Nursing care for the person with acute epiglottitis focuses on monitoring and maintaining airway patency. Monitor oxygen saturation continuously. Observe closely for signs of airway obstruction, including nasal flaring, restlessness, stridor, use of accessory muscles and decreased oxygen saturation measurements. If the person is not intubated, supplies for emergency intubation should be kept in the unit. Epiglottitis is frightening for both the person and the nurse. Maintaining a calm, reassuring manner is an essential nursing role.

Laryngitis

Laryngitis, inflammation of the larynx, is a common disorder that may occur alone or in conjunction with other upper respiratory infections. It is commonly associated with a viral URTI such as influenza. It may also occur with bronchitis, pneumonia or other respiratory infections. Excessive use of the voice, sudden changes in temperature or exposure to dust, irritating fumes, smoke or other pollutants can also cause acute or chronic laryngitis. It is more common in the winter and in colder climates.

In laryngitis, the mucous membrane lining the larynx becomes inflamed; the vocal cords also may become oedematous. The primary symptom of laryngitis is a change in the voice. Hoarseness or *aphonia*, complete loss of the voice, may occur. The throat is often sore and scratchy and a dry, harsh cough may be present.

There is no specific treatment for viral laryngitis. Any identified precipitating factors such as overuse of the voice and exposure to irritants should be eliminated. Voice rest is advised, as is abstinence from tobacco and alcohol, which are chemical irritants. Treatment may also include inhaling steam or spraying the throat with antiseptic solutions. Identifying and eliminating irritants are helpful to prevent future attacks.

Impaired verbal communication is the priority nursing problem for people with laryngitis. The meaning of messages is conveyed not only by the words used but also by the tone and loudness of voice. Instruct to rest the voice as much as possible. Encourage speaking in short sentences or using alternate methods of communication, such as writing. Resting the voice hastens recovery and decreases throat discomfort. Advise the person to use soothing throat lozenges, sprays or other comfort measures such as gargling with a warm antiseptic solution. Help identify potential irritants, such as fumes, chemicals or cold temperature, to prevent future bouts of laryngitis.

THE PERSON WITH PERTUSSIS

Pertussis, or *whooping cough*, is a highly contagious acute upper respiratory infection caused by the bacterium *Bordetella pertussis*. Although it is thought by many to be a childhood disease that has been virtually eliminated by aggressive immunisation of infants, Australia is recovering from an outbreak which started in 2008 and peaked in 2011 at more than four times the average notification rates of the preceding 20 years. Figure 34.3 reports the trend in laboratory-confirmed pertussis infections in Australia from 1992 to 2014. Up to 45% of people affected by pertussis are adolescents and adults. Figure 34.4 shows the distribution of pertussis infection across age.

Pathophysiology

B. pertussis is a Gram-negative rod that is spread by respiratory droplets. The bacteria attach to ciliated epithelial cells of the nasopharynx, multiplying and invading respiratory tissues. The damage and effects of pertussis are not due to the infection itself but to toxins produced by the bacteria. These toxins damage the mucosa and paralyse the cilia. As a result, clearance of respiratory secretions is impaired, increasing the risk of pneumonia. The toxins also prompt an inflammatory response and inhibit immune defences.

Although immunisation does not appear to confer lifetime immunity, the disease tends to be milder in adolescents, adults and people who have been immunised. These infected individuals can, however, transmit the disease to other susceptible people, including unimmunised or under-immunised infants (Teng & Wang, 2012).

Young infants have the highest risk of complications of the disease, such as death, pneumonia and neurological complications. Neurological complications are thought to result from hypoxia due to prolonged paroxysms of coughing.

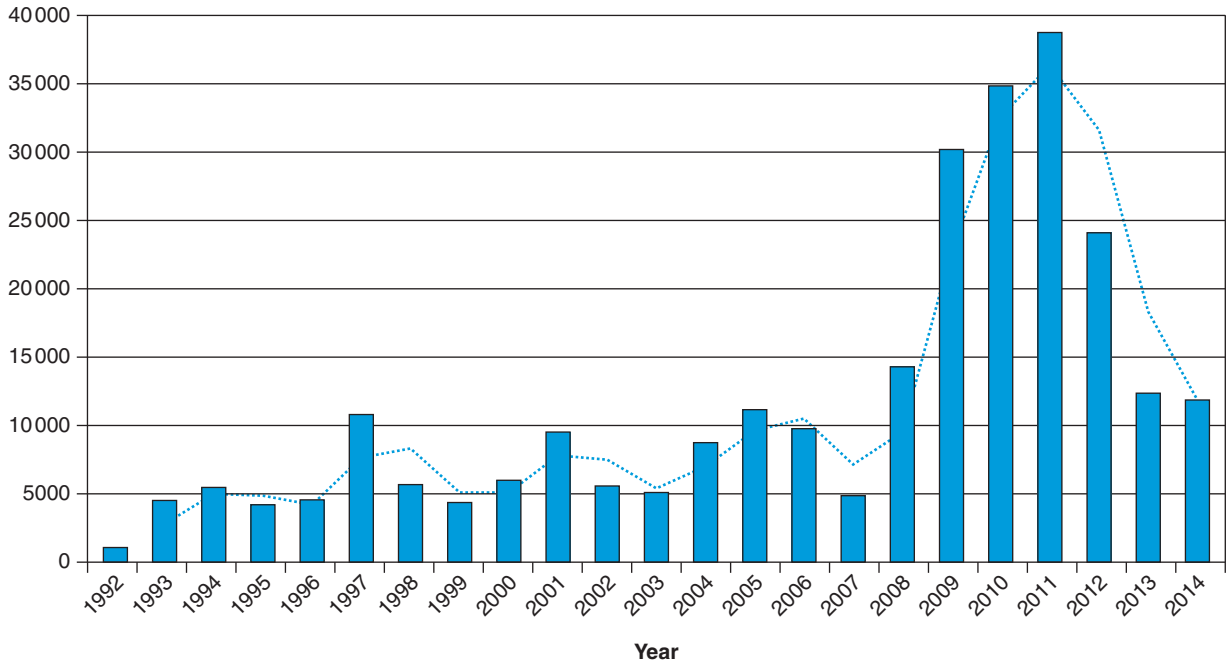

FIGURE 34.3 ■ *Bordetella pertussis* incidence in Australia 1992–2014

Source: Derived using data from National Notifiable Diseases Surveillance System (NNDSS) (Department of Health, 2015e). *Notifications of* Bordetella pertussis *by year.* Retrieved from www9.health.gov.au/cda/source/cda-index.cfm.

Complications in adolescents and adults may occur as a result of increased intrathoracic pressure during prolonged coughing spells. These may include pneumothorax, weight loss, inguinal hernia, rib fracture and *cough syncope* (fainting due to hypoxia) (Teng & Wang, 2012).

Manifestations

Classic pertussis follows a predictable pattern, with typical URTI symptoms (coryza, sneezing, low-grade fever and mild cough) beginning 7 to 10 days after exposure. After 1 to 2 weeks, the cough becomes more frequent, occurring in

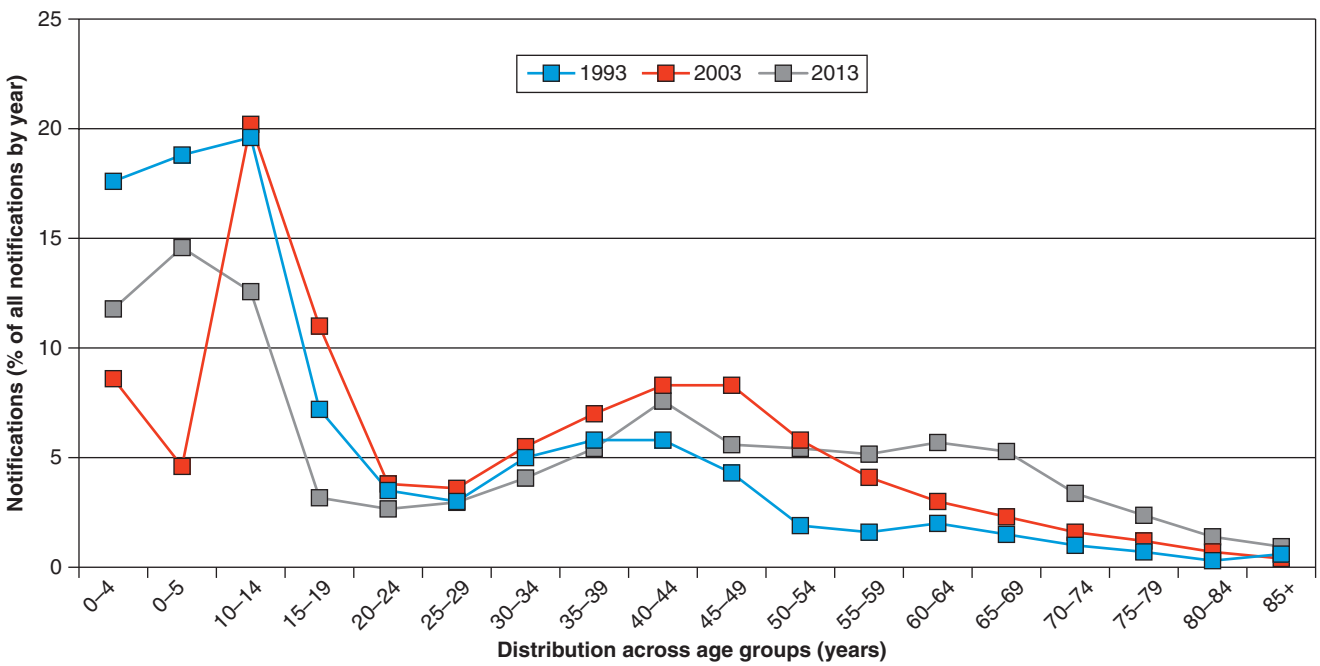

FIGURE 34.4 ■ Distribution of *Bordetella pertussis* laboratory-confirmed infections across age groups for selected years

Source: Derived using data from National Notifiable Diseases Surveillance System (NNDSS) (Department of Health, 2015f). *Notifications of* Bordetella pertussis *by age group and year.* Retrieved from www9.health.gov.au/cda/source/cda-index.cfm.

paroxysms or bursts of rapid coughs, often ending with an audible whoop caused by rapid inspiration. This whoop is less common in adolescents and adults, often delaying diagnosis. Vomiting commonly follows an episode of coughing (Bocka, 2014). Coughing paroxysms vary in frequency from several per hour to 5 to 10 per day, interfering with eating and sleep. This stage of the disease, called the *paroxysmal stage*, usually lasts no more than 6 weeks, after which coughing becomes less severe and gradually resolves over a period of up to 3 months.

In adolescents and adults, pertussis is suspected when an upper respiratory infection produces a cough that persists longer than 7 days, is accompanied by vomiting and is worse at night.

INTERPROFESSIONAL CARE

Active immunisation with pertussis vaccine is the primary preventive strategy for pertussis. Acellular pertussis vaccines that are effective but produce fewer adverse reactions than traditional whole-cell vaccines are available and preferred for immunisation.

The diagnosis of pertussis is established by culture of nasopharyngeal secretions. However, nasopharyngeal secretions may remain positive for the organism for only about 3 weeks after the onset of symptoms, so blood tests for antibodies to the organism may be necessary to confirm the diagnosis. Lymphocytosis (elevated lymphocyte count) may be present.

Azithromycin and clarithromycin are the antibiotics of choice to eradicate *B. pertussis* infection. In individuals where macrolide antibiotics are contraindicated, trimethoprim-sulfamethoxazole may be used (Antibiotic Expert Groups, 2014). Hospitalisation rarely is required for adults, although children and infants with severe disease often are hospitalised to prevent complications such as neurological effects of hypoxia and malnutrition. Respiratory isolation is instituted for 5 days after antibiotic therapy is started. Prophylactic antibiotics may be given to household and close contacts of the infected person depending on age, health, and immunisation status.

Nursing care

Nurses are instrumental in promoting effective immunisation of all infants and young children against pertussis. The Immunise Australia Program recently has started to recommend that parents, grandparents and carers of infants under 6 months of age should receive a single pertussis vaccine (dTpa) booster at least 2 weeks before beginning close contact with the infant (Department of Health, 2015d). Education is a key nursing role related to immunisation, as significant controversy currently exists about potential long-term adverse consequences of the vaccine.

Recommend nasopharyngeal culture for people complaining of persistent cough, especially when the cough is accompanied by vomiting or is significantly worse at night, or if other members of the household or close contacts have a similar illness.

CONSIDERATION FOR PRACTICE

Pertussis is a reportable communicable disease. All probable and confirmed cases must be reported to the local health department.

Education is a primary nursing role related to pertussis. Adults usually remain in the community for treatment. Teach respiratory isolation measures to be used until the disease is no longer communicable. Discuss ways to control respiratory secretions and the importance of disposing of tissues and secretions personally to prevent exposure of others. Stress the importance of prophylactic treatment for all household and close contacts. Discuss measures to maintain fluid and nutrient intake and use of a cough suppressant at night to promote rest. Encourage increased fluid intake to promote expectoration of respiratory secretions. Teach about the prescribed antibiotic, including its potential adverse effects and measures to reduce them, such as taking erythromycin with meals to prevent gastric upset. Contact the state or territory health department for follow up of contacts and compliance with prescribed treatment.

CONSIDERATION FOR PRACTICE

The National Immunisation Program requires the diphtheria, tetanus and acellular pertussis immunisation to be administered at 2, 4 and 6 months of age, with a booster to be administered at 4 years, and also between 10 and 15 years (Department of Health, 2015d).

UPPER RESPIRATORY TRAUMA OR OBSTRUCTION

Obstruction of the upper airway due to trauma (fracture of the nasal septum or the larynx), bleeding (e.g. epistaxis) or a tumour is not only frightening for the person but also may interfere with the ability to breathe.

THE PERSON WITH EPISTAXIS

The nose has a rich blood supply, receiving major arterial vessels from both the internal and external carotid artery systems. **Epistaxis**, or nosebleed, may be precipitated by a number

of factors. Trauma (picking the nose or blunt trauma) can cause epistaxis, as can drying of nasal mucous membranes, infection, substance abuse (e.g. cocaine), arteriosclerosis or hypertension. Epistaxis may also indicate a bleeding disorder related to acute leukaemia, thrombocytopenia, aplastic anaemia or severe liver disease. Additionally, treatment with an anticoagulant or antiplatelet drug may cause nosebleed. In adults, men more frequently have nosebleeds than women.

Pathophysiology and manifestations

Ninety per cent of all nosebleeds arise in the anterior nasal septum from Kiesselbach's area, a rich vascular plexus. Because of their location, these vessels are susceptible to trauma from nose picking, drying and infection. Posterior epistaxis more often develops secondarily to systemic disorders such as blood dyscrasias, hypertension or diabetes. In posterior epistaxis, bleeding is from the terminal branches of the sphenopalatine and internal maxillary arteries. Posterior epistaxis tends to be more severe and occurs more frequently in the older adult.

Anterior nosebleeds usually produce obvious bleeding from the nares, as well as bleeding into the posterior nasal and oral pharynx. The bleeding from a posterior nosebleed may be less apparent, with most of the blood draining into the posterior nasopharynx and swallowed by the person. Nausea and vomiting may occur due to swallowed blood.

INTERPROFESSIONAL CARE

The goal of treatment for epistaxis is to identify and control the source of bleeding.

Anterior bleeding can usually be managed by simple first-aid measures, such as applying pressure (pinching the nose towards the septum) for 5 to 10 minutes and applying ice packs to the nose and forehead to cause vasoconstriction. The person is placed in a sitting position to decrease blood flow to the head and reduce venous pressure. Leaning forward reduces drainage of blood backward into the nasopharynx and decreases swallowing of blood. The person is instructed to spit out the blood to help estimate the amount of bleeding and to prevent nausea and vomiting as a result of swallowed blood.

If applying pressure does not control the bleeding, medications, nasal packing or surgery may be necessary.

Medications

Topical vasoconstrictors such as cocaine (0.5%), phenylephrine (Neo-Synephrine) (1:1000) or adrenaline (1:1000) may be used to control anterior bleeding. These medications may be applied by nasal spray or on a cotton swab held against the bleeding site. Chemical cauterisation of the bleeding vessel may be done using agents such as silver nitrate. A topical anaesthetic such as lignocaine or cocaine may be used prior to nasal packing. If posterior nasal packing is required, prophylactic antibiotic therapy is initiated to prevent sinusitis or possible toxic shock syndrome.

Nasal packing

If bleeding cannot be controlled with pressure and local medications, a nasal tampon (a soft balloon filled with air) may be used to apply direct pressure to the bleeding vessel or the nasal cavity may be packed with 2.5–5 cm petroleum gauze. For an anterior pack, approximately 1–1.5 m of packing may be placed carefully and systematically along the floor of the nasal cavity and then into the vault of the nose. This is often available prepacked, impregnated with triamcinoline and an antibiotic cream. Anterior nasal packs are usually left in place for 24 to 72 hours. If epistaxis is caused by a bleeding disorder, the packing may be left in place for 4 to 5 days while the disorder is treated.

Posterior nosebleeds are more difficult to control, requiring both anterior and posterior packing (see Figure 34.5).

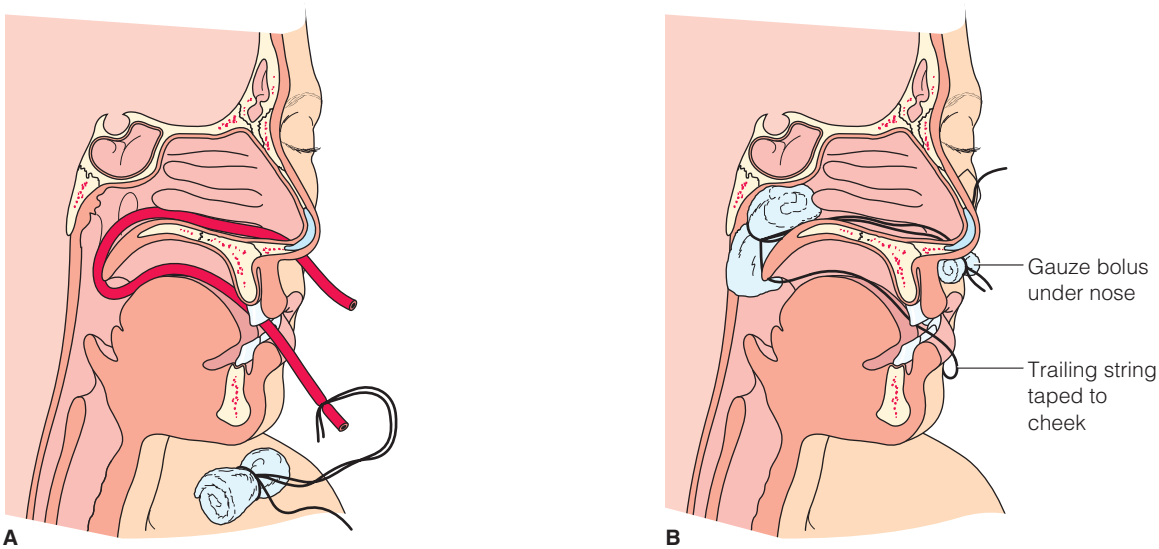

FIGURE 34.5 ■ Posterior nasal packing. *A*, A rubber catheter is inserted through the nose and out the mouth and attached to the packing. *B*, The catheter is withdrawn through the nose to position the packing in the posterior nasopharynx. Ties exiting through the nose and mouth are used to stabilise the packing in position and remove it when it is no longer needed

Posterior packs are usually left in place for 2 to 5 days. A loose anterior nasal pack may also be inserted. Posterior nasal packing is very uncomfortable and can cause respiratory and cardiovascular complications. Hypoxaemia is common; supplementary oxygen is administered. Endotracheal intubation may be necessary to maintain adequate ventilation and gas exchange. Narcotic analgesics are prescribed to manage the discomfort. Hypertension, arrhythmias and even acute myocardial infarction may occur in people with severe cardiovascular disease. Toxic shock syndrome is another potential complication of posterior nasal packing. The pack may occlude the eustachian tube and sinus openings, resulting in ear discomfort, possible otitis media or sinusitis. Oral and nasal dryness can be minimised by use of a high-humidity face tent. Nursing care of the person with nasal packing is outlined in the box below.

An indwelling catheter or inflatable nasal balloon may be used as an alternative to posterior nasal packing for effective tamponade. The catheter or nasal balloon is inserted through the nose into the nasopharynx, inflated and left in place for 2 to 3 days.

Surgery

Chemical or surgical cautery procedures may be used to sclerose involved vessels in the anterior aspect of the nose. The resulting scab must be left undisturbed until the mucosa has healed or further bleeding may occur.

Surgical procedures to control bleeding are often preferred to posterior nasal packing for posterior bleeding. The bleeding vessel may be cauterised using an endoscopic approach. In some cases, surgery is required to occlude the internal maxillary artery by ligation (tying off) or embolisation. These procedures may be done under either conscious sedation and local anaesthesia or general anaesthesia. Facial paralysis, paraesthesia, facial pain and dental injury are potential complications.

Nursing care

Assessment

Nursing assessment of the person with a nosebleed focuses on the immediate problem and possible underlying conditions.

- *Health history:* duration of current bleed; any identified precipitating factors such as trauma; history of prior nosebleeds; current medications; chronic conditions such as hypertension, bleeding disorders and so on.
- *Physical examination:* estimated amount of bleeding; presence of blood in oropharynx; vital signs; evidence of facial or nasal trauma.
- *Diagnostic tests:* haemoglobin, haematocrit and FBC as indicated; oxygen saturation; tests of organ function such as liver function tests (bilirubin, AST, ALT, LDH) or kidney function tests (serum creatinine and urea).

Nursing diagnoses and interventions

Nosebleeds can be frightening, particularly when they occur without preceding trauma. Nurses provide care for people with epistaxis in outpatient and emergency settings and may care for hospitalised people with nasal packing. Support, reassurance and education are important nursing roles related to epistaxis. Priority nursing concerns include assisting possible anxiety and monitoring to reduce the potential risk of aspiration.

Anxiety

The amount of blood lost in a nosebleed can be frightening. The sensation of blood draining down the throat and the inability to breathe through the nose contribute to anxiety. Spontaneous epistaxis may lead to fear of a major health problem such as high blood pressure.

CONSIDERATION FOR PRACTICE

Maintain an attitude of calm reassurance. By remaining calm and confident, the nurse reassures the person that the nosebleed is not a life-threatening event.

- Instruct the person to pinch the nares together at the bridge of the nose. *Most nosebleeds are anterior in origin; direct pressure usually stops the bleeding. Having the person place pressure on the nose provides a focus and helps restore a sense of control, reducing anxiety.*
- Encourage slow, deep breathing through the mouth. *Controlled mouth breathing maintains lung ventilation and reduces anxiety.*
- Provide a basin and tissues; encourage the person to expectorate blood, not swallow it. *These measures give the person greater control and reduce the fear of choking on blood.*
- Apply ice or a cold compress to the nose. *Cold causes vasoconstriction, reducing bleeding.*

CONSIDERATION FOR PRACTICE

Assess the person with nasal packing frequently for adequate oxygenation. Maintain supplemental oxygen as ordered. Cerebral hypoxia produces a sense of apprehension and fear.

Risk of aspiration

Anxiety and blood draining into the nasopharynx increase the risk of aspiration of blood into the trachea. When nasal packing is in place, the person is unable to breathe through the nose, increasing the risk of aspiration when food or fluids are consumed.

CONSIDERATION FOR PRACTICE

Position upright with head forward. Provide a basin for expectorating blood. These measures minimise the amount of blood draining down the nasopharynx and swallowed, reducing the risk of aspiration and minimising nausea from swallowed blood. Vomiting of swallowed blood increases the risk of aspiration.

NURSING CARE OF THE PERSON with nasal packing

- Continuously monitor oxygen saturation. Administer supplementary oxygen as ordered. *Posterior nasal packing causes hypoxaemia. Supplemental oxygen is given to maintain tissue oxygenation.*
- Frequently monitor vital signs and respiratory rate or pattern. *Posterior nasal packing increases the risk of respiratory and cardiovascular complications. Tachycardia and tachypnoea may be early signs of cardiac or respiratory compromise.*
- Inspect the mouth and oropharynx. Notify the doctor if the packing is seen in the oropharynx. *Misplacement of nasal packing can obstruct the upper airway.*
- Elevate the head of the bed. *Elevating the head of the bed facilitates ventilation.*
- Encourage deep, slow breathing through the mouth. Provide psychological support, reassurance and teaching. *Inability to breathe through the nose causes anxiety and fear.*
- Check for blood at the back of the throat and frequent swallowing. *Visible blood or frequent swallowing could indicate posterior bleeding.*
- Report haematemesis. *Bleeding from the posterior portion of the nose often drains down the nasopharynx and is swallowed. Haematemesis may indicate continued bleeding.*
- Apply cold compresses to nose. *An ice or cold compress decreases pain and promotes vasoconstriction, decreasing bleeding and swelling.*
- Provide for rest. *Rest reduces the metabolic demands and oxygen consumption.*
- Ensure adequate oral fluid intake. *Fluid intake helps maintain fluid balance and decreases dryness of oral mucous membranes because of mouth breathing.*
- Provide frequent oral hygiene. Use a bedside humidifier. *These measures reduce drying of oral mucous membranes and promote comfort.*

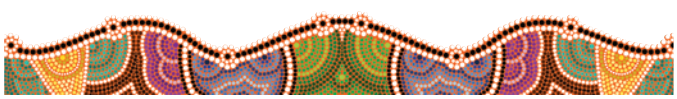
CONSIDERATION FOR PRACTICE

Position the person with nasal packing with the head elevated and on the side when asleep. This position reduces the risk of aspiration of oral secretions.

Community-based care

Following an episode of epistaxis, teaching for home care focuses on measures to prevent further bleeding. Include the following teaching topics:

- Avoid strenuous exercise for several days or weeks, depending on the severity of the nosebleed and its treatment.
- Do not blow the nose or engage in activities such as heavy lifting or bending that could increase pressure and dislodge the crust; sneeze with the mouth open to avoid increasing pressure in nasal vessels.
- For an anterior nosebleed, use petroleum jelly or a water-soluble lubricant to lubricate nasal mucosa and reduce the risk of spontaneous bleeding.
- Use a humidifier or vaporiser to minimise dryness of the mucous membranes.
- Do not forcefully blow the nose or pick the nose.
- For spontaneous nosebleed, seek medical evaluation for any possible underlying problem, such as hypertension or a bleeding disorder.



THE PERSON WITH NASAL TRAUMA OR SURGERY

The nose is the most commonly broken bone of the face. A nasal fracture (broken nose) usually is caused by a sports injury or trauma related to violence or motor vehicle crashes. The nasal septum normally divides the nose into two equal parts. Deviation of the septum can result from nasal trauma. Soft tissue trauma commonly accompanies nasal fracture.

Pathophysiology and manifestations

One or both sides of the nose may be broken. A *unilateral fracture* involves only one side of the nose. It causes little displacement or cosmetic deformity. It is usually not serious, but septal deviation and swelling can obstruct the airway. *Bilateral fractures* are more common, with depression or displacement of both nasal bones to one side. The nose appears flattened or deviated with an S or C configuration. *Complex fractures* may also involve the septum, ascending processes of the maxilla and frontal bones of the face.

Soft tissue trauma commonly accompanies nasal fracture. Mucous membrane tears cause epistaxis. Soft tissue haematomas (black eye) are also frequent. Swelling develops rapidly following the injury and may obscure the fracture. Bony crepitus may be felt on gentle palpation. Septal haematoma may develop, increasing the risk of infection. The manifestations of nasal fracture are listed in the box below.

MANIFESTATIONS Nasal fracture

- Epistaxis
- Deformity or displacement to one side
- Crepitus
- Periorbital oedema and ecchymosis
- Nasal bridge instability

Complications

Potential complications of nasal fracture include septal haematoma and abscess formation, septal perforation or deviation, and

cerebrospinal fluid (CSF) leakage. Septal haematoma can lead to complete and bilateral nasal obstruction. If undrained, haematoma increases the risk of staphylococcal abscess, which can lead to necrosis of septal cartilage and *saddle nose deformity*.

Septal deviation causes varying degrees of nasal obstruction. The septal cartilage bulges or deviates to one side, partially or totally obstructing the nares. Mild deviation is generally asymptomatic. Partial obstruction of air flow through one side may cause noisy breathing while awake and snoring during sleep. Major deviations can cause pain because of sinus obstruction or infection. They may also cause nosebleeds due to dryness of the nasal mucosa. Occasionally, the defect is severe enough to cause cosmetic deformity. Perforations are usually not serious and do not usually require repair unless obstruction or external deformity occurs.

Fractures of other facial bones may accompany a broken nose, particularly when facial trauma is severe. Fractures in the nasoethmoidal or frontal region can disrupt the dura, causing CSF leakage or rhinorrhoea. CSF rhinorrhoea is suspected if watery nasal drainage tests positive for glucose.

INTERPROFESSIONAL CARE

The main treatment goals for nasal fractures are to maintain a patent airway and prevent deformity. Respirations are closely monitored.

Diagnosis

Head and facial x-rays are done to identify the fracture and assess for other facial fractures. The intranasal cavity is examined using a nasal speculum to rule out septal haematoma. If a CSF leak is suspected, a CT scan is done. A radiopaque substance or fluorescein dye may be instilled into the intrathecal or lumbar subarachnoid space to identify the site of leakage.

Treatments

Ideally, the fracture is reduced early, before significant oedema develops. Nasal fractures heal rapidly. Simple reduction may be done in the emergency department with local anaesthesia. An external splint may be applied for 7 to 10 days to maintain proper alignment until healing occurs. The splint is padded to prevent skin breakdown. Ice may be gently applied to the face and nose to control oedema and bleeding. Nasal packing may be used to control epistaxis.

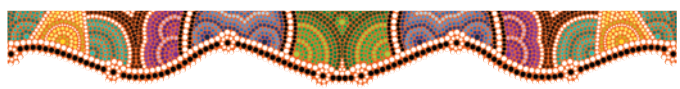
Surgery

Complex nasal fractures, nasal septal deviation or persistent CSF leakage may require surgical repair or realignment of nasal bones. Rhinoplasty with concurrent septoplasty is the most common procedure used to repair nasal fracture or a deviated nasal septum.

Rhinoplasty is surgical reconstruction of the nose. It is done to relieve airway obstruction and repair visible deformity of the nose following fracture. If oedema is excessive after nasal fracture, surgery is delayed for 7 to 10 days to allow swelling to subside. Using an intranasal incision, the nasal skin is lifted and the framework of the nose reshaped by removing, rearranging or augmenting bone or cartilage. The skin is then repositioned over the reconstructed frame. Prosthetic implants may help reshape the nose. Either local or general anaesthesia may be used; hospitalisation is often unnecessary. Following surgery, nasal packing is left in place for up to 72 hours to minimise bleeding and provide tissue support. A temporary plastic splint moulded to the shape of the nose is removed in 3 to 5 days. The splint protects the reshaped nose and helps to control swelling. Most swelling and bruising subside within 10 to 14 days; normal sensation returns within several months following surgery. Rhinoplasty generally has few complications.

Either a septoplasty or a submucosal resection may be done under local anaesthesia to correct a deviated septum. *Septoplasty* involves incising one side of the septum, elevating the mucous membrane and removing or straightening the deviated portion of septal cartilage. In a *submucosal resection*, bone and cartilage are removed. In both procedures, packing is applied to both sides of the nose to prevent bleeding and to keep the septal mucosa in the midline position.

Small defects in the cribriform plate, fovea ethmoidalis or sphenoid sinus associated with persistent CSF leakage may require endoscopic repair. Either a tissue graft or fibrin glue may be used to repair the defect. The graft or glue is held in place with absorbable packing. Large defects may require craniotomy for repair.



Nursing care

Health promotion

Teach all people—children and adolescents, in particular—about the importance of wearing appropriate protective equipment during exercise or sports. Reinforce the compulsory use of seat belts and air bags in vehicles to reduce the risk of facial injury in motor vehicle crashes.

Assessment

Focused nursing assessment for the person with a suspected nasal fracture includes:

- *Health history:* nature and circumstances of the injury; pain; ability to breathe through the nose.
- *Physical examination:* evident trauma, swelling, ecchymosis or deformity of the nose; vital signs, respiratory rate and ease; gently palpate nose and facial bones for crepitus; inspect oropharynx for drainage; test nasal discharge for glucose.

Nursing diagnoses and interventions

Nursing care for the person with nasal fracture focuses on controlling pain, bleeding and swelling. Airway management is a priority. Most nasal fractures are managed on an outpatient basis and education is a vital nursing function.

Risk of airway compromise

Immediately following nasal trauma and fracture, the airway is at risk of obstruction by bleeding and oedema. Deformity resulting from inappropriate fracture position during healing also can impair nasal airway clearance. This is a consideration when inserting nasogastric tubes or suctioning people with septal deviation.

CONSIDERATION FOR PRACTICE

Monitor airway patency. Oedema and bleeding may obstruct the airway, causing signs of respiratory distress such as tachypnoea, dyspnoea, shortness of breath, tachycardia and use of accessory muscles.

- Monitor cough effectiveness and ability to clear airway secretions. *Pain, oedema and nasal bleeding may impair the ability to cough effectively.*
- Maintain adequate hydration. Assess mucous membranes and skin turgor for evidence of dehydration. *Decreased oral fluid intake may lead to dehydration and thick, viscous secretions that are more difficult to expectorate.*

CONSIDERATION FOR PRACTICE

Have suction equipment available. Airway patency is a priority; oropharyngeal suctioning may be necessary to remove secretions and maintain a clear airway. Suctioning of the nasopharynx is avoided to prevent additional tissue trauma.

- Assess patency of both nares before inserting a nasogastric tube or feeding tube. If airflow is obstructed through one side, insert the tube through the unobstructed nare. Carefully monitor respiratory status following tube insertion. *The nasogastric tube is inserted through the unobstructed nare to avoid mucosal trauma; however, a large gastric tube may interfere with nasal breathing, necessitating close monitoring.*

Risk of infection

The person with a nasal fracture is at increased risk of infection. The nasal mucosa is a natural barrier to infection, and trauma increases the risk of invasion by pathogens. Septal haematoma can lead to abscess formation and staphylococcal infection. A cerebrospinal fluid leak indicates disruption of the dura, increasing the risk of ascending infection and meningitis.

CONSIDERATION FOR PRACTICE

Test watery, clear fluid dripping from the ear or nose for glucose. CSF will test positive for glucose on a glucose test strip.

- Avoid suctioning if possible. *Suctioning catheters could introduce microorganisms and cause additional trauma to tissues.*
- Monitor vital signs every 4 hours. *A rise in temperature may indicate infection.*
- Administer antibiotics as ordered. *Antibiotics may be prescribed to prevent abscess formation and, if CSF leakage is present, to prevent meningitis.*

Community-based care

Provide the following teaching when preparing the person with a nasal fracture for home care:

- Elevate the head of the bed and apply ice or cold packs to the nose for 20 minutes four times a day to reduce swelling.
- Swelling usually subsides in several days; bruising may persist for several weeks.
- It is difficult to determine the final cosmetic outcome until swelling has subsided.
- If indicated, discuss the potential benefits of rhinoplasty for fracture reduction or correction of this malformation.

If CSF leakage is present, also include the following instructions:

- Rest in bed with the head of the bed elevated to 30 to 45 degrees.
- Restrict fluid intake as ordered and take the prescribed diuretic to reduce intracranial pressure and CSF leakage.
- Distribute allowed fluids throughout the day.
- List name, purpose, effects and precautions for any prescribed medication.
- Avoid straining, blowing the nose, sneezing or vigorous coughing until allowed by the doctor.
- Immediately report manifestations of infection, including stiff neck, headache and fever, to the doctor.

Following rhinoplasty or septoplasty, provide the following instructions:

- Apply ice packs to the nose to relieve discomfort and reduce swelling.
- Elevate the head of the bed to decrease local oedema.
- Do not blow the nose for 48 hours after the packing is removed to prevent bleeding.
- Vigorous coughing or straining at stool may cause bleeding and should be avoided.
- Clean teeth and mouth frequently and increase fluid intake to decrease oral dryness due to mouth breathing.
- Bruising around the eyes and nose will last for several days.

THE PERSON WITH LARYNGEAL OBSTRUCTION OR TRAUMA

The larynx is the narrowest portion of the upper airway. As such, it is at risk of obstruction. Laryngeal obstruction is a life-threatening emergency. Blows to the neck or traumatic injuries may damage the larynx, interfering with its patency and function.

Pathophysiology and manifestations

The larynx may be partially or fully obstructed by aspirated food or foreign objects or by laryngospasm or oedema due to inflammation, injury or anaphylaxis. Anything that occludes the larynx can obstruct the airway. The most common cause of obstruction in adults is ingested meat that lodges in the airway. Risk factors for food aspiration include ingesting large boluses of food and chewing them insufficiently, consuming excess alcohol and wearing dentures. A foreign body in the larynx causes pain, laryngospasm, dyspnoea and inspiratory stridor. Aspirated foreign bodies may pass through the larynx into the trachea and lungs, causing pneumonitis.

Laryngospasm occurs due to repeated or traumatic intubation attempts, chemical irritation or hypocalcaemia. An acute type I hypersensitivity response may cause anaphylaxis with release of inflammatory mediators, leading to angioedema of upper airways and severe laryngeal oedema.

The most common manifestations of laryngeal obstruction are coughing, choking, gagging, obvious difficulty breathing with use of accessory muscles and inspiratory stridor. As the airway is obstructed, signs of asphyxia become apparent. Respirations are laboured and noisy with wheezing and stridor. Cyanosis may develop. Respiratory arrest and death may result without prompt treatment.

Trauma to the larynx can occur in motor vehicle crashes or assaults (e.g. blows to the neck or attempted strangulation). The larynx also may be traumatised during endotracheal intubation or tracheotomy. Trauma may fracture thyroid and/or cricoid cartilage, resulting in loss of airway patency. Soft tissue injuries can cause swelling that further impairs the airway. Manifestations of laryngeal trauma may include subcutaneous emphysema or crepitus, voice change, dysphagia and pain with swallowing, inspiratory stridor, haemoptysis and cough.

INTERPROFESSIONAL CARE

The treatment goal is to maintain an open airway. If airway obstruction is partial and the person is able to cough and move air in and out of the lungs, radiological and laryngoscopic examination may be done to locate the foreign body. An endotracheal tube may be inserted to maintain airflow through the larynx in spasm or an oedematous larynx. For anaphylaxis, adrenaline may be administered to reduce laryngeal oedema and relieve obstruction.

A CT scan is used to identify laryngeal fractures; however, emergency treatment may be required prior to diagnosis to ensure airway patency and preserve life. Soft tissue injuries may be managed conservatively with a bedside humidifier, intravenous fluids, antibiotics and corticosteroids to reduce oedema. More severe injuries require endotracheal intubation or immediate tracheostomy. Nursing care related to caring for the person with a tra.cheostomy is presented later in this chapter. See Chapter 36 for more information about endotracheal intubation and nursing care for the intubated person.

Nursing care

CONSIDERATION FOR PRACTICE

The priority of nursing care in laryngeal obstruction or trauma is restoring a patent airway to prevent cerebral anoxia and death. Laryngeal obstruction and trauma are medical emergencies requiring immediate intervention.

Closely monitor people at risk of laryngeal obstruction (e.g. following neck trauma, newly extubated people and people receiving medications with a high risk of anaphylaxis, such as intravenous antibiotics or radiological dyes) for manifestations of obstruction, including dyspnoea, nasal flaring, tachypnoea, anxiety, wheezing and stridor. Suction the airway as needed; small aspirated foreign bodies might possibly be removed by suctioning. If obstruction is complete, initiate a cardiopulmonary arrest procedure until the obstruction is relieved or the emergency response team arrives. Prepare to assist with emergency intubation or tracheotomy as needed. Provide emotional support, reassurance and teaching for the person and family to reduce anxiety.

Community-based care

Health promotion and teaching for home care focus on preventing laryngeal obstruction and early intervention techniques. Everyone should be aware of the risk factors for adult aspiration. Caution people who wear dentures to take small bites, chewing each bite carefully before swallowing. Discuss the relationship between excess alcohol intake and food aspiration. Participate in promoting training of the general public in CPR and the appropriate manoeuvres such as back, chest or abdominal thrusts. The more people who are adequately trained in emergency procedures, the more likely it is that emergency procedures will be initiated in a timely manner. Individuals with a known risk of anaphylaxis, such as people with a previous anaphylactic response and those allergic to bee venom, should wear a MedicAlert® tag and carry a bee-sting kit to allow early intervention to prevent severe laryngeal oedema and spasm.

THE PERSON WITH OBSTRUCTIVE SLEEP APNOEA (OSA)

Obstructive **sleep apnoea**, intermittent absence of airflow through the mouth and nose during sleep, is a serious and potentially life-threatening disorder. It affects at least 2% of middle-aged women and 4% of middle-aged men. Sleep apnoea is a leading cause of excessive daytime sleepiness and may

contribute to other problems such as poor work performance and motor vehicle crashes (Morton, 2012). Recent studies have linked sleep apnoea with an increased risk of hypertension, ischaemic heart disease and exacerbation of heart failure.

Types of sleep apnoea include obstructive and central. In *obstructive sleep apnoea*, the more common type, the respiratory drive remains intact but airflow ceases due to occlusion of the oropharyngeal airway. *Central sleep apnoea* is a rare neurological disorder that involves transient impairment of the neurological drive to respiratory muscles.

Risk factors

In addition to male gender, risk factors for obstructive sleep apnoea include increasing age and obesity (Bullock & Hales, 2012). Large neck circumference is also a known risk factor for obstructive sleep apnoea (Downey, 2014). Use of alcohol and other CNS depressants may contribute to sleep apnoea.

Pathophysiology

During sleep, skeletal muscle tone decreases (except the diaphragm). The most significant decrease occurs during rapid eye movement (REM) sleep. Loss of normal pharyngeal muscle tone permits the pharynx to collapse during inspiration as pressure within the airways becomes negative in relation to atmospheric pressure. The tongue is also pulled against the posterior pharyngeal wall by gravity during sleep, causing further obstruction. Obesity or skeletal or soft tissue changes that decrease inspiratory tone, such as a relatively large tongue in a relatively small oropharynx, contribute to the problem. Airflow obstruction causes the oxygen saturation, PO_2 and pH to fall and the PCO_2 to rise. This progressive asphyxia causes brief arousal from sleep, which restores airway patency and airflow. Sleep can be severely fragmented because these episodes may occur hundreds of times each night.

