use 2 to 3 teaspoons of unprocessed bran with meals (sprinkled on fruit or cereal) or up to ¼ cup daily to supply adequate fibre.

Fluids are also important to maintain bowel motility and soft stools. If not contraindicated a person should drink 6 to 8 glasses (i.e. 250 mL each) of fluid per day. It is important to advise the person to increase fluid intake when dietary fibre is initially increased to decrease flatus and help maintain softer stools.

In older adults, constipation may be due to inadequate food and fluid intake. Carefully evaluate the person's diet history and usual daily fluid intake.

Enemas

Significant or chronic constipation or a faecal impaction may require the administration of an enema. As a general rule, enemas should be used only in acute situations and only on a short-term basis. These may also be ordered to prepare the bowel for diagnostic testing or examination. Enema administration is contraindicated in a person with diarrhoea, cardiac dysrhythmias, following recent myocardical infarction, undiagnosed abdominal pains and following recent surgery to the rectum, bowel or prostate gland (Long, 2015).

The following types of enemas may be prescribed:

- *Isotonic—saline enema* using 500 to 1000 mL of warmed normal saline solution is the least irritating to the bowel. It distends the colon, stimulates peristalsis and softens faeces. The enema solution should be retained for 5 to 10 minutes as tolerated. Evacuation usually occurs within approximately 15 to 20 minutes. Sodium retention is a possible adverse effect of these enemas.
- *Hypotonic—tap-water enemas* use 500 to 1000 mL of water to soften faeces and irritate the bowel mucosa, stimulating peristalsis. The enema solution should be retained for 5 to 10 minutes as tolerated. Evacuation is within approximately 15 to 20 minutes. Adverse effects include fluid and electrolyte imbalance and water intoxication.
- *Soap-suds enemas*—consist of a tap-water solution (500 to 1000 mL) to which soap (3 to 5 mL) is added to distend the colon, stimulate peristalsis and soften faeces. The enema solution should be retained for 5 to 10 minutes as tolerated. Evacuation is usually within 10 to 15 minutes. Adverse effects include irritation and damage to mucosa.
- *Hypertonic—phosphate enemas* (e.g. Fleet) use a hypertonic saline (sodium phosphate) solution (90 to 120 mL) to draw fluid into the bowel and irritate the mucosa, leading to evacuation in approximately 5 to 10 minutes. Adverse effect is possible sodium retention.

MEDICATION ADMINISTRATION Laxatives

BULK-FORMING AGENTS

Bran
Psyllium (Metamucil)
Ispaghula (Fybogel)
Sterculia (Normafibe)

Bulk-forming agents are the only safe laxatives for long-term use. These contain vegetable fibre, which is not digested or absorbed in the gut. This natural fibre creates bulk and draws water into the intestine, softening the stool mass, resulting in increased peristalsis (see Figure 23.1).

Nursing responsibilities

- Mix the agent (e.g. one sachet of Fybogel or 1½ to 3 teaspoons of Metamucil one to three times per day) in a 250 mL glass of cool liquid just prior to administering and followed by an additional glass of water. Sterculia (Normafibe) granules (1 to 2 heaped 5 mL teaspoons of granules one or two times per day) can be placed dry on the tongue and swallowed whole with 250 mL of water.
- Do not administer to a person with possible stool impaction or bowel obstruction, or who is dehydrated or on fluid restrictions—for example, a person with chronic kidney disease.

Health education for the person and family

- Drink at least 6 to 8 full glasses (250 mL) of non-alcoholic fluid per day. Adequate hydration is necessary to produce the medication's laxative effect.
- These agents may be mixed with water, milk or fruit juice. Sterculia (Normafibe) granules can be mixed with jam, honey or ice-cream.
- Take the medication in the morning or with meals. To reduce the risk of impaction, do not take at bedtime.
- Because of the increased risk of impaction, check with the doctor before increasing dietary fibre while you are taking these medications.

FAECAL SOFTENERS

Docusate sodium (Coloxyl)
Paraffin liquid (Agarol)

Faecal softeners reduce stool surface tension and form an emulsion of fat and water, softening the stool. These are used primarily to prevent straining and reduce the discomfort of expelling hard stools after rectal and perianal surgery. These medications have limited use in the management of acute or chronic constipation (Bullock & Manias, 2014).

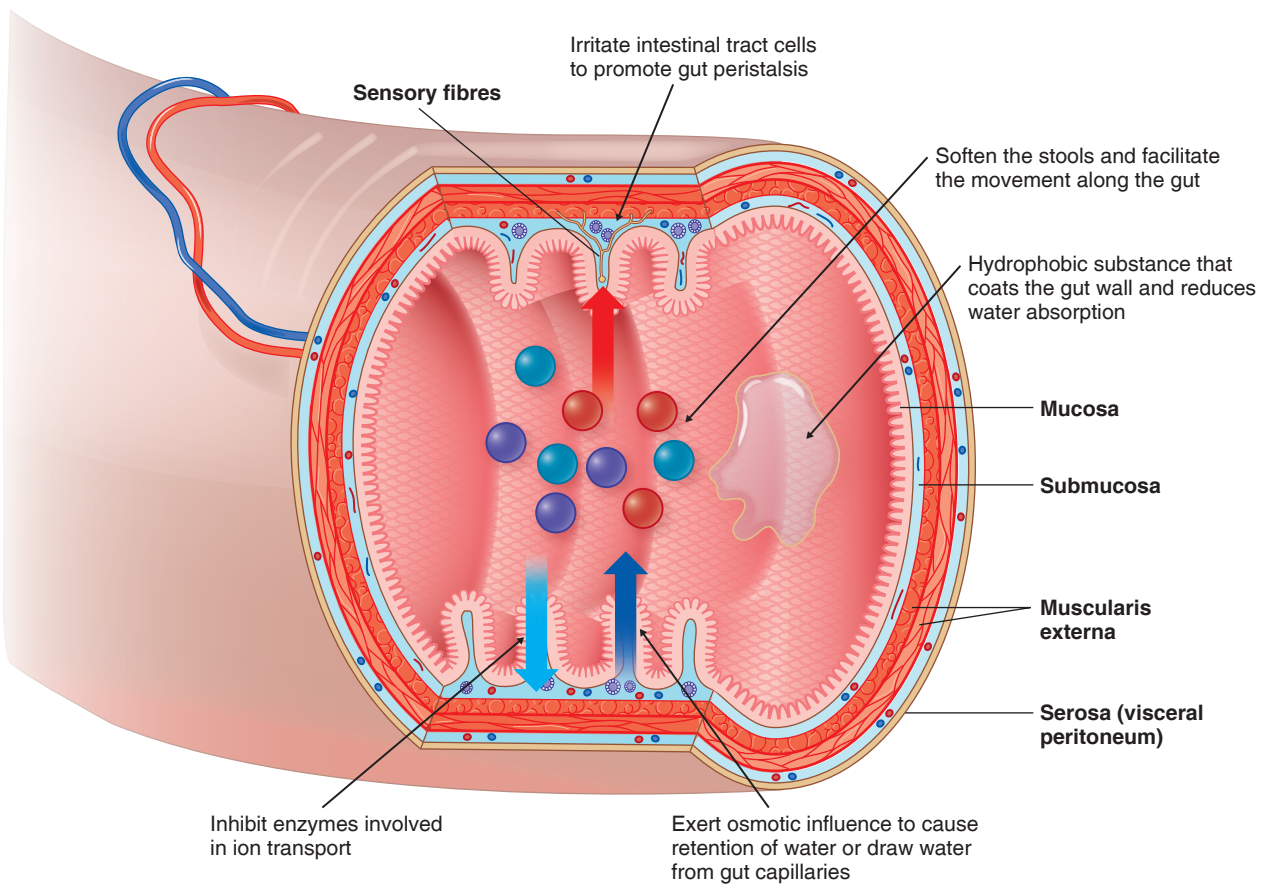


FIGURE 23.1 ■ Mechanisms of laxative action

Source: Fundamentals of Pharmacology (7th ed.) by S. Bullock & E. Manias (2014), p. 715, Figure 57.1. Frenchs Forest, NSW: Pearson Australia.

MEDICATION ADMINISTRATION Laxatives (continued)

Nursing responsibilities

- Administer with ample fluids to promote softening effect.
- Faecal softening agents may alter the absorption of other drugs. Do not administer within 1 to 2 hours of other oral medications.
- Do not attempt to crush or open capsules; a liquid form is available for a person unable to swallow pills or capsules.
- Caution needs to be taken with the administration of docusate sodium (Coloxyl) tablets in a person with hypertension or congestive cardiac failure, due to the sodium content.

Health education for the person and family

- Do not use for more than 1 week unless specifically recommended by the doctor.
- Take the medication in the morning or evening; remember to avoid taking it with other medications.
- Adequate fluid is necessary to obtain the beneficial effect of the medication. Drink 6 to 8 (250 mL) glasses of non-alcoholic fluid per day.

OSMOTIC AND SALINE LAXATIVES/CATHARTICS

Lactulose (Duphalac)
Sorbitol (Sorbilax)
Magnesium salts (Epsom salts)
Sodium phosphate (Fleet phospho-soda buffered saline mixture)
Polyethylene glycol-electrolyte solution (ColonLYTELY)

Laxatives in this group contain poorly absorbed salts or carbohydrates which remain in the bowel, increasing osmotic pressure and drawing water into the intestine. Stool volume increases, consistency decreases and peristalsis is stimulated. Many of these agents also have an irritant effect on the bowel, further stimulating peristalsis. They are used to stimulate rapid or complete bowel evacuation to relieve constipation. Sodium phosphate (Fleet phospho-soda buffered saline mixture) and polyethylene glycol-electrolyte solution (ColonLYTELY) are used to prepare the bowel for diagnostic and surgical procedures. Their use should be limited to acute, short-term use; chronic use may suppress normal bowel reflexes.

Nursing responsibilities

- Assess for possible contraindications to osmotic or saline laxatives, including bowel ulceration or obstruction, dehydration, electrolyte imbalances, heart failure (may be aggravated by the sodium content) or kidney injury.
- Sodium phosphate (Fleet phospho-soda buffered saline mixture) and polyethylene glycol-electrolyte solution (ColonLYTELY) should have no additional flavouring added unless instructed by the doctor. Red, green and orange cordials stain the bowel. Advise the person to slowly drink the solution: the first bowel action usually occurs approximately 1 hour after commencing the preparation. Preparation is complete when the person is passing clear fluid from the bowels.
- Other osmotic laxatives are administered with a full glass of liquid, preferably in the morning to avoid sleep disturbance.
- Monitor fluid and electrolyte status: skin turgor, mucous membranes, intake and output; daily weight and laboratory studies, such as haemoglobin and haematocrit levels, serum osmolality and electrolytes and urine specific gravity.

Health education for the person and family

- Do not use these agents on a routine basis to treat or prevent constipation. Long-term use can produce electrolyte disturbances.
- Chilling the solution increases its palatability.
- Expect some abdominal cramping.
- Use only as directed. Increase fluid intake to at least 6 to 8 (250 mL) glasses of non-alcoholic fluid.
- Notify the doctor if adverse effects occur, including abdominal pain, bloody stool, excessive skin or mucous membrane dryness, rapid weight loss, dizziness or other unusual symptoms.
- These agents work in 3 to 6 hours; take in the morning or early evening to avoid sleep disturbance.

IRRITANT OR STIMULANT LAXATIVES

Bisacodyl (Durolax, Bisolax)
Sennosides (Sennakot, Laxettes)
Castor oil (no longer in common use)

Stimulant laxatives work by stimulating the motility and secretion of intestinal mucosa. Their use results in watery stools, often accompanied by abdominal cramping and pain. These are used to relieve constipation. However, they should not be used as the initial treatment. Long-term use results in the bowel adapting to the strong stimulations of these medications. Rebound constipation can occur when the stimulant laxative is ceased. A normal diet does not provide adequate stimulation as the afferent messages from the intestines to the brain are ignored (Bullock & Manias, 2014). Stimulant laxatives are also used to prepare the bowel for diagnostic testing.

Nursing responsibilities

- Assess for potential contraindications to these laxatives, including abdominal pain and cramping, nausea and vomiting, anal or rectal fissures.
- Administer on an empty stomach to minimise the effects of food on its dissolution and absorption.
- Do not crush enteric-coated bisacodyl tablets or administer with alkaline products. This may hasten their dissolution in the stomach, leading to gastric distress.

Health education for the person and family

- Discourage the use of this type of laxative, even in over-the-counter preparations, for the initial or continuing relief of constipation.
- Do not use the laxative for more than 1 week; chronic use can be habit forming and may suppress normal bowel reflexes.
- These laxatives are excreted in breast milk and should not be used by lactating women.
- Phenolphthalein-containing products may discolour the urine pink or red. Report possible hypersensitivity manifestations, such as difficulty breathing, dizziness or light headedness, or skin rashes, to general practitioner and stop taking the medication.

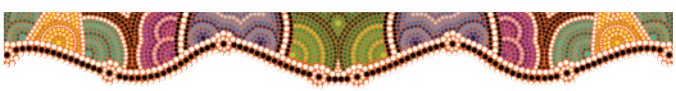
- *Oil retention enemas*—instil 90 to 120 mL mineral or olive or cottonseed oil into the bowel to lubricate the colonic mucosa and the faeces and soften the faecal mass. The instilled oil is retained for as long as possible (30 minutes to 1 hour) before evacuation.

The repeated use of enemas not only leads to impaired bowel function, bowel irritation and loss of muscle tone of the bowel and anal sphincter but also to fluid and electrolyte imbalances (Long, 2015). These imbalances are more likely to be caused by tap water and phosphate enemas. In acute conditions with a risk of bowel obstruction, perforation or ulceration, enemas should not be administered until their safe use is established.

Complementary and alternative therapies

Herbal or homeopathic therapies are used to help relieve constipation. Flaxseed oil lubricates the colon for easier passage of stool. Individuals are instructed to take 1 to 2 tablespoons daily. Flaxseed is a highly concentrated source of fibre; 1 to 2 tablespoons of ground flaxseeds can be sprinkled on cereals or salads daily, followed by 300 mL of water.

Biofeedback can be used to restore normal coordination of the anal sphincter and pelvic floor muscles. However, Chen (2014) suggests that due to the absence of clear research findings, biofeedback and sphincter exercises should be based on clinical judgment. Additionally, Slade (2014) recommends exercise, which stimulates intestinal contractions, encourages normal bowel function and improves appetite.



Nursing care

Health promotion

Education can prevent constipation. Highlight to people the importance of maintaining a diet high in natural fibre. Foods such as fresh fruit, vegetables, wholegrain products and bran provide natural fibre. Encourage reducing consumption of meats and refined foods, which are low in fibre and can be constipating. Emphasise the need to maintain a high fluid intake every day, particularly during hot weather and exercise. Discuss the relationship between exercise and bowel regularity. Encourage the person to engage in daily exercise; for example, walking.

Discuss normal bowel habits and explain that a daily bowel movement is not the norm for all people. Highlight that constipation has more to do with ease of a bowel evacuation, rather than the frequency of bowel movements (Bullock & Manias, 2014). Encourage people to respond to the urge to defecate when it occurs. Suggest establishing a routine by setting aside a time, usually following a meal, for elimination.

Assessment

To assess a person with real or perceived constipation, collect the following data:

- *Health history:* usual and current pattern of defecation, including time of day, amount and stool consistency; usual diet, fluid intake and activity pattern. Assess for possible contributing factors such as narcotic analgesics, activity limitations, painful haemorrhoids, perianal surgery; chronic diseases such as endocrine or neurological disorders; prescribed and non-prescription medications.
- *Physical examination:* abdominal girth and shape, bowel sounds, tenderness and percussion tone; digital exam of the rectum if impaction is suspected. Maintaining a bowel assessment chart (see Figure 23.2), incorporating, for example, the Bristol Stool Scale, provides a better assessment of potential constipation than the absence of faeces. The Bristol Stool Chart or Bristol Stool Scale developed by Heaton and Lewis at the University of Bristol and first published in the *Scandinavian Journal of Gastroenterology* in 1997 is an aid classifying faeces into seven groups. Types 1 and 2 indicate constipation; 3 and 4 are the 'ideal stools' (especially the latter), as these are the easiest to pass; 5 and 6 are more symptomatic of diarrhoea; and type 7 may be a sign of cholera or food poisoning or urgency (see Figure 23.3). Advising individuals or their carers how to use the Bristol Stool Chart enables appropriate intervention to be implemented, resulting in better management of constipation (Slade, 2014).

See 'Nursing care of the older adult' below for a discussion about constipation in older adults.

Nursing diagnoses and interventions

Nursing interventions for a person with constipation focus chiefly on education.

Constipation

Whether real or perceived, constipation is disruptive to a person's activities of daily living (ADLs) and life satisfaction.

- Monitor pattern of defecation and stool consistency. *This information helps to establish the person's usual pattern of defecation and differentiate between actual and perceived constipation.*
- If not contraindicated provide additional fluids to maintain an intake of at least 2500 mL per day. *A generous fluid intake helps to maintain soft stool consistency and promotes intestinal motility.*
- Encourage drinking a glass of warm water before breakfast. Provide time and privacy following breakfast for bowel elimination. *This helps develop a pattern of natural elimination; warm water provides mild stimulation of bowel peristalsis.*
- Consult with the nutritionist to provide a diet high in natural fibre unless contraindicated. Provide foods such as natural bran, prunes or prune juice. *Natural fibre adds bulk to the stool and has a mild stimulant effect.*
- Encourage activities such as ambulation or chair exercises (e.g. range of motion, stretching, wheelchair lifts) as

tolerated. *Activity stimulates peristalsis and strengthens abdominal muscles, facilitating elimination.*

- If indicated, consult with doctor about the use of bulk laxatives, stool softeners or other laxatives as needed. Laxatives may be necessary to relieve acute constipation. *People with long-term activity or nutritional restrictions or impaired abdominal muscle strength may need a bulk-forming laxative to maintain normal elimination patterns and prevent constipation.*

Community-based care

Include the following topics when teaching self-care measures to prevent and manage constipation:

- Increase dietary fibre intake by including fresh fruit and vegetables, whole grains, high-fibre breakfast cereals and unprocessed bran in the diet. (Bran can be sprinkled on cereals, mixed into bread or muffin recipes, or mixed with fruit juice to increase its palatability.)

FIGURE 23.3 ■ Bristol Stool Chart

- Unless contraindicated maintain fluid intake of 6 to 8 (250 mL) glasses of water per day.
- Remain physically active to promote bowel function and maintain muscle tone.
- Respond to the urge to defecate when perceived.

NURSING CARE OF THE OLDER ADULT

Constipation and older adults

Constipation and perceived constipation are common problems in older adults. Although constipation is not a normal consequence of ageing, factors such as slowed peristalsis, lowered activity levels, reduced food and fluid intake, and decreased sensory perception contribute to the higher incidence of constipation seen in older adults. Chronic diseases such as diabetes mellitus, restricted mobility and medications also increase the risk of constipation in older adults.

Cultural influences and advertising lead many older adults to believe a daily bowel movement is important for health. This belief contributes to an increased incidence of perceived constipation in older adults. Because of this perception, the older adult may come to rely on laxatives, suppositories or enemas to facilitate regular bowel movements. These external aids to defecation further impair the ability to maintain 'normal' bowel habits—a movement of soft stool every 2 to 3 days for older adults. See Box 23.1 for best practice management of constipation in older adults.

BOX 23.1 JBI best practice recommendations for management of constipation in older adults (2014)

- Prevention is better than cure, so it is recommended that older adults receive advice and education about hydration and a good diet with fibre sources such as cereals, nuts and seeds, wholemeal breads, vegetables and raw vegetables, and fruit. However, careful consideration is required as chewing or swallowing can be difficult for some older people. They may also have a poor tolerance to a high-fibre diet.
- Assessment of the older person should include an initial history of diet, medication, activity level and bowel habits. Also, the person should be asked to describe any symptoms such as bloating or pain when passing movements and associated straining. Screen older adults for the following: history of medication use (especially polypharmacy and taking laxatives) and, where feasible, replacement of constipation-causing medications with alternatives.
- For individuals unable to walk or restricted to bed or otherwise incapacitated, exercises such as low trunk rotation, pelvic tilt and single leg lifts are advised.
- Monitor and record bowel movements for frequency, character and pattern, episodes of constipation/faecal spoiling and use of oral or rectal laxative interventions.
- Osmotic laxatives such as polyethylene glycol (PEG), lactulose and bulking agents such as psyllium and bran are beneficial in managing constipation in older adults and should be promoted; it is necessary to determine individual requirements.

Source: Slade, S. (2014). *Constipation management.* Adelaide, Australia: Joanna Briggs Institute.

- Use laxatives appropriately:
  - Do not use laxatives, suppositories or enemas on a regular basis.
  - Bulk-forming agents provide insoluble fibre and are safe for long-term use; it is important to drink at least 6 to 8 (250 mL) glasses of water daily when using these (or any) laxatives.
  - Other laxatives such as docusate sodium (Coloxyl), bisacodyl (Durolax) and sennosides (Senna) should only be used occasionally to relieve constipation.
- Report any change in bowel habits such as new or persistent constipation or diarrhoea, abdominal pain, black or bloody stools, nausea or anorexia, weakness or unexplained weight loss to your general practitioner.

THE PERSON WITH IRRITABLE BOWEL SYNDROME

Irritable bowel syndrome (IBS), also known as spastic bowel or functional colitis, is a motility disorder of the lower GI tract. It is a functional disorder with no identifiable organic cause. IBS is often characterised by abdominal pain with constipation, diarrhoea or both.

Globally IBS is common, affecting 7–21% of the population depending on the diagnostic criteria used and the presence of co-morbidities (Chey, Kurlander & Eswaran, 2015). It usually affects young people, with about 50% of people diagnosed before the age of 35. There is a higher prevalence of IBS in women than in men (Björkman et al., 2014).

Pathophysiology

In IBS, it appears the central nervous system regulation of the motor and sensory functions of the bowel is altered. IBS may develop as a sequela of gastroenteritis, particularly when caused by *Camplylobacter*, *Salmonella* or *Shigella.*

People with IBS often experience increased motor reactivity of the small bowel and colon in response to stimuli such as food intake, hormonal influences and physiological or psychological stressors. Chey et al. (2015) suggest that, although the cause of IBS is ill-defined, many people with IBS attribute diet as a significant trigger of symptoms. IBS is characterised by visceral hypersensitivity and hyperactivity of the GI tract. Hypersecretion of colonic mucus is a common feature of the syndrome.

A lower visceral pain threshold is often found in people with IBS. A person may report pain, bloating and distension even when intestinal gas levels are normal. Serotonin, a neurotransmitter involved in regulating GI motility, and visceral perception may play a role in IBS. Higher than expected postprandial plasma serotonin levels are noted in some individuals with IBS (Chey et al., 2015). Rey de Castro et al. (2015) describe the subcategories of IBS as constipation (IBS-C), diarrhoea (IBS-D), mixed constipation and diarrhoea (IBS-M) or unspecified. Psychological factors such as depression or anxiety have been linked to IBS. However, these have not been identified as causes of IBS. A person may respond to counselling or stress management techniques designed to manage a chronic uncomfortable condition.

Manifestations

Irritable bowel syndrome is characterised by abdominal pain often relieved by defecation and a change in bowel habits (see the 'Manifestations' box below). The pain may be colic-like, occurring in spasms, or dull and continuous. Altered patterns of defecation may include:

- a change in frequency
- abnormal stool form (hard or lumpy, loose or watery)
- altered stool passage (straining, urgency or a sensation of incomplete evacuation)
- the passage of mucus.

A person may also describe abdominal bloating and excess gas. Other manifestations include nausea, vomiting and anorexia, fatigue, headache, depression or anxiety. The abdomen is often tender to palpation, particularly over the sigmoid colon.

MANIFESTATIONS Irritable bowel syndrome

ABDOMINAL PAIN
- May be relieved by defecation
- May be intermittent and colicky or dull and continuous

ALTERED BOWEL ELIMINATION
- Constipation
- Diarrhoea
- Mucus stools
- Abdominal bloating and flatulence
- Abdominal tenderness, especially over sigmoid colon
- Possible nausea or vomiting

INTERPROFESSIONAL CARE

Diagnosis of IBS is based on the presence of abdominal pain or discomfort with two of the following three characteristics: (1) relieved by defecation; (2) associated with a change in frequency of elimination; (3) associated with a change in stool form (Chey et al., 2015). Management is directed towards relieving manifestations and reducing or eliminating precipitating factors. Many people report benefits from psychotherapy and cognitive–behavioural therapy (Sharma, 2014b).

Diagnosis

The primary purpose of diagnostic testing is to rule out other causes of abdominal pain and altered faecal elimination. The stools may be examined for occult blood, ova, cysts and parasites, and white blood cells. A sigmoidoscopy, colonoscopy and/or a small-bowel series (upper GI series with small-bowel follow-through) and barium enema may be performed to visually examine the bowel mucosa, measure intraluminal pressures and biopsy suspicious lesions. Nursing care for these procedures is outlined in Chapter 20. Laboratory tests include a full blood count (FBC) with differential and erythrocyte sedimentation rate (ESR) to evaluate for anaemia from bleeding or a possible tumour. Increased WBCs indicate a bacterial infection.

Medications

Although not curative, medications are prescribed to manage the manifestations of IBS. Bulk-forming laxatives (such as bran or psyllium) may help reduce bowel spasm and normalise the number and form of bowel movements. An anticholinergic drug such as hyoscyamine (Buscopan) may be ordered to inhibit bowel motility by interfering with parasympathetic stimulation of the gastrointestinal tract (Chey et al., 2015). This relieves postprandial abdominal pain when taken 30 to 60 minutes before meals. Because of side effects, such as dry mouth, blurred vision and urinary hesitancy, these medications are used cautiously in older adults. In a person with diarrhoea, loperamide (Imodium) or diphenoxylate (Lomotil) may be used prophylactically to prevent diarrhoea in selected situations.

Antispasmodic medications are often used to control intestinal muscle spasm associated with IBS. Most antispasmodics are antimuscarinic medications blocking muscarinic receptors

on gastrointestinal smooth muscle, inhibiting contractions. One medication used exclusively to manage smooth muscle spasms is mebeverine (Colase). Mebeverine relaxes vascular, cardiac and other smooth muscles. It contains lactose so is contraindicated in a person with lactose intolerance. Additionally, it is used cautiously in a person with cardiac dysrhythmias, angina, ischaemic heart disease and hepatic or renal dysfunction (Tiziani, 2013).

Antidepressant drugs, including tricyclics and selective serotonin reuptake inhibitors (SSRIs), may relieve abdominal pain associated with IBS. Although the anticholinergic side effects of tricyclics (such as amitriptyline (Tryptanol) and imipramine (Tofranil)) may help decrease diarrhoea, these have more adverse effects than SSRIs such as sertraline (Zoloft) and fluoxetine (Prozac). Alosetron (Lotronex) is a serotonin receptor antagonist reducing abdominal pain and diarrhoea in individuals with IBS. Its use is limited, however, by its association with ischaemic colitis.

A systematic review and meta-analysis by Ford et al. (2008) found ispaghula husk, antispasmodics (particularly hyoscine) and peppermint oil to be effective treatments for IBS.

Nutrition

Many people with IBS benefit from additional dietary fibre. Soluble fibres include pectin, beta glucans (oats and barley) and gums in psyllium fibre. Insoluble fibres include cellulose, lignin and hemicelluloses (McKenzie et al., 2012). Adding bran to meals was thought to provide added bulk and water content to the stool, reducing the incidence of both loose diarrhoeal stools and hard, constipated stools. McKenzie et al. (2012) do not recommend increasing intake of insoluble dietary fibre or dietary fibre intake from mixed food sources (cereal and fruit fibre) as these did not improve symptoms associated with IBS. However, inclusion of linseeds for a trial period up to 3 months is recommended by Sharma (2014b) for treatment of constipation associated with IBS. Other dietary changes are specific to individual triggers for IBS manifestations. Some people may benefit from limiting lactose, fructose or sorbitol intake (see Table 23.1). When excess gas and flatulence are problems, reducing the intake of gas-forming foods, such as beans, cabbage, apple and grape juices, nuts and raisins, may be helpful. Caffeinated drinks, such as coffee, tea and soft drinks, act as gastrointestinal stimulants; limiting intake of these fluids may also prove beneficial.

Complementary and alternative therapies

Herbal preparations may provide some benefit for a person with IBS. Herbs with an antispasmodic effect, such as anise, chamomile and sage, may be used to reduce the manifestations of IBS. Peppermint oil is a carminative, causing relaxation of the sphincters; it is considered an effective alternative to antispasmodic medications (Sharma, 2014a). Dill and aniseed are carminatives included in some commercial preparations to relieve wind or colic in babies (Bullock & Manias, 2014). Ginger root when consumed as a tea or capsule assists with reducing gas, bloating and diarrhoea, and improves stomach functioning (Braun & Cohen, 2015). According to Sharma (2014b), probiotic therapies (such as yoghurt with active bacterial cultures, particularly *Bifidobacterium lactis*), improve overall IBS-C symptoms, abdominal pain and urgency. Although it was stressed that probiotic therapies had no effect on bloating, distension, flatulence or stool symptoms. Sharma (2014b) advised informing a person electing to try probiotics to try one preparation at a time for at least 4 weeks and monitor the effects on symptoms of IBS.

Nursing care

People with irritable bowel syndrome rarely require acute care for IBS as a primary problem. However, nurses frequently interact with individuals with IBS in clinics and other community settings.

Assessment

Careful assessment is important to help identify the effects of IBS on the person. Collect the following assessment data:

- *Health history:* current manifestations, their onset and duration; current treatment measures; effect of manifestations on lifestyle; exploration of mental health status.
- *Physical examination:* apparent general state of health; abdominal shape and contour, bowel sounds, tenderness.

Nursing diagnoses and interventions

The primary nursing responsibility is education; providing referrals and counselling are additional nursing responsibilities to a person with IBS. See the previous sections on diarrhoea and constipation for selected nursing interventions.

Community-based care

Include the following topics in teaching for the person with IBS:

- the nature of the disorder and the reality of the person's manifestations
- the relationship between IBS and stress, anxiety and depression
- stress and anxiety reduction techniques, such as meditation, visualisation, exercise, 'time out' and progressive relaxation
- dietary influences that may contribute to IBS and suggested dietary changes; an increase in intake of insoluble dietary fibre is not recommended
- the use and role of prescribed medications, their adverse effects and when to contact the doctor
- stress the importance of routine follow-up appointments and of notifying the primary care provider if manifestations change (such as blood in the stool, significant constipation or diarrhoea, increasing abdominal pain or weight loss).

If needed, refer the person to a counsellor or other mental health professional for assistance in dealing with psychological factors associated with living with a chronic condition.

THE PERSON WITH FAECAL INCONTINENCE

Faecal incontinence, the loss of voluntary control of defecation, occurs less frequently than urinary incontinence; however, it is no less distressing to the person.

Multiple factors contribute to faecal incontinence, including both physiological and psychological conditions (see Box 23.2). Bowel incontinence is usually considered a manifestation of a disorder rather than a disorder in itself. A person often does not reveal faecal incontinence when discussing health concerns. There are approximately 1.3 million Australians (15 years and older) with faecal incontinence (Continence Foundation of Australia (CFA), 2015). The National Continence Management Strategy (NCMS), established in 1998 by the Australian Government Department of Health and Ageing, provides funding to research and service development initiatives aimed at prevention and treatment of this significant problem.

Older adults are more affected by faecal incontinence due to aetiological factors. Le (2015) cites epidemiological data indicating that 1–10% of adults are affected with faecal incontinence and that 0.5–1.0% of adults experience regular faecal incontinence which affects their quality of life. Faecal incontinence is one of the three main causes (along with decreased mobility and dementia) for admittance to a residential aged care facility in Australia (CFA, 2011).

Pathophysiology

To understand the pathophysiology of faecal incontinence, it is necessary to understand normal defecation mechanisms. The rectum is normally empty. When it is distended by faeces entering from the sigmoid colon, the defecation reflex is stimulated. This reflex causes involuntary relaxation of the internal sphincter and stimulates the urge to defecate. When the external sphincter, which is under both somatic (voluntary) and autonomic (involuntary) control, relaxes, defecation occurs. Adults normally can override the defecation reflex by voluntary contraction of the external sphincter and pelvic floor muscles. The wall of the rectum gradually relaxes and the urge to defecate subsides.

The most common causes of faecal incontinence are those interfering with either sensory or motor control of the rectum and anal sphincters. If the external sphincter is paralysed as a result of spinal cord injury or disease, defecation occurs automatically when the internal sphincter relaxes with the defecation reflex. If sphincter muscles are damaged or excessive pelvic floor relaxation occurs, it may not be possible to override the defecation reflex with voluntary control.

Age-related changes in anal sphincter tone and response to rectal distension increase the risk of faecal incontinence in older adults. Resting and maximal anal sphincter pressures are decreased, particularly in older women. Additionally, older females need less rectal distension to produce sustained relaxation of the anal sphincter.

BOX 23.2 Selected causes of faecal incontinence

Neurological causes
- Spinal cord injury or disease
- Head injury, stroke or brain tumour
- Degenerative neurological disease, such as multiple sclerosis, amyotrophic lateral sclerosis (ALS), dementia
- Diabetic neuropathy

Local trauma
- Obstetric tears
- Anorectal injury
- Anorectal surgery with sphincter damage

Inflammatory processes
- Infection
- Radiation

Other causes
- Diarrhoea
- Stool impaction
- Pelvic floor relaxation or loss of sphincter tone
- Tumours

Psychological causes
- Depression
- Confusion and disorientation

INTERPROFESSIONAL CARE

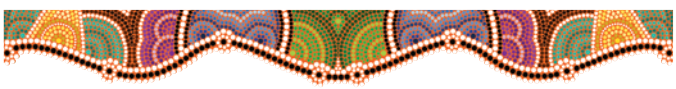
The diagnosis of faecal incontinence based on the person's history is fraught with difficulty as people are often reluctant to reveal faecal incontinence, or their carer may be unaware of previous continence history (Brown, 2007). Physical examination of the pelvic floor and anus evaluates muscle tone and rules out a faecal impaction. Impaired sphincter muscle may be palpable on digital exam. An anorectal manometry or a rectal motility test is used to evaluate the functional ability of the sphincter muscles. In this test, a small, flexible balloon catheter is introduced into the rectum and pressures are measured in the rectum and internal and external sphincters. Normally, rectal dilation causes the internal sphincter to relax and the external sphincter to contract. Sigmoidoscopy may also be used to examine the rectum and anal canal.

Management of faecal incontinence is directed towards the identified cause. D'Arcy (2014) recommends a comprehensive person-centred bowel management program based on formal assessment be developed and then reassessed 6 monthly for a person with faecal incontinence. Medications to relieve diarrhoea or constipation may be prescribed. A high-fibre diet, ample fluids and regular exercise are helpful for many people. Exercises to improve sphincter and pelvic floor muscle tone (Kegel exercises) may be of long-term benefit. See Chapter 26 for more information about Kegel exercises.

A person may also benefit from using loperamide before meals and prophylactically before leaving home. The National Institute for Health and Clinical Excellence (NICE) (2007) advises that antidiarrhoeal medication (e.g. loperamide hydrochloride

(Imodium)) can be used long term in doses from 0.5 mg to 16 mg per day, as required. Codeine phosphate may be offered for people who do not tolerate loperamide. Biofeedback therapy is suggested for mentally alert individuals with intact sphincter muscles but low muscle tone. It is thought that, with motivation and reinforcement, the person can achieve improved sphincter control in response to a stimulus. The goal of biofeedback is to improve sensation, coordination and strength of the sphincter muscle (Joanna Briggs Institute, 2008). However, D'Arcy (2014) suggests that due to the absence of clear research findings, biofeedback and sphincter exercises in adults with faecal incontinence need to be based on clinical judgment.

When damage to the sphincter or rectal prolapse (protrusion of rectal mucous membrane through the anus) is the cause of faecal incontinence, surgical repair is the treatment of choice. Surgery may also be indicated when conservative measures have been ineffective. Permanent colostomy, the creation of an opening from the large bowel on the abdominal wall, is a last-choice option for some people to control faecal output when other measures fail.



Nursing care

Health promotion

A bowel training program to establish a regular pattern of elimination is often effective in relieving faecal incontinence. Encourage the person to establish a regular time of day for elimination, usually 15 to 30 minutes after breakfast. A stimulant, such as a cup of coffee, a rectal suppository or even a phosphate enema, may be given to prompt defecation. A person with neurological incontinence can learn to stimulate the anal canal digitally to initiate defecation.

Dietary changes may be useful in managing faecal incontinence. If incontinence occurs only with mild loose or liquid stools, increasing dietary fibre or using a bulking agent to increase stool bulk and solidity may be effective. The majority of the fibre should come from a fibre-rich diet because fibre supplements provide only a limited amount of additional fibre (D'Arcy, 2014). When incontinence of solid stool occurs, a low-residue diet of easily digested and absorbed foods may be prescribed to reduce the frequency of defecation.

Assessment

- *Health history:* extent, onset and duration of incontinence; identified contributing factors; history of spinal cord or anorectal injury or surgery; chronic diseases such as diabetes mellitus, multiple sclerosis or other neurological disorders.
- *Physical examination:* mental status; general health; examination of perianal tissues; digital rectal examination.

Nursing diagnoses and interventions

Bowel incontinence

Nurses are often responsible for instituting bowel training programs and other measures to manage faecal incontinence.

- Teach caregivers to place the person on a toilet or commode and provide for privacy at a certain time of day. *Placing the person in the normal position to defecate at a consistent time of day stimulates the defecation reflex and helps re-establish a pattern of stool evacuation.*
- If necessary, insert a glycerin or bisacodyl (Durolax) suppository 15 to 20 minutes before positioning the person on the toilet or commode. This helps to stimulate evacuation. *Once a regular elimination pattern is established, it may be possible to discontinue suppository use.*
- Maintain a caring, non-judgmental manner when providing care. *This promotes a feeling of acceptance when the person may feel unacceptable.*

CONSIDERATION FOR PRACTICE

Provide room odour control with deodoriser tablets, sprays or other devices. Controlling odour is important to preserve the person's self-esteem.

Risk of impaired skin integrity

Good skin care is vital for a person with faecal incontinence. Stools contain enzymes and other irritating substances that promote skin breakdown when these are not promptly removed. This can lead to pressure ulcers, particularly when a neurological disorder (such as spinal cord injury, dementia or stroke) impairs mobility.

- Clean the skin thoroughly with mild soap and water after each bowel movement. *Toilet paper may be more irritating to the skin and less effective in removing faecal material.*
- Apply a skin barrier cream or ointment after each bowel movement. *These help to protect the skin from irritating substances in the faeces.*
- If disposable pads or briefs are used, check frequently for soiling and change when faeces are noted. *Although these help to protect bedding and clothing from soiling, these contribute to skin breakdown if they are not checked and changed frequently*.

Community-based care

Managing faecal incontinence is a challenging problem for the person and family caregivers. For the person with intact cognition, it can be psychologically devastating. The person may become socially isolated from fear of odour or soiling clothing. Self-esteem may suffer from a sense of lost control over body functions and the inability to provide self-care. It is important to stress that incontinence is never normal (i.e. ageing alone is not a cause of incontinence) and often is treatable. Encourage the person to seek medical evaluation of the problem.

Topics to include in education for the person and their family education are:

- Recommended dietary measures—for example, consuming a high-fibre diet and ample fluids to maintain soft, formed stools or a low-residue diet to reduce the number of stools.

- Suggestions for regular exercise stimulating bowel peristalsis and regular evacuation.
- Avoid constipation as straining often to achieve bowel movements stretches and weakens the pelvic floor muscles.
- Use of bulk-forming laxatives, such as psyllium seed (Metamucil), to provide stool bulk and reduce the number of small, liquid stools.
- Bowel training program instructions, including correct sitting position on the toilet or commode; techniques for digital anal stimulation, inserting suppositories or administering enemas as recommended. When sitting on the toilet or commode, advise the person or their carer to position with the feet firmly supported. This helps to fully relax the pelvic floor and sphincter muscles. For digital anal simulation, teach to insert a lubricated gloved finger through the anal sphincter into the rectum 2 to 3 cm while seated on the toilet or commode and then to use a circular side-to-side movement to gently stretch the rectal wall until the internal sphincter relaxes.
- Recommend smoking cessation as chronic coughing associated with smoking weakens the pelvic floor muscles, leading to bowel control problems. Encourage discussion with a doctor or pharmacist for information on quitting smoking and managing chronic coughing.
- Prescribed medications (such as loperamide to reduce the number of stools), their appropriate use and management of adverse effects (such as constipation).
- The importance of good skin care, particularly if the person has a neurological impairment.
- The potential benefits and associated risks of biofeedback and surgical treatment, if recommended.
- Provide referrals to appropriate home care or community health services.

ACUTE INFLAMMATORY AND INFECTIOUS BOWEL DISORDERS

The GI tract is particularly vulnerable to inflammation and infection because of its continual exposure to the external environment. Although most pathogens affecting the GI tract are ingested in food or water, infection may also be spread by direct contact, possibly by the respiratory route. Pathogens may also be transmitted sexually through anal intercourse.

Acute disease of the GI tract may be caused by the pathogen itself or by a bacterial or other toxin. Acute inflammatory disorders such as appendicitis and peritonitis result from contamination of damaged or normally sterile tissue by the person's own endogenous or resident bacteria.

THE PERSON WITH APPENDICITIS

Appendicitis, inflammation of the vermiform appendix, is a common cause of acute abdominal pain. It is the most common reason for emergency abdominal surgery, affecting 7% to 14 % of the population (Solomon & Flum, 2015). Appendicitis occurs at any age, but is more common in adolescents and young adults and slightly more common in males than females.

Pathophysiology

The appendix is a tube-like pouch attached to the caecum just below the ileocecal valve. It is usually located in the right iliac region, at an area designated as McBurney's point (see Figure 23.4A). The function of the appendix is not fully understood, although it regularly fills with and empties digested food.

Obstruction of the proximal lumen of the appendix is apparent in most acutely inflamed appendices. The obstruction is often caused by a *faecalith* or hard mass of faeces. Other obstructive causes include a calculus or stone, a foreign body, inflammation, a tumour, parasites (e.g. pinworms) or oedema of

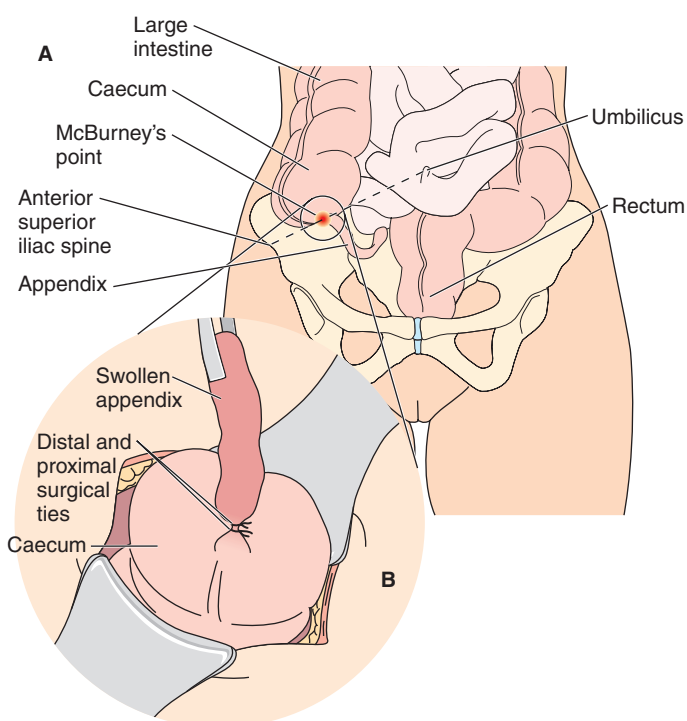


FIGURE 23.4 ■ *A*, McBurney's point, located midway between the umbilicus and the anterior iliac crest in the right lower quadrant. It is the usual site for localised pain and rebound tenderness due to appendicitis. *B*, During an appendectomy, the appendix and caecum are brought through the incision to the surface of the abdomen. The base of the appendix is clamped and ligated; the appendix is then removed

lymphoid tissue. Following obstruction, the appendix distends with fluid secreted by its mucosa. As pressure within the lumen of the appendix increases, blood supply is impaired, leading to inflammation, oedema, ulceration and infection. The formation of purulent exudate further distends the appendix. Within 24 to 36 hours, tissue necrosis and gangrene results, leading to perforation if treatment is not initiated. Perforation results in bacterial peritonitis.

Appendicitis is classified as simple, gangrenous or perforated, depending on the stage of the process. In *simple appendicitis*, the appendix is inflamed but intact. When areas of tissue necrosis and microscopic perforations are present in the appendix, it is classified as *gangrenous appendicitis*. A *perforated appendi*x shows evidence of gross perforation and contamination of the peritoneal cavity.

Manifestations

Continuous mild generalised or upper abdominal pain is the initial characteristic manifestation of acute appendicitis. Over the next 4 hours, the pain intensifies and localises in the right lower quadrant of the abdomen. It is aggravated by moving, walking or coughing. On palpation, localised and rebound tenderness are noted at McBurney's point. Rebound tenderness is demonstrated by relief of pain with direct palpation of McBurney's point followed by pain on release of pressure. Extension or internal rotation of the right hip increases the pain. Pain and local tenderness in the lower right quadrant as a presenting symptom are absent in approximately 45% of older adults compared with less than 5% of younger adults with appendicitis. This delays diagnosis in older adults, contributing to a 15% mortality of perforated appendicitis in older adults (McPhee, Papadakis & Tierney, 2008). Additionally, acute appendicitis in older adults is more virulent with complications developing sooner.

The classic manifestation of appendicitis is abdominal pain developing over 4 to 48 hours accompanied by nausea, vomiting, anorexia and a low-grade temperature. However, clinical manifestations occur in less than 50% of people developing appendicitis. More commonly, people with appendicitis present with a combination of these symptoms.

Pregnant women may develop right lower quadrant, periumbilical or right subcostal (under the rib cage) pain due to possible displacement of the appendix by the distended uterus. Women in their third trimester are at risk of appendicitis. During pregnancy, abdominal pain, nausea and vomiting are more common and many women developing appendicitis during pregnancy do not experience the classic symptoms, making early identification of appendicitis difficult.

Children, like older adults and pregnant women, often have fewer symptoms, making their diagnosis less obvious and the incidence of complications more frequent.

Complications

Perforation, peritonitis and abscess are possible complications of acute appendicitis. Perforation is manifested by increased pain and a high fever. It can lead to a small, localised abscess, local peritonitis or significant generalised peritonitis. The very young, older adults and those with impaired immune systems—for example, those with diabetes mellitus—generally are at increased risk of complications.

A less common disorder is chronic appendicitis, characterised by chronic abdominal pain and recurrent acute attacks at intervals of several months or more. Other conditions, such as inflammatory bowel disease and renal disorders, cause similar manifestations attributed to chronic appendicitis.

INTERPROFESSIONAL CARE

An acutely inflamed appendix can perforate within 24 hours, so rapid diagnosis and treatment is important. Because of this urgency and the low incidence of surgical complications, diagnostic testing and preoperative treatment are limited. The person is admitted to the hospital and intravenous fluids and antibiotics are initiated. Food and oral fluids are withheld until a diagnosis is confirmed. Once the diagnosis is established, an appendectomy is performed.

Diagnosis

Diagnostic and laboratory tests are used to help confirm the diagnosis and rule out other possible causes for the manifestations. Abdominal ultrasound is the most effective test assisting in diagnosing acute appendicitis, reducing the incidence of exploratory surgery, and is particularly useful in a person with atypical symptoms, such as pregnant women, children and older adults (Solomon & Flum, 2015). Other diagnostic tests used to accurately diagnose appendicitis include abdominal x-rays, an intravenous pyelogram, a urinalysis and a pelvic examination. Additionally, a WBC count with differential is obtained. With appendicitis, the total white count is elevated (10 000 to 20 000/mm^3), with an increased number of immature WBCs (bands).

Medications

Prior to surgery, intravenous fluids are given to restore or maintain vascular volume and prevent electrolyte imbalance. Antibiotic therapy with a third-generation cephalosporin effective against many gram-negative bacteria, such as cefotaxime (Cefotaxime Sandoz), ceftazidime (Fortum) or ceftriaxone (Rocephin), is initiated prior to surgery. The antibiotic is repeated during surgery and continued for at least 48 hours postoperatively. (The nursing implications for cephalosporin antibiotics are discussed in Chapter 11.) Analgesic medications are administered as prescribed.

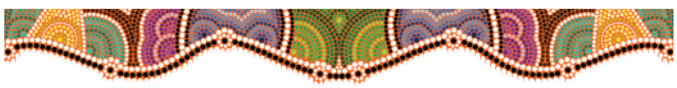
Surgery

The treatment of choice for acute appendicititis is an *appendectomy*, surgical removal of the appendix.

Either a laparoscopic approach (insertion of an endoscope to view abdominal contents) or via a laparotomy (surgical opening of the abdomen) are used for appendectomy. Laparoscopic appendectomy requires a very small incision through which the laparoscope is inserted. This procedure has several advantages: (1) direct visualisation of the appendix allows

definitive diagnosis without laparotomy; (2) postoperative hospitalisation is short; (3) postoperative complications are infrequent; and (4) recovery and resumption of normal activities is rapid.

An open appendectomy is performed by laparotomy. A small transverse incision is made at McBurney's point (see Figure 23.4A); the appendix is isolated and ligated (tied off) to prevent contamination of the site with bowel contents, and then removed (Figure 23.4B). A laparotomy is generally performed when the appendix has ruptured. It allows removal of contaminants from the peritoneal cavity by irrigation with sterile normal saline. Occasionally the wound may be left unsutured for periodic irrigation. Recovery is generally uneventful. Refer to Chapter 3 for specific discussion of preoperative and postoperative nursing care.



Nursing care

A nursing care plan for a person with acute appendicitis is included below.

Assessment

Because appendicitis rapidly progresses from inflammation to perforation, prompt assessment is vital. Obtain the following assessment data:

- *Health history:* current manifestations, including onset, duration, progression and aggravating or relieving factors; most recent food or fluid intake; known medication or other allergies and reaction to allergen; current medications; history of chronic diseases.
- *Physical examination:* vital signs, including temperature; apparent general health; abdominal shape and contour, bowel sounds, tenderness to light palpation.

Nursing diagnoses and interventions

Preoperative nursing care is directed towards preparing the person physically and psychologically for emergency surgery. Generally, limited time is available for preoperative teaching.