Manifestations

Narrowed upper airways produce loud snoring during sleep, often years before obstructive sleep apnoea occurs. Excessive daytime sleepiness, headache, irritability and restless sleep also are common manifestations. See the box below.

MANIFESTATIONS Obstructive sleep apnoea

- Loud, cyclical snoring
- Periods of apnoea lasting 15 to 120 seconds during sleep
- Gasping or choking during sleep
- Restlessness, thrashing during sleep
- Daytime fatigue and sleepiness
- Morning headache
- Personality changes, depression
- Intellectual impairment
- Impotence
- Hypertension

Complications

Recurrent episodes of apnoea and arousal during sleep have secondary physiological effects. Sleep fragmentation and loss of slow-wave sleep are thought to contribute to neurological and behavioural problems such as excessive daytime sleepiness, impaired intellect, memory loss and personality changes. Recurrent nocturnal asphyxia and negative intrathoracic pressure due to airway obstruction increase the workload of the heart. People with coronary heart disease may develop myocardial ischaemia and angina. Arrhythmias such as significant bradycardia and dangerous tachyarrhythmias may develop. Left ventricular function may be impaired and heart failure may occur. Systemic blood pressure remains high during sleep and may contribute to the systemic hypertension. Pulmonary hypertension also may develop. Sudden cardiac death is believed to be a potential fatal complication of obstructive sleep apnoea (Morton, 2012).

Obstructive sleep apnoea is a common condition in people who are morbidly obese. When these individuals undergo any surgery, sleep apnoea places them at significant risk of postoperative respiratory complications. Obesity not only interferes with chest movement and ventilation, but also increases metabolic demands and carbon monoxide production. Anaesthetic and analgesics used during surgery and in the postoperative period can lead to hypoxaemia due to muscle relaxation and depression of the respiratory drive. Individuals with OSA also experience an increased risk of pneumonia (Su et al., 2014).

INTERPROFESSIONAL CARE

The goal of care for OSA is to restore airflow and prevent the adverse effects of the disorder. Sustained weight loss may cure obstructive sleep apnoea.

Diagnosis

The diagnosis of OSA is based on *polysomnography*, an overnight sleep study. Several variables are recorded during the study, including:

- electroencephalogram and measurements of ocular activity and muscle tone
- recordings of ventilatory activity and airflow
- continuous arterial oxygen saturation readings
- heart rate.

Transcutaneous arterial PCO_2 readings also may be monitored during the study. Because sleep studies are time consuming and expensive, overnight monitoring of oxygen saturation by pulse oximetry may be used to confirm the diagnosis of sleep apnoea when symptoms indicate a high probability of the disorder. Nursing implications for pulmonary function studies and pulse oximetry are presented in Chapter 33. See Chapter 40 for more information about electroencephalography.

FIGURE 34.6 ■ A person using a nasal mask and CPAP to treat sleep apnoea

Treatments

Mild to moderate obstructive sleep apnoea may be treated by weight reduction, alcohol abstinence, improving nasal patency and avoiding the supine position for sleep. Although weight reduction often cures the disorder, maintaining optimal weight is difficult. Oral appliances designed to keep the mandible and tongue forward also may be prescribed.

Nasal continuous positive airway pressure (CPAP) is the treatment of choice for obstructive sleep apnoea. Positive pressure generated by an air compressor and administered through a tight-fitting nasal mask (see Figure 34.6) splints the pharyngeal airway, preventing collapse and obstruction. With proper training, this device is well tolerated by the person. Nasal airways can become dry and irritated with CPAP, so an in-line humidifier or a room humidifier may be utilised. A newer device, the bilateral BiPAP ventilator, delivers higher pressures during inhalation and lower pressures during expiration, providing less resistance to exhaling.

Surgery

Tonsillectomy and adenoidectomy may relieve upper airway obstruction in some people. Excision of obstructive tissue from the soft palate, uvula and posterior lateral pharyngeal wall may be accomplished by *uvulopalatopharyngoplasty (UPPP)*. Although only about 50% of these surgeries are successful in treating sleep apnoea, UPPP is useful in selected cases. In severe cases, tracheostomy may also be performed to bypass the area of obstruction.

Nursing care

Obstructive sleep apnoea usually is treated in the home. Nursing care focuses on teaching the person and family about equipment use and strategies to decrease contributing factors such as obesity and alcohol intake. The following nursing diagnoses are appropriate for individuals with sleep apnoea:

- *Disturbed sleep pattern* related to repeated apnoeic episodes manifested by continual interruptions to the sleep cycle.
- *Fatigue* related to interrupted sleep patterns manifested by tiredness and lack of attention.
- *Ineffective breathing pattern* related to obstruction of upper airway during sleep manifested by alterations in the normal sleep and breathing cycle.
- *Impaired gas exchange* related to altered lung ventilation during obstructive episodes manifested by changes in blood chemistry when assessed.
- *Risk of injury* related to daytime somnolence and altered judgment manifested by increasing number of accidents due to inattention.
- *Risk of sexual dysfunction* related to impotence resulting from sleep apnoea manifested by inability to achieve or maintain an erection.

Community-based care

Effective sleep apnoea management depends on the person's willingness to participate in care. Provide teaching about the following topics:

- relationship between obesity and sleep apnoea
- plans, resources and referrals as needed for weight loss (e.g. programs such as Weight Watchers to provide additional support)
- relationship of alcohol and sedatives to sleep apnoea; referral to an alcohol treatment program or Alcoholics Anonymous as indicated
- how to use CPAP if ordered
- the importance of using CPAP continuously at night
- measures to reduce airway dryness, including supplemental humidity and an adequate fluid intake to maintain moist mucous membranes.

If a support group for people with sleep apnoea syndrome is available in the local area, refer the person and family to the group.

UPPER RESPIRATORY TUMOURS

Although tumours of the upper respiratory tract are relatively uncommon, they have the potential to impair the upper airways and interfere with breathing and ventilation of the lungs. Of the upper respiratory tract structures, the larynx is affected by abnormal growths most often.

THE PERSON WITH NASAL POLYPS

Nasal polyps are benign grape-like growths of the mucous membrane lining the nose. These benign tumours can interfere with air movement through nasal passages or obstruct sinus

openings, leading to sinusitis. They usually affect people who have chronic allergic rhinitis or asthma.

Pathophysiology and manifestations

Chronic irritation and swelling of the mucous membranes from allergic rhinitis may cause slow polyp formation. Polyps form in areas of dependent mucous membrane, presenting as pale, oedematous masses covered with mucous membrane. They are usually bilateral and have a stem-like base, making them fairly movable. Polyps can continue to enlarge, eventually becoming larger than a grape. Polyps may be asymptomatic, although large polyps may cause nasal obstruction, rhinorrhoea and loss of sense of smell. Manifestations of sinusitis may develop. The voice may have a nasal tone. Asthmatics who have nasal polyps may have an associated aspirin allergy of which they are not aware.

INTERPROFESSIONAL CARE

When polyps occur in conjunction with an acute upper respiratory infection, they may regress spontaneously with resolution of the infection. When symptomatic, polyps may be managed with topical corticosteroid nasal sprays or low-dose oral corticosteroids to shrink the oedematous polyps and manage allergic symptoms. However, polyps continue to enlarge when corticosteroid therapy is discontinued and therefore surgery is sometimes required.

Nursing care

Teaching about home care following polypectomy is the primary nursing responsibility for the person with nasal polyps. Provide postoperative care instructions and discuss measures to reduce the risk of bleeding:

- Apply ice or cold compresses to the nose to decrease swelling, promote comfort and prevent bleeding.
- Avoid blowing the nose for 24 to 48 hours after nasal packing is removed.
- Avoid straining at stool, vigorous coughing and strenuous exercise.

Discuss manifestations of possible bleeding, such as frequent swallowing or visible blood at the back of the throat. Swallowed blood may cause nausea and vomiting. Encourage the person to rest for 2 to 3 days after surgery to reduce the risk of bleeding. Instruct to increase fluid intake and clean mouth frequently to reduce oral dryness associated with mouth breathing while nasal packing is in place.

THE PERSON WITH A LARYNGEAL TUMOUR

Laryngeal tumours may be either benign or malignant. Benign tumours of the larynx include papillomas, nodules and polyps. People who chronically shout, project or vocalise in an abnormally high or low tone, abusing the voice, are at risk of developing benign laryngeal tumours. In adults, vocal cord nodules are often referred to as ‘singer’s nodules’; public speakers may also develop them. Voice abuse also contributes to the development of vocal cord polyps, as do cigarette smoking and chronic irritation from industrial pollutants. Malignant tumours of the larynx, although uncommon, can have devastating effects if diagnosis and treatment are delayed.

FAST FACTS

- Age-standardised mortality rates for laryngeal cancer have decreased to 0.8 deaths per 100 000 people in 2012, from 1.9 in 1981 (Australian Institute of Health and Welfare (AIHW), 2015).
- In 2013, 220 people died from laryngeal cancer in Australia (Australian Bureau of Statistics, 2015).
- A person who has had a surgical removal of the larynx (laryngectomy) is known as a laryngectomee.

Risk factors

Men are affected by laryngeal cancer more than three times as often as women. Cancer of the larynx usually develops between ages 50 and 70. Tobacco use is the main risk factor for laryngeal cancer: the risk of developing laryngeal cancer is significantly greater in smokers (cigarette, pipe or cigar) than in non-smokers. A person who smokes one pack a day is 20 times more at risk of laryngeal cancer than a non-smoker (Cancer Council, 2015). Alcohol consumption is a significant co-factor in increasing the risk. Other risk factors include poor nutrition, human papillomavirus infection, exposure to asbestos and other occupational pollutants. Race is also considered a risk factor, with Aboriginal and Torres Strait Islander Australians and Maori New Zealanders experiencing higher rates of laryngeal cancer (AIHW, 2013; Soeberg et al., 2012).

Pathophysiology and manifestations

Papillomas are small, wart-like growths believed to be viral in origin. Polyps and nodules may develop on the vocal cords of the larynx as a result of voice abuse (see Figure 34.7). Nodules occur as paired lesions on the free edges of the vocal cords. Hoarseness and a breathy voice quality are manifestations of benign vocal cord tumours.

Laryngeal cancer

Squamous cell carcinoma is the most common malignancy of the larynx. Changes in the laryngeal mucosa occur over time as it is subjected to noxious irritants such as cigarette smoke. White, patchy, precancerous lesions known as *leucoplakia* appear. Red, velvety patches, called *erythroplakia*, are thought to represent a later stage of carcinoma development. The initial cancerous lesion, carcinoma in situ (CIS), is superficial. Malignant cells replace the lining layer, but do not invade into deeper

FIGURE 34.7 ■ Laryngoscopy showing a polyp on the left vocal cord

Source: Dr M.A. Ansary/Science Source.

tissues. Untreated, most CIS lesions develop into squamous cell cancer (American Cancer Society, 2015). Laryngeal cancer spreads both by direct invasion of surrounding tissues and by metastasis. It may metastasise to the lungs; however, metastases from other cancers to the larynx are rare.

Laryngeal cancer may develop in any of the three areas of the larynx: the glottis, the supraglottis and the subglottis. Manifestations vary according to the site of the lesion.

Lesions of the true vocal cords or glottis account for nearly 60% of all laryngeal cancers. Fortunately, these cancers tend to be well differentiated and slow growing. Metastasis occurs late in the course of the disease because of a limited lymphatic supply. The usual symptom of glottic cancer is hoarseness or a change in the voice because the tumour prevents complete closure of the vocal cords during speech.

Approximately 35% of laryngeal cancers develop in the supraglottic area, which includes the epiglottis, aryepiglottic folds, arytenoid muscles and cartilage, and false vocal cords (see Figure 34.8). Lymphatic supply to this region of the larynx is rich; tumours often invade locally and metastasise early. Symptoms often do not develop until the tumour is relatively large, delaying diagnosis. Manifestations of supraglottic cancer include painful swallowing, sore throat or a feeling of a lump in the throat. Later manifestations include dyspnoea, foul breath and pain that radiates to the ear.

Subglottic tumours (below the vocal cords) are the least common, accounting for the remaining 5% of laryngeal tumours. They often are asymptomatic until the enlarging tumour obstructs the airway. Common manifestations of laryngeal cancer are listed below.

MANIFESTATIONS Laryngeal cancer

- Hoarseness
- Change in the voice
- Painful swallowing
- Dyspnoea
- Foul breath
- Palpable lump in neck
- Earache

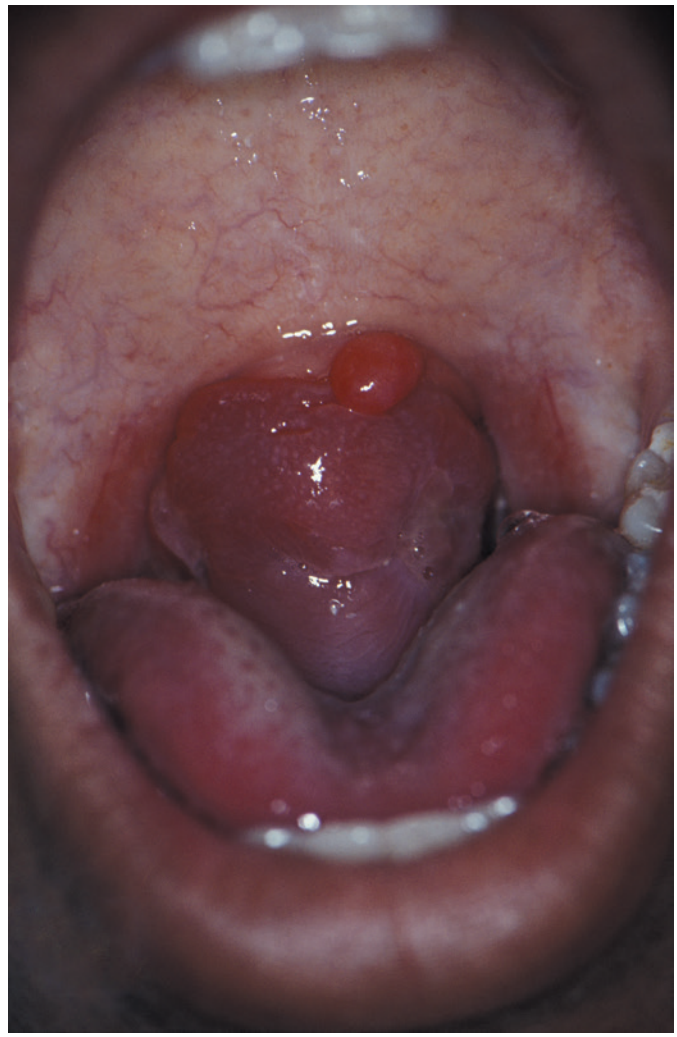


FIGURE 34.8 ■ Cancer of the larynx and epiglottis

Source: Biophoto Associates/Science Source.

INTERPROFESSIONAL CARE

Benign laryngeal tumours may resolve with correction of the underlying problem, such as voice training with a speech therapist or smoking cessation. Treatment of laryngeal malignancy varies with the extent of the cancer. Early diagnosis and treatment are important: 75% of individuals with small, localised cancer are still alive after 5 years. As the stage at diagnosis advances, 5-year survival rates drop to approximately 15% (AIHW, 2015).

Diagnosis

- *Direct* or *indirect laryngoscopy* is used for initial evaluation when laryngeal cancer is suspected. A fibreoptic laryngoscope is used for direct laryngoscopy; mirrors are used to visualise the larynx in indirect laryngoscopy.
- *Biopsy* is obtained from suspicious lesions to examine the cells. Biopsy is usually obtained under general anaesthesia or conscious sedation. Tissue may be obtained via endoscopy or by fine-needle aspiration of the mass.

- *Imaging studies* such as CT scan, MRI and chest x-ray are obtained to evaluate the size of the mass, possible extension into deeper tissues, involvement of lymph nodes and possible metastasis to the lungs. A barium swallow may be done to evaluate the effects of the tumour on swallowing. A positron emission tomography (PET) scan also may be done (possibly in conjunction with CT) to detect tumour metastasis.

Treatments

An inhaled steroid spray may be used for vocal cord polyps. In some cases, surgical excision of benign nodules or polyps is required. This usually is performed via laryngoscopy, using microforceps or a laser. A biopsy of the tumour is done to rule out malignancy.

Laryngeal cancer treatment is determined by *staging* the cancer. Information such as tumour size and location (T), number of involved lymph nodes (N) and presence or absence of metastases (M) is combined to assign a stage, designated by Roman numerals I to IV. The staging also takes into consideration whether the laryngeal cancer is supra-, peri- or subglottic.

RADIATION THERAPY Radiation therapy is often the treatment of choice for early laryngeal cancer. Radiation disrupts the DNA of the cell, causing it to die. External radiation commonly is used; brachytherapy, implants of iridium seeds placed into hollow plastic needles that are inserted directly into or near the tumour site during surgery to deliver radiation, is less frequently used for laryngeal or hypopharyngeal cancer. Radiation therapy is extremely effective for treating glottic cancer, with cure rates equal to those achieved by surgery. Radiation therapy preserves the voice, although the tone or timbre of the voice may be affected.

Radiation therapy may be used in combination with chemotherapy (*chemoradiotherapy*) to treat more advanced laryngeal cancers. In some institutions, and depending on the stage of cancer, chemoradiotherapy may be used in place of laryngectomy (Sheahan, 2014).

Radiation therapy also may be used in conjunction with surgery to destroy any remaining cancerous cells or as a palliative treatment for advanced tumours. See Chapter 13 for more information about radiation therapy and its nursing implications.

CHEMOTHERAPY Chemotherapy is used in combination with radiation therapy as the primary treatment for some laryngeal cancers. It also is used to treat distant metastasis and for palliation when the tumour is unresectable. See Chapter 13 for the nursing implications for chemotherapy.

Surgery

The type of surgery used to treat laryngeal cancer is based on site, size and invasiveness of the tumour into the larynx and surrounding tissues. The goals of surgery are to remove the malignancy, maintain airway patency and achieve optimal cosmetic appearance.

Carcinoma in situ, vocal cord polyps and early vocal cord cancers may be removed by laser during a laryngoscopy procedure. The cure rate for early tumours using this method is excellent. This surgery may be performed on an outpatient basis. The degree of trauma to the vocal cords varies, depending on the size of the lesion. The voice is preserved, but total voice rest with whispering only may be ordered for a week or more following surgery. In some cases, a temporary tracheostomy may be done at the time of surgery to ensure that swelling does not interfere with airway patency. Once the tracheostomy tube is removed and the opening is closed, the person can eat, speak and breathe normally.

Laryngectomy, removal of the larynx, may be necessary. A partial laryngectomy (hemilaryngectomy, vertical partial laryngectomy) may be used for tumours localised to a portion of the larynx with limited extension beyond the larynx. In a partial laryngectomy, 50% or more of the larynx is removed. The voice generally is well preserved, although it may be changed by the surgery. A tracheostomy tube may be inserted for early postoperative airway management. It is usually removed in 5 to 7 days as postoperative swelling subsides and the stoma is allowed to close. Normal speaking, breathing and swallowing are restored. If the epiglottis has been removed, careful monitoring for aspiration is necessary. Enteral tube feedings or parenteral nutrition may be required for several weeks after surgery. Swallowing techniques to prevent aspiration are taught.

A *total laryngectomy* is required for cancers that extend beyond the vocal cords. The entire larynx is removed, along with the epiglottis, thyroid cartilage, several tracheal rings and the hyoid bone. Because the trachea and the oesophagus are permanently separated by this surgery (see Figure 34.9), there

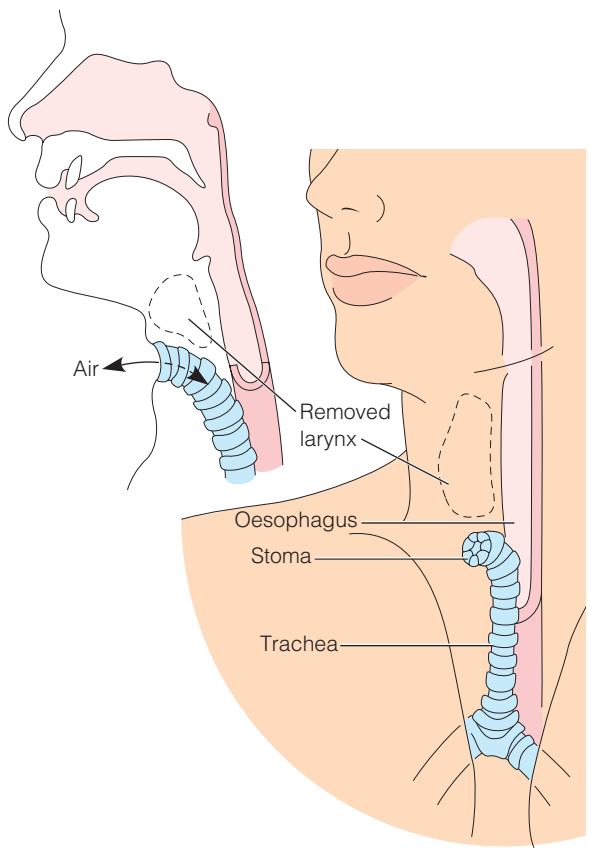

FIGURE 34.9 ■ Following a total laryngectomy, the person has a permanent tracheostomy. No connection between the trachea and oesophagus remains

is no risk of aspiration during swallowing. Normal speech is lost and a permanent tracheostomy is created. The tracheostomy tube inserted during surgery may be left in place for several weeks and then removed, leaving a natural stoma, or it may be left in place permanently. See below for nursing care of the person undergoing a total laryngectomy. Procedure 34.1 below outlines tracheostomy care.

If cervical lymph nodes are involved but there is no evidence of distal metastasis, *radical* or *modified neck dissection* may be performed along with total laryngectomy. In a radical neck dissection, all soft tissue from the lower edge of the mandible down to the clavicle is removed, including cervical lymph nodes, the sternocleidomastoid muscle, internal jugular vein, cranial nerve XI (spinal accessory) and submaxillary

NURSING CARE OF THE PERSON having a total laryngectomy

PREOPERATIVE CARE

- Provide routine preoperative care and teaching as explained in Chapter 3.
- Assess knowledge and understanding of the diagnosis and proposed surgery. Clarify information and reinforce previous teaching as needed. *A clear understanding by the person and family of the purpose, anticipated benefits and consequences of total laryngectomy prior to surgery is vital to promote postoperative recovery.*
- Assess anxiety levels of the person and family related to the diagnosis and proposed surgery. *High levels of anxiety interfere with learning and the ability to cooperate in care. Interventions to reduce anxiety may be required prior to teaching and providing preoperative instructions.*
- Without increasing fear, emphasise that total laryngectomy results in a loss of speech and that the person will breathe through a permanent stoma in the neck. *Although person and family members may verbalise an understanding of the loss of speech following surgery, they may believe that verbal communication will still be possible through the stoma.*
- Establish a means of communicating postoperatively, using an alphabet board, eye or hand signals, or other strategies. *Learning techniques for communicating preoperatively decreases the person's and family's postoperative anxiety. Long-term speech rehabilitation measures, such as the tracheoesophageal puncture, are not appropriate for use in the immediate postoperative period.*
- Point out that surgery will affect the senses of taste and smell, and hence eating, in the initial postoperative period. Reassure that nutritional and fluid needs will be met with intravenous or enteral feedings until eating can be resumed. *The person may not be prepared for the effect of surgery on taste and smell and, therefore, the enjoyment of food.*
- If possible and desired by the person and family, arrange a visit by a person post laryngectomy who effectively uses an alternative form of verbal communication. *The person and family may feel more comfortable expressing their fears and asking questions of someone who has gone through the same experience they are facing.*

POSTOPERATIVE CARE

- Provide routine postoperative nursing care and monitoring as explained in Chapter 3.
- Frequently monitor airway patency and respiratory status, including respiratory rate and pattern, lung sounds and oxygen saturation. *Excessive or retained respiratory secretions can impair gas exchange, increase the work of breathing and lead to complications such as pneumonia.*
- Encourage deep breathing and coughing. *Deep breathing helps ensure adequate ventilation of lower airways; coughing helps to move secretions out of airways.*
- Elevate the head of the bed. *The upright position promotes effective ventilation of the lungs and reduces oedema and swelling of the neck.*
- Maintain humidification of inspired gases. *With a tracheostomy, humidification of inspired air in the upper airways is lost. Humidified air helps maintain moist mucous membranes and secretions, promoting secretion removal by coughing or suctioning.*
- Maintain an adequate fluid intake (intravenously, enterally and orally when allowed). *Adequate hydration keeps secretions liquid and mucous membranes moist.*
- Suction via tracheostomy using sterile technique as needed. *Surgery, impaired nutrition and the effects of radiation therapy may cause fatigue and a weak cough effort. Suctioning may be necessary to clear secretions and maintain airway patency.*
- Provide tracheostomy care as needed (see Procedure 34.1). *Periodic cleaning of the tracheostomy tube is necessary to remove accumulated secretions and maintain airway patency.*
- Teach to protect the stoma from particulate matter in the air with gauze square or other stoma protector. *Permanent tracheostomy results in loss of the protective mechanisms of the upper airway that prevent foreign material from entering the lungs.*
- Instruct to support the head when moving in bed. *Additional head support reduces the strain on tissues in the operative area.*
- Place the call bell within easy reach at all times; answer the call bell promptly. *The person who is unable to speak needs reassurance that help is within reach at all times.*
- Encourage family members to remain present when possible. *Supportive family presence helps reassure the person that they will not be left alone or helpless.*
- Spend as much time as possible with the person. When leaving the room, specify the time when you will return. *These measures help establish trust and relieve anxiety.*

PROCEDURE 34.1 Providing tracheostomy care

GATHER SUPPLIES

- Dressing pack
- Sterile suction catheter and glove kit
- Sterile disposable replacement inner cannula, if appropriate
- Cleaning solutions (e.g. sterile normal saline)
- Sterile 4 × 4 gauze dressings (not cotton filled) or precut dressing
- Sterile cotton-tipped applicators
- Single-use tracheostomy tube holder or cotton twill ties
- Scissors
- Clean exam gloves

BEFORE THE PROCEDURE

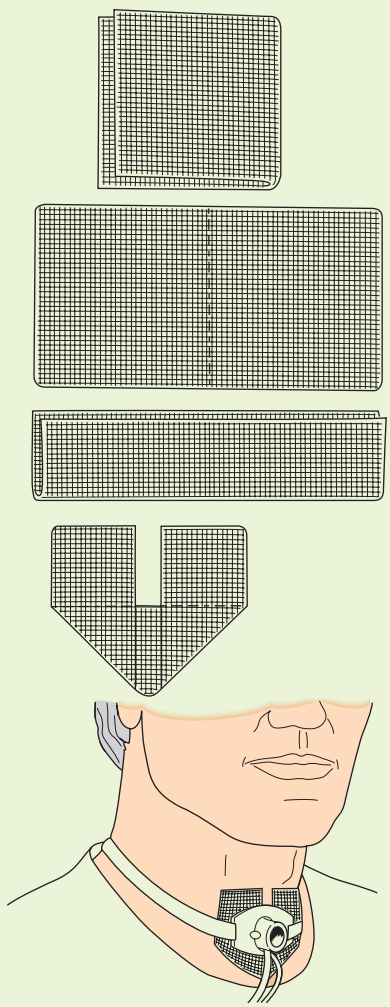
Provide for privacy. Explain the procedure. Provide for a means of communication (e.g. eye blinking or raising a finger to indicate distress). If the person's condition permits, provide a pencil and paper for questions. Place in semi-Fowler's or Fowler's position to facilitate lung ventilation. Assess lung sounds; suction the tracheostomy using sterile technique as needed.

DURING THE PROCEDURE

- Use standard precautions.
- Wearing a clean disposable glove, remove the tracheostomy dressing. Dispose of the glove and dressing.
- Open sterile supplies and add additional materials (dressing, cleaning solution etc). Don gloves.
- Clean area using aseptic technique.
- If the tracheostomy tube has an inner cannula that can be removed for disposal or cleaning, remove the tube and set it aside for disposal or clean with solution. Cleanse the flange of the outer cannula.
- Clean reusable inner cannulas using a small brush, pipe cleaners or cotton-tipped applicators.
- Rinse the inner cannula thoroughly in normal saline. Tap it gently against the inner aspect of the sterile bowl to remove excess liquid.
- Suction the outer cannula using sterile technique.
- Replace the inner cannula into the tracheostomy tube.
- Replace the dressing, using either a commercially prepared tracheostomy dressing or an opened gauze 4 × 4 refolded into a V shape (see the accompanying figure). Do not cut the dressing or use a cotton-filled dressing to prevent aspiration of foreign material into the respiratory tract.
- Apply a clean tracheostomy holder or clean ties.
- Once the clean ties are secured, remove the old ties.

AFTER THE PROCEDURE

Assess breathing and tolerance of the procedure. Dispose of supplies and used solutions. Wash hands. Chart the procedure and any observations made during the procedure such as amount, colour and consistency of sputum and appearance of the incision.



Steps for folding a gauze 4 × 4 into a tracheostomy dressing

salivary gland. Extensive tissue dissection can result in significant deformity. Skin grafts or flaps may be used to close the wound. Bellovac drains are placed in the wound to prevent haematoma and extensive oedema formation. After surgery, the person may have difficulty lifting and turning the head because of muscle loss. Resection of the spinal accessory nerve causes shoulder drop on the affected side. In a modified neck dissection, neck contents are removed, with the exception of the sternocleidomastoid muscle, internal jugular vein and spinal accessory nerve.

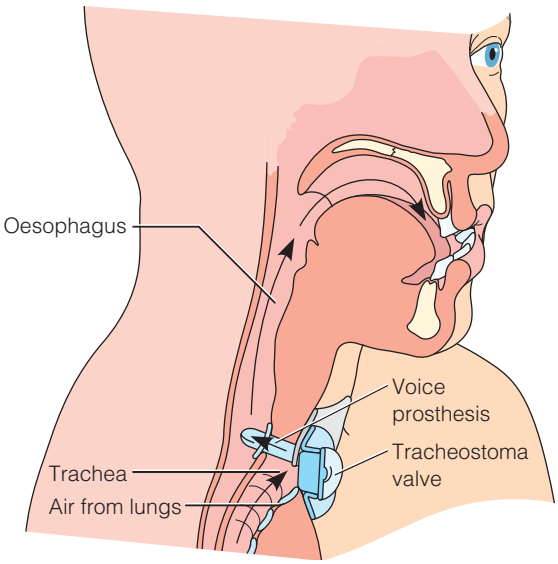


FIGURE 34.10 ■ The tracheoesophageal prosthesis allows diversion of air from the trachea through a one-way valve into the oesophagus and oropharynx, producing speech when the tracheostomy stoma is occluded. The one-way valve prevents food from entering the trachea

A gastrostomy also may be performed to maintain nutrition in the person with laryngeal or hypopharyngeal cancer. See Chapter 22 for more information about caring for the person with a gastrostomy tube.

Speech rehabilitation

Various techniques may be used to restore speech after total laryngectomy. *Tracheoesophageal puncture (TEP)* is the usual method used to restore speech. A small fistula is created between the posterior tracheal wall and the anterior oesophagus. A small, one-way shunt valve is fitted into the fistula (see Figure 34.10). Occluding the tracheostomy stoma with a finger forces exhaled air through the valve into the oesophagus and hypopharynx, creating vibration and sound. The muscles of speech are used to form words. The one-way valve prevents aspiration from the oesophagus into the trachea. An external tracheostoma valve may be used to avoid using the hand to occlude the stoma. This device covers the entire tracheal stoma and closes during exhalation, forcing air directly into the voice prosthesis. Not all post-laryngectomy people are candidates for this device because its use requires motivation and manual dexterity.

Oesophageal speech uses swallowed air to create sound and form words as it is expelled in a controlled belch. The pharyngoesophageal segment vibrates with the belch, creating sound. Muscles of the mouth and tongue are used to control the sound and to form words. This form of speech takes practice and fluent speech may not be restored.

Several speech generators (electrolarynx) are available. One type is held to the neck and creates vibrations that are transmitted to the neck and into the mouth (see Figure 34.11A). The transmitted vibrations are formed into words using the normal muscles of speech. Another device delivers a tone into the mouth via a plastic tube inserted into the corner of the mouth (see Figure 34.11B). The lips, tongue and mouth muscles are used to form the sound into words.

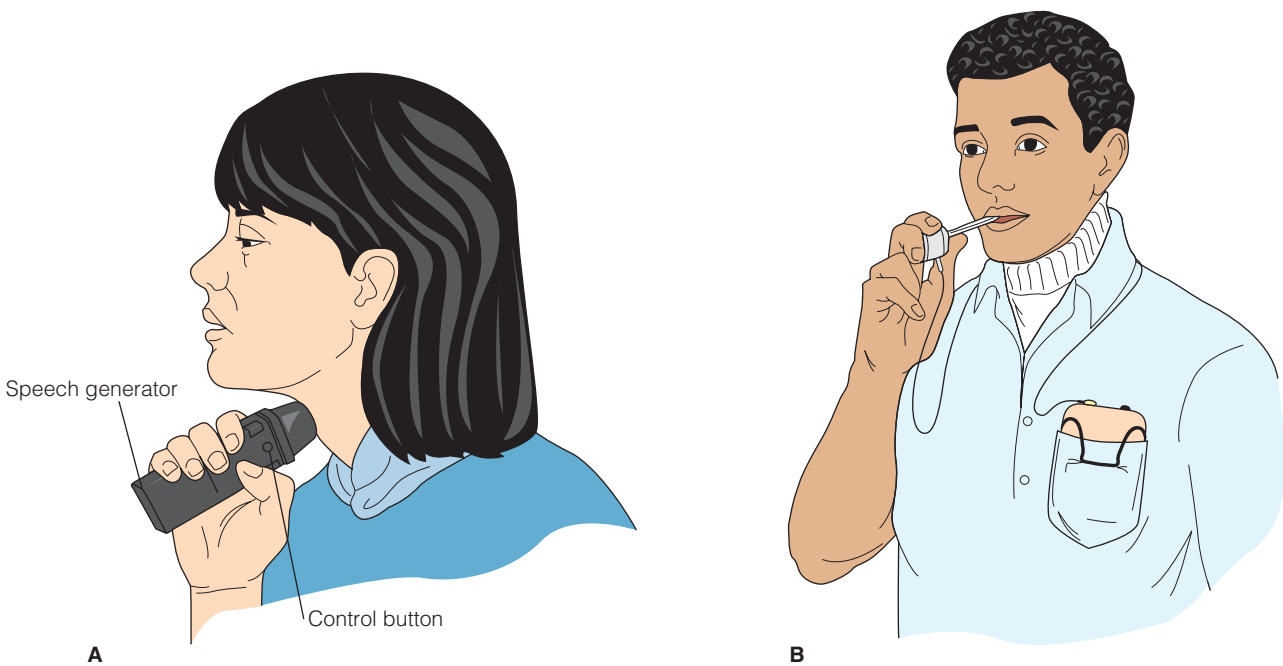

FIGURE 34.11 ■ Speech generators. *A*, The person holds the vibrating tip of the speech generator against the throat, using the mouth to form words. *B*, A plastic handpiece of the generator is held in the corner of the mouth. The audible tone produced by the generator is formed into words

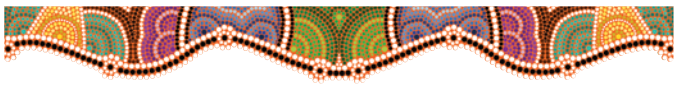


Nursing care

Nurses can be instrumental in early identification and treatment of laryngeal disorders by emphasising the need for the person with new chronic hoarseness to seek treatment.

Health promotion

Health promotion activities to prevent laryngeal cancer focus on preventing smoking by children, adolescents and young adults, and promoting smoking cessation in people who do smoke. Activities to promote abstinence or moderate alcohol use also are beneficial in reducing a significant risk factor for laryngeal cancer.

Assessment

Nurses can be instrumental in identifying early signs of laryngeal cancer, facilitating early diagnosis and treatment.

- *Health history:* current symptoms, including voice change, difficulty swallowing, throat pain; risk factors such as voice abuse, family history of cancer, occupational exposures; smoking history, use of alcohol and amount consumed.
- *Physical examination:* voice character; general appearance and apparent state of health; swallowing ability; visible or palpable mass in neck.

Nursing diagnoses and interventions

Nursing care for the person with a benign tumour of the larynx focuses on maintaining a patent airway and teaching about the disorder and strategies to prevent its recurrence. The person with laryngeal cancer has multiple nursing care needs. The risk of impaired verbal communication is significant. Dysphagia may interfere with swallowing and nutrition. Nutrition also may be impaired by radiation, chemotherapy and surgery. The diagnosis of cancer is frightening for most people, no matter what the potential for cure is with treatment. See the nursing care plan that follows for additional nursing diagnoses and interventions.

CONSIDERATION FOR PRACTICE

During the immediate postoperative period, closely monitor for signs of airway obstruction, such as laboured breathing or inspiratory stridor. The larynx is the narrowest portion of the upper airways. Tissue oedema following surgery can further restrict the airway, interfering with lung ventilation and gas exchange.

Risk of impaired airway clearance

Following resection of a benign or malignant vocal cord nodule, local tissue oedema may interfere with airway patency.

- Apply cold packs to the neck as ordered or indicated. *Cold application constricts local blood vessels and reduces oedema development.*
- Withhold food and fluids until the cough and gag reflexes have returned. *Local anaesthesia used during removal of benign tumours and nodules impairs the cough and gag reflexes, increasing the risk of aspiration.*

Impaired verbal communication

Treatment of laryngeal cancer often alters the quality of the voice, results in short-term restriction of speaking or, in the case of total laryngectomy, causes loss of the voice. The person ultimately determines treatment choices for laryngeal cancer; some choose to forgo laryngectomy to avoid voice loss when the chance for long-term success and cancer cure is minimal.

- Prior to surgery, assess for additional obstacles to communication. *Communication may be impaired by hearing loss, illiteracy or weakness associated with the disease process, altering the ability to use alternative communication strategies.*
- Assess the importance of verbal communication to self-concept, occupation and lifestyle. *Many factors influence adaptation to the loss of normal verbal communication. If the ability to speak is central to an occupation (e.g. school teacher, singer) or self-concept (e.g. politician or barrister), adapting to a total laryngectomy may be difficult. For these people, laryngectomy may mean a loss of employment or career.*

CONSIDERATION FOR PRACTICE

Prior to surgery, introduce non-verbal communication strategies such as pencil and paper or an alphabet board. Encourage the person to practise using each method and to choose the most acceptable one. Having the person determine a means of communication prior to surgery helps to alleviate anxiety and increases the sense of control.

- Arrange consultation with a speech therapist about alternative forms of oral communication prior to surgery if possible. *Determining a means of communicating on a continuing basis prior to surgery helps to relieve fear of inability to communicate and may guide the choice of a surgical procedure.*

CONSIDERATION FOR PRACTICE

After surgery, assess frequently. Place the call bell at hand. The presence of a caring nurse helps to decrease anxiety and promotes communication. Knowing that help is readily available enhances feelings of security and decreases anxiety.

- Reinforce teaching about alternative communication strategies. *Anxiety or information overload may impair the ability to retain information; reinforcement facilitates learning.*

- Maintain a positive attitude about postoperative communication, but do not promote unrealistic expectations. *Not everyone is able to use all alternative methods of verbal communication after the laryngectomy. Some people remain non-verbal.*
- If desired, arrange a visit by a rehabilitated laryngectomy person who has mastered an alternative form of verbal communication and has a positive attitude about rehabilitation. *Many people and their families find that they are better able to communicate their fears with someone who has gone through the same experience they are facing.*

Impaired swallowing

Disruption of laryngeal structures by the tumour itself or due to radiation or surgery can impair the swallowing mechanism. Additionally, even when a total laryngectomy has been performed and a connection between the oropharynx and trachea no longer exists, swallowing may cause fear of choking.

- Maintain intravenous fluids and enteral feedings or parenteral nutrition until adequate food and fluids can be ingested orally. *It is important to maintain nutritional and fluid balance until normal eating can be resumed.*

NURSING CARE PLAN A person with total laryngectomy

David Tom is a 61-year-old accountant who is divorced and has two adult children. He has smoked two packets of cigarettes daily since high school and usually has three or four rum and cokes each evening. After several months of persistent sore throat and hoarseness, Mr Tom was diagnosed with cancer of the larynx. He has been admitted to the surgical care unit from the critical care unit 2 days post total laryngectomy.

ASSESSMENT

Mr Tom's vital signs are stable: BP 146/84, P 92 and regular, R 18, T 36.7°C axillary. A tracheostomy tube is sutured in place and he is receiving humidified oxygen at 28% per tracheostomy collar. Pulse oximetry is 94%. He is receiving continuous tube feeding per nasogastric feeding tube. Two Bellovac wound drains are present in the right neck area. A moderate amount of oedema is noted in the right facial and submandibular area. Mr Tom is ambulatory within the room.

DIAGNOSES

- *Risk of airway compromise* related to postoperative oedema manifested by difficulty in clearing secretions.
- *Risk of ineffective breathing* related to pain and anxiety manifested by decreased oxygen intake and symptoms of increased pain and anxiety.
- *Disturbed body image* related to total laryngectomy and presence of tracheostomy stoma manifested by the person self-reporting body image issues or reluctance to engage in the community.
- *Impaired verbal communication* related to total laryngectomy manifested by difficulty communicating verbally when required.
- *Pain* related to surgical procedure manifested by increased respiratory rate and pulse and the person self-reporting discomfort.
- *Nutritional imbalance* related to insufficient oral intake manifested by lack of appetite and pain when eating and difficulty swallowing fluids.

PLANNING

- Assess respiratory status, including rate, pattern, lung sounds and cough effectiveness, at least every 4 hours.
- Monitor quantity, colour and odour of secretions.
- Assess vital signs and pain at least every 4 hours. Administer analgesics as ordered.

Expected outcomes

- Maintain clear airways and lung sounds.
- Maintain oxygen saturation level greater than 92%.
- Demonstrate interest in providing incision and stoma care.
- Accept information about potential communication strategies.
- Communicate effective pain management.
- Maintain appropriate body weight, intake and output.

IMPLEMENTATION

- Schedule time to sit with Mr Tom and discuss his concerns and feelings intermittently throughout your shift.
- Provide written information as requested.
- Monitor intake, output and daily weight.
- Arrange dietary consultation to determine kilojoule requirements.

EVALUATION

Mr Tom reports in writing that his pain is adequately controlled. His respiratory status is stable with clear breath sounds throughout and an oxygen saturation of 94%. He is afebrile. Mr Tom is tolerating tube feedings well and expresses a desire to begin eating. The dietitian has visited and assisted in planning to begin oral feedings. Intake and output are stable, as is his weight. Mr Tom has been receptive to receiving information about follow-up care and exploration of various modalities of speech.

CRITICAL THINKING IN THE NURSING PROCESS

1. Compare and contrast advantages and disadvantages of various methods to allow speech following total laryngectomy.
2. Develop a plan of care for Mr Tom for the nursing diagnosis of *Disturbed body image*.
3. Discuss nursing interventions to provide wound care for the person with laryngectomy and radical neck dissection.
4. List strategies to optimise ventilation.

REFLECTION ON THE NURSING PROCESS

1. Discuss the various strategies that can be utilised when communicating with Mr Tom and evaluate which patient education strategies may be most useful in this situation.
2. Outline what you have learned from the case study that you will implement in your future practice.

- Postoperatively, initiate oral intake with soft foods, not liquids. *Soft foods are easier to handle and swallow initially. As recovery progresses, thickened liquids can be swallowed and, eventually, a normal diet can be resumed.*
- Following total laryngectomy, reassure that choking is not possible because there is no connection between the oesophagus and trachea. *People often fear that swallowing will result in choking and they will be unable to cough effectively.*
- Instruct to initiate a swallow by placing a small amount of food on the back of the tongue, flex the head forward and then think 'swallow'. *Swallowing is no longer an automatic function and needs to be relearned.*

CONSIDERATION FOR PRACTICE

Provide for privacy during initial attempts at eating. Eating in the presence of others may cause embarrassment until confidence in eating is regained. Privacy also reduces distractions, allowing concentration on swallowing.

Nutritional imbalance related to insufficient oral intake

Large laryngeal tumours often place pressure on the oesophagus and may cause dysphagia (difficulty swallowing) or odynophagia (painful swallowing). In either case, difficulty eating may ultimately impair nutrition. Additionally, cancer often produces a hypermetabolic state, increasing kilojoule requirements. If surgery is performed, difficulty swallowing and a fear of aspiration in the early postoperative period also interfere with eating. Enteral or parenteral feedings are usually needed initially to meet nutritional status. After a total laryngectomy, the senses of taste and smell are disrupted. Although the sense of taste may be partially recovered, people may complain that eating no longer is pleasurable.

- Assess nutritional status using height and weight charts, reported weight loss and anthropometric measurements such as skin folds. *Thorough assessment of nutritional status is important in planning to meet current and anticipated kilojoule needs.*

CONSIDERATION FOR PRACTICE

Monitor food and fluid intake and urinary output. Pain or fatigue, rather than a sensation of fullness, may prompt the decision to stop eating, resulting in inadequate intake.

- Evaluate current and preferred eating habits and foods, as well as understanding of nutrition. *This evaluation provides additional information about nutrition as well as a basis for future planning.*
- Refer to a dietitian for further evaluation, planning and education. *A professional can identify nutritional needs and help plan a diet that will meet them.*
- Encourage experimentation with foods of different textures and temperatures. *Very cold foods, or foods of a soft texture, may be easier to swallow.*

CONSIDERATION FOR PRACTICE

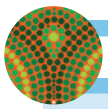
Weigh daily. Daily weight is an accurate measure of both fluid balance and nutritional status.

- Encourage frequent, small meals rather than three large meals per day. *Frequent, small quantities of food improve overall intake when dysphagia, odynophagia or fatigue interfere with nutrition.*
- Recommend liquid supplements, such as Ensure, when kilojoule needs are not being met. Provide information about where to obtain nutritional supplements. *Liquid dietary supplements provide balanced nutrition as well as additional kilojoules and are an effective way of increasing intake. They are available without prescription in major supermarkets.*
- Provide mouth care before meals and supplemental feedings. Provide a topical anaesthetic such as viscous lignocaine before eating for stomatitis or oesophagitis related to radiation or chemotherapy. *The tumour or its treatment may cause bad breath or a foul taste in the mouth, which suppresses appetite. Inflamed mucosa may make eating uncomfortable. A topical anaesthetic may relieve this discomfort and thus promote food intake.*
- Provide an anti-emetic 30 minutes before eating as needed to relieve nausea. *Nausea interferes with food intake. An anti-emetic can relieve nausea and make eating possible.*
- Suggest enteral (tube) feedings via nasogastric or gastrostomy tube if the person is unable to consume enough food to maintain weight and nutritional status. *Both cancer and surgery increase kilojoule needs. Supplemental enteral feedings may be necessary to prevent catabolism and to promote healing and recovery.*

CONSIDERATION FOR PRACTICE

Following laryngectomy, place in semi-Fowler's or Fowler's position. Elevating the head of the bed facilitates swallowing of oral secretions and helps prevent regurgitation of tube feedings.

- Instruct to perform mouth rinses before initiating feeding postoperatively. *Rinsing helps clean the mouth and also provides practice in using tongue and cheek muscles to control fluid in the mouth.*
- Refer to a physical or speech therapist for swallowing rehabilitation following laryngectomy. *Because surgery changes the relationship of the trachea, oesophagus and oropharynx, swallowing needs to be relearned before eating.*
- Reinforce swallowing instructions. *Reinforcement promotes learning.*



TRANSLATION TO PRACTICE Evidence-based practice: quality of life after total laryngectomy

A study by Perry, Casey & Cotton (2015) assessing psychosocial and functional issues following a laryngectomy surveyed 86 people from New South Wales and Victoria, measuring various functional and quality-of-life indicators.

The results demonstrated significant declines in quality of life and social relationship indicators. The individuals also had higher levels of depression and anxiety than normative samples. A strong relationship was demonstrated between the psychological wellbeing scores and important functional measures of speech and swallowing.

IMPLICATIONS FOR NURSING

Psychosocial health is an important part of rehabilitation following a laryngectomy. Follow up with experienced mental health practitioners and methods to support psychosocial health should be pivotal following surgery. Nurses and other healthcare professionals such as speech pathologists need to work together to maximise speech and swallowing function to not only assist individuals with critical safety issues, but also to support and maximise a person's psychosocial wellbeing following laryngectomy and well beyond discharge.

CRITICAL THINKING IN PERSON-CENTRED CARE

1. In this study, there was a strong relationship between swallowing and speech function and the person's psychological wellbeing. As the nurse caring for a person who has had a laryngectomy, what can you do prior to discharge to assist with swallowing and speech function?
2. There were no data comparing male and female outcomes as the number of females in the cohort was too small. Would you expect there to be any difference in quality of life or psychological wellbeing scores between men and women laryngectomees? Explain.
3. How will the findings of this study impact on the care that you give to the person having a laryngectomy or partial laryngectomy?

Anticipatory grieving

The person with laryngeal cancer faces not only the diagnosis of cancer, which is often perceived as a death sentence, but also the prospect of mutilating surgery. If laryngectomy is necessary, the person grieves the loss of both a body part and an important function, speech, which is a vital aspect of social interaction and often necessary for their career. It also enables people to express their needs when they cannot meet them alone. The loss of speech, therefore, is a major loss. In addition, the tracheal stoma changes the manner in which the person breathes. If radical neck dissection is required, loss of neck musculature and function also alters body image and self-concept.

- Provide opportunities for expressing feelings of grief, anger or fear about the diagnosis of cancer, the impending surgery and the anticipated loss of speech. *The person with laryngeal cancer needs the opportunity (and may need permission) to grieve anticipated losses. A cancer diagnosis may precipitate grieving for unfulfilled plans and expectations, even though a cure may be anticipated. Laryngectomy causes a major change in body image, with loss of a vital body part and creation of a stoma. The person also grieves the loss of speech. This loss can have a significant impact on occupation and social interaction.*
- Help the person and family discuss the potential impact of the loss on family structure and function. *Discussion helps family members understand each other's feelings and support one another.*
- Refer for psychological or spiritual counselling as appropriate. *Counselling and spiritual guidance can help the person and family deal with the diagnosis and proposed treatment and help prevent a sense of defeat and hopelessness.*
- Help identify additional resources, such as coping strategies that have been successfully used in the past to deal with crises. *This exercise helps the person and family identify strengths they can use to deal with the present situation.*

CONSIDERATION FOR PRACTICE

Provide a calm, supportive environment with adequate privacy and emotional support for the person and family members as they work through the grieving process. It is important for the person and family to know that their feelings of loss are real and accepted by caregivers.

Community-based care

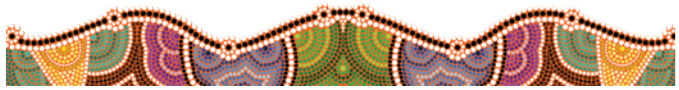
Teaching for the person with a benign laryngeal tumour emphasises management of contributing factors. Stress the importance of not yelling or screaming. Refer people, particularly singers, to a speech therapist for voice training. Emphasise the need to keep the voice within its normal range to reduce vocal cord stress. Encourage smoking cessation, particularly if the person is also a singer. Discuss the relationship of industrial pollutants to laryngeal tumours and help explore ways of reducing pollutant exposure.

Teaching the person and family about laryngeal cancer, treatment options and home care related to those treatments is an important nursing responsibility. Include the following topics when teaching:

- Clarification of treatment options, including risks and benefits.
- Importance of early intervention to reduce the risk of local spread and metastases.
- If a total laryngectomy is proposed, options for communication after surgery, including the pros and cons of each:
  a. The tracheoesophageal puncture device requires some manual dexterity to manipulate.
  b. Only about 30% of people are able to master oesophageal speech.
  c. A trial of the speech generator prior to surgery may reduce frustration in learning to use it postoperatively.
- Care related to radiation therapy, including skin and mouth care, management of secretions (see Chapter 13 for more information about radiation therapy and its effects).
- Strategies and resources for smoking cessation and alcohol abstinence.

- Ways to achieve and maintain optimal nutrition.
- Tracheostomy stoma care and preventing respiratory infection. Provide opportunities to practise and redemonstrate techniques. Clean technique (rather than sterile) is used; the tracheostomy tube may not be needed once the stoma is fully healed. Discuss these additional measures:
  a. Using a humidifier or vaporiser to add humidity to inspired air.
  b. Increasing fluid intake to maintain mucosal moisture and loosen secretions.
  c. Shielding the stoma with a stoma guard, such as a gauze square on a tie around the neck, to prevent particulate matter from entering the lower respiratory tract.
  d. Promptly removing secretions from skin surrounding the stoma to prevent irritation and skin breakdown.
  e. Water sports are contraindicated with a permanent tracheostomy; there is no restriction on other activities, although lifting may be more difficult because of inability to hold the breath (the Valsalva manoeuvre).
  f. Showering and bathing (without submerging the neck or head) are allowed; protect the stoma with a cupped hand or washcloth.
- Manifestations of potential complications of laryngectomy to be reported to the doctor, including loss of hearing or facial expression due to auditory or facial nerve injury or shoulder drop due to damage to the spinal accessory nerve.

The person and family need emotional and motivational support through this trying time. Refer to local support groups. If the person and family are having difficulty adjusting to the diagnosis of cancer and the effects of treatment, provide referral to counselling.



CHAPTER HIGHLIGHTS

- Upper respiratory infections (the common cold) are caused by a multitude of different viruses. Most are mild, self-limiting infections, appropriate for self-care; some viruses, however, such as RSV, can cause serious lower respiratory illness in the very young or very old.
- Three different strains of influenza virus are identified; type A causes most outbreaks of influenza. Because this disease increases the risk of pneumonia in older adults, people with chronic diseases and people who are immunocompromised, annual immunisation is important for these populations and their caregivers.
- Influenza is differentiated from URTI primarily by the presence of systemic manifestations, the duration and degree of fever, and the presence of persistent cough.
- Pharyngitis (sore throat) may be either viral or bacterial in origin; manifestations are similar. People with persistent or severe symptoms that include fever, enlarged lymph nodes and myalgias should be evaluated to rule out streptococcal pharyngitis, which can have significant complications such as rheumatic fever or post-streptococcal glomerulonephritis.
- The incidence of pertussis, a highly contagious reportable disease, is increasing due to waning immunity and improved identification of the infection in adults. In adults, it is often recognised by prolonged and persistent coughing spells. Pertussis is treated in community settings with antibiotic therapy.
- Epistaxis (nosebleed) and nasal fracture are relatively common and pose a risk only when airway clearance is impaired. Emergency care for epistaxis includes pinching the nares or bridge of the nose, sitting upright and leaning forward and applying ice to the nose. When nasal packing is required to control bleeding, close monitoring of respiratory status (respiratory rate and effort, oxygen saturation) is critical.
- Persistent voice hoarseness is the primary manifestation of laryngeal cancer. When identified and treated early, the rate of cure for laryngeal cancer is high. Some laryngeal tumours, however, have few manifestations until advanced. They may be treated by radiation therapy, chemotherapy or surgery (laryngectomy and neck dissection).
- Following total laryngectomy, a permanent tracheostomy is created and the upper trachea and oesophagus are separated, preventing aspiration when feedings are resumed. A tracheoesophageal puncture may be created to allow verbal communication following total laryngectomy.

CONCEPT CHECK

1 A person with hypertension asks the nurse what he can do to relieve the symptoms of an acute URTI. The nurse recommends that he:
1 ask his doctor for an antibiotic prescription
2 use an over-the-counter decongestant such as pseudoephedrine to relieve symptoms
3 take 1000 mg of vitamin C and zinc tablets on a regular basis
4 use an over-the-counter nasal spray for no more than 3 days to relieve congestion

2 Which of the following health promotion activities planned by a nurse working with a group of community-dwelling senior citizens would be most likely to prevent influenza and pneumonia?
1 Indoor exercise programs during winter months.
2 Influenza vaccine clinics at the senior centre.
3 Teaching effective handwashing.
4 Advising seniors to avoid crowds.

3 In teaching a person with bacterial sinusitis about home care, the nurse stresses the importance of:
1 completing the antibiotic prescription as ordered
2 sleeping with the head of the bed elevated to 45 degrees
3 using a humidifier to promote sinus drainage
4 maintaining a liberal fluid intake to help liquefy secretions

4 Which of the following nursing interventions for the person with posterior nasal packing is of highest priority?
1 Elevate the head of the bed.
2 Apply cold compresses to the nose.
3 Maintain oxygen therapy.
4 Provide frequent oral hygiene.

5 A person in the emergency department following facial trauma complains that his nose 'just keeps dripping'. The drainage appears like watery blood. The most appropriate nursing action would be to:

1 provide a box of tissues
2 reassure the person that this is expected with a nasal fracture
3 suction the nasopharynx
4 obtain a specimen for glucose testing

6 Expected findings in a person with obstructive sleep apnoea would include (select all that apply):
1 confusion and signs of dementia
2 enlarged tongue
3 complaints of daytime sleepiness
4 decreased oxygen saturation levels while awake
5 elevated blood pressure
6 complaints of morning headache

7 The nurse in a doctor's office notes that a person's voice is hoarse, a change from previous visits. The most appropriate question to ask the person would be:
1 'How long has your voice been hoarse?'
2 'Do you smoke?'
3 'Do you have a sore throat?'
4 'Would you like a prescription for throat lozenges?'

8 The nurse evaluates his teaching as effective when a person with stage I laryngeal cancer states:
1 'I'm glad I don't have to worry about treating this cancer now because it is so early.'
2 'I hate to think about eventually losing the ability to speak, but I'd rather treat it aggressively than lose my life to cancer.'
3 'I'm glad this was diagnosed early, when it can be treated with radiation, so I won't lose my voice.'
4 'Thank goodness this type of cancer usually doesn't spread anywhere else.'

9 Place the following nursing interventions for a person who has undergone total laryngectomy and radical neck dissection in order of priority.
1 Arrange consultation with speech therapist.
2 Provide small, frequent meals.
3 Encourage to express feelings regarding loss of voice.
4 Suction via tracheostomy as needed.
5 Instruct to support head when moving.

10 When providing tracheostomy care, the nurse:
1 cuts the dressing using sterile scissors
2 secures clean ties before removing soiled ones
3 uses clean technique to cleanse the outer cannula
4 cleanses the incision with an iodine-based antiseptic

CHAPTER 35

NURSING CARE OF PEOPLE WITH VENTILATION DISORDERS

MAJELLA HALES

LEARNING OUTCOMES

- Relate the pathophysiology of lower respiratory tract infections and inflammatory disorders to a person's alteration in oxygenation.
- Discuss the development, consequences and management of a person experiencing selected pleural disorders.
- Explore the pathophysiology, clinical considerations and care of an individual experiencing a thoracic or inhalation injury.
- Review the causes and consequences of lung cancer and responsibilities of caring for individuals requiring surgery or other invasive procedures.

CLINICAL COMPETENCIES

- Assess the lower respiratory tract and chest wall disorders on ventilation and gas exchange.
- Use assessment data and knowledge of the effects of lower respiratory tract disorders to identify priority nursing care.
- Use the nursing process and evidence-based nursing research to plan and implement individualised nursing care.
- Develop measures to promote ventilation and gas exchange.
- Plan and provide appropriate teaching for health promotion in vulnerable populations.
- Evaluate the effectiveness of nursing interventions and teaching, revising strategies and teaching plans as needed.
- Coordinate interprofessional care and administer prescribed medications and treatments for people with lower respiratory tract disorders.

KEY TERMS

Disorders affecting the lower respiratory tract (below the larynx), pleural cavity and chest wall can affect the ability to effectively move air into and out of the lungs (ventilation). The exchange of oxygen and carbon dioxide across the alveolar–capillary membrane (respiration) is also affected. The disorders discussed in this chapter—respiratory infections and inflammation, trauma and disorders of the chest wall or pleural cavity, and neoplasms of the lung—all affect the ability to maintain clear and patent airways and ventilate the lungs. Nursing care for individuals with these disorders generally focuses on maintaining airway patency and an effective breathing pattern. Disorders that primarily affect gas exchange are discussed in Chapter 36.

The lower respiratory tract and chest wall disorders discussed in this chapter and Chapter 36 both have local and systemic effects. Local effects include cough, excess mucus production, **dyspnoea** (shortness of breath), **haemoptysis** (bloody sputum) and chest pain. Systemic effects may include fever, anorexia and malaise, **cyanosis** (grey/blue skin colour caused by oxygen-poor haemoglobin) and other manifestations of impaired gas exchange. Respiratory disease is very common. Figure 35.1 demonstrates the incidence and disparity of respiratory illness in Australians between 2011 and 2013, by Indigenous status, sex and jurisdiction. Before continuing, review the anatomy, physiology and assessment of the lower respiratory tract in Chapter 33.

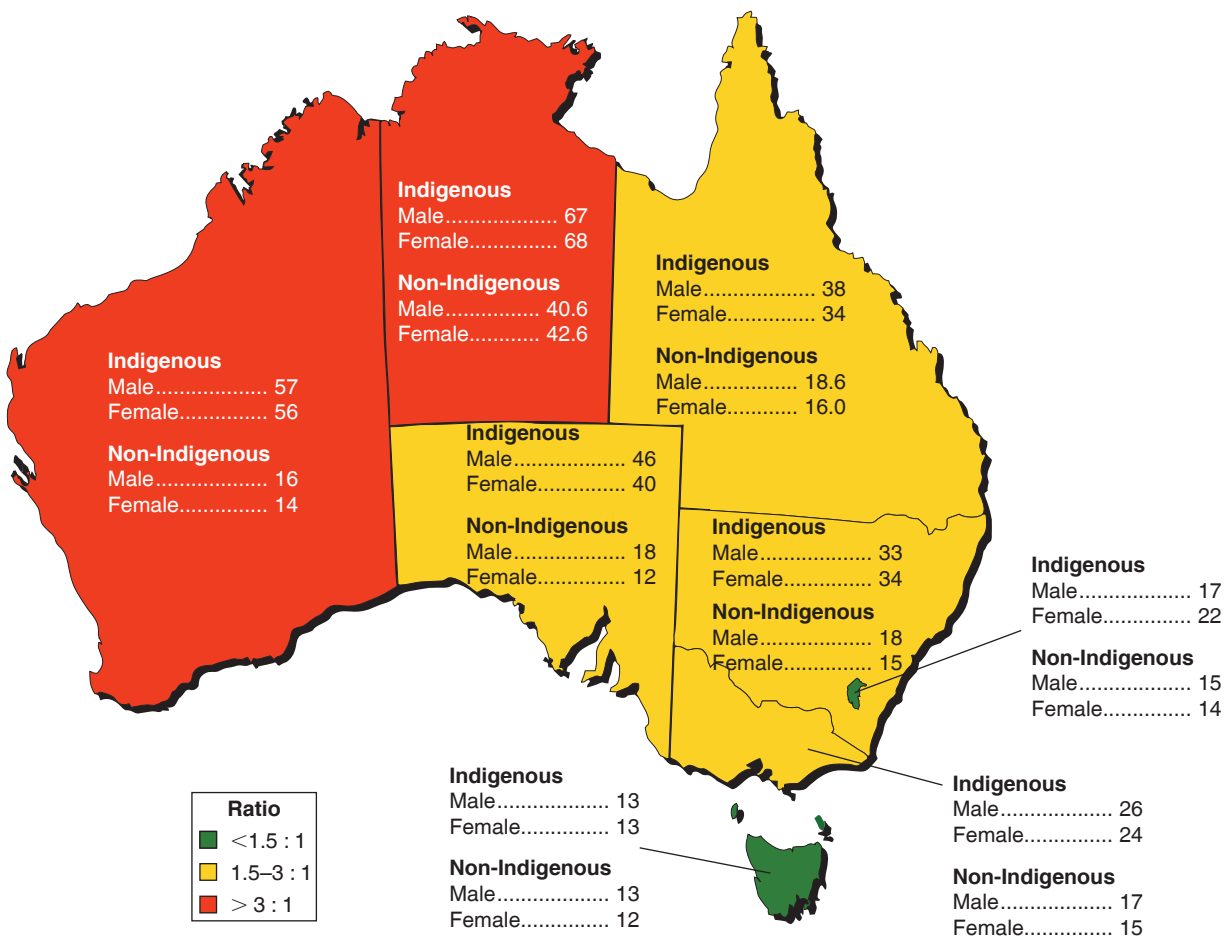

FIGURE 35.1 ■ Age-standardised hospitalisation rates for respiratory disease (per 1000), by Indigenous status, gender and jurisdiction, 2011–2013 (text) and ratios comparing Indigenous and non-Indigenous respiratory disease rates (colour)

INFECTIONS AND INFLAMMATORY DISORDERS

Infections and inflammation of the lower respiratory tract are common and vary in type and severity. The respiratory tree is constantly exposed to the environment as air moves into and out of the lower respiratory tract. In addition, the oropharynx is colonised by large numbers of microorganisms that may be aspirated into the bronchial tree. Both anatomical and

physiological defences help maintain the sterility of the lower respiratory tract. When these defences are impaired, the risk of infection increases. Drugs, alcohol or neuromuscular disease may suppress the cough reflex and the influenza virus can leave the respiratory epithelium vulnerable to bacterial infection. Even in healthy people, microorganisms and other foreign material occasionally enter the bronchial tree and lung parenchyma.

THE PERSON WITH ACUTE BRONCHITIS

Bronchitis, inflammation of the bronchi, may be either an acute or a chronic condition. Acute bronchitis is relatively common in adults. In Australia in 2013–2014, 2.2% of all visits to the general practitioner (GP) for new problems were for management of acute bronchitis/bronchiolitis (Britt et al., 2014). Impaired immune defences and cigarette smoking increase the risk of acute bronchitis. In otherwise healthy adults, it typically follows a viral upper respiratory tract infection (URTI). Chronic bronchitis is a component of chronic obstructive pulmonary disease (COPD) and is discussed in Chapter 36.

FAST FACTS

Chronic obstructive pulmonary disease (COPD) is sometimes referred to by other names:

- COAD—chronic obstructive airways disease
- COLD—chronic obstructive lung disease
- CORD—chronic obstructive respiratory disease
- CAL—chronic airways limitation

Pathophysiology and manifestations

Infectious bronchitis can be caused by any pathogen. However, it is most commonly caused by bacteria and viruses that damage the respiratory mucosa. In healthy adults, bacterial bronchitis generally only occurs as a complication of viral infection. Inhalation of toxic gases or chemicals can lead to inflammatory bronchitis (Bullock & Hales, 2012).

The inflammatory response to infection or tissue damage from inhaled substances causes capillary dilation and oedema of the mucosal lining of the bronchi. Inflammatory cells infiltrate the affected mucosa, leading to exudate formation and increased mucus production. Ciliated epithelium is damaged by the inflammatory response and ciliary function is impaired (Papadakis, McPhee & Rabow, 2013). The immune response of lymphocytes and tissue macrophages is inhibited by some viruses and mycobacteria, increasing the risk of bacterial infection. Mucosal irritation and increased mucus production initiate the cough reflex. The respiratory tract may become hyperirritable for an extended period of time, leading to paroxysms of coughing and bronchospasm (Carolan, 2015).

Acute bronchitis is typically evidenced by a non-productive cough that becomes productive. The cough often occurs in paroxysms and may be aggravated by cold, dry or dusty air. Pleuritic pain (chest pain related to lung issues), often substernal, is common. Other manifestations include moderate fever and general malaise.

INTERPROFESSIONAL CARE

The diagnosis of acute bronchitis typically is based on the history and clinical presentation. A chest x-ray may be ordered to rule out pneumonia because the presenting manifestations can be similar. Other diagnostic testing is rarely indicated. Management focuses on symptom relief and includes rest, increased fluid intake and the use of paracetamol to relieve fever and malaise. Bronchodilators may also be beneficial. Antibiotics and corticosteroids are of limited value in the management of an individual with bronchitis. The Australian Lung Foundation (2014) suggests that acute bronchitis is viral in more than 95% of cases. However, antibiotics may still be used excessively; for example, a document produced by the AIHW (2012) reported that in Australia in 2008, 75% of people with a concession card who were dispensed any respiratory medication were also dispensed an oral antibiotic.

In order to encourage more judicious use of antibiotics, the National Prescribing Service (2014) recommended a creed for prescribing principles that minimises antibiotic resistance. The antibiotic creed uses the acronym MINDME (see Box 35.1).

Other medications may include a codeine-based preparation to ease the coughing paroxysms. However, care must be taken when using medication to suppress the cough reflex, as the infection will have affected the mucociliary escalator and therefore the cough will be the last line of defence.

BOX 35.1 The antibiotic creed

- **M**icrobiology guides therapy wherever possible
- **I**ndications should be evidence based
- **N**arrowest spectrum required
- **D**osage appropriate to the site and type of infection
- **M**inimise duration of therapy
- **E**nsure monotherapy in most situations

Source: National Prescribing Service (2014). *Therapeutic guidelines: Antibiotic* (15th ed.), p. 1, Box 1. Melbourne: Therapeutic Guidelines Ltd.

Nursing care

Nursing interventions for people with acute bronchitis are primarily educational and should include the following teaching topics:

- Increase fluid intake to keep mucus thin and meet increased fluid loss related to fever.
- Use over-the-counter (OTC) analgesics and cough preparations containing pseudoephedrine for symptom relief.

- Be aware of the ingredients of each of the preparations so as not to overdose on a drug that may be in several of the combination medications taken.
- Stress the importance of smoking cessation (as appropriate).

THE PERSON WITH PNEUMONIA

Inflammation of the lung **parenchyma** (the respiratory bronchioles and alveoli) is known as **pneumonia**. Despite significant advances in medical management of respiratory disorders, in 2013 influenza and pneumonia were ranked as the fifteenth leading causes of death in Australia for Aboriginal and Torres Strait Islander people and the sixteenth leading causes of death for non-Indigenous Australians (Australian Bureau of Statistics (ABS), 2015a). In 2013, almost 2500 deaths in Australia were attributed to pneumonia and influenza (ABS, 2015b). Rates of hospitalisation for pneumonia vary depending on age, gender and the state in which an individual lives. Incidence and mortality rates are highest in older adults and people with debilitating diseases. It is estimated that the financial burden of pneumonia is approximately $20 million per year (Li et al., 2012).

Pneumonia may be either infectious or non-infectious. Bacteria, viruses, fungi, protozoa and other microbes can lead to infectious pneumonia. Non-infectious causes include aspiration of gastric contents and inhalation of toxic or irritating gases. Pneumonias are often classified as community acquired, healthcare associated, nosocomial (hospital acquired) or opportunistic. Currently, as no universal nomenclature for the classification of pneumonia exists, there is some disparity in the use of these terms. Some authors use the terms 'nosocomial' and 'healthcare associated' interchangeably. Some authors consider exposure to a pathogen from an aged care facility, dialysis unit or outpatient clinic as a type of community-acquired pathogen. However, within this textbook these are considered healthcare associated. They often differ from both hospital-acquired and community-acquired pneumonia, not only in transmission but also in causative pathogens.

Different organisms are implicated in each of these classifications (see Table 35.1). The most common causative organisms for community-acquired pneumonia are the respiratory viruses *Streptococcus pneumoniae* (also called pneumococcus) and *Mycoplasma pneumonia. Haemophilus influenza, Legionella species* and *Chlamydia* species are also common community-acquired pneumonia pathogens (Centre for Healthcare Related Infection Surveillance and Prevention (CHRISP), 2015; Cunha, 2014). *Staphylococcus aureus* and Gram-negative bacteria such as *Pseudomonas aeruginosa*, *Klebsiella pneumoniae* and enteric bacilli, including *Escherichia coli*, are often implicated as nosocomial causes of pneumonia. Organisms such as *Pneumocystis jiroveci* generally cause infections more often in immunocompromised people (opportunistic infections).

FOCUS ON CULTURAL DIVERSITY

- Aboriginal and Torres Strait Islander children are five times more likely to die from pneumonia than non-Indigenous Australians (Ley, 2015).
- In Victoria, a group evaluating the primary health needs of the local refugee population within its area determined that, although the local refugees were 23% more likely to present to an emergency department and 47% more likely to be admitted for healthcare issues (than non-refugee locals), the refugees were actually no more likely to require admission for pneumonia or influenza than non-refugees within the area (Cheng et al., 2011).

Physiology review

In health, the lower respiratory tract is sterile. A number of defence mechanisms help maintain this sterile environment. Infectious particles trapped by the mucous membranes of the nose are removed by sneezing, while those deposited in the nasopharynx usually are swallowed or expectorated. Reflex closure of the epiglottis and the branching bronchial tree present anatomical barriers to entry of microorganisms and other possible contaminants. The cilia and mucus that line the respiratory tract and the cough reflex serve to trap and eliminate foreign matter that enters the lower respiratory tract. Organisms that make it past these barriers are usually rapidly phagocytised in the alveolus by resident macrophages, then attacked by the inflammatory and immune defences of the body. Ageing impairs these immune responses, increasing the risk of pneumonia.

TABLE 35.1 Common organisms causing pneumonia in adults

HOSPITAL ACQUIRED	HEALTHCARE ASSOCIATED	COMMUNITY ACQUIRED	OPPORTUNISTIC
Staphylococcus aureus	*Streptococcus pneumoniae*	*Streptococcus pneumoniae*	*Pneumocystis jiroveci*
Pseudomonas aeruginosa	*Staphylococcus aureus*	*Mycoplasma pneumoniae*	*Mycobacterium tuberculosis*
Klebsiella pneumoniae	*Haemophilus influenzae*	*Haemophilus influenzae*	Cytomegalovirus (CMV)
Legionella spp.	Influenza virus	*Chlamydia pneumoniae*	Atypical mycobacteria
Escherichia coli	*Enterobacter* spp.	*Legionella* spp.	Fungi
		Influenza virus	

Pathophysiology

The most common portal of entry for pathogens into the lung is aspiration of oropharyngeal secretions containing microbes. Microorganisms also may be inhaled after having been released when an infected person coughs, sneezes or talks. Finally, bacteria may spread to the lungs through the bloodstream from infection elsewhere in the body. Host defences must be overwhelmed either by the number of organisms or their *virulence* (disease-causing ability) in order for an infection to develop.

When the invading microorganisms colonise the alveoli, an inflammatory and immune response is initiated. The body's antigen–antibody response and endotoxins released by some organisms damage bronchial and alveolar mucous membranes, causing inflammation with vascular congestion and oedema. Infectious debris and exudate can fill alveoli, interfering with ventilation and gas exchange (see Figure 35.2). Pneumonia may develop in four distinct patterns: lobar pneumonia, bronchopneumonia, interstitial pneumonia and miliary pneumonia (see Table 35.2). The pathological process, anatomical location and manifestations of pneumonias vary according to the infective organism.

Lifespan considerations

When compared with an adult, the anatomical development and physiological maturation of an infant's respiratory tract increases the child's risk of developing respiratory tract infections. At birth, only 10% of alveoli are present, resulting in a greater surface area to volume ratio. Alveolar multiplication occurs until approximately 8 years of age. Airway lumens in children are smaller and chest wall recoil and underdeveloped respiratory musculature can result in fatigue sooner than in an adult. The breathing zone of a child is lower and therefore heavier particles can travel deeper into the respiratory system.

However, in advancing age, several changes associated with ageing and disease also affect respiratory function and airway clearance. The number of cilia decreases and the cough weakens. Gag and cough reflexes diminish. The older adult is at greater risk of dehydration, leading to thick, viscous mucus that is difficult to expectorate. Immune function declines with ageing. These factors increase the risk of pulmonary infection and reduce the older adult's ability to respond effectively to infectious processes (Bullock & Hales, 2012). Other factors also may increase the risk for and severity of lower respiratory tract infections in the older adult: immobility, smoking history, surgical procedures, use of multiple medications, malnutrition and such diseases as COPD and heart disease.

Acute bacterial pneumonia

Of the bacterial pneumonias, the pathogenesis of pneumococcal (*Streptococcus pneumoniae*) pneumonia is best understood (see Figure 35.3). These bacteria reside in the upper respiratory tract of up to 70% of adults. They may be spread by droplet contamination. In many cases, infection results from aspiration of resident bacteria. In the lower respiratory tract, the inflammatory response initiated by these organisms causes alveolar oedema and the formation of exudate. As alveoli and respiratory bronchioles fill with serous exudate, blood cells, fibrin and bacteria, *consolidation* (swelling) of lung tissue occurs. The lower lobes of the lungs are usually affected because of gravity. Consolidation of a large portion of an entire lung lobe is known as *lobar pneumonia*. This is the typical pattern for pneumococcal pneumonia. *Bronchopneumonia* is patchy consolidation involving several lobules. Other bacterial pneumonias often present with the patchy involvement of bronchopneumonia; pneumococcal pneumonia may also follow this pattern (see Figure 35.4). The process resolves when macrophages predominate, digesting and removing inflammatory exudate from the infected lung.

FIGURE 35.2 ■ In pneumonia, the inflammatory response causes fluid to accumulate in the alveoli and oedema to form as alveolar capillaries dilate and allow fluid to leak into interstitial tissues

Source: SPL/Custom Medical Stock Photo.

MANIFESTATIONS The presentation of bacterial pneumonia is usually acute, with rapid onset of chills, fever and cough productive of rust-coloured or purulent sputum. Chest aching or *pleuritic pain* (sharp, localised chest pain that increases with breathing and coughing) is common. Limited breath sounds and fine crackles are heard over the affected area of lung. A pleural friction rub may be audible. If the involved area is large and gas exchange is impaired, dyspnoea and cyanosis may be noted.

A more insidious onset with low-grade fever, cough and scattered crackles is more typical of bronchopneumonia. Dyspnoea is less commonly seen. The older adult or debilitated person may have atypical manifestations of pneumonia, with little cough,

TABLE 35.2 Patterns of lung involvement in pneumonia

PATTERN OF INVOLVEMENT	DESCRIPTION
Lobar pneumonia	Typically involves an entire lobe of a lung. Early in the process, when the immune response is minimal, bacteria spread throughout the affected lobe by rapid accumulation of fluid exudate. As the immune and inflammatory responses develop, RBCs and neutrophils, damaged epithelial cells and fibrin accumulate in the alveoli. Purulent exudate containing neutrophils and macrophages forms. As alveoli and respiratory bronchioles fill with exudate, blood cells, fibrin and bacteria, *consolidation* (solidification) of lung tissue occurs. Finally, the process resolves as enzymes destroy the exudate and residual debris is reabsorbed, phagocytised or coughed out.
Bronchopneumonia	Usually involves dependent portions of lung tissue, characterised by patchy consolidation. Exudate tends to remain primarily in the bronchi and bronchioles, with less oedema and congestion of the alveoli than in lobar pneumonia.
Interstitial pneumonia	The inflammatory process primarily involves the interstitium: the alveolar walls and connective tissue supporting the bronchial tree. Involvement may be patchy or diffuse as lymphocytes, macrophages and plasma cells infiltrate the alveolar septa. While alveoli typically do not contain significant exudates, protein-rich hyaline membranes may line the alveoli, interfering with gas exchange.
Miliary pneumonia	In miliary pneumonia, numerous discrete inflammatory lesions develop as a result of spread of the pathogen to the lungs via the bloodstream. Miliary pneumonia is primarily seen in people who are severely immunocompromised. As a result, the immune response is poor and damage to pleural tissue may be significant.

scant sputum and minimal evidence of respiratory distress. Fever, tachypnoea and altered mentation or agitation may be the primary presenting symptoms.

COMPLICATIONS Pneumonia typically resolves uneventfully; normal lung structure is restored on completion of the process. Local extension of the infection to involve the pleura (*pleuritis*) is the most common complication. Pneumonias caused by *Staphylococcus aureus* and some Gram-negative bacteria often cause extensive parenchymal damage with necrosis, lung abscess and empyema or pleural effusion. Progressive destruction of lung tissue and functional impairment is a possible consequence of *Klebsiella* pneumonia.

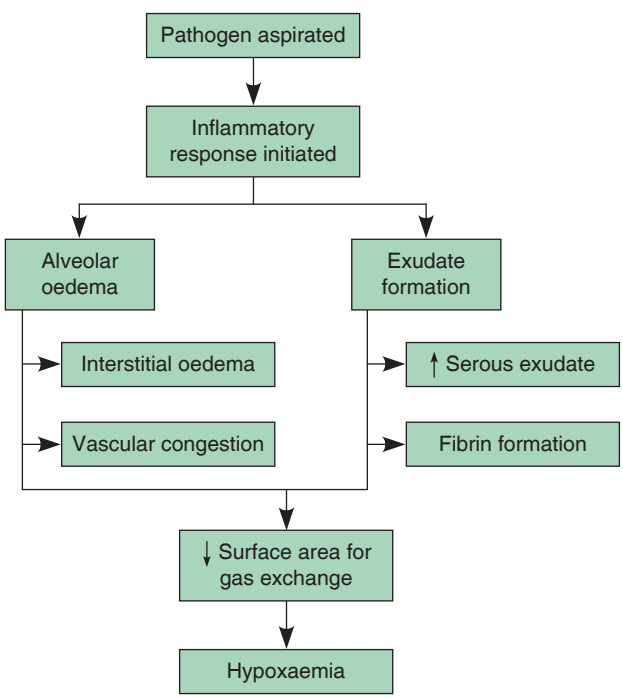

FIGURE 35.3 ■ The pathogenesis of pneumonia

A *lung abscess* is a local area of necrosis and pus formation within the lung itself. It is relatively uncommon. The manifestations of lung abscess develop slowly and include weight loss, malaise, night sweats, fever and a productive cough. Sputum is foul smelling and tasting. Rupture of the abscess into a larger airway is evidenced by production of copious amounts of purulent sputum.

Empyema is accumulation of purulent exudate in the pleural cavity. It is identified by chest x-ray or computed tomography (CT) scan. Thoracentesis may be performed or a chest tube inserted to remove purulent exudates. (Nursing care of the person undergoing thoracentesis or with a chest tube is discussed later in this chapter.)

Bacteraemia can spread the infection to other tissues, leading to meningitis, endocarditis or peritonitis, and increasing the risk of mortality.

Legionnaires' disease

Legionnaires' disease (legionellosis) is a form of atypical bronchopneumonia caused by *Legionella* bacteria. Although there are over 40 strains, not all cause disease in humans. The most common strain is *Legionella pneumophila* (Whiley et al., 2014). This Gram-negative bacterium is found in warm water or warm damp places. Legionnaires' disease occurs sporadically and in outbreaks, such as that which occurred at an American Legion convention in 1976 when the disease was first recognised. Contaminated water-cooled air-conditioning systems and other water sources have been implicated in its spread. In Australia in 2014, there were 425 notifications of legionellosis, which equates to 1.8 for every 100 000 people, down from 20.2 in 2013 (Department of Health, 2015a). See Figure 35.5 for Australian legionellosis statistics by year.