CONSIDERATION FOR PRACTICE

Keep the person with suspected appendicitis nil by mouth (NBM). Do not administer laxatives or enemas, which may cause perforation of the appendix. No heat should be applied to the abdomen; this may increase circulation (vasodilation) to the appendix, also causing perforation.

Risk of infection

Preventing complications during the perioperative period is a primary nursing care goal. Perforation and peritonitis are the most likely preoperative complications; postoperative complications include wound infection, abscess and possible peritonitis.

CONSIDERATION FOR PRACTICE

Assess abdominal status frequently, including distension, bowel sounds and tenderness. Increasing generalised pain, a rigid, board-like abdomen and abdominal distension may indicate developing peritonitis.

- Monitor vital signs, including temperature and pain. Perforation is manifested by increased pain and a high fever. *Tachycardia and rapid shallow respirations may indicate perforation of the appendix with resulting peritonitis. The blood pressure may fall if sepsis is present.*
- Maintain intravenous infusion until oral intake is adequate. *Intravenous fluids are given to maintain vascular volume and to provide a route for antibiotic administration.*
- Assess wound, abdominal girth and postoperative pain. *Swelling of the wound, increased abdominal girth or an increase in pain may indicate infection or peritonitis.*

Acute pain

A person with appendicitis experiences pain before and after surgery. Analgesia is limited until the diagnosis is established. Postoperative pain is controlled by narcotic or non-narcotic analgesics.

- Assess pain, including its character, location, severity and duration. Report any unexpected changes in the nature of pain. *Both preoperatively and postoperatively, the person's pain provides important clues about the diagnosis and possible complications such as rupture of the appendix or peritonitis.*

CONSIDERATION FOR PRACTICE

Sudden relief of preoperative pain may signal rupture of a distended and oedematous appendix.

- Administer analgesics as ordered. *Preoperatively, pain medication can be given after a diagnosis is established. Postoperatively, provide analgesics to maintain comfort and enhance mobility.*
- Assess effectiveness of medication 30 minutes after administration. Report increasing or unrelieved pain. *Increasing or pain unrelieved by prescribed analgesic may indicate a complication or the need for further assessment. For example, continued abdominal discomfort and distension may indicate excess intestinal gas that may be better relieved by ambulation.*

Community-based care

Often preoperative teaching is limited by pain and the urgent nature of the surgery. Explain why food and fluids are not permitted during this time. If time allows, teach postoperative turning, coughing, deep breathing and pain management.

Following an uncomplicated appendectomy, the person is often discharged either the day of, or the day following, surgery. Postoperative teaching includes:

- wound or incision care, including hand hygiene and dressing change procedures as indicated

NURSING CARE PLAN A person with acute appendicitis

Lynne James is a 19-year-old university student in her first year of a nursing degree. Ms James arrives at the emergency department (ED) at 0100 hrs. She describes a general lower abdominal pain which started the previous evening. By midnight, the pain was more localised over the right lower quadrant. She is also nauseated and reports episodes of vomiting.

ASSESSMENT

Sue Grady, RN, completes the admission assessment in the ED. Ms James reports nausea and abdominal pain, rating it at 9/10 (0 to 10 pain scale) stating, 'Walking makes my stomach hurt worse.' Physical assessment findings include T 37.8°C, P 84, R 16 and BP 110/70; skin warm to touch; abdomen flat and guarded, with marked tenderness in right lower quadrant. Ms James' FBC shows WBC 14 000/mm^3; neutrophils 81.1%; lymphocytes 12.5%. The diagnosis of acute appendicitis is made. Ms James is kept fasting; prepared for theatre, consented and transferred to operating theatre for a laparoscopic appendectomy.

DIAGNOSES

- *Risk of infection* related to impaired skin integrity secondary to surgical incision.
- *Alteration in comfort* related to acute pain secondary to surgical intervention.
- *Anxiety* related to situational crisis.

PLANNING

When planning nursing care with Ms James, it is vital to consider and ensure her religious and cultural beliefs are incorporated into her plan of care.

Expected outcomes

- Ms James' incision will heal without infection or complications.
- Ms James will verbalise adequate pain relief.
- Ms James will verbalise decreased anxiety.
- Ms James will return to preoperative activities.

IMPLEMENTATION

- Assess Ms James' pain using a pain scale; provide analgesics as needed. Monitor Ms James for effectiveness and adverse reactions.
- Teach Ms James pain management following discharge.
- Teach Ms James abdominal splinting during coughing, turning or ambulating as needed.
- Teach Ms James home care of incision.
- Discuss with Ms James activity limitations as ordered.
- Instruct Ms James to report fever or warmth, redness or drainage from the incision, or increasing abdominal pain.

EVALUATION

On discharge the following evening, Ms James was fully mobile. Her appetite had returned and she was tolerating diet and fluids well. Her temperature was 36.3°C. The RN provided Ms James with written and verbal information on postoperative care following an appendectomy.

CRITICAL THINKING IN THE NURSING PROCESS

1. Outline the physiological basis for Ms James' elevated WBC.
2. Describe differences in Ms James' postoperative care and teaching if she had undergone a laparotomy instead of a laparoscopic appendectomy.
3. Outline the teaching plan you would develop with Ms James for home care following a laproscopic appendectomy.
4. Develop a care plan for Ms James for the nursing diagnosis *Anxiety* related to a situational crisis.

REFLECTION ON THE NURSING PROCESS

1. Reflect on what you learned from completing this section. Outline how you will apply this knowledge to assist you in your clinical reasoning when next on your professional experience placement.
2. Describe nursing interventions you can incorporate into your clinical practice to reduce a person's anxiety levels while they wait for surgery.

- instructions to report fever, increased abdominal pain, swelling, redness, drainage, bleeding or warmth of the operative site to the doctor
- any activity limitations (e.g. lifting, driving)
- when it is appropriate to return to work.

THE PERSON WITH PERITONITIS

Peritonitis, inflammation of the peritoneum, is a serious complication of many acute abdominal disorders. It is usually caused by enteric bacteria entering the peritoneal cavity through a perforated ulcer, ruptured appendix, perforated diverticulum or necrotic bowel, or during abdominal surgery. Pelvic inflammatory disease, gallbladder rupture, abdominal trauma or peritoneal dialysis can also lead to peritonitis.

Pathophysiology

The peritoneum is a double-layered serous membrane lining the walls (parietal peritoneum) and organs (visceral peritoneum) of the abdominal cavity. There is a potential space between the parietal and visceral layers of the peritoneum containing a small amount of serous fluid. This space, the peritoneal cavity, is sterile.

Peritonitis results from contamination of the normally sterile peritoneal cavity by infection or a chemical irritant. Chemical peritonitis often precedes bacterial peritonitis. Perforation of a peptic ulcer or rupture of the gallbladder releases gastric juices (hydrochloric acid and pepsin) or bile into the peritoneal cavity, causing an acute inflammatory response.

Bacterial peritonitis is usually caused by infection by *Escherichia coli*, *Klebsiella*, *Proteus* or *Pseudomonas* bacteria normally inhabiting the bowel. *Neisseria gonorrhoeae* can also cause peritonitis in untreated women with the disease. Inflammatory and

immune defence mechanisms are activated when bacteria enter the peritoneal space. These defences can effectively eliminate small numbers of bacteria. However, they are overwhelmed by a massive or continued contamination. When this occurs, mast cells release histamine and other vasoactive substances, causing local vasodilation and increased capillary permeability. Polymorphonuclear leucocytes (a type of WBC) infiltrate the peritoneum to phagocytise bacteria and foreign matter. A fibrinogen-rich plasma exudate, promoting bacterial destruction and forming fibrin clots, seals off and segregates the bacteria. This process helps limit and localise the infection, allowing host defences to eradicate it. Continued contamination, however, leads to generalised inflammation of the peritoneal cavity. The inflammatory process causes fluid to shift into the peritoneal space (third spacing). Circulating blood volume is depleted, leading to hypovolaemia. *Septicaemia*, a systemic disease caused by pathogens or their toxins in the blood, may develop.

Manifestations

Manifestations of peritonitis depend on the severity and extent of the infection, as well as the age and general health of the person. Both local and systemic manifestations are present (see accompanying box). A person often presents with evidence of an *acute abdomen*, an abrupt onset of diffuse, severe abdominal pain. The pain may localise and intensify near the area of infection. Movement may intensify the pain. The entire abdomen is tender, with guarding or rigidity of abdominal muscles. The acute abdomen is often described as board-like. Rebound tenderness may be present over the area of inflammation. Peritoneal inflammation inhibits peristalsis, resulting in a paralytic ileus. Bowel sounds are markedly diminished or absent. Progressive abdominal distension is noted. Pooling of GI secretions may cause nausea and vomiting. Systemic manifestations of peritonitis include fever, malaise, tachycardia and tachypnoea, restlessness and possible disorientation. The person may be oliguric (having little urine output) with signs of dehydration and shock.

Older adults or chronically debilitated or immunosuppressed individuals may present with few of the classic manifestations of peritonitis. Increased confusion and restlessness, a decreased urinary output and vague abdominal complaints may be the only clinical manifestations. These individuals are at increased risk of delayed diagnosis, contributing to a higher mortality rate.

Complications

Complications of peritonitis may be life threatening. Abscess formation is common. The very defence mechanisms isolating and localising the infection can protect it from immune responses and systemic antibiotics. Fibrous adhesions in the abdominal cavity are a late complication and may lead to subsequent obstruction.

Without prompt and effective treatment, septicaemia and septic shock develop. Fluid loss into the abdominal cavity leads to hypovolaemic shock. These potentially lethal complications require immediate and aggressive intervention to prevent multiple-organ failure and death. Shock and its management are discussed in Chapter 10.

MANIFESTATIONS Peritonitis

ABDOMINAL/GASTROINTESTINAL MANIFESTATIONS
- Diffuse or localised pain
- Tenderness with rebound
- Board-like rigidity of abdomen
- Diminished or absent bowel sounds
- Distension
- Anorexia, nausea, and vomiting

SYSTEMIC MANIFESTATIONS
- Fever
- Malaise
- Tachycardia
- Tachypnoea
- Restlessness
- Confusion or disorientation
- Oliguria

INTERPROFESSIONAL CARE

Care of individuals with peritonitis focuses on establishing the diagnosis and identifying and treating its cause as well as the peritonitis. Preventing complications is a vital aspect of care.

Diagnosis

Diagnostic tests are performed to establish the diagnosis of peritonitis, rule out other disorders and help identify the cause. The tests may include a WBC count (elevated to approximately 20 000/mm^3 in peritonitis), blood cultures, abdominal x-rays, liver and renal function studies, serum electrolytes and an abdominal paracentesis. (In peritonitis, peritoneal fluid contains increased protein and WBCs.) Increased numbers of immature blood cells are present as the bone marrow releases these in response to the infection.

Medications

Until the infecting organism is identified, a broad-spectrum antibiotic effective against organisms commonly implicated in peritonitis is prescribed. Beta-lactum antibiotics such as imipenem (Primaxin) or meropenem (Merrem) are prescribed due to

FAST FACTS

Mortality from peritonitis
- The overall mortality rate associated with peritonitis is about 40%.
- People with other medical conditions, older adults and those with greater bacterial contamination have a higher mortality.
- Young people with perforated ulcers or appendicitis, those with less extensive bacterial contamination and those receiving early surgical intervention have mortality rates of less than 10%.

their broad spectrum of action. Once culture results are obtained, antibiotic therapy is modified to the specific organism(s) responsible.

Other antibiotics ordered may include ampicillin (e.g. Ampicyn), metronidazole (Flagyl), ciprofloxacin (Cipro), clindamycin (Cleocin), a cephalosporin such as ceftriaxone (Rocephin) or an aminoglycoside antibiotic such as gentamicin (Genoptic) or amikacin (Amikin). Nursing implications for antibiotic therapy are discussed in Chapter 11. Analgesics are prescribed to promote comfort.

Surgery

If peritonitis is caused by a perforation, gangrenous bowel or inflamed appendix, a laparotomy is done to close the perforation or remove the damaged and inflamed tissue. If an abscess is present, it may be surgically drained or removed.

Peritoneal lavage, washing of the peritoneal cavity with copious amounts of warm isotonic fluid, may be done during surgery. This procedure dilutes residual bacteria and removes gross contaminants, blood and fibrin clots. In rare instances, peritoneal lavage may be continued for several days following surgery. The solution is infused into the upper portion of the peritoneal cavity and removed via drains in the pelvic cul-de-sac. Careful assessment of fluid and electrolyte status and maintaining aseptic techniques are necessary.

Following a laparotomy for peritonitis, the person often returns from surgery with either Penrose or closed drain systems such as a Jackson–Pratt drain. In some cases, the incision is left unsutured. With severe and long-standing peritonitis, the abdomen may be closed temporarily with polypropylene mesh containing a nylon zipper or Velcro, allowing repeated abdominal exploration and drainage of infectious sites.

Nutrition

Intravenous fluids and electrolyte replacements are administered to maintain vascular volume and fluid and electrolyte balance. Parenteral nutrition is given until adequate oral intake resumes.

Other treatments

The individual is placed on bed rest in Fowler's position; this helps localise the infection and promotes lung ventilation. Oxygen is often ordered, facilitating cellular metabolism and healing.

INTESTINAL DECOMPRESSION The inflammatory process of peritonitis draws large amounts of fluid into the abdominal cavity and the bowel. Additionally, peristaltic activity of the bowel is slowed or halted by the inflammation, causing *paralytic ileus* (or *ileus*), impaired propulsion or forward movement of bowel contents. Intestinal decompression is used to relieve abdominal distension, facilitate closure and minimise postoperative respiratory complications. A nasogastric or long intestinal tube is inserted and connected to continuous drainage (see Figure 23.5). If prolonged intestinal decompression is anticipated, a jejunostomy may be performed for comfort. Suction is maintained until peristalsis resumes, bowel sounds are present and the person is passing flatus. Food and fluids are withheld until intestinal motility has returned and suction is discontinued.

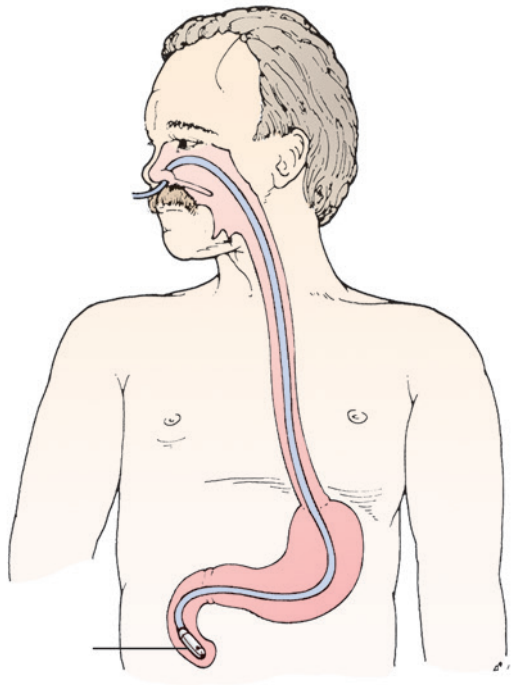


FIGURE 23.5 ■ The weighted tip or inflated balloon at the end of an intestinal tube is drawn into the intestine by gravity and peristalsis

Nursing care

Peritonitis is a serious illness. Early recognition and treatment are important to minimise the risk of complications.

Assessment

- *Health history:* pain, its onset, character, severity, location, aggravating and relieving factors; associated symptoms such as anorexia, nausea, vomiting; current and previous history of peptic ulcer disease, gallbladder disease, chronic diseases; current medications.
- *Physical examination:* vital signs, including temperature; level of consciousness; skin colour, temperature, warmth, capillary refill and turgor; abdominal shape, contour, bowel sounds, tenderness, tympany and guarding.

Nursing diagnoses and interventions

A person with peritonitis requires intensive nursing and medical care to prevent complications and enable a full recovery. Nursing priorities include interventions to relieve pain, restore fluid balance, manage altered protection due to infection and reduce anxiety.

Acute pain

Abdominal distension and acute inflammation contribute to the pain associated with peritonitis. Surgery further disrupts

abdominal muscles and other tissues, and exacerbates pain. See Chapter 8 for specific discussion on acute pain and its management. Effective pain management promotes immune function, healing, mobility and recovery.

- Assess pain at rest and on movement, including its location, severity (using a standard pain scale) and type. Monitor analgesic effectiveness. Report adverse changes to the primary care provider.

CONSIDERATION FOR PRACTICE

Unrelieved pain or a change in the location, severity or type of pain may indicate spread of infection, abscess formation or other complications of peritonitis.

- Place in Fowler's or semi-Fowler's position with the knees and feet elevated. *This position reduces stress on abdominal structures and facilitates respirations, promoting comfort.*
- Administer analgesics as ordered on a routine basis or using patient-controlled analgesia (PCA). *Routine analgesic administration maintains a therapeutic blood level and helps maintain comfort, facilitating healing and movement.*
- Teach and assist with adjunctive pain management techniques such as meditation, visualisation, massage and progressive relaxation. *Adjunctive measures augment analgesics and help promote a sense of control over pain.*

Deficient fluid volume

In peritonitis, significant amounts of fluid are drawn into the abdominal cavity and bowel, reducing vascular volume and cardiac output. Fluid is also lost from the body by intestinal suction or through drains placed in the abdomen during surgery. An unsutured incision causes additional significant fluid loss.

- Maintain accurate intake and output records. Measure urine output every 1 to 2 hours; report outputs less than 0.5 mL/kg/hr. *Measure gastrointestinal output at least every 4 hours. Intake and output records provide valuable assessment of fluid volume status.*

CONSIDERATION FOR PRACTICE

Urine output of less than 0.5 mL/kg/hr may indicate hypovolaemia, decreased cardiac output and impaired tissue perfusion.

- Monitor vital signs, peripheral pulses, capillary refill and haemodynamic parameters (such as central venous pressure, cardiac output and pulmonary artery pressures (if Swan–Ganz catheter in situ)) every hour or as indicated. *These measurements provide important information about fluid and vascular volumes and cardiovascular status.*
- Assess skin turgor, colour, temperature and mucous membranes at least every 8 hours. *Warm, dry skin with poor turgor and dry, shiny mucous membranes indicate dehydration.*
- Measure or estimate fluid losses via abdominal drains and on dressings. *Significant amounts of exudative fluid may be lost.*
- Weigh daily. Weight is an accurate indicator of fluid status. *Rapid weight gains or losses reflect changes in fluid volume.*
- Monitor laboratory values, including haemoglobin and haematocrit, urine specific gravity, serum osmolality and electrolytes and ABGs. Report changes to the doctor. *Laboratory results provide information about fluid and electrolyte status and acid–base balance.*
- Administer intravenous fluids and electrolytes as ordered. Gastrointestinal drainage may be replaced millilitre for millilitre with a balanced electrolyte solution. *Intravenous fluids are necessary to meet daily fluid intake needs, as well as to replace continuing losses of water and electrolytes.*
- Provide meticulous skin care and frequent oral hygiene. *Fluid deficit increases the risk of skin breakdown and mucous membrane ulcerations.*

Delayed surgical recovery

Repeated surgeries, an unsutured incision and the presence of drains and intravenous cannula interrupt skin integrity, the body's first line of defence against microorganisms. Additionally, immune defences are stressed by the infection and potential malnutrition. As a result, the risk of impaired healing and further infection is increased.

- Practise meticulous hand hygiene and use standard precautions at all times. *Hand hygiene reduces transient bacteria on the skin. Hand hygiene remains the most important method of controlling infection. Standard precautions reduce the risk of spreading infection to or from the person.*
- Monitor temperature, pulse rate and pain, and for localised signs of infection, such as redness and swelling around incisions and drain sites, increased or purulent drainage, and cloudy or malodorous urine. *Impaired defences increase the risk of extension of the infection or unrelated infections.*
- Use aseptic non-touch technique for dressing changes, wound care and irrigations. *Disruption of the protective barrier of the skin increases the risk of contamination and further infection.*
- Obtain cultures of purulent drainage from any site. *Early identification of any additional infection allows timely intervention.*
- Monitor WBC and differential, serum protein and albumin. *An increased WBC with a higher percentage of immature cells present in the blood is an indicator of infection and normal immune response. Serum albumin and protein levels are indicators of nutritional status as well as immune function.*
- Maintain fluid balance and nutritional status through enteral or parenteral feedings, as indicated. See the 'Translation to practice' box below for evidence-based recommendations for care of enterally fed people. *Adequate nutrition and fluid balance are necessary for optimal immune system function.*

TRANSLATION TO PRACTICE Evidence-based practice: malnutrition and the critically ill

A vital component of the treatment and care of critically ill people (such as those with peritonitis) is providing nutritional support, primarily through enteral feedings. Malnutrition is common in critically ill people and is associated with poor clinical outcomes as well as increased healthcare spending. Enteral nutrition (EN) is the method of choice for nutrition delivery for many critically ill people. However, EN delivery practices vary widely, and underfeeding is widespread in critical care. Interruptions in enteral nutrition due to performance of procedures, positioning, technical issues with feeding accesses and gastrointestinal intolerance contribute to underfeeding. Strategies such as head-of-bed positioning, use of prokinetic agents, tolerance of higher gastric residual volumes, consideration of postpyloric feeding access and use of a nutrition support protocol may decrease time spent without nutrition.

Stewart (2014) highlighted the consequences of malnutrition for critically ill people and current nursing routines contributing to EN interruptions in critically ill people, and described nursing interventions to improve a critically ill person's nutritional support. Despite strong evidence that early enteral feeding is beneficial to critically ill people, the mean time to enteral feeding remains high at 46.5 hours from admission to initiation of feedings.

Strategies to minimise interruptions include:

- Position the head of the bed at 30 to 45 degrees.
- Assess the gastric residual volume (GRV) every 4 hours. Withhold feedings if GRV is > 500 mL and assess.
- Consider prokinetic agents after two episodes of GRV > 250 mL.
- Consider postpyloric access when gastric feeding intolerance demonstrated.

IMPLICATIONS FOR NURSING

Based on Stewart's (2014) review, further research is warranted into methods to reduce time a critically ill person spends without EN, such as reduced fasting time before procedures or extubations. Alternative continuous enteral feeding methods, incorporating increased hourly rates to compensate for predicted losses in feeding volumes and compensatory increases in hourly rate to make up for experienced losses in feeding volumes, also requires exploration.

CRITICAL THINKING IN PERSON-CENTRED CARE

1. Malnutrition results when nutritional intake does not meet a person's metabolic demands. Describe the clinical implications when the nutritional intake of a person who is critically ill does not meet their increased metabolic demands.
2. Discuss how routine nursing interventions interrupt administration of enteral nutrition.
3. Outline nursing responses to improve EN to ensure a person's metabolic demands are maintained.

CONSIDERATION FOR PRACTICE

An acute infection such as peritonitis causes a stress response with excess energy expenditure and loss of body proteins and cell mass. Glycogen stores are rapidly depleted and body proteins are used to meet energy needs. Withholding food further complicates this process, leading to rapid development of protein energy malnutrition (PEM). PEM impairs the immune response and delays healing.

Anxiety

The severity and potential threat to life associated with peritonitis present a situational crisis for the individual and their family. Anxiety is a common response.

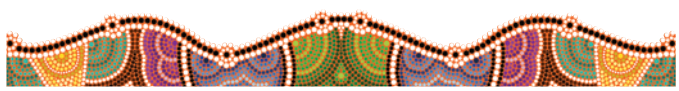
- Present a calm, reassuring manner. Encourage expression of concerns, listen carefully and acknowledge their validity. *This helps establish trust.*
- Assess the individual and their family's anxiety level and present coping skills. *Interventions need to be tailored to the needs and strengths of the individual and their family.*
- Explain all treatments, procedures, tests and examinations. *An increased understanding of what is being done reduces anxiety.*
- Reinforce and clarify information as needed. *This improves understanding and promotes acceptance.*
- Teach and assist with relaxation techniques such as meditation, visualisation and progressive relaxation. *These measures promote positive coping skills and reduce physical manifestations of anxiety.*
- Maintain consistent caregiver assignments. *Consistency of nursing care and care providers helps reduce anxiety. Complex wound care and irrigation procedures are best performed by people familiar with prescribed techniques.*

Community-based care

Education for home care includes the following topics:

- Wound care procedures, including dressing changes or irrigations. Provide verbal and written instructions on how to change dressings or do irrigations, as well as on where to obtain supplies, and provide opportunities for the person to practise and demonstrate the procedure prior to discharge.
- Prescribed medications, including name and purpose of the drug, dosage, how to take the medication correctly (e.g. not chewing or crushing enteric-coated tablets), potential adverse effects and their management.
- Manifestations of further infection (redness, heat, swelling, purulent drainage, chills and fever, and increasing pain) and potential complications to be reported to the care provider.
- Prescribed activity restrictions.
- Instructions for a high-kilojoule, high-protein diet for healing and optimal immune function.

Provide a referral to home health services for assessment, wound care and further assistance, as required.



THE PERSON WITH GASTROENTERITIS

Gastroenteritis, or *enteritis*, is an inflammation of the stomach and small intestine. Enteritis may be caused by bacteria, viruses, parasites or toxins. Gastroenteritis is a major health problem throughout the world, particularly in developing countries. Upper GI manifestations such as anorexia, nausea and vomiting are common. Diarrhoea of varying intensity and abdominal discomfort are nearly universal features of gastroenteritis. In Australia, transmission is mainly via contaminated food or water. However, in many remote Indigenous communities there is a high incidence of gastroenteritis due to poor sanitation facilities and sewage disposal, as is the case in many developing countries where diarrhoeal diseases are major causes of morbidity and mortality.

Globally there are nearly 1.7 billion cases of diarrhoeal diseases each year (World Health Organization (WHO), 2013). Diarrhoeal disease is a leading cause of child mortality and morbidity globally, mostly resulting from contaminated food and water sources. World Health Organization (2013) statistics highlight that worldwide about 1 billion people lack access to improved water and 2.5 billion have no access to basic sanitation. In developing countries, children under 3 years experience on average three episodes of diarrhoea every year. Each episode deprives the child of the nutrition necessary for growth. As a result, diarrhoeal diseases are a major cause of malnutrition, and malnourished children are more likely to fall ill from diarrhoea (WHO, 2013).

The infectious organism is usually acquired by the faecal–oral route, from contaminated water, food or hands. For this reason, gastroenteritis is often called 'food poisoning'. Viruses commonly cause acute diarrhoeal illness. Diarrhoea due to rotaviruses or the noroviruses (formerly known as Norwalk virus) occurs year round (with seasonal peaks in June and December) in both adults and children.

Rotavirus is the most common cause of acute severe gastroenteritis in early childhood and a significant cause of death in young children; more than 500 000 deaths per year (WHO, 2015a). Two rotavirus vaccines were added to the Australian National Immunisation Program in July 2007. Immunisation reduces the risk of developing severe rotavirus gastroenteritis by 85–100% and any rotavirus gastroenteritis by around 70% (Queensland Health, 2016). Prior to vaccine introduction, it is estimated the virus was responsible for up to 50% of diarrhoea hospitalisations in childhood, with approximately 10 000 Australian children hospitalised each year. Australian Aboriginal and Torres Strait Islander children have a higher burden of rotavirus illness—being three to five times more likely to be hospitalised, and for longer periods—than non-Indigenous children (Snelling et al., 2012). Most infections occur in children under 2 years of age and are potentially life threatening due to severe dehydration. Older children and adults generally experience a mild self-limiting illness. However, in older adults or those with impaired immune function, as with children less than 2 years of age, rotavirus can also have severe complications.

Pathophysiology

Bacterial or viral infection of the GI tract produces inflammation, tissue damage and manifestations by two primary mechanisms:

1. *The production of exotoxins.* A number of bacteria produce and excrete an exotoxin that enters the surrounding environment (intestinal lumen), causing damage and inflammation. Exotoxins in the GI tract are often referred to as *enterotoxins*. These impair intestinal absorption and can cause secretion of significant amounts of electrolytes and water into the bowel, resulting in diarrhoea and fluid loss. Common bacterial enterotoxins include those produced by *Staphylococcus*, *Clostridium perfringens*, *Clostridium botulinum*, some strains of *Escherichia coli*, *Vibrio cholera* and *C. difficile*.
2. *Invasion and ulceration of the mucosa.* Other bacteria, including some *Shigella*, *Salmonella* and *E. coli* species, damage tissue more directly. These invade the intestinal mucosa of the small bowel or colon, producing microscopic ulceration, bleeding, fluid exudates and water and electrolyte secretion.

In some cases, the mechanism of injury is unclear. It may be a combination of direct and toxic damage. For example, noroviruses damages the mucosa of the jejunum, with fluid and electrolyte secretion.

Manifestations

Although the manifestations of bacterial and viral enteritis vary according to the organism involved, several features are common (see the 'Manifestations' box below). Anorexia, nausea and vomiting are caused by distension of the upper GI tract from unabsorbed chyme and excess water. Bowel distension, irritation of the bowel mucosa and gas production from fermentation of undigested food lead to abdominal pain and cramping. *Borborygmi*, excessively loud and hyperactive bowel sounds, are another result. The abdomen is often distended and tender.

Diarrhoea is usually predominant with enteritis. Fluid is secreted into the bowel lumen and the unabsorbed chyme and electrolytes create an osmotic pull of fluid into the bowel.

MANIFESTATIONS Gastroenteritis

GASTROINTESTINAL EFFECTS
- Anorexia, nausea and vomiting
- Abdominal pain and cramping
- Borborygmi
- Diarrhoea

GENERAL EFFECTS
- Malaise, weakness and muscle aches
- Headache
- Dry skin and mucous membranes
- Poor skin turgor
- Orthostatic hypotension, tachycardia
- Fever

Motility is stimulated and stools become watery and frequent. Loss of fluids and electrolytes through diarrhoea can lead to serious manifestations of enteritis. Fluid volume is rapidly depleted, leading to dehydration and hypovolaemia. Initally, orthostatic hypotension and fever may be noted. However, if fluid loss continues, hypovolaemic shock develops.

Complications

Electrolyte and acid–base imbalances may result from gastroenteritis. Extensive vomiting leads to metabolic alkalosis due to the loss of hydrochloric acid from the stomach. When diarrhoea predominates, metabolic acidosis is more likely. Potassium is lost in either case, leading to hypokalaemia. Hyponatraemia may develop if fluids are replaced with pure water. Headache, cardiac irregularities, changes in respiratory rate and pattern, malaise and weakness, muscle aching and signs of neuromuscular irritability are the possible manifestations of disturbances in homeostasis.

Specific types of gastrointestinal infections

Several gastrointestinal infections produce specific effects. These are discussed below and summarised in Table 23.3.

TABLE 23.3 Selected bacterial infections of the bowel

DISEASE AND ORGANISM	INCUBATION/ DURATION OF ILLNESS	PATHOGENESIS	MANIFESTATIONS	MANAGEMENT
Traveller's diarrhoea: *Escherichia coli*, *Campylobacter*	24–72 hours/ 5–10 days	Enterotoxin causes hypersecretion of the small intestine.	Abrupt onset of diarrhoea; vomiting rare	Prophylactic bismuth subsalicylate; antidiarrhoeals such as loperamide or diphenoxylate; 3- to 5-day course of norfloxacin, ciprofloxacin or trimethoprim-sulfamethoxazole
Staphylococcal food poisoning	1–8 hours/12–24 hours	Enterotoxin impairs intestinal absorption and affects vomiting centres in the brain.	Severe nausea and vomiting; abdominal cramping and diarrhoea; headache and fever	Fluid and electrolyte replacement as needed
Cholera: *Vibrio cholerae*	1–3 days/5–7 days	Enterotoxin affects entire small intestine, causing secretion of water and electrolytes into bowel lumen.	Severe diarrhoea with 'rice-water stool', grey, cloudy, odourless, with no blood or pus; vomiting; thirst, oliguria, muscle cramps, weakness; dehydration and vascular collapse	Oral or intravenous rehydration; possible antimicrobial therapy with antimicrobial agents sensitive to specific *V. cholerae* strain
Haemorrhagic colitis (*E. coli*)	1–3 days/5–10 days	Enterotoxin causes direct mucosal damage in large intestine; also toxic to vascular endothelial cells.	Severe abdominal cramping, watery diarrhoea becoming grossly bloody; fever; possible complications: haemolytic uraemic syndrome and thrombotic thrombocytopenic purpura	Supportive care with fluid replacement and bland diet; may require dialysis or plasmapheresis for complications
Salmonellosis: *Salmonella*	8–48 hours/2–7 days	Superficial infection of the GI tract without invasion or production of toxins.	Diarrhoea with abdominal cramping, nausea and vomiting; low-grade fever, chills, weakness	Treatment of symptoms; trimethoprim sulfamethoxazole, ampicillin or ciprofloxacin for severe illness
Shigellosis (bacillary dysentery): *Shigella*	1–4 days/1–3 days	Local tissue invasion, primarily involving large intestine and distal ileum; endotoxin causes fluid and electrolyte secretion into bowel lumen.	Watery diarrhoea with severe abdominal cramping and tenesmus; lethargy	Fluid and electrolyte replacement; correction of acidosis; antibiotic therapy with trimethoprim sulfamethoxazole, ciprofloxacin or ampicillin
Clostridium difficile colitis (*C. difficile*)	1 day to 8 weeks following antibiotic exposure	Antibiotic therapy interferes with normal protective bacteria in the colon; *C. difficile* colonises and releases toxins causing mucosal inflammation and damage.	Diarrhoea, abdominal cramps, malaise, fever, anorexia	Cessation of the causative antibiotic; antibiotic therapy with vancomycin or metronidazole (specific for *C. difficile*)

Campylobacter infections

Campylobacter species are a major cause of diarrhoeal illness in humans and are generally regarded as the most common bacterial cause of gastroenteritis worldwide. In Australia, as in other developed and developing countries, they cause more cases of diarrhoea than, for example, food-borne *Salmonella* bacteria. In Australia, 14 000 to 17 000 cases are reported annually (Communicable Diseases Network Australia—National Notifiable Diseases Surveillance System (CDNA–NNDSS), 2015). In developing countries, *Campylobacter* infections in children under the age of 2 years are especially frequent, sometimes resulting in death. A fatal outcome is rare and is usually confined to the very young or older adults, or to those already immunosuppressed from another disease (e.g. HIV/AIDS).

The onset of disease symptoms usually occurs 2 to 5 days after infection, but ranges from 1 to 10 days. Usually, *Campylobacter* infections are acquired from eating contaminated and poorly cooked food, especially poultry, red meats and unpasteurised milk. The most common clinical symptoms of *Campylobacter* infections include diarrhoea (frequently with blood in the faeces), abdominal pain, fever, headache, nausea and/or vomiting. The symptoms last typically for 3 to 6 days.

Complications such as bacteraemia, hepatitis, pancreatitis and abortion have been reported with various degrees of frequency. Post-infection complications may include reactive arthritis (painful inflammation of the joints lasting for several months) and neurological disorders such as Guillain–Barré syndrome, a polio-like form of paralysis resulting in respiratory and severe neurological dysfunction or death in a small, but significant, number of cases (Lee & Bishop, 2013). In Australia, as in almost all developed countries, the incidence of human *Campylobacter* infections has been steadily increasing for several years. The reasons for this are unknown.

Traveller's diarrhoea

People travelling overseas frequently develop diarrhoea within 2 to 10 days, particularly when there is a significant difference in climate, sanitation standards or food and drink. Strains of enterotoxin-producing *E. coli*, *Shigella* species, *Salmonella* and *Campylobacter* are the most frequent causes of traveller's diarrhoea (Lee & Bishop, 2013). Other bacteria and viruses also cause traveller's diarrhoea.

Up to 10 or more loose stools per day and abdominal cramping are common manifestations. Nausea and vomiting are less frequent; fever is rare. Manifestations usually resolve within 2 to 7 days. Complications are rare.

Staphylococcal food poisoning

Certain foods rich in protein, salt and sugar provide an excellent medium for staphylococcal growth when contaminated and left at room temperature. Examples include ham, fish, salads with mayonnaise and bakery products (e.g. cream-filled cakes). Foods usually become contaminated by resident staphylococci in the nose or on the skin of food handlers (Lee & Bishop, 2013). The organism itself does not affect the bowel. However, the enterotoxin produced impairs intestinal absorption and acts on receptors in the gut, stimulating the medullary centre, inducing vomiting.

The onset of staphylococcal food poisoning is abrupt, occurring within 1 to 6 hours after consuming the contaminated food. Nausea and vomiting are severe. Manifestations typically include abdominal cramping, diarrhoea, headache and fever lasting 12 to 24 hours. Complications such as fluid and electrolyte imbalances are rare; however, they may develop in older adults and people with underlying chronic disease processes.

Cholera

Cholera is an acute diarrhoeal illness caused by strains of *Vibrio cholerae*. It is endemic in South-East Asia, the Middle East, parts of Africa and most of Central and South America. In endemic areas, water is the primary vehicle of cholera transmission, although secondary transmission may occur via food. Transmission of cholera in non-endemic areas is more commonly associated with consumption of foods, such as raw or undercooked seafood, imported from cholera-endemic regions (WHO, 2015b). Cholera appears to be increasing worldwide in terms of both the number of cases and their distribution. Epidemics occur periodically, often associated with natural disasters (floods and earthquakes) and situations of social unrest and upheaval. Lee and Bishop (2013) outline an outbreak in Kirkuk, Northern Iraq, where a cholera epidemic in 2007 affected more than 30 000 people. Fortunately, as most people were able to access adequate treatment in time, the fatality rate was low, with only 14 deaths.

In Australia, two to six cases (almost all imported from other countries) are reported annually (CDNA–NNDSS, 2015). *V. cholerae* is established in coastal rivers in some parts of Queensland and New South Wales; however, human disease from these sources is rare (Lee & Bishop, 2013). The importance of not eating raw or undercooked seafood from endemic areas was highlighted by Forssman et al. (2007) in their review of the first reported cluster of cholera in Australia for over 30 years, reported in Sydney in November 2006. Three Italian-born women (aged 71, 72 and 84 years) living within a few kilometres of each other but who did not know each other became unwell with severe watery diarrhoea within a 4-day period. It was an unusual outbreak as the women had no history of recent travel or contact with anyone visiting cholera-endemic areas. However, all three women were undergoing long-term therapy with proton-pump inhibitors, which may have contributed to their susceptibility to the disease by reducing their gastric acidity (Forssman et al., 2007). A food trace-back investigation found the only exposure common to all three cases was consumption of raw whitebait imported from Indonesia. All women reported eating cooked seafood before their illness. Forssman et al. (2007) explained that further investigation revealed the women had independently prepared the same dish—whitebait fritters—over the same weekend. During preparation, the women sampled a spoonful of the uncooked fritter mixture of whitebait, eggs, flour and seasoning, for taste and consistency. The mixture was then cooked. As no other food exposures were common to the women, the raw whitebait mixture was considered to be the source of infection.

V. cholerae causes infections only in humans, with symptomatic and asymptomatic carriers being reservoirs of infection (Lee & Bishop, 2013). Cholera is spread by the faecal–oral

route through contaminated water or food. The organism produces an enterotoxin, enzymes and other substances affecting the entire small intestine. The cholera toxin increases the levels of cyclic adenosine monophospate (AMP) in intestinal epithelial cells, resulting in a massive outflow of water and electrolytes into the bowel lumen (Lee & Bishop, 2013). The enzymes and other substances produced by the bacteria may affect mucosal protection of bowel endothelium.

Cholera ranges in severity from very mild, with few or no manifestations, to acute and fulminant. Its onset is typically abrupt, with severe, frequent, watery diarrhoea. Up to 30 L of stool may be passed in a day, rapidly depleting fluid volume. Stool is often described as 'rice-water stool', characteristically grey and cloudy, with no faecal odour, blood or pus. Vomiting may accompany the diarrhoea. Other manifestations related to the loss of fluid and electrolytes include thirst, oliguria, muscle cramps, weakness and significant signs of dehydration. Metabolic acidosis and hypokalaemia develop. Altered fluid, electrolyte and acid–base balance are discussed in Chapter 9.

Among those infected, about 20% develop acute watery diarrhoea, of which 10–20% develop severe watery diarrhoea with vomiting. The mainstay of treatment is rehydration, with up to 80% of cholera cases treated successfully using only oral rehydration salts (WHO, 2015b). If untreated, circulatory collapse and acute kidney injury or dysfunction occurs. The WHO (2015b) warns without fluid and electrolyte replacement, mortality can be as high as 30–50%, mostly observed in crisis situations with overcrowding, limited access to healthcare and precarious environmental management. However, with prompt and adequate fluid replacement, mortality is less than 1%. Recovery from cholera usually occurs spontaneously within 3 to 6 days.

The WHO (2015b) recommends vaccination when travelling to cholera-endemic areas. It is a live vaccine and therefore is used cautiously in immunocompromised individuals, young children and pregnant women. It contains phenylalanine so caution is needed in those with phenylketonuria. The person should be advised to avoid contact with anyone who is immunosuppressed for at least 8 days after taking the vaccine (Tiziani, 2013). Chloroquine (antimalarial prophylaxis) should not be started within 1 week of taking the vaccine. The vaccine should be separated by at least 8 hours from oral typhoid vaccine (Tiziani, 2013).

Escherichia coli haemorrhagic colitis

Most pathological forms of *E. coli* bacteria cause little more than common traveller's diarrhoea. However, some strains—the most common serotype 0157:H7 and *E. coli* 0111—produce potent enterotoxins in the large intestine after being ingested. These toxins damage bowel mucosa and the endothelial cells of blood vessels in the GI tract. If absorbed, the toxin damages other blood vessels as well, such as those of the kidney.

Cattle provide the reservoir for *E. coli* 0157:H7. It is usually spread through undercooked beef (mince, in particular) and unpasteurised milk or apple juice. It may also be spread by direct contact via the faecal–oral route. The onset of haemorrhagic colitis is abrupt, with severe abdominal cramping and watery diarrhoea that becomes grossly bloody within 24 hours. Fever may be present.

Throughout the world, *E. coli* 0157:H7 is the most common serotype associated with haemolytic uraemic syndrome (HUS) (Lee & Bishop, 2013). HUS is characterised by uraemia, thrombocytopenia and acute kidney injury or dysfunction, occurring within the first few days of the infection. HUS is a severe complication of *E. coli* haemorrhagic colitis, affecting about 5% of people with the disease. HUS can occur in any age group; however, it is most common in children under 4 years. Older adults have the highest risk of developing complications. HUS has been a notifiable disease in Australia since 1998, with approximately 10 to 30 cases notified each year (CDNA–NNDSS, 2015).

Clostridium difficile colitis

Clostridium difficile colitis is associated with antibiotic therapy. While antibiotics are recognised as the main predisposing factor, anything disrupting the intestinal flora of the gut, including another gastrointestinal infection, can lead to *C. difficile* infection. The normal colonic flora of adults and children over the age of 1 year effectively prevent the colonisation by *C. difficile*; however, treatment with antibiotics (especially broad-spectrum antibiotics) interferes with the normal protective bacteria of the colon, allowing colonisation of *C. difficile* by the faecal–oral route.

The subsequent release of two exotoxins, A and B, by the bacteria is cytotoxic to a number of cell types, causing mucosal damage and haemorrhage. This induces a local inflammatory response and destruction of the intestinal mucosa, resulting in a pseudomembrane forming consisting of necrotic tissue, mucus, neutrophils and monocytes (Lee & Bishop, 2013) (see Figure 23.6).

C. difficile infection is primarily a problem in hospitalised individuals, in whom infection occurs after ingestion of spores. The spores enable the organism to survive for long periods in the hospital environment. It has been cultured from floors, toilets, bedding, mops and furniture, and also from the hands of healthcare workers (Lee & Bishop, 2013). Transmission of the organism to a susceptible person can readily occur in hospital. It is also being seen in the community in healthy adults.

A hypervirulent strain called ribotype 027, associated with high morbidity and mortality, has emerged and is responsible for hospital outbreaks in North America and Europe.

An infection with *C. difficile* manifests in various ways, from mild diarrhoea and abdominal cramping to the potentially life-threatening pseudomembranous colitis. Perforation of the bowel, abscess formation and vascular thrombi are late complications. Lee and Bishop (2013) advise that *C. difficile* infection should be considered in any person receiving antimicrobial therapy who develops diarrhoea. It commonly begins within 1 to 2 weeks; however, it can commence from 1 day up to 8 weeks after commencing antibiotic treatment (Lee & Bishop, 2013).

The bacteria can be identified in the stool by anaerobic culture and the detection of toxin B in stool filtrate. An enzyme immunoassay method to detect *C. difficile* toxin in the stool

sample is also commonly used. It is less sensitive than culture, but a much quicker process (Lee & Bishop, 2013).

Salmonellosis

Salmonellosis is food poisoning caused by ingesting raw or improperly cooked meat, poultry, eggs and dairy products contaminated with *Salmonella* bacteria. In developed countries, salmonellae are the second main cause of diarrhoea; 7000–9000 cases are reported annually in Australia (CDNA–NNDSS, 2015). These bacteria do not produce a toxin; they cause superficial infection of the GI tract, rarely invading further.

Manifestations develop from 8 to 48 hours after ingesting the bacteria. Diarrhoea may be violent, with abdominal cramping, nausea and vomiting. A low-grade fever, chills and weakness may accompany GI manifestations. The disease is usually self-limiting, resolving within 3 to 5 days. Many people become asymptomatic carriers for weeks to months, continuing to shed organisms in faeces. Bacteraemia, particularly in the very young, older adults or immunosuppressed individuals, may cause arthritis, osteomyelitis, pneumonia or meningitis when the organism invades the mesenteric lymph nodes (Lee & Bishop, 2013).

Shigellosis (bacillary dysentery)

Shigellosis (or bacillary dysentery) occurs worldwide, accounting for 5–10% of diarrhoeal illness in some regions. It may be endemic or it may occur in epidemics. In Australia, shigellosis is more common in disadvantaged communities and more prevalent among Indigenous children than non-Indigenous children. Approximately 500 to 900 cases are notified annually, with the highest notifications rates in Australian Aboriginal and Torres Strait Islander children less than 4 years of age (CDNA–NNDSS, 2015). Humans are reservoirs for *Shigella* organisms, which spread directly via the faecal–oral route or indirectly through contaminated food, fomites (inanimate objects) and vectors (such as fleas). The incubation period for shigellosis is 1 to 4 days.

Shigella organisms infect the lower intestine and sometimes the distal ilium. They invade the tissue, causing inflammation and producing an enterotoxin. The result is watery diarrhoea containing blood, mucus and inflammatory exudate. The onset of diarrhoea is abrupt, with severe abdominal cramping and *tenesmus*, a sensation of urgent and continuing need to defecate. Lethargy is common; rarely, neurological manifestations occur.

In adults, shigellosis is usually mild and self-limiting. Older adults and immunosuppressed people are at risk of volume depletion and electrolyte imbalances. Secondary infection is another potential complication, as is acute blood loss from mucosal ulcerations.

INTERPROFESSIONAL CARE

The goals of care for gastroenteritis are to manage the manifestations, prevent complications, identify the cause of the infection and prevent its spread. The history and manifestations provide valuable clues about the cause. Diagnostic testing is used to identify the pathogen and evaluate its effects. In most cases, treatment is supportive, directed towards relieving manifestations, restoring fluid and electrolyte balance, and maintaining function.

Diagnosis

If manifestations are severe or do not resolve within about 48 hours, laboratory testing is used to identify the causative organism and to assess fluid, electrolyte and acid–base balance. A stool specimen for culture, ova, cysts and parasites, and faecal leucocytes usually reveals the infective organism. Some bacteria require up to 6 weeks to be identified. In infections such as botulism, the toxin itself may be isolated in the stool. Contamination of the stool by urine or treatment with antibiotics, bismuth subsalicylate or mineral oil interferes with pathogen growth, altering stool culture results. Use a clean bedpan or collection device to obtain the stool specimen and instruct the person to avoid mixing the stool with urine or toilet paper.

A colonoscopy may be done to differentiate inflammatory bowel disease from infectious processes. It does not replace stool cultures, because the lesions associated with some infectious processes are indistinguishable from those of ulcerative colitis. (Nursing care of a person having a colonoscopy is discussed in Chapter 20.)

Serum osmolality and electrolytes and ABGs are done to assess and monitor fluid, electrolyte and acid–base balance. Common imbalances associated with enteritis and diarrhoea are outlined in Table 23.4.

TABLE 23.4 Laboratory values associated with enteritis and diarrhoea

TEST	NORMAL VALUE	CHANGE WITH SIGNIFICANT DIARRHOEA
Serum osmolality	275–295 mOsm/kg	Increased; levels above 320 mOsm/kg indicate significant dehydration.
Serum potassium	3.5–5.0 mmol/L	Decreased due to loss through stool and vomitus; levels below 2.5 mmol/L are critical.
Serum sodium	136–148 mmol/L	Decreased due to loss through stool and vomitus; may be significant when fluid losses are replaced with pure water; levels below 120 mmol/L are critical.
Serum chloride	96–106 mmol/L	Increased when sodium loss is greater than chloride loss; decreased with severe diarrhoea and with vomiting; possible critical values are below 80 mmol/L or above 115 mmol/L.
Blood gases		
• pH	Arterial: 7.35–7.45	Decreased in metabolic acidosis, a possible result of severe diarrhoea; increased in metabolic alkalosis, a possible result of severe vomiting and chloride loss; values below 7.25 or above 7.55 are critical.
• PCO_2	Arterial: 35–45 mmHg	Typically decreased in metabolic acidosis as the body attempts to eliminate excess acid by 'blowing off' CO_2; increased with metabolic alkalosis as the body retains CO_2 in an attempt to normalise pH.
• Bicarbonate	22–26 mmol/L	Decreased in metabolic acidosis; increased in metabolic alkalosis.
Haematocrit	Male: 40–50% Female: 37–47%	Increased with dehydration and hypovolaemia as a result of concentration of blood cells.
Urine specific gravity	1.010–1.025	Increased with dehydration and hypovolaemia as kidneys attempt to conserve fluid.

Medications

Acute enteritis usually resolves spontaneously and no drug treatment is required. If the person is severely ill and manifestations are prolonged, medications may be prescribed.

Antibiotic therapy specific to the organism is used to treat bacterial colitis, cholera, salmonellosis or shigellosis. Trimethoprim-sulfamethoxazole (Septra, Bactrim), ciprofloxacin (Cipro), ampicillin (Ampicin) or another antibiotic may be prescribed. Stool culture is obtained prior to commencing antibiotics. However, treatment may begin before culture results are available. A presumptive diagnosis based on history and presenting manifestations guides the choice of antibiotic. Multidrug-resistant (MDR) strains of *Salmonella* are now encountered frequently and the rate of multidrug resistance has increased considerably since the 1990s (WHO, 2013). Some variants of *Salmonella* have developed multidrug resistance as an integral part of the genetic material of the organism and are likely to retain their drug-resistant genes even when antimicrobial drugs are no longer used, whereas other resistant strains typically lose their resistance. The emergence of MDR *Salmonella* strains with resistance to fluoroquinolones and third-generation cephalosporins is a serious development, severely limiting possibilities for effective treatment of human infections (WHO, 2013).

An antidiarrhoeal drug may be prescribed to promote comfort and reduce fluid loss. Nursing measures related to antidiarrhoeal medications are outlined in the 'Medication administration' box on page 704.

Treatments nutrition and fluids

Replacing lost fluids and electrolytes is vital when vomiting and/or diarrhoea are severe or prolonged. In many cases of enteritis, fluid and electrolyte replacement are all that is required until the infection resolves.

Oral rehydration is preferred for replacing physiological fluids. An oral glucose–electrolyte solution is often well tolerated in sips, even when vomiting is present. Commercial preparations such as Gastrolyte are available.

Intravenous rehydration may be necessary with severe diarrhoea and fluid loss. In some cases, a combination of oral and intravenous fluids is used to replace lost fluids and maintain vascular volume. Balanced electrolyte solutions, such as dextrose in normal saline and Hartmann's solution, are used. Hartmann's solution or another alkalinising solution may be ordered if metabolic acidosis is present.

GASTRIC LAVAGE Gastric lavage and catharsis—in effect, 'washing out' the stomach and intestines—may be performed to remove unabsorbed toxin from the GI tract if botulism is suspected. A person with botulism is closely observed for clinical manifestations of respiratory distress. Respiratory support with endotracheal intubation or tracheostomy and mechanical ventilation may be required (see Chapter 34).

PLASMAPHERESIS Plasmapheresis (plasma exchange therapy) may be performed to remove circulating toxins for haemorrhagic colitis caused by *E. coli*. See Chapter 27 for more information on plasmapheresis. Potential complications include those associated with intravenous catheters, shifts in fluid balance and altered blood clotting.

DIALYSIS Acute tubular necrosis and kidney injury associated with haemorrhagic colitis may necessitate dialysis to remove wastes and prevent severe fluid and electrolyte imbalances, and metabolic acidosis. Although acute kidney injury or

dysfunction often resolves spontaneously and renal function improves, dialysis can be lifesaving. Either haemodialysis or peritoneal dialysis is used, generally as a temporary measure. Nursing care related to acute kidney injury or dysfunction and dialysis is discussed in Chapter 27.

Nursing care

Although *C. difficile* colitis bacterial infections are hospital acquired, few people with acute enteritis require hospitalisation. Most are treated in community settings. Assessment, education and support of self-care measures are the main nursing responsibilities.

Health promotion

Nurses play a significant role in preventing enteritis as educators, community health providers and advocates for environmental safety.

Teach the importance of proper food handling and maintaining appropriate temperatures. Advise those working as food handlers to use disposable paper towels or an air dryer to dry hands rather than cloth towels as cloth towels get dirty quickly and transmit organisms from one person to another.

Adequate cooking of meat products is vital to prevent disorders such as staphylococcal food poisoning, *E. coli* haemorrhagic colitis and salmonellosis. Emphasise the importance of not consuming raw meat products and cooking mince, in particular, to the point where no redness is noted in the meat and the juice from the meat is clear. The highly pathogenic *E. coli* serotype 0157:H7 is present in the gut of infected animals. Meats from the animal may be contaminated with bowel contents. The organism is readily destroyed by heat, so cuts of meat such as steaks or roasts are less likely to cause infection, since the organism is on the outside of the meat. However, the process of mincing meat allows *E. coli* to be mixed throughout the meat. Thorough cooking destroys the organism. This pathogen (and others) may also be spread through unpasteurised milk. Discuss the dangers of consuming unpasteurised milk and encourage people to avoid it. Children should avoid eating unpasteurised and uncooked dairy products, and uncooked meat products such as salami.

Dairy products, eggs and egg products left at room temperature provide a good growth medium for bacteria. Discuss the importance of prompt refrigeration of meats and these products to minimise this risk. Many gastrointestinal infections are spread through contaminated water. Encourage travellers to consume only bottled water and to avoid ice added to drinks unless local water supplies are safe. Water purification tablets are available for bushwalkers and campers and can be used when travelling overseas if local water sources are considered unsafe.

Assessment

- *Health history:* onset, duration and severity of manifestations; recent activities such as attending a picnic or barbecue, camping, international travel or contact with someone recently returned from overseas; other affected members of the household; measures taken to relieve manifestations or replace fluids.
- *Physical examination:* vital signs, including temperature and orthostatic blood pressure; skin colour, temperature, moisture and turgor; peripheral pulses and capillary refill; abdominal shape, contour, bowel sounds, tenderness.

Nursing diagnoses and interventions

Diarrhoea and fluid volume deficit are priority nursing diagnoses. See the earlier section of this chapter on diarrhoea for specific nursing interventions related to these diagnoses. Nausea and vomiting frequently accompany diarrhoea associated with gastroenteritis. Nursing care of a person experiencing nausea and vomiting is discussed in Chapter 22.

Community-based care

Discuss the following topics with the person for self-care:

- the importance of thorough handwashing, with soap and warm running water, for at least 15 seconds, particularly before handling food (preparing food, between handling raw and ready-to-eat foods), before eating, after going to the toilet or changing nappies, and after playing with pets or working in the garden
- the need to wash clothing and linen contaminated with faeces separately in hot water (if available) and detergent
- oral solutions to replace lost fluids and electrolytes
- appropriate use of antidiarrhoeal medications if recommended
- manifestations of complications to report to the healthcare provider.

THE PERSON WITH A PROTOZOAL BOWEL INFECTION

Parasites live within, on or at the expense of other organisms. Parasitic intestinal infections are common in developing countries. These include both protozoal and helminthic (parasitic worm) infections. Parasites infecting the bowel usually enter the GI tract through the mouth by the faecal–oral route; some are spread by direct contact or through sexual activity.

Of the protozoal bowel infections, *giardiasis* is the most common in Australia. Cryptosporidiosis, a form of coccidiosis, is an important worldwide cause of sporadic mild diarrhoea, traveller's diarrhoea and severe diarrhoea in immunocompromised people. Amoebiasis (*Entamoeba histolytica*) is found chiefly in the tropics and where sanitation infrastructure is limited.

Pathophysiology and manifestations

The most common protozoal infections of the bowel are discussed below and summarised in Table 23.5.

TABLE 23.5 Common protozoal infections of the bowel

DISEASE AND ORGANISM	INCUBATION	PATHOGENESIS	MANIFESTATIONS	MANAGEMENT
Giardiasis: *Giardia lamblia*	1–3 weeks or more	Trophozoite attaches to mucosa in duodenum and jejunum, causing superficial invasion, inflammation and tissue destruction.	Diarrhoea, mild or severe, daily or intermittent; anorexia, nausea, vomiting; epigastric pain, cramping, distension; flatulence and belching; may be asymptomatic	Metronidazole quinacrine, furazolidone
Amoebiasis: *Entamoeba histolytica*	2–4 weeks	Organisms may reside in large intestine without causing disease or can invade colon wall, causing ulceration; may be carried via blood to liver to produce abscess.	Usually asymptomatic; diarrhoea may be mild with few semi-formed, mucus-containing stools per day, or severe with 10–20 blood-streaked liquid stools per day; abdominal cramps and flatulence; colic, tenesmus, vomiting, tenderness; fatigue, weight loss; prostration and toxicity	Metronidazole and diloxanide furoate; chloroquine for hepatic abscess
Cryptosporidiosis: *Cryptosporidium*	2–10 days	Organisms attach to epithelial surface of small bowel (jejunum), causing villous atrophy and mild inflammatory changes; may secrete enterotoxin.	In immunocompetent people: asymptomatic to profuse, watery diarrhoea of sudden onset, abdominal cramping; malaise, fever; anorexia, nausea, vomiting. In immunodeficient people: profuse watery diarrhoea with loss of up to 15–20 L/day; severe malabsorption, electrolyte imbalance; weight loss; lymphadenopathy	Self-limiting in immunocompetent people. For immunodeficient people: spiramycin, zidovudine (AZT), paromomycin (Humatin), octreotide, eflornithine; fluid and electrolyte replacement; parenteral nutrition as needed

Giardiasis

Giardiasis is a flagellate protozoal infection of the upper small intestine caused by *Giardia lamblia*, the most common intestinal pathogen worldwide (O'Dempsey, 2014). Humans and other mammals are the reservoir for *Giardia*. Giardiasis occurs where there is overcrowding, or inadequate sanitation or treatment of drinking water. In developed countries, the prevalence rates range between 2% and 7%; the faecal–oral route is the most common form of transmission (O'Dempsey, 2014). It is also spread by direct contact. *Giardia* is readily transmitted in institutions, such as daycare centres, where there is a higher probability of faecal–oral transmission. Other risk factors for infection include travel to high-risk areas, immunosuppression, unprotected anal sexual intercourse and if a person has achlorhydria (Kelly, 2014). In tropical and temperate countries, children are more frequently infected than adults, particularly those who are malnourished (Kelly, 2014).

In Australia, high rates of infection are reported in remote Aboriginal communities. A high prevalence of the parasite has been found in domestic cats and dogs in Australia. However, it is uncertain if they act as a reservoir for human infection (Lee & Bishop, 2013).

When the cyst form of the organism is ingested, trophozoites emerge in the duodenum and jejunum. These attach to the intestinal mucosa, leading to superficial invasion, inflammation and destruction of the mucosa of the small intestine.

Giardiasis is usually asymptomatic or manifests as acute or chronic diarrhoea associated with abdominal cramps, bloating, nausea, vomiting, fever and fatigue, and weight loss. Other manifestations include weight loss and weakness, anorexia, nausea and vomiting, epigastric pain, abdominal distension and cramping, foul flatulence and belching.

Giardiasis is usually self-limiting with symptoms lasting 1 to 2 weeks; however, it may persist for months. Fat malabsorption leads to steatorrhoea (frequent, copious, frothy, malodorous and greasy stools).

In Australia, Aboriginal and Torres Strait Islander children have high rates of chronic giardiasis (Holt, McCarthy & Carapetis, 2010). Chronic giardiasis is associated with fat, d-xylose and vitamin A and B_{12} malabsorption, exacerbating malnutrition which contributes to growth and developmental delays in Aboriginal and Torres Strait Islander children (Holt et al., 2010). Those with chronic infections often manifest with symptomatic episodes alternating with periods when asymptomatic.

Amoebiasis

Amoebiasis (amoebic dysentery) is caused by the protozoan *Entamoeba histolytica*, which is thought to infect as much as

10% of the world's population (Kelly, 2014). Several strains of protozoa have been identified. Tropical strains tend to be more virulent and pathogenic than those found in temperate climates. It is endemic in Mexico, India and Africa, where up to 50% of the population may be infected (Kelly, 2014). It is also endemic in northern parts of Australia, with the highest incidence in the Indigenous population (Lee & Bishop, 2013).

Humans are the host for this parasite. It is usually transmitted through food or water contaminated by faeces, and by person-to-person contact. The parasite enters the intestines, where it lives without causing disease, or it invades the intestinal wall, causing ulceration and inflammation. The caecum, appendix, ascending colon, sigmoid colon and rectum are most often affected. Ulcers may deepen to cause haemorrhage, oedema and mucosal sloughing. The trophozoites of some strains may spread via the blood to the liver, lungs or brain.

Amoebiasis is usually asymptomatic. Mild manifestations include abdominal cramps, flatulence and intermittent diarrhoea containing blood and mucus. Severe manifestations of amoebic dysentery include frequent watery stools containing blood, mucus and necrotic tissue; colic, tenesmus and abdominal tenderness; nausea and vomiting; and fever. The liver may be enlarged and tender to palpation.

Complications are rare, and include appendicitis, bowel perforation with peritonitis and fulminating colitis.

Cryptosporidiosis (coccidiosis)

Cryptosporidiosis causes sporadic mild diarrhoea and traveller's diarrhoea in all age groups. In people with impaired immune function, such as those with human immunodeficiency virus (HIV) disease, it causes severe diarrhoea, malabsorption and significant weight loss.

This organism is transmitted by the faecal–oral route. Contaminated water is a frequent source of infection. *Cryptosporidium* is resistant to the usual levels of chlorine in swimming pools, able to survive for days and may be spread through swallowing contaminated swimming pool water (Lee & Bishop, 2013). High doses of chlorine and the cleaning of filters remove *Cryptosporidium* from a contaminated pool.

The organism attaches to bowel epithelium, causing surface damage and inflammation. It does not invade the tissues but secretes an enterotoxin causing characteristic watery diarrhoea. Watery diarrhoea may be accompanied by low-grade fever, nausea, vomiting, abdominal cramps and general malaise.

The disease is self-limiting in people with competent immune systems. In an immunocompromised person, clinical manifestations include profuse watery diarrhoea with significant fluid and electrolyte losses, and severe malabsorption. Lymphadenopathy (enlarged lymph nodes) may also develop.

INTERPROFESSIONAL CARE

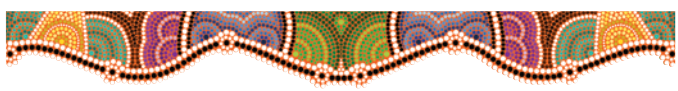
Management of protozoal bowel infections includes identifying the causative organism and administering medications.

Diagnosis

Diagnostic testing includes a stool examination for ova, cysts and parasites and possibly for their antigens. Many protozoa are shed intermittently rather than continuously; stools are collected sequentially (e.g. every other day for a total of three specimens). These organisms are often fragile, requiring a fresh stool specimen. Serology testing for an immune response to the suspected parasite may also be performed. A sigmoidoscopy may be performed to examine the bowel mucosa and collect a stool specimen for examination. (In this case, no bowel prep is done prior to the test.) When giardiasis is suspected, duodenal aspirate may be stained and examined microscopically for the protozoa. Small-bowel biopsy can identify giardiasis or *Cryptosporidium* infection.

Medications

Pharmacological treatment includes local and systemic antiparasitic medications—for example, tinidazole (Fasigyn), cotrimoxazole (trimethoprim with sulfamethoxazole–Bactrim), metronidazole (Flagyl) or albendazole (Eskazole). Treatment is usually provided on an outpatient basis. Severe amoebic dysentery requires hospitalisation for intravenous fluid and electrolyte replacement. Nursing care related to common antiprotozoal drugs is outlined in the 'Medication administration' box below.



Nursing care

Nursing assessment, diagnoses and interventions for the person with a protozoal GI infection are similar to those indicated for people with bacterial or viral infections. *Diarrhoea* and *Risk of deficient fluid volume* are priority nursing diagnoses. See previous sections of this chapter for specific nursing interventions related to these diagnoses.

Nurses need to teach the public how parasitic diseases are transmitted and how to avoid spreading the infection. Prevention of amoebiasis, cryptosporidiosis and giardiasis infections involves the following:

- Maintain good personal hygiene. Everyone should wash their hands thoroughly with soap and warm running water for at least 15 seconds before preparing food and eating, after going to the toilet or after changing nappies, and after cleaning up when someone has vomited. The towels and face washers of someone diagnosed with protozal GI infections should not be used by others.
- Ensure safe food storage, handling and preparation.
- Instruct people living in high-risk areas (e.g. tropical climates, areas with untreated water supplies) to boil, filter or treat water supplies with iodine to eliminate protozoal contamination, and to avoid foods that cannot be peeled or cooked. Teach the manifestations of protozoal infections and where to obtain treatment.
- Emphasise the importance of keeping toilet areas clean, paying particular attention to cleaning surfaces such as

MEDICATION ADMINISTRATION Antiprotozoal agents

LOCAL (GASTROINTESTINAL) AGENTS

Tinidazole (Fasigyn)
Co-trimoxazole (trimethoprim with sulfamethoxazole—Bactrim)
Metronidazole (Flagyl)

These medications exert a local amoebicidal effect in the intestines and are poorly absorbed when administered orally. Local agents have the advantage of provoking fewer side effects than systemically active agents.

Nursing responsibilities

- Assess for potential contraindications or hypersensitivity to the drug or drug class.
- Observe for adverse effects: anorexia, nausea, vomiting, abdominal cramping, diarrhoea or constipation, and increased flatulence; report skin rash, visual disturbances, dizziness, somnolence, vertigo, tremor or changes in blood work (leucopenia, neutropenia) to primary care provider.

Health education for the person and family

- Take as prescribed for the full course of therapy.
- Take with food to reduce gastrointestinal effects.
- Advise against driving or operating machinery if drowsy or dizzy.
- Report any of the following adverse effects to doctor:
  a. any change in vision
  b. numbness, tingling or pain in extremities
  c. chills, fever, skin rash or boils
  d. a change in urination or character of urine
  e. diminished hearing or tinnitus
  f. weight loss, diarrhoea, fatty stools
  g. candidiasis of the mouth or vagina.
- Keep follow-up appointments to evaluate the effects of treatment.

SYSTEMIC AGENTS

Metronidazole (Flagyl)
Pentamidine (Pentamidine Isethionate for injection)
Albendazole (Eskazole)

A person with symptomatic protozoal infections is generally treated with a systemic antiprotozoal agent. Metronidazole is the most widely used of these antiprotozoal agents and is the medication of choice for treating amoebiasis.

Nursing responsibilities

- Assess for possible contraindications to therapy:
  a. hypersensitivity to the prescribed agent or related medications
  b. liver dysfunction or blood dyscrasias
  c. concurrent use of alcohol or a monoamine oxidase inhibitor (MAOI)
  d. pregnancy.
- Administer as ordered.
  a. Metronidazole may be given orally after meals or as a continuous or intermittent intravenous infusion.
  b. Administer albendazole orally with meals to minimise gastric distress.
- Observe for possible adverse effects; notify the doctor if significant. Gastrointestinal effects are common.
  a. Peripheral neuropathy and CNS effects may occur with metronidazole.
  b. Severe hypotension, syncope, cardiac arrhythmias, including ventricular tachycardia and cardiac arrest, may occur with pentamidine.
  c. Blood dyscrasias may develop with albendazole; monitor FBC and report abnormal results.
  d. Pentamidine can cause severe hypoglycaemia; sometimes followed by hyperglycaemia. Carefully monitor blood glucose levels, particularly in people with diabetes mellitus.
  e. Report abnormal liver function test results and increased serum amylase.
- Monitor the character and number of stools; obtain specimens as ordered to evaluate the effectiveness of therapy.

Health education for the person and family

- Take the drug as prescribed for the full duration of the prescription.
- Taking oral preparations after meals helps minimise gastrointestinal side effects. Notify the physician if nausea and vomiting continue.
- Report adverse effects to the doctor, including dizziness and other nervous system changes, sore throats, fatigue, bruising or infection.
- Candidiasis of the mouth or vagina may occur with metronidazole therapy. Report symptoms to doctor.
- A harmless change in urine colour to deep yellow, rust or brown (metronidazole or chloroquine) may occur while taking these drugs.
- If you are a diabetic taking pentamidine, carefully monitor blood glucose levels because hypoglycaemia may develop.

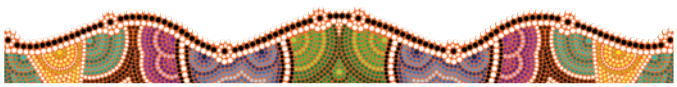
ADVICE REGARDING ALCOHOL

Do not use alcohol while taking these drugs and for 72 hours after stopping tinidazole therapy. A disulfiram–alcohol (Antabuse) type response with severe headache, flushing and vomiting, tachycardia, hypertension initially then hypotension, vertigo, blurred vision, chest pain and, in severe cases, cardiopulmonary arrest may occur. Disulfiram reaction is managed by administering 1 g ascorbic acid intravenously, chlorpromazine 5 to 100 mg intramuscularly and resuscitation measures as required (Tiziani, 2013).

toilet seats and handles, taps and nappy change tables. Ensure all potentially contaminated areas are regularly cleaned and disinfected using a hypochlorite solution of about 1000 ppm (250 mL or 1 cup of household bleach diluted in 10 L or one bucket of water) strength.

- Ensure sandpits do not become contaminated with animal faeces and urine: cover the area when not in use, rake the sand frequently and remove any animal faeces.
- Advise the person to avoid rectal contact during sexual activity. Other household members should also have stool specimens examined for parasites. Following a

cryptosporidiosis infection do not use swimming pools for 2 weeks after diarrhoea stops.
- Provide safe water supplies.
- Dispose of human faeces appropriately.



THE PERSON WITH A HELMINTHIC DISORDER

Helminths are parasitic worms capable of causing infectious diseases in humans. Helminths are subclassified as round worms (nematodes), flukes (trematodes) or tapeworms (cestodes). Parasitic helminths are a major cause of morbidity and sometimes death in humans, particularly in the tropics, subtropics and where sanitation is poor. In Australia, helminth infections occur mostly in the northern tropical parts. However, the most common helminth, the pin (or thread) worm (*Enterobius vermicularis*), is found throughout Australia (Lee & Bishop, 2013). Intestinal nematodes are found in northern Aboriginal communities with poor sanitation and inadequate health facilities. The WHO (2016) warns that infestations compromise nutritional status, affecting cognitive processes, inducing tissue reactions (e.g. granuloma) and provoking intestinal obstruction or rectal prolapse. Control of helminthiasis is based on drug treatment, improved sanitation and health education.

Pathophysiology

Although all helminths can infect humans, the definitive host and intermediate hosts vary with each organism. In nearly all instances of helminthic disorders, the organism enters the body through the GI tract in contaminated and inadequately cooked foods. Some of these organisms remain in the intestinal tract; others migrate to infect the liver, lungs or other structures. Table 23.6 summarises the most common helminths and their effects.

INTERPROFESSIONAL CARE

The management of helminthic disorders includes diagnostic testing and medications.

Diagnosis

The primary means of diagnosing helminthic disorders is examination of the stool for ova and parasites. Enterobiasis is diagnosed by the presence of the parasite's eggs on the perianal skin or on cellulose tape placed over the anus.

A full blood count may also be ordered. Anaemia may be present, particularly with hookworm disease. *Eosinophilia* (an increased percentage of eosinophils in the blood) is common in helminthic disorders. With trichinosis, serum muscle enzymes such as creatinine kinase (CK) and aspartate aminotransferase (AST) are typically elevated. Serological testing for antibodies to the worm may also be performed. Blood, duodenal washings and cerebrospinal fluid (CSF) may be examined for the presence of the trichinosis larvae. Inflamed muscle may be biopsied.

Medications

Helminthic infections are often treated with a single oral dose or a 3-day course of aldendazole (Eskazole) or mebendazole (Vermox). Doses may need to be repeated every 2 weeks for a person with heavy infections. These medications are generally safe, requiring few precautions. Giving the drug after meals minimises GI side effects. Treatment is followed by a stool culture at 2 weeks to evaluate effectiveness. If necessary, an additional course of the medication is prescribed. Other members of the household are generally also treated.

Trichinosis is a serious infection caused by the roundworm *Trichinella spiralis*, acquired by eating raw or undercooked pork contaminated with cysts of the worm. It is not a problem in Australia as the pork sold is currently free of the parasite; however, it is widespread in North America (Lee & Bishop, 2013). Most people with trichinosis recover spontaneously without long-term effects. Hospitalisation may be required during the muscle invasion phase of the disease if the infection is severe. Corticosteroids may be used to reduce the inflammation and manage the clinical manifestations.

Strongyloides stercoralis is a commonly seen threadworm in tropical and subtropical areas (Lee & Bishop, 2013). It is acquired by larval penetration through the skin (see Figure 23.7). If only a few worms are present, the person may be asymptomatic. Heavy infestations cause abdominal pain; rashes and pruritus also occur (Holt et al., 2010). *Strongyloides* infection is often difficult to diagnose and is done by finding larvae in fresh stools. Serological testing is available; however, this does not identify between a past or current acute infection. It is usually treated with ivermectin or thiabedazole. However, worm eradication is difficult, especially in an immunosuppressed person. Immunocompromised or malnourished individuals often have more severe symptoms and repeated regular treatment is required to eradicate the infection (Lee & Bishop, 2013).

Strongyloides parasites are important causes of morbidity in Indigenous communities in northern Australia and their presence is of particular concern in children, contributing to poor weight gain and failure to thrive (Holt et al., 2010).

Hookworm infections are caused by *Anclostoma duodenale* and *Nector americanus*. In Australia, hookworms are endemic in some remote areas with poor sanitation (Lee & Bishop, 2013). The Aboriginal and Torres Strait Islander population is particularly susceptible due to chronic malnutrition and the practice of walking barefoot, as the larvae burrow through the skin, enter the blood vessels and are carried to the lungs. The larvae are coughed up in sputum. If swallowed, the larvae finally arrive in the intestine, attaching to mucosal cells and establishing an infection (Lee & Bishop, 2013).

Humans are the intermediate host for *Echinococcus granulosis*, causing a condition known as hydatid cysts. Eggs are shed in the faeces and may be transmitted to humans from faeces on the fur or tongue of animals. Eggs hatch in the intestines and migrate to various parts of the body, forming hydatid cysts—large fluid-filled sacs containing thousands of larvae (O'Dempsey & Beeching, 2014). These most commonly form in the liver, lungs and brain, with serious consequences. Young

TABLE 23.6 Selected helminthic diseases

INFECTION	HOST	AREA	PATHOGENESIS	MANIFESTATIONS
Nematode infections				
Ascariasis (roundworm)	Humans	Worldwide, cosmopolitan; warm, moist climates. Common in Australia	Eggs are ingested in faecally contaminated food and drink; motile larvae migrate to lungs and back to small intestine, where they mature to produce more eggs.	Pulmonary: low-grade fever, cough, blood-tinged sputum, wheezing, dyspnoea, substernal chest pain. GI: ulcer-like epigastric pain, vomiting, abdominal distension.
Enterobiasis (pinworm infection)	Humans	Worldwide, cosmopolitan. Common in Australia	Infect caecum; eggs deposit on perianal skin. Organisms may be transmitted to others or reinfect host by oral ingestion.	Nocturnal perianal and perineal pruritus; insomnia, irritability, restlessness.
Hookworm disease	Humans	Tropics and subtropics. Common in remote areas in Australia	Larvae enter through skin or by ingestion and migrate to lungs, up bronchial tree and down oesophagus to mature in upper small bowel, where they attach and suck blood.	Skin: pruritic dermatitis at site of entry. Pulmonary: dry cough, wheezing, blood-tinged sputum. GI: anorexia, diarrhoea, abdominal pain. Systemic: anaemia, pallor, cardiac insufficiency.
Trichinosis	Pigs, dogs, cats, rats, many wild animals	Temperate areas where pork is consumed. Not found in Australian pork	Larvae are ingested in undercooked meat; adult female burrows into mucosa of small intestine to produce larvae that disseminate via blood and lymphatic system to body tissues and become encysted in striated muscle.	GI: diarrhoea, abdominal cramps, malaise. Muscle: fever; muscle pain, tenderness, oedema and spasm. Systemic: periorbital and facial oedema, sweating; photophobia and conjunctivitis; manifestations of inflammation in tissues invaded by larvae.
Cestode infections				
Fasciolopsiasis (intestinal fluke)	Humans; other mammals and fish	Worldwide. Sheep-raising areas in mainland Australia	Organism is ingested by eating uncooked fish or meat containing embryo cysts, by faecal contamination or by swallowing infected intermediate hosts, such as arthropods, fleas or lice. Head (scolex) of adult worm attaches in upper small intestine and eggs form in individual segments.	Large tapeworms: often asymptomatic; infection may cause mild nausea, diarrhoea, abdominal pain, anaemia, thrombocytopenia and mild leucopenia. Small tapeworms: may be asymptomatic; diarrhoea, abdominal pain, anorexia, vomiting, weight loss and irritability.
Tapeworm (beef tapeworm in cattle-raising areas and occasionally dwarf tapeworm found in Northern Australia)	Dogs and cats Humans are intermediate host			
Echinococcus granulosi Hydatid cysts			Eggs of organism transmitted to humans from faeces on fur or tongue of infected animal. Eggs hatch in human intestines, migrating commonly to liver, lungs and brain, forming large fluid-filled sacs—hydatid cysts.	Localised pressure of cyst on the infected organ. Manifestations vary depending on organ involved. Occasional anaphylactic reaction to hydatid antigens when cysts burst.

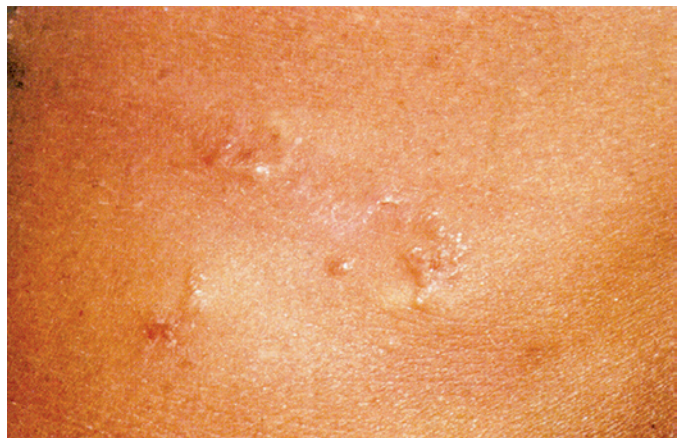


FIGURE 23.7 ■ Strongyloides infection

children in sheep-farming areas are at greatest risk. In Australia, there are approximately 50 notifications of hydatid infection, with an average of three deaths per year (Lee & Bishop, 2013; Queensland Health, 2015).

Nursing care

Because many people with these disorders are asymptomatic, nurses need to be alert for histories indicating risk and subtle manifestations of the disorder. Use standard precautions to minimise the risk of spreading these infections to others. Wear gloves and gowns as necessary to prevent faecal contamination of hands and clothing. On rare occasions, parasites may be present in the sputum or vomitus, so handle these secretions with care. Disinfect toilets, toilet seats and commodes after use. Teach the person the importance of washing hands after using the toilet and before handling food to prevent reinfection.

Discuss measures to prevent spread of the disease in the household. Emphasise the importance of hygiene measures, including changing bedding, daily cleaning of toilets with disinfectant and handwashing.

Many helminthic disorders are acquired by consuming faecally contaminated food or food containing larvae of the organism. Explain the importance of not fertilising food or grain crops with faecal material, particularly human faeces. Teach individuals to cook all meats and fish adequately to destroy possible larvae. In general, pickled or salt-preserved meats and fish are no safer than if raw. Smoking, another means of preserving fish and meat, may not achieve temperatures high enough to destroy the organisms. Vegetables grown in soil that may be contaminated with eggs or larvae should be peeled or cooked prior to eating. Hydatids can be avoided by deworming domestic animals regularly and not feeding them uncooked meat.

Emphasise the importance of safe water supplies. Encourage people travelling to areas where water supplies are questionable to drink only bottled water or carry purification tablets. Work with individuals with private water systems to protect water from faecal contamination by either humans or animals.

A person with a helminthic disorder may feel dirty or be ashamed of the disease. Emphasise the prevalence of these disorders, assuring the person that infections can occur despite good health practices when the eggs or larva of the organism are prevalent.

CHRONIC INFLAMMATORY BOWEL DISORDERS

THE PERSON WITH INFLAMMATORY BOWEL DISEASE

Chronic **inflammatory bowel disease (IBD)** includes two separate but closely related conditions: ulcerative colitis and Crohn's disease. These conditions have a number of similarities. The aetiology of both illnesses is unknown, although current evidence implicates both genetic and environmental factors. The geographical distribution of ulcerative colitis and Crohn's disease is similar worldwide, the highest incidences being in the United States, Canada, the United Kingdom and Scandinavia (Crohn's & Colitis Foundation of America (CCFA), 2009).

IBD affects certain ethnic groups more than others: it is prevalent among Ashkenazi Jews and decreases progressively

in other people of Jewish descent, in non-Jewish Caucasians, Africans, Hispanics and Asians. In Australia, it affects approximately 1 in 250 people aged 5–40. Almost 75 000 Australians have Crohn's disease or ulcerative colitis, with this number projected to increase to 100 000 by 2022 (Crohn's & Colitis Australia (CCA), 2014).

Irritable bowel disease tends to run in families, with 20–25% of people having a close relative with one of the types of IBD (CCA, 2014). Factors such as an abnormal immune response to microogranisms normally found in the gut are thought to play a role in IBD development. IBD has been linked to the recently discovered TH cell (TH 17), certain cytokines and a deficit of antimicrobial substances (lysoenzyme, defensins and other) secreted by the gut mucosa (Marieb & Hoehn, 2013). Autoimmunity is thought to play a role (see Chapter 12) and lifestyle factors (such as smoking) may also affect its development. Smoking certainly worsens Crohn's disease. CCA (2014) stresses that those who stop smoking have a 65% lower risk of flare-up (comparable to the benefit conferred by drugs such as Imuran) than continuing smokers. Children developing Crohn's disease are more likely to have been exposed to passive smoking at home (CCA, 2014).

The peak incidence of IBD is in adolescents and young adults between the ages of 15 and 35 years but it can also affect older adults (Solomon & Flum, 2015). IBD is a chronic and recurrent disease process. Responses to physiological or psychological stresses do not cause IBD, but often play a role in exacerbations of the disease.

Despite the similarities, ulcerative colitis and Crohn's disease have distinct differences. Ulcerative colitis primarily affects the large bowel in a continuous pattern, progressing distally to proximally. In Crohn's disease, a patchy pattern of involvement is seen, affecting primarily the small intestine. Ulcerative colitis shows mainly mucosal involvement; in Crohn's disease, the submucosal layers of the bowel are affected. A comparison of ulcerative colitis and Crohn's disease is found in Table 23.7. The multisystem effects of inflammatory bowel disease are illustrated below.

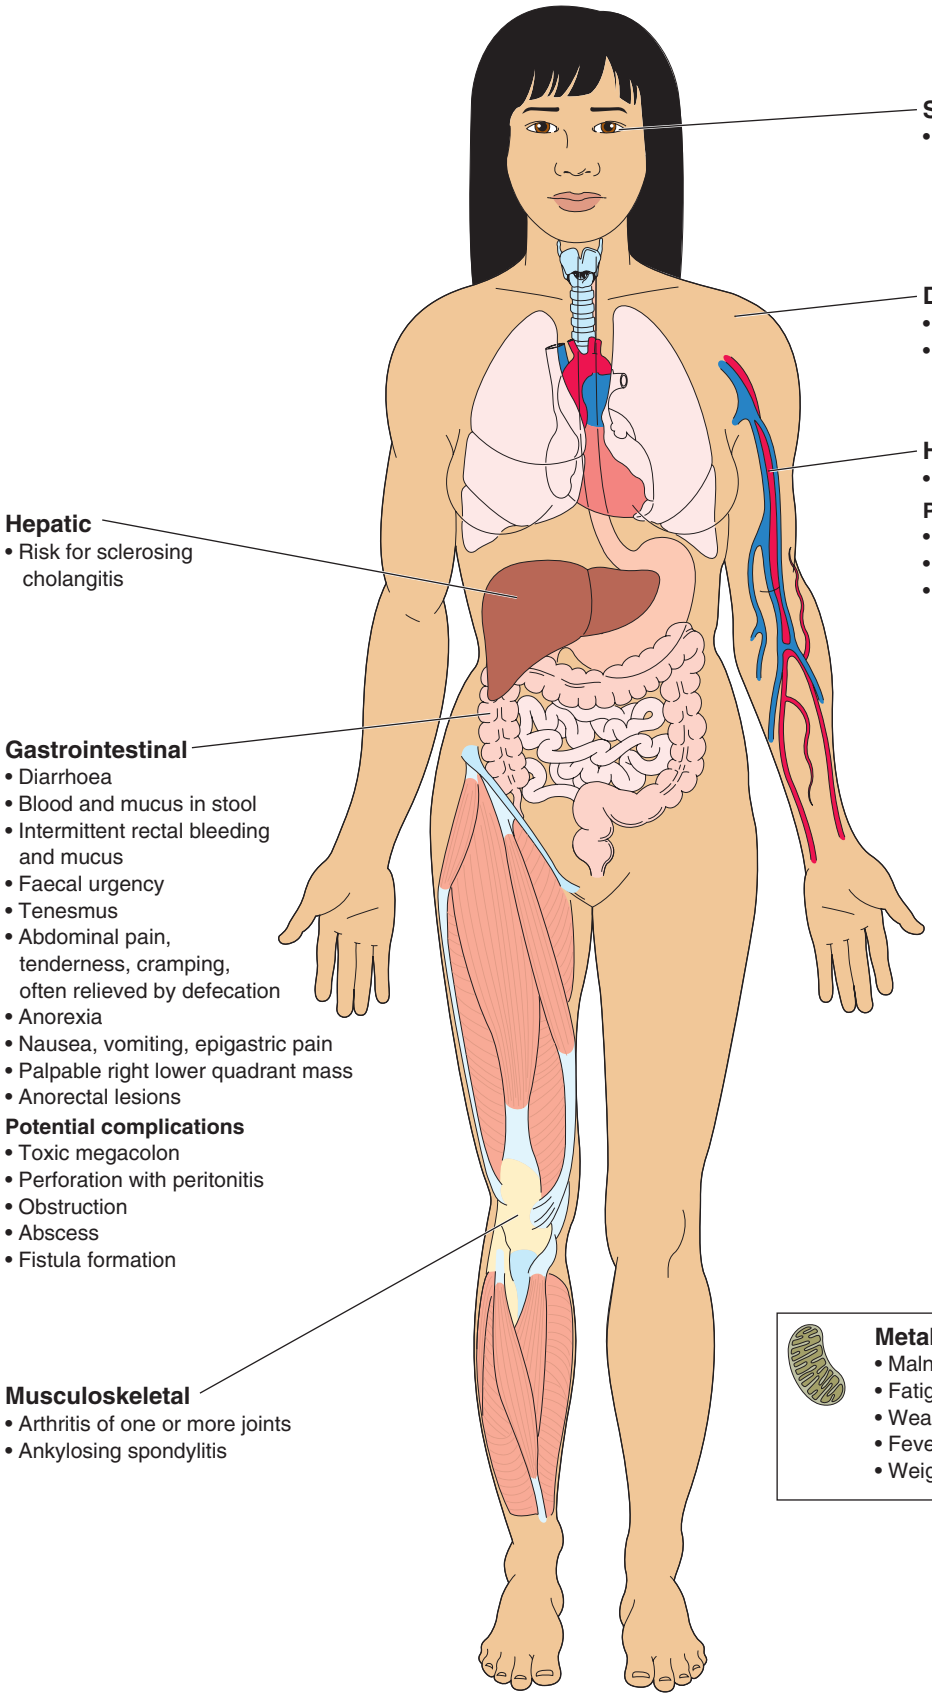
Ulcerative colitis

Ulcerative colitis is a chronic inflammatory bowel disorder affecting the mucosa and submucosa of the colon and rectum. *Chronic intermittent colitis* (recurrent ulcerative colitis) is the most common form of the disease and affects 33 000 people in Australia each year, resulting in steep hospital and drug costs as well as lost work (CCA, 2014). Most people with ulcerative colitis have mild or moderate disease, with six or fewer stools per day. Its onset is insidious, with attacks lasting 1 to 3 months occurring at intervals of months to years. Typically, only the distal colon is affected, with few systemic manifestations of the disease. Approximately 15% of people with ulcerative colitis develop *fulminant colitis*, with the entire colon involved, severe bloody diarrhoea, acute abdominal pain and fever. Those with fulminant disease are at high risk of complications.

TABLE 23.7 Characteristics of ulcerative colitis and Crohn's disease

	CHARACTERISTIC	ULCERATIVE COLITIS	CROHN'S DISEASE
Clinical	Gender	Equal	Equal
	Age at onset	15 to 35 years; secondary peak between 60 and 80 years	15 to 30 years; secondary peak between 60 and 80 years
	Course of disease	Typically chronic and intermittent	Slowly progressive, relapsing
	Diarrhoea	5 to 30 stools per day with blood and mucus	Common, usually less severe than colitis, with no obvious blood or mucus in stool
	Abdominal pain	Cramping in left lower quadrant; relieved by defecation	Cramping or steady right lower quadrant or periumbilical pain; tenderness and mass noted in right lower quadrant
	Nutritional deficit	Common; involves anaemia, hypoalbuminaemia and weight loss	Common and significant: involves anaemia, weight loss and multiple vitamin and mineral deficits
	Constitutional manifestations	Fever rare; may have associated arthritic, skin or other organ involvement, such as erythema nodosum or uveitis	Fever, malaise, fatigue; may have some associated conditions plus urinary complications
Pathological	Depth of involvement	Mucosa and submucosa	Transmural (entire bowel wall)
	Portion of bowel involved	Typically rectum and sigmoid colon; may extend to involve entire large bowel	Any portion of GI tract; terminal ileum and ascending colon involvement predominates
	Distribution	Continuous from rectum	Patchy; skip lesions
	Appearance of mucosa	Granular, dull, hyperaemic, friable; disease uniform in affected bowel; pseudopolyps may be seen	Cobblestone appearance, with areas of normal tissue surrounded by ulceration and fissures
Complications	Acute	Toxic megacolon, perforation, massive haemorrhage	Obstruction, fistulisation, abscess formation, malabsorption
	Long term	Colorectal cancer	Colon cancer

MULTISYSTEM EFFECTS OF INFLAMMATORY BOWEL DISEASE



Sensory
- Uveitis

Dermatological
- Skin lesions
- Mucous membrane lesions

Haematological
- Anaemia

Potential complications
- Thromboemboli
- Haemorrhage
- Hypovolaemia

Hepatic
- Risk for sclerosing cholangitis

Gastrointestinal
- Diarrhoea
- Blood and mucus in stool
- Intermittent rectal bleeding and mucus
- Faecal urgency
- Tenesmus
- Abdominal pain, tenderness, cramping, often relieved by defecation
- Anorexia
- Nausea, vomiting, epigastric pain
- Palpable right lower quadrant mass
- Anorectal lesions

Potential complications
- Toxic megacolon
- Perforation with peritonitis
- Obstruction
- Abscess
- Fistula formation

Musculoskeletal
- Arthritis of one or more joints
- Ankylosing spondylitis

Metabolic processes
- Malnutrition
- Fatigue
- Weakness
- Fever
- Weight loss

Pathophysiology

The inflammatory process of ulcerative colitis begins at the rectosigmoid area of the anal canal and progresses proximally. In most individuals, it is confined to the rectum and sigmoid colon. It may progress to involve the entire colon, stopping at the ileocaecal junction.

Ulcerative colitis begins with inflammation at the base of the crypts of Lieberkühn in the distal large intestine and rectum. Microscopic, pinpoint mucosal haemorrhages occur and crypt abscesses develop (see Figure 23.8). These abscesses penetrate the superficial submucosa and spread laterally, leading to necrosis and sloughing of bowel mucosa. Further tissue damage is caused by inflammatory exudates and the release of inflammatory mediators, such as prostaglandins and other cytokines (see Chapter 11 for further discussion of the inflammatory process). The mucosa is red and oedematous due to vascular congestion, friable (easily broken) and ulcerated. It bleeds easily and haemorrhage is common. Oedema creates a granular appearance. Pseudopolyps, tongue-like projections of bowel mucosa into the lumen, may develop as the epithelial lining of the bowel regenerates. Chronic inflammation leads to atrophy, narrowing and shortening of the colon, with loss of its normal haustra.

Manifestations

Diarrhoea is the predominant manifestation of ulcerative colitis. Stools contain both blood and mucus. Nocturnal diarrhoea may occur. Mild ulcerative colitis is characterised by fewer than 4 stools per day, intermittent rectal bleeding and mucus, and few systemic manifestations. Severe ulcerative colitis leads to more than 6 to 10 bloody stools per day, extensive colon involvement, anaemia, hypovolaemia and malnutrition. Rectal inflammation causes faecal urgency and tenesmus. Left lower quadrant cramping relieved by defecation is common. Other manifestations include fatigue, anorexia and weakness.

Individuals with severe disease may also have systemic manifestations such as arthritis involving one or several joints, skin and mucous membrane lesions, or *uveitis* (inflammation of the uvea, the vascular layer of the eye, which may also involve the sclera and cornea). Some individuals develop thromboemboli, with blood vessel obstruction due to clots carried from the site of their formation. The liver and biliary system may be affected by the disease as may the kidneys, with an increased risk of gallstones, cirrhosis, renal calculi and ureteral obstruction (Martin, Chan & Hart, 2014).

Complications

Most people with ulcerative colitis (80–90%) respond well to treatment and do not develop complications (CCA, 2014). Acute complications of ulcerative colitis include haemorrhage, toxic megacolon and colon perforation. Massive haemorrhage may occur with severe attacks of the disease. *Toxic megacolon* is a condition characterised by acute motor paralysis and dilation of the colon to greater than 6 cm, affecting part or the entire colon. The transverse segment of the bowel is most commonly affected. Toxic megacolon may be triggered by the use of laxatives, narcotics and anticholinergic drugs, and the presence of hypokalaemia (Devuni, 2014). Manifestations of toxic megacolon include fever, tachycardia, hypotension, dehydration, abdominal tenderness and cramping, and a change in the number of stools per day. Perforation is rare; however, this is a dangerous complication increased with toxic megacolon. Perforation leads to peritonitis.

The risk of colorectal cancer is increased in people with ulcerative colitis. Beginning 8 to 10 years after diagnosis, annual or biennial colonoscopies with biopsy to detect masses or cell dysplasia are recommended for individuals with extensive ulcerative colitis (Devuni, 2014).

Crohn's disease

Like ulcerative colitis, **Crohn's disease**, also known as regional enteritis, is a chronic, relapsing inflammatory disorder affecting the gastrointestinal tract. Crohn's disease can affect any portion of the GI tract from the mouth to the anus, but usually affects the terminal ileum and ascending colon. Only the small bowel is involved in about 30–40% of people with Crohn's disease. The disease is limited to the colon only in 30% of those affected. Both the small and the large intestine are involved in the remaining 30% of individuals (Porth & Matfin, 2013).

Pathophysiology

Crohn's disease typically begins as a small inflammatory *aphthoid lesion* (shallow ulcers with a white base and elevated margin, similar to a canker sore) of the mucosa and submucosa of the bowel. These initial lesions may regress or the inflammatory process can progress to involve all layers of the intestinal wall. Deeper ulcerations, granulomatous lesions and fissures (knife-like clefts extending deeply into the bowel wall) develop. The inflammatory process involves the entire bowel wall (transmural).

The lumen of the affected bowel assumes a 'cobblestone appearance' as fissures and ulcers surround islands of intact mucosa over oedematous submucosa. The inflammatory lesions of Crohn's disease are not continuous; rather, they often occur as 'skip' lesions with intervening areas of normal-appearing bowel. Some evidence suggests that, despite its normal appearance, the entire bowel is affected by this disorder.

As the disease progresses, fibrotic changes in the bowel wall cause thickening and decreased flexibility of the bowel (which takes on an appearance likened to a rubber hose). The inflammation, oedema and fibrosis can lead to local obstruction, abscess development and the formation of fistulas between loops of the bowel or the bowel and other organs (see Figure 23.9). Fistulas between loops of the bowel are called enteroenteric fistulas. Enterovesical fistulas occur between the bowel and bladder, and enterocutaneous fistulas occur between the bowel and skin. Perineal fistulas originating in the ileum are relatively common.

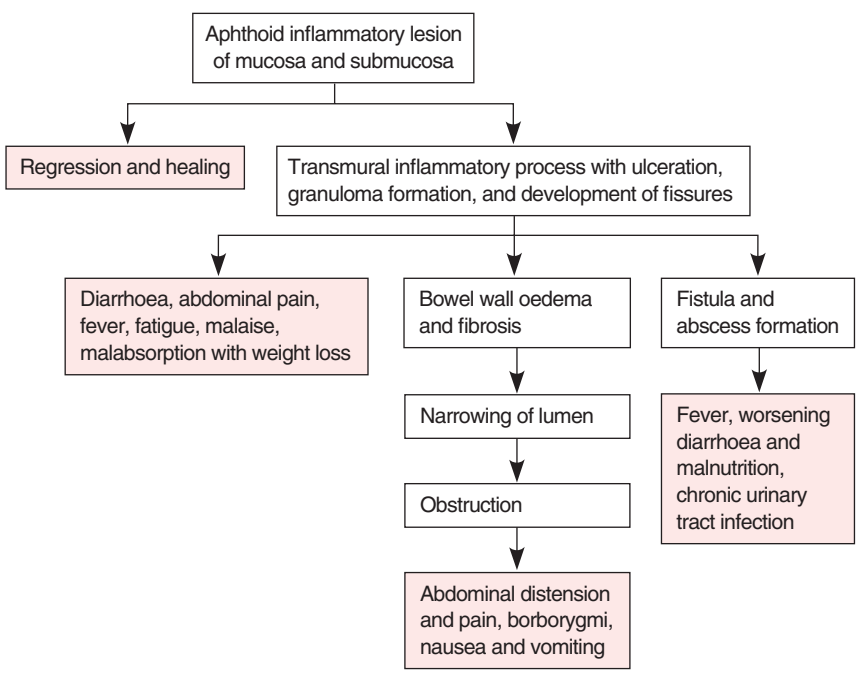

FIGURE 23.9 ■ The progression of Crohn's disease

Depending on the severity and extent of the disease, malabsorption and malnutrition may develop as the ulcers prevent absorption of nutrients. When the jejunum and ileum are affected, the absorption of multiple nutrients may be impaired, including carbohydrates, proteins, fats, vitamins and folate. Disease in the terminal ileum can lead to vitamin B_{12} malabsorption and bile salt reabsorption. The ulcerations also lead to protein loss and chronic, slow blood loss with consequent anaemia.

Manifestations

The diverse nature of GI system involvement in Crohn's disease means that clinical manifestations vary between individuals. The majority of people with Crohn's disease experience persistent diarrhoea. Stools are liquid or semi-formed and typically do not contain blood, although blood may be passed if the colon is involved. Abdominal pain and tenderness are also common. Pain may be located in the right lower quadrant and relieved by defecation. A palpable right lower quadrant mass is often present. Systemic manifestations such as fever, fatigue, malaise, weight loss and anaemia are common. Anorectal lesions such as fissures, ulcers, fistulas and abscesses are also common and may occur years before intestinal disease is apparent. If the stomach and duodenum are involved, nausea, vomiting and epigastric pain occur.

Complications

Certain complications of Crohn's disease (e.g. intestinal obstruction, abscess and fistula) are so common that they are considered part of the disease process. For many people, the disease initially presents with one of these complications. Intestinal obstruction is a common complication caused by repeated inflammation and scarring of the bowel, leading to fibrosis and stricture. Obstruction of the bowel lumen causes abdominal distension, cramping pain and borborygmi. Nausea and vomiting may occur.