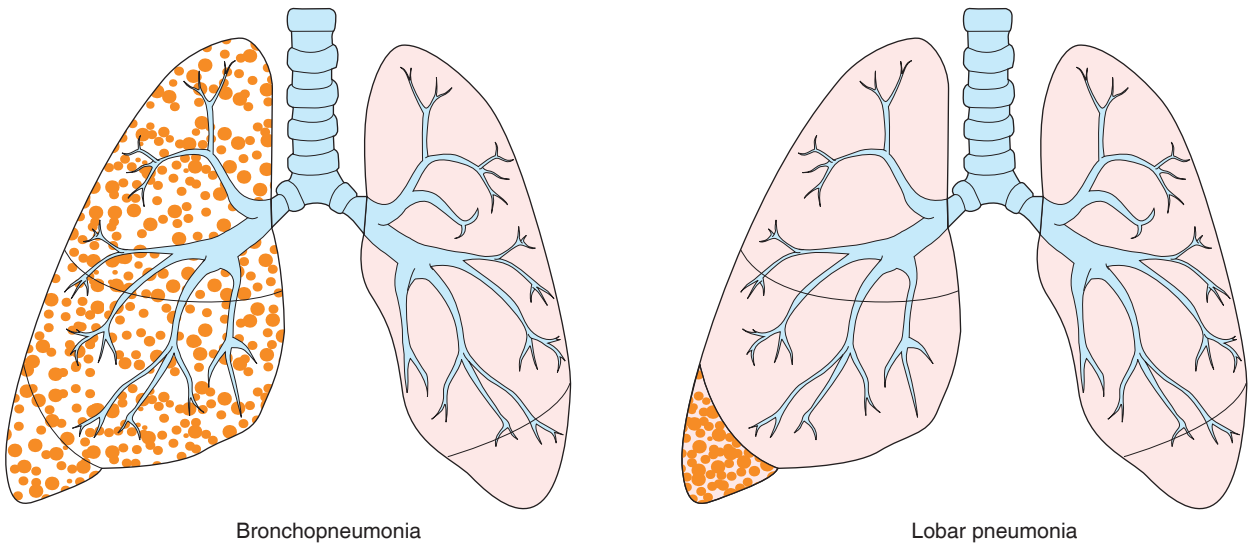

FIGURE 35.4 ■ Comparison of bronchopneumonia and lobar pneumonia

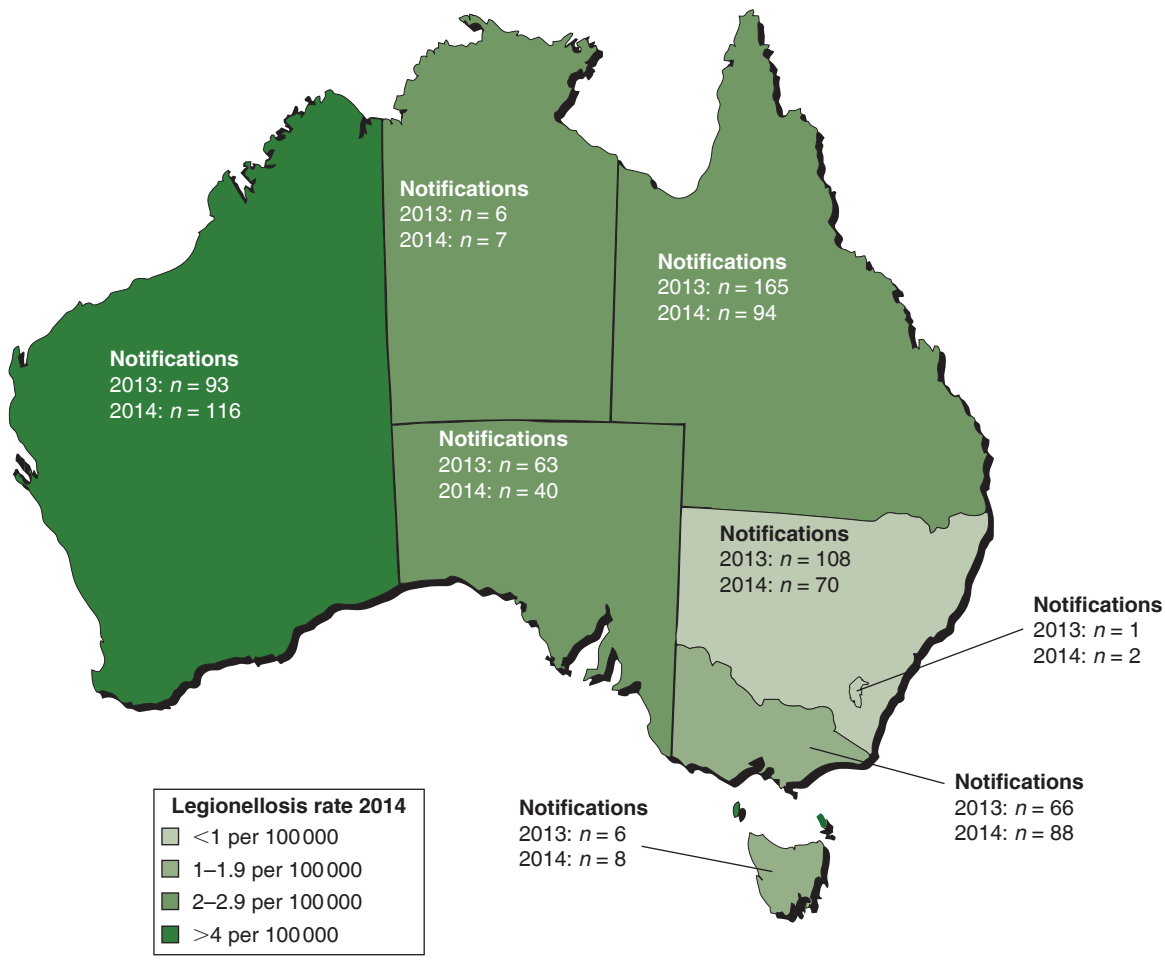

FIGURE 35.5 ■ Number of notifications for legionellosis in Australia for 2013 and 2014 (text) and notification rates per 100 000 for 2014 (colour)

Source: Generated using data from Department of Health (2015a). *National Notifiable Diseases Surveillance System. Number of notifications for legionellosis by year, Australia, 1991 to 2015.* Retrieved from www9.health.gov.au/cda/source/rpt_4_sel.cfm.

FAST FACTS

The largest outbreak of legionellosis in Australia occurred in 2000 at the Melbourne Aquarium.

- 125 cases were confirmed.
- 76% of the infected individuals required hospitalisation.
- Four people died.
- *Legionella pneumophila* was the organism isolated in the cooling towers.
- Cigarette smoking (>70/week) was a critical risk factor for the development of Legionnaires' disease in the individuals visiting the aquarium during the relevant 16 days in April 2000 (Greig et al., 2000).

More recently, in 2013 in a major private hospital in Queensland, two people were found to be infected with *Legionella pneumophila.* Subsequently one of the individuals died. As a result, all of Queensland's public, private and day hospitals were tested for *Legionella* spp. Although 159 facilities were free from contamination, 106 facilities returned positive samples for *Legionella* bacteria (Springborg, 2013; Queensland Government, 2014).

Smokers, older adults and people with chronic diseases or impaired immune defences are most susceptible to Legionnaires' disease. Symptoms develop gradually, beginning 2 to 10 days after exposure. Dry cough, dyspnoea, general malaise, chills and fever, headache, confusion, anorexia and diarrhoea, myalgias and arthralgias are common manifestations. Consolidation of lung tissue is patchy or lobar.

Viral pneumonia

Viral pneumonia is more common in children (Mosenifar, 2015). However, it is relatively common to have a secondary bacterial pneumonia as a direct result of a primary viral infection. Other viruses such as herpes viruses and measles virus also may cause viral pneumonia. As in primary atypical pneumonia, lung involvement in viral pneumonia is limited to the alveolar septum and interstitial spaces.

Viral pneumonia is typically a mild disease that often affects older adults and people with chronic conditions. It usually occurs in community epidemics. Flu-like symptoms of headache, fever, fatigue, malaise and muscle aching are common, along with a dry cough.

See Box 35.2 for examples of emerging zoonotic viral pneumonias.

Aspiration pneumonia

Aspiration of gastric contents into the lungs results in a chemical and bacterial pneumonia known as *aspiration pneumonia*. Major risk factors for aspiration pneumonia include emergency surgery or obstetric procedures, depressed cough and gag reflexes, and impaired swallowing. Older adults are at significant risk. Enteral nutrition by either nasogastric or gastric tube also increases the risk of aspiration pneumonia. Vomiting is not always apparent; silent regurgitation of gastric contents may occur when the level of consciousness is decreased. Measures to reduce the risk of aspiration pneumonia include minimising the use of preoperative medications, promoting anaesthetic elimination from the body and preventing nausea and gastric distension.

The low pH of gastric contents causes a severe inflammatory response when aspirated into the respiratory tract. Pulmonary oedema and respiratory failure may result. Common complications of aspiration pneumonia include abscesses, bronchiectasis (chronic dilation of the bronchi and bronchioles) and gangrene of pulmonary tissue.

BOX 35.2 Emerging zoonotic viral pneumonias

Severe acute respiratory syndrome (SARS) is a lower respiratory tract illness caused by the SARS coronavirus (SARS Co-V). The pathogen is zoonotic (causing disease that can cross the species barrier). Originally described in Asia in 2002, it quickly became a global concern and was identified as an epidemic in Asia, Europe and North America. However, the World Health Organization (WHO) reported there have only been six probable cases of SARS in Australia, and no deaths (WHO, 2014a). Following the declaration by the WHO that the cumulative total of global SARS cases exceeded 8000 people, it is believed that there have been no cases anywhere in the world since 2004 (WHO, 2015a).

Middle East respiratory syndrome (MERS) is a lower respiratory tract illness caused by the MERS coronavirus (MERS Co-V). It is thought to have originated in Saudi Arabia in 2012. Unlike SARS, which demonstrated relatively efficient transmission yet low mortality rates (~11%), MERS has relatively inefficient transmission but a higher mortality rate (~36%). Currently, there are no reports of MERS cases in Australia (WHO, 2015b).

Typical symptoms for both these viral illnesses include shortness of breath and cough. The person often has a fever and pneumonia is common. Transmission is most likely droplet. There are currently no vaccines and treatment is supportive, managing the person's signs and symptoms.

INTERPROFESSIONAL CARE

Prevention is a key component in managing pneumonia. Identifying vulnerable populations and instituting preventive strategies are measures to reduce the mortality and morbidity associated with pneumonia. With early identification of the infecting organism, appropriate treatment and support of respiratory function, most people recover uneventfully. However, pneumonia remains a serious disease with significant mortality, especially in aged and debilitated populations.

Diagnosis

The history and physical examination, along with diagnostic testing, are used to establish the diagnosis, determine the extent of lung involvement and identify the causative organism. See Chapter 33 for more information about the following tests and their nursing implications:

- *Chest x-ray* is obtained to determine the extent and pattern of lung involvement. Fluid, infiltrates, consolidated lung tissue and atelectasis (areas of alveolar collapse) appear as densities on the film. The *CT scan* provides a more detailed image of pulmonary tissue and may be used when the chest x-ray is not diagnostic.
- *Sputum Gram stain* rapidly identifies the infecting organisms as Gram-positive or Gram-negative bacteria. Antibiotic therapy can then be directed at the predominant type of organism until culture and sensitivity results are obtained.
- *Sputum culture and sensitivity* is ordered to identify the infecting organism and determine the most effective antibiotic therapy. When obtaining sputum for culture, it is important to obtain secretions from the lower respiratory tract, not the mouth and nasal passages (see Procedure 33.1).
- *Full blood count (FBC) with white blood cell (WBC) differential* shows an elevated WBC (>10 × 10^9/L) with increased circulating immature leucocytes in response to the infectious process. White blood cell changes are minimal in viral and other pneumonias.
- *Serology testing*, blood tests to detect antibodies to respiratory pathogens, may be used to identify the infecting organism when blood and sputum cultures are negative.
- *Pulse oximetry*, a non-invasive method of measuring peripheral oxygen saturation, is ordered to continuously monitor gas exchange. The saturation of peripheral oxygen (SpO_2) is normally 95% or higher. An SpO_2 of less than 95% may indicate impaired alveolar gas exchange.
- *Arterial blood gases (ABGs)* may be ordered to evaluate gas exchange. Respiratory secretions or pleuritic pain can interfere with alveolar ventilation. Alveolar inflammation can interfere with gas exchange across the alveolar–capillary membrane, especially if exudate or consolidation is present. An arterial oxygen tension (PaO_2) of less than 75 to 80 mmHg indicates impaired gas exchange or alveolar ventilation. See Chapters 9 and 33 for more information about gas transport, ABGs and normal or expected values.
- *Fibre-optic bronchoscopy* may be done to obtain a sputum specimen or remove secretions from the bronchial tree (see Figure 33.9). Nursing care related to bronchoscopy is summarised in the 'Diagnostic tests' box in Chapter 33.

Immunisation

Vaccines offer some degree of protection against the most common bacterial and viral pneumonias.

In Australia, a few pneumococcal vaccines are available (see Table 35.3). The critical difference is the number of serotypes contained within the vaccine. Recently a 7-valent pneumococcal vaccine has been replaced by a 13-valent one. There is also a pneumococcal vaccine with 10 serotypes and one with 23 serotypes. The individual's medical conditions, age, Indigenous status, overall immunisation status and geographical area can influence the choice of vaccine.

TABLE 35.3 Serotypes in current Australian pneumococcal vaccines

10-VALENT PNEUMOCOCCAL CONJUGATE VACCINE (10vPCV)	13-VALENT PNEUMOCOCCAL CONJUGATE VACCINE (13vPCV)	23-VALENT PNEUMOCOCCAL POLYSACCHARIDE VACCINE (23vPPV)

Source: Department of Health (2015b). Pneumococcal disease. *Australian immunisation handbook* (10th ed.). Retrieved from www.immunise.health.gov.au/internet/immunise/publishing.nsf/Content/Handbook10-home~handbook10part4~handbook10-4-13.

The predominant strain of influenza virus varies from year to year. A new vaccine formulation is prepared yearly, incorporating antigens of the influenza strains predicted to be the most prevalent for the upcoming flu season (typically the winter months). Vulnerable populations for whom yearly vaccine is recommended include individuals with chronic conditions involving lung, heart, diabetes or kidney disease, healthcare workers and residents of long-term care facilities. The vaccine contains egg protein and is not recommended for people who have a severe allergy to eggs or who have previously experienced a severe hypersensitivity response to the vaccine.

Medications

Medications used to treat pneumonia may include antibiotics to eradicate bacterial infection and bronchodilators to reduce bronchospasm and improve ventilation.

Broad-spectrum antibiotic therapy is initially used; then, based on the results of sputum microscopy/culture and sensitivity results, more specific antibiotic therapy may be commenced.

When an inflammatory response to the infection causes bronchospasm and constriction, bronchodilators may be ordered to improve ventilation and reduce hypoxia. Bronchodilators generally belong to one of two main groups: the sympathomimetic drugs, such as salbutamol (Ventolin) and the anticholinergic drugs, such as ipratropium bromide (Atrovent). Use of these drugs and related nursing implications are discussed in detail in the section on asthma in Chapter 36. Figure 35.6 demonstrates the actions of common respiratory drugs.

A mucolytic agent 'breaks up' mucus or reduces its viscosity. Acetylcysteine (Mucomyst) helps to liquefy mucus, making it easier to expectorate. For many people, however, increasing fluid intake is an effective means of liquefying mucus.

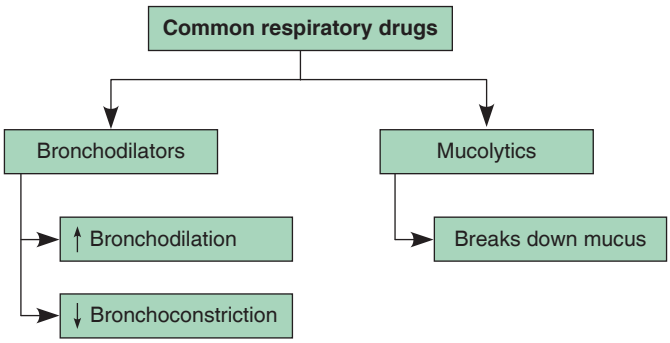

FIGURE 35.6 ■ Common drugs used in respiratory disorders

Treatments

When mucus secretions are thick and viscous, increasing fluid intake to 2500 to 3000 mL per day helps liquefy secretions, making them easier to cough up and expectorate. If the person is unable to maintain an adequate oral intake, intravenous fluids and nutrition may be required.

Incentive spirometry may be used to promote deep breathing, coughing and clearance of respiratory secretions. Endotracheal suctioning may be required if the cough is ineffective. This invasive technique is discussed in Chapter 36 in Procedure 36.1, describing nursing care for the person undergoing endotracheal suctioning.

OXYGEN THERAPY Oxygen therapy may be indicated for the person who is tachypnoeic or hypoxaemic.

Inflammation of the alveolar–capillary membrane interferes with diffusion of gases across the membrane. Diffusion is affected by several other factors, including the partial pressure of gases on each side of the membrane. Increasing the percentage of inspired oxygen above that of room air (21%) increases the partial pressure of oxygen in the alveoli and enhances its diffusion into the capillaries. Supplemental oxygen improves oxygenation of the blood and tissues in people with pneumonia.

Depending on the degree of hypoxia, oxygen may be administered by either a low-flow or a high-flow system. Low-flow systems include nasal prongs, simple face mask, partial rebreathing mask and non-rebreathing mask (see Figure 35.7). Nasal prongs can deliver 24–45% oxygen concentrations with flow rates of 2 to 6 L/min. The nasal prongs are comfortable and do not interfere with eating or talking. A simple face mask delivers 40–60% oxygen concentrations with flow rates of 5 to 8 L/min. Up to 100% oxygen can be delivered by the non-rebreather mask, the highest concentration possible without mechanical ventilation. When the amount of oxygen delivered must be precisely regulated, a high-flow system such as a Venturi mask is used (see Figure 35.8). The Venturi mask regulates the ratio of oxygen to room air, allowing precise regulation of the oxygen percentage delivered, from 24% to 50%. Severe hypoxia may necessitate intubation and mechanical ventilation. Endotracheal intubation and methods of mechanical ventilation are discussed in Chapter 36.

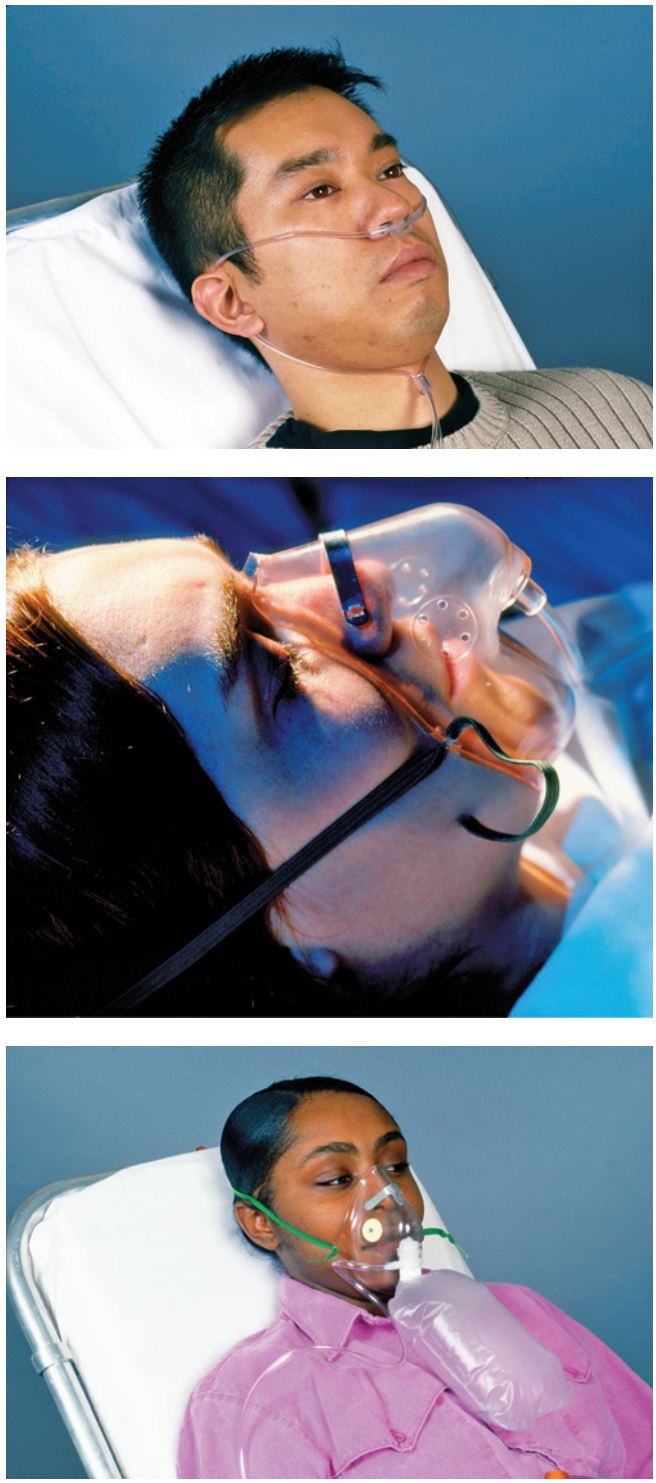

FIGURE 35.7 ■ Oxygen delivery devices: *A*, nasal prongs; *B*, simple face mask; *C*, non-rebreather mask

Sources: A and *C*, Michal Heron/Pearson Education; *B*, Tony McConnell/Science Source.

CHEST PHYSIOTHERAPY Chest physiotherapy, including percussion, vibration and postural drainage, may be prescribed to reduce lung consolidation and prevent atelectasis. *Percussion* is performed by rhythmically striking the chest wall with

FIGURE 35.8 ■ Venturi mask, a high-flow oxygen delivery system

Source: Michal Heron, Pearson Education/Ph College.

cupped hands (see Figure 35.9A), using rapid wrist flexion and extension. Cupping traps air between the palm and the person's skin, setting up vibrations through the chest wall that loosen respiratory secretions. The trapped air also provides a cushion, preventing injury. When performed correctly, percussion produces a hollow, popping sound. The breasts, sternum, spinal column and kidney regions are avoided during percussion.

Vibration facilitates secretion movement into larger airways. It usually is combined with percussion, although it may be used when percussion is contraindicated or poorly tolerated. Vibration is performed by repeatedly tensing the arm and hand muscles while maintaining firm but gentle pressure over the affected area with the flat of the hand (see Figure 35.9B).

Percussion and vibration are done in conjunction with *postural drainage*, which uses gravity to facilitate removal of secretions from a particular lung segment. The person is positioned with the segment to be drained superior to or above the trachea or mainstem bronchus. Drainage of all lung segments requires a variety of positions (see Figure 35.10); rarely do all segments require drainage. Bronchodilators or nebuliser treatments are administered as ordered prior to postural drainage. It is best to perform postural drainage before meals to avoid nausea and vomiting.

Nursing care

Health promotion

Health promotion activities focus on pneumonia prevention. Make sure individuals in high-risk groups are aware of the benefits of immunisations against influenza and pneumococcal pneumonia. A single dose of pneumococcus vaccine usually produces immunity to most strains of pneumococcal pneumonia, although repeat doses may be needed for older adults and people who are immunosuppressed. (Pneumococcus vaccine is contraindicated for people receiving immunosuppressive therapy.) Annual influenza vaccine helps prevent pneumonia because pneumonia often occurs as a sequelae to influenza.

CONSIDERATION FOR PRACTICE

Inquire about allergic responses to eggs or previous influenza vaccinations prior to administering influenza vaccine. A significant hypersensitivity response may occur in people who are allergic to eggs as the vaccine contains egg protein.

Assessment

Focused assessment of the person with pneumonia includes the following:

- *Health history:* current symptoms and their duration; presence of shortness of breath, chest pain and its relationship to breathing; cough, productive or non-productive, colour, consistency of sputum; other symptoms; recent upper respiratory or other acute illness; chronic diseases such as diabetes, chronic lung disease or heart disease; current medications; medication allergies.
- *Physical examination:* presentation, apparent distress; level of consciousness; vital signs, including temperature; skin colour, temperature; respiratory excursion, use of accessory muscles of respiration; lung sounds.
- *Diagnostic tests:* WBC with differential, sputum Gram stain, culture and sensitivity, chest x-ray or CT scan.

Nursing diagnoses and interventions

People with lower respiratory tract disorders such as pneumonia may have multiple nursing care needs, depending on the severity of the illness. Alveolar ventilation and the process of

alveolar respiration can be affected by inflammation and secretions. **Hypoxaemia**, low levels of oxygen in the blood, and tissue hypoxia may result. Nursing care focuses on supporting optimal respiratory function and promoting rest to reduce metabolic and oxygen needs.

CONSIDERATION FOR PRACTICE

Promptly report signs of respiratory distress, including tachypnoea, tachycardia, nasal flaring, use of accessory muscles, intercostal retractions, cyanosis, increasing restlessness, anxiety or decreased level of consciousness (LOC). These may be early manifestations of respiratory failure and inability to maintain ventilatory effort.

Ineffective airway clearance

The inflammatory response to infection causes tissue oedema and exudate formation. In the lungs, the inflammatory response can narrow and potentially obstruct bronchial passages and alveoli. Assessment findings supporting this nursing diagnosis include adventitious breath sounds such as crackles (rales) and wheezes; dyspnoea and tachypnoea; coughing; and indicators of hypoxia such as cyanosis, reduced SpO_2 levels, anxiety and apprehension.

- Assess respiratory status, including vital signs, breath sounds, SpO_2 and skin colour, at least every 4 hours. *Early identification of respiratory compromise allows intervention before tissue hypoxia is significant.*
- Assess cough and sputum (amount, colour, consistency and possible odour). *Assessment of the cough and the nature of sputum produced allows evaluation of the effectiveness of respiratory clearance and the response to therapy.*
- Monitor ABG results; report increasing hypoxaemia and other abnormal results to the doctor. *Blood gas changes may be an early indicator of impaired gas exchange due to airway narrowing or obstruction.*
- Place in Fowler's or high-Fowler's position. Encourage frequent position changes and ambulation as allowed. *The upright position promotes lung expansion; position changes and ambulation facilitate the movement of secretions.*
- Assist to cough, deep breathe and use assistive devices. Provide endotracheal suctioning using aseptic technique as required if the person is intubated. *Coughing, deep breathing and suctioning help clear airways.*
- Provide a fluid intake of at least 2500 to 3000 mL per day. *A liberal fluid intake helps liquefy secretions, facilitating their clearance.*
- Work with the doctor and physiotherapist to provide pulmonary hygiene measures, such as postural drainage, percussion and vibration. *These techniques help mobilise and clear secretions.*
- Administer prescribed medications as ordered and monitor their effects. *If the infecting organism is resistant to the prescribed antibiotic, little improvement may be seen with treatment. Bronchodilators help maintain open airways but may have adverse effects such as anxiety and restlessness.*

Ineffective breathing pattern

Pleural inflammation often accompanies pneumonia, causing sharp localised pain that increases with deep breathing, coughing and movement, which can lead to rapid and shallow breathing. Distal airways and alveoli may not expand optimally with each breath, increasing the risk of atelectasis and decreasing gas exchange. Fatigue from the increased work of breathing is an additional problem in pneumonia. This, too, can lead to decreased lung inflation and an ineffective breathing pattern.

- Provide for rest periods. *Rest reduces metabolic demands, fatigue and the work of breathing, promoting a more effective breathing pattern.*
- Assess for pleuritic discomfort. *Provide analgesics as ordered. Adequate pain relief minimises splinting and promotes adequate ventilation.*
- Provide reassurance during periods of respiratory distress. *Hypoxia and respiratory distress produce high levels of anxiety, which tends to further increase tachypnoea and fatigue and decrease ventilation.*
- Administer oxygen as ordered. *Oxygen therapy increases the alveolar oxygen concentration and facilitates its diffusion across the alveolar–capillary membrane, reducing hypoxia and anxiety.*
- Teach slow abdominal breathing. *This breathing pattern promotes lung expansion.*

Activity intolerance

Impaired airway clearance and gas exchange interfere with oxygen delivery to body cells and tissues. At the same time, the infectious process and the body's response to it increase metabolic demands on the cells. The net result of this imbalance between oxygen delivery and oxygen demand is a lack of physiological energy to maintain normal daily activities.

- Assess activity tolerance, noting any increase in pulse, respirations, dyspnoea, diaphoresis or cyanosis. *These assessment findings may indicate limited or impaired activity tolerance.*
- Schedule activities, planning for rest periods. *Rest periods minimise fatigue and improve activity tolerance.*
- Provide assistive devices. *Assistive devices facilitate movement and reduce energy demands.*
- Enlist the family's help to minimise stress and anxiety levels. *Stress and anxiety increase metabolic demands and can decrease activity tolerance.*
- Perform active or passive range-of-motion (ROM) exercises. *Exercises help maintain muscle tone and joint mobility and prevent contractures if bed rest is prolonged.*
- Provide emotional support and reassurance that strength and energy will return to normal when the infectious process has resolved and the balance of oxygen supply and demand is restored. *The person may be concerned that activity intolerance will continue to be a problem after the acute infection is resolved.*

CONSIDERATION FOR PRACTICE

Activity intolerance may be an early sign of cardiorespiratory compromise, particularly in the older adult or person with pre-existing heart disease. New or worsening manifestations of activity intolerance should be reported to the doctor.

Community-based care

Individuals with pneumonia usually are treated in the community, unless their respiratory status is significantly compromised (e.g. altered mental status, tachypnoea, tachycardia, hypotension, hypo- or hyperthermia, and altered blood gases) or if risk

NURSING CARE PLAN A person with pneumonia

Mary O'Neal is a 35-year-old personal assistant and part-time university student. On returning home from class one evening, she begins to experience a chill. She alternates between chills and sweats all night. Staying home from work, she remains in bed most of the next day. Her fever continues and she develops a cough and dull aching chest pain. When the cough becomes productive of rust-coloured sputum the following day, she seeks medical treatment from her family doctor.

ASSESSMENT

Mrs O'Neal is admitted. She denies any previous history of respiratory diseases 'other than the usual colds, flu and such'. She also denies any history of smoking or medication allergies. She says her symptoms began abruptly with the onset of the chills. She describes her chest pain as a dull ache that was initially substernal but now is localised in her lower lateral right chest. The pain increases with deep breathing, coughing and moving. Her cough is increasing in frequency and severity and her sputum appears rusty brown. Her vital signs are BP 116/74, P 104 and regular, R 26, T 38.7°C. Skin warm and flushed, with no evidence of cyanosis. Respirations shallow, unlaboured; respiratory excursion equal. Diminished breath sounds in bases bilaterally, crackles noted in right posterior and lateral base. Faint pleural rub heard at right midaxillary line.

A FBC shows a WBC of 18.4 x 10^9/L; differential shows increased numbers of neutrophils and immature WBCs (bands). Mrs O'Neal provides a sputum specimen for culture and Gram stain prior to seeing the doctor.

The doctor orders a chest x-ray after examining Mrs O'Neal. Based on her history, examination and the chest x-ray, he makes the diagnosis of acute bacterial pneumonia, probably pneumococcal. He prescribes the current antibiotic medication for pneumonia.

DIAGNOSES

- *Ineffective breathing pattern* related to pleuritic chest pain manifested by tachypnoea and shallow breaths.
- *Hyperthermia* related to inflammatory process manifested by febrile temperature.

PLANNING

- Assess knowledge and understanding of pneumonia and its effects.
- Assist to develop a medication schedule that coordinates with normal daily routine.

Expected outcomes

- Maintain normal pulmonary function.
- Describe measures to minimise elevations in body temperature.
- Identify a schedule for taking her medication that will facilitate compliance with the regimen.
- Describe manifestations that should be reported to the doctor.

IMPLEMENTATION

- Teach about the following:
  a. importance of avoiding use of a cough suppressant except at night to facilitate rest
  b. ways to increase fluid intake to reduce fever and maintain thin mucus for easy expectoration
  c. beneficial effects of rest, especially during the acute phase of her illness
  d. safe use of aspirin and paracetamol to reduce fever
  e. importance of taking all prescribed medication doses as scheduled
  f. common side effects of medications and their management
  g. early manifestations of penicillin allergy that necessitate stopping the medication and notifying the doctor
  h. signs of complications of pneumonia or worsening pneumonia to report.

EVALUATION

The sputum culture confirms *S. pneumoniae* as the cause of Mrs O'Neal's pneumonia. When she returns for her follow-up appointment, she reports that she began to feel better after 2 days on the penicillin and returned to work the following Monday. Her examination reveals good breath sounds throughout with no adventitious sounds. The follow-up sputum culture is free of pathogens.

CRITICAL THINKING IN THE NURSING PROCESS

1. Do any of the factors identified in the case study increase Mrs O'Neal's risk of acute bacterial pneumonia?
2. Even though Mrs O'Neal has no history of medication allergies, an anaphylactic reaction remains a potential risk. Describe the sequence of events leading to anaphylactic shock, its initial symptoms and immediate nursing interventions.
3. Had Mrs O'Neal required hospitalisation to treat her acute pneumonia, interruption of her usual activities and responsibilities could have led to anxiety. Develop a care plan for this situation, using the nursing diagnosis of *Ineffective role performance* related to hospitalisation.

REFLECTION ON THE NURSING PROCESS

1. Outline what you have learned from this case study that you will apply to your future practice.
2. You developed and undertook an eight-point teaching plan for Mrs O'Neal (see implementation above). Which evaluation data will demonstrate that this comprehensive teaching plan has been understood and will be successful?

factors such as advanced age and/or coexisting heart, kidney or liver disease are present.

Discuss the following topics when preparing the person and family for home care:

- the importance of completing the prescribed medication regimen as ordered
- recommendations for limiting activities and increasing rest
- maintaining adequate fluid intake to keep mucus thin for easier expectoration
- ways to maintain adequate nutritional intake, such as small, frequent, well-balanced meals
- the importance of avoiding smoking or exposure to second-hand smoke to prevent further irritation of the lungs
- manifestations to report to the doctor, such as increasing shortness of breath, difficulty breathing, increased fever, fatigue, headache, sleepiness or confusion.

CONSIDERATION FOR PRACTICE

Beware of any person with cardiac co-morbidities who develops a respiratory illness. Individuals with hypertension or cardiac failure may be inadvertently ordered both a sympathomimetic and a beta-blocker concomitantly (e.g. salbutamol and metoprolol). These two classes of drugs are contraindicated—sympathetic agonist and sympathetic antagonist.

The accompanying nursing care plan provides further nursing interventions for people treated in the community.

CONSIDERATION FOR PRACTICE

Epidemic: when there are more cases in a region than normal.
Pandemic: a worldwide epidemic.

THE PERSON WITH LUNG ABSCESS

A **lung abscess** is a localised area of lung destruction or necrosis and pus formation. The most common cause of lung abscess is aspiration and resulting pneumonia. Risk factors, therefore, are those for aspiration: decreased LOC due to anaesthesia, injury or disease of the central nervous system (CNS), seizure, excessive sedation or alcohol abuse; swallowing disorders; dental caries; and debilitation secondary to cancer or chronic disease. Lung abscess may also occur as a complication of some types of pneumonia, including those due to *S. aureus*, *Klebsiella* and *Legionella*. Many organisms can cause a lung abscess (see Figure 35.11).

Pathophysiology and manifestations

A lung abscess forms after lung tissue becomes consolidated (i.e. after alveoli become filled with fluid, pus and microorganisms). Consolidated tissue may become necrotic. This necrotic process can spread to involve the entire bronchopulmonary segment and progress proximally until it ruptures into a bronchus. With rupture, the contents of the abscess empty into the bronchus, leaving a cavity filled with air and fluid, a process known as *cavitation*. If purulent material from the abscess is not expectorated, the infection may spread, leading to diffuse pneumonia or a syndrome similar to acute respiratory distress syndrome.

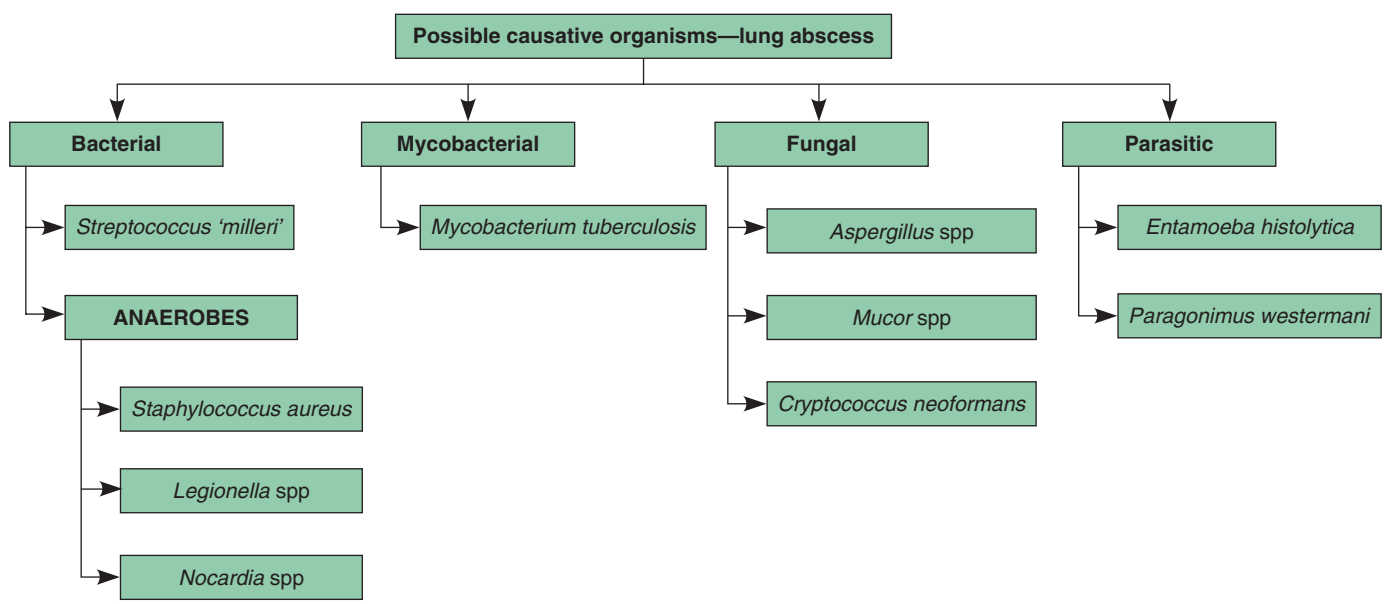

FIGURE 35.11 ■ Possible causative organisms—lung abscess

Source: Generated from information from the Royal College of Pathologists Australasia (RCPA) (2015). Retrieved from www.rcpa.edu.au/Library/Practising-Pathology/RCPA-Manual/Items/Clinical-Problems/L/Lung-absces.

Manifestations of lung abscess typically develop about 2 weeks after the precipitating event (aspiration, pneumonia and so on). Their onset may be either acute or insidious. Early symptoms are those of pneumonia: productive cough, chills and fever, pleuritic chest pain, malaise and anorexia. The temperature may be significantly elevated, 39.4°C or higher. When the abscess ruptures, the person may expectorate large amounts of foul-smelling, purulent and possibly blood-streaked sputum. Breath sounds are diminished and crackles may be noted in the region of the abscess. A dull percussion tone is also present.

INTERPROFESSIONAL CARE

The diagnosis of lung abscess usually is based on the history and presentation. The FBC may indicate leucocytosis. Sputum culture may not show the organism involved unless rupture occurs. Chest x-ray shows a thick-walled, solitary cavity with surrounding consolidation, although differentiating lung abscess from consolidation can be difficult until cavitation occurs.

Lung abscess is treated with antibiotic therapy. Postural drainage may be ordered to relieve obstruction and promote drainage. In some cases, bronchoscopy is used to drain the abscess. If the pleural space becomes involved, a chest tube (*tube thoracostomy*) may be used to drain the abscess. See the section on pneumothorax later in this chapter for further discussion of chest tubes.

Nursing care

Although most persons with lung abscess recover fully with appropriate antibiotic treatment, rupture and drainage of the abscess into a bronchus is a frightening experience. Nursing care needs of the individual relate primarily to maintaining a patent airway and adequate gas exchange.

Health education for the person and family focuses on the importance of completing the prescribed antibiotic therapy. Most lung abscesses are successfully treated with antibiotics; however, treatment may last up to 1 month or more. Emphasise the importance of completing the entire course of therapy to eliminate the infecting organisms. Infection from lung abscess can spread not only to lung and pleural tissue but also systemically, causing sepsis. If postural drainage is ordered, teach the person and family how to perform this procedure. When procedures such as bronchoscopy or thoracostomy are performed to drain the abscess, provide preoperative teaching and instruction on postoperative care.

THE PERSON WITH TUBERCULOSIS

Tuberculosis (TB) is a chronic, recurrent infectious disease that usually affects the lungs, although any organ can be affected. This disease, caused by *Mycobacterium tuberculosis*, is relatively uncommon in Australia. Although only 49 people in Australia died of tuberculosis in 2013 (ABS, 2015b), since 1999 an average of over 1100 people per year have been diagnosed with tuberculosis (see Figure 35.12). Many hospitalisations for tuberculosis are for migrants from the Philippines, India, Vietnam and China (King, Douglas & Beath, 2011).

Mycobacterium tuberculosis is a relatively slow-growing, slender, rod-shaped, acid-fast organism with a waxy outer capsule, which increases its resistance to destruction. Although the lungs are usually infected, tuberculosis can involve other organs as well. It is transmitted by *droplet nuclei*—airborne droplets produced when an infected person coughs, sneezes, speaks or sings. The tiny droplets can remain suspended in the air for several hours. Infection may develop when a susceptible host breathes in air containing droplet nuclei and the contaminated particle eludes the normal defences of the upper respiratory tract to reach the alveoli.

Incidence and prevalence

The incidence of tuberculosis in Australia is low in comparison with many other developing and developed countries, with a rate of approximately 5.7 per 100 000 people (Department of Health, 2015c). These results compare well with other countries; for example, South Africa records incidence at approximately 860 per 100 000 people and both Mozambique and Zimbabwe at approximately 552 per 100 000 people (WHO, 2014b). See Figure 35.13 for the WHO's estimated 2014 incidence globally by region.

In many other countries, including the US, TB is primarily attributed to the resurgence of HIV/AIDS; however, in Australia, only approximately 1% of individuals with TB have HIV/AIDS (Australian Government Department of Health, 2012). The highest incidence rates occur in the age group 20 to 44 years. The Northern Territory reports the highest incidence rates and Tasmania the lowest (see Figure 35.14).

The emergence of multidrug-resistant (MDR) strains of TB has complicated the treatment and control of this infectious respiratory disease. Nevertheless, mechanisms to reduce the development of drug resistance have been implemented to assist with this problem. Directly observed therapy (DOT), in which individuals are observed taking each and every medication dose, is recommended by the WHO. In Australia, the Department of Health has devised a 4-year strategic plan for the control of tuberculosis with priorities including improving surveillance, reducing disparities within subgroups and managing the risk of increasing drug resistance.

Risk factors

The risk of infection by *M. tuberculosis* is affected by characteristics of the infectious person, the extent of air contamination, duration of exposure and susceptibility of the host. The number of microbes in the sputum, frequency and force of coughing, and behaviours such as covering the mouth when coughing, affect

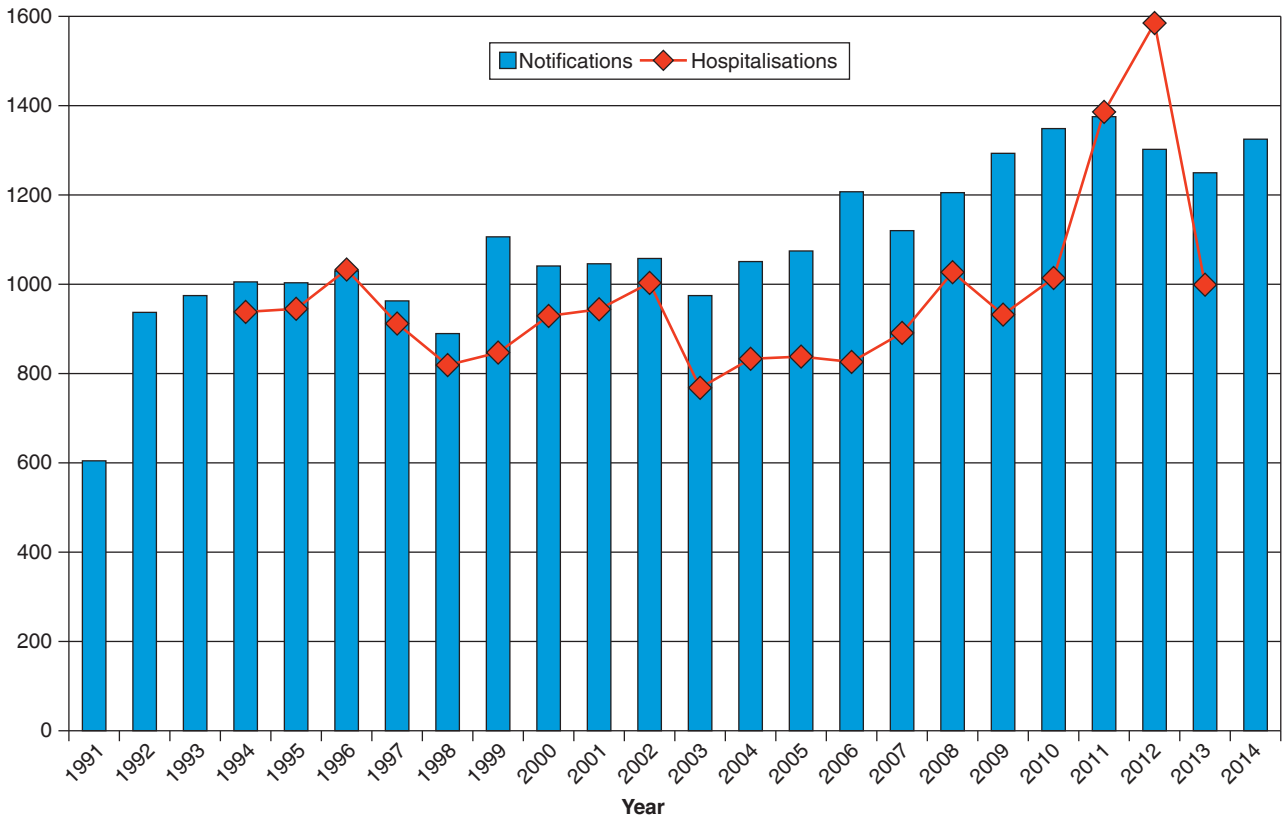

FIGURE 35.12 ■ Australian tuberculosis incidence 1991–2014, and hospitalisation admissions 1994–2013

the production of droplet nuclei. In a small, closed or poorly ventilated space, droplet nuclei become more concentrated, increasing the risk of exposure. Prolonged contact, such as living in the same household, increases the risk. Less-than-optimal immune function—a problem for people in lower socioeconomic groups, injecting drug users, the homeless, alcoholics and people with HIV infection—increases the susceptibility of the host.

Pathophysiology

Pulmonary tuberculosis

Minute droplet nuclei containing one to three bacilli that elude upper airway defence systems to enter the lungs implant in an alveolus or respiratory bronchiole, usually in an upper lobe. As the bacteria multiply, they cause a local inflammatory response. The inflammatory response brings neutrophils and macrophages to the site. These phagocytic cells surround and engulf the bacilli, isolating them and preventing their spread. *M. tuberculosis* continues to slowly multiply; some bacilli enter the lymphatic system to stimulate a cellular-mediated immune response. (See Chapter 11 for a review of immune responses.) Neutrophils and macrophages isolate the bacteria but cannot destroy them. A granulomatous lesion called a *tubercle*, a sealed-off colony of bacilli, is formed (Bullock & Hales, 2012). Within the tubercle, infected tissue dies, forming a cheese-like centre, a process called *caseation necrosis*.

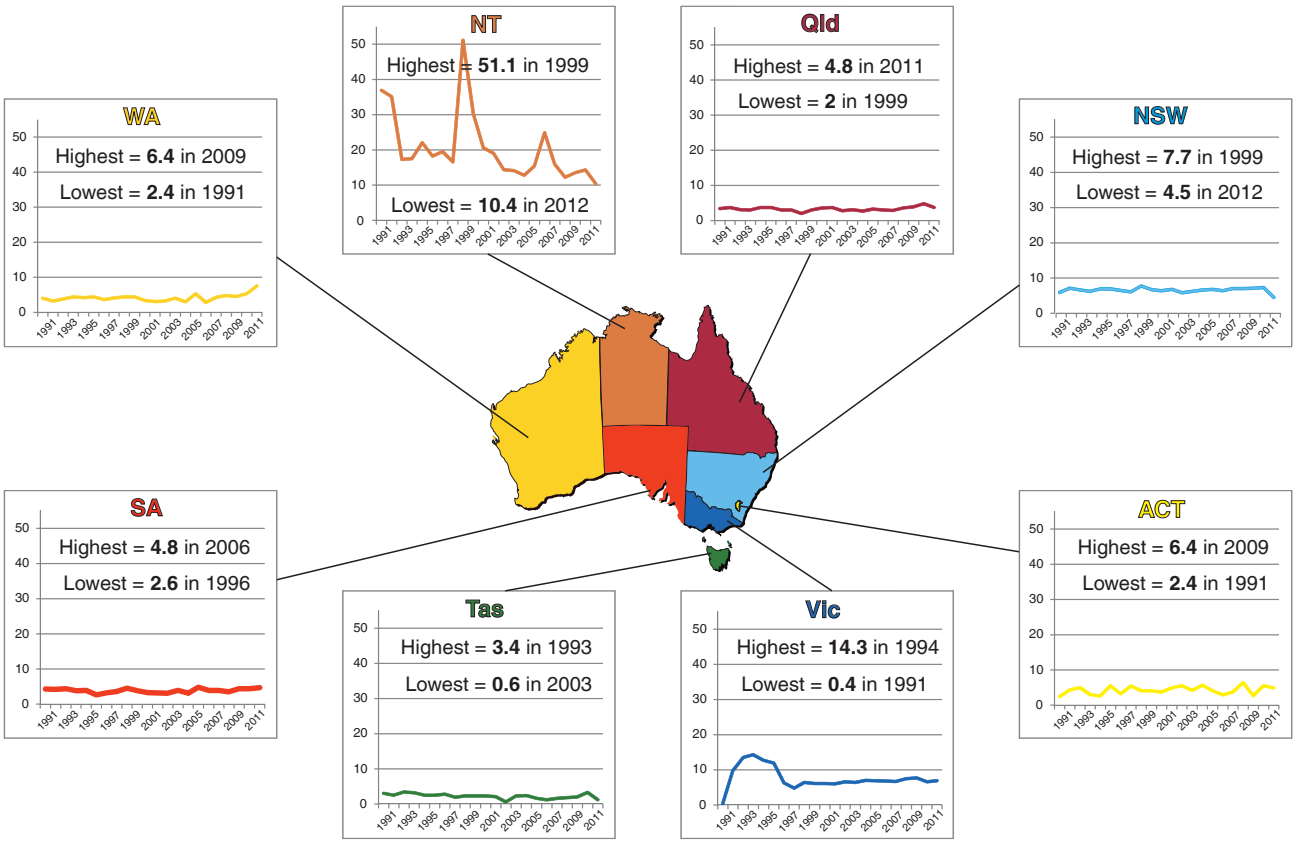

FIGURE 35.14 ■ Incidence of tuberculosis per state 1991–2012 (per 100 000 population)

Source: Generated from Department of Health (2015c). *National Notifiable Diseases Surveillance System. Number of notifications for tuberculosis by year, Australia, 1991 to 2015*. Retrieved from www9.health.gov.au/cda/source/rpt_4.cfm.

If the immune response is adequate, scar tissue develops around the tubercle and the bacilli remain encapsulated. These lesions eventually calcify and are visible on x-ray. The person, although infected by *M. tuberculosis*, does not develop TB, disease. If the immune response is inadequate to contain the bacilli, the disease of TB can develop. Occasionally, the infection can progress, leading to extensive destruction of lung tissue. In *primary tuberculosis*, granulomatous tissue may erode into a bronchus or into a blood vessel, allowing the disease to spread throughout the lung or other organs. This severe form of TB is uncommon in adults.

A previously healed TB lesion may be reactivated. *Reactivation tuberculosis* occurs when the immune system is suppressed due to age, disease or use of immunosuppressive drugs. The extent of lung disease can vary from small lesions to extensive cavitation of lung tissue. Tubercles rupture, spreading bacilli into the airways to form satellite lesions and produce tuberculosis pneumonia. Without treatment, massive lung involvement can lead to death or a more chronic process of tubercle formation and cavitation may result (Herchline, 2014). People with chronic disease continue to spread *M. tuberculosis* into the environment, potentially infecting others. 'Pathophysiology illustrated: tuberculosis' illustrates the pathogenesis of TB.

Individuals with HIV are at high risk of developing active TB, due to primary infection or reactivation. HIV infection suppresses cellular immunity, which is vital to limiting the replication and spread of *M. tuberculosis*.

MANIFESTATIONS AND COMPLICATIONS The initial infection causes few symptoms and typically goes unnoticed until the tuberculin test becomes positive or calcified lesions are seen on chest x-ray. Manifestations of primary progressive or reactivation TB often develop insidiously and are initially non-specific (see the 'Manifestations' box below). Fatigue, weight loss, anorexia, low-grade afternoon fever and night sweats are common. A dry cough develops, which later becomes productive of purulent and/or blood-tinged sputum. It is often at this stage that the person seeks medical attention.

MANIFESTATIONS Pulmonary tuberculosis

- Fatigue
- Weight loss
- Anorexia
- Low-grade afternoon fever and night sweats
- Cough: initially dry, later productive of purulent and/or blood-tinged sputum

NURSING CARE OF THE OLDER ADULT Tuberculosis

Presenting symptoms of tuberculosis in the older adult are often vague, including coughing, weight loss, anorexia, night sweats or periodic fevers. These signs and symptoms should not be dismissed as a normal part of ageing.

Tuberculin skin testing with purified protein derivative (PPD) is required when diagnosis is considered. A chest x-ray and sputum culture for acid-fast bacilli are obtained if the PPD is positive.

Successful treatment for TB generally requires four drugs for at least 6 months to totally eradicate the organism. Individuals are most often required to take the medication under the direct supervision of a nurse or other healthcare worker to improve adherence to the management regimen and decrease the risk of multidrug-resistant strains forming.

ASSESSING FOR HOME CARE

Community-dwelling older adults are susceptible to tuberculosis as well as those in care facilities.

Assess risk factors for tuberculosis:

- general health and nutritional status, including intake of specific nutrients such as vitamin D (lack of vitamin D is associated with a higher risk of developing active TB)
- presence of a chronic disease such as silicosis, diabetes, alcoholism or HIV infection; past history of a gastrectomy
- past history of a positive tuberculin test that now has converted to negative
- medications such as corticosteroids or other immunosuppressive drugs.

Assess living and social situation:

- natural light and ventilation in the home
- access to clean water, cooking facilities, supermarkets and other services
- possible exposure to infected people; for example, sharing a household with someone with active TB, crowded living facilities, homelessness, frequent participation in senior activities, volunteer work in residential care facilities or other institutional settings
- access to healthcare.

HEALTH EDUCATION FOR THE PERSON AND FAMILY

Teaching focuses on improving the older adult's ability to self-manage the disease and treatment. Teach about tuberculosis and how it is spread. Emphasise the importance of taking all medications as prescribed and complying with follow-up appointments and testing. Discuss the importance of:

- using disposable tissues to contain respiratory secretions, especially during the first 2 weeks of treatment when the disease may be transmitted to others
- avoiding exposure to crowds or people with infectious diseases
- eating a well-balanced diet with adequate nutrients
- getting adequate rest, sleep and exercise to maintain good general health
- ensuring that housemates or others having frequent contact with the person are tested and receive prophylactic treatment if indicated.

Teach about possible side effects of the prescribed medications and the importance of reporting these to healthcare providers (see Table 35.4).

TABLE 35.4 Antitubercular medications

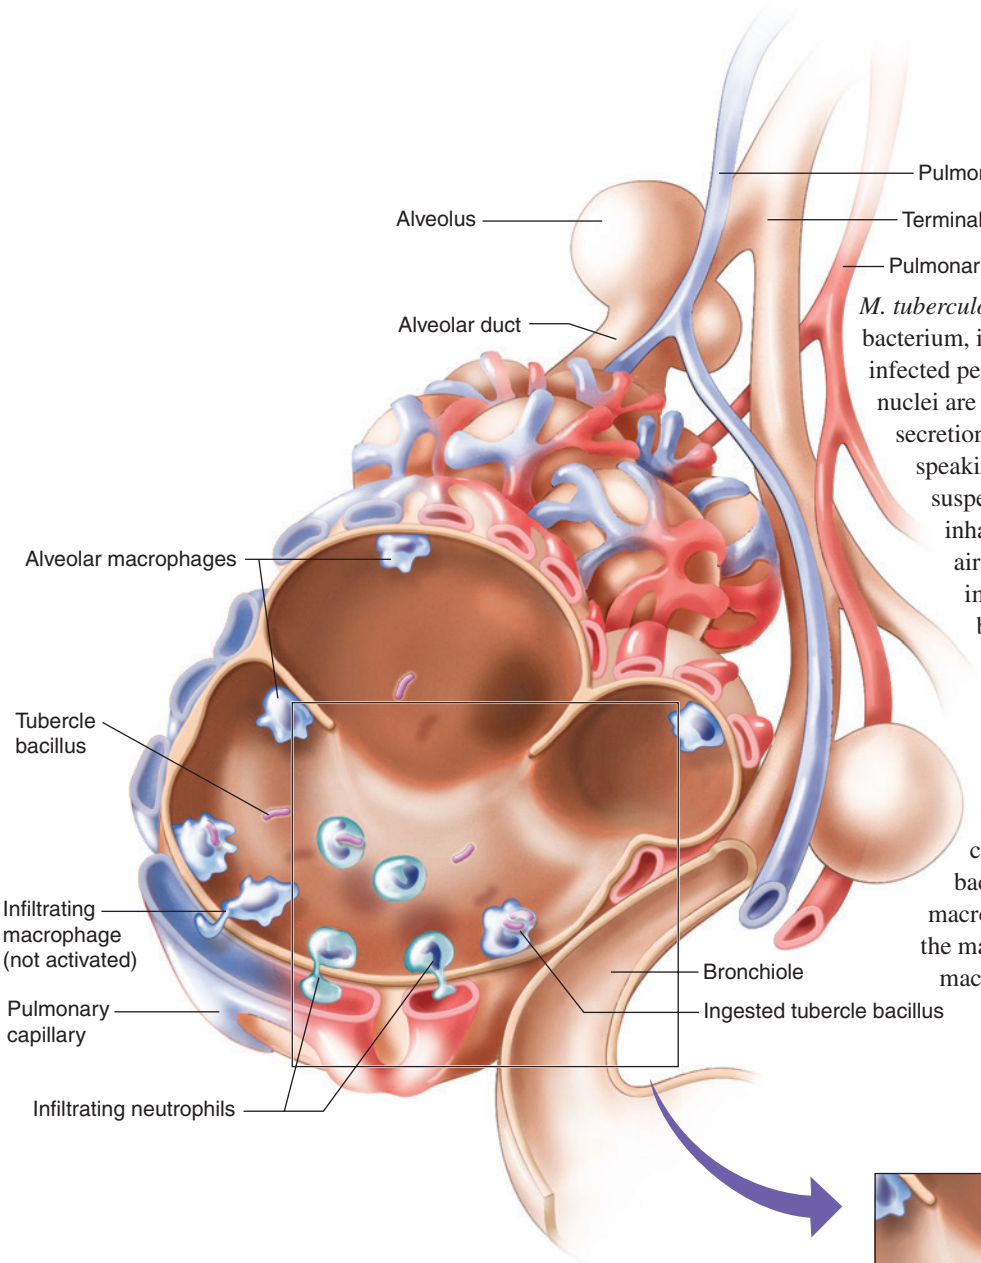
DRUG AND DOSAGE	ADVERSE EFFECTS	NURSING IMPLICATIONS
Isoniazid (INH), oral: 300 mg daily or 900 mg 1, 2 or 3 times weekly	Peripheral neuropathy Hepatitis	Administer pyridoxine (vitamin B_6) concurrently. Monitor liver function studies (AST and ALT); avoid other hepatotoxins.
Rifampicin (RMP), oral: 600 mg daily or 2 or 3 times weekly	Hepatitis Flu-like syndrome; fever Colours body fluids—including sweat, urine, saliva, tears and cerebrospinal fluid (CSF)—orange–red	As for INH. Do not miss or skip doses; flu-like syndrome and fever occur when drug is resumed. Contact lenses may become discoloured and should not be worn.
Pyrazinamide (PZA), oral: 1 to 2 g daily; or 2 to 4 g twice weekly	Hyperuricaemia Hepatotoxicity	Monitor uric acid levels. Monitor AST and ALT; avoid other hepatotoxins.
Ethambutol (EMB), oral: 800 mg to 1600 mg daily; or 2 to 4 g twice weekly	Optic neuritis	Monitor red–green colour discrimination and visual acuity.

Tuberculosis empyema and bronchopleural fistula are the most serious complications of pulmonary tuberculosis. When a tuberculosis lesion ruptures, bacilli may contaminate the pleural space. Rupture also may allow air to enter the pleural space from the lung, causing pneumothorax.

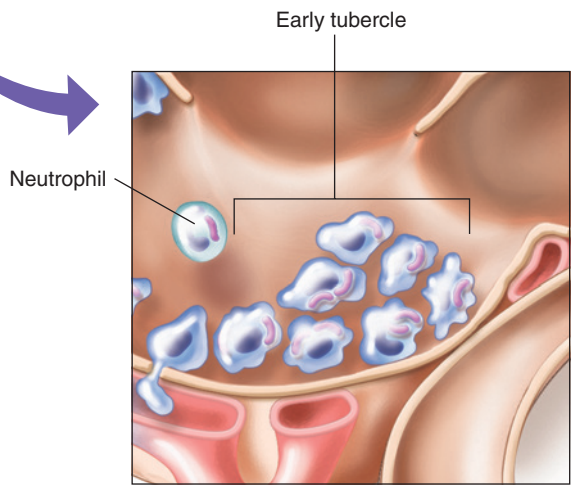
Extrapulmonary tuberculosis

When primary disease or reactivation allows live bacilli to enter the bronchi, the disease may spread through the blood and lymph system to other organs. These distant disease metastases may produce an active lesion or may become dormant

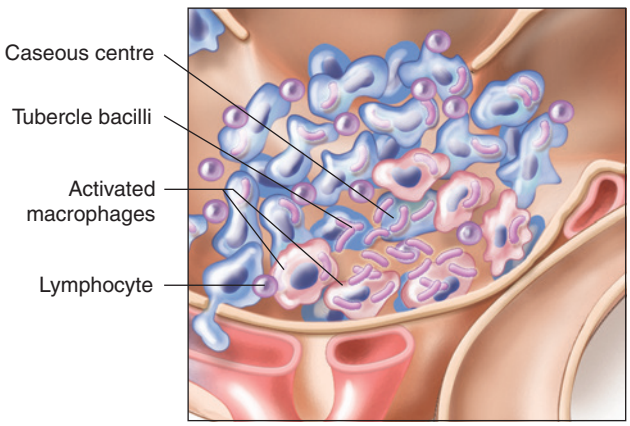
Tuberculosis



M. tuberculosis, a rod-shaped aerobic bacterium, is spread via droplet nuclei from an infected person to a susceptible host. Droplet nuclei are tiny droplets of respiratory secretions spread via coughing, sneezing or speaking. When dried, they can remain suspended in air for several hours. Most inhaled bacilli are trapped in the upper airways; those reaching distal airways implant in the respiratory bronchioles and alveoli. Rarely, these tubercle bacilli multiply unchecked to cause primary tuberculosis. In most cases, activated alveolar macrophages ingest the bacilli. The bacilli may be destroyed; however, unique characteristics of the tuberculosis bacillus resist its destruction by the macrophage. The bacilli multiply within the macrophage, eventually killing the macrophage.

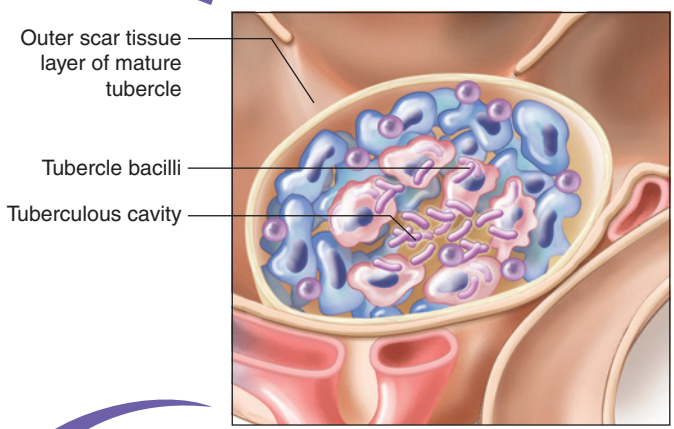


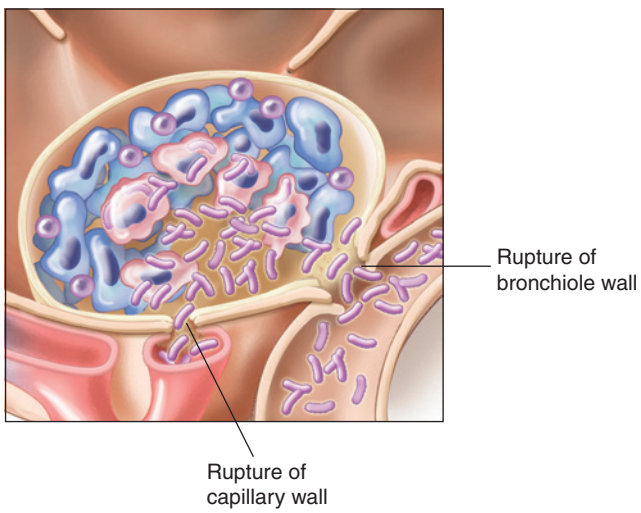
The dead macrophages lyse, releasing various chemotaxic factors into the bloodstream. Neutrophils and non-activated macrophages are attracted to the site. These phagocytic cells ingest the tubercle bacilli released from the lysed macrophages.



After several weeks, a delayed hypersensitivity response to bacterial antigens destroys many of the macrophages. Concurrently, a cell-mediated immune response activates additional macrophages, which ingest and destroy the bacilli. The lysed macrophages and bacilli are surrounded by a mass of live, activated macrophages and lymphocytes. Scar (granulomatous) tissue forms, encapsulating the primary lesion. Most lesions calcify and are visible on x-ray. These lesions may remain dormant for a year or more (in some cases, many years) before being reactivated to produce secondary or reactivation tuberculosis.

When the immune and macrophage-activating responses are weakened by age or disease (e.g. HIV disease), the tuberculosis bacilli continue to multiply within the lesion. The caseous material at the centre of the lesion liquefies, and the lesion grows.





The enlarging lesion damages surrounding bronchial walls and blood vessels. Granulomatous tissue surrounding the lesion can erode into a bronchus, forming an air-filling cavity. Within this cavity, the bacilli multiply, spreading into the airways and the environment via infected sputum. Bacilli also spread via the blood and within macrophages to regional lymph nodes, and from there to many organs and tissues. Resulting extrapulmonary lesions evolve in the same sequence as pulmonary lesions.

and reactivate at a later time. Extrapulmonary tuberculosis is especially prevalent in people with HIV.

FAST FACTS

- Immunisation with bacillus Calmette–Guérin (BCG) vaccine is not part of the standard vaccination regimen in Australia. However, individuals with high risk are encouraged to receive it.
- High-risk individuals include:
  - Indigenous Australian neonates in high TB incidence regions
  - infants born in Australia to migrant parents
  - children travelling (for an extended period) to countries of high TB prevalence
  - healthcare workers in frequent contact with people with TB.

Source: Department of Health (2015b). *Australian immunisation handbook* (10th ed.). Retrieved from www.immunise.health.gov.au/internet/immunise/publishing.nsf/Content/Handbook10-home~handbook10part4~handbook10-4-13.

FAST FACTS

- The organism causing tuberculosis, *Mycobacterium tuberculosis*, is spread through droplet nuclei that remain suspended in air for several hours.
- A tubercle is a sealed-off colony of bacilli; if it ruptures, organisms spread, leading to tuberculosis pneumonia.
- Primary or secondary TB lesions may affect other body systems such as the kidneys, genitalia, bone and brain.

INTERPROFESSIONAL CARE

Tuberculosis was a major public health concern early in the last century, before the development of effective sanitation measures and drug treatment. The development of drug-resistant strains, susceptibility of people with HIV disease and inadequate access to healthcare for high-risk populations contribute to TB continuing to be a significant public health threat. Interprofessional care, therefore, focuses on the following:

- early detection
- accurate diagnosis
- effective disease treatment
- preventing TB spread to others.

With appropriate treatment, individuals become non-infective to others fairly rapidly. Nurses and other healthcare workers are at risk of exposure if the disease has not yet been diagnosed. When a person with TB is hospitalised, maintain respiratory isolation to minimise the risk of infection to other people and the healthcare workers.

Non-adherence with prescribed treatment is a major problem in treating active TB: the person can continue transmitting the disease to others and drug-resistant strains of bacteria can develop when treatment is incomplete. Tuberculosis is a communicable disease and state and territory health authorities must be notified. Contact tracking will commence and individuals may be identified and examined. People who share living or work environments with the person are tested and may receive prophylactic treatment. Local health authorities or services will often continue contact with people who have active TB to facilitate effective containment and infection control.

Screening

The tuberculin test is used to screen for TB infection. A cellular or delayed hypersensitivity response to *M. tuberculosis* develops within 3 to 10 weeks after the infection. Injecting a small amount of *purified protein derivative (PPD)* of tuberculin any time thereafter activates this response, attracting macrophages to the area and causing a pronounced local inflammatory response. The amount of induration surrounding the injection site is used to determine infection (see Figure 35.15).

It is important to remember that a positive response indicates that infection and a cellular (T-cell) response have

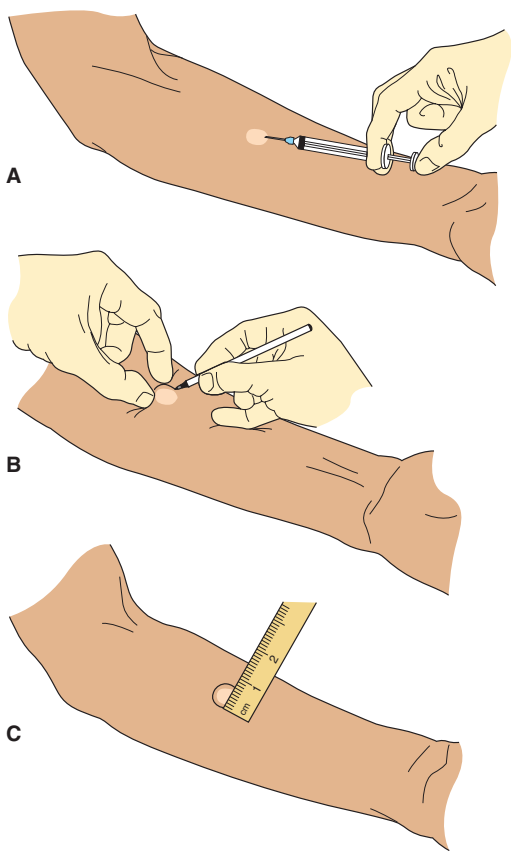


FIGURE 35.15 ■ *A*, Intradermal injection for tuberculin testing. *B*, The injection causes a local inflammatory response (wheal). *C*, Measurement of induration following tuberculin testing

developed; however, it does not mean that active disease is present or that the person is infectious to others.

Tuberculin testing should only be performed by individuals competent in the administration and assessment of the Mantoux test.

An intradermal injection of 5 units of PPD is administered into the inside forearm of the individual. The reaction is read at 48–72 hours. A negative test is defined as induration < 5 mm. All other results should be considered in the context of the clinical picture (RCPA, 2015).

Diagnosis

A positive tuberculin test alone does not indicate active disease. Sputum tests for the bacillus and chest x-rays are routinely used to diagnose and evaluate active disease. A series of three consecutive early morning sputum specimens is typically examined for bacilli (see Procedure 33.1).

See the 'Diagnostic tests' box in Chapter 33 for nursing care related to bronchoscopy.

- *Sputum smear* is microscopically examined for acid-fast bacilli. *M. tuberculosis* resists decolour chemicals after staining. This property is called *acid fast*. The acid-fast smear provides a rapid indicator of the tubercle bacillus.
- *Sputum culture* positive for *M. tuberculosis* provides the definitive diagnosis. However, *M. tuberculosis* is slow growing, requiring 4 to 8 weeks before it can be detected using traditional culture techniques. Automated radiometric culture systems (such as Bactec) allow detection of *M. tuberculosis* in several days.
- Once the organism is detected, *sensitivity testing* is performed to identify appropriate drug therapy.
- *Polymerase chain reaction (PCR)* permits rapid detection of DNA from *M. tuberculosis*.
- *Chest x-ray* is ordered to diagnose and evaluate TB. Typical findings in pulmonary TB include dense lesions in the apical and posterior segments of the upper lobe and possible cavity formation.

Nursing care

Health promotion

Tuberculosis today presents a greater threat to public health than it does to individuals. Nurses play a key role in maintaining public health. Education and tuberculosis screening are major nursing strategies to prevent TB.

Public health teaching includes increasing awareness of TB as a re-emerging threat. Teach people in all settings how to reduce the spread of TB by covering their mouths when coughing or sneezing and disposing of sputum appropriately. The benefit of screening programs to identify infected (though not necessarily infective) people also needs to be included in public health education.

The best TB prevention is early diagnosis of infections and appropriate treatment to achieve cure. BCG vaccine is recommended for infants born in countries where TB is prevalent.

Assessment

Focused assessment for the person with suspected TB includes the following:

- *Health history:* complaints of fatigue, weight loss, night sweats, difficulty breathing, cough (productive or nonproductive), bloody sputum or chest pain; known exposure to TB; most recent tuberculin test and results; living circumstances; alcohol and other recreational drug use.
- *Physical examination:* vital signs, including temperature; general appearance; respiratory rate and lung sounds.
- *Diagnostic tests:* tuberculin test results, presence of acid-fast bacilli in sputum, chest x-ray.

Nursing diagnoses and interventions

Nursing care related to tuberculosis focuses primarily on infection control and compliance with prescribed treatment.

Deficient knowledge

Adequate knowledge and information are necessary to manage the disease and prevent its transmission to others. The person needs to understand reasons for prolonged drug therapy and the importance of complying with treatment and follow up. Antitubercular agents are relatively toxic. The person needs to know how to minimise toxicity.

- Teach about TB and the prescribed treatment, including:
  a. nature of the disease and its spread
  b. purpose of treatment and follow-up procedures
  c. measures to prevent spreading the disease to others
  d. importance of maintaining good general health by eating a well-balanced, high-protein, high-carbohydrate diet; balancing exercise with rest; and avoiding crowds and people with upper respiratory infections
  e. names, doses, purposes and adverse effects of prescribed medications
  f. importance of avoiding alcohol and other substances that may damage the liver while taking chemotherapeutic drugs
  g. fluid intake needs of 2 to 3 L per day
  h. manifestations to report to the doctor: chest pain, haemoptysis, difficulty breathing; anorexia, nausea or vomiting; yellow tint to skin or sclera; sudden weight gain, swollen feet, ankles, legs or hands; hearing loss, tinnitus or vertigo; change in vision or difficulty discriminating colour.

  Tuberculosis is a chronic disease requiring lengthy treatment with antitubercular medications. A good understanding of the disease, its treatment and the potential adverse effects of therapy prepares the person to manage care.
- Document teaching and level of understanding. Reinforce teaching and learning as needed. *Teaching is not complete until the person can demonstrate learning of the information.*

NURSING CARE PLAN A person with tuberculosis

Harry Flanders, aged 53, arrives at a metropolitan public health clinic complaining of aching chest pain that has lasted for the past few days. He says that his sputum also is bloody. He is afraid he might have lung cancer, so he came in to see a doctor.

ASSESSMENT

The public health nurse at the clinic obtains an admission history and physical examination of Mr Flanders. The nurse notes that Mr Flanders is a homeless person who has lived on the streets and in various shelters for the past '10 years or so'. He usually prefers to sleep outdoors, taking refuge in shelters only during very cold or very wet weather. He has a small disability income, but usually scrounges for food or eats with other homeless people at soup kitchens. Mr Flanders states that he has had a cough for a long time, which has become worse recently. It is now productive, especially in the mornings. He also admits that he has recently been waking up drenched with sweat in the middle of the night and is more tired than usual.

Although Mr Flanders' clothes are tattered, he is fairly clean. He answers questions appropriately and intelligently. The nurse does not detect any odour of alcohol on his breath. He is very thin, almost emaciated. Mr Flanders' vital signs are BP 152/86, P 92, R 20 and T 37.8°C.

Suspecting tuberculosis, the nurse obtains a sputum specimen for Gram stain and culture, administers a tuberculin test and sends Mr Flanders for a chest x-ray before he sees the clinic doctor. Although the chest x-ray is inconclusive, the Gram stain is positive for acid-fast bacilli. The diagnosis of probable active pulmonary TB is made. The doctor prescribes isoniazid, 300 mg orally; rifampicin, 600 mg orally; and pyrazinamide, 1500 mg orally daily for 2 months, to be followed by twice-weekly isoniazid 900 mg orally and rifampicin 600 mg orally. The doctor also orders weekly sputum cultures for the first month.

DIAGNOSES

- *Ineffective health maintenance* related to homelessness.
- *Risk of non-adherance with prescribed treatment* related to lack of understanding and resources manifested by failure to attend clinic for direct observation therapy.
- *Inadequate nutrition* related to increased metabolic needs associated with infection manifested by very low body mass index.
- *Risk of altered sensory perception* related to effects of isoniazid therapy manifested by reports of altered sensory deficits.

PLANNING

- Utilise social work services to facilitate securing accommodation.
- Organise for directly observed medical therapy (DOT) to increase medication compliance and reduce multidrug-resistant TB.
- Identify verbally and in writing manifestations to report to the doctor.

Expected outcomes

- Keep all follow-up appointments as scheduled.
- Verbalise an understanding of his disease and its treatment.
- Follow the prescribed plan of care.
- Demonstrate measures to prevent spread of the organism to others.
- Gain 0.5–1 kg of weight per week.
- Promptly report symptoms of peripheral neuropathy, including numbness, tingling or burning sensations.

IMPLEMENTATION

- Teach about TB and provide an education pamphlet about the disease.
- Instruct about the prescribed medications, potential adverse effects and the importance of completing the entire prescribed regimen.
- Emphasise the importance of continued follow up.
- Teach and demonstrate sputum and droplet control measures.

EVALUATION

The healthcare team secures Mr Flanders accommodation and community assistance for DOT. He often still sleeps outside when the weather permits but he adheres to the requirement for supervised medication administration because he 'likes the food there'. Always a clean person, Mr Flanders is able to demonstrate appropriate sputum control measures and practises them faithfully. The sputum culture done after 2 months of treatment is negative for tubercle bacilli and his chest x-ray indicates no disease progression.

CRITICAL THINKING IN THE NURSING PROCESS

1. Many homeless people have schizophrenia or other mental diseases. How would you adapt the care plan for a homeless person with schizophrenia with active tuberculosis?
2. The public health nurse was fortunate in having access to an incentive shelter with healthcare workers to supervise medication compliance. Identify available resources in your area for homeless people infected with tuberculosis.
3. Develop a care plan for the nursing diagnosis of *Ineffective airway clearance* related to mucopurulent sputum and weak cough.

REFLECTION ON THE NURSING PROCESS

1. Outline what you have learned from this case study that you will apply to your future practice.
2. In this case study accommodation was found for Mr Flanders. Consider the situation where an individual chooses not to accept accommodation. Given that tuberculosis is a public health issue, which next steps would be necessary?

Risk of infection

- Place a mask on the person during transport to other parts of the facility for diagnostic or treatment procedures. *Covering the person's nose and mouth during transport minimises air contamination and the risk to visitors and personnel.*
- Inform all personnel having contact with the person of the diagnosis. *This allows personnel to take appropriate precautions.*
- Assist visitors to mask prior to entering the room. *Providing visitors with appropriate masks or respirators reduces their risk of infection.*
- Teach the person how to limit transmitting the disease to others:
  a. Always cough and expectorate into tissues.
  b. Dispose of tissues properly, placing them in a closed bag.
  c. Wear a mask if you are sneezing or unable to control respiratory secretions.
  d. The disease is not spread by touching inanimate objects, so no special precautions are required for eating utensils, clothing, books or other objects used.

Community-based care

Most people with TB are managed in community settings; few require institutionalisation. In addition to the teaching topics and strategies identified above, discuss the following topics when preparing the person and significant others for home care:

- importance of screening close contacts for infection and possibly prophylactic treatment
- effect, dose and timing for all medications, and potential side effects and their management
- importance of long-term therapy in eradicating the disease
- principles of good nutrition, dietary guidelines for a person with TB and other measures to help maintain good health, such as balancing rest with exercise
- signs and symptoms of complications to report to the doctor or healthcare provider.

Provide referrals as appropriate:

- smoking cessation clinics or support groups
- alcohol treatment facilities, Alcoholics Anonymous, other treatment programs or support groups
- drug treatment facilities, Narcotics Anonymous, other outpatient or inpatient treatment programs or support groups
- community clinics and incentive programs for people with TB
- counselling, support groups and other community resources that provide additional assistance and support.

THE PERSON WITH A FUNGAL INFECTION

Fungal spores are endemic and present in the air everyone breathes. Normal respiratory defence mechanisms allow few of these spores to reach the lungs. If they reach the lungs, pulmonary macrophages and neutrophils efficiently remove them in most people. When they do cause infection, it is typically mild and self-limiting. Most fungi are opportunistic, able to cause infection only in people who are immunocompromised. For this reason, people with AIDS, kidney failure, leukaemia, burns or chronic diseases, as well as people receiving corticosteroids or immunosuppressants, are particularly susceptible to fungal diseases.

The course and manifestations of fungal lung diseases resemble those of tuberculosis. Lung lesions are slow to develop and symptoms are mild. The fungus can disseminate from the lung to other organs.

Pneumocystis carinii pneumonia

Pneumocystis carinii pneumonia (PCP) is caused by a fungus, recently renamed *Pneumocystis jiroveci*. PCP is common in people with AIDS, and others with significant immunocompromise are at risk of developing an opportunistic pneumonia. Opportunistic infection may develop in people treated with immunosuppressive or cytotoxic drugs for cancer or organ transplant and in people with genetic or acquired immunodeficiency.

Infection with PCP produces patchy involvement throughout the lungs, causing affected alveoli to thicken, become oedematous and fill with foamy, protein-rich fluid. Gas exchange is severely impaired as the disease progresses.

PCP has an abrupt onset with fever, tachypnoea and shortness of breath, and a dry, non-productive cough. Respiratory distress can be significant, with intercostal retractions and cyanosis. Table 35.5 compares the manifestations of infectious pneumonias.

Aspergillosis

Aspergillus spores are common in the environment, but rarely cause disease except in the immunocompromised. When they do cause infection, *Aspergillus* species invade blood vessels and produce hyphae that branch at acute angles, frequently causing venous or arterial thrombosis. In the lungs, aspergillosis can cause an acute, diffuse, self-limited pneumonitis. The manifestations of pulmonary aspergillosis include dyspnoea, non-productive cough, pleuritic chest pain, chills and fever. If the organism invades a pulmonary blood vessel, haemoptysis or massive pulmonary haemorrhage can occur (Harman, 2015). In individuals with underlying lung disease, balls of *Aspergillus* hyphae may form within cysts or cavities, usually in the upper lobes of the lung. When this occurs, symptoms often are milder and more insidious in onset, with fever, weight loss, night sweats and cough.

INTERPROFESSIONAL CARE

Most fungal lung infections can be diagnosed by microscopic examination of a sputum specimen for the fungus. Blood cultures also may be taken, as well as cultures of cerebrospinal

TABLE 35.5 Manifestations of infectious pneumonias

TYPE	ONSET	RESPIRATORY MANIFESTATIONS	SYSTEMIC MANIFESTATIONS
Pneumococcal or lobar pneumonia	Abrupt	Cough productive of purulent or rust-coloured sputum; pleuritic or aching chest pain; decreased breath sounds and crackles over affected area; possible dyspnoea and cyanosis	Chills and fever
Bronchopneumonia	Gradual	Cough, scattered crackles; minimal dyspnoea and respiratory distress	Low-grade fever
Legionnaires' disease	Gradual	Dry cough; dyspnoea	Chills and fever; general malaise; headache; confusion; anorexia and diarrhoea; myalgias and arthralgias
Primary atypical pneumonia	Gradual	Dry, hacking, non-productive cough	Fever, headache, myalgias and arthralgias predominate
Viral pneumonia	Sudden or gradual	Dry cough	Flu-like symptoms
Pneumocystis pneumonia	Abrupt	Dry cough; tachypnoea and dyspnoea; significant respiratory distress	Fever

fluid if indicated. Chest x-ray may show typical changes in lung tissue or widening of the mediastinum, depending on the infecting organism.