Fistulas may be asymptomatic, particularly those occurring between loops of small bowel. When fistulisation causes an abscess, chills and fever, a tender abdominal mass and leucocytosis develop. A fistula between the small bowel and colon may exacerbate diarrhoea, weight loss and malnutrition. When the bladder is involved, recurrent urinary tract infections occur.

Perforation of the bowel is uncommon. However, it can lead to generalised peritonitis. Massive haemorrhage also is an uncommon complication of Crohn's disease. Long-standing Crohn's disease increases the risk of cancer of the small intestine or colon by 5 to 6 times, which is significantly lower than the risk associated with ulcerative colitis.

INTERPROFESSIONAL CARE

Interprofessional care for inflammatory bowel disease begins by establishing the diagnosis and the extent and severity of the disease. Treatment is supportive, including medications and dietary measures to decrease inflammation, promote intestinal rest and healing, and reduce intestinal motility. Many people with IBD require surgery at some point to manage the disease or its complications.

Diagnosis

Diagnostic testing is used to establish the diagnosis of IBD, assess the extent of the disease and evaluate the effects of the disorder. A colonoscopy or barium upper and lower x-ray series is performed to inspect the bowel mucosa for characteristic changes of IBD. (Nursing implications for these diagnostic tests are outlined in Chapter 20.)

Laboratory tests to differentiate IBD and identify effects and complications of the disease include a stool examination for blood and mucus and stool cultures to rule out infectious causes of bowel inflammation and diarrhoea. FBC with haemoglobin and haematocrit shows anaemia from chronic inflammation, blood loss and malnutrition, and leucocytosis due to inflammation and possible abscess formation. ESR and C-reactive protein levels are typically elevated during periods of acute inflammation. Serum albumin may be decreased because of malabsorption, malnutrition, protein loss through intestinal lesions and chronic inflammation. Folic acid and serum levels of most vitamins, including A, B complex, C and the fat-soluble vitamins are often decreased due to malabsorption. Liver function tests may show elevated liver enzymes (such as ALT, ALP, AST, GGTP and LDH) and bilirubin levels if sclerosing cholangitis is present.

Medications

The ultimate goal of care is to terminate acute attacks as quickly as possible and reduce the incidence of relapse. Drug therapy plays a key role in achieving this goal. Locally acting and systemic anti-inflammatory drugs are the primary medications used to manage mild to moderate IBD. Medications suppressing the immune response may be used to treat people with severe disease.

Sulfasalazine (Azulfidine) is a sulfonamide antibiotic poorly absorbed from the gastrointestinal tract and acts topically on the colonic mucosa to inhibit the inflammatory process. The active anti-inflammatory ingredient in sulfasalazine, 5-aminosalicylic acid (5-ASA), is also available in sulfa-free preparations, such as olsalazine and mesalazine. These have the advantage of causing fewer adverse effects than sulfasalazine. Azo compounds, such as balsalazide and olsalazine, are 5-aminosalicylic acid compounds released in the colon and are especially useful to treat ulcerative colitis. Mesalamine is an orally or rectally administered 5-ASA compound providing topical anti-inflammatory action in the colon of individuals with ulcerative colitis. Specific preparations, their method of action and nursing implications for these medications are outlined in the 'Medication administration' box below.

For acute exacerbations of IBD, corticosteroids are given to reduce inflammation and induce remission. For ulcerative colitis, the drug may be administered rectally for its local effect and to minimise systemic effects. Hydrocortisone can be administered rectally. Intravenous corticosteroids may be required to treat severe disease; oral preparations are used for less severe manifestations and long-term therapy. Corticosteroids are tapered off once remission is achieved. However,

MEDICATION ADMINISTRATION Inflammatory bowel disease

SULFASALAZINE (SALAZOPYRIN)

Sulfasalazine is an anti-inflammatory drug used for its local effect on the intestinal mucosa in inflammatory bowel disease. The active part of the drug, 5-aminosalicylic acid, inhibits prostaglandin production in the bowel. Prostaglandin is an important mediator of the inflammatory process; blocking its production reduces inflammation.

Nursing responsibilities

- Assess for contraindications, including pregnancy or a history of hypersensitivity to sulfonamides or salicylates.
- Assess baseline values for renal function tests (serum creatinine, BUN, urinalysis), liver function tests and FBC. Monitor these routinely during therapy.
- Administer as ordered. Suppositories or retention enemas may be administered at bedtime. Administer oral forms with a full glass of water.
- Have resuscitation equipment available, as anaphylactic responses may occur.
- Evaluate for therapeutic response, including reduced number of stools, reduced mucus and blood, and improved stool consistency. Onset of action may take 6 to 12 weeks.
- Monitor for possible adverse responses:
  a. skin rash, dermatitis, urticaria or pruritus
  b. evidence of blood dyscrasias, such as bleeding, easy bruising or fever
  c. leucopenia, thrombocytopenia, haemolytic anaemia or agranulocytosis
  d. changes in urinary output or renal function analysis (including urinalysis)
  e. evidence of hepatitis or myocarditis.

Health education for the person and family

- Take oral preparations after meals to decrease gastric distress.
- Drink at least 2–3 L of fluid per day to reduce the risk of kidney damage.
- Use sunscreen to prevent burns; this drug increases sensitivity to sun.
- Do not take aspirin, vitamin C or any other over-the-counter medications containing aspirin or vitamin C without consulting your doctor.
- This medication may interfere with the effectiveness of oral contraceptives; use alternative methods of contraception.
- Notify your doctor if you develop skin rash or hives, a sore throat or mouth, bleeding gums or joint pain, or bruise easily or develop fever.

MESALAZINE (MESASAL) AND OLSALAZINE (PREDSOL)

Mesalamine and olsalazine contain the same active ingredient, 5-aminosalicylic acid, as sulfasalazine; however, they cause fewer adverse effects. Their mechanism of action is the same as sulfasalazine. These drugs are available as suppositories, suspension for enema or oral tablets.

Nursing responsibilities

- Assess for possible contraindications such as pregnancy, lactation or hypersensitivity to these drugs or aspirin.
- Administer as ordered. If more than one dose per day is ordered; space doses evenly over the 24-hour period.
- Evaluate for desired effects (as for sulfasalazine) and potential adverse effects:
  a. nausea, diarrhoea, abdominal cramps or flatulence
  b. CNS effects, including headache, dizziness, insomnia, weakness or fatigue
  c. rash or itching
  d. flu-like symptoms or general malaise.

Health education for the person and family

- Teach the recommended method of administration, including how to insert rectal suppositories or administer a retention enema.
- Shake suspension forms well prior to using.
- Diarrhoea is the most common side effect of these drugs. Notify your doctor if adverse effects occur.

CORTICOSTEROIDS

Methylprednisolone (Medrol, Solu-Medrol)
Prednisolone (Delta-Cortel) Prednisone

Glucocorticoids are hormones produced by the adrenal cortex. See Chapter 18 for discussion on hormones and stress response. These hormones are necessary for the stress response. Cortisol, the main glucocorticoid, has potent anti-inflammatory effects. Corticosteroids are used to treat acute episodes of IBD. Because of their multiple and significant side effects, they are not used to maintain remission.

Nursing responsibilities

- Assess for conditions adversely affected by corticosteroid medications: peptic ulcer disease, glaucoma or cataracts, diabetes mellitus or psychiatric disorders.
- Obtain baseline vital signs and weight; monitor both routinely during therapy. Hypertension and weight gain may result from sodium and water retention.
- Monitor for oedema.
- Administer as ordered. For daily or alternate-day dosing, administer in the morning, when physiological glucocorticoid levels are highest, to reduce adrenal cortisone suppression.
- Administering oral preparations with food decreases gastrointestinal side effects. Antacids or histamine H_2-receptor blocking agents may be prescribed during corticosteroid therapy.
- Monitor for desired effects: reduced diarrhoea, less blood and mucus in the stool and less abdominal cramping.
- Monitor for adverse effects:
  a. increased susceptibility to infection and masking of early signs of infection
  b. hyperglycaemia
  c. hypokalaemia, as manifested by muscle weakness, nausea, vomiting and cardiac rhythm disturbances
  d. oedema, hypertension and signs of heart failure
  e. peptic ulcer formation and possible gastrointestinal haemorrhage (abdominal pain, black or tarry stools, and signs of bleeding)

(continued)

MEDICATION ADMINISTRATION Inflammatory bowel disease (continued)

f. changes in mental status, including depression, euphoria, aggression and behavioural changes
g. with long-term use, Cushingoid effects, such as abnormal fat deposits in the face (moon facies) and trunk (buffalo hump), muscle wasting and thin extremities, thinning of the skin and osteoporosis. See Chapter 18 for discussion of nursing care of a person with hypercortisolism (Cushing's syndrome).

Health education for the person and family

- Take as prescribed; do not change the dose or time of day. Do not stop the medication abruptly. The dose will be tapered down gradually when the medication is discontinued.
- Notify the doctor if adverse or Cushingoid effects occur.
- Take with food or at mealtimes to decrease the gastrointestinal effects.
- Monitor weight. If more than 2.5 kg gain is noted, notify the doctor.
- Moderate salt intake and avoid foods and snacks high in sodium, such as processed meats and potato chips. Increase intake of foods high in potassium, such as fruits, vegetables and lean meats.
- Carry a card or wear a MedicAlert® bracelet or tag at all times identifying corticosteroid use.

many individuals are unable to withdraw from steroid therapy without experiencing relapse and require long-term, low-dose therapy.

Mercaptopurine (6-MP, Purinethol) and other immunosuppressive agents such as azathioprine (Imuran) and cyclosporin (Sandimmun) are used to treat individuals unresponsive to other treatments or who require long-term steroid therapy. These drugs may allow withdrawal of corticosteroids, maintain remission and facilitate healing. Long-term therapy may be required to produce a beneficial effect. For more information about immunosuppressive medications, see Chapter 12.

Newer treatments for IBD employ other immune response modifiers, such as the monoclonal antibody infliximab (Remicade) to suppress tumour necrosis factor (TNF, an inflammatory mediator substance) in those unresponsive to standard therapies. Mesalazine (Mesal) is an orally or rectally administered anti-inflammatory medication providing topical anti-inflammatory action in the colon of individuals with ulcerative colitis.

Although antibiotic therapy generally is not indicated in IBD, metronidazole (Flagyl) has active anti-inflammatory effects. It may be prescribed to help prevent remission after ileal resection in Crohn's disease. Ciprofloxacin (Cipro) is an alternative to metronidazole.

Antidiarrhoeal agents, such as loperamide and diphenoxylate, may be given to slow gastrointestinal motility and reduce diarrhoea. These drugs are safe for individuals with mild, chronic manifestations. However, these are not given during acute attacks because they may precipitate toxic dilation of the colon.

Nutrition

Antigens in the diet may stimulate the immune response in the bowel, exacerbating IBD. As a result, dietary management for inflammatory bowel disease is individualised. Some people benefit from eliminating all milk and milk products from the diet. Increased dietary fibre may help reduce diarrhoea and relieve rectal manifestations. However, this is contraindicated for individuals with intestinal strictures caused by repeated inflammation and scarring.

All food may be withheld to promote bowel rest during an acute exacerbation of Crohn's disease. Nutritional status is maintained using enteral or total parenteral nutrition (TPN). See Chapter 21 for more information about enteral feedings and TPN. TPN carries a higher risk of complications than does enteral nutrition.

Surgery

Surgical interventions for IBD differ, depending on the primary disease process and the portion of bowel affected. Generally, surgery is performed only when necessitated by complications of the disease or failure of conservative treatment measures.

Bowel obstruction is the leading indication for surgery in Crohn's disease. Other complications requiring surgical intervention include perforation, internal or external fistula, abscess and perianal complications. Resection of the affected portion of bowel with an end-to-end anastomosis to preserve as much bowel as possible is the usual treatment. The disease process tends to recur in other areas following removal of affected bowel segments. There is an increased risk of fistula formation following surgery. Bowel strictures may be treated with a stricturoplasty in which longitudinal incisions are made in the narrowed segment, relieving the stricture while preserving bowel.

COLECTOMY Individuals with extensive chronic ulcerative colitis may require a total **colectomy** (surgical resection and removal of the colon) to treat the disease itself; for complications such as toxic megacolon, perforation or haemorrhage; or as a prophylactic measure due to the high colon cancer risk associated with extensive ulcerative colitis.

The surgical procedure of choice for extensive ulcerative colitis is a total colectomy with an *ileal pouch–anal anastomosis (IPAA)*. In this procedure, the entire colon and rectum are removed; a pouch is then formed from the terminal ileum and is brought into the pelvis and anastomosed to the anal canal (see Figure 23.10). A temporary or loop ileostomy (described in the next section) is generally performed at the same time and maintained for 2 to 3 months, allowing the anal anastomosis to heal. When the healing is complete, the ileostomy is closed. The person then has six to eight

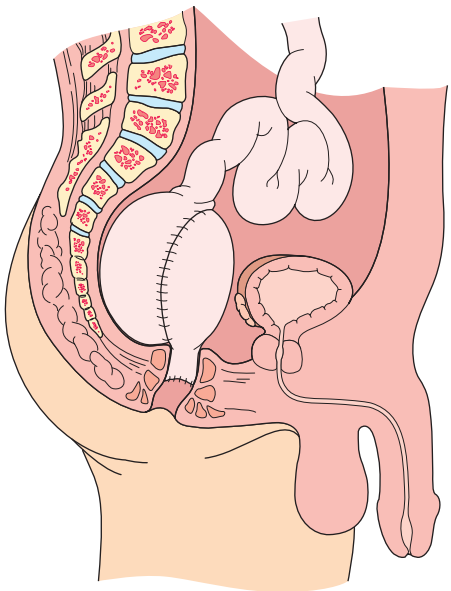

FIGURE 23.10 ■ Ileal pouch–anal anastomosis (IPAA)

daily bowel movements through the anus. Advanced age, obesity or other factors may preclude an IPAA. For these individuals, a permanent ileostomy or continent ileostomy may be created.

OSTOMY An intestinal ostomy is a surgically created opening between the intestine and the abdominal wall that allows the passage of faecal material. The surface opening is called a **stoma** (see Figure 23.11). The precise name of the ostomy depends on the location of the stoma. An **ileostomy** is an ostomy made in the ileum of the small intestine. In an ileostomy, the colon, rectum and anus are usually completely removed (*total proctocolectomy with permanent ileostomy*). The anal canal is closed and the end of the terminal ileum is brought to the body surface through the right abdominal wall to form the stoma. A *temporary* or *loop ileostomy* may be formed to eliminate faeces and allow tissue healing for 2 to 3 months

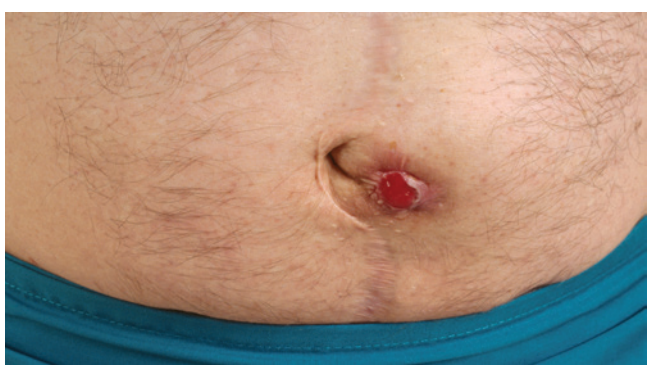

FIGURE 23.11 ■ A healthy-appearing stoma

Source: CMSP/Custom Medical Stock Photo.

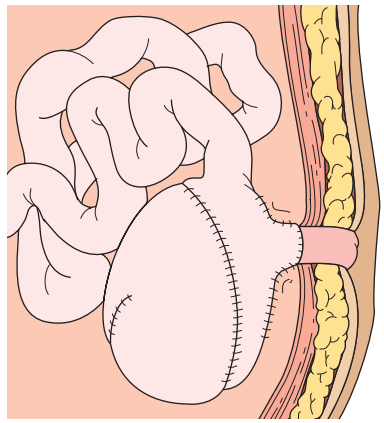

FIGURE 23.12 ■ Continent (Kock's) ileostomy

following an IPAA. A loop of ileum is brought to the body surface to form a stoma, allowing stool drainage into an external pouch. When the ileostomy is no longer necessary, surgery is performed to close the stoma and repair the bowel, restoring faecal elimination through the anus.

In a *continent ileostomy* (see Figure 23.12), an intra-abdominal reservoir is constructed and a nipple valve formed (the ileum folded back on itself) from the terminal ileum, before it is brought to the surface of the abdominal wall. Stool collects in the internal pouch. The nipple valve prevents leaking through the stoma. A catheter is inserted into the pouch to drain the stool.

Nursing care of a person with an ileostomy is outlined in the box below. When devising nursing care plans for a person requiring stoma care it is important to incorporate the person's cultural, religious and personal viewpoints into their care plan. Procedure 23.1 describes how to apply one- and two-piece drainable ostomy pouches.

Complementary and alternative therapies

The chronic nature of inflammatory bowel disease the adverse effects of many of the prescribed treatments leads up to 50% of people with IBD to seek or use complementary and alternative therapies. The most common complementary therapies used by people with IBD include herbal therapies, nutritional supplements, probiotics and fish oil (Solomon & Flum, 2015). Herbal remedies such as aloe vera gel and curcumin appear to have beneficial effects, as do Chinese traditional medicine including Jian Pi Ling tablets and Yukui tang tablets. Probiotics, bacteria similar to those normally found in the gut, appear to have beneficial anti-inflammatory effects in the bowel (Sharma, 2014a). Probiotics are available in foods such as yoghurt, miso and soy beverages, as well as in dietary supplements. Results are mixed from studies of the beneficial effects of fish oil or omega-3 fatty acid supplements for IBD. Peppermint tea is an excellent tonic for reducing nausea, relieving abdominal pain and providing a calming effect. Chamomile tea helps to reduce intestinal inflammation (Bullock & Manias, 2014).

NURSING CARE OF THE PERSON having an ileostomy

PREOPERATIVE CARE

- Provide routine pre-operative care and teaching as outlined in Chapter 3.
- Refer to a stomal therapist for marking and teaching about the stoma location, ostomy care and options for ostomy appliances. *It is important to begin teaching prior to surgery to facilitate learning and acceptance of the ostomy postoperatively.*
- Discuss the availability of a local Stoma Association and provide a referral as necessary or desired. *Local branches often have members with ostomies willing to provide both preoperative and postoperative teaching, listening and support.*
- Provide preoperative bowel preparation as ordered. *Laxatives, enemas and preoperative antibiotics are often ordered to reduce the risk of abdominal contamination and infection after surgery*.

POSTOPERATIVE CARE

- Provide routine postoperative care and teaching as outlined in Chapter 3.
- Apply an ostomy pouch over the stoma (see Procedure 23.1). *Stool from an ileostomy is expressed continuously or irregularly and is liquid in nature; continuous use of a pouch to collect the drainage is necessary.*
- Assess frequently for bleeding, stoma viability and function. In the early postoperative period, small amounts of blood in the pouch are expected. *A healthy stoma is pink or red and moist as a result of mucus production (see Figure 23.11) and protrudes approximately 2 cm from the abdominal wall. Frequent assessment is important in the initial postoperative period to ensure stoma health and to monitor for possible complications. A dusky, brown, black or white stoma indicates circulatory compromise. Other possible stoma complications include retraction (indentation or loss of the external portion of the stoma) or prolapse (outward telescoping of the stoma—that is, an abnormally long stoma).*
- As the stoma starts functioning, empty the pouch, explaining the procedure to the person. Initial drainage is dark green, viscid and usually odourless. Drainage gradually thickens and becomes yellow-brown. Empty the pouch when it is one-third full. Measure drainage and include it as output on fluid balance records. Rinse the pouch and reapply the clamp. *Emptying the pouch when it is no more than one-third full helps prevent the skin seal from breaking as a result of the weight of the pouch. Because of the potential for excess fluid loss through ileostomy drainage, it is important to include it as fluid output.*
- Assess the peristomal skin. Skin around the stoma should remain clean and pink and free of irritation, rashes, inflammation or excoriation. *Skin complications may arise from appliance irritation or hypersensitivity, excoriation from a leaking appliance or* Candida albicans *(a yeast infection).*
- Protect peristomal skin from enzymes and bile salts in the ileostomy effluent. Using a skin barrier on the pouch is essential. Change the pouch if leakage occurs or if the person reports burning or itching skin. *Enzymes and bile salts normally reabsorbed in the large intestine are irritating to the skin. Excoriation of skin surrounding the stoma impairs the first line of defence against microorganisms and can interfere with the ability to achieve a tight skin seal and prevent pouch leakage.*
- Report the following abnormal assessment findings to the surgeon:
  a. Allergic or contact dermatitis. *A rash may result from contact with faecal drainage or indicate sensitivity to pouch, paste, tape or sealant.*
  b. Purulent ulcerated areas surrounding the stoma. *Disruption of the protective barrier of the skin allows bacterial entry.*
  c. A red, bumpy, itchy rash or white-coated area. *This is a manifestation of* Candida albicans, *a yeast infection.*
  d. Bulging around the stoma. *This finding may indicate herniation, caused by loops of intestine protruding through the abdominal wall.*
- Apply protective ointments to the perirectal area of people with newly functioning ileoanal reservoirs and anastomoses. This helps protect the skin from the initial stools. *As stools thicken and become fewer per day, the person experiences less perirectal irritation.*

HEALTH EDUCATION FOR THE PERSON AND FAMILY

- While caring for the stoma, explain procedures to the person. *Teaching is immediate and ongoing to assist in acceptance of the stoma and facilitate self-care.*
- Teach to manage the pouch clamp, to empty, rinse and perform pouch changes. *Self-care is vital to independence and self-esteem.*
- Instruct now to use an electric razor to shave the peristomal hair if necessary. *An electric razor prevents accidental cutting of the stoma with a razor blade.*
- Teach to check the stoma and peristomal skin with each pouch change. Ongoing assessment is important for optimal health and function of the stoma and surrounding skin. Stripping of tape or excessively frequent pouch removal may cause mechanical trauma to peristomal skin. *Chronic skin irritation by ileostomy effluent may lead to pseudoverrucous lesions or wartlike nodules.*
- Instruct to report abnormal appearance of the stoma or surrounding skin (as noted previously and below) to the doctor:
  a. Narrowing of the stoma lumen. *This indicates stenosis and may interfere with faecal elimination.*
  b. Lacerations or cuts in the stoma. *The stoma contains no nerves, so trauma may occur without pain.*
  c. Separation of the stoma from the abdominal surface. *This potential complication may require surgical repair.*
- Emphasise the importance of adequate fluid and salt intake; the risk of dehydration and hyponatraemia is increased particularly during hot weather, when fluid is lost through perspiration as well as ileostomy drainage. Water intake should be sufficient to maintain pale urine and an output of at least 2.5 L per day. When exercising in

NURSING CARE OF THE PERSON having an ileostomy (continued)

hot weather, the person needs to consume extra water and salt. High-potassium foods, such as bananas and oranges, may also be recommended. *Loss of the re-absorptive surface of the large bowel increases the amount of water and sodium loss in the stool. If the ileostomy is high (more proximal in the ileum), additional potassium losses may also occur.*

- Discuss manifestations of fluid and electrolyte imbalances:
  a. Extreme thirst
  b. Dry skin and oral mucous membrane
  c. Decreased urine output
  d. Weakness, fatigue
  e. Muscle cramps
  f. Abdominal cramps, nausea, vomiting
  g. Shortness of breath
  h. Orthostatic hypotension (feeling faint when suddenly changing positions).
- Discuss dietary concerns. A low-residue diet is recommended initially (see Table 23.8). Foods causing excessive odour or gas are typically avoided as well. Because food blockage is a potential problem, high-fibre foods are limited and foods that may cause blockage, such as popcorn, corn, nuts, cucumbers, celery, fresh tomatoes, figs, strawberries, blackberries and caraway seeds, are avoided. *Symptoms of food blockage include abdominal cramping, swelling of the stoma and absence of ileostomy output for more than 4 to 6 hours.*
- Teach self-care measures to relieve food blockage:
  a. Take a warm shower or bath. *This can help relax the abdominal muscles.*
  b. Assume a knee–chest position. *The knee–chest position reduces intra-abdominal pressure.*
  c. Drink warm fluids or grape juice if not vomiting. *This provides a mild cathartic effect.*
  d. Massage peristomal area. *Massage may stimulate peristalsis and faecal elimination.*
  e. Remove pouch if the stoma is swollen and apply a pouch with a larger opening. *If the stoma swells, the pouch may create a mechanical obstruction to output.*
- Notify the doctor or stomal therapy nurse if:
  a. The above measures fail to relieve the obstruction.
  b. Signs of a partial obstruction persist, including high-volume odorous fluid output, abdominal cramps, nausea and vomiting.
  c. There is no ileostomy output for 4 to 6 hours.
  d. Clinical manifestations of fluid and electrolyte imbalance occur, such as weakness, dizziness, light-headedness or headache.

Should self-care measures not succeed in breaking up a blockage, ileostomy lavage, as described in Procedure 23.2, may be required.

TABLE 23.8 Low-residue diet

FOOD GROUP	ALLOWED	AVOID
Beverages	Coffee, teas, juices, carbonated beverages; milk limited to 300 mL per day	Alcohol, prune juice
Breads and cereals	Products made from refined flours (white bread, water crackers) or finely milled grains (e.g. cornflakes, rice bubbles, puffed wheat)	Wholegrain breads, rolls or cereal; breads or rolls with seeds, nuts or bran
Desserts	Gelatins, tapioca, plain custards or puddings; instant puddings; sponge cake; ice-cream or frozen desserts without fruit or nuts	Any desserts containing dried fruits, nuts, seeds or coconut; rich pastries, pies
Fruits	Fruit juices and strained fruits; cooked or canned apples, apricots, cherries, peaches, pears; bananas	All other raw or cooked fruits
Meats and other protein sources	Roasted, baked or grilled tender or minced beef, veal, pork, lamb, poultry or fish; smooth peanut butter; cottage, creamed cheese or mild cheddar cheeses in small amounts	Tough or spiced meats and those prepared by frying; highly flavoured cheeses; nuts
Potatoes, rice and pasta	Peeled potatoes; white rice; most pasta products	Potato skins, potato chips or fried potatoes; brown rice; wholegrain pasta products
Sweets	Sugar, honey, jelly, hard-boiled lollies and gumdrops, plain chocolates	Jam, marmalade; lollies made with seeds, nuts, coconut
Vegetables	Vegetable juices and strained vegetables; cooked or canned vegetables	Raw or whole cooked vegetables
Other	Salt, ground seasonings; cream sauce and plain gravy	Chilli sauce, horseradish; popcorn, seeds of any kind; whole spices, olives, vinegar

PROCEDURE 23.1 Changing a one- or two-piece drainable ostomy pouch

GATHER SUPPLIES

- Disposable gloves and personal protective equipment (PPE)
- One- or two-piece pouch
- Skin barrier paste
- Skin prep
- Clamp
- Pouch deodorant
- Measuring guide
- Adhesive remover
- Skin cleanser
- Wash cloths
- Plastic bag
- Bed protector
- Air freshener

BEFORE THE PROCEDURE

- Explain the procedure and provide for privacy.
- Position the person (assist as required) in a lying position making removing and applying the pouch easier.
- Use air freshener as required and preferred by the person.
- Follow standard precautions. Don PPE and gloves.

PROCEDURE

1. Remove soiled pouch (and the flange if a two-piece pouch) by gently pulling on the pouch or flange and pushing on skin. Use adhesive remover to remove skin barrier paste.
2. Empty pouch, discarding it and the flange (if applicable) in a plastic bag. Save the tail closure clamp. The pouch from a two-piece system may be cleaned out and reused.
3. Cleanse skin and stoma with warm water and skin cleanser or mild soap. Rinse skin and stoma and pat dry.
4. Note stoma colour and peristomal skin condition.
5. If necessary, clip or shave peristomal hair.
6. Use measuring guide or previous pattern to check size of stoma.
   a. Presized pouch: check to verify size is correct.
   b. Cut-to-fit pouch or flange: trace the correct size of the stoma onto the back of the flange and cut the opening to match the pattern. The opening should be no more than 3 to 4 mm larger than the stoma.
7. Apply skin prep to skin covered by a wafer, pouch or tape. Allow to dry.
8. Remove backings from pouch or flange.
9. Apply a bead of skin barrier paste around the stoma base or around the opening of the pouch or flange. Allow the paste to air dry for 1 to 2 minutes.
10. Centre the pouch or flange over the stoma and press to adhere.
11. For a two-piece pouch, snap the pouch onto the skin barrier flange.
12. Place deodorising powder or a few drops of liquid pouch deodoriser in the pouch. Apply the clamp.
13. 'Picture frame' the pouch with tape to provide extra security.

AFTER THE PROCEDURE

1. Leave the person comfortable.
2. Dispose of equipment correctly.
3. Document assessment of stoma and surrounding skin and the person's response to the procedure.

Anecdotal evidence supports the use of homeopathy to promote comfort in individuals with IBD. Acupuncture improves perceived wellbeing in people with IBD; however, it does not appear to effect remission (Lizarondo, 2015). Herbal remedies, such as slippery elm, fenugreek, devil's claw, Mexican yam, termentil and wei tong ning, have been found to have an antioxidant effects and may provide an effect similar to 5-aminosalicylic acid preparations (Lizarondo, 2015). Many complementary and alternative therapies for IBD may interact with prescribed medications; advise the person to discuss all potential therapies with the primary care provider. Acupressure, body massage, reflexology, aromatherapy and stress reduction therapies can also aid in reducing manifestations of IBD.

Nursing care

Health promotion

Although inflammatory bowel disease cannot, at this time, be predicted or prevented, effective management may help the person avoid complications of the disease. Stress the importance of following the prescribed treatment regimen and promptly reporting manifestations of exacerbations to the doctor.

PROCEDURE 23.2 Ileostomy lavage

GATHER SUPPLIES

- Disposable gloves and PPE
- Disposable irrigation sleeve
- 60 mL catheter-tipped syringe
- #14 Fr. catheter
- Water-soluble lubricant
- Normal saline for irrigation
- Bedpan
- Clean ostomy pouch
- Bed protector
- Air freshener

BEFORE THE PROCEDURE

- Explain the procedure and provide for privacy.
- Follow standard precautions.
- Don PPE and gloves.

PROCEDURE

1. Remove the pouch. Apply disposable irrigation sleeve.
2. Clamp the bottom of the sleeve or place it in the bedpan.
3. Gently examine stoma digitally to break up any faecal mass proximal to stoma and determine direction of the bowel.
4. Lubricate catheter and insert into stoma until blockage is reached. If the catheter does not reach the blockage after 8 to 10 cm, notify the doctor. This may indicate a more proximal obstruction.
5. Instill 30 to 50 mL normal saline.
6. Remove catheter. Allow stoma to drain.
7. Repeat the procedure until the mass is removed.
8. When the blockage is removed, remove the irrigation sleeve.
9. Clean peristomal skin.
10. Apply pouch and clamp.

AFTER THE PROCEDURE

1. Leave the person dry and comfortable.
2. Dispose of equipment correctly.
3. Document the procedure, amount of solution used, consistency of results and the person's response to the procedure.
4. Discuss dietary intake to help determine cause of blockage.

Assessment

Assessment data related to inflammatory bowel disease include the following subjective and objective data:

- *Health history:* current manifestations, including onset, duration, severity (number of stools per day, presence of blood or mucus in stool, abdominal pain or cramping, tenesmus); usual diet, ability to maintain weight and nutrition, smoking habits, food intolerances; associated manifestations such as arthralgias, fatigue, malaise; current medications; previous treatment and diagnostic tests.
- *Physical examination:* general appearance; weight; vital signs, including orthostatic blood pressure, pulse and temperature; abdominal assessment, including shape, contour, bowel sounds, palpation for tenderness and masses, presence of stoma or scars.

Nursing diagnoses and interventions

When planning nursing care with the person with inflammatory bowel disease, it is vital to consider the chronic, recurrent nature of the disorder. Religious and cultural beliefs must also be incorporated when planning care for a person with IDB. Teaching is a major aspect of care. Diarrhoea and disturbed body image are significant nursing care problems for a person with IBD. With severe disease, impaired nutrition must also be considered a priority problem. See accompanying nursing care plan for a person with ulcerative colitis.

Diarrhoea

During an acute exacerbation of IBD, diarrhoea can be frequent and painful. The frequency of defecation and associated abdominal pain and cramping may interfere with ADLs and increase the risk of fluid volume deficit and impaired skin integrity.

- Record the frequency, amount and colour of stools using a stool chart. Measure and record liquid stool as output. *The severity of diarrhoea is an indicator of the severity of the disease and helps determine the need for fluid replacement.*
- Monitor vital signs every 4 hours. *Tachycardia, tachypnoea and fever may be indicators of fluid volume deficit.*
- Weigh daily and record. *Rapid weight loss (over days to a week) usually indicates fluid loss, whereas weight loss over weeks to months may indicate malnutrition.*
- Assess for other indications of fluid deficit: warm, dry skin, poor skin turgor, dry shiny mucous membranes, weakness, lethargy, complaints of thirst. *The extent of fluid loss may not be readily evident with diarrhoea, particularly if the person uses the bathroom without assistance. Systemic manifestations of fluid volume deficit may be the first indicators of the problem.*
- Maintain bowel rest by keeping NBM or limiting oral intake to elemental feedings as indicated. *Bowel rest during an acute exacerbation of IBD promotes healing and reduces diarrhoea and other manifestations.*

CONSIDERATION FOR PRACTICE

Observe stools for obvious blood and test for occult blood as indicated. Report grossly bloody stools (haematochezia), which may indicate haemorrhage and necessitate emergency surgery.

NURSING CARE PLAN A person with ulcerative colitis

Estelle Lewis is a 42-year-old real estate agent and mother of three school-age children. Mrs Lewis has had ulcerative colitis for 18 years and has been treated with prednisone and sulfasalazine. Over the past 4 months she has been having abdominal pain and cramping and frequent bloody diarrhoeal stools. During the same period, she lost 9 kg and has had difficulty maintaining her career. She recently developed several lesions of the lower leg identified as erythema nodosum. A recent colonoscopy revealed extensive involvement of the entire colon. On admission, Mrs Lewis states, 'I'm tired of fighting this disease. I am a prisoner in my home because of the diarrhoea.' She is admitted for a total proctocolectomy and ileal pouch–anal anastomosis.

ASSESSMENT

Janet Wheeler, RN, completes the admission assessment. Mrs Lewis weighs 52.2 kg. She complains of abdominal cramping, pain and frequent bloody diarrhoeal stools. Several reddened lesions are noted on her lower legs. Physical assessment findings include T 36.6°C, P 72, R 20 and BP 104/72. Skin, peripheries cool and pale. Abnormal laboratory findings include haemoglobin 73 g/L (normal 117 to 157 g/L); haematocrit 23.3% (normal 35–47%); WBC 15 580/mm^3 (normal 3500 to 11 000/mm^3); platelet count 995 000/mm^3 (normal 150 000 to 450 000/mm^3); serum protein 46 g/L (normal 60 to 80 g/L); serum albumin 24 g/L (normal 35 to 50 g/L). Preparation for surgery is begun.

DIAGNOSES

- *Imbalanced nutrition: less than body requirements* related to impaired absorption.
- *Diarrhoea* related to inflammation of bowel.
- *Risk of deficient fluid volume* related to abnormal fluid loss.
- *Risk of impaired tissue integrity* related to drainage from temporary ileostomy.
- *Alteration in comfort* related to acute pain secondary to surgical intervention.
- *Risk of sexual dysfunction* related to temporary ileostomy.

PLANNING

When planning nursing care with Mrs Lewis, it is vital to consider her preferences. Religious and cultural beliefs are incorporated into her plan of care.

Expected outcomes

- Mrs Lewis will resume prescribed diet within 5 days after surgery.
- Mrs Lewis will demonstrate normal faecal elimination through the temporary ileostomy.
- Mrs Lewis will maintain adequate fluid balance.
- Mrs Lewis will demonstrate appropriate stoma care prior to discharge.
- Mrs Lewis will report a tolerable level of discomfort at rest and during activity.
- Mrs Lewis will verbalise feelings about sexuality and acknowledge importance of discussing sexual issues with partner.

IMPLEMENTATION

- Discuss with Mrs Lewis dietary modifications related to her nutritional status and presence of the ileostomy. Provide Mrs Lewis with a referral to a dietitian for diet planning and teaching.
- Explain to Mrs Lewis the importance of maintaining a high fluid intake and manifestations of dehydration.
- Teach Mrs Lewis to empty and change ileostomy pouch of choice.
- Teach Mrs Lewis stoma and peristomal skin assessment with each pouch change.
- Teach Mrs Lewis food blockage management.
- Provide Mrs Lewis with information about the Australian Stoma Appliance Scheme. It is subsidised by the Australian government and provides stoma products (medicine and appliances) for people with a permanent or temporary stoma free of charge to members of one of the 22 approved volunteer stoma associations.
- Refer Mrs Lewis to local Stoma Association.

EVALUATION

On discharge, Mrs Lewis is caring for her ileostomy by demonstrating her ability to empty, rinse and change the pouch. The stomal therapy nurse provided written and verbal instructions on ileostomy care. Mrs Lewis verbalises her understanding of the recommended diet and the need to limit high-fibre food intake and avoid enteric-coated and timed-release medications. The stomal therapy nurse discusses sexual aspects of having an ileostomy and has given Mrs Lewis a booklet, *A beginning not an end*, available through the Australian Council of Stoma Associations. Mrs Lewis is looking forward to the planned surgery to close the temporary ileostomy.

CRITICAL THINKING IN THE NURSING PROCESS

1. Why is a person with an ileostomy at risk of dehydration? How can Mrs Lewis monitor her fluid status at home?
2. Why were Mrs Lewis's haemoglobin and haematocrit low on admission? If her haemoglobin had been low but her haematocrit normal on admission, what might be the explanation?
3. Outline a teaching plan Mrs Lewis could be given for home care of her ileostomy.
4. Develop a care plan for Mrs Lewis for the nursing diagnosis *Risk of impaired skin integrity*.

REFLECTION ON THE NURSING PROCESS

1. What are the most important things you feel you have learned from the care planning for Mrs Lewis?
2. If you were caring for a person following the formation of an ileostomy, what additional knowledge and clinical skills do you require to care for a person postoperatively?

- Administer prescribed anti-inflammatory and antidiarrhoeal medications as indicated. *Anti-inflammatory medications reduce the extent of bowel inflammation and diarrhoea. Unless contraindicated, antidiarrhoeal medications help reduce fluid loss and increase comfort.*

CONSIDERATION FOR PRACTICE

When antidiarrhoeal medications are administered to a person with ulcerative colitis, closely observe for manifestations of toxic megacolon: fever, tachycardia, hypotension, dehydration, abdominal pain and cramping, and an abrupt relief of diarrhoea.

- Maintain fluid intake by mouth or intravenously as indicated. *The person with IBD requires fluid to replace ongoing losses, as well as fluid to meet the usual daily needs of the body. If an elemental diet or total parenteral nutrition is prescribed, additional fluids may be required to meet fluid intake needs.*
- Provide good skin care. *Fluid deficit and tissue dehydration increase the risk of skin excoriations or breakdown.*
- Assess perianal area for irritation or denuded skin from the diarrhoea. Use gentle cleansing agents, such as Peri-Wash, nappy wipes or cotton lint-free gauze squares saturated with witch hazel. Apply a protective cream, such as zinc-oxide-based preparations, to protect skin from the irritating effects of diarrhoeal stool. *Digestive enzymes in the stool are very corrosive, increasing the risk of skin breakdown where exposed to diarrhoeal stool.*

Disturbed body image

A person with IBD may experience frustration at not being able to control, or even predict, faecal elimination, particularly when the disease is severe. Diarrhoea interferes with the ability to complete tasks, maintain employment, engage in social activities and even to meet basic needs such as eating, sleeping and sexual activity. Body image can suffer as a result. Treatment of IBD, be it total colectomy with ileal pouch–anal anastomosis, ileostomy or chronic corticosteroid therapy, can affect the view of self.

- Provide care in an accepting, non-judgmental manner. *Acceptance of the person despite potential embarrassment about odours or diarrhoea enhances self-esteem.*
- Accept feelings and perception of self. *Negating or denying the reality of the person's perception impairs trust.*
- Encourage discussion of physical changes and their consequences as they relate to self-concept. *This demonstrates acceptance and provides an opportunity to express the impact of the disease and its treatment on the person's life.*
- Encourage discussion about concerns regarding the effect of the disease or treatment on close personal relationships. *This demonstrates understanding and provides an opportunity for the person to express feelings about the impact of the disease on relationships and significant others.*
- Encourage the person to make choices and decisions regarding care. *This increases the person's sense of control over the disease and their future.*
- Discuss possible treatment options and their effects openly and honestly. *Open discussion allows more informed decisions.*
- Involve the person in their care, teaching and demonstrating as needed. *This encourages and facilitates independence and decision making.*
- Arrange for interaction with other individuals or groups of people with IBD or ostomies. *The person may feel that someone who has not experienced a similar problem cannot understand their feelings.*
- Teach coping strategies (e.g. odour control, dietary modifications) and support their use. *This facilitates healthy adaptation to the disease.*

Imbalanced nutrition: less than body requirements

Crohn's disease can significantly alter the bowel's ability to absorb nutrients. In both forms of IBD, blood and protein-rich fluid may be lost in diarrhoeal stools. With malabsorption and continuing nutrient losses, multiple nutrient deficits can develop, affecting growth and development, healing, muscle mass, bone density and electrolyte balances.

- Monitor laboratory results, including haemoglobin and haematocrit, serum electrolytes, and total serum protein and albumin levels. *These studies provide an indicator of nutritional status.*
- Provide the prescribed diet: high-kilojoule, high-protein, low-fat diet with restricted milk and milk products if lactose intolerance is present. *Kilojoules and protein are important to replace lost nutrients. Fat restriction helps reduce diarrhoea and nutrient loss, particularly when significant portions of the terminal ileum have been resected.*
- Provide parenteral nutrition as necessary if the person is unable to absorb enteral nutrients. *Parenteral nutrition helps reverse nutritional deficits and promotes weight gain and healing in the individual with acute manifestations.*
- Arrange for dietary consultation. Consider food preferences as allowed. *Providing preferred foods in the prescribed diet increases intake and supports nutritional status.*
- Provide or administer elemental enteral nutrition and supplements as ordered. *Elemental enteral nutritional supplements support healing while providing for bowel rest. These replace losses and improve nutritional status more rapidly than diet alone.*
- Include family members—the primary food preparer, especially—in teaching and dietary discussions. *Families can reinforce teaching and help the person maintain required restrictions or kilojoule intake.*

Community-based care

Inflammatory bowel disease is a chronic condition for which the person provides daily self-management. For this reason, teaching is a vital component of care. Teach the person and their family about the following topics:

- the type of IBD affecting the person, including the disease process, short- and long-term effects, the relationship of stress to disease exacerbations and the manifestations of complications
- prescribed medications, including drug names, desired effects, schedules for tapering the doses if ordered (as with corticosteroids), and possible side effects or adverse reactions and their management
- the recommended diet and the rationale for any specific restrictions

- use of nutritional supplements such as Ensure to maintain weight and nutritional status
- indicators of malabsorption and impaired nutrition; recommendations for self-care and when to seek medical intervention
- if discharged with a central venous catheter and home parenteral nutrition, written and verbal instructions on catheter care, troubleshooting and TPN administration (i.e. have the person and a family member demonstrate catheter care and TPN maintenance)
- the importance of maintaining a fluid intake of at least 2 to 3 L per day, and of increasing fluid intake during warm weather, exercise or strenuous work, and when fever is present
- the increased risk of colorectal cancer and the importance of regular bowel exams
- risks and benefits of various treatment options.

If surgery is planned or has been done, include the following topics in home care instructions:

- ileal pouch–anal anastomosis or ileostomy care as indicated
- where to obtain ostomy supplies
- use of non-prescription drugs, such as enteric-coated and timed-release capsules that may not be adequately absorbed before elimination through the ileostomy
- community and national ostomy support groups (see below).

Provide referrals to a nutritionist, a community healthcare agency, home care services and home intravenous care services as indicated. In addition, suggest the following resources:

- Crohn's & Colitis Australia
- Australian Council of Stoma Associations.

MALABSORPTION SYNDROMES

Malabsorption is a condition in which the intestinal mucosa ineffectively absorbs nutrients—including carbohydrates, proteins, fats, water, electrolytes, minerals and vitamins—resulting in their excretion in the stool. Multiple bowel disorders can lead to malabsorption.

Diseases of the small intestine often cause malabsorption. Other medical and/or surgical conditions can result in malabsorption if these affect digestion or the intestinal mucosa. Primary diseases of the small-bowel mucosa, such as coeliac disease (also known as tropical and non-tropical sprue), Crohn's disease and acute gastrointestional tract infections, can lead to malabsorption. It can also result from maldigestion (inadequate preparation of chyme for absorption). For example, major gastric resections, pancreatic disorders with impaired pancreatic enzyme secretion and biliary disorders affecting bile secretion impair digestion and absorption of chyme. Selected causes of impaired absorption and digestion are listed in Table 23.9.

TABLE 23.9 Selected causes of malabsorption

CAUSE	RELATED FACTORS OR CONDITIONS
Impaired absorption	Tropical sprue Short bowel syndrome Acute enteritis and other bowel infections or infestations AIDS-related opportunistic infections and Kaposi's sarcoma Coeliac disease (non-tropical sprue) Crohn's disease Intestinal ischaemia or infarction Scleroderma
Impaired digestion	Lactose intolerance Gastrectomy Chronic pancreatitis, cancer of the pancreas Cystic fibrosis Biliary obstruction Cirrhosis, hepatitis or liver failure Zollinger–Ellison syndrome

Regardless of the cause, malabsorption causes common manifestations resulting from impaired absorption of chyme and the nutrients it contains (see Table 23.10). Predominant GI manifestations include anorexia; abdominal bloating; diarrhoea with loose, bulky, foul-smelling stools; and steatorrhoea (fatty stools). Weight loss, weakness, general malaise, muscle cramps, bone pain, abnormal bleeding and anaemia are common systemic manifestations of malabsorption. These manifestations result from malnutrition and fluid loss due to poor absorption.

Three common malabsorption disorders in adults are coeliac disease (non-tropical sprue), lactose intolerance and short bowel syndrome.

THE PERSON WITH SPRUE

Sprue is a chronic primary disorder of the small intestine in which the absorption of nutrients, particularly fats, is impaired. The severity of the disease depends on the extent of mucosal involvement in the intestine and the duration of the disease. Two major forms of sprue are coeliac disease (coeliac or non-tropical sprue) and tropical sprue.

Pathophysiology

Most absorption of nutrients occurs in the small intestine. The mucosa of the small intestine is arranged in microscopic folds, containing even smaller finger-like projections called *villi*. The cells of the villi are covered with microscopic hairs, *microvilli*, projecting from the cell membrane. The folds, villi and microvilli of the intestinal mucosa provide a huge surface area for nutrient absorption. Cells of the intestines are specialised to absorb different nutrients. Readily digested nutrients are absorbed in the proximal intestine; others are absorbed more distally in the intestines. Nutrients are absorbed by the processes of simple diffusion (water and small lipids), facilitated diffusion (water-soluble vitamins) and active transport (glucose and amino acids). Once

TABLE 23.10 Local and systemic manifestations of malabsorption

CATEGORY	MANIFESTATION	CAUSE
Local (GI)	Diarrhoea	Disruption of bowel mucosa impairing absorption of fluid and electrolytes, leading to excess water in the stool
	Abdominal distension	Gas formation from fermentation of undigested carbohydrates
	Steatorrhoea	Impaired fat absorption, leading to excess fat in faeces
Systemic	Weight loss	Carbohydrate, protein and fat deficit
	Weakness and malaise	Kilojoule deficit, anaemia, fluid and electrolyte losses
	Anaemia	Vitamin B_{12}, folic acid and iron deficits
	Bone pain	Calcium and vitamin D deficits
	Muscle cramps, paresthesias	Protein wasting, vitamin B_{12} and electrolyte deficits
	Easy bruising and bleeding	Vitamin K deficit
	Glossitis, cheilosis	Iron, folic acid and vitamin B_{12} deficits

absorbed into the cells of the villi, nutrients enter the blood or lymph for systemic distribution.

Sprue is characterised by flattening of the intestinal mucosa with a loss of villi and microvilli. With the loss of villi, intestinal absorptive surface is lost and digestive enzyme production, including disaccharidase and particularly lactase, is reduced.

Coeliac disease

Coeliac disease, also known as coeliac sprue or *non-tropical sprue* and gluten-sensitive enteropathy, is a chronic immune-mediated malabsorption disorder characterised by sensitivity to the gliadin fraction of gluten, a cereal protein. Gluten is found in wheat, rye, barley and oats. It is also used as filler in many prepared foods and in medications. The cause of coeliac disease is unknown; however, genetic, environmental and immune factors are known to play a role in its development. The development of coeliac disease involves a particular genetic make-up (HLA type), with the genes HLA-DQ2 and HLA-DQ8 being identified as the 'coeliac genes' (Porth & Matfin, 2013). Coeliac disease more commonly affects Caucasians and West Asians. It is uncommon in the East Asian and Australian Aboriginal and Torres Strait Islander populations (Gastroenterological Society of Australia (GSA), 2007). Environmental factors also play a role. Coeliac disease was considered a rare malabsorption syndrome manifesting during early childhood; however, it is one of the most common genetic diseases, with a mean prevalence of 1% in susceptible populations (Porth & Matfin, 2013).

In coeliac disease, it appears that the intestinal mucosa is damaged by an immunological response. Gliadin acts as an antigen (a substance inducing the formation of antibodies interacting specifically with it), prompting an inappropriate T-cell-mediated immune response. People with coeliac disease have increased antibodies to other antigens as well. The immune response prompts an inflammatory response in the small bowel, resulting in loss of intestinal folds and absorptive surface. Digestive enzyme production, including disaccharidase and particularly lactase, is reduced. The proximal small bowel is affected to the greatest extent, likely due to its greater exposure to dietary gluten.

Manifestations

Manifestations of coeliac sprue may develop at any age. Local manifestations include abdominal bloating and cramps, diarrhoea and steatorrhoea. Systemic manifestations result from the effects of malabsorption and resulting deficiencies. Anaemia is common. People with coeliac disease are often small in stature and may have delayed maturity. Other signs of nutrient deficiencies include tetany, vitamin deficiencies, muscle wasting and osteomalacia (impaired bone development). When gluten is removed from the diet, these manifestations resolve.