A broad-spectrum antifungal agent is commonly prescribed to treat most fungal infections. Some fungal lung diseases and individuals who are immunocompromised are often treated with intravenous amphotericin B. Surgery (lobectomy) may be indicated for individuals with severe haemoptysis associated with aspergillosis.

Nursing care

People with fungal lung infections have different nursing care needs, depending on the disease and their immune status. For most people, nursing care focuses on education. People living in high-prevalence areas or who have specific risk factors such as exposure to bird droppings (e.g. by cleaning chicken coops, pigeon lofts or barns where birds roost), decomposed vegetation, rotting wood or stored grain need to be aware of the risk, common symptoms and measures to reduce the risk. Teach people receiving antifungal drugs about the specific drug, its intended and adverse effects, the duration of therapy and symptoms to report to the doctor. Include teaching about any specific precautions such as drug or food interactions. Amphotericin B is a toxic drug. Administer the initial intravenous dose slowly. Occasionally, premedication with an antihistamine and anti-emetic may be indicated to manage its adverse effects. Monitor carefully during infusion and therapy for changes in vital signs, hydration, nutrition, weight or urine output.

DISORDERS OF THE PLEURA

The *pleura* is a thin membrane with two layers: the visceral pleura, which overlies the lung surface; and the parietal pleura, which lines the inner chest wall. Between the layers of pleura is a potential space, the *pleural cavity*, which contains a thin layer of serous fluid. As the thoracic cavity expands during inspiration, the pressure in this space becomes negative in relation to atmospheric and alveolar pressure. The expansible lung is drawn out and air rushes into the alveoli. When the pleura is inflamed or affected by disease or injury, air or fluid can collect in the pleural cavity, restricting lung expansion, air movement and ventilation.

THE PERSON WITH PLEURITIS

Pleuritis (*pleurisy*), inflammation of the pleura, irritates sensory fibres of the parietal pleura, causing characteristic pain. Pleural inflammation usually occurs secondarily to another process, such as a viral respiratory illness, pneumonia or rib injury.

The onset of pleuritis is typically abrupt. The pain is unilateral and well localised; it is usually sharp or stabbing in nature. Pain may be referred to the neck or the shoulder. Deep breathing, coughing and movement aggravate the pain. Respirations

are rapid and shallow, and chest wall movement is limited on the affected side. Breath sounds are diminished and a pleural friction rub may be heard over the site.

The diagnosis of pleuritis is based on its manifestations. Chest x-ray and ECG may be ordered to rule out other causes of chest pain. Treatment for pleuritis is symptomatic. Analgesics and non-steroidal anti-inflammatory drugs (NSAIDs)—indomethacin (Indocin), in particular—help relieve the pain. Codeine may be ordered, both to relieve pain and to suppress the cough.

Nursing care for the person with pleuritis is directed towards promoting comfort, including administration of NSAIDs and analgesics. Positioning and splinting the chest while coughing also are helpful.

Teach the individual and family that pleuritis is generally self-limited and of short duration. Discuss symptoms to report to the doctor: increased fever, productive cough or shortness of breath. Provide information about prescription and non-prescription NSAIDs and analgesics, including the drug ordered, how to use it and its desired and possible adverse effects.

THE PERSON WITH A PLEURAL EFFUSION

The pleural space normally contains only about 10 to 20 mL of serous fluid.

Pleural effusion is collection of excess fluid in the pleural space. Pleural effusions result from either systemic or local disease. Systemic disorders that may lead to pleural effusion include heart failure, liver or kidney disease, and connective tissue disorders, such as rheumatoid arthritis and systemic lupus erythematosus (SLE). Pneumonia, atelectasis, tuberculosis, lung cancer and trauma are local conditions that may cause pleural effusion.

Pathophysiology and manifestations

Excess pleural fluid may be either *transudate*, formed when capillary pressure is high or plasma proteins are low, or *exudate*, the result of increased capillary permeability. Heart failure is the most common precipitating factor in transudate formation; it may also accompany kidney failure, nephrosis, liver failure and malignancy. Exudate, a protein-rich fluid, is seen with inflammatory processes such as infections, systemic inflammation (e.g. rheumatoid arthritis or SLE), pulmonary infarction (leading to tissue necrosis and an inflammatory response) and malignancy (Bullock & Hales, 2012). Other pleural fluid collections include *empyema*, pus in the pleural cavity; *haemothorax*, the presence of blood in the cavity; *haemorrhagic pleural effusion*, a mixture of blood and pleural fluid; and *chylothorax*, a collection of lymph in the pleural space. In adults, chylothorax may be iatrogenic resulting from thoracic surgery or placement of a central line in one of the great veins (Adams, 2014).

A large pleural effusion compresses adjacent lung tissue. This causes the characteristic manifestation of dyspnoea. Pain may develop, although with inflammatory processes pleuritic pain often is relieved by formation of an effusion, as the fluid reduces friction between inflamed visceral and parietal pleura. Breath sounds are diminished or absent and a dull percussion tone is heard over the affected area. Chest wall movement may be limited.

INTERPROFESSIONAL CARE

Chest x-ray often provides the first evidence of a pleural effusion. Because fluid typically collects in dependent regions, it is seen at the base of the affected lung on an upright chest x-ray and along the lateral wall when the person is positioned on the affected side. CT scans and ultrasonography also are used to localise and differentiate pleural effusions.

Thoracentesis

If the cause of pleural effusion is not apparent, a thoracentesis is undertaken. **Thoracentesis** is an invasive procedure in which fluid (or occasionally air) is removed from the pleural space with a needle. Aspirated fluid is analysed for appearance, cell counts, protein and glucose content, the presence of enzymes such as LDH and amylase, abnormal cells and culture.

When pleural effusion is significant and interferes with respirations, thoracentesis is the treatment of choice to remove the fluid (see Figure 35.16). Thoracentesis may be performed at the bedside, in a procedure room or in an outpatient setting. Local anaesthesia is used and the procedure can be performed in less than 30 minutes. Percussion, auscultation, radiography or ultrasonography are used to locate the effusion and needle insertion site. The amount of fluid removed is limited to 1200 to 1500 mL at one time to reduce the risk of cardiovascular collapse from rapid removal of too much fluid. Pneumothorax is a possible complication of thoracentesis if the visceral pleura is punctured or a closed drainage system is not maintained during the procedure. Nursing care for the person undergoing a thoracentesis is outlined in the box below.

Treatments

Because pleural effusion usually occurs secondarily to another disease or disorder, medical management also focuses on treating the underlying condition to prevent further fluid accumulation. An empyema may require repeated drainage, as well as high doses of parenteral antibiotics. Occasionally, thoracotomy and surgical excision may be necessary. See the box later in this chapter for nursing care of the person having lung surgery. Recurrent pleural effusions, often due to cancer, may be prevented by instilling an irritant, such as talc, into the pleural space to cause adhesion of the parietal and visceral pleura (*pleurodesis*). Water-seal chest tube drainage is often employed for haemothorax.

Nursing care

Nursing care for the person with a pleural effusion is directed towards supporting respiratory function and assisting with procedures to evacuate collected fluid. With a large pleural effusion and partial lung collapse, *Impaired gas exchange* and

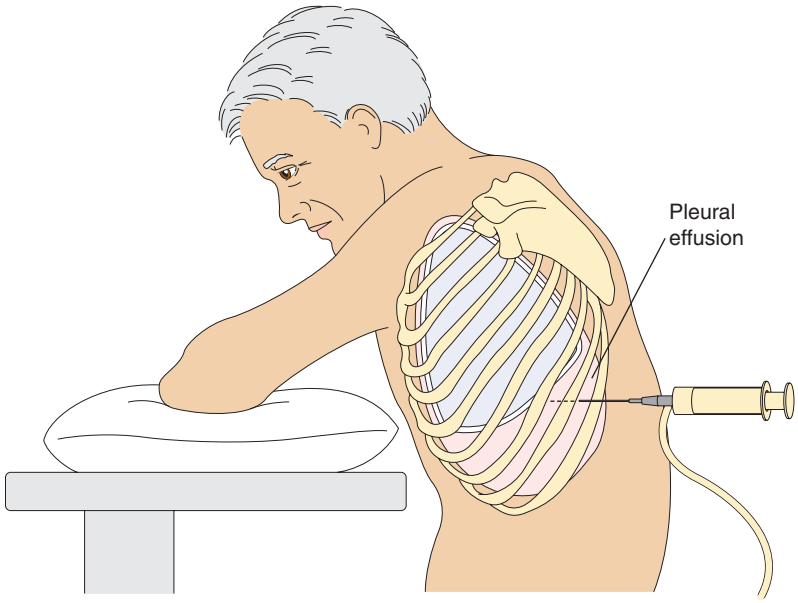

FIGURE 35.16 ■ Thoracentesis. With the person seated, a needle is inserted between the ribs into the pleural space to withdraw accumulated fluid

Activity intolerance are high-priority nursing problems. *Risk of impaired gas exchange* is also a priority problem during the initial period following thoracentesis.

Teaching for home care focuses on symptoms of recurrent effusion or complications following a thoracentesis to report to the doctor: increasing dyspnoea, cough and haemoptysis. Pleuritic pain may be an early sign of effusion and should also be reported. Further teaching about an underlying condition also may be necessary; for example, the person with heart failure may need teaching about a salt-restricted diet.

NURSING CARE OF THE PERSON having a thoracentesis

BEFORE THE PROCEDURE

- Verify a signed informed consent for the procedure. *This invasive procedure requires informed consent.*
- Assess knowledge and understanding of the procedure and its purpose; provide additional information as needed. *A person who is fully informed will be less apprehensive and more able to cooperate during the thoracentesis.*
- Pre-procedure fasting or sedation is not required. *Only local anaesthesia is used in this procedure and the gag and cough reflexes remain intact.*
- Administer a cough suppressant if indicated. *Movement and coughing during the procedure may cause inadvertent damage to the lung or pleura.*
- Obtain a thoracentesis tray, sterile gloves, injectable lignocaine, povidone-iodine, dressing supplies and an extra over-bed table or Mayo stand. *These supplies are used by the doctor performing the procedure.*
- Position the person upright, leaning forward with arms and head supported on an anchored over-bed table. *This position spreads the ribs, enlarging the intercostal space for needle insertion.*
- Inform the person that, although local anaesthesia prevents pain as the needle is inserted, a sensation of pressure may be felt. *A pressure sensation occurs as the needle punctures the parietal pleura to enter the pleural space.*

DURING AND AFTER THE PROCEDURE

- Monitor pulse, colour, oxygen saturation and other signs during thoracentesis. *These are indicators of physiological tolerance of the procedure.*
- Apply a dressing over the puncture site and position on the unaffected side for 1 hour. *This allows the pleural puncture to heal.*
- Label obtained specimen with name, date, time, source; send specimen to the laboratory for analysis. *Fluid obtained during thoracentesis may be examined for abnormal cells, bacteria and other substances to determine the cause of the pleural effusion.*
- During the first several hours after thoracentesis, frequently assess and document vital signs; oxygen saturation; respiratory status, including respiratory excursion, lung sounds, cough or haemoptysis; and puncture site for bleeding or crepitus. *Frequent assessment is important to detect possible complications of thoracentesis, such as pneumothorax.*
- Obtain a chest x-ray. *Chest x-ray is ordered to detect possible pneumothorax.*
- Normal activities generally can be resumed after 1 hour if no evidence of pneumothorax or other complication is present. *The puncture wound of thoracentesis heals rapidly.*

THE PERSON WITH PNEUMOTHORAX

Accumulation of air in the pleural space is called **pneumothorax**. Pneumothorax can occur spontaneously, without apparent cause, as a complication of pre-existing lung disease, as a result of blunt or penetrating trauma to the chest, or from an iatrogenic cause (e.g. following thoracentesis).

Pathophysiology

Pressure in the pleural space is normally negative in relation to atmospheric pressure. This negative pressure is vital to the process of breathing. Contraction of the diaphragm and the intercostal muscles enlarges the thoracic space. Negative intrapleural pressure draws the lung outwards, increasing its volume so air rushes in to fill the expanded lung space.

When either the visceral or the parietal pleura is breached, air enters the pleural space, equalising this pressure. Lung expansion is impaired and the natural recoil tendency of the lung causes it to collapse to a greater or lesser extent, depending on the size and rapidity of air accumulation. Table 35.6 illustrates the classifications of pneumothorax.

Spontaneous pneumothorax

Spontaneous pneumothorax develops when an air-filled bleb, or blister, on the lung surface ruptures. Rupture allows air from the airways to enter the pleural space. Air accumulates until pressures are equalised or until collapse of the involved lung section seals the leak. Spontaneous pneumothorax may be either *primary* (*simple*) or *secondary* (*complicated*).

Primary pneumothorax affects men who are relatively well, most often smokers, usually tall, slender and between ages 18 and 40 (Daley, 2015). The cause of primary pneumothorax is unknown. Air-filled blebs tend to form in the apices of the lungs. This is considered to be a benign condition, although recurrences are common. Certain activities also increase the risk of spontaneous pneumothorax, such as high-altitude flying and rapid decompression during scuba diving.

Secondary pneumothorax, generally caused by overdistension and rupture of an alveolus, is more serious and potentially life threatening. It develops in people with underlying lung disease, usually COPD. Middle-aged and older adults are primarily affected. Secondary pneumothorax also may be associated with asthma, cystic fibrosis, pulmonary fibrosis, tuberculosis, acute respiratory distress syndrome (ARDS) and other lung diseases. Rarely, a form of secondary pneumothorax called *catamenial pneumothorax* can develop in affected women within 24 to 48 hours of the onset of menstrual flow.

MANIFESTATIONS The manifestations of spontaneous pneumothorax depend on size of the pneumothorax, extent of lung collapse and any underlying lung disease. Typically, pleuritic chest pain and shortness of breath begin abruptly, often while at rest. The respiratory and heart rates increase as gas exchange is affected. Chest wall movement may be asymmetrical, with less movement on the affected side than the unaffected side. The affected side is hyperresonant to percussion and breath sounds may be diminished or absent. Hypoxaemia may develop, although normal mechanisms that shunt blood flow to the unaffected lung often maintain normal oxygen saturation levels. Hypoxaemia is more pronounced in secondary pneumothorax.

Traumatic pneumothorax

Blunt or penetrating trauma of the chest wall and pleura can cause pneumothorax. Blunt trauma—for example, due to a motor vehicle crash, fall or during cardiopulmonary resuscitation (CPR)—can lead to a *closed pneumothorax*. Fractured ribs penetrating the pleura are the leading cause of pneumothorax due to blunt trauma (Daley, 2015). Fracture of the trachea and a ruptured bronchus or oesophagus also may result from blunt trauma, leading to closed pneumothorax.

Open pneumothorax (*sucking chest wound*) results from penetrating chest trauma such as a stab wound, gunshot wound or impalement injury. With open pneumothorax, air moves freely between the pleural space and the atmosphere through the wound. Pressure on the affected side equalises with the atmosphere and the lung collapses rapidly. The result is significant hypoventilation.

Iatrogenic pneumothorax may result from puncture or laceration of the visceral pleura during central-line placement, thoracentesis or lung biopsy. During bronchoscopy, bronchi or lung tissue can be disrupted. Alveoli can become over distended and rupture during anaesthesia, resuscitation procedures or mechanical ventilation.

MANIFESTATIONS With traumatic pneumothorax, manifestations of pain and dyspnoea may be masked or missed due to other injuries. Tachypnoea and tachycardia may be attributed to the primary injury. Focused assessment for evidence of pneumothorax is vital. Chest wall movement on the affected side is diminished and breath sounds are absent. If a penetrating wound is present, air may be heard and felt moving through it with respiratory efforts. Haemothorax frequently accompanies traumatic pneumothorax. The manifestations of iatrogenic pneumothorax are similar to those of spontaneous pneumothorax.

Tension pneumothorax

Tension pneumothorax develops when injury to the chest wall or lungs allows air to enter the pleural space but prevents it from escaping. Pressure within the pleural space becomes positive in relation to atmospheric pressure as air rapidly accumulates with each breath. The lung on the affected side collapses and pressure on the mediastinum shifts thoracic organs to the unaffected side of the chest, placing pressure on the opposite lung as well. Ventilation is severely compromised and venous return to the heart is impaired. Tension pneumothorax is a medical emergency requiring immediate intervention to preserve respiration and cardiac output.

MANIFESTATIONS In addition to manifestations of pneumothorax, hypotension and distended neck veins are evident as venous return and cardiac output are affected. The trachea is displaced towards the unaffected side as a result of the mediastinal shift. Signs of shock may be present. See Chapter 10 for the manifestations and treatment of shock.

TABLE 35.6 Types of pneumothorax

TYPE	PATHOPHYSIOLOGY	MANIFESTATIONS
A Spontaneous 	Rupture of a bleb on the lung surface allows air to enter pleural space from airways. • *Primary pneumothorax* affects previously healthy people. • *Secondary pneumothorax* affects people with pre-existing lung disease (e.g. COPD).	• Abrupt onset • Pleuritic chest pain • Dyspnoea, shortness of breath • Tachypnoea, tachycardia • Unequal lung excursion • Decreased breath sounds and hyperresonant percussion tone on affected side
B Traumatic 	Trauma to the chest wall or pleura disrupts the pleural membrane. • *Open* occurs with penetrating chest trauma that allows air from the environment to enter the pleural space. • *Closed* occurs with blunt trauma that allows air from the lung to enter the pleural space. • *Iatrogenic* involves laceration of visceral pleura during a procedure such as thoracentesis or central-line insertion.	• Pain • Dyspnoea • Tachypnoea, tachycardia • Decreased respiratory excursion • Absent breath sounds in affected area • Air movement through an open wound
C Tension 	Air enters pleural space through chest wall or from airways but is unable to escape, resulting in rapid accumulation. Lung on affected side collapses. As intrapleural pressure increases, heart, great vessels, trachea and oesophagus shift towards the unaffected side.	• Hypotension, shock • Distended neck veins • Severe dyspnoea • Tachypnoea, tachycardia • Decreased respiratory excursion • Absent breath sounds on affected side • Tracheal deviation towards unaffected side

INTERPROFESSIONAL CARE

Treatment for pneumothorax depends on the severity of the problem. A small simple pneumothorax may require no treatment other than monitoring with serial x-rays. Air is absorbed from the pleural space, allowing most small pneumothoraces to resolve spontaneously. A large pneumothorax with significant symptoms usually requires treatment with *thoracostomy* or the placement of chest tubes. Surgical intervention may be necessary to prevent recurrent spontaneous pneumothorax.

Diagnosis

Oxygen saturation measurements are obtained to evaluate the effect of pneumothorax on gas exchange. ABGs may be obtained to further assess gas exchange.

The chest x-ray is an effective diagnostic tool for pneumothorax. In tension pneumothorax, air is evident on the affected side and mediastinal structures are shifted towards the opposite or unaffected side.

Treatments

CHEST TUBES The treatment of choice for significant pneumothorax is placement of a closed-chest catheter to allow the lung to re-expand. When a tube is placed in the pleural cavity to remove air or fluid, it must be sealed to prevent air from also entering the tube and, in essence, creating an open pneumothorax. Chest tubes are sealed with a Heimlich (one-way) valve (see Figure 35.17) or connected to a closed drainage system with a 'water seal'. The valve or water seal prevents air from entering the chest cavity during inspiration and allows air to escape during expiration. Applying a low level of suction to the system helps to re-establish negative pressure in the pleural space, allowing the lung to re-expand.

A number of closed-drainage chest tube systems are available. Most are self-contained disposable systems (see Figure 35.18). Drainage from the chest tube is collected in the first collection chamber. This sealed chamber is connected to a water seal chamber, which is in turn connected to the suction control chamber. Nursing care of the person with chest tubes is discussed in the box below.

A large-bore needle or plastic intravenous catheter may be inserted through the chest wall as emergency treatment of a tension pneumothorax. This allows air to escape from the affected side, relieving pressure on mediastinal structures and the opposite lung.

FIGURE 35.17 ■ The Heimlich one-way valve allows air to escape from the pleural space, helping to re-establish negative pressure and allowing the lung to re-expand

Source: George Draper/Pearson Education.

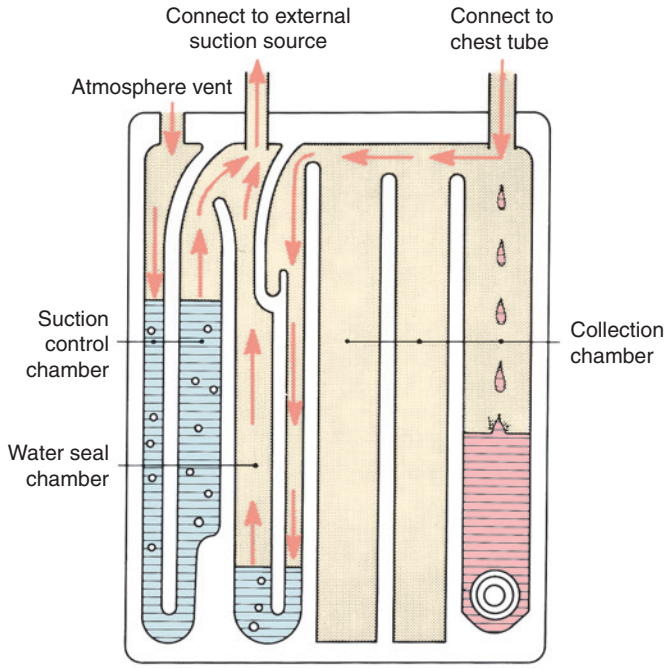

FIGURE 35.18 ■ A closed-chest drainage system

PLEURODESIS Although controversial, *pleurodesis*, or creation of adhesions between the parietal and visceral pleura, may be used to prevent recurrent pneumothorax. This procedure involves instilling a chemical agent such as talc into the pleural space. The subsequent inflammatory response creates scar tissue and adhesions between the pleural layers. This procedure reduces the recurrence rate to as low as 2% but can make subsequent surgery more difficult (Daley, 2015).

Surgery

The risk of recurrence of spontaneous pneumothorax increases with each attack. People at high risk of recurrent pneumothorax may have surgery to reduce the risk of future ruptures. A thoracotomy is done to excise or oversew blebs (usually at the apices of the lungs). The overlying pleura is then roughened or irritated to induce scarring and adhesion to the surface of the lung. In some cases, the parietal pleura may be partially excised. These procedures can be done using video-assisted thoracoscopic surgery (VATS), a minimally invasive surgical technique (Daley, 2015).

Nursing care

Health promotion

Health promotion activities to prevent spontaneous and traumatic pneumothorax primarily involve health teaching. Initiate and participate in programs to prevent smoking by children and teenagers.

NURSING CARE OF THE PERSON with chest tubes

BEFORE THE PROCEDURE

- Ensure a signed informed consent for chest tube insertion. *This invasive procedure requires informed consent.*
- Provide additional information as indicated. Explain that local anaesthesia will be used but that pressure may be felt as the trocar is inserted. Reassure that breathing will be easier once the chest tube is in place and the lung re-expands. *The person may be extremely anxious and may need reassurance that this invasive procedure will provide relief.*
- Gather all needed supplies, including thoracostomy tray, injectable lignocaine, sterile gloves, chest tube drainage system, sterile water and a large, sterile, catheter-tipped syringe to use as a funnel for filling water-seal and suction chambers. *These supplies are used during the insertion procedure to establish a water-seal drainage system.*
- Position as indicated for the procedure. *Either an upright position (as for thoracentesis) or a side-lying position may be used, depending on the site of the pneumothorax.*
- Assist with chest tube insertion as needed. The procedure may be performed in a procedure room, in the surgical suite or at the bedside. *Although chest tube insertion is a relatively simple procedure, nursing assistance is necessary to support the person and rapidly establish a closed drainage system.*

AFTER THE PROCEDURE

- Assess respiratory status at least every 4 hours. *Frequent assessment is necessary to monitor respiratory status and the effect of the chest tube.*
- Maintain a closed system. Tape all connections and secure the chest tube to the chest wall. *These measures are important to prevent inadvertent tube removal or disruption of system integrity.*
- Keep the intercostal catheter's underwater-seal drain system below the level of the chest. *Pleural fluid drains into the collection apparatus by gravity flow.*
- Check tubes frequently for kinks or loops. *These could interfere with drainage.*
- Check the water seal frequently. The water level should fluctuate with respiratory effort. If it does not, the system may not be patent or intact. Periodic air bubbles in the water-seal chamber are normal and indicate that trapped air is being removed from the chest. *Frequent assessment of the system is important to ensure appropriate functioning.*
- Measure swinging, bubbling and drainage every hour, marking the level on the drainage chamber. Report drainage that is cloudy, in excess of 70 mL per hour or red, warm and free flowing. *Red, free-flowing drainage indicates haemorrhage; cloudiness may indicate an infection.*
- Periodically assess water level in the suction control chamber, adding water as necessary. *Adequate water in the suction control chamber prevents excess suction from being placed on delicate pleural tissue.*
- Assist with frequent position changes and sitting and ambulation as allowed. Chest tubes should not prevent performance of allowed activities. *Care is needed to prevent inadvertent disconnection or removal of the tubes.*
- When the chest tube is removed, immediately apply a sterile occlusive dressing. *An occlusive dressing prevents air from re-entering the pleural space through the chest wound.*

Teach safe behaviours such as always wearing a seat belt in a motor vehicle, driving safely and using precautions to prevent falls when working or recreating in high places.

Assessment

The person with pneumothorax may be in acute respiratory distress, necessitating rapid and focused assessment.

- *Health history:* current symptoms and their duration; precipitating factors or activities if known; previous episodes of pneumothorax; smoking history; chronic pulmonary diseases such as COPD.
- *Physical assessment:* general appearance and degree of apparent respiratory distress; evidence of chest trauma; vital signs, oxygen saturation, skin colour, LOC; respiratory excursion, percussion tone and breath sounds anterior and posterior chest; neck vein inspection, position of trachea; peripheral pulses.
- *Diagnostic tests:* chest x-ray, ABGs.

Nursing diagnoses and interventions

Maintaining or restoring adequate alveolar ventilation and gas exchange is of highest priority for the person with a pneumothorax. Chest tubes may interfere with physical mobility, contributing to a high risk of injury.

Impaired gas exchange

Loss of negative pressure in the pleural cavity and the resulting collapse of lung tissue can cause poor chest expansion and loss of alveolar ventilation. As the pneumothorax is removed or reabsorbed, ventilation and gas exchange improve.

- Assess and document vital signs and respiratory status, including rate, depth, lung sounds and oxygen saturation at least every 4 hours. *Frequent assessment is important to monitor the adequacy of respirations and lung expansion.*
- Place in Fowler's or high-Fowler's position. *This position facilitates lung expansion.*
- Administer oxygen as ordered. *Supplemental oxygen is given to improve oxygenation of the blood and tissues.*
- Assess chest tube, system function and drainage every hour. The system must remain patent and intact to function effectively. Assess swinging, bubbling and draining.
- Provide rest. *Adequate rest is important to conserve energy and reduce oxygen demand.*

CONSIDERATION FOR PRACTICE

Provide emotional support, particularly in early stages and during chest tube insertion. Dyspnoea and hypoxaemia can cause extreme anxiety and apprehension, impairing the ability to cooperate with procedures.

Risk of injury

Pain and the presence of chest tubes can reduce the perceived ability to ambulate and provide self-care. Moderate activity is encouraged unless respiratory function is significantly impaired. Caution is taken to maintain integrity of the chest tube system. If the tube is inadvertently pulled out or system integrity is disrupted, the pneumothorax may increase or infection may develop.

CONSIDERATION FOR PRACTICE

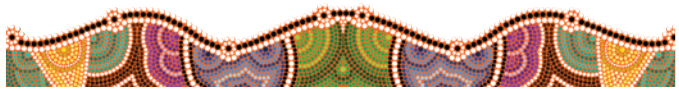
Avoid placing tension on chest tubes during positioning, ambulation and care activities. The chest tubes are minimally secured to the chest wall and can be dislodged if tension is placed on them.

- Secure a loop of drainage tubing to the gown. *Looping the drainage tubing prevents direct pressure on the chest tube itself.* Be sure not to dislodge tube when removing gown.
- When turning to the affected side, ensure that neither the chest tube nor the drainage tubing is kinked or occluded under the person. *This maintains patency of the system.*
- Teach the person how to ambulate with the drainage system, keeping the system lower than the chest. In most cases, suction can be discontinued during ambulation. *Ambulation facilitates lung ventilation and expansion. Drainage systems are portable to allow ambulation while chest tubes are in place. Keeping the drainage system lower than the chest promotes drainage and prevents reflux.*
- Observe insertion site for redness, swelling, pain or drainage. Report any signs of infection, including fever, to the doctor. *Interruption of skin integrity by chest tube insertion increases the risk of infection.*
- If a connection comes loose, reconnect it as soon as possible. *A closed, sealed system is vital to prevent air from entering the pleural space and an open pneumothorax.*

Community-based care

People who have experienced spontaneous pneumothorax need education about their future risk. After a single episode of spontaneous pneumothorax, the risk of recurrence is 15–30%. This risk increases with subsequent episodes (Daley, 2015). Stress the importance of quitting smoking to reduce the risk. Other activities that can precipitate recurrent episodes include mountain climbing or those involving exposure to high altitudes, flying in unpressurised aircraft and scuba diving (Daley, 2015). The person may be advised to avoid contact sports.

Following a pneumothorax, instruct the person to gradually increase exercise and activity to previous levels. Stress the importance of follow-up care and monitoring. Discuss manifestations to report to the doctor: upper respiratory infections; fever, cough or difficulty breathing; sudden, sharp chest pain; or redness, pain, swelling, tenderness or drainage from the chest tube puncture wound.



THE PERSON WITH HAEMOTHORAX

Haemothorax, or blood in the pleural space, usually occurs as a result of chest trauma, surgery or diagnostic procedures. Haemothorax develops in about 30–60% of people with chest trauma, usually due to laceration of the lung, an intercostal vessel or the internal mammary artery. If a major thoracic vessel is disrupted, haemorrhage can be massive (Mancini, 2014; Papadakis et al., 2013). Tumour, pulmonary infarction and infections such as tuberculosis also can cause haemothorax. When blood collects in the pleural space, pressure on the affected lung impairs ventilation and gas exchange. With significant haemorrhage, a risk of shock exists.

Haemothorax causes symptoms similar to those of pneumothorax or pleural effusion. Lung sounds are diminished and a dull percussion tone is noted over the collected blood, typically at the base of the lung. Chest x-ray is used to confirm the diagnosis of haemothorax.

Thoracentesis or thoracostomy with chest tube drainage is used to remove blood from the pleural space. With significant haemorrhage (e.g. due to trauma or surgery), the blood may be collected for subsequent autotransfusion; this blood should be collected and reinfused within 4 hours. Strict aseptic technique is used in collecting the blood. It is collected through a gross particulate filter into a container primed with anticoagulant and reinfused when the container is full or when transfusion is necessary. Air is removed from the blood container prior to reinfusion and a filter is used to eliminate debris such as degenerating blood cells, fat particles and fibrin.

Priority nursing care for the person with haemothorax focuses on assessing and maintaining adequate respiratory function and cardiac output. The priority of care depends on the rate and extent of haemothorax. In a large, slow-developing haemothorax, ventilatory status may be affected significantly. In this instance, *Impaired gas exchange* and *Ineffective breathing pattern* are priority nursing diagnoses. When haemothorax develops rapidly and haemorrhage is significant, additional priority nursing diagnoses include *Decreased cardiac output* and *Risk of deficient fluid volume*.

When preparing the person for home care following a haemothorax, discuss the importance of avoiding smoking and preventing respiratory infection. Include symptoms to report to the doctor. If trauma or infection caused the haemothorax, discuss measures to prevent future trauma and continuing treatment for the infection as indicated.

TRAUMA OF THE CHEST OR LUNG

Chest injury is a leading cause of death from trauma. It is commonly associated with motor vehicle crashes, violent crime and falls. Chest injuries can range from mild, such as a simple rib fracture, to severe and fatal. Traumatic injury to the chest may involve both the chest wall and underlying thoracic structures, including the lungs, heart, great vessels and oesophagus. Chest and lung injury can result from several different mechanisms: penetrating trauma, such as a stab or gunshot wound; blunt trauma, such as a fall, motor vehicle accident (MVA), vehicle–pedestrian impact or crush injury; or inhalation injury, such as smoke inhalation or near drowning.

Rapid and continuing primary survey assessing airway, breathing and circulation (ABC) is vital in chest or lung injuries. Chest trauma can disrupt any or all of these functions. Chest injuries that may be life threatening include airway obstruction, tension pneumothorax, open pneumothorax, massive haemothorax and flail chest with pulmonary contusion.

THE PERSON WITH A THORACIC INJURY

Thoracic injuries may be minor and have little effect on respiratory status; for example, simple rib fracture in a previously healthy person. When pain or chest wall instability impairs breathing or the underlying lung tissue is damaged, the risk is more significant. Thoracic trauma usually is caused by motor vehicle crashes or falls.

Pathophysiology and manifestations

Acceleration–deceleration injury and direct mechanisms of injury (e.g. crush injuries) are the most common mechanisms of thoracic injuries. Acceleration–deceleration injuries are caused by a rapid change in velocity such as occurs in an MVA or fall. The body stops suddenly, but the tissues and organs within the chest cavity continue to move forward until they impact with the chest wall. Injuries sustained can be significant, depending on the velocity (speed) of the vehicle or body at the point of impact, the surface with which the body impacts and individual characteristics (e.g. size and bone structure).

Rib fracture

Simple rib fracture, usually involving a single rib, is the most common chest wall injury. Rib fracture generally is tolerated well and heals rapidly in a young, previously healthy person. In an older adult or person with pre-existing lung disease, however, a fractured rib may lead to significant complications, such as pneumonia, atelectasis and, potentially, respiratory failure. Displaced fractured ribs can penetrate the pleura, leading to pneumothorax and possible haemothorax. Fractures of certain ribs are more frequently associated with underlying tissue damage. Intrathoracic vessels may be damaged or torn with fractures of the first and second ribs. Fractures of the seventh to tenth ribs may cause liver or spleen injuries.

Rib fracture causes pain on inspiration and coughing. This leads to voluntary splinting, with rapid, shallow respirations and inhibited cough. Bruising may be seen over the fracture and crepitus may be palpated with respiratory movement. Breath sounds are diminished, especially in the bases, due to splinting. If pneumothorax develops, chest wall movement on the affected side may be reduced and breath sounds absent or significantly diminished. A hyper-resonant percussion tone usually is noted. Haemothorax also causes diminished or absent breath sounds on the affected side, with a dull percussion note.

Flail chest

Multiple rib fractures may impair chest wall stability and normal chest wall function. When two or more consecutive ribs are fractured in multiple places, a free-floating segment of the chest wall, or **flail chest**, results. Physiological function of the chest wall is impaired as the flail segment is sucked inwards during inhalation and moves outwards with exhalation. This is known as *paradoxical movement* (see Figure 35.19).

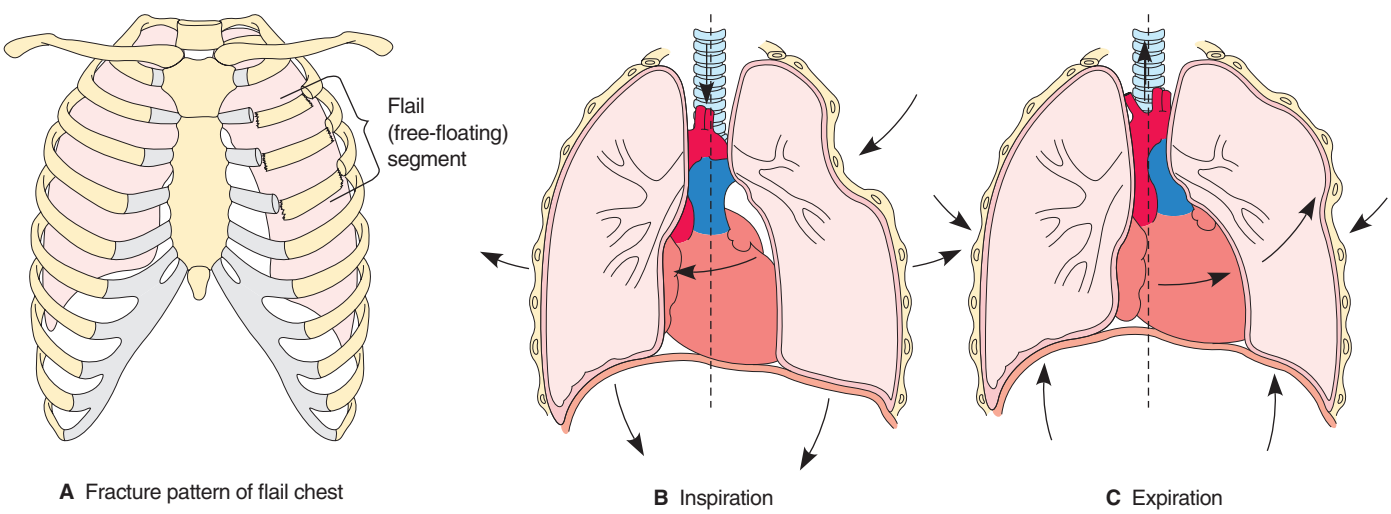


FIGURE 35.19 ■ Flail chest with paradoxical movement

Flail chest can significantly affect ventilation and, consequently, gas exchange. Lung expansion is impaired and the work of breathing increases. Flail chest is frequently associated with underlying pulmonary contusion, which may lead to respiratory failure.

Flail chest causes dyspnoea and pain, especially on inspiration. Paradoxical chest movement is evident with inspection. Chest expansion is unequal and palpable crepitus is present. Breath sounds are diminished and crackles may be heard on auscultation.

Pulmonary contusion

Pulmonary contusion, or lung tissue injury, is frequently associated with flail chest and other blunt chest trauma. It may occur unilaterally or bilaterally. Pulmonary contusion often results from abrupt chest compression followed by sudden decompression, as can occur with MVA, significant fall or crush injury. Alveoli and pulmonary arterioles rupture, causing intra-alveolar haemorrhage and interstitial and bronchial oedema. The resulting inflammatory response increases capillary permeability, leading to oedema, which may be localised to the damaged lung tissue or more generalised. Inflammation and oedema impair the production of surfactant within the alveoli, decreasing compliance. Pulmonary vascular resistance increases and blood flow decreases. Airway obstruction, atelectasis and impaired gas diffusion result. Associated chest wall injury impairs the ability to clear secretions effectively and the work of breathing is significantly increased.

Manifestations of pulmonary contusion may not be apparent until 12 to 24 hours after the injury. Increasing shortness of breath, restlessness, apprehension and chest pain are early signs. Copious sputum, which may be blood tinged, is present. Later manifestations include tachycardia, tachypnoea, dyspnoea and cyanosis. Even with appropriate treatment, pulmonary contusion can lead to acute respiratory distress and potential death.

INTERPROFESSIONAL CARE

Diagnosis

Chest x-ray is used to identify most chest wall injuries. Rib fractures are evident on x-ray. Pulmonary contusion may show as initial patchy opacifications progressing to diffuse opacification or ‘white out’. Changes in oxygen saturation and ABGs depend on the degree to which ventilation and gas exchange are affected by the injury.

Management

Simple rib fractures typically heal uneventfully. Providing adequate analgesia to promote breathing, coughing and movement is the primary intervention. With multiple rib fractures, an intercostal nerve block may be used to ensure adequate ventilation. Rib belts, binders and taping to stabilise the rib cage are not recommended, because they may interfere with ventilation and lead to atelectasis. Even with simple rib fracture, older people and individuals with pre-existing lung disease require close monitoring to prevent and detect atelectasis, pneumonia and other complications.

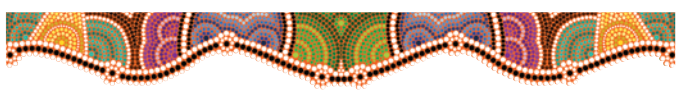
Intercostal nerve blocks or continuous epidural analgesia may be employed to manage the pain associated with flail chest. For a small flail chest, analgesia combined with supplemental oxygen therapy may be adequate. In some cases, internal or external fixation of the flail segment may be done.

Mechanical ventilation

The preferred treatment for flail chest is intubation and mechanical ventilation. Positive-pressure ventilation provides support and stabilisation of the flail segment and improves ventilation and gas exchange. The work of breathing is decreased and healing improved.

People with pulmonary contusion often are critically ill, requiring intensive care management. Treatment is supportive, directed at maintaining adequate ventilation and alveolar gas exchange. Endotracheal intubation and mechanical ventilation are necessary in most cases. Repeated bronchoscopy may be done to remove secretions and cellular debris, preventing atelectasis. Although adequate hydration is necessary to prevent shock, overhydration can increase pulmonary oedema. Pulmonary arterial pressure monitoring with a Swan–Ganz catheter and frequent ABG measurement is sometimes used to assist in the assessment of optimal fluid replacement and management of ventilatory support. See Chapter 36 for nursing care of the person who is intubated and ventilated.

Unilateral pulmonary contusion may present a unique management problem. Mechanical ventilation with positive end-expiratory pressure (PEEP) to maintain open alveoli and adequate gas exchange can damage the unaffected lung. Intubation with a double-lumen endotracheal tube that permits independent ventilation of each lung may be used.



Nursing care

Health promotion

Encourage the use of seat belts, shoulder harnesses and supplemental restraint systems such as air bags to significantly reduce the incidence of thoracic injury associated with motor vehicle crashes. Discuss the importance of appropriate protective equipment and gear for people engaging in potentially hazardous activities such as contact sports or mountain climbing and occupations such as roofing or house painting.

Assessment

The nursing assessment of the person with a thoracic injury may need to be rapid and focused.

- *Health history:* pain, difficulty breathing; circumstances of the injury, including position in the motor vehicle, use of restraints, speed and type of impact; distance of a fall, surface and position on impact; history of chronic lung or heart disease; smoking history.
- *Physical examination:* airway, breathing, circulation; LOC; colour, vital signs; respiratory rate, depth, ease; symmetry of chest movement; lung sounds and percussion tone; presence of bruising, crepitus or paradoxical chest movement.

Nursing diagnoses and interventions

Chest wall trauma can interfere with adequate chest expansion and alveolar ventilation. When a pulmonary contusion is also present, gas exchange is affected as well. Priorities for nursing management include controlling pain, ensuring adequate ventilation and promoting gas exchange.

Acute pain

With many thoracic injuries, pain interferes with lung expansion and coughing, leading to such complications as pneumonia and atelectasis. Adequate pain management is a key component of medical and nursing management for these individuals.

- Frequently assess pain, using a standard pain scale and objective data. *Increased respiratory rate, shallow respirations, diminished breath sounds and reluctance to move and cough may indicate inadequate pain control in a thoracic injury.*
- Administer analgesics by patient-controlled analgesia or on a schedule to maintain pain control. *Analgesics are more effective when pain is not allowed to become intense.*

CONSIDERATION FOR PRACTICE

Assess for possible respiratory depression due to narcotic analgesia. Respiratory depression can further compromise ventilation in the person with thoracic injury.

- Notify the doctor if pain relief is inadequate or excess sedation and respiratory depression occur. An intercostal nerve block may be done to reduce the need for narcotic analgesia. *Assess for bleeding and adequate ventilation following a nerve block.*

Ineffective airway clearance

Aggressive respiratory hygiene may be necessary to maintain open airways and adequate ventilation.

- Assess lung sounds and respiratory rate, depth and effort frequently. Encourage to cough, deep breathe and change position every 1 to 2 hours, and to use the incentive spirometer. *Frequent assessment and measures to maintain airway patency are vital to prevent complications in the person with thoracic injury.*
- Teach how to splint the affected area with a blanket or pillow when coughing. *Splinting reduces movement and discomfort of the affected area.*
- Suction airway as indicated. Work with respiratory therapy to maintain optimal mechanical ventilation. Secure the endotracheal tube to maintain appropriate position and lung ventilation. *Endotracheal tube security is* particularly *important when a double-lumen endotracheal tube is in place because malposition can occlude one main bronchus and prevent ventilation of the affected lung.*
- Elevate the head of the bed. *Elevating the head of the bed facilitates lung expansion and reduces the work of breathing.*

Impaired gas exchange

Impaired gas exchange is of particular concern in pulmonary contusion. Alveolar damage and pulmonary oedema can significantly impair oxygenation of the blood and removal of carbon dioxide.

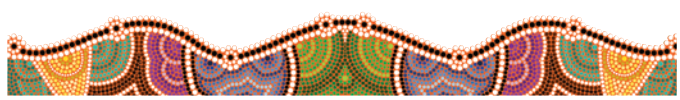
- Monitor vital signs, colour, oxygen saturation and ABGs. Assess for manifestations such as anxiety or apprehension, restlessness, confusion, lethargy or complaints of headache. *These assessment data alert the nurse and care providers to potential hypoxaemia or hypercapnia due to impaired gas exchange.*
- Maintain oxygen therapy and mechanical ventilation as ordered. Hyperoxygenate prior to suctioning. *Oxygen and mechanical ventilation support alveolar gas exchange. Hyperoxygenation prior to suctioning reduces the degree of hypoxaemia that occurs during suctioning.*
- Monitor intake and output, weigh daily and monitor central venous pressure and pulmonary artery pressure as ordered. Maintain any ordered fluid restriction. *Fluid volume status is monitored to reduce the effects of pulmonary oedema on lung tissues.*
- Maintain bed rest or activity restriction as ordered. Space activities to allow periods of uninterrupted rest. *Rest reduces the metabolic rate and oxygen consumption.*

Community-based care

Simple rib fracture and minor chest wall injuries often are managed on an outpatient basis. Include the following topics when teaching for home care:

- pain management and its importance in preventing respiratory complications
- importance of coughing and deep breathing; how to splint the rib cage during coughing
- reasons for not taping or wrapping the chest
- symptoms to report to the doctor: chills and fever, productive cough, purulent or bloody sputum, shortness of breath and increasing chest pain
- importance of avoiding respiratory irritants, such as cigarette smoke and occupational or environmental pollutants.

Significant pulmonary contusion can result in long-term respiratory insufficiency. Discuss activity modifications and occupational changes with the person and family as indicated. Refer to home care services if needed.



THE PERSON WITH INHALATION INJURY

The internal environment of the lungs normally is protected from noxious substances by respiratory defence mechanisms. If these defences are breached, inhaled agents, such as gases, fumes, toxins and water, can cause internal trauma to the lungs.

Pathophysiology and manifestations

Smoke inhalation

Pulmonary injury due to inhalation of hot air, toxic gases or particulate matter is the leading cause of death in burn injury (Lafferty, 2014). Smoke inhalation can significantly affect normal respiratory function through three different mechanisms:

1. thermal damage to the airways, leading to impaired ventilation
2. carbon monoxide or cyanide poisoning, resulting in tissue hypoxia
3. chemical damage to the lung from noxious gases, which can impair gas exchange.

Smoke inhalation is suspected whenever a burn occurs in a closed space; if there are burns to the face or upper torso or singed nasal hairs; if sputum contains ash-like material; and when manifestations such as dyspnoea, wheezing or rales develop.

The lower airways of the lungs typically are protected from thermal damage by cooling of the inhaled gases in the upper airway and laryngeal spasm. Upper airway obstruction due to tissue oedema and laryngeal spasm can occur quickly, however, resulting in **asphyxiation** or oxygen deprivation, without lung damage. Steam inhalation can cause thermal damage to tissues of the lower respiratory tract.

Inhalation of carbon monoxide or cyanide gas poses an immediate threat to life. Carbon monoxide is a colourless, odourless gas produced in a fire. It binds readily with haemoglobin. The affinity of carbon monoxide for haemoglobin is 200 to 250 times stronger than that of oxygen. Haemoglobin bound to carbon monoxide reduces the oxygen-carrying capacity of blood and oxygen delivery to cells of the body. Carbon monoxide poisoning is suspected if the burn occurred in a closed space, if there is evidence of inhalation injury or if dyspnoea develops.

The manifestations of carbon monoxide poisoning depend on the level of carboxyhaemoglobin saturation. When haemoglobin is 10–20% saturated with carbon monoxide, symptoms include headache, dizziness, dyspnoea and nausea. A characteristic cherry-red colour of the skin and mucous membranes may be seen. With increasing levels, confusion, visual disturbances, irritability, hallucinations, hypotension, seizures and coma develop. Permanent neurological deficit can occur in survivors of severe, acute carbon monoxide poisoning.

Many other toxic chemicals may be present in smoke, especially in a house fire or industrial plant fire. Hydrogen cyanide can be lethal when inhaled. Inhalation of toxic chemicals causes bronchospasm and oedema of the airways and alveoli. Acute respiratory distress syndrome may develop within 1 to 2 days. Sloughing of damaged mucosa leads to airway obstruction and atelectasis. Pneumonia is common following smoke inhalation.

Near drowning

Drowning is a leading cause of preventable accidental death in Australia. Between July 2013 and June 2014, 266 people died of drowning (Royal Life Saving Society, 2014). In 2012–2013, 536 people were admitted to hospital for a near drowning or submersion (AIHW, 2015a).

In a small percentage of drowning victims, laryngeal spasm causes asphyxiation, not the aspiration of water. This is known as ‘dry drowning’. However, in most cases, asphyxiation and hypoxaemia result from aspiration of fluid. Loss of consciousness can occur within 3 to 5 minutes after total immersion. Circulatory impairment, brain injury and brain death can occur within 5 to 10 minutes. Immersion in very cold water and the *dive reflex*—a protective mechanism that slows the heartbeat, constricts peripheral vessels and shunts blood to the brain and heart—may prolong survival.

When aspirated, the type of water will directly affect the outcome. Freshwater is hypotonic; when aspirated, it is rapidly absorbed from the alveoli, leading to hypervolaemia and haemodilution. Haemolysis occurs as blood cells are subjected to a hypotonic environment and serum electrolytes are diluted. Electrolyte imbalances can cause cardiac arrhythmias and death. Haemolysis can lead to acute tubular necrosis and acute kidney failure. Aspiration of freshwater impairs pulmonary surfactant and damages the alveolar–capillary membrane. Respiratory failure can result. Nearly the opposite effects occur with saltwater aspiration. As a hypertonic fluid, saltwater draws fluid into the alveoli, resulting in hypovolaemia. Haemolysis is insignificant and small elevations in serum sodium and chloride levels rarely cause life-threatening effects. With either type of near drowning episode, inhaled microorganisms and debris can lead to pneumonia. The pathophysiological changes associated with freshwater and saltwater near drowning are illustrated in Figure 35.20.

Manifestations of near drowning may include altered LOC, restlessness and apprehension. The person may complain of headache or chest pain. Other signs include vomiting, possible cyanosis, apnoea, tachypnoea and wheezing. If pulmonary oedema is present, pink froth may be visible in the mouth and nose. Other manifestations include tachycardia, arrhythmias, hypotension, shock and cardiac arrest. Hypothermia may be present.

INTERPROFESSIONAL CARE

With inhalation injuries, the most effective treatment is prevention. A working smoke detector (with functioning batteries) could prevent the majority of deaths from smoke inhalation occurring in the home. The statement, ‘A smoke detector was found, but the batteries had been removed’ is all too familiar in news reports of fire-related deaths.

The second most important line of defence against death or permanent injury from inhalation injuries is removing the victim from the area of the fire or water and administering effective CPR. In many cases, immediate restoration of effective breathing and circulation is key to preserving life. Hypoxaemia progresses rapidly until breathing is restored; reversal of tissue hypoxia depends on adequate circulation. In both smoke inhalation and near drowning, intubation may be necessary to establish an airway. Oxygen is administered as soon as possible. Attempts to drain water from the lungs of the near

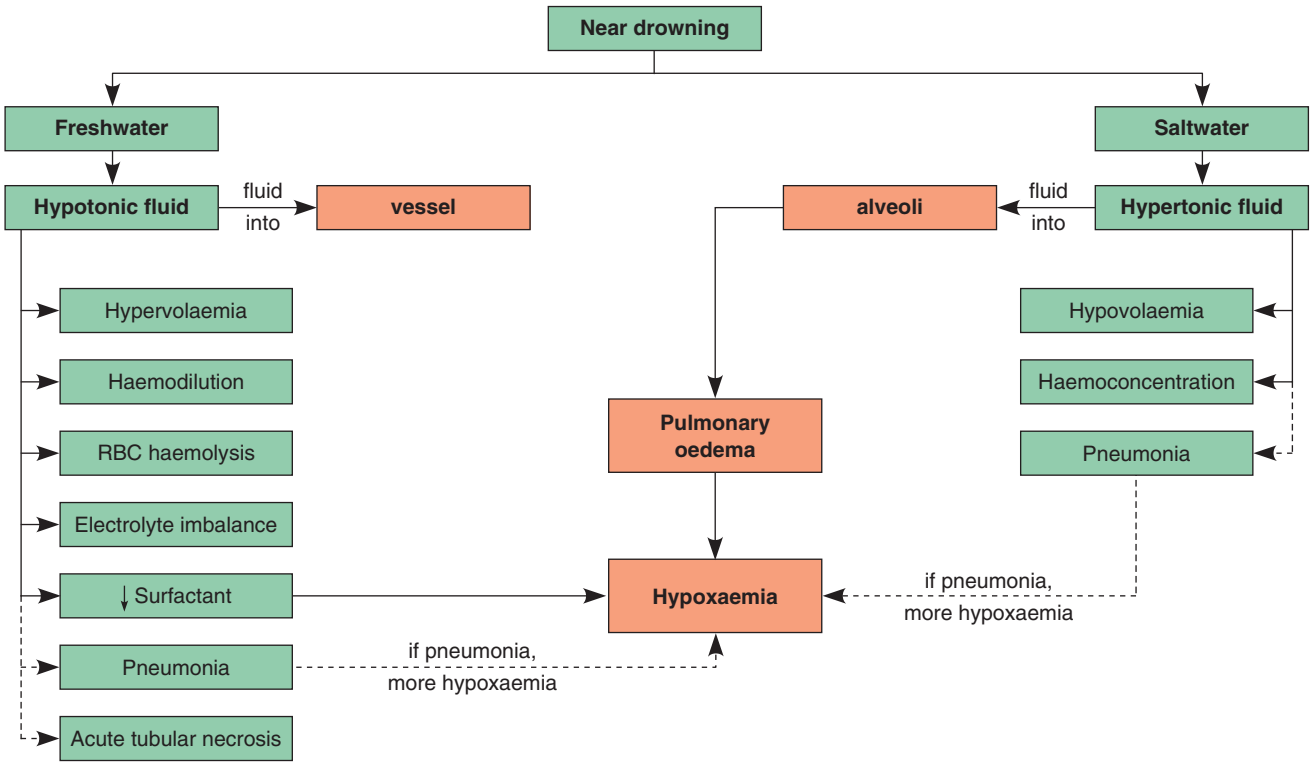


FIGURE 35.20 ■ The pathogenesis of near drowning: freshwater and saltwater

drowning victim waste time and are generally ineffective in restoring alveolar ventilation. External cardiac defibrillation may be necessary to re-establish an effective cardiac rhythm and circulation. When the victim is hypothermic, resuscitation measures are continued until the core body temperature reaches approximately 32°C. The basic rule in hypothermia is that the person is not declared dead until the body has been rewarmed and life signs remain absent.

To prevent drowning, life preservers and flotation vests or jackets should be worn on the body, not stored in the hold of the boat. These devices are designed to keep the head above water. Even accomplished swimmers should never enter the water alone in unguarded areas. Just as alcohol and driving do not mix, neither do alcohol and boating nor other water sports.

Diagnosis

When inhalation injury is known or suspected, the following diagnostic tests may be done:

- *ABGs* are drawn to evaluate gas exchange and the degree of hypoxaemia. Combined respiratory and metabolic acidosis may be apparent. With effective ventilation and supplemental oxygen, acidosis may reverse quickly. With carbon monoxide poisoning, arterial PO_2 may be normal, but oxyhaemoglobin saturation is less than normal.
- *Carboxyhaemoglobin levels* are drawn in suspected carbon monoxide poisoning. Normal levels are less than 5% in non-smokers and less than 10% in smokers. Higher levels indicate carbon monoxide poisoning. Levels less than 20% are considered mild poisoning; between 20% and 40% is moderate poisoning; and 40% to 60% is severe poisoning. Levels higher than 60% are generally fatal.
- *Serum electrolytes* and *osmolality levels* vary in near drowning, depending on the type of water aspirated. In freshwater drowning, serum electrolyte levels and osmolality may be significantly reduced. With saltwater drowning, serum sodium and chloride may be somewhat high, and osmolality is increased because of hypovolaemia.
- *Chest x-ray* is done, but may not show changes until 12 or more hours after the insult. Evidence of ARDS may be seen 24 to 48 hours after inhalation injury.
- *Bronchoscopy* may be ordered to inspect damaged lung tissue, particularly with smoke inhalation and possible thermal injury.

Treatments

Treatment of inhalation injury is generally supportive. Endotracheal intubation and mechanical ventilation often are required to maintain the airway and provide adequate alveolar ventilation and oxygenation. All people with inhalation injury require supplemental oxygen, even when intubation and ventilation are not required. *Hyperbaric oxygen therapy*, the delivery of 100% oxygen at increased atmospheric pressure, may be used to treat carbon monoxide poisoning. This treatment carries some risks, such as oxygen toxicity and potential trauma to lung tissues, sinuses and ears due to the increased pressures.

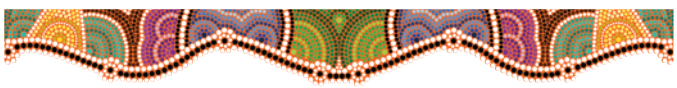
Other treatment measures may include bronchodilator therapy to manage bronchospasm. Bronchodilators can be administered by aerosol inhalation or intravenous infusion.

Coughing and suctioning are important to remove secretions and debris. Chest physiotherapy with percussion and postural drainage may be performed.

Intravenous fluids may be ordered; if significant haemolysis has occurred, packed red blood cells may be given to improve the oxygen-carrying capacity of the blood. Fluid therapy is monitored carefully, using pulmonary artery or central venous pressures to reduce the risk of pulmonary oedema.

With near drowning victims, measures such as inducing hypothermia or barbiturate-induced coma and administering corticosteroids and osmotic diuretics may be employed to help prevent neurological damage.

Careful monitoring for complications such as pneumonia and ARDS is vital throughout the course of treatment. Respiratory status, vital signs and other data are frequently assessed to identify complications and allow early intervention.



Nursing care

Health promotion

Prevention of inhalation injuries is an important nursing responsibility. Teach everyone the value of a working smoke detector, especially in the sleeping areas of the house. Encourage families to develop an escape plan in case of fire and to use fire drills to rehearse getting out of the house. Smouldering cigarettes are a leading cause of house fires; help people develop a plan to stop smoking. Teach people to drop and roll should clothing catch fire. (Flames rise, increasing the risk of respiratory injury when upright.)

Learning to swim safely is important to prevent drowning. Teach individuals never to swim alone, when fatigued or immediately following a meal. Remind people that knowing how to swim will not prevent drowning in very cold water or in large bodies of water, such as lakes, rivers or the ocean. Instruct to always wear flotation devices while boating, water skiing, surfing or windsurfing. Wetsuits help prevent hypothermia during activities in very cold water. Advise covering or fencing swimming pools and ponds to prevent inadvertent entry and drowning.

A population well trained in effective, safe CPR provides the best second line of defence against inhalation injury. Rapid restoration of breathing is essential to prevent hypoxia and brain damage. Encourage all people to be trained and regularly update CPR skills. Work with communities to increase the number of trained people. Refer individuals to Australian Red Cross, Surf Life Saving, St John's Ambulance or any other accredited CPR training facility.

Assessment

Inhalation injuries may be a medical emergency, necessitating focused and timely nursing assessment.

- *Health history:* circumstances of the injury, including duration of exposure to smoke or time under water, explosion or fire in a closed area, type and temperature of water immersed in; resuscitation measures used; allergies and current medical problems.
- *Physical examination:* airway, breathing, circulation; LOC; colour, oxygen saturation level; vital signs; heart and lung sounds; urine output; evidence of burns or soot around nares or mouth.
- *Diagnostic tests:* carboxyhaemoglobin levels, serum electrolytes and osmolality; ABGs; chest x-ray.

Nursing diagnoses and interventions

Nursing care priorities for the person with an inhalation injury are determined by the type of injury or tissue damage. Airway clearance is a major concern in all inhalation injuries, as is impaired gas exchange. Tissue hypoxia also can be a significant problem.

Ineffective airway clearance

Nursing measures to maintain an adequate airway begin with careful and frequent assessment of respiratory status, including rate, depth and effort, as well as breath sounds. Note amount, colour and consistency of sputum. Assist to cough frequently; suction the intubated person as needed to remove secretions. Elevate the head of the bed to facilitate alveolar ventilation unless otherwise ordered. Stabilise the endotracheal tube to prevent displacement into a mainstem bronchus, which could lead to ventilation of only one lung. Report changes in the character of secretions that may indicate complications: pink, frothy sputum suggesting pulmonary oedema or purulent sputum suggestive of pneumonia. Administer bronchodilators as ordered. Perform percussion and postural drainage as ordered.

Impaired gas exchange

Support gas exchange by administering supplemental oxygen, with or without mechanical ventilation, as required. Frequently assess oxygen saturation, skin colour and mental status. Decreasing level of consciousness may be an early sign of hypoxaemia. Monitor exhaled carbon dioxide, ABGs and pulmonary artery pressures as ordered and indicated. Report changes to the doctor. Maintain oxygen flow rates as ordered. Provide frequent mouth care to reduce the discomfort of dry mucous membranes and prevent tissue breakdown. Work with physiotherapists to maintain effective oxygen delivery with mechanical ventilation. Administer sedation as required. Maintain fluid restriction if ordered.

Ineffective cerebral tissue perfusion

Impaired cerebral tissue perfusion is a priority problem, especially with near drowning. Hypoxia and possible hypervolaemia can lead to cerebral oedema and increased intracranial pressure (IICP), further impairing blood flow. Monitor vital signs and neurological status frequently. A change in level of consciousness or behaviour is typically the earliest sign of IICP. Changes noted on an intracranial pressure monitor also provide early evidence of IICP. Increasing systolic blood pressure and pulse pressure and slowed heart rate are late signs. Other manifestations may include pupillary changes and decreasing muscle strength. Report changes promptly to the

doctor. Elevate the head of the bed and keep the head in neutral position to promote drainage from the cranial vault. Maintain effective ventilation and oxygenation; hypercapnia and hypoxaemia increase cerebral oedema. Administer sedation, osmotic diuretics or corticosteroids as ordered to reduce cerebral oedema. Maintain fluid restriction. Space activities and promote rest to reduce metabolic demands.

Community-based care

Teach individuals who do not require hospitalisation for inhalation injury about symptoms that may indicate a complication and should be reported to the doctor: increasing dyspnoea, cough productive of purulent or pink frothy mucus, confusion or other changes. Manifestations of respiratory damage may not be apparent for 24 to 48 hours following the injury.

Significant hypoxia due to near drowning or carbon monoxide poisoning may cause permanent neurological effects. Work with the family to develop communication techniques and identify remaining strengths. Help the family identify future care needs and means for meeting them, such as community-based care, personal care aides or long-term care facilities. Provide social services and support group referrals.

LUNG CANCER

THE PERSON WITH LUNG CANCER

Incidence and risk factors

Lung cancer is the second leading underlying cause of death for Australian males and the sixth for females. Death rates for lung cancer have risen gradually since the 1940s (see Figure 35.21).

In Australia, the estimated incidence of lung cancer in 2014 was well over 11000 people. It is the fourth most common cancer for both males and females; however, of all the cancers, lung cancer is the most common cause of death in both male and females. Between 1991 and 2009, lung cancer incidence fell by 26% in males but rose by 37% in females (AIHW, 2014).

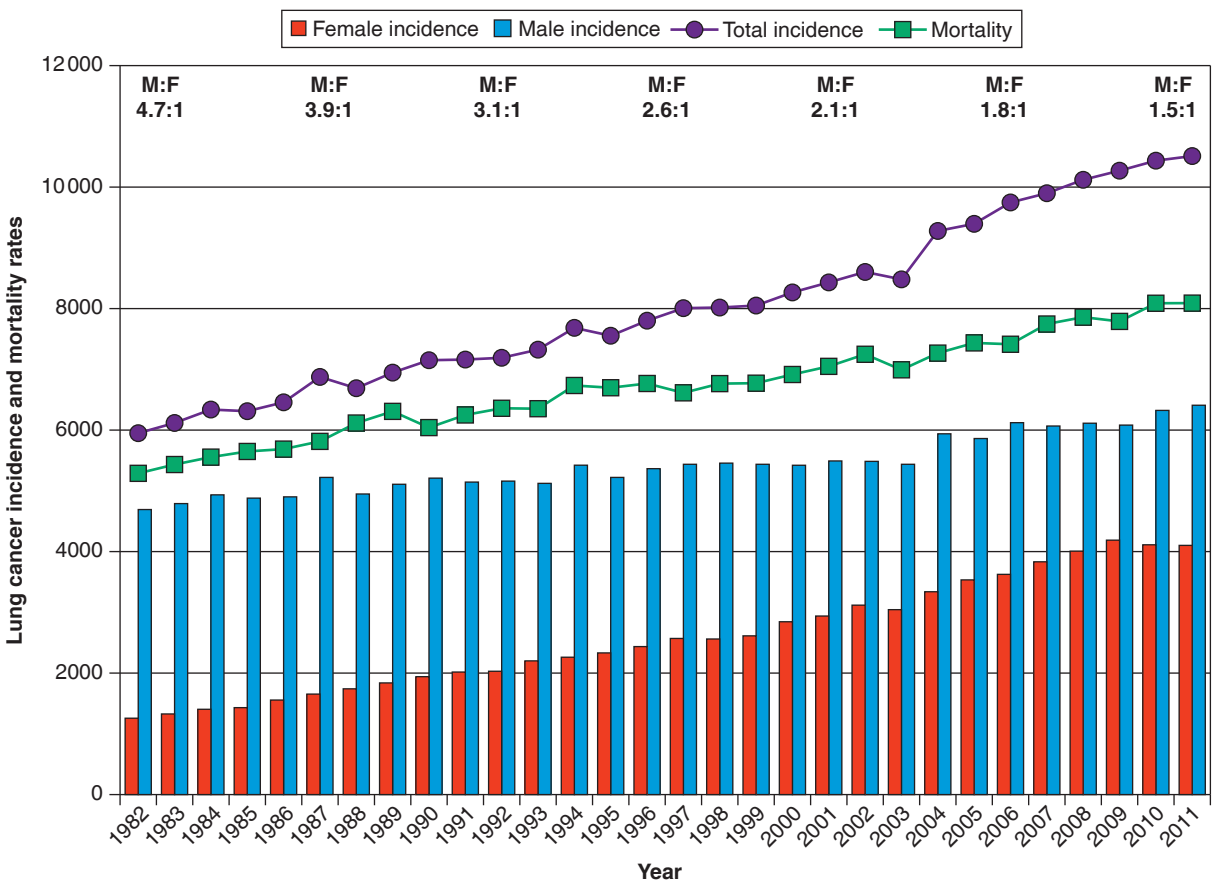


FIGURE 35.21 ■ Lung cancer incidence in Australia, 1982–2011; mortality rates, 1982–2011; and male:female incidence ratio for selected dates

Source: Generated from AIHW (2015c). *Australian cancer incidence and mortality books: Lung cancer*. Retrieved from www.aihw.gov.au/acim-books/.

Nearly 90% of lung cancers are caused by tobacco smoking, and smokers have 16 times more chance of developing lung cancer than a non-smoker (Cancer Council, 2015). Cigarette smoke, which contains over 40 known chemical carcinogens and cancer promoters, is clearly the most significant cause of lung cancer. Even former smokers who have abstained for a number of years have a higher risk of developing lung cancer than non-smokers.

Pathophysiology

Lung cancer develops as damaged bronchial epithelial cells mutate over time to become neoplastic. The genetic abnormality commonly seen is on chromosome 3, with loss of genetic material. Alterations of suppressor genes are also seen in some types of lung cancer.

The vast majority of primary lung lesions are bronchogenic carcinoma tumours of the airway epithelium. These tumours are further differentiated by cell type: small-cell carcinoma, adenocarcinoma, squamous cell carcinoma and large-cell carcinoma. For clinical purposes, the latter three cell types frequently are classified together as non-small-cell carcinomas. *Small-cell carcinomas*, which account for approximately 18% of lung cancers, grow rapidly and spread early. These tumours have paraneoplastic properties; that is, they produce manifestations at sites that are not directly affected by the tumour. Small-cell lung carcinomas can synthesise bioactive products and hormones such as adrenocorticotropic hormone (ACTH), antidiuretic hormone (ADH), a parathormone-like hormone and gastrin-releasing peptide. *Non-small-cell carcinoma* accounts for about 70% of lung cancers. Each cell type differs in its incidence, presentation and manner of spread.

Table 35.7 outlines the incidence and unique characteristics of each cell type.

Bronchogenic cancer, regardless of cell type, tends to be aggressive and locally invasive, and to have widespread metastatic lesions. Tumours begin as mucosal lesions that grow to form masses that obstruct the bronchi or invade adjacent lung tissue. All types frequently spread via the lymph system to nodes and other organs such as the brain, bones and liver.

Manifestations

The manifestations of lung cancer are related to the location and spread of the tumour. People may present with symptoms related to the primary tumour, manifestations of metastatic disease or with systemic symptoms. Initial symptoms often are attributed to smoking or chronic bronchitis. Chronic cough is common, as is haemoptysis. Wheezing and shortness of breath occur as a result of airway obstruction. Dull, aching chest pain occurs as the tumour spreads to the mediastinum; pleuritic pain occurs when the pleura is invaded. Hoarseness and/or dysphagia indicate pressure of the tumour on the trachea or oesophagus.

Systemic and paraneoplastic manifestations of lung cancer include weight loss, anorexia, fatigue and weakness; bone pain, tenderness and swelling; clubbing of the fingers and toes; and various endocrine, neuromuscular, cardiovascular and haematological symptoms.

Confusion, impaired gait and balance, headache and personality changes may indicate brain metastasis. Bone metastases cause bone pain, pathological fractures and possible spinal cord compression, as well as thrombocytopenia and anaemia if bone marrow is invaded. When the liver is affected, symptoms of liver dysfunction and biliary obstruction—including jaundice, anorexia and upper right quadrant pain—are evident.

See 'Multisystem effects of lung cancer' on page 1299.

Complications and course

Superior vena cava syndrome, partial or complete obstruction of the superior vena cava, is a potential complication of lung cancer, particularly when the tumour involves the superior mediastinum or the mediastinal lymph nodes. Obstructed venous flow from the head and neck produces the symptoms of superior vena cava syndrome (oedema of the neck and face, headache, dizziness, vision disturbances and syncope) and may develop acutely or more gradually. Veins of the upper chest and neck are dilated; flushing occurs, followed by cyanosis. Cerebral oedema may affect the level of consciousness; laryngeal oedema may impair respirations.

Paraneoplastic syndromes commonly associated with lung cancer include syndrome of inappropriate ADH secretion (SIADH) with fluid retention, hyponatraemia and oedema, Cushing's syndrome (see Chapter 18) related to abnormal ACTH production, and hypercalcaemia. Lung tumours may also produce procoagulation factors, increasing the risk of venous thrombosis, pulmonary embolism and thrombotic endocarditis (Bullock & Hales, 2012). In lung cancer, neuromuscular symptoms such as muscle weakness and wasting of the limbs may be the first indication of the disease.

At the time of diagnosis, cancer of the lung is typically well advanced, with distant metastasis present in 55% of people and regional lymph node involvement in another 25%. The prognosis is generally poor: the overall 5-year survival rate is only 13% for males and 17% for females (Cancer Council, 2015).

INTERPROFESSIONAL CARE

Because lung cancer typically is advanced when diagnosed and the prognosis generally is poor, prevention of the disease must be a primary goal for all healthcare providers. Reducing cigarette smoking can have a significant impact on the death rate from lung cancer—a far greater impact than advances in treatment.

Establishing an accurate diagnosis is the first step in treating lung cancer. Treatment decisions are based on the tumour location, type of cancer cell, staging of the tumour and the person's ability to tolerate treatment. Lung cancer is staged by the tumour size, location, degree of invasion of the primary tumour and the presence of metastatic disease. Lung cancer staging is summarised in Table 35.8. Surgery is the treatment of choice for most forms of lung cancer.

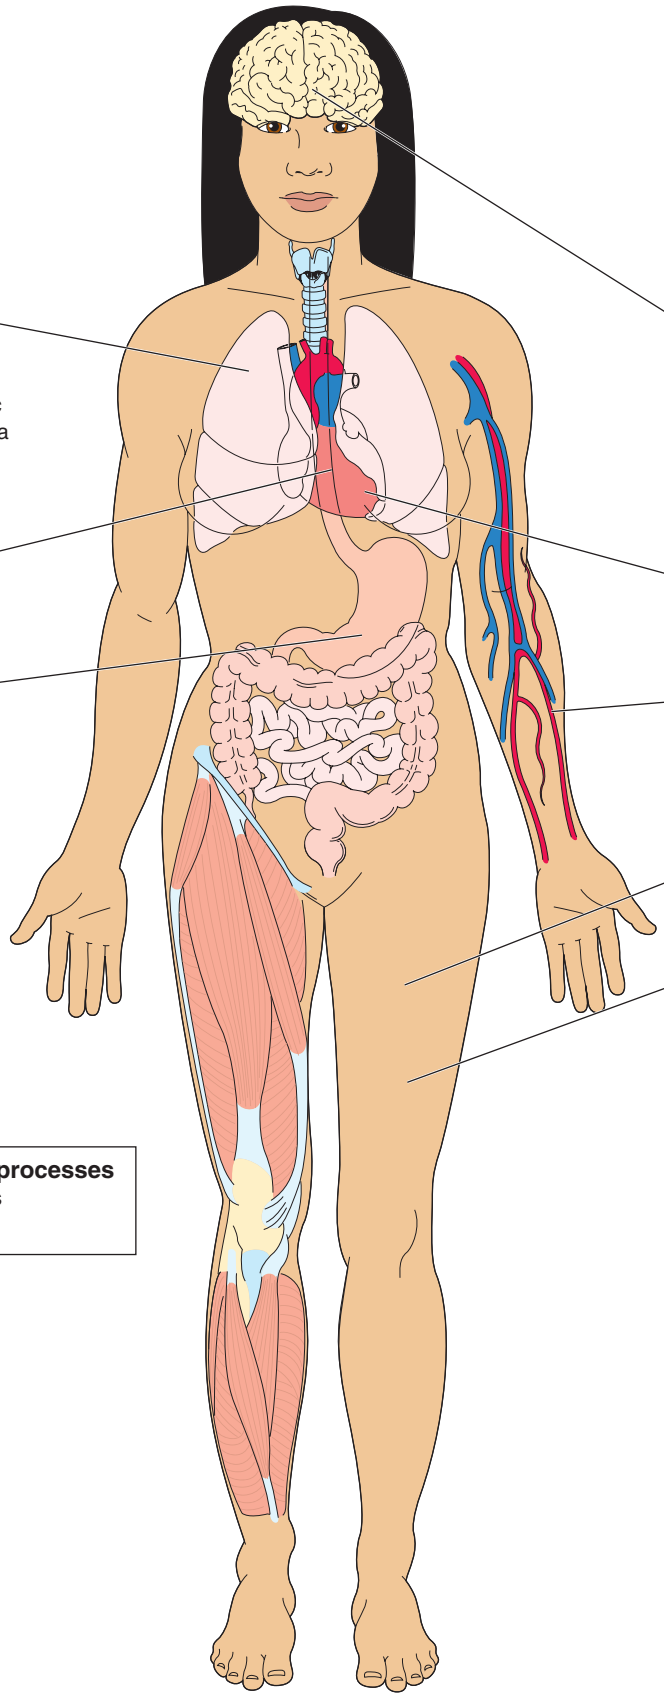
TABLE 35.7 Comparison of lung cancer cell types

	CELL TYPE AND PREVALENCE	PRESENTATION AND ASSOCIATED MANIFESTATIONS	SPREAD
	Small-cell (oat-cell) carcinoma: 18% of all lung cancers	Central lesion with hilar mass common, early mediastinal involvement, no cavitation; SIADH, Cushing's syndrome, thrombophlebitis	Aggressive tumour; more than 40% of people have distant metastasis at time of presentation
	Adenocarcinoma: 32% of all lung cancers	Peripheral mass involving bronchi; few local symptoms; hypertrophic pulmonary osteoarthropathy	Early metastasis to CNS, skeleton and adrenal glands
	Squamous cell carcinoma: 29% of all lung cancers	Central lesion located in large bronchi; person presents with cough, dyspnoea, atelectasis and wheezing; hypocalcaemia common	Spreads by local invasion
	Large-cell carcinoma: 9% of all lung cancers	Usually, peripheral lesion that is larger than that associated with adenocarcinoma and tends to cavitate; gynaecomastia, thrombophlebitis	Early metastasis

Diagnosis

- *Chest x-ray* usually provides the first evidence of lung cancer. It is particularly reliable as a diagnostic tool when compared with a previous chest x-ray. In high-risk populations, the chest x-ray may be used as a screening tool for lung cancer.
- *Sputum specimen* is sent for *cytological examination* to establish the diagnosis of lung cancer. The sputum sample is collected on arising in the morning. If malignant cells are found in the sputum, more expensive and invasive examinations may be unnecessary. However, a sputum sample negative for malignant cells does not rule out lung cancer; it may simply indicate that the tumour is not shedding cells into mucus secretions.
- *Bronchoscopy* is frequently done to visualise and obtain tissue for biopsy from the tumour. When a tumour mass or suspicious tissue is identified visually, a cable-activated instrument is used to obtain a biopsy specimen. If the tumour cannot be seen, the airways may be flushed with a saline solution (bronchial washing) to obtain cells for cytological examination. Nursing care of the person undergoing a bronchoscopy is included in the 'Diagnostic tests' box in Chapter 33.
- *CT scan* is used to evaluate and localise tumours, particularly tumours in the lung parenchyma and pleura. It also is completed prior to needle biopsy to localise the tumour. CT scanning can also detect distant tumour metastasis and evaluate tumour response to treatment.

MULTISYSTEM EFFECTS OF LUNG CANCER



Respiratory
- Cough
- Haemoptysis
- Wheezing and dyspnoea
- Chest pain, dull or pleuritic
- Hoarseness and dysphagia
- Pleural effusion

Cardiovascular
- Compression of the superior vena cava

Gastrointestinal
- Anorexia

Metabolic processes
- Weight loss
- Fever

Paraneoplastic syndromes

Endocrine system
- Hypercalcaemia
- Hyperphosphataemia
- Cushing's syndrome
- Syndrome of inappropriate antidiuretic hormone (SIADH) with water retention and hyponatraemia

Cardiovascular system
- Thrombophlebitis
- Endocarditis

Haematological effects
- Anaemia
- Disseminated intravascular coagulation (DIC)
- Eosinophilia

Connective tissue
- Osteoarthropathy with clubbing and periosteal inflammation

Neuromuscular effects
- Peripheral neuropathy
- Cerebellar degeneration
- Myasthenia-like muscle weakness

TABLE 35.8 Lung cancer staging

	PRIMARY TUMOUR (T STAGE)	REGIONAL LYMPH NODES (N)	DISTANT METASTASIS (M)
	T_0—No evidence of primary tumour		
Stage 0	T_X—Malignant cells in bronchopulmonary secretions, but no tumour visualised		M_X—Presence of distant metastasis cannot be assessed
Stage I	T_1S—Carcinoma in situ	N_0—No regional lymph node metastasis	M_0—No distant metastasis
	T_1—Tumour that is 3 cm in diameter or less, with no evidence of invasion		
Stage II	T_2—Tumour that is greater than 3 cm in diameter or invades visceral pleura or has associated atelectasis or pneumonitis	N_1—Metastasis or direct extension to peribronchial or ipsilateral hilar nodes	
Stage III	T_3—Tumour with direct extension into an adjacent structure or any tumour with associated pleural effusion or atelectasis or pneumonitis of entire lung	N_2—Metastasis to ipsilateral mediastinal or subcarinal nodes	
Stage IV	T_4—Tumour that invades mediastinum or involves the heart, great vessels, trachea, oesophagus, vertebral body or carina; presence of malignant pleural effusion	N_3—Metastasis to contralateral mediastinal, scalene or supraclavicular nodes	M_1—Distant metastasis present

- *Cells or tissue for cytological examination and biopsy* may be obtained by aspirating fluid from a pleural effusion, percutaneous needle biopsy and lymph node biopsy. These procedures may be done in an outpatient or a surgical setting.
- *FBC, liver function studies* and *serum electrolytes* including calcium are obtained to evaluate for evidence of metastatic disease or paraneoplastic syndromes.
- *Tuberculin test (PPD)* is performed to rule out tuberculosis as the cause of symptoms and abnormalities seen on chest x-ray.
- *Respiratory function tests (RFTs)* and *ABGs* may be performed prior to the initiation of treatment if the person has manifestations of respiratory insufficiency (e.g. dyspnoea, activity intolerance, low oxygen saturation levels).

See Chapter 33 for nursing care related to commonly used diagnostic tests for lung cancer.

Medications

Combination chemotherapy (often combined with radiation therapy and/or surgery) is the treatment of choice for small-cell lung cancer because of its rapid growth, dissemination and sensitivity to cytotoxic drugs. Used in combination, chemotherapeutic drugs allow tumour cells to be attacked at different parts of the cell cycle and in different ways, increasing the effectiveness of therapy. Fifty per cent of individuals with tumours at early stages achieve complete tumour remission with combination chemotherapy. When a complete tumour response is achieved in the first few cycles of chemotherapy, the chances for long-term survival are much greater.

Combination chemotherapy is used also as an adjunct to surgery or radiation therapy for other types of lung cancer. It may be used to reduce the size of advanced local tumours prior to surgery and to lengthen survival when distant metastases are present. See Chapter 13 for further discussion of chemotherapy.

Bronchodilators may be prescribed to reduce airway obstruction. Analgesics and pain management strategies are vital when the cancer is advanced. See Chapter 8 for more information about postoperative and cancer pain management.

Surgery

Surgery offers the only real chance for a cure in non-small-cell lung cancer. Unfortunately, most tumours are inoperable or only partially resectable at the time of diagnosis. The type of surgery performed depends on the location and size of the tumour, as well as the person's pulmonary and general health. The goal of surgery is to remove all involved tissue while preserving as much functional lung as possible. Table 35.9 outlines various surgical procedures used to treat lung cancer. Nursing care for the person having lung surgery is outlined in the box below.

Radiation therapy

Radiation therapy is used alone or in combination with surgery or chemotherapy for lung cancer (Tan, 2015). The treatment goal may be either cure or symptom relief (palliative). Prior to surgery, radiation therapy is used to 'debulk' tumours. When cancer has spread by direct extension to other thoracic structures and surgery is not feasible, radiation therapy may be the treatment of choice. It also may be used to relieve manifestations such as cough, haemoptysis, pain due to bone metastasis and dyspnoea from bronchial obstruction. Complications of lung cancer, such as superior vena cava syndrome, may be treated with radiation.

Radiation therapy may be delivered by external beam to the primary tumour site or by intraluminal radiation or

TABLE 35.9 Types of surgery for lung cancer

PROCEDURE	DESCRIPTION	USED FOR
Laser bronchoscopy	Bronchoscopy-guided laser used to resect tumour	Tumours localised in a main bronchus
Mediastinoscopy	Visualisation of the mediastinum using an endoscope passed through a suprasternal incision	Evaluation and biopsy of a mediastinal tumour and lymph nodes
Thoracotomy	Incision into the chest wall	Access the lung and thoracic cavity for surgery
Wedge resection	Removal of a small section (wedge) of peripheral lung tissue	Small, peripheral lung tumours
Segmental resection	Removal of an individual bronchovascular segment of a lobe	Peripheral lung tumour with no evidence of extension to the chest wall or metastasis
Sleeve resection (bronchoplastic reconstruction)	Resection of a section of a major bronchus with reconstruction of remaining normal bronchus	Small lesion of a major bronchus
Lobectomy	Removal of a single lung lobe	Tumours confined to a single lobe
Pneumonectomy	Removal of an entire lung	Tumour widespread throughout the lung, involving the main bronchus or fixed to the hilum

brachytherapy. Radiation therapy and related nursing care are discussed further in Chapter 13. Specific nursing measures for the person undergoing radiation therapy for lung cancer are outlined in the 'Nursing care' box below.