Gastrointestinal malignancies and intestinal lymphoma are potential complications of coeliac disease. Other complications include intestinal ulceration and development of refractory sprue or disease no longer responding to a gluten-free diet.

Tropical sprue

Tropical sprue is a chronic disease of unknown cause, although bacterial infection or toxins are thought to contribute. It seems likely that tropical sprue is not a single disease, but rather a pathophysiological process with manifestations resulting from a combination of the initial infection and the person's diet, living standards and genetic predisposition. A milder form of this may lead to asymptomatic abnormalities referred to as tropical enteropathy, while more severe expression leads to debilitating tropical sprue syndrome. The nature and the extent of the nutritional deficiencies are likely to be related to the duration of the disease and the extent of bowel involved (Beeching & Beadsworth, 2014). Tropical sprue occurs chiefly in the Caribbean, south India and South-East Asia. Hanson (2005) described three cases of tropical sprue in Aboriginal people living in remote Aboriginal or Torres Strait Islander communities in far north Queensland. A number of studies of chronic diarrhoea in Australian Aboriginal and Torres Strait Islander children have documented partial villous atrophy on small bowel biopsy. Additionally, other studies identified higher colony counts and more frequent isolation of gram-negative organisms in duodenal aspirates from Australian Aboriginal and Torres Strait Islander children with chronic diarrhoea. Some of these studies, Hanson (2005) noted, had similarity with contemporary Indian studies of tropical sprue, suggesting that tropical sprue should be considered in people from remote Australian Aboriginal or

Torres Strait Islander communities presenting with weight loss, diarrhoea and nutritional deficiency. The pathophysiological changes in bowel mucosa closely resemble those of coeliac sprue, although gluten intake has no effect on this condition. Its onset may be abrupt or insidious.

Manifestations

Clinical manifestations of tropical sprue include sore tongue, diarrhoea and weight loss. Initially, diarrhoea may be explosive and watery; as the disease progresses, stools become fewer in number and more solid with obvious steatorrhoea. Folic acid deficiency is common. Vitamin B_{12} and iron deficiencies may occur, resulting in glossitis; stomatitis; dry, rough skin; and anaemia.

INTERPROFESSIONAL CARE

With any malabsorptive disorder, the initial focus of management is to identify the cause. Once this has been determined, specific therapy can be prescribed.

Diagnosis

Laboratory and diagnostic testing are used to make the differential diagnosis for various causes of malabsorption syndromes and determine the severity of nutrient deficiencies.

An endoscopy permits direct examination of intestinal mucosa and collection of a tissue specimen for biopsy. Upper GI series with small-bowel follow-through may be done to evaluate the structures of the upper GI tract. With sprue, the typical 'feathery' pattern of barium in the small bowel is lost and the barium may precipitate and clump. Nursing implications of diagnostic tests are included in Chapter 20.

Laboratory tests are used to identify pathophysiological effects and monitor concordance with the prescribed diet. Faecal fat is measured to document the presence of steatorrhoea. The expected result is 2 to 7 g per 24 hours for adults (Kee, 2013). The fat content of stool is increased in many malabsorptive disorders, including coeliac and tropical sprue. Serological testing for IgA endomysial antibodies and IgG and IgA antigliadin antibodies is used to diagnose coeliac disease and evaluate concordance with the prescribed gluten-free diet. Serum levels of protein, albumin, cholesterol, electrolytes and iron may be ordered to evaluate for nutrient deficiencies. The haemoglobin, haematocrit and RBC indices are used to evaluate anaemia. Prothrombin time is increased in vitamin K deficiency.

Medications

Individuals with severe nutritional deficits require vitamin and mineral supplements, as well as iron and folic acid to correct anaemia. Vitamin K may be administered parenterally if the prothrombin time is prolonged. In those whose disease fails to respond to dietary management, corticosteroids may be ordered to suppress the inflammatory response.

Tropical sprue is treated with a combination of folic acid and tetracyclines. This regimen is continued for 3 to 6 months.

Nutrition

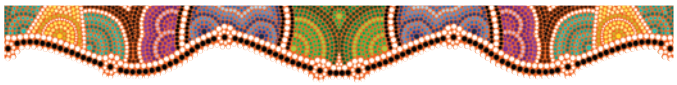
An individual with coeliac disease is placed on a gluten-free diet. The GSA (2007) stresses that all people with coeliac disease require a strict gluten-free diet irrespective of clinical manifestations of the disease. This treatment is generally successful, as long as the individual avoids gluten totally. However, gluten is so widely used in prepared foods that this is no easy task. In Australia, food labelled gluten-free contains no detectable gluten, oats or malt, and most packaged food containing grain (wheat, rye, oats or barley (GSA, 2007)) must list gluten. Individuals need to be aware of hidden sources of gluten and to analyse dietary labels. The GSA (2007) warns that alchoholic beverage labels are not required to list ingredients derived from gluten-containing grain, and highlights that all regular beers contain gluten. Common sources of gluten and foods to be avoided are indicated in Table 23.11.

Consultation with a nutritionist to obtain detailed dietary instructions is necessary.

TABLE 23.11 Dietary sources of gluten

FOOD GROUP	CONTAINS GLUTEN	MAY CONTAIN GLUTEN
Cereals, grains and grain products	Bread, biscuits, cereal and pasta containing wheat, rye or barley grain or flour	Seasoned rice and potato mixes
Beverages	Malt, Milo, Ovaltine, beers and ales	Commercial chocolate milk, cocoa and other beverage mixes, such as instant tea mix, dietary supplements
Desserts	Cakes, biscuits and pastries made with wheat, rye or barley flour	Commercial ice-cream and gelato
Meats and other protein sources		Meat loaf, manufactured and prepared meats, crumbed meats and fish; cheese products; soy protein meat substitutes; commercial egg products
Fruits and vegetables		Commercial seasoned vegetable mixes or vegetables with sauce; canned baked beans; commercial pie fillings
Miscellaneous		Commercial salad dressings and mayonnaise; tomato sauce and prepared mustard; gravy, white sauce; non-dairy creamer; syrups; commercial pickles

The prescribed diet is high in kilojoules and protein to correct nutrient deficits. Fat content is restricted to minimise steatorrhoea. Initially, the diet is usually restricted in lactose as well to compensate for the loss of lactase-containing microvilli. Foods containing lactose may be reintroduced once remission has occurred (Marieb & Hoehn, 2013).



Nursing care

Nursing care of a person with sprue (tropical and non-tropical) focuses on the effects of the disorder on health and nutrition, as well as the person's ability to manage their disease.

Assessment

- *Health history:* onset, duration and severity of manifestations; number and character of stools; history of travel to the Caribbean, southern India or South-East Asia, or living in remote Indigenous communities in northern Queensland; previous teaching related to the disorder; current treatment and diet.
- *Physical examination:* vital signs; abdominal shape, contour, bowel sounds; manifestations of malnutrition (e.g. anaemia, small stature, muscle wasting, signs of other nutrient deficiencies).

Nursing diagnoses and interventions

Diarrhoea and malnutrition are significant problems for a person with sprue and the priority foci for nursing intervention.

Diarrhoea

Steatorrhoea and diarrhoea typically occur with sprue because fat, water and other nutrients are poorly absorbed, remaining in the bowel to be eliminated in the stool. Diarrhoea interferes with lifestyle, ADLs, skin integrity, and fluid and electrolyte balance.

- Assess and document the frequency and nature of stools. *Bowel elimination reflects the severity of the disease and efficacy of treatment. With effective treatment, stools become less frequent and more normal in colour and appearance.*
- Weigh daily, monitor intake and output, and assess skin turgor and mucous membranes for indications of fluid balance. *Diarrhoea increases the risk of hypovolaemia and dehydration resulting from excess fluid loss in the stool.*
- Assess and document perianal skin condition. *Frequent defecation irritates skin and mucous membranes, increasing the risk of breakdown.*
- Encourage a liberal fluid intake. *Oral fluids help replace fluid lost through diarrhoeal stool.*

Imbalanced nutrition: less than body requirements

Coeliac disease is a chronic condition. With continuing malabsorption, multiple nutrient deficits may occur, resulting in impaired growth and development, impaired healing, muscle wasting, bone disease and electrolyte imbalances.

- Maintain accurate dietary intake records. *Assessment of dietary intake provides information about compliance with the prescribed diet as well as the adequacy of nutrient intake.*
- Monitor laboratory results, including haemoglobin and haematocrit, serum electrolytes, total serum protein and albumin levels. *These studies provide information about nutritional status.*
- Arrange for nutritionist consultation. Provide for food preferences as allowed. *An individualised diet developed to address the person's food preferences as well as nutrient needs will promote appetite and food intake.*
- Provide the prescribed high-kilojoule, high-protein, low-fat, gluten-free diet for the person with coeliac disease. Restrict lactose (dairy product) intake as indicated. *Kilojoules and protein are important to replace lost nutrients. Fat restriction helps reduce diarrhoea and nutrient loss. Lactose may be restricted during initial treatment and then slowly reintroduced into the diet as the gut heals and its normal structure is restored.*
- Provide parenteral nutrition as ordered if the person is unable to absorb enteral nutrients. *Parenteral nutrition can help reverse nutritional deficits and promote weight gain when manifestations are acute.*
- Encourage nutritional supplements. *Nutritional supplements often are necessary to replace losses and restore nutrient levels to normal more rapidly than diet alone can achieve.*

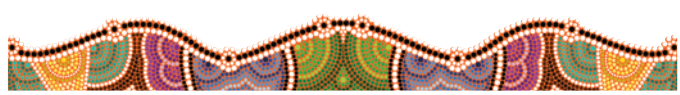
Include family members—the primary food preparer, in particular—in teaching and dietary discussions. *Families can reinforce teaching and help the person maintain required restrictions or kilojoule intake.*

Community-based care

Although tropical sprue is treated with antibiotic and folic acid therapy, *a person with coeliac sprue has a chronic condition requiring lifelong dietary management.* Encourage the person to join the Coeliac Society of Australia (CSofA). The CSofA provides information, including the availability of gluten-free foods, recipes and support for individuals with coeliac disease and their families (CSofA, 2015).

Provide a detailed list of foods containing gluten which need to be eliminated from the person's diet, as well as foods that are allowed. Teach the person and their family how to identify gluten-containing commercial products by reading labels and lists of ingredients. Encourage the purchase and use of a gluten-free cookbook.

If corticosteroids are prescribed, stress the importance of taking the medication as ordered. Emphasise the need to avoid stopping the medication abruptly and to notify all caregivers that a corticosteroid is part of the individual's medication regimen. Instruct to monitor weight frequently. A weight gain of 2.3 kg or more in less than a week usually reflects fluid gain, a possible adverse effect of corticosteroids. Other potential effects include decreased resistance to infection, an impaired inflammatory response and changes in carbohydrates, protein and fat metabolism.



THE PERSON WITH LACTASE DEFICIENCY

For carbohydrates to be absorbed from the small intestine, they first must be broken down into simple sugars (monosaccharides). Lactose is the primary carbohydrate in milk and milk products. It is a disaccharide, requiring the enzyme lactase for digestion and absorption. Lactase deficiency leads to lactose intolerance and manifestations of malabsorption. Lactase deficiency is usually genetic in origin, but also occurs secondarily to coeliac disease, Crohn's disease and other disorders affecting the mucosa of the small intestine. There is a racial/ethnic component to the disorder; it is rare for Caucasians to develop lactose intolerance. However, it is common among people from Asia, Africa, the Middle East and some Mediterranean countries, as well as among Australian Aboriginal and Torres Strait Islander peoples (Genauer & Hammer, 2010).

Manifestations

Many people with lactase deficiency are asymptomatic. Small to moderate amounts of milk (250 mL) may be well tolerated. Manifestations of lactose intolerance include lower abdominal cramping, pain and diarrhoea following milk ingestion. Undigested lactose ferments in the intestine, forming gases and contributing to bloating and flatus. Lactic and fatty acids produced by this fermentation irritate the bowel, leading to increased motility and abdominal cramping. The undigested lactose draws water into the intestine, leading to increased motility and diarrhoea. The diarrhoea associated with lactose intolerance may be explosive.

INTERPROFESSIONAL CARE

The diagnosis of lactose intolerance is usually based on a history of intolerance to milk and milk products and a trial of a lactose-free diet. If manifestations resolve when lactose intake is eliminated, the diagnosis of lactose intolerance is confirmed.

Diagnosis

The lactose breath test is a non-invasive test used to diagnose lactose intolerance. Expired hydrogen gas (H_2) is measured following oral administration of 50 g of lactose. If lactose is digested and absorbed normally, then little change occurs in the amount of exhaled H_2 from fasting to post lactose administration. With lactose intolerance, exhaled H_2 increases following lactose administration as the sugar ferments in the bowel.

For the *lactose tolerance test*, 100 g of lactose solution is orally administered, followed by measurement of blood glucose levels at intervals of 30, 60 and 120 minutes. If lactose is digested and absorbed normally, the blood glucose rises more than 20 mg/dL. The expected blood glucose elevation does not occur in lactose intolerance.

Nutrition

A lactose-free or reduced lactose diet relieves the manifestations of the disorder. Some people require total elimination of milk and milk products from the diet. Many can tolerate limited amounts of lactose. Avoid low-fat or non-fat milk as this travels quickly through the gut and tends to cause symptoms in those who are lactose intolerant. Also, many low-fat milk products contain skim-milk powder, providing a higher lactose dose. The fat content in full-cream milk slows the absorption of the milk through the intestines, allowing the lactase enzymes more time to break down the sugars. Milk pre-treated with lactase is available. Non-prescription lactase enzyme preparations are available to improve milk tolerance. Yoghurt containing bacterial lactases may be well tolerated. Soy foods are lactose free and provide a good substitute source of calcium. Calcium supplements are often recommended, particularly for women on a reduced-lactose or lactose-free diet.

Nursing care

Nursing care for a person with lactose intolerance focuses on providing education and support. Discuss sources of lactose: milk, ice-cream and cottage cheese are high in lactose; aged cheese and yoghurt contain much smaller amounts. Potential hidden sources of lactose include desserts made from milk and milk chocolate, sauces and gravies, and cream soups. Suggest a trial of lactase-treated milk or lactase enzyme supplements. Emphasise the importance of obtaining nutrients contained in dairy products from other sources. Proteins may be obtained from meats, eggs, legumes and grains. Other sources of calcium include soy products, sardines, oysters and salmon, as well as plant sources such as beans, cauliflower, rhubarb and green leafy vegetables.

THE PERSON WITH SHORT BOWEL SYNDROME

The small bowel may be resected due to tumours, infarction of bowel mucosa, incarcerated hernias, Crohn's disease, trauma and enteropathy resulting from radiation therapy. Resection of significant portions of the small intestine may result in a condition known as *short bowel syndrome*. The severity of the disorder depends on the total amount of bowel resected, as well as the portions of bowel removed. Removal of the proximal portions, including the duodenum, jejunum and proximal ileum, and of the distal portion of the ileum is associated with more severe malabsorption and manifestations than is resection of mid portions of the ileum.

Resection of the small intestine affects the absorption of water, nutrients, vitamins and minerals. Transit time of ingested foods and fluids is reduced and digestive processes are impaired. The bowel undergoes an adaptive process in which the remaining villi enlarge and lengthen to increase the absorptive surface following resection. For many people, absorption and bowel function return to preoperative or near-normal levels. Others continue to have

significant impairment of digestion and absorption, leading to nutrient deficiencies, weight loss and diarrhoea.

INTERPROFESSIONAL CARE

Management of short bowel syndrome focuses on alleviating manifestations. The person often requires frequent, small, high-kilojoule and high-protein meals.

Diagnosis

Laboratory and diagnostic studies are used to evaluate nutrient deficiencies. Total serum proteins and albumin are reduced, as are serum levels of folate, iron, vitamins, minerals and electrolytes. Anaemia and a prolonged prothrombin time (indicative of vitamin K deficiency) may develop.

Medications

Multivitamin and mineral supplementation are also frequently necessary. Antidiarrhoeal medications are used to reduce bowel motility, allowing a greater amount of time for nutrient absorption. Some people are affected by gastric hypersecretion following bowel resection. For these individuals, a proton-pump inhibitor such as omeprazole (Losec) may be ordered. Individuals with severe manifestations of short bowel syndrome may require TPN.

Nursing care

Nursing care for a person with short bowel syndrome focuses on the problems of potential fluid volume deficit, malnutrition and diarrhoea.

Fluid losses are generally greatest in the initial periods following surgery, warranting the closest attention during that time. Close monitoring of vital signs, intake and output, daily weights, skin turgor and condition of mucous membranes is vital. It is important to remember the risk is also high when other abnormal fluid losses occur through, for example, fever, wound drainage or excessive diaphoresis.

Documentation of nutritional status includes weight, anthropometric measurements, laboratory values and kilojoule intake. Provide nutritional supplementation with enteral feedings as needed. Maintain central lines and TPN, using aseptic technique.

For diarrhoea, document the number, volume and character of stools. Administer antidiarrhoeal medications as ordered. If the person is lactose intolerant, limit intake of milk and milk products. Provide good skin care for the perianal region to prevent breakdown from frequent bowel movements. Refer to the discussion of nursing care for a person with coeliac disease for other measures for altered nutrition and diarrhoea.

A person affected by this condition and their family require extensive education. Because there is no way to cure or replace the lost bowel, the individual must manage the disorder on a daily basis. Provide instructions about the recommended diet and medication regimen. Emphasise the importance of maintaining an adequate fluid intake, particularly in hot weather or during strenuous exercise. Teach the person to monitor their weight frequently and report changes. Include teaching about possible manifestations of dehydration and nutrient deficiencies to be reported to the doctor. Referring the person to a nutritionist or counsellor helps the person manage and cope with what will be a lifelong condition.

NEOPLASTIC DISORDERS

Cancer is the fourth leading cause of death in Australia, preceded by heart disease, stroke, and dementia and Alzheimer's disease (Australian Bureau of Statistics (ABS), 2015). Although cancer may affect any portion of the digestive tract, the large intestine and rectum are common sites. Colorectal cancer (CRC) comprises cancers of the colon and rectum, the two main sections of the large bowel. It is the most commonly diagnosed cancer in Australia after prostate cancer and is a major contributor to mortality, making it a significant healthcare concern (ABS, 2015).

THE PERSON WITH POLYPS

A *polyp* is a mass of tissue arising from the bowel wall and protruding into the lumen. Polyps may develop in any portion of the bowel, occurring most often in the sigmoid colon and rectum. They vary considerably in size and may be single or multiple. It is estimated that approximately 30% of people over the age of 50 have polyps. Although most polyps are benign, some have the potential to become malignant. Familial adenomatous polyposis (FAP) is a syndrome with a dominant inheritance pattern leading to hundreds to thousands of adenomatous polyps developing. Some of these polyps inevitably become malignant (Fauci et al., 2008).

Pathophysiology

Polyps are identified by their structure and tissue type. Most polyps are adenomas, benign epithelial tumours considered premalignant lesions. More than 95% of adenocarcinomas arise from adenomas. However, less than 1% of polyps become malignant (Shussman & Wexner, 2014). Of polyps removed during colonoscopy, more than 70% are adenomatous (Shussman & Wexner, 2014).

Adenomatous polyps represent disruption of the normal process of cell proliferation to replace epithelial cells lining the intestine. Cells are constantly being reproduced

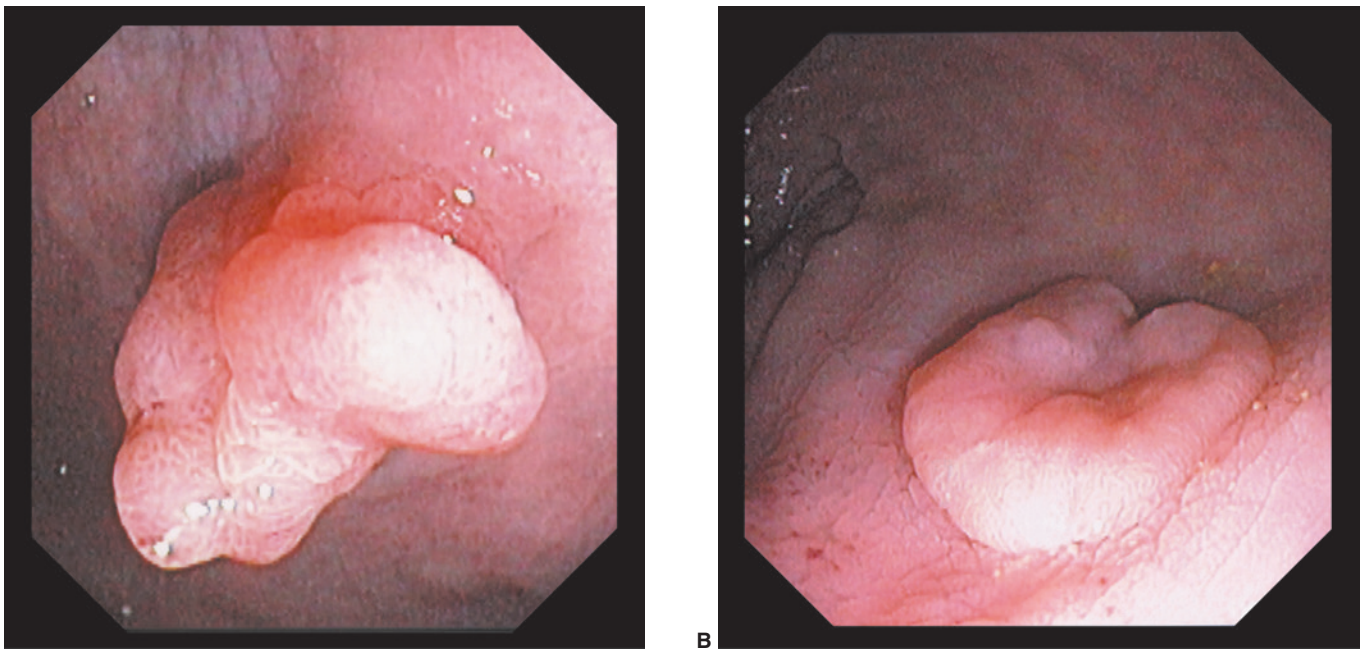


FIGURE 23.13 ■ *A*, Tubular (or pedunculated) polyps; *B*, villous (or sessile) polyps

Source: © David M. Martin MD/Science Source.

to replace those shed as faeces move through the colon. Disruption of the normal process of cell division and maturation lead to formation of a polyp composed of tightly packed epithelial cells. The cells may appear grossly normal or show signs of dysplasia. Polyps may develop as tubular, villous or tubulovillous adenomas. Polyps are named by the way they are attached to the bowel wall as either sessile (raised nodules) or pedunculated (attached by a stalk) (see Figure 23.13).

Tubular adenomas (also called pedunculated polyps) are more common than sessile polyps and account for about 65% of benign polyps of the large intestine (Marieb & Hoehn, 2013). A tubular adenoma is a globe-like structure attached to the intestinal wall by a thin, stalk-like stem. The incidence of this type of polyp increases with age, although it occurs in all age groups and in both genders. Most are small, 1 cm or less in diameter, although they may be as large as 4 to 5 cm. The malignant potential of these polyps seems to be related to their size. Adenomas smaller than 1 cm have a low risk of being malignant and adenomas larger than 1 cm have a much higher risk of harbouring malignancy or a high-grade dysplasia. Adenomatous polyps are present in 35% of adults over 50 years of age (Shussman & Wexner, 2014).

Villous adenomas (also called sessile polyps) are broad based with an elevated, cauliflower-like surface (see Figure 23.13B). These typically develop in the rectosigmoid colon. This type of polyp is often larger than tubular adenomas; usually more than 5 cm. Villous adenomas are not common, accounting for about 10% of colon polyps. These have a higher malignant potential than tubular adenomas. Some adenomatous polyps contain both tubular epithelium and villi and are known as *tubulovillous adenomas*.

Manifestations

Most polyps are asymptomatic, found coincidentally during routine examination or diagnostic testing. Intermittent painless bright or dark red rectal bleeding is the most common presenting complaint. A large polyp may cause abdominal cramping, pain or manifestations of obstruction. Diarrhoea and mucus discharge are associated with a large villous adenoma.

INTERPROFESSIONAL CARE

The diagnosis of intestinal polyps is generally based on diagnostic studies such as sigmoidoscopy or colonoscopy. A rectal polyp may be palpable on digital examination. However, further studies are necessary to determine its size and type and the extent of colon involvement and to assess for malignancy.

Once identified, polyps are removed because of the risk of malignancy. Pedunculated polyps and small villous lesions may be removed during colonoscopy using an electrocautery snare or hot biopsy forceps passed through the scope. This relatively safe procedure has less than a 2% risk of complications such as perforation or haemorrhage. Large villous adenomas are completely excised and examined histologically for evidence of malignancy. In some cases, the colon segment containing the polyp is resected. A person with FAP usually undergoes a total colectomy with ileorectal anastomosis before age 20 years to significantly reduce their risk of developing colon cancer.

Treatment following polypectomy depends on histological examination of the excised tissue. Because polyps tend to

recur, follow-up colonoscopy is recommended in 3 years and then every 5 years if no further polyps are detected. When the polyp is found to be malignant, follow-up care is determined by the tissue type and degree of invasion.

Nursing care

Health promotion

The incidence of intestinal polyps increases with age. They affect men and women equally. It is believed an adenomatous polyp requires more than 5 years of growth to become significant in size and malignant potential. Advise the individual to have a screening for colorectal cancer (with a colonoscopy being the 'gold standard' for diagnosis) at age 50 and as recommended thereafter for early detection of polyps (Australian Institute of Health and Welfare (AIHW), 2015).

Assessment

Polyps are a 'silent' disease, with few or no manifestations.

- *Health history:* rectal bleeding; personal or family history of intestinal polyps or colorectal cancer.

Nursing diagnoses and interventions

Nursing care for a person with polyps focuses on informing and assisting the person through diagnostic testing and polyp removal. Before and after the colonoscopy and polypectomy, provide direct care and teaching about the procedure, expected sensations during the procedure and anticipated postoperative care. Cathartics are prescribed prior to colonoscopy; cleansing enemas may also be ordered. Observe for evidence of fluid and electrolyte imbalance during preoperative preparation. If enemas are ordered, use normal saline (not tap water) to reduce the risk of electrolyte imbalances. Following polypectomy, observe closely for possible complications such as haemorrhage.

Community-based care

Include the following topics when teaching for home care:

- the significance of polyps and their relationship to colorectal cancer
- the importance of keeping follow-up appointments and undergoing repeat colonoscopy as recommended: at 3 years following polypectomy, then every 5 to 10 years unless additional polyps are found
- manifestations to be reported to the doctor, such as diarrhoea, pain, rectal bleeding, light headedness or other indications of possible blood loss.

THE PERSON WITH COLORECTAL CANCER

Colorectal cancer (cancer of the colon or rectum) is the second most common cancer diagnosed in Australia (ABS, 2015). In 2012, it was estimated that 15 840 (8760 males and 7080 females) were diagnosed with colorectal cancer (AIHW, 2015). In Australia in 2011, the risk of being diagnosed with colorectal cancer by the age of 85 years was 1 in 10 for males and 1 in 15 for females; however, from the age of 45 years the risk increases sharply (AIHW, 2015). Colorectal cancer occurs most frequently after age 50. The incidence continues to rise with increasing age.

Bowel cancer accounts for 12.7% of all deaths from invasive cancers, with 3092 deaths in 2010, making bowel cancer the second most common cause of cancer-related death after lung cancer (AIHW, 2015). Unfortunately, there is no national data on the incidence of colorectal cancer in Australian Aboriginal and Torres Strait Islander peoples as not all states and territories record the incidence of cancer in Indigenous Australians. However, where the incidence of cancer is recorded specifically for Aboriginal and Torres Strait Islander peoples, colorectal cancer is a commonly occurring cancer in Indigenous men. Cancer has a greater impact on Aboriginal and Torres Strait Islander peoples, who are less likely to have an early diagnosis and receive adequate treatment such as preventive, curative and palliative services (AIHW, 2015).

Earlier diagnosis and improved treatment have improved the survival rate for colorectal cancer. With early diagnosis and treatment, the 5-year survival rate for colorectal cancer is around 90%; however, only 39% of colorectal cancers are diagnosed at this early stage (AIHW, 2015). Survival varies according to the extent of the cancer development at diagnosis: at stage I colorectal cancer, 90% of individuals are still alive at 5 years; this falls to 87% with stage II, 57% with stage III and 10% for widespread disease (AIHW, 2015).

Although the specific cause of colorectal cancer is unknown, a number of risk factors have been identified (see Box 23.3). Genetic factors are strongly linked to the risk of colorectal cancer. Up to 25% of people developing colorectal cancer have a family history of the disease (Shussman & Wexner, 2014). People with familial adenomatous polyposis inevitably develop colon cancer unless the colon is removed. Hereditary nonpolyposis colorectal cancer (also known as Lynch syndrome) is an autosomal dominant disorder that significantly increases the risk of developing colorectal and other cancers. Tumours associated with Lynch syndrome often affect the ascending colon

BOX 23.3 Risk factors for colorectal cancer

- Age over 50 years
- Polyps of the colon and/or rectum
- Family history of colorectal cancer
- Inflammatory bowel disease
- Exposure to radiation
- Diet: high animal fat and kilojoule intake

and occur at an earlier age. Inflammatory bowel diseases also increase the risk of colorectal cancer.

Diet plays a role in the development of colorectal cancer. The disease is prevalent in economically prosperous countries where people consume diets high in kilojoules, meat proteins and fats. This dietary pattern, common in Australia, is thought to increase the population of anaerobic bacteria in the gut. These anaerobes convert bile acids into carcinogens. Diets high in fruits and vegetables, folic acid and calcium appear to reduce the risk of colorectal cancer. Cereal fibre, once thought to reduce colorectal cancer risk, does not appear to play a role either way in its development. Other factors that may reduce the risk of colorectal cancer include regular exercise, taking a daily multivitamin and the use of aspirin and other NSAIDs.

Pathophysiology

Nearly all colorectal cancers are adenocarcinomas beginning as adenomatous polyps. Most tumours develop in the rectum and sigmoid colon, although any portion of the colon may be affected (see Figure 23.14). The tumour typically grows undetected, producing few manifestations. By the time manifestations occur, the disease may have spread into deeper layers of the bowel tissue and adjacent organs. Colorectal cancer spreads by direct extension to involve the entire bowel circumference, the submucosa and the outer bowel wall layers.

Neighbouring structures such as the liver, greater curvature of the stomach, duodenum, small intestine, pancreas, spleen, genitourinary tract and abdominal wall may also be involved by direct extension. Metastasis to regional lymph nodes is the most common form of tumour spread. This is not always an orderly process; distal nodes may contain cancer cells while regional nodes remain normal. Cancerous cells from the primary tumour may also spread via the lymphatic system or circulatory system to secondary sites such as the liver, lungs, brain, bones and kidneys. 'Seeding' of the tumour to other areas of the peritoneal cavity can occur when the tumour extends through the serosa or during surgical resection.

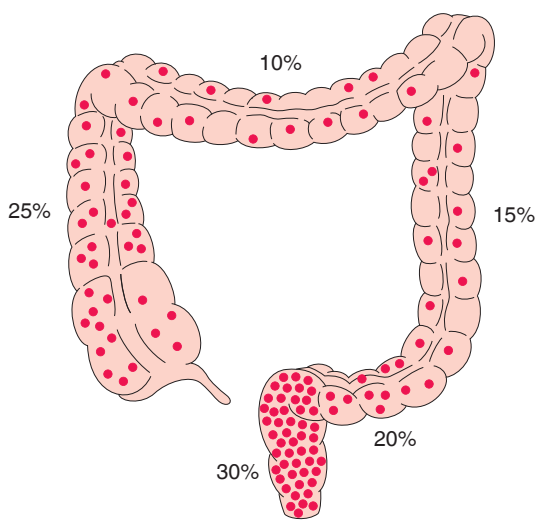

FIGURE 23.14 ■ The distribution and frequency of cancer of the colon and rectum

Manifestations

Bowel cancer often produces no manifestations until it is advanced. Because it grows slowly, 5 to 15 years of growth may occur before manifestations develop. The manifestations depend on its location, type and extent, and complications. Rectal bleeding is often the initial manifestation prompting a person to seek medical care. Other common early manifestations include a change in bowel habits, either diarrhoea or constipation. Pain, anorexia and weight loss are characteristic in advanced disease. A palpable abdominal or rectal mass may be present. Occasionally a person presents with anaemia from occult bleeding.

Complications

The primary complications associated with colorectal cancer are (1) bowel obstruction due to narrowing of the bowel lumen by the lesion; (2) perforation of the bowel wall by the tumour, allowing contamination of the peritoneal cavity by bowel contents; and (3) direct extension of the tumour to involve adjacent organs.

Most recurrences of colorectal cancer after tumour removal occur within the first 4 years. The size of the primary tumour does not necessarily relate to long-term survival. The numbers of lymph nodes involved, penetration of the tumour through the bowel wall and tumour adherence to adjacent organs are better predictors of the prognosis for the disease.

INTERPROFESSIONAL CARE

The focus of interprofessional care for colorectal cancer is prevention, early detection and intervention. Colorectal cancer is always treated by surgical resection, with chemotherapy and radiation therapy used as adjuncts.

Prevention

Measures to prevent colon cancer considered effective and safe include diets high in fruit and vegetables and low in saturated fat and red meat, regular exercise, avoiding obesity and quitting smoking. Consuming fibre supplements, minerals such as calcium, vitamins and non-steriodal anti-inflammatory medications may help prevent colorectal cancer; however, their effectiveness is not yet proven (Principi & DeCensi, 2015). Although considered safe, these measures are the subject of further research to demonstrate conclusive proof of effectiveness (Principi & DeCensi, 2015).

Screening

Cancer Council Australia (2015) recommends one of the following testing schedules for the early detection of colorectal cancer, beginning at age 50. These options are acceptable choices for average-risk adults. Screening for blood in the faeces (faecal occult blood test (FOBT)) is available through the National Bowel Cancer Screening Program (NBCSP) to Australians turning 50. From 2015 NBCSP is being expanded

to implement a biennial screening interval for those aged 50–74 by 2020 (AIHW, 2015). Abnormal tests are followed up with a colonoscopy.

- Yearly FOBT or faecal immunochemical test (FIT). (For FOBT, the take-home multiple sample method should be used.)
- Flexible sigmoidoscopy every 5 years.
- Yearly FOBT or FIT plus flexible sigmoidoscopy every 5 years.
- Double-contrast barium enema every 5 years.
- Colonoscopy every 10 years.

Diagnosis

Diagnostic and laboratory tests are used for screening, diagnosis and monitoring purposes. Diagnostic tests include a sigmoidoscopy or colonoscopy as the primary diagnostic test used to detect and visualise tumours. While flexible sigmoidoscopy detects 50% to 65% of colorectal cancers, many clinicians recommend colonoscopy. Tissue for biopsy is obtained at the time of endoscopy to confirm cancerous tissue and evaluate cell differentiation (see Chapter 13).

Laboratory tests used are an FOBT (by guaiac or haemoccult testing) to detect blood in the faeces, an FBC to identify anaemia resulting from chronic blood loss and tumour growth, and a carcinoembryonic antigen (CEA) level, a tumour marker detected in the blood of individuals with colorectal cancer. CEA levels are used to estimate prognosis, monitor treatment and detect cancer recurrence. Newer screening methods for diagnosis of colorectal cancer in the very early stage of development include faecal DNA, immunochemical faecal occult blood tests (iFOBTs) and computed tomographic colonography (CTC) (Leggett & Hewitt, 2015).

Current staging methods primarily use the TNM (tumour, node, metastasis) system, as outlined in Table 23.12. Radiological examinations may include a chest x-ray to detect tumour metastasis to the lung, and computed tomography (CT) scan, magnetic resonance imaging (MRI) or ultrasonic examination may be used to assess tumour depth and involvement of other organs by direct extension or metastasis.

Laser photocoagulation

Laser photocoagulation uses a very small, intense beam of light to generate heat in tissues towards which it is directed. The heat generated by the laser beam can be used to destroy small tumours. It is also used for palliative surgery of advanced tumours to remove obstruction. Laser photocoagulation can be performed endoscopically and is useful for people unable to tolerate major surgery.

Surgery

Stage I and II disease can be treated with surgery to remove the bowel and surrounding lymph nodes. Stage III disease requires surgery and additional chemotherapy to try to prevent recurrence. Widespread disease is treated with chemotherapy. More recently, targeted therapies are being trialled in addition to chemotherapy. Surgical resection of the tumour, adjacent colon and regional lymph nodes is the treatment of choice for colorectal cancer. Options for surgical treatment vary from destruction of the tumour by laser photocoagulation performed during endoscopy to abdominoperineal resection with permanent colostomy. When possible, the anal sphincter is preserved and colostomy avoided.

Other surgical treatment options for small, localised tumours include local excision and fulguration. These procedures may also be performed during endoscopy, eliminating the need for

TABLE 23.12 The TNM classification for colorectal cancer

STAGE	PRIMARY TUMOUR (T)	REGIONAL LYMPH NODES (N)	DISTANT METASTASIS (M)
	TX—Primary tumour cannot be assessed T0—No evidence of primary tumour	NX—Regional lymph node cannot be assessed N0—No regional lymph node metastasis	MX—Presence of distant metastasis cannot be assessed M0—No distant metastasis
Stage 0	Tis—Carcinoma in situ		
Stage I	T1—Tumour invades submucosa		
	T2—Tumour invades muscularis propria		
Stage II	T3—Tumour invades through muscularis propria into subserosa or into non-peritonealised pericolic or perirectal tissues		
	T4—Tumour perforates visceral peritoneum or directly invades other organs or structures		
Stage III	Any T	N1—Metastasis in 1 to 3 pericolic or perirectal lymph nodes	
		N2—Metastasis in 4 or more pericolic or perirectal lymph nodes	
		N3—Metastasis in any lymph node along course of a major named vascular trunk	
Stage IV	Any T	Any N	M1—Distant metastasis

abdominal surgery. Local excision may be used to remove a disk of rectum containing a tumour in a person with a small, well-differentiated, mobile polypoid lesion. *Fulguration* or electrocoagulation is used to reduce the size of some large tumours in a person who is a poor surgical risk. This procedure requires general anaesthesia and may need to be repeated at intervals.

Most people with colorectal cancer undergo surgical resection of the colon with anastomosis of remaining bowel as a curative procedure. The distribution of regional lymph nodes determines the extent of resection because these may contain metastatic lesions. Most tumours of the ascending, transverse, descending and sigmoid colon can be resected.

Tumours of the rectum usually are treated with an abdominoperineal (AP) resection in which the sigmoid colon, rectum and anus are removed through both abdominal and perineal incisions. A permanent sigmoid colostomy is performed to provide for elimination of faeces. Nursing care for a person having bowel surgery is outlined below.

COLOSTOMY

Surgical resection of the bowel may be accompanied by a colostomy for diversion of faecal contents. A **colostomy** is an ostomy made in the colon. It may be created if the bowel is obstructed by the tumour, as a temporary measure to promote healing of anastomoses or as a permanent means of faecal evacuation when the distal colon and rectum are removed. Colostomies take the name of the portion of the colon from which they are formed: ascending colostomy, transverse colostomy, descending colostomy and sigmoid colostomy (see Figure 23.15).

A *sigmoid colostomy* is the most common permanent colostomy performed, particularly for cancer of the rectum. It is usually created during an AP resection. This procedure involves the removal of the sigmoid colon, rectum and anus through abdominal and perineal incisions. The anal canal is closed and a stoma formed from the proximal sigmoid colon. The stoma is usually located on the lower left quadrant of the abdomen.

When a *double-barrel colostomy* is performed, two separate stomas are created (see Figure 23.16). The distal colon is not

NURSING CARE OF THE PERSON requiring bowel surgery

PREOPERATIVE NURSING CARE

- Provide routine preoperative care for a person undergoing surgery as outlined in Chapter 3.
- Arrange for consultation with stomal therapy (ST) specialist if appropriate. *The ST nurse is trained to identify and mark an appropriate stoma location, taking into consideration the level of stoma, skinfolds and the person's clothing preferences. Initial stomal care teaching also is provided by the ST nurse during the preoperative visit.*
- Insert a nasogastric tube if ordered. *Although it is often inserted in the operating theatre just prior to surgery, the nasogastric tube may be placed preoperatively to remove secretions and empty stomach contents.*
- Perform bowel preparation procedures as ordered. *Oral and parenteral antibiotics as well as laxatives and enemas may be prescribed preoperatively to clean the bowel and reduce the risk of peritoneal contamination by bowel contents during surgery.*

POSTOPERATIVE NURSING CARE

- Provide routine care for the person postoperatively (see Chapter 3).
- Monitor bowel sounds and degree of abdominal distension. *Surgical manipulation of the bowel disrupts peristalsis, resulting in an initial ileus. Bowel sounds and the passage of flatus indicate a return of peristalsis.*
- Assess the position and patency of the nasogastric tube, connecting it to low suction. If the tube becomes clogged, gently irrigate with sterile normal saline. *A nasogastric or gastrostomy tube is used postoperatively to provide gastrointestinal decompression and facilitate healing of the anastomosis. Ensuring its patency is important for comfort and healing.*
- Assess colour amount and odour of drainage from surgical drains and the colostomy (if present), noting any changes or the presence of clots or bright bleeding. Initial drainage may be bright red and then become dark and finally clear or greenish yellow over the first 2 to 3 days. *A change in the colour, amount or odour of the drainage may indicate a complication such as haemorrhage, intestinal obstruction or infection.*
- Alert all personnel caring for the person with an AP resection to avoid rectal temperatures, suppositories or other rectal procedures. *These procedures could disrupt the anal suture line, causing bleeding, infection or impaired healing.*
- Maintain intravenous fluids while nasogastric suction is in place. *A person on nasogastric suction is unable to take oral food and fluids, and is losing electrolyte-rich fluid via the nasogastric tube. If replacement fluid and electrolytes are not maintained, the person is at risk of dehydration; sodium, potassium and chloride imbalance; and metabolic alkalosis.*
- Provide antacids, histamine$_2$ receptor antagonists and antibiotic therapy as ordered. *The above medications may be ordered for the person postoperatively depending on the procedure performed. Antibiotic therapy is a common measure to prevent infection resulting from contamination of the abdominal cavity with gastric contents.*
- Resume oral food and fluids as ordered. Initial feedings may be clear fluids, progressing to free fluids and then frequent small feedings of regular foods. Monitor bowel sounds and for abdominal distension frequently during this period. *Oral feedings are reintroduced slowly, minimising abdominal distension and trauma to the suture lines.*
- Begin discharge planning and teaching. Consult with a nutritionist for instructions and menu planning; reinforce teaching. *Advise about potential postoperative complications such as abdominal abscess or bowel obstruction, their preventive measures and clinical manifestations.*

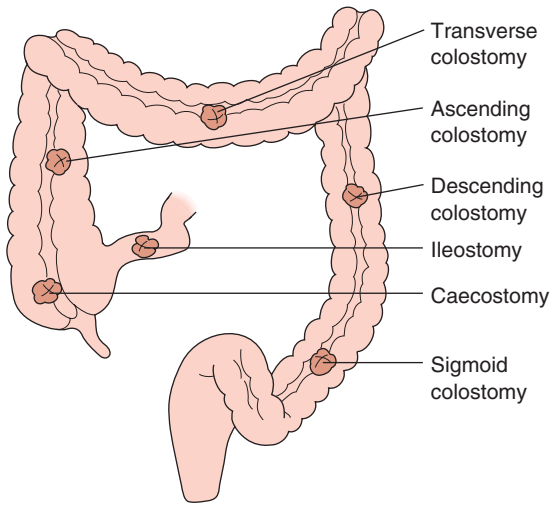

FIGURE 23.15 ■ Various ostomy levels and sites

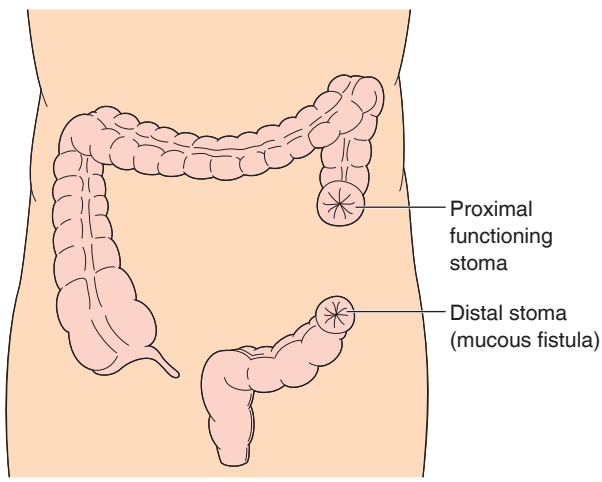

FIGURE 23.16 ■ A double-barrel colostomy. The proximal stoma is the functioning stoma; the distal stoma expels mucus from the distal colon

removed, but bypassed. The proximal stoma, which is functional, diverts faeces to the abdominal wall. The distal stoma, also called the mucous fistula, expels mucus from the distal colon. It may be pouched or dressed with a 4 × 4 lint-free gauze dressing. A double-barrel colostomy may be created for cases of trauma, tumour or inflammation, and may be temporary or permanent.

An emergency procedure used to relieve an intestinal obstruction or perforation is called a *transverse loop colostomy*. During this procedure, a loop of the transverse colon is brought out from the abdominal wall and suspended over a plastic rod or bridge, preventing the loop from slipping back into the abdominal cavity. The loop stoma may be opened at the time of surgery or a few days later at the person's bedside. The bridge may be removed in 1 to 2 weeks. Transverse loop colostomies are generally temporary.

In a *Hartmann procedure*, a common temporary colostomy procedure, the distal portion of the colon is left in place and is over-sewn for closure. A temporary colostomy may be done to allow bowel rest or healing, such as following tumour resection or inflammation of the bowel. It may also be created following traumatic injury to the colon, such as a gunshot wound. Anastomosis of the severed portions of the colon is delayed because bacterial colonisation of the colon prevents proper healing of the anastomosis. About 3 to 6 months after a temporary colostomy, the colostomy is closed and the colon is reconnected. A person with a temporary colostomy requires the same care as an individual with permanent colostomy. See the 'Nursing care of a person with a colostomy' box below.

Radiation therapy

Although radiation therapy is not used as a primary treatment for colon cancer, it is used with surgical resection for treating rectal tumours. Small rectal cancers may be treated with intracavitary, external or implantation radiation. Rectal cancer has a high rate of regional recurrence following complete surgical resection, particularly when the tumour has invaded tissues outside the bowel wall or regional lymph nodes. Pre- or postoperative radiation therapy reduces the recurrence of pelvic tumours, although the effect of radiation therapy on long-term survival is less clear. Radiation therapy is also used preoperatively to shrink large rectal tumours enough to permit their surgical removal. Further discussion about radiation therapy and nursing implications is included in Chapter 13.

Chemotherapy

Chemotherapeutical agents, such as intravenous fluorouracil (5-FU) and folinic acid (leucovorin), are also used postoperatively as adjunctive therapy for colorectal cancer. When combined with radiation therapy, chemotherapy reduces the rate of tumour recurrence and prolongs survival in people with stage II and stage III rectal tumours. The benefit for colon cancers is less clear, but chemotherapy may be used to reduce its spread to the liver and prevent recurrence. Irinotecan (CPT-11) or oxaliplatin may also be used in chemotherapy regimens for colorectal cancer. Further discussion about chemotherapy and nursing implications is included in Chapter 13.

Nursing care

Health promotion

Primary prevention of colorectal cancer is a significant nursing care issue. Discuss the dietary recommendations provided by the Cancer Council Australia (2015) for the prevention of colorectal cancer. These recommendations include decreasing the amount of fat, refined sugar and red meats in the diet while increasing intake of dietary fibre. Foods containing high amounts of fibre include raw fruit and vegetables, legumes and wholegrain products.

NURSING CARE OF THE PERSON with a colostomy

- Assess the location of the stoma and the type of colostomy performed. *Stoma location is an indicator of the section of bowel in which it is located and a predictor of the type of faecal drainage to expect.*
- Assess stoma appearance and surrounding skin condition frequently (see the box 'Nursing care of a person having an ileostomy' on page 746). *Assessment of stoma and skin condition is particularly important in the early postoperative period, when complications are most likely to occur and are most treatable.*
- Position a collection bag or drainable pouch over the stoma. Initial drainage may contain more mucus and serosanguineous fluid than faecal material. As the bowel resumes function, drainage becomes faecal in nature. *The consistency of drainage depends on the stoma location in the bowel.*
- If ordered, irrigate the colostomy, instilling water into the colon similar to an enema procedure. *The water stimulates the colon to empty.*
- When colostomy irrigation is ordered for a person with a double-barrel or loop colostomy, irrigate the proximal stoma. Digital assessment of the bowel direction from the stoma can assist in determining the proximal stoma. *The distal bowel carries no faecal contents and does not need irrigation. It may be irrigated for cleansing just prior to reanastomosis.*
- Empty a drainable pouch or replace the colostomy bag as needed or when it is no more than one-third full. *If the pouch is allowed to overfill, its weight may impair the seal, causing leakage.*
- Provide stomal and skin care for a person with a colostomy as for a person with an ileostomy (see the box 'Nursing care of a person having an ileostomy' on page 746). *Good skin and stoma care is important to maintain skin integrity and function as the first line of defence against infection.*
- Use caulking agents, such as Stomahesive or karaya paste and a skin barrier wafer, as needed to maintain a secure ostomy pouch. *This is particularly important for a person with a loop colostomy. The main challenge for a person with a transverse loop colostomy is to maintain a secure ostomy pouch over the plastic bridge.*
- If the pouch does not incorporate an air vent, a small needle hole high on the colostomy pouch allows flatus to escape. This hole may be closed with a Band-Aid, and opened when the person is in the bathroom, for odour control. *Ostomy bags may 'balloon' out, disrupting the skin seal, if excess gas collects.*

HEALTH EDUCATION FOR THE PERSON AND FAMILY

- Prior to discharge, provide written, verbal and psychomotor instruction on colostomy care, pouch management, skin care and irrigation to the person. Whether the colostomy is temporary or permanent, the person will be responsible for its management. *Good understanding of procedures and care enhances the ability to provide self-care, as well as self-esteem and control.*
- Allow ample time for the person (and their family, if necessary) to practise changing the pouch, either on the person or a model. *Practice of psychomotor skills improves learning and confidence.*
- If an abdominoperineal resection has been performed, emphasise the importance of using no rectal suppositories, rectal temperatures or enemas. Suggest the person carry medical identification or a MedicAlert® tag or bracelet. *These measures are important to prevent tissue trauma when the rectum has been removed.*
- The diet for a person with a colostomy is individualised and may require no alteration from that consumed preoperatively. Dietary teaching should, however, include information on foods causing stool odour and gas, and foods that thicken or loosen stools. *Foods causing these effects on ostomy output are listed below.*

Foods increasing stool odour

- Asparagus
- Beans
- Cabbage
- Eggs
- Fish
- Garlic
- Onions
- Some spices

Foods increasing intestinal gas

- Beer
- Broccoli
- Brussels sprouts
- Cabbage
- Carbonated drinks
- Cauliflower
- Corn
- Cucumbers
- Dairy products
- Dried beans
- Peas
- Radishes
- Spinach

Foods thickening stools

- Apple sauce
- Bananas
- Bread
- Cheese
- Pasta
- Pretzels
- Rice
- Smooth peanut paste
- Tapioca
- Yoghurt

Foods loosening stools

- Chocolate
- Dried beans
- Fried foods
- Greasy foods
- Highly spiced foods
- Leafy green vegetables
- Raw fruits and juices
- Raw vegetables

Foods colouring stools

- Beetroot
- Red and green jelly

Stress the importance of regular health examinations, including digital rectal exams. Discuss recommendations for regular haemoccult testing of stool after age 50. Include the importance of seeking medical treatment if blood is noted in or on the stool. Teach the warning signs for cancer, including those specific to bowel cancer, such as a change in bowel habits.

Assessment

- *Health history:* usual bowel patterns and any recent changes; weight loss, fatigue, decreased activity tolerance; presence of blood in the stool; pain with defecation, abdominal discomfort, perineal pain; usual diet; family history of colon cancer; other specific risk factors such as inflammatory bowel disease or colon polyps.
- *Physical examination:* general appearance; weight; abdominal shape, contour; bowel sounds, abdominal tenderness; stool haemoccult or guaiac.

Nursing diagnoses and interventions

In planning and implementing care, consider both physical care needs and the person's psychological response to the diagnosis. The psychological recovery of a person who is diagnosed with colorectal cancer may be influenced by the possible permanent changes to their body image and lifestyle. When planning care, open and genuine communication enables nurses to understand the person's anxieties, personal, family and social needs (Kunde, 2012). As colorectal cancer is often advanced at the time of diagnosis, the prognosis, even with treatment, may be poor. Denial and anger are common. Extensive abdominal surgery and potentially a colostomy may be necessary and the effects of chemotherapy and radiation therapy can leave the person fatigued and discouraged. A nursing care plan for a person with colorectal cancer follows.

Nursing care includes providing emotional support, teaching and direct care before and after diagnostic procedures and surgery and during adjunctive treatments. When developing nursing care plans it is imperative to incorporate the person's cultural, religious and personal viewpoints into the plan of care. Priority nursing diagnoses include *Acute pain*, *Imbalanced nutrition* and *Anticipatory grieving*. *Risk of sexual dysfunction* should be considered as a priority diagnosis if a colostomy was created.

CONSIDERATION FOR PRACTICE

If an adominoperineal resection (AP) resection was performed, alert all care personnel to avoid rectal temperatures, suppository use or other procedures that could damage sutures.

Acute pain

A person with colorectal cancer may experience pain related to preparatory procedures, diagnostic examinations and surgery. Following an AP, 'phantom' rectal pain related to the severing of nerves during the wide excision of the rectum may develop. Finally, the primary tumour itself and, potentially, metastatic tumours may impinge on nerves and other organs, causing pain. In the early postoperative period, an epidural infusion or PCA is often used to manage pain. PCA, routine administration of ordered analgesics or a continuous analgesia delivery (CAD) system may also be used for pain management when the tumour is far enough advanced to preclude surgical resection. See Chapter 8 for more information on caring for a person with pain, Chapter 13 for discussion of pain associated with cancer and Chapter 4 for discussion of end-of-life care.

- Assess and monitor for adequate pain relief. Use subjective and objective information, including the location, intensity and character of the pain, as well as non-verbal signs such as grimacing, muscle tension, apparent dozing, changes in pulse or blood pressure, and rapid, shallow respirations. Response to pain varies between individuals and is influenced by culture, beliefs, pathophysiological factors and psychological factors such as previous pain events (McArthur, 2011). A person may assume that pain is to be expected or tolerated or may fear becoming addicted to analgesic medications. *Careful questioning and a holistic assessment can provide accurate information about pain status, allowing better control of discomfort.*
- Ask the person to rate pain using a 0 to 10 pain scale. Document the level of pain. Pain is a subjective experience. *People perceive and respond to pain differently. Religion and ethnic background may affect the response to pain.*
- Monitor analgesic effectiveness 30 minutes after administration. Monitor for pain relief and adverse effects. *The method of delivery, dosage or medication itself may need to be adjusted to provide adequate pain relief.*
- Assess the incision for inflammation or swelling; assess drainage catheters and tubes for patency. *Poorly controlled pain, or pain that changes, may be related to organ distension from an obstructed nasogastric tube, urinary catheter or wound drain, or may indicate an infection.*
- Assess the abdomen for distension, tenderness and bowel sounds. *Intra-abdominal bleeding, peritonitis or paralytic ileus can cause pain that may be confused with incisional pain.*
- Administer analgesia prior to an activity or procedure. *Adequate pain relief reduces muscle tension, allowing for more comfortable participation in activities.*
- Assist with adjunctive comfort measures, such as positioning, diversional activities, management of environmental stimuli, guided imagery and teaching relaxation techniques. *These measures enhance the effects of analgesia by reducing muscle tension.*
- Splint incision with a pillow and teach the person how to self-splint when coughing and deep breathing *to prevent respiratory complications related to fear of pain.*

Imbalanced nutrition: less than body requirements

Bowel preparation for diagnostic procedures, surgery, radiation therapy and chemotherapy place the person with colorectal cancer at risk of nutritional deficiencies. Fluid and electrolyte replacement is provided following surgery, along with possible TPN (see Chapter 21). Adequate kilojoule and nutrient intake is necessary for healing after surgery. Additionally, if the

NURSING CARE PLAN A person with colorectal cancer

Bill Cunningham is a 65-year-old retired railway employee, husband and father of three grown children. For the past 3 months, Mr Cunningham has noticed small amounts of blood and occasional mucus in his stools. He has a sensation of pressure in the rectum and noticed his stools are smaller in diameter, about the size of a pencil. After palpating a mass on digital examination of the rectum, the doctor orders a colonoscopy. A large sessile lesion is found in the rectum and biopsied. The pathology report shows the lesion to be adenocarcinoma. Mr Cunningham is scheduled for an abdominoperineal resection and sigmoid colostomy.

ASSESSMENT

Madonna Hart, RN, completes the admission assessment. Mr Cunningham states his bowel habits have recently changed, but denies pain or other symptoms. Physical assessment findings include T 36.9°C, P 82, R 18 and BP 118/78. He is 178 cm tall and weighs 84 kg. Laboratory findings are normal except for the previous pathology report of adenocarcinoma of rectal lesion.

Mr Cunningham states, 'I really don't want a colostomy, but if that is what it takes to get rid of this, I'm ready to get it over with.'

DIAGNOSES

- *Altered comfort* related to acute pain secondary to surgical intervention.
- *Risk of impaired skin integrity (peristomal)* related to faecal drainage and pouch adhesive.
- *Risk of constipation/diarrhoea* related to effects of surgery on bowel function.
- *Disturbed body image* related to colostomy.
- *Risk of sexual dysfunction* related to wide rectal incision, radiation therapy and colostomy.

PLANNING

When planning nursing care with Mr Cunningham, it is vital to consider his preferences, religious and cultural beliefs for incorporation into his plan of care.

Expected outcomes

- Mr Cunningham will report pain within an acceptable range that allows ease of movement and ambulation.
- Mr Cunningham will perform colostomy care using correct technique.
- Mr Cunningham will demonstrate willingness to discuss changes in sexual function.
- Mr Cunningham will wear clothing to enhance physical and emotional self-esteem.

IMPLEMENTATION

- Provide Mr Cunningham with analgesia as ordered, evaluating its effectiveness and monitoring for adverse reactions.
- Provide for privacy when teaching and discussing concerns about ostomy.
- Discuss with Mr Cunningham foods that cause odour and gas.
- Teach Mr Cunningham how to care for his colostomy.
- Maintain consistent nursing personnel assignment to facilitate trust.
- Provide Mr Cunningham information about the Australian Stoma Appliance Scheme. It is subsidised by the Australian government and provides stoma products (medicine and appliances) for people with a permanent or temporary stoma free of charge to members of one of the 22 approved volunteer stoma associations.
- Refer Mr Cunningham to the local Stoma Association.

EVALUATION

At discharge, Mr Cunningham is able to empty and rinse out his colostomy pouch. He is changing the pouch and caring for surrounding skin appropriately. RN Hart gave him verbal and written instructions on colostomy care. He verbalised understanding of phantom rectal pain and the importance of avoiding rectal suppositories. He expresses an understanding of the need to avoid heavy lifting and the importance of follow-up care. RN Hart refers Mr Cunningham to a home healthcare agency in his community if he has further questions and for his follow-up care.

CRITICAL THINKING IN THE NURSING PROCESS

1. Describe the cause of phantom rectal pain.
2. Outline why it is important to discuss dietary concerns with a person with a colostomy, especially odour- and gas-forming foods.
3. Outline a plan to teach Mr Cunningham how to irrigate a colostomy.
4. Develop a care plan for Mr Cunningham for the nursing diagnosis *Disturbed body image*.

REFLECTION ON THE NURSING PROCESS

1. Reflect on what you learned from completing this section. Outline how you will apply this knowledge to assist you in your clinical reasoning when next on clinical placement.
2. Describe nursing interventions you can incorporate into your clinical practice to assist a person to be independent in caring for their colostomy.

tumour is advanced, metabolic needs may be increased and the appetite decreased.

- Assess nutritional status using data such as height and weight, skinfold measurements, body mass index (BMI) calculation (see Chapter 20) and laboratory data including serum albumin level. Refer to nutritionist for dietary management. *A person malnourished before beginning aggressive cancer treatment requires more vigorous nutrition management to promote healing.*
- Assess readiness for resumption of oral intake after surgery or procedures using data such as statements of hunger, presence of bowel sounds, passage of flatus and minimal abdominal distension. *Manipulation of the bowel interrupts peristalsis of the GI tract. It is important to ensure that peristalsis has resumed prior to resumption of oral intake.*
- Monitor and document food and fluid intake. *Documentation helps identify the adequacy of kilojoule and other nutrient intake.*

- Weigh daily. *Weight fluctuation may indicate adequate or inadequate dietary intake.*
- Maintain TPN and central intravenous lines as ordered. *Parenteral nutrition prevents tissue catabolism and promotes healing when food intake is disrupted for more than 2 to 3 days.*
- When oral intake resumes, help the person develop a meal plan incorporating their food preferences and that considers their schedule and environment. *Consideration of likes, dislikes and circumstances in meal planning promotes adequate intake.*

Anticipatory grieving

When a bowel resection is performed for colorectal cancer, the person needs to adjust to the loss of a major body part as well as to the diagnosis of cancer. Even when the prognosis for recovery is good, many people perceive cancer as fatal. Supporting the person and their family during the initial stages of grieving can improve physical recovery as well as psychological coping and eventual adaptation. See Chapter 4 for discussion of nursing care of people experiencing loss and grief.

- Work to develop a trusting relationship with the person and their family. *This increases the nurse's effectiveness in helping them work through the grieving process.*
- Listen actively, encouraging the person and their family to express their fears and concerns. Assist to identify strengths, experiences and support systems.
- Demonstrate respect for cultural, spiritual and religious values and beliefs; encourage use of these resources to cope with losses.
- Encourage discussion of the potential impact of loss on individual family members, family structure and family function. Assist family members to share concerns with one another.
- Refer to cancer support groups, social services or counselling as appropriate. *These resources can be used throughout the grieving process.*

Risk of sexual dysfunction

Colorectal cancer and ostomy surgery increase the risk of sexual dysfunction, defined as a change in sexual function so that it becomes unsatisfying, unrewarding or inadequate (NANDA-I, 2011). Physical factors leading to sexual dysfunction include disruption of nerves and blood vessels supplying the genitals, radiation therapy, chemotherapy and other medications prescribed after surgery.

Psychologically, an *ostomate* (person with an ostomy) experiences an altered body image and may develop low self-esteem. The person may feel undesirable and fear rejection. They may be concerned about odours or pouch leakage during sexual activity. This emotional stress can also contribute to sexual dysfunction.

- Provide opportunities for the person and their family to express feelings about the cancer diagnosis, stoma and effects of other treatments. *Encouraging verbalisation of feelings about the diagnosis, stoma and treatments provides an opportunity to validate that feelings of anger and depression are normal responses to the diagnosis and change in body function.*
- Provide consistent care. *An accepting attitude and consistent care by nurses, as well as securing the appliance and controlling odour and leakage, can increase the person's confidence and independence in caring for the appliance.*
- Encourage expression of sexual concerns. Provide privacy for discussions with a caregiver who has an established trust with the person and their partner. Sexuality is a private concern to most people. *The person and their partner are not likely to express their concerns openly unless trust has been established.*
- Reassure the person and their partner that the effect of physical illness and prescribed interventions on sexuality is usually temporary. *The person and their partner may misinterpret an initial decrease in libido as evidence sexual activity will not be possible or resume following recovery.*
- Refer the person and their partner to social services or a family counsellor for further interventions. A person is often discharged from acute care settings well before concerns about sexual activity surface. *Ongoing counselling provides a continuing resource.*
- Arrange for a visit from a member of the Stoma Association. *People living and coping with an ostomy can provide information and support, helping the new ostomate overcome feelings of isolation and rejection.*

Community-based care

During the diagnostic and preoperative periods, provide instruction about the following topics:

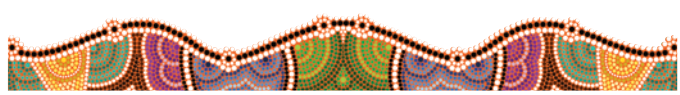
- tests to be performed and preparatory procedures, including dietary restrictions, laxatives, enemas and food and fluid restrictions just prior to the procedure
- recommended postprocedure care and potential adverse effects to report
- preoperative care, such as intestinal preparation and food and fluid restrictions.

If a colostomy is planned, refer to a stomal therapist for stoma placement and initial teaching.

Once treatment has been initiated, include the following topics (as appropriate) in teaching for home care:

- pain management
- skin care and management of potential adverse effects of radiation therapy and/or chemotherapy (Refer to Chapter 13 for further discussion of teaching needs related to these therapies.)
- incision and stoma care
- recommended diet
- follow-up appointments and care.

If the tumour is inoperable or a cure is not anticipated, provide information about pain and symptom management. Discuss the hospice philosophy and available services. Provide a referral to a local hospice or home health department. See Chapter 4 for discussion of end-of-life care and Chapter 13 for nursing care of a person with cancer.



STRUCTURAL AND OBSTRUCTIVE BOWEL DISORDERS

Any portion of the intestines may be affected by a structural or obstructive disorder. When the structural defect is in the bowel wall, the intestine may be directly affected, as is the case with diverticula. Defects in the abdominal wall may allow intra-abdominal contents (such as loops of bowel) to protrude, indirectly affecting bowel function. Likewise, obstructions may result from disease of the bowel itself or from obstruction of the bowel lumen by an external force.

THE PERSON WITH A HERNIA

A hernia is a defect in the abdominal wall allowing abdominal contents to protrude out of the abdominal cavity. Trauma, surgery and increased intra-abdominal pressure caused by such conditions as pregnancy, obesity, weight lifting or tumours are risk factors for hernia formation.

Pathophysiology

Hernias are classified by location (see Figure 23.17) and are congenital or acquired. Most hernias occur in the groin (inguinal or femoral hernias). Inguinal hernias are often congenital, caused by improper closure of the tract developing as the testes descend into the scrotum during foetal development. Inguinal hernias may be acquired, resulting from weakness of fascia in a region called Hesselbach's area or from dilation of the femoral ring (e.g. during pregnancy and childbirth). Ventral or incisional hernias of the abdominal wall generally are acquired, caused by weakening of normal abdominal wall musculature. Umbilical hernias also are congenital and usually are detected in infancy. Hiatal hernias develop in the diaphragm (see Chapter 22).

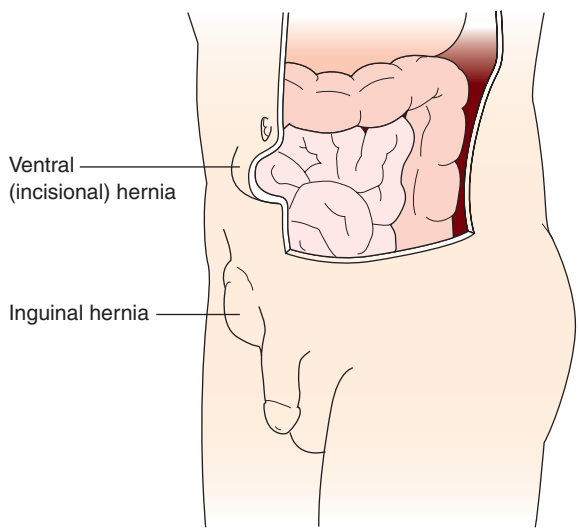


FIGURE 23.17 ■ An abdominal wall (ventral or incisional) hernia and an inguinal hernia

Inguinal hernia

Inguinal hernias usually affect males and are classified as indirect or direct inguinal hernias. *Indirect inguinal hernias* are caused by improper closure of the tract developing as the testes descend into the scrotum before birth. A sac comprising abdominal contents protrudes through the internal inguinal ring into the inguinal canal. It often descends into the scrotum. Although indirect inguinal hernias are congenital defects, these often are not evident until adulthood, when increased intra-abdominal pressure and dilation of the inguinal ring allow abdominal contents to enter the channel.

Direct inguinal hernias are acquired defects resulting from weakness of the posterior inguinal wall. Direct inguinal hernias usually affect older adults. *Femoral hernias* are also acquired defects in which a peritoneal sac protrudes through the femoral ring. These hernias usually affect obese or pregnant women.

Inguinal hernias may produce no manifestations and are discovered during routine physical examination. These may cause a lump, swelling or bulge in the groin, particularly during lifting or straining. An inguinal hernia may cause sharp pain or a dull ache radiating into the scrotum. A palpable mass may be present in the groin, although it may be felt only with increased intra-abdominal pressure (as occurs during coughing) and invagination of the scrotum towards the inguinal ring.

Umbilical hernia

Pregnancy and obesity contribute to the development of umbilical hernias in adults. *Umbilical hernias* may be congenital and evident during infancy, or acquired as the tissue closing the umbilical ring weakens, allowing protrusion of abdominal contents. These hernias are more common in women. Other predisposing factors include multiple pregnancies with prolonged labour, ascites and large intra-abdominal tumours.

Umbilical hernias tend to enlarge steadily and contain omentum, although these may also contain small or large bowel. These hernias may cause sharp pain on coughing or straining, or a dull, aching sensation. Strangulation is a common complication of umbilical hernias.

Incisional or ventral hernia

Incisional or *ventral hernias* occur at a previous surgical incision or following abdominal muscle tears. Inadequate healing of the incision or tear leads to hernia development. Contributing factors include poor wound closure, postoperative infection, age or debility, obesity, inadequate nutrition and excess incisional stress caused by vigorous coughing.

Ventral hernias are characterised by a bulge at the incisional site, often noted when the person pulls to a sitting position from a lying position. Ventral hernias often are asymptomatic and the risk of incarceration is low because of the size of the defect.

Manifestations

Abdominal contents (peritoneum, bowel and other abdominal organs) can protrude through the abdominal wall forming a sac covered by skin and subcutaneous tissues. In most cases,

abdominal contents move into the sac when intra-abdominal pressure increases, then return to the abdominal cavity when pressure returns to normal or when manual pressure is placed on the bulging sac. This is known as a *reducible hernia*.

Complications

The risk of complications is low with a reducible hernia. If the contents of a hernia cannot be returned to the abdominal cavity, it is said to be *incarcerated*. Contents of an incarcerated hernia are trapped, usually by a narrow neck or opening to the hernia. Incarceration increases the risk of complications, including obstruction and strangulation. Obstruction occurs when the lumen of the bowel contained within the hernia becomes occluded, much like crimping of a hose. A *strangulated hernia* develops when blood supply to bowel and other tissues in the hernia sac is compromised, leading to necrosis. The affected bowel infarcts, leading to perforation and contamination of the peritoneal cavity. Clinical manifestations of a strangulated hernia include severe abdominal pain and distension, nausea, vomiting, tachycardia and fever.

INTERPROFESSIONAL CARE

The diagnosis of a hernia is made by a physical examination. The person is examined in a supine or standing position. A bulge may be seen or felt when the person coughs or bears down. No laboratory or diagnostic testing is usually required, unless bowel obstruction or strangulation is suspected.

Surgical repair, or *herniorrhaphy*, is the usual treatment of hernia. Surgery is generally well tolerated by people of all ages and carries a much lower risk than the complications of incarceration, obstruction and strangulation. Emergency surgery is indicated for hernias that are incarcerated, painful or tender. In a herniorrhaphy, the abdominal wall defect is closed by suturing or with wire or mesh over the defect. If incarceration occurs or strangulation is suspected, the abdominal cavity is explored during surgery and any infarcted bowel resected. Heavy lifting and heavy manual labour are restricted for approximately 3 weeks after surgery.

When surgery is contraindicated, a person can be taught to reduce their hernia by lying down and gently pushing against the mass. However, the person needs to be instructed if suspected hernia incarceration is suspected, not to attempt to reduce their hernia and to seek medical assistance. A binder or truss may be worn to prevent or control the protrusion.

Nursing care

Assessment

- *Health history:* manifestations of hernia, such as bulging in the groin or of the abdominal wall when coughing, straining or moving from lying to standing; pain (abdominal, groin or scrotal); history of hernia or abdominal surgery.
- *Physical examination:* observe for bulging of the abdominal wall or around the umbilicus when raising head and shoulders from supine position; wearing gloves, palpate inguinal region for bulges when the person coughs or bears down (Valsalva manoeuvre) while standing.

Nursing diagnoses and interventions

Herniorrhaphy is generally an uncomplicated procedure, usually performed as day surgery. Preoperative assessment and teaching and immediate postoperative care are the primary nursing care needs. Care is similar to that provided for a person following an appendectomy.

Risk of decreased gastrointestinal tissue perfusion

When providing care for a person with a known hernia, the possibility of obstruction and strangulation must be considered throughout nursing assessments. Although nursing interventions may not be able to prevent these complications, rapid identification of the problem allows timely surgical treatment. Prompt treatment may prevent major complications related to infection and peritoneal contamination by bowel contents.

- Assess bowel sounds and abdominal distension at least every 8 hours. A change in bowel sounds—either cessation of sounds or an onset of hyperactive, high-pitched sounds—may indicate obstruction. *With obstruction, abdominal girth may increase.*

CONSIDERATION FOR PRACTICE

Promptly report any acute increase in abdominal, groin, perineal or scrotal pain. An abrupt increase in the intensity of pain may indicate bowel ischaemia due to strangulation.

- Notify medical staff if the hernia becomes painful or tender. *Pain and tenderness indicates incarceration and increased risk of strangulation.*
- If signs of possible obstruction or strangulation occur, notify the doctor. Place the person in a supine position with the hips elevated and knees slightly bent. Withhold all food and fluids (NBM) and begin preparations for surgery. *This position helps relax abdominal muscles and may facilitate reduction of the hernia. Strangulation or obstruction requires immediate surgical intervention.*

Community-based care

Include the following topics when teaching a person about hernias and home care:

- rationale for examining the groin and abdomen for bulges
- the nature of hernia, risk factors and manifestations
- surgical intervention for hernia
- how to reduce a hernia if necessary
- the importance of seeking immediate medical intervention for signs of strangulation or obstruction
- the need to notify the doctor if upper respiratory infection and cough develop preoperatively (forceful coughing is not recommended postoperatively)
- postoperative pain management and activity restrictions.

THE PERSON WITH INTESTINAL OBSTRUCTION

Intestinal obstruction is failure of intestinal contents to move through the bowel lumen. Intestinal obstructions affect either the large or small bowel. The small intestine is more commonly affected; however, bowel obstructions may also occur in the large intestine. Obstruction is the most common reason for small-bowel surgery.

Pathophysiology

Intestinal obstructions are either mechanical or functional in nature. *Mechanical* obstructions may be caused by: (1) problems outside the intestine, such as bands of scar tissue or hernias; (2) problems within the intestine—for example, tumours or inflammatory bowel disease; or (3) obstruction of the intestinal lumen. Intestinal obstructions are partial or complete. *Functional* obstruction occurs when peristalsis fails to propel intestinal contents although there is no mechanical obstruction. *Adynamic ileus* (also known as **paralytic ileus** or simply *ileus*) is the most common functional obstruction after abdominal surgery and probably accounts for most intestinal obstructions (Porth & Matfin, 2013). Obstructions are further classified by the portion of intestine affected.

When the intestine is obstructed, gas and fluid accumulate proximal to and within the obstructed segment, distending the bowel. Swallowed air accounts for most of the gas. Ingested fluid, saliva, gastric juice and pancreatic secretions contribute to accumulated fluid. Water and sodium are drawn into the bowel lumen, contributing to fluid accumulation, distension and vascular fluid losses. Distension of the bowel lumen interferes with peristaltic movement, leading to atony and further distension. Significant distension of the bowel lumen comprises blood flow to mucosa, and eventually leads to necrosis. Gangrenous bowel may perforate resulting in peritonitis. Rapid bacterial growth in the obstructed bowel leads to sepsis and often death.

Significant bowel distension, vomiting and third spacing of fluids in the bowel and peritoneal cavity leads to massive loss of fluids and electrolytes with resulting hypovolaemia, hypokalaemia, renal insufficiency and shock.

Small-bowel obstruction

Adhesions or bands of scar tissue and hernias account for most mechanical small-bowel obstructions. In adults, adhesions develop following abdominal surgery or inflammatory processes. Adhesions usually produce a *simple obstruction* or single blockage in one portion of the intestine (see Figure 23.18A). The obstruction produced by an incarcerated hernia is a *closed-loop obstruction*, with two different portions of the bowel lumen obstructed (see Figure 23.18B).

Tumours, either intrinsic (of the bowel itself) or extrinsic (of another organ but affecting the bowel because of their size), can progressively occlude the bowel lumen and eventually obstruct it (see Figure 23.18C). Other, less common causes of bowel obstruction include intussusception (rare in adults) (see Figure 23.18D); volvulus, the rotation of loops of bowel about a fixed point (see Figure 23.18E); foreign bodies; stricture; and inflammatory bowel disease.

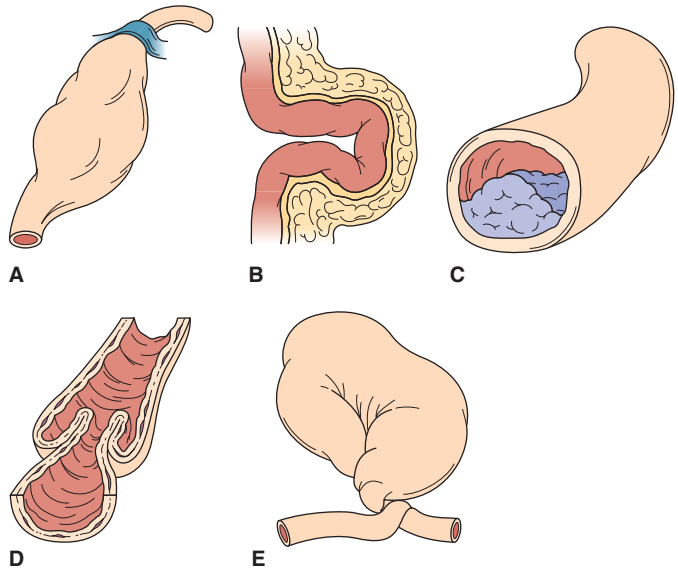

FIGURE 23.18 ■ Selected causes of mechanical obstruction. *A*, Adhesions; *B*, incarcerated hernia; *C*, tumour; *D*, intussusception; *E*, volvulus

Both volvulus and an incarcerated hernia can cause a *strangulated obstruction*. In a strangulated obstruction, not only is the lumen of the bowel obstructed, but the blood supply to the affected portion is also compromised.

In a functional obstruction or adynamic ileus, peristalsis stops due to either neurogenic or muscular impairment. The bowel lumen remains patent; however, the contents are not propelled forward. Temporary ileus commonly follows gastrointestinal surgery. It may also result from tissue anoxia or peritoneal irritation due to haemorrhage, peritonitis or perforation of an organ. Other conditions precipitating paralytic ileus include renal colic, spinal cord injuries, uraemia and electrolyte imbalances, particularly hypokalaemia. Additionally, the effects of some narcotics, anticholinergic drugs and antidiarrhoeal medications such as diphenoxylate can produce a functional obstruction.

MANIFESTATIONS The manifestations of a small-bowel obstruction vary, depending on the level of obstruction and how rapidly it develops. Cramping or colic-like abdominal pain may be intermittent or increasing in intensity. Vomiting is common, particularly in high or proximal obstructions, because lumen distension stimulates the vomiting centre. As bacterial fermentation occurs, vomitus often contains faecal matter, particularly with a low or distal obstruction. Flatus and faeces already present in the lower bowel may be expelled early in the obstructive process. However, this expulsion ceases as the obstruction continues.

Early in the course of a mechanical obstruction, borborygmi and high-pitched tinkling bowel sounds are present, as

the intestine attempts to propel contents past the obstruction. Visible peristaltic waves may be noted in the distended loops of bowel in thin people. In the later stages, the bowel becomes silent. With a paralytic ileus, bowel sounds are greatly diminished or absent throughout the process. Abdominal distension is minimal with proximal obstructions, but may be pronounced with distal obstruction and paralytic ileus. The abdomen may be tender to palpation as well.

In addition to abdominal and gastrointestinal manifestations, signs of fluid and electrolyte imbalance develop. Hypovolaemia can develop rapidly as extracellular fluid is sequestered in the bowel and vomiting occurs. Although early vital signs may be normal, changes are noted as dehydration and hypovolaemia develop. The person becomes tachycardic and tachypnoeic and blood pressure falls. Temperature may be elevated. Urine output decreases and clinical manifestations of hypovolaemic shock may be seen. The clinical manifestations of mechanical small-bowel obstruction with their accompanying pathophysiological process are outlined in Table 23.13.

COMPLICATIONS Hypovolaemia and hypovolaemic shock with multiple-organ dysfunction is a significant complication of bowel obstruction and can lead to death. Renal insufficiency from hypovolaemia leads to acute kidney injury or dysfunction. Pulmonary ventilation may be impaired because abdominal distension elevates the diaphragm, impeding respiratory processes.

Strangulation associated with incarcerated hernia or volvulus impairs the blood supply to the bowel. Gangrene may rapidly result, causing bleeding into the bowel lumen and peritoneal cavity and eventual perforation. With perforation, bacteria and toxins from the strangulated intestine enter the peritoneum and, potentially, the circulation, resulting in peritonitis and possible septic shock. Strangulation greatly increases the risk of mortality.

Large-bowel obstruction

Obstruction of the large intestine occurs much less frequently than small-bowel obstruction. Although any portion of the colon may be affected, obstruction usually occurs in the sigmoid segment. Bowel cancer is the most common cause; other causes include volvulus, diverticular disease, inflammatory disorders and faecal impaction.

MANIFESTATIONS Constipation and colic-like abdominal pain are usual manifestations of large-bowel obstruction. The pain is often deep and cramping; severe continuous pain signals bowel ischaemia and possible perforation. Vomiting is a late sign, if it occurs at all. The abdomen is distended, with high-pitched, tinkling bowel sounds with rushes and gurgles. On palpation, localised tenderness or a mass may be noted.

COMPLICATIONS If the ileocaecal valve between the small and large intestines is competent, distension proximal to the obstruction is limited to the colon itself. This is known as a *closed-loop obstruction*. It leads to massive colon dilation as the ileum continues to empty gas and fluid into the colon. Increasing pressure within the obstructed colon impairs circulation to the bowel wall. Gangrene and perforation are potential complications.

INTERPROFESSIONAL CARE

The management of a bowel obstruction focuses on relieving the pressure and obstruction and providing supportive care. The intestine is decompressed and fluid and electrolyte balance is restored. Surgery may be necessary to relieve a mechanical obstruction or if strangulation is suspected.

TABLE 23.13 Clinical manifestations and pathophysiological processes of mechanical small-bowel obstruction

MANIFESTATION	PATHOPHYSIOLOGY
Abdominal pain: intermittent mid-abdominal, colicky; intensity may initially decrease, then become severe and steady	Peristaltic waves attempt to propel bowel contents past the obstruction. As the bowel becomes increasingly distended, peristalsis is inhibited and pain may decrease in intensity. If unrelieved, distension of bowel lumen impairs mucosal blood supply, leading to ischaemia and necrosis. Bowel infarction or perforation may occur, leading to chemical and bacterial peritonitis.
Bowel sounds: initially loud, possibly high pitched; may correspond with waves of abdominal pain; later infrequent or absent	Initial distension of the bowel proximal to the obstruction stimulates peristalsis as the bowel attempts to propel contents past the obstruction. With further distension and resulting electrolyte imbalances, peristalsis is inhibited and bowel sounds become less frequent to inaudible.
Vomiting	Distension of the bowel stimulates the vomiting centre of the brain, which, in turn, stimulates the vomiting reflex.
Abdominal distension	Fluid (saliva, gastric juice, bile, pancreatic secretions) and air are trapped in the bowel proximal to the obstruction.
Hypovolaemia, electrolyte imbalance	Normal movement of water and sodium from the bowel lumen to the interstitial and intravascular spaces is initially inhibited. Fluids and electrolytes are lost through vomiting. With continued obstruction and bowel distension, sodium and water move from the vascular system into the bowel lumen, further distending it. Intestinal venous return is inhibited, leading to tissue oedema and accumulation of fluid and electrolytes within the peritoneal cavity.

Diagnosis

Radiological studies (x-rays and CT scan) are used to confirm the diagnosis of bowel obstruction. Laboratory testing is used to evaluate for the presence of infection and fluid and electrolyte imbalances.

An abdominal x-ray often shows distended loops of intestine with fluid and gas in a small-bowel obstruction. Free air under the diaphragm indicates a perforation. X-ray or CT scan with contrast media may be required to confirm a mechanical obstruction and assess the completeness of the obstruction. Meglumine diatrizoate (Gastrografin) is often used to provide contrast, rather than barium, when a bowel obstruction is suspected. Barium enema may be used to confirm the diagnosis of large-bowel obstruction and determine its location, unless perforation is suspected.

Laboratory tests include WBC, serum amylase, serum osmolality, electrolytes and arterial blood gases. These tests will show the following results with a bowel obstruction:

- *WBC* often shows mild leucocytosis due to an inflammatory response to changes within the obstructed bowel lumen. With strangulation, leucocytosis is marked.
- *Serum amylase levels* may be elevated, particularly when strangulation is present.
- *Serum osmolality* and *electrolyte levels* are affected by fluid and electrolyte losses from vomiting and fluid sequestering in the bowel lumen. With hypovolaemia, the serum osmolality and urine specific gravity increase. Potassium and chloride are lost through vomiting, leading to hypokalaemia and hypochloraemia.
- *ABGs* may reveal metabolic alkalosis (pH > 7.45, bicarbonate > 26 mmol/L, PCO_2 > 45 mmHg) with small-bowel obstruction due to loss of hydrochloric acid from the stomach.

Gastrointestinal decompression

Most partial small-bowel obstructions are successfully treated with gastrointestinal decompression using a nasogastric or long intestinal tube. Functional obstructions respond to treatment with bowel rest and intestinal decompression as well. Intestinal tubes (see Figure 23.5) may be inserted through the nares or via gastrostomy. A balloon or weighted tip draws the tube from the stomach into the intestine and to the area of obstruction. Collected fluid and gas are removed using low suction until peristalsis resumes or the obstruction is relieved. Sayakkara (2012) outlined the current clinical guidelines for low-pressure gastric suctioning, including regularly checking suction reaches the specified pressure level—gastric contents move back down the tube towards the person when the suction is off and rise towards the container when the suction is on. If the fluid fails to move, the Salem sump may be blocked or the suction container is positioned too low or high relative to the height of the person's stomach. In a few hours a person can lose more than 1500 mL containing electrolytes and hydrogen ions when low-pressure suction is used (Sayakkara, 2012). It is important to closely assess the person's fluid, electrolyte and acid–base balance.

Surgery

Surgical intervention is required for complete mechanical obstructions as well as for strangulated or incarcerated obstructions of the small intestine. A person with incomplete mechanical obstruction may also require surgery if the obstruction persists.

Prior to surgery, a nasogastric tube is inserted to relieve vomiting and abdominal distension and to prevent aspiration of intestinal contents. Fluid and electrolyte balance must be restored before surgery. Isotonic intravenous fluids, such as normal (physiological) saline, Hartmann's solution or other balanced electrolyte solutions are used. Additional electrolytes may be added to the solution to correct low levels. It is particularly important to correct hypokalaemia prior to surgery. Acid–base imbalances are also addressed, often using intravenous acidifiers or alkalinising agents. If strangulation has occurred, the person may require plasma or blood replacement. Intravenous broad-spectrum antibiotics are administered prophylactically (see the section on peritonitis).

A laparotomy usually is performed to allow inspection of the small intestine and removal of infarcted or gangrenous tissue. If the obstruction was caused by adhesions, these are removed or lysed. Obstructing tumours are resected and foreign bodies are removed. Any bowel appearing gangrenous is resected, usually followed by an end-to-end anastomosis of remaining intestine. If a large tumour mass or dense adhesions are found, the area of obstruction may be bypassed by anastomosis of proximal small bowel to small or large intestine distal to the obstruction. See the box 'Nursing care of the person requiring bowel surgery'.

Obstructions of the large intestine usually necessitate surgery. The primary goal is to relieve colonic distension and prevent perforation. The secondary goal is to remove the obstructing lesion. In some cases, colonoscopy may be used to relieve the distension. If the person's condition prohibits major surgery or the obstructing tumour is advanced, laser photocoagulation may be used to enlarge the bowel lumen. Removal of the obstructing lesion is the preferred treatment. The proximal and distal bowel segments may be anastomosed or a permanent colostomy or ileostomy may be required.

Nursing care

Health promotion

Advise the person, particularly older adults, regarding health promotion activities, such as increasing dietary fibre intake, maintaining a generous fluid intake and exercising daily to help prevent constipation and possible large-bowel obstruction. Stress the importance of maintaining dietary restrictions (such as avoiding popcorn) for a person experiencing repeated small-bowel obstructions.

Assessment

Nurses may be instrumental in the early identification of intestinal obstructions in older adults, the homebound or the institutionalised individual. Early identification and intervention significantly reduce morbidity from bowel obstruction.

- *Health history:* complaints of abdominal pain and bloating, constipation; previous history of bowel obstruction or risk factors such as hernia, inflammatory bowel disease, diverticulosis or previous abdominal surgery; current medications.
- *Physical examination:* vital signs including orthostatic blood pressure, temperature; skin colour, temperature, texture and turgor; colour and moisture of mucous membranes; abdominal shape, contour, bowel sounds, presence of tenderness or masses on palpation.

Nursing diagnoses and interventions

In a person with suspected or confirmed bowel obstruction, frequent assessment for complications such as fluid and electrolyte imbalance, acid–base imbalances, hypovolaemic shock, perforation and peritonitis is necessary.

Deficient fluid volume

Because of the large collection of fluid in the bowel proximal to an obstruction, and the accompanying vomiting and nasogastric suction, a person with an intestinal obstruction often has a fluid volume deficit. If not corrected promptly, hypovolaemic shock, acute kidney injury and multiple-organ system dysfunction from poor tissue perfusion may result.

- Monitor vital signs, peripheral perfusion (skin temperature, peripheral pulses and capillary refill); pulmonary artery pressures, cardiac output (CO) (if Swan–Ganz catheter in situ) and central venous pressure (CVP) hourly (if able). *A decrease in blood pressure, tachycardia, tachypnoea and a decrease in peripheral perfusion may indicate hypovolaemia. Although invasive, haemodynamic parameters such as pulmonary artery pressures, CO and CVP allow accurate assessment of fluid volume status.*
- Measure urinary output hourly and nasogastric drainage every 2 to 4 hours. *A urinary output of 0.5 mL/kg/hr or more usually indicates an adequate glomerular filtration rate (GFR). Nasogastric output provides a tool for evaluating fluid replacement needs.*

CONSIDERATION FOR PRACTICE

Report promptly urine output of less than 0.5 mL/kg/hr for 2 consecutive hours. This often indicates hypovolaemia and an increased risk of shock and acute kidney injury or dysfunction.

- Maintain intravenous fluids and blood volume expanders as ordered. *The amount of fluid administered is calculated to meet ongoing fluid needs and replace previous and current losses. Restoration and maintenance of blood volume are necessary to maintain cardiac output and tissue and organ perfusion.*
- Measure abdominal girth every 4 to 8 hours. Mark the level of measurement on the abdomen. *A reference mark allows consistent, accurate measurements. An increase in abdominal girth indicates increasing intestinal distension.*
- Notify the doctor of changes in status. *Changes in vital signs, pain and signs of increasing distension can indicate the need for immediate surgical intervention.*

Ineffective tissue perfusion: gastrointestinal

Perfusion of the intestinal wall and mucosa may be impaired by the obstructive process itself (e.g. strangulation or volvulus) or by significant intestinal distension. The goal is to maintain tissue perfusion and promote normal peristalsis and bowel elimination.

- Monitor vital signs hourly. Assess peripheral pulses, skin colour, temperature and capillary refill. *Cardiovascular assessment is vital to detect early signs of hypovolaemic shock resulting from sequestering large volumes of fluid in the intestines. Hypovolaemia and shock can convert mild bowel ischaemia to infarction as the blood supply to the tissue falls.*
- Monitor urine output hourly. Report output of less than 0.5 mL/kg/hr. *Urine output is a good indicator of the GFR and tissue perfusion. The urine output often falls before vital sign changes are apparent in hypovolaemia.*
- Monitor temperature at least every 4 hours. *An elevated temperature may be an early indication of sepsis from bowel perforation as a result of gangrene.*
- Frequently assess pain. *A change in the character of pain or a rapid increase in its intensity may signal bowel infarction or perforation.*
- Maintain NBM status until peristalsis resumes. *Enteral food or fluids may increase distension and bowel ischaemia. These also are restricted until the possibility of perforation is eliminated.*

Ineffective breathing pattern

Significant abdominal distension from a bowel obstruction can cause the diaphragm to flatten, impairing pulmonary ventilation. Following surgery, splinting of abdominal muscles to avoid pain can lead to shallow respirations. These factors, plus the risk of aspiration of gastrointestinal contents during vomiting, place a person at high risk of respiratory complications, particularly with a small-bowel obstruction.

- Assess respiratory rate, pattern, pulse oximetry and lung sounds at least every 2 to 4 hours. *Tachypnoea, shortness of breath or apparent dyspnoea are early signs of respiratory compromise. Diminished breath sounds, particularly in the bases of the lungs, or crackles indicate poor lung expansion and possible impaired ventilation.*
- Monitor ABG results for possible effects of altered respiratory status. *Tachypnoea may lead to respiratory alkalosis as excess carbon dioxide is eliminated. Conversely, impaired chest expansion can lead to respiratory acidosis because of alveolar hypoventilation.*
- Elevate the head of the bed. *Elevating the head of the bed reduces the work of breathing and improves alveolar ventilation by reducing the pressure of abdominal distension on the diaphragm.*
- Provide a pillow or folded towel to use in splinting the abdomen while coughing postoperatively. *Splinting abdominal muscles and incisions improves the ease and effectiveness of coughing postoperatively.*
- Maintain nasogastric or intestinal tube patency. *Maintaining gastrointestinal suction helps reduce*

abdominal distension and prevent aspiration associated with vomiting.

- Encourage use of incentive spirometer or other assistive device hourly. *These devices encourage deep breathing, opening distal airways and preventing atelectasis.*
- Contact physiotherapist as indicated. *The physiotherapist may suggest or perform additional measures to maintain effective pulmonary ventilation.*
- Provide good oral care 2 to 4 hourly. *Dehydration and nasogastric suction dry the mucous membranes of the mouth and throat, increasing the risk of bacterial growth. Many respiratory infections result from aspirated organisms.*

Community-based care

Include the following topics when teaching a person with intestinal obstruction in preparation for home care:

- wound care
- activity level, return to work and any other recommended restrictions
- recommended follow-up care
- care of temporary colostomy (if appropriate) and planned reanastomosis
- recurrent obstructions, their cause, early identification of manifestations and possible preventive measures.

THE PERSON WITH DIVERTICULAR DISEASE

Diverticula are small (0.5 to 1.0 cm) outpouchings of the colon occurring in rows (see Figure 23.19). Diverticula may occur anywhere in the intestinal tract, excluding the rectum. The vast majority, however, affect the large intestine, with 85–95% occurring in the sigmoid colon (Fauci et al., 2008; McPhee et al., 2008).

FAST FACTS

Diverticular disease

- People in Australia, the United Kingdom, France and the United States have high and increasing incidence rates of diverticular disease. The incidence of diverticula increases with age, with 5–10% of the population older than 45 years of age and almost 80% of those older than 85 years of age experiencing it.
- Most people diagnosed with diverticular disease remain asymptomatic.
- Men and women are equally affected.

Cultural factors—diet, in particular—are thought to play an important role in the development of diverticula. A diet consisting of highly refined and fibre-deficient foods is believed to be a major contributor to the disease. Decreased activity levels and delaying defecation have also been suggested as contributing factors. The increasing incidence of diverticula with ageing suggests dietary factors (lack of fibre), a decrease in physical activity, poor bowel habits (neglecting the urge to defecate) and the effects of ageing contribute to development of the disease (Marieb & Hoehn, 2013).

Pathophysiology

Diverticula form when increased pressure within the bowel lumen causes bowel mucosa to herniate through defects in the colon wall. The circular and longitudinal muscles often thicken or hypertrophy in the area affected by diverticula. This narrows the bowel lumen, increasing intraluminal pressure. Deficient dietary fibre and a lack of faecal bulk contribute to muscle hypertrophy and narrowing of the bowel. Contraction of the muscles in response to normal stimuli such as meals may occlude the narrowed lumen, further increasing intraluminal pressure. The high pressure causes mucosa to herniate through the muscle wall, forming a diverticulum. Areas where

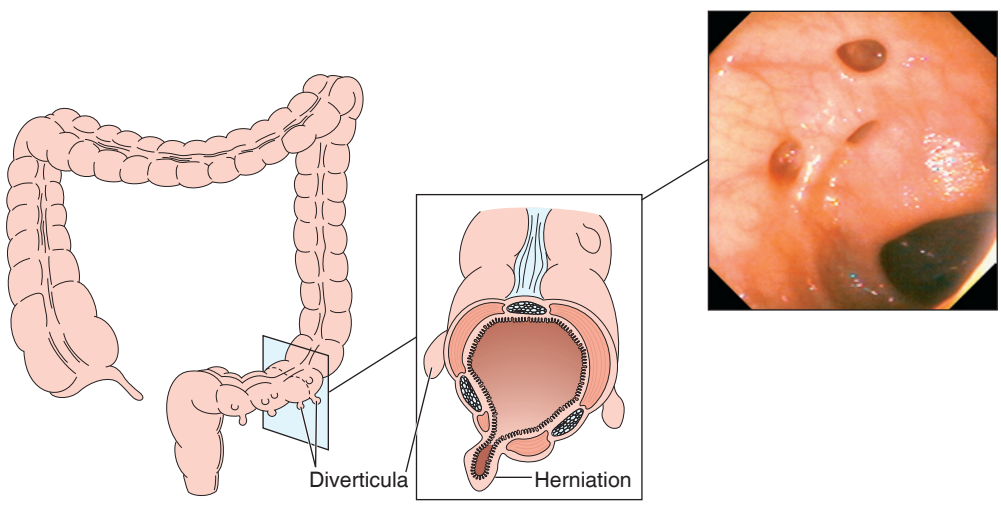

FIGURE 23.19 ■ Diverticula of the colon

Source: Image © David M. Martin MD/Science Source.

nutrient blood vessels penetrate the circular muscle layer are the most common sites for diverticula formation.

Diverticulosis

Diverticulosis indicates the presence of diverticula. More than two-thirds of people with diverticulosis are asymptomatic. When manifestations such as episodic pain (usually left-sided), constipation and diarrhoea occur, these often are attributed to irritable bowel syndrome, commonly accompanying diverticular disease. As the disease progresses, abdominal cramping, narrow stools (decrease in calibre), increased constipation, bleeding in the stools, weakness and fatigue may develop.

Complications of diverticulosis include haemorrhage and diverticulitis. A diverticulum may bleed, whether it is inflamed or not, possibly due to erosion of an adjacent blood vessel by a faecalith (hard mass) in the diverticulum.

Diverticulitis

Diverticulitis is inflammation in and around the diverticular sac. It typically affects only one diverticulum, usually in the sigmoid colon. Undigested food and bacteria collect in the diverticula, forming a hard mass impairing the mucosal blood supply, allowing bacterial invasion. Mucosal ischaemia leads to perforation. With microscopic perforation, inflammation is localised. Gross perforation of a diverticulum results in more extensive bacterial contamination, leading to abscess formation or peritonitis.

MANIFESTATIONS Pain is a common clinical manifestation of diverticulitis. It is usually left-sided and may be mild to severe and either steady or cramping. The person may also experience either constipation or increased frequency of defecation. Depending on the location and severity of the inflammation, nausea, vomiting and a low-grade fever may occur. On examination, the abdomen may be distended, with tenderness and a palpable mass in the left lower quadrant resulting from the inflammatory response.

Older adults may have less specific manifestations, complaining of vague abdominal pain. A palpable mass and signs of a large-bowel obstruction may be present.

COMPLICATIONS Complications associated with diverticulitis (in addition to peritonitis and abscess formation) include bowel obstruction, fistula formation and haemorrhage. Severe or repeated episodes of diverticulitis may lead to scarring and fibrosis of the bowel wall, further narrowing the bowel lumen. This increases the risk of obstruction of the large bowel. Acutely inflamed tissue adheres to the small bowel, increasing the potential for small-bowel obstruction as well. Fistulas may form, usually between the sigmoid colon and the bladder. Urinary tract infection is the usual sign of a colovesical fistula. Fistulas may also perforate into the small intestine, ureter, vagina, perineum or abdominal wall. Bleeding from perforation of a vessel wall can occur with diverticulitis. Although it may be significant, bleeding usually stops spontaneously.

INTERPROFESSIONAL CARE

Management of diverticular disease varies from no prescribed treatment to surgical resection of affected colon, depending on the severity of the disease and its complications.

Diagnosis

Diagnostic testing is used to identify diverticular disease when the disease is symptomatic or complications develop. In addition to illustrating diverticula, a barium enema and x-rays can reveal segmental spasm and muscular thickening with a narrowed bowel lumen. Flexible sigmoidoscopy or colonoscopy may be done to detect diverticulosis, assess for strictures or bleeding, and rule out tumour as the cause of the person's manifestations. Abdominal x-ray films may show free abdominal air associated with diverticulitis and perforation. CT scan may be done with or without contrast media to assess inflammation and detect an abscess or fistula.

Laboratory tests include haemoccult or guaiac testing of stool to identify the presence of occult blood, and a WBC count may show leucocytosis with a left shift (an increased number of immature WBCs) due to inflammation in diverticulitis.

Medications

Systemic broad-spectrum antibiotics effective against usual bowel flora are prescribed to treat acute diverticulitis. Oral antibiotics such as metronidazole (Flagyl) and ciprofloxacin (Cipro) or trimethoprim-sulfamethoxazole (Septra, Bactrim) may be prescribed if manifestations are mild. Rifixamin (Xifaxan) is a poorly absorbed antibiotic that may be used together with fibre to treat unmanaged diverticular disease. Severe, acute attacks often require hospitalisation and treatment with intravenous fluids and antibiotics effective against anaerobic and gram-negative bacteria. Therapy may include a second-generation cephalosporin such as cefoxitin (Mefoxin) or another antibiotic such as piperacillin-tazobactam (Tazocin) or ticarcillin-clavulanate (Timentin). Antibiotics and their nursing implications are discussed in Chapter 11.

Although a stool softener such as docusate sodium (Coloxyl) may be prescribed, it is important to note that laxatives (which can further increase intraluminal pressure in the colon) are avoided for a person with diverticular disease.

Nutrition

Dietary modification is central to the management of diverticular disease. Dietary changes appear to reduce the risk of complications of diverticulosis. A high-fibre diet is recommended; this increases stool bulk, decreases intraluminal pressures and may reduce spasm (see Table 23.14). Bran is a low-cost fibre supplement that can be added to cereal, soups, salads or other foods. Commercial bulk-forming products—for example, psyllium seed (Metamucil)—may be recommended. These products are discussed in the 'Medication administration' box—'Laxatives'—on pages 708–709. A person should be advised to avoid foods with small seeds (such as caraway seeds, figs or berries), which could obstruct diverticula.

Bowel rest is prescribed during an acute episode of diverticulitis. Initially the person may be NBM with intravenous fluids

TABLE 23.14 Foods recommended in a high-fibre, high-residue diet

FOOD GROUP	RECOMMENDED FOODS
Cereals and grains	Wheat or oat bran; cooked cereals, such as oatmeal; dry cereals, such as bran buds or flakes, cornflakes, shredded wheat; wholegrain breads or biscuits; brown rice; popcorn
Fruits	Unpeeled raw apples, peaches and pears; blackberries, raspberries, strawberries; oranges
Vegetables	Dried beans (navy, kidney, pinto), lima beans; broccoli; peas; corn; squash; raw vegetables, such as carrots, celery and tomatoes; potatoes (with skins)

and occasionally TPN. Feeding is resumed gradually. Initially, a clear liquid diet is prescribed, with gradual advancement to a soft, low-roughage diet (i.e. a diet low in insoluble fibre) with daily added psyllium seed to soften stool and increase its bulk. Among foods a person should avoid are wheat and corn bran, vegetable and fruit skins, nuts and dry beans. The high-fibre diet is resumed following full recovery.

Surgery

A person with acute diverticulitis may require surgery, usually to treat generalised peritonitis or an abscess failing to respond to medical treatment. Haemorrhage that recurs or cannot be controlled may also necessitate surgery. Elective surgery may be performed for recurrent episodes of diverticulitis or persistent diverticulitis with continuing pain, tenderness and a palpable mass.

The affected bowel segment is resected and if possible an anastomosis of the proximal and distal portions is performed. When an acute infection and diverticulitis are present, a two-stage Hartmann procedure is required. A temporary colostomy is created and anastomosis delayed until the inflammation has subsided. A second surgery is performed 2 to 3 months later to reconnect the bowel and close the temporary colostomy.

Nursing care

Health promotion

Advising a person about the benefits of a high-fibre diet is important primary prevention for diverticular disease. Nurses working with groups and individuals in the community should emphasise the importance of a high-fibre diet and its benefits in preventing diverticular disease and other disorders. In facilities such as residential settings, nurses can work with dietary staff and care providers to increase the amount of fibre in residents' diets, unless this is contraindicated by a pre-existing condition.

Assessment

Because most people with diverticular disease have few or no manifestations, nursing assessment focuses on manifestations of complications.

- *Health history:* abdominal pain or cramping, chronic constipation or irregular bowel habits; nausea and vomiting; history of diverticular disease or irritable bowel syndrome.
- *Physical examination:* bowel sounds, presence of abdominal tenderness of masses and location; stool for occult blood.

Nursing diagnoses and interventions

A person with acute diverticulitis is acutely ill and has multiple nursing care needs. Priority nursing diagnoses include *Potential complication: perforation*, *Acute pain* and *Anxiety* related to the possibility of a significant complication or possible surgery.

Potential complication: perforation

During an acute attack of diverticulitis, inflammation and mucosal ischaemia the person is at risk of perforation and peritonitis. In addition to maintaining bowel rest to reduce the risk of perforation, nurses monitor for manifestations of perforation and possible sepsis.

- Monitor vital signs including temperature at least every 4 hours. *Tachycardia and tachypnoea may be early indications of increased inflammation and resulting fluid shift. Fever greater than 38.3°C may indicate increased inflammation or spread of inflammation. Note, however, that little temperature elevation may occur in older adults. A change in behaviour or increasing lethargy may be subtle indications of infection in the older adult.*
- Assess abdomen every 4 to 8 hours or more often as indicated, including measuring abdominal girth, auscultating bowel sounds and palpating for tenderness. Report promptly significant changes to the doctor. *Increasing abdominal distension, a decrease or change in the quality of bowel sounds, and/or increasing tenderness or guarding may indicate spread of the infectious process or peritonitis.*
- Assess for evidence of lower intestinal bleeding by visual examination and guaiac testing of stools for occult blood. *Perforation of a diverticulum may produce either intestinal or intra-abdominal bleeding and require immediate treatment such as surgery.*
- Maintain intravenous fluids, TPN and accurate intake and output records. *During acute diverticulitis, oral intake is usually prohibited or restricted. Intravenous fluids are given to maintain fluid and electrolyte balance; TPN is used to maintain nutritional status, facilitating healing and recovery.*

Acute pain

Pain is a common clinical manifestation of acute diverticulitis. It results from inflammation of the bowel and oedema of affected tissues. If surgery is required, postoperative pain is managed with narcotic analgesics.

- Ask the person to rate pain using a 0 to 10 pain scale. Document the level of pain and note any changes in location or character of pain. *The perception and response to pain is individual and is affected by past experiences, culture, ethnic background and other factors. A change in the character or intensity of the pain indicates a complication such as perforation or abscess formation.*
- Administer prescribed analgesic or maintain PCA as ordered. Assess analgesic effectiveness. Avoid administering morphine. Provide adjunctive medications as ordered and encourage use of adjunctive techniques, such as relaxation, positioning and distraction. Notify the doctor if pain management is inadequate. *If a person has not obtained adequate pain relief, further assessment and intervention are required.*
- Maintain bowel rest and total body rest (bed rest with limited activity). *Rest helps reduce inflammation and promotes healing, increasing comfort.*
- Reintroduce oral foods and fluids slowly, providing a soft, low-fibre diet with bulk-forming agents. *This allows continued healing of the affected bowel while promoting soft, easily expelled stools.*

Anxiety

A person with acute diverticulitis faces not only hospitalisation but also potential serious complications such as peritonitis and haemorrhage. Surgery and formation of a temporary colostomy may be necessary. Furthermore, episodes of acute diverticulitis are often recurrent and the person may fear future problems.

- Demonstrate empathy and awareness of the perceived health threat. *It is important to recognise and respect the person's feelings and perceptions as reality.*
- Assess level of understanding about disease and condition. *This allows misperceptions contributing to anxiety to be corrected.*
- Assess and document level of anxiety. *Severe anxiety or panic states interfere with the ability to respond to instructions and assist with care. Low to moderate anxiety levels enhance learning and compliance with prescribed interventions.*
- Assist the person to identify and use appropriate coping mechanisms. *Coping mechanisms provide immediate relief of anxiety while the person adapts to the situation.*
- Attend to physical care needs. *This provides reassurance these needs will be met and relieves concerns about them.*
- Spend as much time as possible with the person. *Presence of caring nurses helps relieve fears of abandonment or that help will not be available if needed. It also enhances trust and provides opportunity for expression of fears or concerns.*
- Encourage family and friends to remain with the person as much as possible. *This provides a supportive environment for the person and also distracts from physical concerns.*
- Involve the person and their family (as appropriate) in care decisions. *This increases a person's sense of control over the situation.*

Community-based care

A person with diverticular disease is responsible for self-care. Discuss the following topics for home care:

- prescribed high-fibre diet and the need to maintain the diet for life to reduce the incidence of complications, including ways to increase dietary fibre
- complications and their manifestations of diverticular disease
- provide a referral to a nutritionist for teaching as indicated.

Prior to discharge of a person with acute diverticulitis, discuss the following:

- food and fluid limitations, including recommendations for a low-residue diet during the initial period of healing
- colostomy management (if a temporary colostomy has been created), including where to obtain supplies and dietary management
- planned procedure to reanastomose the colon and revise the colostomy. Refer to community healthcare organisations as indicated.

ANORECTAL DISORDERS

Anorectal lesions include haemorrhoids, anal fissure, anorectal abscess, anorectal fistula and pilonidal disease.

THE PERSON WITH HAEMORRHOIDS

The anus and anal canal contain two superficial venous plexuses with the haemorrhoidal veins. When pressure on these veins is increased or venous return impeded, they can develop varices or varicosities, becoming weak and distended. This condition is commonly known as **haemorrhoids** or 'piles'. When asymptomatic, haemorrhoids are considered to be a normal condition found in all adults.

Pathophysiology and manifestations

Haemorrhoids develop when venous return from the anal canal is impaired. Straining to defecate increases venous pressure and is the most common cause of distended haemorrhoids. Pregnancy increases intra-abdominal pressure, raising venous pressure, and is another cause of haemorrhoids. Other factors that may contribute to symptomatic haemorrhoids include prolonged sitting, obesity, chronic constipation and a low-fibre diet.

Haemorrhoids are classed as either internal or external. *Internal haemorrhoids* affect the venous plexus above the

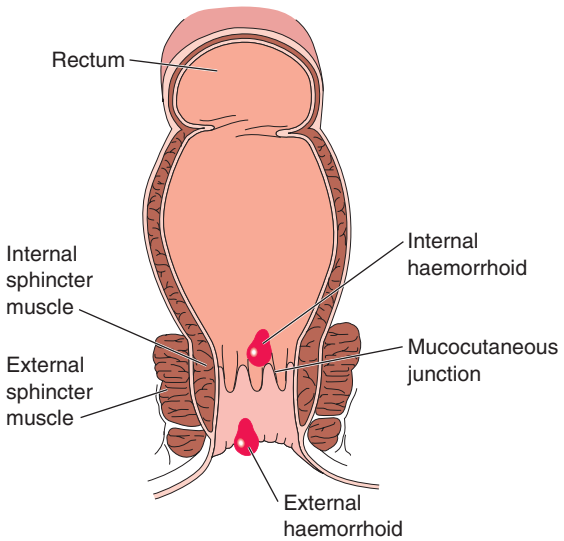

FIGURE 23.20 ■ The location of internal and external haemorrhoids

mucocutaneous junction of the anus (see Figure 23.20). Internal haemorrhoids rarely cause pain, usually presenting with bleeding. Bleeding from internal haemorrhoids is bright red and unmixed with the stool. It varies in quantity from streaks on toilet tissue to enough to colour the water in the toilet. Recurrent bleeding of internal haemorrhoids may be sufficient to cause anaemia. Mucus discharge and a feeling of incomplete evacuation of stool may also be manifestations of internal haemorrhoids.

External haemorrhoids affect the inferior haemorrhoidal plexus below the mucocutaneous junction. Bleeding is rare with external haemorrhoids. Anal irritation, a feeling of pressure and difficulty cleaning the anal region may be manifestations of external haemorrhoids.

As these enlarge, haemorrhoids may prolapse or protrude through the anus. Initially, prolapse occurs only with defecation and the haemorrhoids spontaneously regress back into the anal canal. Eventually, a person may need to manually replace internal haemorrhoids after defecation or these may become permanently prolapsed, in which case replacement is not possible. Manifestations of permanently prolapsed haemorrhoids include mucus discharge and clothing soilage.

'Normal' haemorrhoids are not painful. Prolapsed haemorrhoids may become strangulated as a result of congestion and oedema, leading to thrombosis. Haemorrhoidal thrombosis causes extreme pain and may lead to infarction of skin and mucosa overlying the haemorrhoid. Internal haemorrhoids associated with portal hypertension in liver disease may bleed profusely if ruptured. (See Chapter 24 for further discussion of portal hypertension.)

A *thrombosed external haemorrhoid* is a thrombosis of the subcutaneous external haemorrhoidal veins of the anal canal, rather than a true haemorrhoid. It appears as a painful bluish haematoma beneath the skin and typically occurs following a sudden increase in venous pressure—for example, heavy lifting, coughing or straining. Pain is significant at onset; however, it gradually subsides. Spontaneous rupture with bleeding may occur. Thrombosed external haemorrhoids resolve without intervention.

INTERPROFESSIONAL CARE

Because haemorrhoids are a normal condition, management is conservative unless complications such as permanent prolapse or thrombosis occur.

Diagnosis

Haemorrhoids are diagnosed by the person's history and by examination of the anorectal area. External haemorrhoids can be seen on visual inspection, especially if thrombosed. The person is asked to strain (Valsalva's manoeuvre) during the examination to detect prolapse. Internal haemorrhoids are usually not palpable or tender on digital examination of the rectum. *Anoscopic* examination is used to detect and evaluate internal haemorrhoids. For this exam, a speculum or endoscope is introduced into the anus to provide visual inspection of the tissues. Additional diagnostic examinations include testing of stool for occult blood and sigmoidoscopy, performed to rule out colon or rectal cancer, which may aggravate haemorrhoidal manifestations or produce similar manifestations. If liver disease with portal hypertension is suspected, liver function studies are ordered.

Medications

Bulk-forming laxatives such as psyllium seed (Metamucil) or stool softeners such as docusate sodium (Coloxyl) may be prescribed to relieve constipation as well as reducing discomfort. Suppositories and local ointments such as Preparation H or Nupercaine have an anaesthetic and astringent effect, reducing discomfort and irritation of surrounding tissues. These medications have little or no effect on the haemorrhoid itself. Warm sitz baths, bed rest and local astringent compresses may be recommended to reduce the swelling of oedematous prolapsed haemorrhoids after digital reduction.

Nutrition

Haemorrhoids that are not permanently prolapsed or acutely thrombosed generally are treated conservatively. A high-fibre diet and increased water intake to increase stool bulk, improve its softness and reduce straining are effective for most people with internal or external haemorrhoids.

Sclerotherapy

Haemorrhoids that are permanently prolapsed, are thrombosed or produce significant manifestations are treated more aggressively. *Sclerotherapy* involves injecting a chemical irritant into tissues surrounding the haemorrhoid to induce inflammation and eventual fibrosis and scarring. It is used to treat recurrent bleeding and early prolapse of internal haemorrhoids. The treatment produces minimal pain. Enlarged or prolapsing haemorrhoids may also be treated with rubber band ligation. A rubber band is placed snugly around the haemorrhoidal plexus

and surrounding mucosa, causing the tissue to necrose and slough within 7 to 10 days. Treatment is limited to one haemorrhoidal complex at a time, so repeat treatments may be necessary. Pain should be minimal if the band is placed appropriately; persistent pain following band ligation may signal an infection. Bleeding can occur as the haemorrhoid sloughs. Other procedures used to treat haemorrhoids include cryosurgery (in which haemorrhoids are necrosed by freezing with a cryoprobe), infrared photocoagulation or electrocoagulation.

Haemorrhoidectomy

A person with chronic manifestations, permanent prolapse, chronic bleeding with associated anaemia or painful thrombosed haemorrhoids may be treated surgically with a *haemorrhoidectomy*. In this procedure, haemorrhoids are surgically excised, leaving normal skin and surrounding tissues. This procedure may use conventional techniques or a laser to remove both internal and external haemorrhoids. Few complications are associated with haemorrhoidectomy.

Nursing care

Primary prevention of symptomatic haemorrhoids involves education of people of all ages. Stress the importance of maintaining an adequate intake of dietary fibre, a liberal fluid intake and regular exercise to maintain stool bulk, softness and regularity. Discuss the need to respond to the urge to defecate rather than postponing defecation. Teach appropriate constipation management, including the use of bulk-forming laxatives.

Most people with haemorrhoids are treated in community settings where the primary nursing focus is educational. Discuss the appropriate use of over-the-counter preparations and sitz baths for the relief of minor haemorrhoidal manifestations. If necessary, teach the person how to reduce prolapsed haemorrhoids digitally.

Advise the person about possible haemorrhoidal complications, such as chronic bleeding, prolapse and thrombosis. Stress the need to seek medical evaluation if manifestations persist. Discuss the link between manifestations of haemorrhoids and colorectal cancer and urge the person to seek medical intervention for persistent, unresolved or progressive manifestations.

When a haemorrhoidectomy is performed, a person requires more direct nursing intervention. Postoperative care of a person with perianal surgery is outlined in Box 23.4. Anal packing may be in place for the first 24 hours following the procedure. When removed, observe the person closely for bleeding. Pain is a common postoperative problem. Although the operative procedure is minor, postoperative discomfort can be significant because the anal region is richly innervated and muscle spasms may occur. In addition to systemic analgesics, sitz baths usually are ordered. These not only help promote relaxation and reduce discomfort but also clean the anal area. Use of a rubber ring or doughnut device minimises pressure on the surgical site while the person sits in the bath.

BOX 23.4 Perianal postoperative care

Assessment
- Monitor vital signs every 4 hours for 24 hours.
- Inspect rectal dressing every 2 to 3 hours for 24 hours.
- Monitor fluid balance—urinary output.

Pain control
- Assist to position of comfort, usually side lying.
- Provide analgesics as prescribed.
- Keep fresh ice packs over the rectal dressing as ordered.
- Assist with sitz bath water sprays three to four times per day.
- Provide a flotation pad for use when sitting.

Elimination
- Give stool softeners as prescribed.
- Give an analgesic before the first postoperative bowel movement if possible.
- When tolerated, encourage fluid intake of at least 2000 mL per day.

Individual and family teaching
- Take sitz bath or water spray after each bowel movement for 1 to 2 weeks after surgery.
- Drink at least 2000 mL of fluid per day.
- Eat adequate dietary fibre and exercise moderately.
- Take stool softeners as prescribead.
- Report to the doctor the following symptoms: rectal bleeding, continued pain on defecation, fever greater than 38.3°C, purulent rectal drainage.

A person may remain hospitalised until after the first postoperative bowel movement. Stool softeners, adequate fluids and analgesia before defecation aid in reducing anxiety and discomfort. Adequate cleaning following defecation, usually with a sitz bath, is vital.

Whether caring for a person with haemorrhoids or following a haemorrhoidectomy, consider the following nursing diagnoses:
- *Altered comfort* related to acute or chronic pain secondary to inflamed anal tissues.
- *Constipation* related to dietary habits and/or delay of defecation.
- *Risk of infection* related to disruption of anal tissue.

THE PERSON WITH AN ANORECTAL LESION

Unlike the rectum, which is relatively insensitive to pain, the anal canal is richly supplied with sensory nerves and is highly sensitive to painful stimuli. Lesions of the anorectal area may cause significant pain, particularly with defecation. Infection is a potential complication of anorectal lesions because of contamination by

faecal bacteria. The superior boundary of the anal canal (the anorectal juncture or pectinate line) contains 8 to 12 anal crypts where anorectal abscesses or fistulas can form. Lesions of the anorectal area include fissures, abscesses, fistulas and pilonidal disease.

Anal fissure

Anal fissures or ulcers occur when the epithelium of the anal canal over the internal sphincter becomes denuded or abraded. Irritating diarrhoeal stools and tightening of the anal canal with increased sphincter tension are frequent causes of anal fissures. Other factors contributing to their development include childbirth trauma, habitual purgative use, laceration by a foreign body and anal intercourse. Chronic inflammation and infection of surrounding tissues accompanies an anal fissure.

A person with an anal fissure typically has periods of exacerbation and remission. Because these occur below the mucocutaneous line, anal fissures are painful. Pain occurring with defecation is described as tearing, burning or cutting. Bright red bleeding is noted with a bowel movement. Bleeding is typically minor and noted on toilet paper. Because of fear of defecation, the person may develop constipation, further disrupting normal bowel habits and aggravating manifestations.

The diagnosis of anal fissure is made by gentle digital examination of the anal canal and anoscopy using a small anoscope. Treatment is usually conservative, involving dietary changes to increase fibre intake and stool bulk, increased fluid intake and use of bulk-forming laxatives. A topical agent such as hydrocortisone cream may be prescribed. Surgical intervention with an internal sphincterotomy, an incision into the internal sphincter to increase its diameter, is considered when the fissure does not heal with medical intervention.

Anorectal abscess

Invasion of the pararectal spaces by pathogenic bacteria can lead to an *anorectal abscess*. Commonly caused by infection extending from the anal crypt into a pararectal space, the abscess may appear small but often contains a large amount of pus. Multiple pathogens may be present, including *Escherichia coli*, *Proteus*, streptococci and staphylococci. Other factors contributing to the development of an anorectal abscess include infection of a hair follicle, sebaceous gland or sweat gland, and abrasions, fissures or anal trauma. The incidence of anorectal abscess is higher in men.

Pain is the primary manifestation of an anorectal abscess. Sitting or walking may aggravate the pain, but it is unrelated to defecation. External swelling, redness, heat and tenderness are apparent on examination. With a deeper abscess, swelling may not be visible, but the abscess is palpable on digital examination.

If the abscess either does not drain spontaneously or is not drained surgically, adjacent anatomical spaces are affected. Systemic sepsis is also a potential complication.

Incision and drainage is the treatment of choice for an anorectal abscess because it rarely resolves with antibiotic therapy alone. This treatment often leads to a persistent fistula, which is surgically closed after the infection has cleared.

Anorectal fistula

A fistula is a tunnel or tube-like tract with openings at each end. *Anorectal fistulas* have one opening in the anal canal, with the other usually found in perianal skin. Most occur spontaneously or as a result of anorectal abscess drainage. Crohn's disease is also a predisposing factor to fistula development.

The primary manifestation of an anorectal fistula is intermittent or constant drainage or purulent discharge. This may be accompanied by local itching, tenderness and pain associated with defecation.

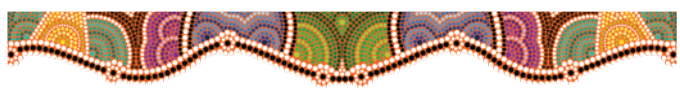
Anoscopic and digital examination with gentle probing of the fistula tract are used to establish the diagnosis. Although some fistulas may heal spontaneously, the treatment of choice is a fistulotomy. The primary opening of the fistula is removed and the tract is opened to allow it to heal by secondary intention, from the inside outward. If the sphincter is involved, a two-stage operation may be done to preserve the muscle and prevent faecal incontinence.

Pilonidal disease

A person with *pilonidal disease* has an acute abscess or chronic draining sinus in the sacrococcygeal area. Underlying the abscess or sinus is a cyst with granulation tissue, fibrosis and, often, hair tufts. This disease usually affects young hirsute (hairy) males and is probably due to hair entrapment in deep tissues of the sacrococcygeal area. Some researchers, however, believe it is a congenital disorder.

The lesion of pilonidal disease is generally asymptomatic unless it becomes acutely infected. Manifestations of acute inflammation accompany infection, including pain, tenderness, redness, heat and swelling of the affected area. Purulent discharge may be noted from one or more sinuses or openings in the midline.

The preferred treatment option for pilonidal disease is incision and drainage. The sinus tract and underlying cyst are excised and closed by either primary- or secondary-intention healing. The person may be instructed to remove hair from the area routinely by shaving or using a depilatory to prevent further hair entrapment and recurrence of the problem.



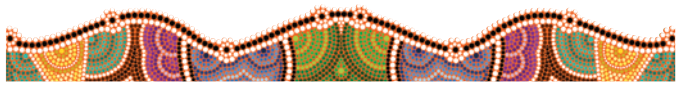
Nursing care

People with anorectal disorders are often treated in the community and the primary nursing responsibility is education. Highlight the importance of maintaining a high-fibre diet and liberal fluid intake to increase stool bulk and softness, thereby decreasing discomfort with defecation. Stress the importance of responding to the urge to defecate to prevent constipation.

Following surgical treatment of any of these disorders, inform the person to keep the perianal region clean and dry. If a dressing is in place, instruct to avoid soiling it with urine or faeces during elimination. Following removal of the dressing, teach to clean the area gently with soap and water following a bowel movement. Discuss the use of sitz baths for cleaning and comfort. Sitz baths are often recommended conservative management pre- and postoperatively for anorectal disorders. A systematic review by Slade (2014) found no strong evidence to support the use of the sitz bath for pain relief or to accelerate fissure or wound healing among adult people with anorectal disorders. However, people

with anorectal disorders were more satisfied when using interventions such as sitz baths and water sprays. Slade (2014) highlighted that a person may find the use of the water spray method more convenient and an appropriate alternative to the sitz bath. The use of sitz baths is a personal choice.

Suggest taking an analgesic if necessary prior to defecation. However, caution that some analgesics promote constipation. Teach clinical manifestations of infection or other possible complications to report to the doctor. If an antibiotic has been prescribed, provide written and verbal instructions about its use, its desired and possible adverse effects, and their management.



CHAPTER HIGHLIGHTS

- Disorders of intestinal motility include diarrhoea, constipation, irritable bowel syndrome and faecal incontinence. Diarrhoea is a manifestation of many other bowel disorders, including lactose intolerance, infections with bacteria, and inflammatory diseases of the bowel. Constipation may be a primary problem (especially for the older adult) or a manifestation of another disorder. Irritable bowel syndrome (IBS) is a functional disorder without any identifiable organic cause. Faecal incontinence is usually considered to be the manifestation of a disorder, rather than a disorder itself.
- Appendicitis is an acute inflammation of the vermiform appendix, manifested by abdominal pain that localises in the right lower quadrant of the abdomen. On palpation, localised and rebound tenderness is present at McBurney's point. It is treated most often with an appendectomy.
- Peritonitis (inflammation of the peritoneum from infection or chemical irritant) is a serious complication of a wide variety of acute abdominal disorders, including perforated ulcer, ruptured appendix, abdominal trauma or surgery, or necrotic bowel. Complications may be life threatening; without prompt and effective treatment, septicaemia and septic shock may occur.
- Gastroenteritis may result from bacterial or viral infections, parasites or toxins, and is often the result of consuming contaminated water or food. Manifestations include nausea and vomiting, diarrhoea and abdominal discomfort.
- Nurses provide education to help prevent protozoal infections (e.g. giardiasis, amoebiasis) and helminthic infestations (by roundworms or tapeworms). Both are treated with medications.
- Chronic inflammatory bowel disease (IBD) includes two separate but closely related conditions: ulcerative colitis and Crohn's disease. Ulcerative colitis affects the mucosa and submucosa of the colon and rectum. Crohn's disease can affect any part of the GI tract, but usually involves the terminal ilium and ascending colon. Diarrhoea is common to both disorders. A colectomy (removal of the large colon) may be performed to treat ulcerative colitis; an ileostomy (artificial opening from the abdomen to the ileum) may be performed to treat Crohn's disease.
- Malabsorption syndromes, in which the intestinal mucosa ineffectively absorbs nutrients, are caused by a wide variety of diseases. However, three common malabsorption disorders in adults are coeliac disease (non-tropical and tropical), lactose intolerance of milk and milk products (resulting from a lactase deficiency) and short-bowel syndrome (a condition developing following resection of the small bowel).
- Malignant tumours of the lower bowel are the third leading cause of death from cancer in Australia. The risk of colon cancer may be reduced through health-related screenings and a diet high in fruits, vegetables, folic acid and calcium. Rectal bleeding is the most common initial manifestation but may not occur until the cancer is well advanced. Surgical treatment is through surgical resection of the bowel, accompanied by a colostomy for diversion of faecal contents.
- A hernia is a defect in the abdominal wall allowing intra-abdominal contents to protrude out of the abdominal cavity. Hernias may follow trauma, surgery and increased intra-abdominal pressure (as from pregnancy or obesity). Hernias may be congenital or acquired and may be inguinal, umbilical, incisional or ventral.
- Intestinal obstructions occur when intestinal contents cannot move through the lumen of the bowel. These may occur in either the large or small intestine, may be partial or complete, and are caused by many factors, ranging from surgical ileus following abdominal surgery to adhesions or tumours.
- Diverticula are sac-like projections of mucosa through the muscular layer of the colon. When these sacs become inflamed, the condition is labelled diverticulitis. A diet high in fibre is recommended for self-care.
- Anorectal disorders include haemorrhoids, anorectal lesions (fissures, abscess and fistula) and pilonidal disease. These disorders are painful and pose a risk of bleeding and infection.

CONCEPT CHECK

1 Mr William Brown presents at the urgent care clinic with complaints of diarrhoea for the past week. The RN should first:

1. advise Mr Brown to abstain from all food intake until the diarrhoea subsides
2. ask Mr Brown to describe the number and character of daily stools
3. question Mr Brown about possible exposure to an enterotoxin or protozoal infection
4. recommend an over-the-counter antidiarrhoeal preparation such as Kaomagma with Pectin Suspension

2 RN Sandra Smith, who is caring for Ms Wong admitted with possible appendicitis, appropriately plans which of the following?

1. Initiate bowel preparation for a barium enema.
2. Restrict intake to clear liquids.
3. Prepare for possible immediate appendectomy.
4. Insert saline lock for intravenous antibiotic therapy.

3 RN David Smith is teaching Mrs Doris Bishop with inflammatory bowel disease about prescribed sulfasalazine. RN Smith instructs Mrs Bishop to:

1. use a sunscreen while taking the drug
2. take the drug on an empty stomach
3. limit fluid intake to 1500 mL per day or less
4. take vitamin C while on this drug

4 Mr Adam Jones reports frequent large, fatty, foul-smelling stools. RN Brown recognises this as:
1 haematochezia, a manifestation of GI bleeding
2 characteristic of inflammatory bowel disease
3 a common early manifestation of colorectal cancer
4 steatorrhoea, a manifestation of malabsorption

5 Mr Stanley Green tells RN Davis that his father and grandfather died of colon cancer and he is worried that he is going to die from 'the same horrible disease'. Which of the following does RN Davis include in his recommendations?
1 There is no genetic link seen in colon cancer, so his risk is equal to that of people with no family history of the disease.
2 He should plan for annual digital rectal exams and periodic colonoscopy for early identification of possible tumours.
3 He should have annual CEA levels drawn to screen for early tumour development.
4 It is imperative that he change his diet immediately, significantly increasing his intake of dietary fibre.

6 Mrs Phyllis Jones is a 75 year old with a nasogastric tube in place to maintain gastric decompression. Which nursing actions are important in monitoring responses to *Deficient fluid volume* when caring for Mrs Jones? (Select all that apply.)
1 Low suction is used to decompress the stomach.
2 Give her as much water as she wants to drink.
3 Listen to bowel sounds prior to checking the placement of the NG tube.
4 Document the amount and colour of NG tube drainage every shift.
5 Keep an accurate record of intake and output every 2 to 4 hours.
6 Listen to bowel sounds after palpating the stomach for tenderness.
7 Measure abdominal girth every 4 to 8 hours.

7 Ms Stella Black developed a paralytic ileus following a recent abdominal surgery. What is the most important nursing consideration when caring for Ms Black?
1 Ensure Ms Black is able to eat a clear liquid diet.
2 Maintain Ms Black on strict bed rest.
3 Monitor Ms Black's bowel sounds every hour.
4 Ensure Ms Black's nasogastric tube is functioning.

8 Mrs Jones has a history of diverticulosis and has been having abdominal pain recently. When advising Mrs Jones about her diet prior to discharge from the hospital, what type of foods should Mrs Jones exclude from her diet?
1 wholemeal bread
2 popcorn
3 soup
4 apples

9 Mr Allen, an 85 year old, was admitted with a diagnosis of constipation. Which of the following is important for you to incorporate in Mr Allen's discharge education? (Select all that apply.)
1 Eat plenty of fresh fruits and vegetables daily.
2 Take bisacodyl (Durolax) daily.
3 Drink 6 to 8 glasses of non-alcoholic fluid daily.
4 Take docusate (Coloxyl) at night time only.
5 Eat wholemeal bread instead of white bread.
6 Eat a bran cereal for breakfast.

10 A small-bowel obstruction can occur due to:
1 eating extra fibre in the diet
2 abdominal adhesions
3 drinking too much water
4 a nasogastric tube

CHAPTER 24

NURSING CARE OF PEOPLE WITH GALLBLADDER, LIVER AND PANCREATIC DISORDERS

NICOLE KNOX

KEY TERMS

LEARNING OUTCOMES

- Discuss the pathophysiology, manifestations and associated nursing care of the person suffering from a disorder of the gallbladder.
- Compare and contrast the pathophysiology, manifestations and complications of hepatitis, cirrhosis, trauma and cancer of the liver.
- Discuss pathophysiology, manifestations and interprofessional care of a person with pancreatitis or cancer of the pancreas.

CLINICAL COMPETENCIES

- Assess functional health status of people with gallbladder, liver or pancreatic disease.
- Monitor for, document and report expected and unexpected manifestations in people with gallbladder, liver or pancreatic disease.
- Prepare people for, and understand the purpose and significance of, diagnostic tests for gallbladder, liver and pancreatic disorders.
- Integrate appropriate dietary, pharmacological and other interprofessional measures into nursing care and teaching of the person with a gallbladder, liver or pancreatic disorder.
- Provide appropriate nursing care for the person who has surgery of the gallbladder, liver or pancreas.
- Integrate psychosocial, cultural and spiritual considerations into the plan of care for a person with a gallbladder, liver or pancreatic disorder.
- Use evidence-based practice to develop, implement, evaluate and, as needed, revise the plan of care for people with disorders of the gallbladder, liver or pancreas.
- Provide appropriate person and family health education to promote, maintain and restore functional health status for people with gallbladder, liver and pancreatic disorders.

Gallbladder, liver and exocrine pancreatic disorders may occur as primary disorders or develop secondarily to other disease processes. One organ's functioning frequently affects that of another. Duct inflammation or obstruction and changes in the multiple functions of these organs can cause significant health effects.

People with a gallbladder, liver or pancreatic disorder may experience pain, multiple metabolic and nutritional disturbances, and altered body image. Nursing care addresses the physiological and psychosocial needs of the person and family.

GALLBLADDER DISORDERS

Altered bile flow through the hepatic, cystic or common bile duct is a common problem. It often leads to inflammation and other complications. Gallstones are the most common cause of obstructed flow. Tumours and abscesses also can obstruct bile flow.

THE PERSON WITH GALLSTONES

Cholelithiasis is the formation of stones (*calculi* or *gallstones*) within the gallbladder or biliary duct system. Cholelithiasis is a common problem worldwide with an estimated prevalence of 10–15% in white adults (Stinton, Myers & Schaffer, 2010; Venneman & van Erpecum, 2010). Box 24.1 lists risk factors for gallstones. The incidence of gallstones varies among people of different ethnic backgrounds.

Physiology review

Normally bile is formed by the liver and stored in the gallbladder. Bile contains bile salts, bilirubin, water, electrolytes, cholesterol, fatty acids and lecithin. In the gallbladder, some of the water and electrolytes are absorbed, further concentrating the bile. Food entering the intestine stimulates the gallbladder to contract and release bile through the common bile duct and sphincter of Oddi into the intestine. The bile salts in bile increase the solubility and absorption of dietary fats.

Pathophysiology and manifestations

Cholelithiasis

Gallstones form when several factors interact: abnormal bile composition, biliary stasis and inflammation of the gallbladder. Most gallstones (80%) consist primarily of cholesterol; the rest contain a mixture of bile components. Excess cholesterol in bile is associated with obesity; a high-kilojoule, high-cholesterol diet; and drugs that lower serum cholesterol levels. When bile is supersaturated with cholesterol, it can precipitate out to form stones. Biliary stasis, or slowed emptying of the gallbladder, contributes to cholelithiasis. Stones do not form when the gallbladder empties completely in response to hormonal stimulation. Slowed or incomplete emptying allows cholesterol to concentrate and increases the risk of stone formation. Finally, inflammation of the gallbladder allows excess water and bile salt reabsorption, increasing the risk of lithiasis.

CONSIDERATION FOR PRACTICE

Certain very-low-kilojoule diets are associated with a high risk of cholelithiasis. Increased cholesterol concentration in the bile and decreased gallbladder contractions associated with fasting increase the risk of gallstone formation.

Most gallstones are formed in the gallbladder. They then may migrate into the ducts (see Figure 24.1), leading to *cholangitis* (duct inflammation). Although some people with cholelithiasis are asymptomatic, many develop manifestations. Early manifestations of gallstones may be vague: epigastric fullness or mild gastric distress after eating a large or fatty meal. Stones that obstruct the cystic duct or common bile duct lead to distension and increased pressure behind the stone. This causes **biliary colic**, a severe, steady pain in the epigastric region or right upper quadrant of the abdomen.

BOX 24.1 Risk factors for gallstones

- Age
- Family history of gallstones
- Race or ethnicity
- Obesity, hyperlipidaemia
- Rapid weight loss
- Female gender; use of oral contraceptives
- Biliary stasis: pregnancy, fasting, prolonged parenteral nutrition
- Diseases or conditions: cirrhosis; ileal disease or resection; sickle cell anaemia; glucose intolerance

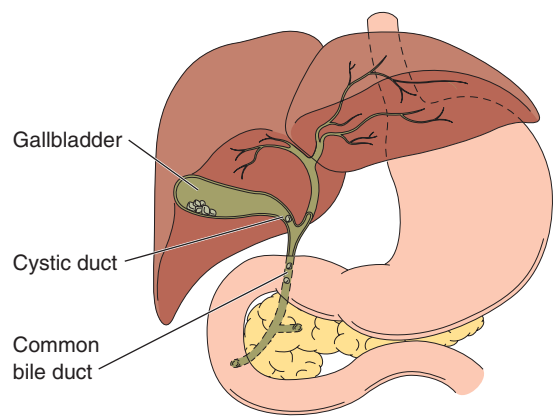

FIGURE 24.1 ■ Common locations of gallstones

TABLE 24.1 Manifestations and complications of cholelithiasis and cholecystitis

MANIFESTATIONS	CHOLELITHIASIS	CHOLECYSTITIS
Pain	• Abrupt onset • Severe, steady • Localised to epigastrium and RUQ of abdomen • May radiate to back, right scapula and shoulder • Lasts 30 minutes to 5 hours	• Abrupt onset • Severe, steady • Generalised in RUQ of abdomen • May radiate to back, right scapula and shoulder • Lasts 12 to 18 hours • Aggravated by movement, breathing
Associated symptoms	• Nausea, vomiting	• Anorexia, nausea, vomiting • RUQ tenderness and guarding • Rigors and fever
Complications	• Cholecystitis • Common bile duct obstruction with possible jaundice and liver damage • Common duct obstruction with pancreatitis	• Gangrene and perforation with peritonitis • Chronic cholecystitis • Empyema • Fistula formation • Gallstone ileus

The pain may radiate to the back, right scapula or shoulder. The pain often begins suddenly following a meal and may last as long as 5 hours. It often is accompanied by nausea and vomiting.

Obstruction of the common bile duct may cause bile reflux into the liver, leading to jaundice, pain and possible liver damage. If the common duct is obstructed, pancreatic enzymes will be unable to enter the small intestine and pancreatitis (discussed later in this chapter) becomes a potential complication.

Cholecystitis

Cholecystitis is inflammation of the gallbladder. *Acute cholecystitis* usually follows obstruction of the cystic duct by a stone. The obstruction increases pressure within the gallbladder, leading to ischaemia of the gallbladder wall and mucosa. Chemical and bacterial inflammation often follows. The ischaemia can lead to necrosis and perforation of the gall bladder wall.

Acute cholecystitis usually begins with an attack of biliary colic. The pain involves the entire right upper quadrant (RUQ) and may radiate to the back, right scapula or shoulder. Movement or deep breathing may aggravate the pain. The pain usually lasts longer than biliary colic, continuing for 12 to 18 hours. Anorexia, nausea and vomiting are common. Fever often is present and may be accompanied by rigors. The RUQ is tender to palpation.

Chronic cholecystitis may result from repeated bouts of acute cholecystitis or from persistent irritation of the gallbladder wall by stones. Bacteria may be present in the bile as well. Chronic cholecystitis is often asymptomatic.

Complications of cholecystitis include *empyema*, a collection of infected fluid within the gallbladder; gangrene and perforation with resulting peritonitis or abscess formation; formation of a fistula into an adjacent organ (such as the duodenum, colon or stomach); or obstruction of the small intestine by a large gallstone (*gallstone ileus*). Table 24.1 compares the manifestations and complications of acute cholelithiasis with those of cholecystitis.

INTERPROFESSIONAL CARE

Treatment of the person with cholelithiasis or cholecystitis depends on the acuity of the condition and the person's overall health status. When gallstones are present but asymptomatic and the person has a low risk of complications, conservative treatment is indicated. However, when the person experiences frequent symptoms, has acute cholecystitis or has very large stones, the gallbladder and stones are usually surgically removed.

Diagnosis

Diagnostic tests are ordered to identify the presence and location of stones, identify possible complications and help differentiate gallbladder disease from other disorders.

- *Serum bilirubin* is measured. Elevated direct (conjugated) bilirubin may indicate obstructed bile flow in the biliary duct system (see Box 24.2).
- *Full blood count (FBC)* may indicate infection and inflammation if the white blood cell (WBC) count is elevated.
- *Serum amylase* and *lipase* are measured to identify possible pancreatitis related to common duct obstruction.
- *Abdominal x-ray* may show gallstones that have high calcium content.
- *Ultrasonography of the gallbladder* is a non-invasive exam that can accurately diagnose cholelithiasis. It also can be used to assess emptying of the gallbladder.
- *Oral cholecystogram* is performed using a dye administered orally to assess the gallbladder's ability to concentrate and excrete bile.
- *Gallbladder scans* use an intravenous radioactive solution that is rapidly extracted from the blood and excreted into the biliary tree to diagnose cystic duct obstruction and acute or chronic cholecystitis.

See Chapter 20 for more information about these diagnostic tests and their nursing implications.

The primary disadvantages of pharmacological treatment for gallstones include its cost, long duration (2 years or more) and the high incidence of recurrent stone formation when

BOX 24.2 Total, direct and indirect bilirubin levels

When serum bilirubin levels are measured, the results usually are reported as the total bilirubin, direct bilirubin and indirect bilirubin levels. Most bilirubin is formed from haemoglobin, as ageing or abnormal red blood cells (RBCs) are removed from circulation and destroyed. It is then bound to protein and transported to the liver. This protein-bound bilirubin is called *indirect* or *unconjugated* bilirubin. Once in the liver, bilirubin is separated from the protein and converted to a soluble form, *direct* or *conjugated* bilirubin. Conjugated bilirubin is then excreted in the bile.

- *Total* (serum) *bilirubin*, the total bilirubin in the blood, includes both indirect and direct forms. In adults, the normal total bilirubin is 0.3 to 1.2 mg/dL. Total bilirubin levels increase when more is being produced (e.g. RBC haemolysis) or when its metabolism or excretion is impaired (e.g. liver disease or biliary obstruction).
- *Direct* (conjugated) *bilirubin* levels, normally 0 to 0.2 mg/dL in adults, rise when its excretion is impaired by obstruction within the liver (e.g. in cirrhosis, hepatitis, exposure to hepatotoxins) or in the biliary system.
- *Indirect* (unconjugated) *bilirubin* levels, normally < 1.1 mg/dL in adults, rise in RBC haemolysis (e.g. sickle cell disease or transfusion reaction).

treatment is discontinued. If infection is suspected, antibiotics may be ordered to cure the infection and reduce associated inflammation and oedema. People with pruritus (itching) due to severe obstructive jaundice and an accumulation of bile salts on the skin may be given cholestyramine (Questran Lite). This drug binds with bile salts to promote their excretion in the faeces. A narcotic analgesic such as morphine may be required for pain relief during an acute attack of cholecystitis.

Treatments

SURGERY **Laparoscopic cholecystectomy** (removal of the gallbladder) is the treatment of choice for symptomatic cholelithiasis or cholecystitis. This minimally invasive procedure has a low risk of complications and generally requires a hospital stay of less than 24 hours. Not all people are candidates for laparoscopic cholecystectomy and there is a risk that a laparoscopic cholecystectomy may be converted to a *laparotomy* (surgical opening into the abdomen) during the procedure. See below for nursing care for a person having a laparoscopic cholecystectomy. The 'Translation to practice' box below discusses evidence-based practice for managing pain in people undergoing laparoscopic cholecystectomy.

When stones are lodged within the ducts, a cholecystectomy with common bile duct exploration may be done. A T-tube (see Figure 24.2) is inserted to maintain patency of the duct and promote bile passage while the oedema decreases. Excess bile is collected in a drainage bag secured below the surgical site. If it is suspected that a stone has been retained following surgery, a postoperative cholangiogram via the T-tube or direct visualisation of the duct with an endoscope may be performed. See the box below for nursing care for a person with a T-tube.

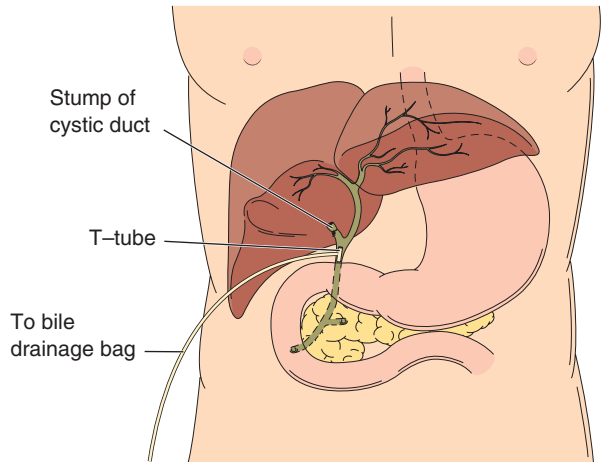

FIGURE 24.2 ■ T-tube placement in the common bile duct. Bile fluid flows with gravity into a drainage collection device below the level of the common bile duct

Some people who are poor surgical risks and for whom laparoscopic cholecystectomy is inappropriate may have either a *cholecystostomy* to drain the gallbladder or a *choledochostomy* to remove stones and position a T-tube in the common bile duct.

NUTRITION Food intake may be eliminated during an acute attack of cholecystitis and a nasogastric tube inserted to relieve nausea and vomiting. Dietary fat intake may be limited, especially if the person is obese. If bile flow is obstructed, fat-soluble vitamins (A, D, E and K) and bile salts may need to be administered.

OTHER THERAPIES In some cases, shock wave lithotripsy may be used with drug therapy to dissolve large gallstones. In extracorporeal shock wave lithotripsy, ultrasound is used to align the stones with the source of shock waves and the computerised lithotripter. Positioning is of prime importance throughout the procedure, which usually takes an hour. Mild sedation may be given during the procedure. Nursing care after the procedure includes monitoring for biliary colic, which can result from the gallbladder contracting to remove stone fragments; nausea; and transient haematuria. *Percutaneous cholecystostomy*, ultrasound-guided drainage of the gallbladder, may be done in high-risk people to postpone or even eliminate the need for surgery.

Nursing care

In addition to the nursing care discussed in this section, a nursing care plan for a person with cholelithiasis is found below.

Health promotion

Although most risk factors for cholelithiasis cannot be controlled or modified, several can. Modifiable risk factors include obesity, hyperlipidaemia, extremely low-kilojoule diets and diets high in cholesterol. Encourage people who are obese to increase their activity level and follow a low carbohydrate, low-fat, low-cholesterol diet to promote weight loss and reduce their

risk of developing gallstones. Discuss the dangers of 'yo-yo' dieting, with cycles of weight loss followed by weight gain, and of extremely low-kilojoule diets. Encourage people with high serum cholesterol levels to discuss using cholesterol-lowering drugs with their primary care provider.

Assessment

Assessment data related to cholelithiasis and cholecystitis include the following:

- *Health history:* current manifestations, including RUQ pain, its character and relationship to meals, duration and radiation, nausea and vomiting or other symptoms; duration of symptoms; risk factors or previous history of symptoms; chronic diseases such as diabetes, cirrhosis or inflammatory bowel disease; current diet; use of oral contraceptives or possibility of pregnancy.
- *Physical assessment:* current weight; colour of skin and sclera; abdominal assessment including light palpation for tenderness; colour of urine and stool.
- *Diagnostic tests:* monitor results of WBC count, serum bilirubin, liver enzymes and pancreatic enzymes (amylase and lipase).

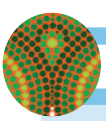
NURSING CARE OF THE PERSON having a laparoscopic cholecystectomy

PREOPERATIVE CARE

- Provide routine preoperative care as ordered (see Chapter 3).
- Reinforce teaching about the procedure and postoperative expectations, including pain management, deep breathing and mobilisation. *Preoperative teaching reduces anxiety and promotes rapid postoperative recovery.*

POSTOPERATIVE CARE

- Provide routine postoperative recovery care as outlined in Chapter 3.
- Assist to chair at bedside as allowed. *Early mobilisation promotes lung ventilation and circulation, reducing the potential for postoperative complications.*
- Advance oral intake from ice chips to regular diet as tolerated. *Oral intake can be rapidly resumed due to minimal disruption of the gastrointestinal tract during surgery.*
- Provide and reinforce teaching: pain management, incision care, activity level and postoperative follow-up appointments. *With early discharge, the person and family assume responsibility for the majority of postoperative care. A clear understanding of this care and expected needs reduces anxiety and the risk of postoperative complications.*
- Initiate follow-up contact 24 to 48 hours after discharge to evaluate adequacy of pain control, incision management and discharge understanding. *Contact following discharge provides an opportunity to evaluate care and reinforce teaching.*



TRANSLATION TO PRACTICE Evidence-based practice: a person undergoing laparoscopic cholecystectomy

The purpose of pre-emptive analgesia administration is to reduce the central sensitisation from a variety of harmful stimuli. Its proposed benefits include better postoperative pain management, therefore reducing the use of analgesia and improving patient outcomes (Singh et al., 2013). In a study of pre-emptive ketamine analgesia administration among laparoscopic cholecystectomy patients, Singh et al. (2013) studied pain scores in the first 24 hours post surgery. This is an important time frame considering the majority of laparoscopic cholecystectomy patients are discharged within the first 24 hours post surgery. Patients were randomised into four groups, the first three groups (A, B and C) receiving 1 mg/kg, 0.75 mg/kg and 0.5 mg/kg of intravenous ketamine respectively, 30 minutes prior to surgery. The final group (group D) received a placebo of isotonic saline. The study found that all groups that received pre-emptive ketamine had a reduced pain score postoperatively compared to the group that did not receive the drug.

IMPLICATIONS FOR NURSING

Effective pain relief is known to promote healing and immune function following surgery. This study indicates a benefit from the use of pre-emptive analgesia administration in people undergoing ambulatory surgery, including laparoscopic cholecystectomy, as a pain management strategy. Effective postoperative pain management requires a combination of good preoperative education, discharge planning related to the person's expectations of pain and postoperative pain management.

CRITICAL THINKING IN PERSON-CENTRED CARE

1. Two people in group A of this study (those that received 1 mg/kg of ketamine) reported hallucinations. How can the nurse ensure appropriate patient safety while promoting effective postoperative pain management? What teaching could you provide to help people manage adverse effects of the prescribed drug?
2. The incidence of nausea and vomiting reported was similar in all four study groups. How will the incidence of nausea and vomiting impact on the pain management of a person undergoing laparoscopic cholecystectomy?

Source: Preemptive analgesia with ketamine for laprascopic cholecystectomy by Singh, H. et al. (2013). *Journal of Anaesthesiology, Clinical Pharmacology, 29*(4), 478–484.

NURSING CARE OF THE PERSON with a T-tube

- Ensure that the T-tube is properly connected to a sterile container; keep the tube below the level of the surgical wound. *This position promotes the flow of bile and prevents backflow or seepage of caustic bile on to the skin. The tube itself decreases biliary tree pressure.*
- Monitor drainage from the T-tube for colour and consistency; record as output. Normally, the tube may drain up to 500 mL in the first 24 hours after surgery; drainage decreases to less than 200 mL in 2 to 3 days and is minimal thereafter. Drainage may be blood tinged initially, changing to green–brown. Report excessive drainage immediately. (After 48 hours, drainage greater than 500 mL is considered excessive.) *Stones or oedema and inflammation can obstruct ducts below the tube, requiring treatment.*
- Place in Fowler's position. *This promotes gravity drainage of bile.*
- Assess skin for bile leakage during dressing changes. *Bile irritates the skin; it may be necessary to apply skin protection with a barrier product.*
- Teach the person how to manage the tube when turning, ambulating and performing activities of daily living. *Direct pulling or traction on the tube must be avoided.*
- If indicated, teach care of the T-tube, how to clamp it, signs of infection and when to report these symptoms to clinicians. People may be discharged home with the tube in place. *Reporting early signs of infection facilitates prompt treatment.*

NURSING CARE PLAN A person with cholelithiasis

Joyce Wing is a 44-year-old married mother of three children. She works full time as a cook at a local restaurant. Recently Mrs Wing has noticed a dull pain in her upper abdomen that gets worse after eating fatty foods; nausea and sometimes vomiting accompany the pain. She had a similar pain after the birth of her last child. She is diagnosed with cholelithiasis and is admitted for a laparoscopic cholecystectomy.

ASSESSMENT

David Corbin, RN, takes Mrs Wing's admission history. It includes intolerance to fatty foods and intermittent 'stabbing' abdominal pain that radiates to her back. Her usual diet includes regular takeaway meals due to her busy lifestyle. She reports 'not wanting to eat much of anything lately'. She states she has never had surgery before and hopes 'everything goes well'. Physical assessment includes T 37.7°C, P 88, R 20 and BP 130/84. She has had a recent 3 kg weight loss, currently weighing 59 kg. She is 160 cm tall. Abdominal examination elicits tenderness in the right upper abdominal quadrant. She has no jaundice, rigors or evidence of complications.

DIAGNOSES

- *Risk of imbalanced nutrition: less than body requirements* related to anorexia and manifested by recent weight loss.
- *Risk of pain* related to inflamed gallbladder and surgical incisions manifested by increased heart rate and blood pressure and decreased inspiratory volume.
- *Risk of infection* related to potential bacterial contamination of abdominal cavity, manifested by increased white cell count, temperature, heart and respiratory rate and decreased blood pressure.
- *Risk of anxiety* related to lack of information about perioperative experience and manifested by restlessness, increased heart rate and blood pressure.

PLANNING

- Teach about the gallbladder and the function of bile.
- Discuss pre- and postoperative care, including self-care following discharge.
- Teach home care of incisions and recognition of signs of infection.

Expected outcomes

- Maintain present weight within 2 kg over the next 3 weeks.
- Resume regular diet, decreasing intake of foods high in fat.
- Verbalise adequate pain control after surgery and with activity resumption.
- Remain free of infection.
- Verbalise a decrease in anxiety before surgery.

IMPLEMENTATION

- Promote mobility as soon as allowed after surgery.
- Review specific high-fat foods to avoid and ways to maintain her weight. Consultation with a dietitian if available would be beneficial.
- Provide analgesia as needed postoperatively. Teach appropriate analgesic use after discharge.

EVALUATION

Mrs Wing is discharged the morning after her surgery. She is afebrile, has no signs of infection and is able to appropriately care for her incisions. She identifies signs of infection and talks about ways to reduce her fat intake while keeping her weight stable. She verbalises understanding of initial activity restrictions and resumption of normal activities. Mrs Wing states, 'It wasn't as bad as I thought it would be at first.' She has an appointment to see her surgeon in 1 week.

CRITICAL THINKING IN THE NURSING PROCESS

1. What is the rationale for a low-fat diet with cholelithiasis? Discuss nutritional practices as they relate to the medical problem and Mrs Wing's lifestyle.
2. How would your discharge teaching for Mrs Wing differ if she had had an open cholecystectomy instead of a laparoscopic cholecystectomy?

REFLECTION ON THE NURSING PROCESS

1. Develop a care plan for Mrs Wing for the nursing diagnosis *Risk of infection.*
2. Discuss strategies you can use to encourage postoperative patients to mobilise.

Nursing diagnoses and interventions

Priority nursing diagnoses for the person with cholelithiasis or cholecystitis often include pain related to biliary colic or surgery, imbalanced nutrition related to the effects of altered bile flow and to nausea and anorexia, and risk of infection related to potential rupture of an acutely inflamed gallbladder. Nursing interventions for the person who has undergone a laparoscopic or open cholecystectomy are similar to those for other people having abdominal surgery. (See Chapter 3.)

Pain

The pain associated with cholelithiasis can be severe. Sometimes a combination of interventions is indicated.

- Discuss the relationship between fat intake and the pain. Teach ways to reduce fat intake. *Fat entering the duodenum initiates gallbladder contractions, causing pain when gallstones are present in the ducts.*
- Withhold oral food and fluids during episodes of acute pain. Insert nasogastric tube and connect to low suction if ordered. *Emptying the stomach reduces both the amount of chyme entering the duodenum and the stimulus for gallbladder contractions, thus reducing pain.*
- For severe pain, administer morphine or other narcotic analgesia as ordered. *Recent research indicates that morphine is not likely to cause spasms of the sphincter of Oddi.*
- Place in Fowler's position. *Fowler's position decreases pressure on the inflamed gallbladder.*
- Monitor vital signs, including temperature, at least every 4 hours. *Bacterial infection often is present in acute cholecystitis and may cause an elevated temperature and respiratory rate.*

Imbalanced nutrition: less than body requirements

The person with severe gallbladder disease may develop nutritional imbalances related to anorexia, pain and nausea following meals and impaired bile flow that alters absorption of fat and fat-soluble vitamins (A, D, E and K) from the gut.

- Assess nutritional status, including diet history, height and weight, and skinfold measurements (see Chapters 20 and 21). *Although often obese, people with gallbladder disease may have an imbalanced diet or may have specific vitamin deficiencies, particularly of the fat-soluble vitamins.*
- Evaluate laboratory results, including serum bilirubin, albumin, glucose and cholesterol levels. Report abnormal results to the doctor. *Elevated serum bilirubin may indicate impaired bilirubin excretion due to obstructed bile flow. A low serum albumin may indicate poor nutritional status. Glucose intolerance and hypercholesterolaemia are risk factors for cholelithiasis.*
- Refer to a dietitian or nutritionist for diet counselling to promote healthy weight loss and reduce pain episodes. *A low-carbohydrate, low-fat, higher-protein diet reduces symptoms of cholecystitis. While fasting and very low kilojoule diets are contraindicated, a moderate reduction in kilojoule intake and increased activity levels promote weight loss.*
- Administer vitamin supplements as ordered. *People who do not absorb fat well due to obstructed bile flow may require supplements of the fat-soluble vitamins.*

Risk of infection

An acutely inflamed gallbladder may become necrotic and rupture, releasing its contents into the abdominal cavity. While the resulting infection often remains localised, peritonitis can result from chemical irritation and bacterial contamination of the peritoneal cavity.

CONSIDERATION FOR PRACTICE

Rupture of an acutely inflamed gallbladder may be heralded by abrupt but transient pain relief as contents are released from the distended gallbladder into the abdomen. Promptly report this change to the doctor.

Following open cholecystectomy (*laparotomy*), the risk of pulmonary infection is significant due to the high abdominal incision.

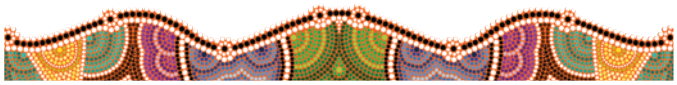
- Monitor vital signs, including temperature, every 4 hours. Promptly report vital sign changes or temperature elevation. *Tachycardia, increased respiratory rate or an elevated temperature may indicate an infectious process.*
- Assess abdomen every 4 hours and as indicated (e.g. when pain level changes abruptly). *Increasing abdominal tenderness or a rigid, board-like abdomen may indicate rupture of the gallbladder with peritonitis.*
- Assist to cough and deep breathe or use an incentive spirometer every 1 to 2 hours while awake. Splint abdominal incision with a blanket or pillow during coughing. *The high abdominal incision of an open cholecystectomy interferes with effective coughing and deep breathing, increasing the risk of atelectasis and respiratory infections such as pneumonia.*
- Place in Fowler's position and encourage ambulation as allowed. *Fowler's position and ambulation promote lung expansion and airway clearance, reducing the risk of respiratory infections.*
- Administer antibiotics as ordered. *Antibiotics may be given preoperatively to reduce the risk of infection from infected gallbladder contents and may be continued postoperatively to prevent infection.*

Community-based care

Teaching varies, depending on the choice of treatment options for cholelithiasis and cholecystitis. If surgery is not an option, teach about maintaining a low-fat, low-carbohydrate diet if indicated. Include an explanation about the role of bile and the function of the gallbladder in terms that the person and family can understand.

Provide appropriate preoperative teaching for the planned procedure. Discuss the possibility of open cholecystectomy even when a laparoscopic procedure is planned. Teach postoperative self-care measures to manage pain and prevent complications. If the person will be discharged with a T-tube, provide instructions about its care (see the 'Nursing care' box above). Discuss manifestations of complications to report to the doctor. Stress the importance of follow-up appointments.

Following cholecystectomy, a low-fat diet may be initially recommended. Refer the person and food preparer to a dietitian to review low-fat foods. (See Box 24.3 for examples of high-fat foods to avoid.) Higher-fat foods may be gradually added to the diet as tolerated.



THE PERSON WITH CANCER OF THE GALLBLADDER

Gallbladder cancer is rare, primarily affecting women over age 65. Manifestations of gallbladder cancer include intense pain and a palpable mass in the RUQ of the abdomen. Jaundice and weight loss are common. Gallbladder cancers spread by direct extension to the liver and metastasise via the blood and lymph system.

At the time of diagnosis, the cancer usually is too advanced to treat surgically. Most people present with advanced, incurable disease and are not candidates for surgical resection. The mean survival for people with inoperable tumours is 2–4 months. Even with surgical intervention, the 5-year survival rate is around 35% (Jayaraman & Jarnagin, 2010).

Nursing care is palliative, focusing on maintaining comfort and independence to the extent possible.

BOX 24.3 Examples of high-fat foods

- Whole-milk products (e.g. cream, ice-cream, cheese)
- Doughnuts, deep-fried
- Sausage, bacon, hot dogs
- Gravies with fat, cream
- Most nuts (e.g. pecans, cashews)
- Corn chips and potato chips
- Butter and cooking oils
- Fried foods (e.g. hamburgers, hot chips)
- Peanut butter
- Chocolate

LIVER DISORDERS

The liver is a complex organ with multiple metabolic and regulatory functions. Optimal liver function is essential to health. Because of the significant amount of blood in the liver at all times, it is exposed to the effects of pathogens, drugs, toxins and possibly malignant cells. As a result, liver cells may become inflamed or damaged, or cancerous tumours may develop.

Physiology review

The essential functions of the liver include the metabolism of proteins, carbohydrates and fats. It also is responsible for the metabolism of steroid hormones and most drugs. It synthesises essential blood proteins, including albumin and clotting factors in particular. The liver detoxifies alcohol and other toxic substances. Ammonia, a toxic by-product of protein metabolism, is converted to urea in the liver for elimination by the kidneys. The liver produces bile, an essential substance for absorbing fats and eliminating bilirubin from the body. Minerals and fat-soluble vitamins are stored in the liver, as is glycogen (stored carbohydrate for energy reserves). The Kupffer cells that line the sinusoids phagocytise foreign cells and damaged blood cells. See Chapter 20 for more information about the liver.

Common manifestations of liver disorders

Although many different disorders can disrupt liver function, their manifestations relate to three primary effects: disrupted liver cell function, impaired bilirubin conversion and excretion leading to jaundice and disrupted blood flow through the liver, with resulting portal hypertension.

Hepatocellular failure

The liver is vital to the digestion and metabolism of nutrients; the production of plasma proteins, including those involved in clotting; and the metabolism and excretion of compounds such as bilirubin, steroid hormones and ammonia, as well as toxins (such as alcohol) and drugs. Impaired function of liver cells has multiple effects, including:

- Impaired protein metabolism with decreased production of albumin and clotting factors. Low albumin levels contribute to oedema in peripheral tissues and **ascites** (accumulation of fluid in the abdomen) as plasma oncotic pressure is reduced. Impaired clotting factor production increases the risk of bleeding.
- Disrupted glucose metabolism and storage with resulting alterations in blood glucose levels (either hyperglycaemia or hypoglycaemia).
- Reduced bile production that impairs the absorption of lipids and fat-soluble vitamins. Inadequate vitamin K, a fat-soluble vitamin, affects the production of clotting factors, leading to a bleeding tendency.
- Impaired metabolism of steroid hormones (including oestrogen and testosterone) leads to feminisation in men and irregular menses in women.

Jaundice

Disrupted metabolism and excretion of bilirubin allows it to accumulate in tissues, leading to **jaundice** (yellow staining of tissues). Jaundice (also called *icterus*) often is first noticeable in the sclera of the eyes, then the skin.

When RBCs are destroyed (due to cell ageing or disease), haemoglobin is released. The haemoglobin molecule breaks up into globin, a protein, and haem, the iron-containing portion of

the molecule. In this process, biliverdin, later converted to fat-soluble bilirubin (*unconjugated bilirubin*), is released. The bilirubin binds with albumin to be transported to the liver. In the liver, it is converted to a water-soluble form (*conjugated bilirubin*) to be excreted in the bile. See Box 24.2 for more information about bilirubin metabolism.

Jaundice can result from disruptions at any point in the production and metabolism of bilirubin:

- *Haemolytic jaundice* develops when excess RBC destruction (haemolysis) releases more bilirubin into circulation than the liver is able to process. High blood levels of unconjugated bilirubin are seen.
- *Hepatic jaundice* occurs when impaired liver cell (*hepatocyte*) function disrupts the conversion and excretion of bilirubin. Blood levels of both conjugated and unconjugated bilirubin may be elevated. Stools may appear normal or clay coloured and urine is dark because the conjugated bilirubin is excreted by the kidneys.
- Obstruction of bile flow within the biliary system (the gallbladder and bile ducts) impairs bilirubin excretion, leading to *obstructive jaundice*. Levels of conjugated bilirubin are elevated. Stools are light or clay coloured due to lack of bile pigment, and urine is dark because the kidneys excrete bilirubin.

Portal hypertension

Impaired blood flow through the liver increases pressure in the portal venous system that drains the gastrointestinal tract, the spleen and surface veins of the abdomen. **Portal hypertension**, increased pressure in the portal system, has several effects when it is prolonged:

- Dilation of veins in the gastrointestinal tract and the abdominal wall. This congestion tends to suppress the appetite and lead to the formation of collateral vessels in the distal oesophagus, stomach and rectum. The dilated, congested vessels in the oesophagus are known as *oesophageal varices*; in the rectum, they lead to the development of haemorrhoids. In advanced liver failure, superficial varices may develop around the umbilicus, a feature known as *caput medusae*.
- Splenomegaly or enlargement of the spleen.
- Ascites (accumulation of fluid in the peritoneal cavity). Increased hydrostatic pressure in abdominal vessels forces fluid out of the vessels and into the peritoneal cavity. Low serum albumin levels (*hypoalbuminemia*) contribute to fluid accumulation by reducing the osmotic draw of fluid back into vessels.
- **Portal systemic encephalopathy** (or hepatic encephalopathy), impaired consciousness and mental status due to the accumulation of toxic waste products in the blood (ammonia, in particular) as blood bypasses the congested liver. It appears that factors other than elevated ammonia levels contribute, including toxic fatty acids, altered neurotransmitters and an imbalance of plasma amino acid ratios. Cerebral oedema develops late in the course of liver failure, resulting from both the accumulation of toxins and vascular mechanisms. As cerebral oedema progresses, intracranial pressure increases, cerebral perfusion decreases and brain cells become hypoxic.
- **Hepatorenal syndrome** is acute renal failure due to disrupted blood flow to the kidneys. See Chapter 27 for more information about renal failure.

See the section of this chapter on cirrhosis for more information about the effects and complications associated with portal hypertension.

THE PERSON WITH HEPATITIS

Hepatitis is inflammation of the liver. It is usually caused by a virus, although it may result from exposure to alcohol, drugs and toxins, or other pathogens. Hepatitis may be acute or chronic in nature. Cirrhosis, discussed in the next section, is a potential consequence of severe hepatocellular damage. Chronic hepatitis also increases the risk of developing liver cancer.

Pathophysiology and manifestations

The inflammatory process of hepatitis, whether caused by a virus, a toxin or another mechanism, damages hepatic cells and disrupts liver function. Cell-mediated immune responses damage hepatocytes and Kupffer cells, leading to hyperplasia, necrosis and cellular regeneration. The flow of bile through bile canaliculi and into the biliary system can be impaired by the inflammatory process, leading to jaundice. When the inflammatory process is mild (e.g. hepatitis A), the liver parenchyma is not significantly damaged. The inflammatory processes associated with hepatitis B and hepatitis C, however, can lead to severe liver damage. The metabolism of nutrients, drugs, alcohol and toxins and the process of bile elimination are disrupted by the inflammation of hepatitis. See Chapter 20 for more information about the liver and the preceding section for more information about the effects of disrupted liver function.

Viral hepatitis

At least five viruses are known to cause hepatitis: hepatitis A virus (HAV), hepatitis B virus (HBV), hepatitis C virus (HCV), the hepatitis B-associated delta virus (HDV) and hepatitis E virus (HEV). With the exception of HBV, all of the hepatitis viruses are RNA viruses; HBV is a DNA virus. The viruses differ from one another in mode of transmission, incubation period, the severity and type of liver damage they cause, and their ability to become chronic or develop a carrier (asymptomatic) state. The illnesses they cause, however, are clinically very similar. Table 24.2 identifies unique features of the primary hepatitis viruses.

Hepatitis viruses replicate in the liver, damaging liver cells (hepatocytes). The viruses provoke an immune response that causes inflammation and necrosis of hepatocytes as well. Although the extent of damage and the immune response vary among the different hepatitis viruses, the disease itself usually follows a predictable pattern.

No manifestations are present during the incubation period after exposure to the virus. The *prodromal* or *preicteric* (before jaundice) *phase* may begin abruptly or insidiously, with general malaise, anorexia, fatigue and muscle and body aches.

TABLE 24.2 Comparison of types of viral hepatitis

VIRUS	HEPATITIS A (HAV)	HEPATITIS B (HBV)	HEPATITIS C (HCV)	HEPATITIS D (HDV)	HEPATITIS E (HEV)
Mode of transmission	Faecal–oral	Blood and body fluids; perinatal	Blood and body fluids	Blood and body fluids; perinatal	Faecal–oral
Incubation (in weeks)	2–6	6–24	5–12	3–13	3–6
Onset	Abrupt	Slow	Slow	Abrupt	Abrupt
Carrier state	No	Yes	Yes	Yes	Yes
Possible complications	Rare	Chronic hepatitis Cirrhosis Liver cancer	Chronic hepatitis Cirrhosis Liver cancer	Chronic hepatitis Cirrhosis Fulminant hepatitis	May be severe in pregnant women
Laboratory findings	Anti-HAV antibodies present	Positive HBsAg (HBV surface antigen); anti-HBV antibodies present	Anti-HCV antibodies present	Positive HDVAg (delta antigen) early; anti-HDV antibodies later	Anti-HEV antibodies present

These manifestations often are mistaken for the flu. Nausea, vomiting, diarrhoea or constipation may develop, as well as mild RUQ abdominal pain. Rigors and fever may be present.

The *icteric* (jaundiced) *phase* usually begins 5 to 10 days after the onset of symptoms. It is heralded by jaundice of the sclera, skin and mucous membranes. Inflammation of the liver and bile ducts prevents bilirubin from being excreted into the small intestine. As a result, the serum bilirubin levels are elevated, causing yellowing of the skin and mucous membranes. Pruritus may develop due to deposition of bile salts on the skin. The stools are light brown or clay coloured because bile pigment is not excreted through the normal faecal pathway. Instead, the pigment is excreted by the kidneys, causing the urine to turn brown. Whereas people with acute hepatitis A or B are likely to develop jaundice, many people with hepatitis C do not develop jaundice. As a result, the infection may go undiagnosed for an extended period of time.

During the icteric phase, the initial prodromal manifestations usually diminish even though the serum bilirubin increases. The appetite increases and the temperature returns to normal. When uncomplicated, spontaneous recovery usually begins within 2 weeks of the onset of jaundice.

The *convalescent phase* follows jaundice and lasts several weeks. During this time, manifestations gradually improve: serum enzymes decrease, liver pain decreases and gastrointestinal symptoms and weakness subside. See the box below for the manifestations of each phase of hepatitis.

HEPATITIS A Hepatitis A, or *infectious hepatitis*, often occurs in either sporadic attacks or mild epidemics. It is transmitted by the faecal–oral route via contaminated food, water, shellfish and direct contact with an infected person. The virus has an incubation period of up to 4 weeks. Once jaundice develops, the amount of virus in the stool and the risk of spreading the disease decrease rapidly (Longo et al., 2012). Although hepatitis A usually has an abrupt onset, it is typically a benign and self-limiting disease with few long-term consequences. Symptoms last up to 2 months.

Focus on cultural diversity Hepatitis

Hepatitis is a significant issue for Indigenous Australians, particularly those in rural and remote communities. The infection rate for HAV, HBV and HCV is considerably higher in Indigenous people than in non-Indigenous people. The infection rate for HAV is exacerbated by poor sanitation, inadequate water supply and overcrowding, all of which are issues for many Indigenous communities (Thomson et al., 2008).

The Australian government has implemented vaccination programs in many states for HAV and HBV, with some success. However, there is a need for more culturally appropriate initiatives to decrease injecting drug rates among Indigenous people and to improve the quality of living conditions (Thomson et al., 2008).

FAST FACTS

- In Australia, hepatitis B and hepatitis C predominate.
- Notification rates of HBV and HCV have remained stable in recent years at just over 1 and just over 2 per 100 000 population, respectively.
- There has been a decline in new HBV infection rates in the 15- to 29-years age group in recent years, possibly due to vaccine programs.
- Injecting drug use accounted for 50% of new cases of HBV infection and heterosexual sex accounted for another 18%.
- Between 2004 and 2008 there was a decline in new HCV infection rates in the 15- to 39-years age group, possibly due to the decrease in intravenous drug use, one of the main causes of HCV transmission (Australian Institute of Health and Welfare (AIHW), 2010).

MANIFESTATIONS Acute hepatitis

PREICTERIC PHASE
- 'Flu-like' symptoms: malaise, fatigue, fever
- Gastrointestinal: anorexia, nausea, vomiting, diarrhoea, constipation
- Muscle aches, polyarthritis
- Mild right upper abdominal pain and tenderness

ICTERIC PHASE
- Jaundice
- Pruritus
- Clay-coloured stools
- Brown urine
- Decrease in preicteric phase symptoms (e.g. appetite improves; no fever)

POSTICTERIC/CONVALESCENT PHASE
- Serum bilirubin and enzymes return to normal levels
- Energy level increases
- Pain subsides
- Appetite returns

HEPATITIS B It is estimated that there are approximately 350 million chronic carriers of HBV worldwide (Hughes, Wedemeyer & Harrison, 2011). Hepatitis B can cause acute hepatitis, chronic hepatitis, *fulminant* (rapidly progressive) hepatitis or a carrier state. In a *carrier state*, the person harbours the active virus and is capable of spreading it to others, even though there are no discernible manifestations of the disease. This virus is spread through contact with infected blood and body fluids. Healthcare workers are at risk through exposure to blood and needle-stick injuries. Other high-risk groups for hepatitis B include intravenous drug users, people with multiple sex partners, men who have sex with men, and people frequently exposed to blood products (such as people on haemodialysis). Hepatitis B is a major risk factor for primary liver cancer.

The exact mechanism of liver injury by HBV is unclear: however, it is known that liver cells are damaged by the immune response to this antigen. The liver shows evidence of injury and scarring, regeneration and proliferation of inflammatory cells. Damage may affect only portions of the liver or the majority of the liver. During the prodromal period, people with HBV may experience nausea, vomiting, fatigue, malaise, muscle and joint pains, headache, photophobia and flu-like symptoms 1 to 2 weeks prior to the onset of jaundice (Longo et al., 2012).

HEPATITIS C It is estimated that up to 170 million people worldwide are infected with HCV (Casey & Lee, 2012; Longo et al., 2012). HCV is a blood-borne infection, transmitted through blood transfusion, sexual intercourse or intravenous drug use. Other at-risk populations include people with haemophilia treated with clotting factors prior to 1987, haemodialysis patients, children born to women with HCV and health workers following a needle-stick or splash injury (Longo et al., 2012).

Acute hepatitis C usually is asymptomatic; if symptoms do develop, they often are mild and non-specific. The disease often is recognised long after exposure occurred, when secondary effects of the disease develop. Out of every 100 people who contract HCV, 75–80% will develop chronic infection, 60–70% will develop chronic liver disease, 5–20% will develop cirrhosis and 1–5% will die from complications of the infection, including liver carcinoma. Worldwide, HCV is the leading cause of liver transplantation (Casey & Lee, 2012).

HEPATITIS DELTA It is estimated that more than 15 million people worldwide are infected with HDV. HDV can only occur in a person who also has the HBV infection; either by simultaneous transmission of the two viruses or via superinfection of an established HBV carrier (Hughes et al., 2011). Like HBV, HDV is transmitted through exposure to infected blood or body fluids. At-risk populations include intravenous drug users and people with high-risk sexual activity (Hughes et al., 2011). People with HBV and HDV co-infection are at greater risk of severe liver disease that progresses swiftly to liver cirrhosis, hepatic failure and death (Hughes et al., 2011).

HEPATITIS E Hepatitis E is rare in Australia. It is transmitted by faecal contamination of water supplies in developing areas such as South-East Asia, parts of Africa and Central America. It primarily affects young adults. It can cause fulminant, fatal hepatitis in pregnant women.

Chronic hepatitis

Chronic hepatitis is chronic infection of the liver. Although it may cause few symptoms, it is the primary cause of liver damage leading to cirrhosis, liver cancer and liver transplantation. Three of the known hepatitis viruses cause chronic hepatitis: HBV, HCV and HDV. Manifestations of chronic hepatitis include malaise, fatigue and hepatomegaly. Occasional icteric (jaundiced) periods may occur. Liver enzymes, particularly serum aminotransferase levels, typically are elevated.

In *chronic active hepatitis*, inflammation extends to involve entire hepatic lobules. Chronic active hepatitis usually leads to cirrhosis and end-stage liver failure.

Fulminant hepatitis

Fulminant hepatitis is a rapidly progressive disease, with liver failure developing within 2 to 3 weeks after the onset of symptoms. Although uncommon, it is usually related to HBV with concurrent HDV infection.

Toxic hepatitis

Many substances, including alcohol, certain drugs and other toxins, can directly damage liver cells. Alcoholic hepatitis can result from chronic alcohol abuse or from an acute toxic reaction to alcohol. Alcoholic hepatitis causes necrosis of hepatocytes and inflammation of the liver parenchyma (functional tissue). Unless alcohol intake is avoided, progression to cirrhosis is common.

Other potential hepatotoxins include paracetamol, benzene, carbon tetrachloride, halothane, chloroform and poisonous mushrooms. These substances directly damage liver cells, leading to necrosis. The degree of damage often depends on age and the extent of exposure to (dose of) the hepatotoxin. Paracetamol overdose is a common cause of hepatocellular damage.

Hepatobiliary hepatitis

Hepatobiliary hepatitis is due to cholestasis, the interruption of the normal flow of bile. Cholestasis may result from obstruction of the hepatic duct with stones or inflammation secondary to cholelithiasis. Other agents, such as oral contraceptives and allopurinol (a drug used to lower uric acid levels), also can cause cholestasis. When bile flow is disrupted, the liver parenchyma may become inflamed. Re-establishing bile flow by removing the stone or other causative agent is the treatment for hepatobiliary hepatitis.

INTERPROFESSIONAL CARE

Management of hepatitis focuses on determining its cause, providing appropriate treatment and support, and teaching strategies to prevent further liver damage. Effective management begins with thorough assessment of diagnostic and laboratory data.

Diagnosis

Liver function tests, such as blood levels of bilirubin and enzymes commonly released when liver cells are damaged, are obtained. These include the following:

- *Alanine aminotransferase (ALT)* is an enzyme contained within each liver cell. When liver cells are damaged, ALT is released into the blood. Levels may exceed 1000 U/L or more in acute hepatitis.
- *Aspartate aminotransferase (AST)* is an enzyme found predominantly in heart and liver cells. AST levels rise when liver cells are damaged; with severe damage, blood levels may be 20 to 100 times normal values.
- *Alkaline phosphatase (ALP)* is an enzyme present in liver cells and bone. Serum ALP levels often are elevated in hepatitis.
- *Gamma-glutamyltransferase (GGT)* is an enzyme present in cell membranes. Its blood levels rise in hepatitis and obstructive biliary disease and remain elevated until function is restored.
- *Lactic dehydrogenase (LDH)*, an enzyme present in many body tissues, is a non-specific indicator of tissue damage. Its isoenzyme, LDH5, is a specific indicator of liver damage.
- *Serum bilirubin* levels, including *conjugated* and *unconjugated*, are elevated in viral hepatitis due to impaired bilirubin metabolism and obstruction of the hepatobiliary ducts by inflammation and oedema. The bilirubin level decreases as inflammation and oedema subside.
- Laboratory tests for viral antigens and their specific antibodies may be done to identify the infecting virus and its state of activity.
- A *liver biopsy* may be done to detect and evaluate chronic hepatitis. (Nursing implications for this test are outlined in the 'Diagnostic tests' box in Chapter 20.)

Medications

PREVENTION Hepatitis A and hepatitis B are preventable diseases. Vaccines are available, as are preparations to prevent the disease following known or suspected exposure.

Vaccines Hepatitis A vaccine provides long-term protection against HAV infection. It is an inactivated whole-virus vaccine available in paediatric and adult formulations. Although more than 95% of adults achieve immunity after one dose of the vaccine, two doses are recommended for full protection. (See Table 24.3.)

Three doses of hepatitis B vaccine provide immunity to HBV infection in 90% of healthy adults. Because the hepatitis delta virus requires the presence of HBV, hepatitis B vaccine also protects against HDV. Hepatitis B vaccine is a recombinant vaccine. Vaccines produced by different manufacturers may be used interchangeably, although their dosages differ. Older adults are less likely to achieve immunity than younger adults. People on haemodialysis and people who are immunocompromised may need larger or more doses of the vaccine to achieve adequate protection. Serological testing for immunity is recommended on completion of the series for people in these high-risk groups.

A combined hepatitis A and hepatitis B vaccine is available for use. It is recommended for the same high-risk populations as the single vaccines. Three doses are given: the initial dose, followed by doses no sooner than 4 weeks and 6 months later.

Post-exposure prophylaxis Post-exposure prophylaxis may be recommended for household or sexual contacts of people with HAV or HBV and other people who are known to have been exposed to these viruses. It may also be necessary for health professionals who are not immunised against HBV post needle-stick injury. It is not necessary if the exposed person has been vaccinated and is known to be immune.

Hepatitis A prophylaxis is provided by a single dose of immune globulin (IG) given within 2 weeks after exposure. IG is recommended for all people with household or sexual contact with a person known to be infected with hepatitis A. See Table 24.3 for further recommendations.

Hepatitis B post-exposure prophylaxis is indicated for people exposed to the hepatitis B virus. Hepatitis B immune globulin (HBIG) is given to provide short-term immunity. HBV vaccine may be given concurrently. Candidates for post-exposure prophylaxis include those with known or suspected percutaneous or permucosal contact with infected blood, sexual partners of people with acute HBV or who are HBV carriers, and household contacts of people with acute HBV infection (Department of Health and Ageing, 2012).

Treatments

In most cases of acute viral hepatitis, pharmacological treatment of the infection is not indicated. Acute hepatitis C generally is treated with interferon alpha, an antiviral agent, to reduce the risk of chronic hepatitis C. While treatment with interferon alpha alone is common, it may be combined with the antiviral drug ribavirin (Virazide).

Interferon alpha is used to treat both chronic hepatitis B and chronic hepatitis C. Interferon alpha interferes with viral replication, reducing the viral load. It is given by intramuscular or subcutaneous injection. Virtually all people treated with interferon alpha develop a flu-like syndrome with fever, fatigue, muscle aches, headache and chills. Paracetamol helps alleviate

TABLE 24.3 Recommendations for hepatitis prevention in adults

DISEASE/ STRATEGY	IMMUNISATION	ADVERSE REACTIONS	POPULATION RECOMMENDATIONS
Hepatitis A			
Prevention	Hepatitis A vaccine (Havrix; VAQTA Adult), 2 doses (initial dose with booster in 6–12 months) given IM into deltoid muscle Combined hepatitis A and hepatitis B vaccine (Twinrix), 3 doses (initial dose followed by doses 1 and 6 months later) given IM into deltoid muscle	Pain at injection site	• All travellers to, and all expatriates living in, moderately to highly endemic areas • Indigenous Australian children residing in the Northern Territory, Queensland, South Australia and Western Australia • Those whose lifestyle may put them at risk of acquiring hepatitis A • People with occupational risk
Post-exposure prophylaxis	Standard immune globulin IM into large muscle mass within 2 weeks of exposure	Rare; risk of anaphylaxis in people with IgA deficiency	• Close contacts of people with known hepatitis A • People potentially exposed to hepatitis A at childcare centre or restaurant with infected food handler
Hepatitis B			
Prevention	Recombinant hepatitis B vaccine (Engerix-B Adult), 3 doses (initial dose followed by doses at 1 and 6 months later) given IM into deltoid muscle Combined hepatitis A and hepatitis B vaccine (Twinrix), 3 doses (initial dose followed by doses 4 weeks and 6 months later) given IM into deltoid muscle	Pain at injection site; fever, nausea, dizziness, malaise, myalgia and arthralgia	• Infants and adolescents • Household contacts of acute and chronic hepatitis B carriers • Men who have sex with men • Haemodialysis patients, HIV-positive individuals and other adults with impaired immunity • Prostitutes; heterosexuals with multiple sexual partners • People with an STD • Intravenous drug users • Long-term male prisoners • Healthcare workers
Post-exposure prophylaxis	Hepatitis B immune globulin (HBIG) given IM into large muscle mass within 72 hours of exposure.	Infrequent; muscle stiffness, pain, fever, nausea, dizziness, malaise, myalgia and arthralgia	• Infants born to women with HBV infection • Percutaneous or permucosal exposure to HBV when unvaccinated or antibody response is negative or unknown

Source: Department of Health and Ageing, Office of Health Protection (2013; updated 2014, 2015). *Australian Immunisation Handbook* (10th ed.). Used by permission of the Australian Government.

some of these adverse effects. Depression also is a common adverse effect of this drug.

An alternative drug for treating chronic hepatitis B is lamivudine (3TC, Zeffix), an antiviral drug that can reduce liver inflammation and fibrosis. Although it has minimal side effects, people may become resistant to the beneficial effects of lamivudine.

The treatment of choice for chronic hepatitis C is combination therapy of interferon alpha with ribavirin, an oral antiviral drug. This combination therapy improves the response rate over either drug used alone. Ribavirin has two major adverse effects: haemolytic anaemia and birth defects. Blood counts are obtained before and during treatment to detect early signs of haemolytic anaemia. Because of the risk of birth defects, this drug is contraindicated for use during pregnancy and two reliable methods of contraception must be used by women taking the drug and female sexual partners of men taking the drug.

Treatment of acute hepatitis also includes as-needed bed rest, adequate nutrition as tolerated and avoidance of strenuous activity, alcohol and agents that are toxic to the liver. In most cases, clinical recovery takes 3 to 16 weeks.

Nursing care

Health promotion

Nurses play an instrumental role in preventing the spread of hepatitis. Stress the importance of hygiene measures such as handwashing after toileting and before all food handling. Discuss the dangers of intravenous drug use and, with drug users, of sharing needles or other equipment. Encourage all sexually active people to use safer sexual practices such as mutual monogamy and barrier protection (such as male or female condoms).

Discuss recommendations for hepatitis A and hepatitis B vaccine with people in high- or moderate-risk groups for these infections. Ensure that nurses and other healthcare workers at risk of exposure to blood and body fluids are effectively vaccinated against hepatitis A and B. Encourage all people with known or probable exposure to HAV or HBV to obtain post-exposure prophylaxis.

Assessment

Collect assessment data related to hepatitis, such as the following:

- *Health history:* current manifestations, including anorexia, nausea, vomiting, abdominal discomfort, changes in bowel elimination or colour of stools; muscle or joint pain, fatigue; changes in colour of skin or sclera; duration of symptoms; known exposure to hepatitis; high-risk behaviours such as intravenous drug use or multiple sexual partners; previous history of liver disorders; current medications, prescription and over the counter.
- *Physical assessment:* vital signs including temperature; colour of sclera and mucous membranes; skin colour and condition; abdominal contour and tenderness; colour of stool and urine.
- *Diagnostic tests:* serum bilirubin, liver function tests, serological antibody–antigen levels.

Nursing diagnoses and interventions

People with acute or chronic hepatitis usually are treated in community settings; rarely is hospitalisation required. Nursing care focuses on preventing spread of the infection to others and promoting the person's comfort and ability to provide self-care.

Risk of infection (transmission)

An important goal when caring for people with acute viral hepatitis is preventing spread of the infection.

- Use standard precautions. Practise meticulous handwashing. The hepatitis viruses are spread by direct contact with faeces or blood and body fluids. *Standard precautions and good handwashing protect both healthcare workers and other people from exposure to the virus.*
- For people with HAV or HEV, use standard precautions and contact isolation if faecal incontinence is present. *The faecal–oral route is the primary mode of transmission of these viruses. Other hepatitis viruses are transmitted through blood and other body fluids.*
- Encourage prophylactic treatment of all members of household and intimate sexual contacts. *Prophylactic treatment of others in close contact with the person decreases their risk of contracting the disease or, if already infected, the severity of the disease.*

CONSIDERATION FOR PRACTICE

If the person diagnosed with hepatitis A is employed as a food handler or childcare worker, contact the local health department to report possible exposure of patrons. Maintain confidentiality. Prophylactic treatment of people who have possibly been exposed to the virus can prevent a local epidemic of the disease.

Fatigue

Fatigue and possible weakness are common in acute hepatitis. Although bed rest is rarely indicated, adequate rest periods and limitation of activities may be necessary. Many people with acute hepatitis may be unable to resume normal activity levels for 4 or more weeks.

- Encourage planned rest periods throughout the day. *Adequate rest is necessary for optimal immune function.*
- Assist to identify essential activities and those that can be deferred or delegated to others. *Identifying essential and non-essential activities promotes the person's sense of control.*
- Suggest using level of fatigue to determine activity level, with gradual resumption of activities as fatigue and sense of wellbeing improves. *Fatigue associated with activity is an indicator of appropriate and inappropriate activity levels. As recovery progresses, increasing activity levels are tolerated with less fatigue.*

Imbalanced nutrition: less than body requirements

Adequate nutrition is important for immune function and healing in people with acute or chronic hepatitis.

- Help plan a diet of appealing foods that provides a high-kilojoule intake of approximately 65 carbohydrate kilojoules per kilogram of ideal body weight. *Sufficient energy is required for healing; adequate carbohydrate intake can spare protein.*
- Encourage planning food intake according to symptoms of the disease. Discuss eating smaller meals and using between-meal snacks to maintain nutrient and kilojoule intake. *People with acute hepatitis often are more anorexic and nauseated in the afternoon and evening; planning the majority of kilojoule intake for in the morning helps maintain adequate intake. Limiting fat intake and the size of meals may reduce the incidence of nausea.*
- Instruct to avoid alcohol intake and diet drinks. *Alcohol avoidance is vital to prevent further liver damage and promote healing. Diet drinks (e.g. diet soft drinks or juice drinks) provide few kilojoules when an increased kilojoule intake is needed for healing.*
- Encourage use of nutritional supplements such as Ensure or instant breakfast drinks to maintain kilojoule and nutrient intake. *Nutritional supplement drinks are an additional source of concentrated kilojoules and nutrients.*

Disturbed body image

Jaundice and associated rashes and itching can affect the person's body image. Nursing measures to prevent skin breakdown and address body image are discussed in the following section on cirrhosis.

Community-based care

Provide discharge teaching to people and their families for home care. Include the following topics:

- recommended prophylactic treatment
- infection control measures such as frequent handwashing, not sharing eating utensils, avoiding food handling or preparation activities by the person with hepatitis A; abstaining from sexual relations during acute infection and using barrier protection if a carrier or for chronic infection
- managing fatigue and limited activity
- managing pruritus and maintaining skin integrity: use warm, not hot, water when bathing, use mild or no soap, limit duration of baths and showers; pat dry, do not rub, apply an alcohol-free lotion soon after bathing to retain skin moisture; wear loose cotton garments that allow moisture to evaporate from skin; reduce room temperature, especially at night, to prevent overheating; keep fingernails short and wear cotton mittens or gloves as needed to prevent scratching during sleep
- promoting nutrient intake
- avoiding hepatic toxins such as alcohol, paracetamol and selected other drugs; encourage to alert all care providers to presence of infection
- recommended follow up.

If chronic hepatitis B or C is being treated with medications, teach how to administer the drug, its dosing schedule, precautions and management of adverse effects. Stress the importance of keeping follow-up appointments, including recommended laboratory testing.

THE PERSON WITH CIRRHOSIS

Cirrhosis is the end-stage of chronic liver disease. It is a progressive, irreversible disorder, eventually leading to liver failure.

Alcoholic or Laënnec's cirrhosis is the most frequent cause of death related to long-term, high-risk alcohol consumption. Excessive alcohol consumption is one of the leading causes of morbidity and mortality in Australia (Liang et al., 2011). Cirrhosis also may result from chronic hepatitis B or C; prolonged obstruction of the biliary (bile drainage) system; long-term, severe right heart failure and other uncommon liver disorders. The incidence of and mortality attributable to cirrhosis and chronic liver disease vary significantly among populations.

Pathophysiology

In cirrhosis, functional liver tissue is gradually destroyed and replaced by fibrous scar tissue. As hepatocytes and liver lobules are destroyed, the metabolic functions of the liver are lost. Structurally abnormal nodules encircled by connective tissue form. This fibrous connective tissue forms constrictive bands that disrupt blood and bile flow within liver lobules. Blood no longer flows freely through the liver to the inferior vena cava. This restricted blood flow leads to portal hypertension (increased pressure in the portal venous system).

FAST FACTS

- Alcoholic liver disease was ranked 20th as a leading cause of death in Australia in 2013 (down from 17th in 2004) (Australian Bureau of Statistics, 2013).
- The mortality from alcoholic liver disease has significantly decreased in Australia from 1993 to 2005, possibly due to a significant increase in hospital admissions for alcoholic liver failure during the same period. Mortality rates for males have decreased by 21.7%, and for females by 8.3% (Liang et al., 2011).

Alcoholic cirrhosis

Alcoholic or Laënnec's cirrhosis is the end result of alcoholic liver disease. Its development is directly related to alcohol consumption: total amount of alcohol consumed, number of years of excessive alcohol consumption and blood alcohol levels. Cirrhosis mortality is less prevalent in women than men due to men generally consuming more alcohol than women and the percentage of men consuming large amounts of alcohol (Addolorato et al., 2009).

Alcohol causes metabolic changes in the liver: triglyceride and fatty acid synthesis increases and the formation and release of lipoproteins decrease, leading to fatty infiltration of hepatocytes (fatty liver). At this stage, abstinence from alcohol can allow the liver to heal. With continued alcohol abuse, the disease progresses. Inflammatory cells infiltrate the liver (alcoholic hepatitis), causing necrosis, fibrosis and destruction of functional liver tissue. In the final stage of alcoholic cirrhosis, regenerative nodules form and the liver shrinks and develops a nodular appearance. Malnutrition commonly accompanies alcoholic cirrhosis. See 'Pathophysiology illustrated: cirrhosis and portal hypertension' on the following pages.

Biliary cirrhosis

When bile flow is obstructed within the liver or in the biliary system, retained bile damages and destroys liver cells close to the interlobular bile ducts. This leads to inflammation, fibrosis and formation of regenerative nodules.

Post-hepatic cirrhosis

Advanced progressive liver disease resulting from chronic hepatitis B or C or from an unknown cause is known as post-hepatic or post-necrotic cirrhosis. The liver is shrunken and nodular, with extensive liver cell loss and fibrosis.

Manifestations and complications

Early in the course of cirrhosis, few manifestations may be present. The liver usually is enlarged and may be tender. Symptoms may be vague such as a dull, aching pain in the RUQ along with fever, nausea, vomiting, diarrhoea, anorexia and malaise (Bacon, 2012).

As the disease progresses, manifestations related to complications of liver cell failure and portal hypertension develop including

MANIFESTATIONS Cirrhosis with underlying cause

MANIFESTATION	UNDERLYING PATHOPHYSIOLOGY
Oedema, ascites	Impaired plasma protein synthesis (hypoalbuminaemia) Disrupted hormone balance and fluid retention Increased pressure in portal venous system
Bleeding, bruising	Decreased clotting factor synthesis Increased platelet destruction by enlarged spleen Impaired vitamin K absorption and storage
Oesophageal varices, haemorrhoids	Increased pressure in portal venous system with collateral vessel development
Gastritis, anorexia, diarrhoea	Engorged veins in gastrointestinal system Alcohol ingestion Impaired bile synthesis and fat absorption
Abdominal wall vein distension (caput medusae)	Portal hypertension
Jaundice	Impaired bilirubin metabolism and excretion
Malnutrition, muscle wasting	Impaired nutrient metabolism Impaired fat absorption Impaired hormone metabolism
Anaemia, leucopenia, increased risk of infection	Bleeding Increased blood cell destruction by spleen
Asterixis, encephalopathy	Accumulated metabolic toxins Impaired ammonia metabolism and excretion
Gynaecomastia, infertility, impotence	Altered sex hormone metabolism

ascites, oedema, gastrointestinal haemorrhage, jaundice or encephalopathy. Men may have decreased body hair, gynaecomastia and testicular atrophy; women may have dysmenorrhoea or amenorrhoea. Laboratory tests may show anaemia from chronic gastrointestinal bleeding, hypersplenism or nutritional deficiencies, total serum bilirubin may be elevated with advanced cirrhosis, clotting factors are prolonged and liver enzymes elevated (Bacon, 2012). See 'Multisystem effects of cirrhosis', page 803.

See the box above for selected manifestations of cirrhosis and their underlying pathophysiology.

PORTAL HYPERTENSION Portal hypertension causes blood to be rerouted to adjoining lower-pressure vessels. This *shunting* of blood involves collateral vessels. Affected veins, which become engorged and congested, are located in the oesophagus, rectum and abdomen. Portal hypertension increases the hydrostatic pressure in vessels of the portal system. Increased hydrostatic pressure in the capillaries pushes fluid out, contributing to ascites formation.

SPLENOMEGALY The spleen enlarges (splenomegaly) because portal hypertension causes blood to be shunted into the splenic vein. Splenomegaly increases the rate at which red and white blood cells and platelets are removed from circulation and destroyed. This increased blood cell destruction leads to anaemia, leucopenia and thrombocytopenia (Porth & Matfin, 2009).

ASCITES Ascites is the accumulation of plasma-rich fluid in the abdominal cavity. Although portal hypertension is the primary cause of ascites, decreased serum proteins and increased aldosterone also contribute to the fluid accumulation. *Hypoalbuminaemia*, low serum albumin, decreases the colloidal osmotic pressure of plasma. This pressure normally holds fluid in the intravascular compartment; when plasma colloidal osmotic pressure decreases, fluid escapes into extravascular compartments. *Hyperaldosteronism*, an increase in aldosterone, causes sodium and water retention, contributing to ascites and generalised oedema.

OESOPHAGEAL VARICES **Oesophageal varices** are enlarged, thin-walled veins that form in the submucosa of the oesophagus. These collateral vessels form when blood is shunted from the portal system due to portal hypertension. The thin-walled varices may rupture, causing massive haemorrhage; even eating high-roughage foods can precipitate bleeding. Thrombocytopenia, platelet deficiency and impaired production of clotting factors by the liver contribute to the risk of haemorrhage.