Nursing care

Health promotion

Teach people of all ages, particularly children and teenagers, about the link between cigarette smoking and lung cancer. Not smoking, and avoiding exposure to second-hand smoke, is the primary preventive measure for lung cancer. In addition, explain the risk of lung cancer to people with occupational risk factors—exposure to asbestos products, in particular.

Assessment

Nursing assessment related to lung cancer focuses on identifying risk factors for the disease, early manifestations of lung cancer and respiratory function in the person undergoing treatment.

- *Health history:* current symptoms, including chronic cough, shortness of breath, blood-tinged sputum; systemic manifestations such as recent weight loss, fatigue, anorexia, bone pain; smoking history; occupational exposure to carcinogens; chronic diseases such as COPD.
- *Physical examination:* general appearance; skin colour, evidence of clubbing; weight and height; vital signs; respiratory rate, depth, excursion; lung sounds to percussion and auscultation.
- *Diagnostic tests:* FBC and coagulation studies, serum electrolytes and osmolality, liver and renal function studies; chest x-ray and CT scan results; ABGs and oxygen saturation levels.

NURSING CARE OF THE PERSON having lung surgery

PREOPERATIVE CARE

- Provide routine preoperative nursing care as outlined in Chapter 3.
- Note any history of smoking, respiratory and cardiac diseases, and other chronic conditions in the nursing history. *These factors may affect the response to surgery and the risk of postoperative complications.*
- Provide emotional and psychological support for the person and family. *In addition to facing surgery, the individual may be adjusting to a new diagnosis of cancer and the possibility that surgical intervention will be only partially successful.*
- Instruct about postoperative procedures, including respiratory therapy, breathing exercises and coughing techniques. *Allow practice time. Learning will be easier in the preoperative period, when pain and analgesia are not affecting mental function.*
- If the person will return from surgery with an endotracheal tube and mechanical ventilation, establish a means of communication using hand or eye signals or a magic slate. *Establishing a means of communication prior to surgery reduces postoperative anxiety at being unable to speak.*
- If the person will return to the critical care unit, introduce the person and family to the unit and any machines, such as ventilators and monitors, that will be used. *The knowledge that this is an expected part of surgical recovery reduces the person's and family's postoperative anxiety.*

(continued)

NURSING CARE OF THE PERSON having lung surgery (continued)

POSTOPERATIVE CARE

- Assess and provide routine postoperative care as outlined in Chapter 3.
- Assess for adequate pain control and provide analgesics as needed. *Incisional pain commonly causes altered breathing patterns in the person who has undergone lung surgery.*
- Frequently assess respiratory status, including colour, oxygen saturation, respiratory rate and depth, chest expansion, lung sounds, percussion tone and ABGs. *Maintaining adequate ventilation and gas exchange postoperatively is vital to reduce mortality and morbidity. Gas exchange may be impaired by complications of lung surgery, including pneumothorax, atelectasis, bronchospasm, pulmonary embolus, bronchopleural fistula and ARDS.*
- Assist with effective coughing techniques, postural drainage and incentive spirometry. Perform endotracheal suctioning as needed while intubated. *Surgical manipulation and anaesthesia can increase mucus production, leading to airway obstruction. Aggressive respiratory hygiene is important to prevent this complication.*
- Monitor and maintain effective mechanical ventilation. *This is vital to ensure adequate ventilation and gas exchange in the early postoperative period.*
- Maintain patent chest tubes and a closed drainage system. Monitor chest tube output every hour initially and then every 2 to 4 or 8 hours as indicated. Notify the doctor if chest tube output exceeds 70 mL per hour and/or is bright red, warm and free flowing. *Maintaining a patent, intact chest drainage system is vital for re-establishing negative pressure within the chest cavity and re-expansion of the lungs. Increased amounts of warm, free-flowing blood indicate intrathoracic haemorrhage that may necessitate surgical intervention.*
- Assess for signs of infection involving the incision or chest tube site(s). Use strict aseptic technique in caring for incisions and invasive monitoring devices. *The postoperative period poses risks for individuals from incisional infections, empyema in the chest cavity and pneumonia.*
- Assist with turning and encourage the person to ambulate as soon as possible. *Early mobility is important to prevent possible complications, such as pneumonia or pulmonary embolus.*
- Assess and maintain nutritional status. Initiate enteral or parenteral nutrition early if intubation and mechanical ventilation will be required for an extended period. Provide frequent small feedings once extubated. *Maintaining nutritional status promotes wound healing and prevents negative nitrogen balance. Giving frequent small feedings reduces the fatigue associated with eating.*

NURSING CARE OF THE PERSON receiving radiation therapy

Although radiation therapy is well controlled and specifically directed towards the tumour cells, some normal cells are also damaged in the process of treatment. Nursing care and teaching help the person cope with uncomfortable side effects associated with radiation therapy.

NURSING RESPONSIBILITIES

- Monitor for potential complications:
  a. radiation pneumonitis—dyspnoea on exertion, dry cough, fever
  b. pericarditis—chest pain, pericardial friction rub; muffled heart sounds, paradoxical pulse, ECG abnormalities (notify the doctor if symptoms develop)
  c. oesophagitis—pain, sore throat, difficulty swallowing.
- Encourage adequate fluid intake to liquefy respiratory secretions.
- Provide local analgesics and local anaesthetics such as viscous lignocaine as ordered to relieve dysphagia and sore throat.
- Offer small frequent meals of soft, cool foods and liquids to maintain nutritional status.

HEALTH EDUCATION FOR THE PERSON AND FAMILY

- If dyspnoea or pneumonitis develops, teach positioning, pursed-lip techniques and relaxation exercises to facilitate breathing.
- Reassure that pneumonitis is generally a self-limiting process and should resolve when the course of radiotherapy is completed.
- Teach the manifestations of pericarditis, which may develop during treatment or up to 1 year after its completion. Chest pain or pressure, rapid heartbeat and fever may signal pericarditis; increasing fatigue, dyspnoea and light headedness can indicate a chronic process with pericardial effusion and possible cardiac tamponade.
- Instruct to eliminate hot, spicy or acidic foods from the diet if oesophagitis is a problem. Alcohol and tobacco should also be avoided.
- Adequate rest and nutrition are important to alleviate the symptoms of radiation fatigue, which is common in people receiving radiation therapy for lung cancer. The fatigue is generally temporary.

Nursing diagnoses and interventions

The person with lung cancer is facing invasive treatments with undesirable side effects, possibly surgery and typically a poor prognosis for long-term survival. Nursing care needs are diverse, related to respiratory status, the cancer itself and possible metastases, and the treatment plan. Priority nursing diagnoses related to respiratory function include *Ineffective breathing pattern* and *Activity intolerance*. *Pain* and *Anticipatory grieving* also are likely to be high-priority problems. See the accompanying nursing care plan.

Ineffective breathing pattern

Breathing pattern and ventilation may be affected by the tumour itself or by treatment of the tumour. Thoracic surgery increases the risk due to the incision and disruption of the muscles of respiration. Maintaining effective lung ventilation is particularly important postoperatively to re-expand remaining lung tissue and prevent surgical complications.

- Assess and document respiratory rate, depth and lung sounds at least every 4 hours; evaluate more frequently in the immediate postoperative period or as indicated by condition. *Early detection of signs of respiratory compromise or adventitious lung sounds is vital for effective intervention.*

CONSIDERATION FOR PRACTICE

Monitor oxygen saturation and/or blood gas results, reporting changes from normal. Changes in levels of blood oxygen may be early indications of respiratory compromise.

- Frequently assess and document pain level (using a standard pain scale); provide analgesics as needed. *Pain and attempting to avoid chest movement to prevent additional pain can lead to rapid, shallow respirations and ineffective ventilation.*
- Elevate the head of the bed to 60 degrees. *Elevating the head of the bed reduces pressure on the diaphragm from the abdominal contents and permits optimal lung expansion.*
- Assist to turn, cough and deep breathe, and to use incentive spirometry. Help splint the chest with a pillow or blanket when coughing. *These measures promote airway clearance.*
- Suction airway as needed. *Suctioning may be required to remove secretions that the person is unable to cough up and expectorate.*

CONSIDERATION FOR PRACTICE

Maintain chest tube integrity and patency by ensuring uninterrupted gravity flow. Chest tubes help re-establish negative pressure in the thoracic cavity, allowing the lung to fully re-expand.

- Provide chest physiotherapy with percussion and postural drainage as needed or ordered. *Percussion and postural drainage help maintain airway patency and effective respirations.*
- If mechanical ventilation is instituted, work with respiratory therapy and use analgesia or sedation as needed to synchronise respirations with the ventilator. *Coordination of the person's respiratory effort with ventilator-delivered breaths is important for fully effective mechanical ventilation.*
- Provide reassurance and emotional support. *These measures help relieve anxiety and promote an effective breathing pattern.*

Activity intolerance

Both resectional lung surgery and inoperable lung cancer reduce the amount of functional lung tissue and surface area for gas diffusion. This can lead to activity intolerance if the oxygen supply is insufficient to meet the body's oxygen demand.

CONSIDERATION FOR PRACTICE

Assess and document physiological responses to activity, including pulse, respiratory rate, dyspnoea and fatigue. These assessments are good indicators of activity tolerance.

- Plan rest periods between activities and procedures. *Rest periods reduce oxygen demands and fatigue.*
- Assist the person to increase activities gradually in the postoperative period. *Increasing activity levels gradually improves exercise tolerance.*
- Teach measures to conserve energy while performing ADLs, such as sitting while showering and dressing, and wearing slip-on shoes. *These energy-conserving measures reduce oxygen demand and allow the person to remain independent as long as possible.*
- Keep frequently used objects within easy reach. *This helps conserve energy.*
- Administer oxygen as prescribed. Teach the person and family about home oxygen use if appropriate. *Supplemental oxygen can help improve activity and exercise tolerance.*
- Encourage maintenance of physical activity to tolerance. *Maintaining activity levels to the degree possible improves physical and emotional wellbeing.*
- Allow family members to provide assistance as needed. *This helps the person conserve energy and allows the family to retain a sense of usefulness.*

Pain

Pain is a priority problem in both the postoperative period and the terminal stages of cancer. Poorly managed pain prolongs recovery from surgery. In the person with terminal cancer,

chronic and acute pain must be managed effectively to allow a peaceful death.

- Assess and document pain using a standardised pain scale and objective data. Pain is a subjective experience, best evaluated by the person. *Changes in vital signs, guarded movement or unwillingness to move may indicate unreported pain.*
- Provide analgesics as needed to maintain comfort. *Postoperative recovery and restoration of function is facilitated by adequate pain management.*
- For cancer pain, maintain an around-the-clock medication schedule using narcotic, non-steroidal anti-inflammatory drugs and other medications as ordered. *Addiction is not a concern in terminal cancer; providing adequate pain relief that does not allow 'breakthrough' pain is important.*
- Provide or assist with comfort measures, such as massage, positioning, distraction and relaxation techniques. *These techniques promote relaxation and enhance pain relief.*
- Assist the person and family to plan and engage in activities that distract from pain, such as reading, watching television and engaging in social interactions. *Distraction helps the individual focus away from the pain.*
- Spend as much time with the person as possible; allow family members to remain with the person. *Physical presence of the nurse and family provides emotional support for the individual.*

NURSING CARE PLAN A person with lung cancer

After coughing up bloody sputum one morning, James Mueller, a 68-year-old retired mill worker, sees his doctor. A chest x-ray shows a suspicious density in the central portion of his right lung. Mr Mueller is admitted to the hospital the following Monday for diagnostic tests.

ASSESSMENT

Mr Mueller is admitted to the oncology unit and the nurse obtains a nursing history. Mr Mueller is married and has three grown children. He worked in a local paper mill for 35 years before retiring at age 62. He describes himself as 'pretty healthy', except for a chronic smoker's cough. He started smoking as a young man in the army. He has a 50-pack-a-year smoking history, having smoked a packet a day for 50 years since age 18. Mr Mueller says he briefly quit smoking following a small heart attack 3 years ago, but started again after 4 months. On further questioning, Mr Mueller says his cough has been productive for the past few months, especially in the morning, and that he is more short of breath than usual with activity.

Mr Mueller's examination data include BP 162/86, P 78 and regular, R 20 and T 36.9°C. Colour good, skin warm and dry. Inspiratory and expiratory wheezes noted in right chest but good breath sounds throughout. No other abnormal findings are noted on examination. The doctor orders early-morning sputum specimens for 3 days for cytological examination and schedules a CT scan of the chest the morning after admission.

Mr Mueller's FBC shows mild anaemia, but the remaining routine laboratory tests are essentially normal. Sputum cytology is positive for small-cell bronchogenic cancer. The CT scan shows a central mass approximately 4 cm in diameter with involved mediastinal and subclavicular lymph nodes. A small mass is also noted on the lumbar spine. After conferring with his doctor and an oncologist, Mr Mueller decides to undergo a trial course of chemotherapy.

DIAGNOSES

- *Impaired gas exchange* related to tumour mass and effects of chronic cigarette smoking manifested by increased shortness of breath.
- *Risk of inadequate nutrition* related to effects of chemotherapy manifested by weight loss and/or anorexia.
- *Risk of increased stress and anxiety* related to new diagnosis of lung cancer manifested by behavioural changes, sleep disturbances and/or changes in eating habits.
- *Knowledge deficit* about lung cancer and aids to smoking cessation manifested by continued smoking habits despite significant health challenges.

PLANNING

- Discuss symptoms to report to the doctor: increased dyspnoea or haemoptysis, severe stridor or wheezing, chest pain.
- Discuss measures to relieve nausea associated with chemotherapy, including premedication with a prescribed anti-emetic.
- Discuss possible effects of lung cancer with Mr and Mrs Mueller.
- Encourage Mr and Mrs Mueller to call a family conference to discuss the disease with their children and grandchildren.
- Refer to local cancer support group.
- Refer to community services for follow up and further teaching.
- Ask the doctor for a prescription for nicotine patches or gum for Mr Mueller.

Expected outcomes

- Maintain a patent airway.
- Maintain current weight.
- Express feelings and concerns about the effect of cancer on the family unit.
- Participate in care.
- Contact appropriate support groups.
- Verbalise an understanding of the disease, its treatment and prognosis.
- Develop a plan to stop smoking.

IMPLEMENTATION

- Evaluate family members' knowledge and understanding of lung cancer, correcting misinformation and teaching as needed.
- Teach coughing, deep breathing and hydration measures to facilitate airway clearance.
- Have a dietitian consult with Mr and Mrs Mueller to develop a diet plan for maintaining ideal weight.

NURSING CARE PLAN A person with lung cancer (continued)

- Have an Australian Lung Foundation volunteer contact the family.
- Work with Mr Mueller to develop a plan to stop smoking.

EVALUATION

Mr Mueller had his first chemotherapy treatment in the hospital and was discharged 4 days after admission. After 3 months of chemotherapy, his tumour shows little regression and a liver scan reveals further metastasis. He and his wife decide to stop chemotherapy, a decision with which the children reluctantly agree. Mr and Mrs Mueller are referred to hospice services. With the help of hospice nurses and volunteers, Mr Mueller is able to remain at home. His pain is managed initially with oral MS Contin, a sustained-release form of morphine sulfate, and later with an intravenous morphine infusion. Mr Mueller dies at home with his family at his side 9 months after his diagnosis of lung cancer.

CRITICAL THINKING IN THE NURSING PROCESS

1. The oncologist prescribed a chemotherapy regimen of cyclophosphamide, doxorubicin and vincristine. Describe how each of these drugs works against cancer cells and discuss the rationale for using this combination.
2. Develop a care plan to deal with the specific side effects for the above treatment regimen.
3. Mr Mueller had small-cell (oat-cell) cancer. How would his presentation and treatment differ if the diagnosis had been non-small-cell adenocarcinoma, stage $T_2N_2M_0$?

REFLECTION ON THE NURSING PROCESS

1. Outline what you have learned from this case study that you will apply to your future practice.
2. Given that Mr Mueller has continued to smoke even after experiencing a myocardial infarction, which communication and education strategies could you use to assist him with success in quitting smoking now he has developed lung cancer?

Anticipatory grieving

Because lung cancer is often advanced when diagnosed, the person faces the very real prospect of dying from the disease. Grieving for the anticipated loss of life is a normal response as the person and family begin to adapt to the diagnosis. Nursing care goals are to promote expression of feelings and thoughts about the loss and to help the person and family initiate grief work, make decisions and use appropriate resources and coping mechanisms to deal with the loss.

- Spend time with the person and family. *Time is necessary to develop a trusting, therapeutic relationship.*
- Answer questions honestly; do not deny the probable outcome of the disease. *Honesty reinforces reality and provides a sense of control over decisions to be made.*

TRANSLATION TO PRACTICE How can communication practices in a multidisciplinary lung cancer care team influence a person's care?

Qualitative research by Rowlands and Callen (2012) was part of a bigger mixed-methods study exploring the methods and efficacy of communication within and between the multidisciplinary, hospital-based, lung cancer care team. Twenty-two members were interviewed using semi-structured in-depth interviews. A thematic grounded theory approach was used to determine that there were two key themes emerging. First, that the characteristics of communication were influenced by roles within the team, where doctors dominated; and second, that current mediums for communication and traditional influences on role delineation impacted on communication. It was noted that face-to-face verbal communication was preferred and that existing cancer care guidelines did not address team communication barriers.

IMPLICATIONS FOR NURSING

Specific attention must be placed on introducing and developing communication skills between nurses and other members of the healthcare team to benefit the management not only of individuals with lung cancer but also of all people in need of quality healthcare. It is critical for healthcare professionals to work effectively together. When staff work within professional 'silos', the concept of a functioning team fails to exist. Also, when face-to-face communication is preferred, there is a risk that failure to document observations or changes to care can compromise the integrity and completeness of the person's medical record. Further investigation and professional development is required to ensure that a person's care is not compromised by failures in communication.

CRITICAL THINKING IN PERSON-CENTRED CARE

1. In this study, the findings indicated that although some literature suggests that multidisciplinary communication is well developed within healthcare, more work is required to ensure that a person's care is not compromised. Which characteristics and interventions should be undertaken to improve a team's capacity to communicate well? Make a table outlining both individual characteristics and team characteristics that will promote improved communication.
2. How will the findings of this study impact on how you will approach communication with other healthcare colleagues? Which further education requirements would be needed to improve multidisciplinary team communication?

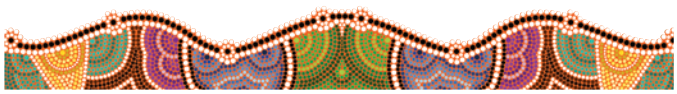
- Encourage the person and family to express their feelings, fears and concerns. *Open expression of feelings helps to promote understanding and acceptance.*
- Assist with understanding the grieving process and acceptance of feelings as normal. *Feelings of guilt, anger or depression may cause the person to withdraw from others. Explanation of the grieving process enhances understanding and ability to cope.*
- Help identify strengths and coping measures that have been used effectively in the past. Provide positive reinforcement for effective coping behaviour. *Past effective coping measures can help the person and family deal with the present situation and regain a sense of control.*
- Help the person and family make decisions regarding treatment and care. *This is also important to give them a sense of control.*
- Encourage use of other support systems, such as spiritual and social groups. Refer the individual and family to support groups, social support services and hospice care as indicated. Provide Cancer Council Australia literature and information as appropriate. *These support systems provide emotional support and help the person and family cope with the diagnosis.*
- Discuss advance directives (living wills) and power of attorney for healthcare with the individual and family. *These documents give the person and family a sense of control over the medical care provided if the person is no longer able to express their own wishes.*

Community-based care

A primary teaching need to prepare the person and family affected by lung cancer for home care is information about the disease itself, expected prognosis and planned treatment strategies. Provide honest information; do not promote false hope. Include the following additional topics in teaching for home care:

- importance of quitting smoking, especially if surgery has been performed. (The person with lung cancer may have difficulty recognising the need to stop smoking. Include information about the effects of nicotine and the tars in cigarette smoke on healing and already compromised lung tissue.)
- planned treatments such as chemotherapy or radiation therapy, including expected effects and usual side effects of each
- strategies to cope with noxious effects of radiation or chemotherapy
- activities and exercises to improve strength and regain function for the individual in the postoperative period
- the need to continue coughing and deep-breathing exercises at home
- symptoms to report to the doctor: fever, increasing or continued shortness of breath, cough, increased or purulent sputum, redness, pain, swelling or incisional drainage
- use of prescribed medications, including desired and potential side effects and interactions with other drugs or foods
- use of analgesics and other pain-relief measures for postoperative or cancer pain
- information about hospice services, community support, local cancer support groups for individuals and caregivers, and Cancer Council Australia services.

Refer the person and family for home health services, including nursing care, assistance with ADLs, respiratory care and respite care as needed.



CHAPTER HIGHLIGHTS

- Pneumonia, inflammation of the respiratory bronchioles and alveoli, usually is bacterial in origin. Different organisms are usually found in hospital-acquired pneumonia than in community-acquired pneumonia. Nursing care focuses on promoting airway clearance, supporting effective gas exchange and promoting rest.
- Infection control measures, including standard, airborne and contact precautions, are vital to prevent the spread of viral severe acute respiratory syndrome.
- Tuberculosis affects many people worldwide; in Australia, the primary affected populations are migrants, people with compromised immunity and people living in crowded or unsanitary conditions.
- The tuberculin test (PPD) detects a cellular immune response to *M. tuberculosis*, indicating infection but not necessarily active disease.
- Effective tuberculosis treatment is a public health concern, requiring therapy and compliance monitoring, contact follow up and assessment for adverse treatment effects.
- Disorders of the pleura, such as pleural effusion and pneumothorax, can affect lung expansion, ventilation and gas exchange when significant.
- Tension pneumothorax develops when air enters the pleural space but is unable to escape, collapsing the lung on the affected side and placing pressure on the unaffected lung and mediastinum. Ventilation, gas exchange, venous return and cardiac output can be significantly affected.
- Trauma may affect the chest wall (rib fracture, flail chest), the surface of the lungs (pulmonary contusion) or the airways and alveoli (smoke inhalation and near drowning). Flail chest and pulmonary contusion often occur concurrently; haemothorax also frequently develops with chest trauma. Chest trauma (chest wall or airways) can endanger effective ventilation and gas exchange.
- Lung cancer, the leading cause of cancer deaths, typically is advanced when diagnosed. Surgery, radiation therapy and chemotherapy are used to treat lung cancer, often in combination.

CONCEPT CHECK

1 Admitting orders for a person with acute bacterial pneumonia include an intravenous antibiotic every 8 hours, oxygen per nasal prongs at 5 L/min, continuous pulse oximetry monitoring, bed rest with bathroom privileges and chair at bedside as desired, diet as tolerated, sputum specimen for culture and sensitivity, FBC, urinalysis and electrolytes. Which order should the nurse carry out first?
1 Start the oxygen per nasal prongs.
2 Insert an intravenous catheter and start the prescribed antibiotic.
3 Provide a dinner tray to the person.
4 Obtain the sputum specimen.

2 When assessing a person with bacterial pneumonia, the nurse notes that the person's overall skin tone is somewhat grey and there is a bluish tinge around the person's finger tips. The nurse should (place the following in the correct order of priority):
1 start oxygen
2 assess breath sounds
3 notify the doctor
4 raise the head of the bed
5 obtain oxygen saturation level

3 The nurse evaluating a tuberculin test result 72 hours after it was administered notes an area of induration 9 mm in diameter. What additional information would indicate to the nurse that this is a positive result? The person:
1 resides in a long-term care facility
2 was born in South-East Asia
3 has HIV disease
4 is an injecting drug user

4 The nurse teaching a person taking prophylactic daily isoniazid (INH) following tuberculin test conversion includes which of the following in the instructions?
1 This drug turns your urine red-orange. This is harmless.
2 Report numbness and tingling of your extremities to your doctor.
3 You will need to have periodic eye examinations during treatment.
4 Do not use aspirin while taking this drug because abnormal bleeding may occur.

5 Which of the following statements made by a person with a new diagnosis of lung cancer would indicate that the nurse's teaching has been effective?
1 'Well, since I'm going to die anyway, I may as well go home, put my affairs in order and spend the rest of my time in the easy chair.'
2 'I understand that because the cancer has already spread, I will be undergoing aggressive cancer treatment for the next several years to beat this thing.'
3 'Even though I can't undo the damage caused by cigarette smoking, I will try to quit to prevent further damage to my lungs.'
4 'Having the "big C" is very scary; I'm just glad it is one of the more curable forms of cancer.'

6 The nurse caring for a person following a lobectomy notes 100 mL of red drainage in the chest drainage container since checking it 30 minutes previously. The nurse should (select all that apply):
1 empty the chest-tube drainage system
2 note the finding and re-evaluate drainage in 30 minutes
3 notify the surgeon
4 assess vital signs and level of consciousness
5 apply pressure to the chest tube insertion site

7 The nurse caring for a person having a thoracentesis appropriately assists the person to:
1 sit upright leaning forward during the procedure
2 breathe deeply as the needle is inserted
3 remain on quiet bed rest for 4 hours following the procedure
4 cough as the fluid is withdrawn

8 The nurse teaches a person being discharged from the emergency department with a diagnosis of fractured rib to:
1 avoid using pain medications to prevent respiratory depression
2 heavily tape the chest wall and promote comfort
3 remain on bed rest for a week to allow the fracture to stabilise
4 use a small pillow to splint the area when coughing

9 Which of the following assessment findings of a person with smoke inhalation does the nurse find of greatest concern?
1 Ash-like material in the sputum
2 Respiratory rate of 36
3 Skin and mucous membranes pink
4 Fine crackles in bilateral bases

10 Which of the following nursing diagnoses does the nurse identify as of highest priority for a person with tension pneumothorax?
1 *Decreased cardiac output*
2 *Ineffective breathing pattern*
3 *Acute pain*
4 *Risk of aspiration*

CHAPTER 36

NURSING CARE OF PEOPLE WITH GAS EXCHANGE DISORDERS

MAJELLA HALES

LEARNING OUTCOMES

- Describe the epidemiology, pathophysiology, manifestations and management of a person with asthma.
- Differentiate between the types, pathophysiology and management of an individual experiencing a chronic obstruction pulmonary disease.
- Compare the progression and potential outcomes for a person with a lung disease such as cystic fibrosis, atelectasis or bronchiectasis.
- Describe the influence on gas exchange for a person experiencing an occupational lung disease or sarcoidosis.
- Differentiate between the types of pulmonary vascular disorders in relation to aetiology, manifestations and management.
- Identify the types, pathophysiology, manifestations and management options for a person with respiratory failure.

CLINICAL COMPETENCIES

- Assess functional health status of a person with a disorder affecting ventilation and gas exchange.
- Use data and knowledge of the effects of the disorder and prescribed treatment to identify priority nursing diagnoses and to plan care for a person with a disorder affecting ventilation and gas exchange.
- Use the nursing process and evidence-based nursing research to plan and implement individualised nursing care for individuals, including measures to promote ventilation and gas exchange.
- Plan and provide appropriate teaching for health promotion in vulnerable populations and to prepare individuals and families for community-based care.
- Evaluate the effectiveness of nursing interventions and teaching, revising strategies and teaching plans as needed.
- Coordinate safe interprofessional care and administer prescribed medications and treatments for people with disorders affecting ventilation and gas exchange.

KEY TERMS

Normal function of the lower respiratory tract depends on several organ systems: the central nervous system, which stimulates and controls breathing; chemoreceptors in the brain, aortic arch and carotid bodies, which monitor the pH and oxygen content of blood; the heart and circulatory system, which provide for blood supply and gas exchange; the musculoskeletal system, which provides an intact thoracic cavity capable of expanding and contracting; and the lungs and bronchial tree, which allow air movement and gas exchange. Impaired function of any of these systems affects ventilation. As a result, tissues may become *hypoxic*, with inadequate oxygen to support metabolic activity.

Although some of the disorders discussed in this chapter can affect ventilation (air movement into and out of the airways and alveoli), all can have significant effects on gas exchange. The mechanisms by which they affect gas exchange differ:

- In reactive airway disease (asthma) and obstructive disorders, air trapping reduces the amount of oxygen available to drive gas exchange.
- Interstitial lung disorders affect the ability of the lungs to expand and the work of breathing—again, reducing alveolar oxygenation and gas exchange.
- Pulmonary vascular disorders affect blood flow to the lungs or a portion of the lungs, reducing gas exchange through their effects on perfusion of the lungs.
- Respiratory failure is the ultimate consequence of impaired gas exchange; the lungs cannot adequately oxygenate the blood or eliminate sufficient carbon dioxide.

With a few exceptions, the disorders discussed in this chapter are relatively common, chronic lung diseases.

Disorders of other body systems, such as neurological disorders (e.g. head injury, spinal cord trauma or disorders, multiple sclerosis and myasthenia gravis) can also affect gas exchange through their effects on the central or peripheral nervous systems. These disorders and their effects on the respiratory system are discussed in subsequent chapters of this text.

FAST FACTS

- Approximately 6.3 million Australians live with a chronic respiratory condition.
- Approximately 10% of Australians have asthma.
- Approximately 5.7% of Australians over 55 have a chronic obstructive pulmonary disease (COPD).
- In 2013, mortality from COPD in males had reduced by two-thirds of that in 1970.
- In 2014, over 6400 people died of COPD (54% males, 45% females).

Sources: Australian Institute of Health and Welfare (AIHW) (2014a); Australian Bureau of Statistics (ABS) (2015a).

Ageing affects pulmonary ventilation and gas exchange as well. The number of alveoli decrease and emphysematous changes reduce the surface area for gas exchange. Alveoli become less elastic, causing increased air trapping and dead space. For most older adults who remain active, these changes have minimal effect on exercise tolerance and activities of daily living (ADLs). When combined with lung disease, however, age-related pulmonary changes increase the person's risk of developing respiratory failure.

In 2013, chronic lower respiratory diseases ranked fourth overall as the leading cause of death for non-Indigenous Australians, and third for Aboriginal and Torres Strait Islander Australians (ABS, 2012; 2015c).

REACTIVE AIRWAY DISEASE

In reactive airway disease, the airways narrow in response to a stimulus. Airway narrowing limits airflow both into and out of the alveoli. Limited airflow increases the work of breathing and the residual volume of the lungs as air is trapped behind narrowed airways. Inspired air mixes with an abnormally large volume of residual air, effectively reducing the amount of oxygen available in the alveoli. Decreased alveolar ventilation further reduces oxygen available for exchange.

THE PERSON WITH ASTHMA

Asthma is a chronic inflammatory disorder of the airways characterised by recurrent episodes of wheezing, breathlessness, chest tightness and coughing. Inflammation causes increased responsiveness of the airways to multiple stimuli. The widespread airflow obstruction that occurs during acute episodes usually reverses either spontaneously or with treatment. While most episodes or asthma 'attacks' are relatively brief, some individuals with asthma may experience longer episodes with some degree of airway impairment daily. In rare cases, an acute episode of asthma is so severe that respiratory failure and death result.

Prevalence and risk factors

In Australia, approximately 10% of the population had asthma in 2013. Rates are decreasing in children and young adults, but have remained stable in adults 35 years and older (ABS, 2015a). Prevalence is similar in males and females aged 5–34, but higher in females aged 35 years and over. Admissions for asthma vary across the lifespan with the significant majority of admissions occurring between 1 and 4 years of age (see Figure 36.1). Although mortality rates have reduced by 45% since 1997, 0.3% of all deaths annually are asthma related (ABS, 2015b; AIHW, 2014b). In comparison with international standards this figure is high. Asthma remains a significant problem and burden on healthcare resources (AIHW, 2014b).

A number of risk factors can be identified for asthma, although many people develop the disease in the absence of known risk factors. Allergies play a strong role in childhood asthma; a lesser role in adults. There is a strong genetic component to the disease, although a specific pattern of inheritance has not been identified. More than 50 different genes have been identified as being involved in a variety of processes contributing to the development of asthma (Weiss, 2015). Environmental factors, including dust

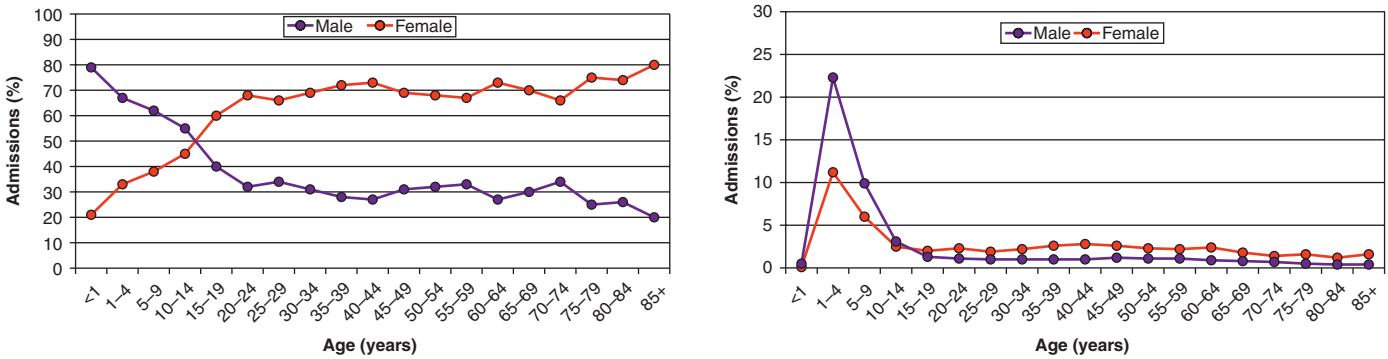

FIGURE 36.1 ■ Asthma admissions. *A*, As a percentage by gender across each age group, 2012–2013, Australia. *B*, As a percentage of all asthma admissions by age and gender, 2012–2013, Australia

Source: Generated using data from AIHW (2015a). *Principal diagnosis data cubes: Separation statistics by principal diagnosis in ICD-10-AM, Australia, 2011–12 to 2012–13—ICD-10 J45-Asthma & J46-Status asthmaticus*. Retrieved from www.aihw.gov.au/hospitals-data/principal-diagnosis-data-cubes/.

mites, animal and fungal allergens, pollution and occupational exposure to industrial compounds, may contribute. Respiratory viruses such as rhinovirus and influenza can precipitate asthma attacks. Other contributory factors include exercise (particularly in cold air) and emotional stress (Morris, 2015).

FAST FACTS

- Only 20% of people with asthma 15 years and over and only 41% of children between 0 and 14 years of age have a written asthma action plan.
- Respiratory tract infections are frequently identified as an exacerbating factor in admission to hospital.
- In 2008–2009*, $665 million was spent on asthma, equating to approximately 0.9% of the healthcare budget.
- Fifty per cent of the healthcare budget is related to the prevision/subsidy of prescription pharmaceuticals.

*Most recent data available.

Sources: Data extracted from AIHW (2015b; 2015c); National Asthma Council Australia (NACA) (2015).

Physiology review

Airways within the lungs contain criss-crossing strips of smooth muscle that control their diameter. This muscle is innervated by the autonomic nervous system. Parasympathetic (cholinergic) stimulation leads to bronchoconstriction or narrowing of the airways. Sympathetic stimulation through β_2-adrenergic receptors causes bronchodilation or expansion of the airways (Martini, Nath & Bartholomew, 2014) and slight bronchoconstriction normally predominates. However, when increased airflow is necessary (e.g. during exercise), the parasympathetic system is inhibited and stimulation of the sympathetic system causes bronchodilation. Inflammatory mediators (such as histamine) released during an antigen–antibody response act directly on bronchial smooth muscle to produce bronchoconstriction.

Pathophysiology

In asthma, the airways are in a persistent state of inflammation. During symptom-free periods, airway inflammation in asthma is subacute or quiet. Even during these periods, however, inflammatory cells such as eosinophils, neutrophils and lymphocytes

FOCUS ON CULTURAL DIVERSITY Prevalence of asthma in certain populations

- Asthma prevalence is higher in Aboriginal and Torres Strait Islander peoples in every age group, as shown in the table below:

AGE IN YEARS	ABORIGINAL AND TORRES STRAIT ISLANDER AUSTRALIANS	NON-INDIGENOUS AUSTRALIANS
0–14	14.5	9.3
15–24	17.1	10.7
45–54	22.0	9.6
> 55	22.2	10.5

- Prevalence of asthma is lower in people who are living in Australia but were born overseas, as represented by the following table:

COUNTRY OF BIRTH	RELATIVE PERCENTAGE OF POPULATION
Australia	11.2 %
North Africa and the Middle East	10.8 %
United Kingdom	10.0 %
Other Oceania	9.0 %
Other North-West Europe	7.5 %
Southern and Eastern Europe	5.9 %
South-East Asia	4.7 %

Sources: Data extracted from ABS (2012; 2013).

may be found in airway tissues, and oedema may be present. An acute inflammatory response, during which resident inflammatory cells interact with inflammatory mediators, cytokines and additional infiltrating inflammatory cells, may be triggered by a variety of factors (Bullock & Hales, 2012). Common triggers for an acute asthma attack include exposure to allergens, respiratory tract infection, exercise, inhaled irritants and emotional upsets.

Attack triggers

Childhood asthma (which may continue into adulthood) is most often linked to inhalation of allergens such as pollen, animal dander (shed skin flakes) or household dust. Individuals with allergic asthma often have a history of other allergies. Environmental pollutants, such as tobacco smoke and irritant gases (e.g. sulfur dioxide, nitrogen dioxide and ozone), can provoke asthma. Exposure to second-hand smoke as a child is associated with a higher risk and increased severity of asthma. Agents found in the workplace, such as noxious fumes and gases, chemicals and dusts, may cause occupational asthma.

Respiratory infections—viral, in particular—are a common internal stimulus for an asthmatic attack. Exercise-induced asthma attacks are also relatively common. Loss of heat or water from the bronchial surface may contribute to exercise-induced asthma. Exercising in cold, dry air increases the risk of an asthma attack in susceptible people.

Emotional stress is a significant aetiological factor for attacks in almost half of people with asthma. Common pharmacological triggers include aspirin and other non-steroidal anti-inflammatory drugs, sulfites (which are used as preservatives in wine, beer, fresh fruits and salad) and beta-blockers.

See Box 36.1 for triggers of asthma.

Responses

When a trigger such as inhalation of an allergen or irritant occurs, an acute or *early response* develops in the hyper-reactive airways predisposed to bronchospasm. Sensitised mast cells in the bronchial mucosa release inflammatory mediators such as histamine, prostaglandins and leukotrienes. Resident and infiltrating inflammatory cells also produce inflammatory mediators such as cytokines, bradykinin and growth factors. These mediators stimulate parasympathetic receptors and bronchial smooth muscle to produce bronchoconstriction. They also increase capillary permeability, which allows plasma to escape and leads to mucosal oedema. Mucus production is stimulated; excess mucus collects in the narrowed airways (Bullock & Hales, 2012).

The attack is prolonged by the *late phase response*, which develops 4 to 12 hours after exposure to the trigger. Inflammatory cells such as basophils and eosinophils are activated, which damage airway epithelium, produce mucosal oedema, impair mucociliary clearance and produce or prolong bronchoconstriction. The degree of hyper-reactivity depends on the extent of inflammation. Together, bronchoconstriction, oedema and inflammation, and mucus secretion narrow the airway. Airway resistance increases, limiting airflow and increasing the work of breathing (see Figure 36.2).

Limited expiratory airflow traps air distal to the spastic, narrowed airways. Trapped air mixes with inspired air in the alveoli, reducing its oxygen tension and gas exchange across the alveolar–capillary membrane. Distended alveoli compress alveolar capillaries, reducing blood flow and further affecting gas exchange. As a result, hypoxaemia develops. Hypoxaemia and increased lung volume due to trapping stimulate the respiratory rate. Hyperventilation causes the $PaCO_2$ to fall, leading to respiratory alkalosis. (See Chapter 9 for more information about acid–base imbalances.)

To summarise, in an acute asthma attack inflammatory mediators are released from sensitised airways followed by activation of inflammatory cells. These events lead to bronchoconstriction, airway oedema and impaired mucociliary clearance. Airway narrowing limits airflow and increases the work of breathing; trapped air mixes with inhaled air, impairing gas exchange.

Manifestations and complications

An asthma attack is characterised by a subjective sensation of chest tightness, cough, dyspnoea and wheezing (see 'Manifestations' box below). The onset of symptoms may be either abrupt or insidious, and an attack may subside rapidly or persist for hours or days. A sense of chest constriction and non-productive cough are common early manifestations of an attack. During an attack, tachycardia, tachypnoea and prolonged expiration are common. Diffuse wheezing is heard on auscultation. With more severe attacks, use of the accessory muscles of respiration, intercostal retractions, loud wheezing and distant breath sounds may be noted. Fatigue, anxiety, apprehension and severe dyspnoea that allows speaking only one or two words between breaths may occur with persistent severe episodes. The onset of respiratory failure is marked by inaudible breath sounds with reduced wheezing and an ineffective cough. Without careful assessment, this apparent relief of symptoms can be misinterpreted as an improvement.

BOX 36.1 Triggers of asthma

- Environmental allergens (often small glycoproteins, e.g. dust mites, animal dander, pollen, fungi)
- Cigarette smoking
- Pollution
- Irritants (fumes from volatile compounds, e.g. cleaning agents, glues, paints)
- Respiratory tract infections
- Medications (aspirin, non-steroidal anti-inflammatory drugs, beta-blockers)
- Physical factors (exercise, changes in temperature)
- Gastro-oesophageal reflux
- Emotional stress
- Occupational exposure to organic compounds
- Food additives

MANIFESTATIONS Acute asthma

- Dyspnoea
- Tachypnoea
- Tachycardia
- Chest tightness
- Wheezing
- Cough
- Anxiety

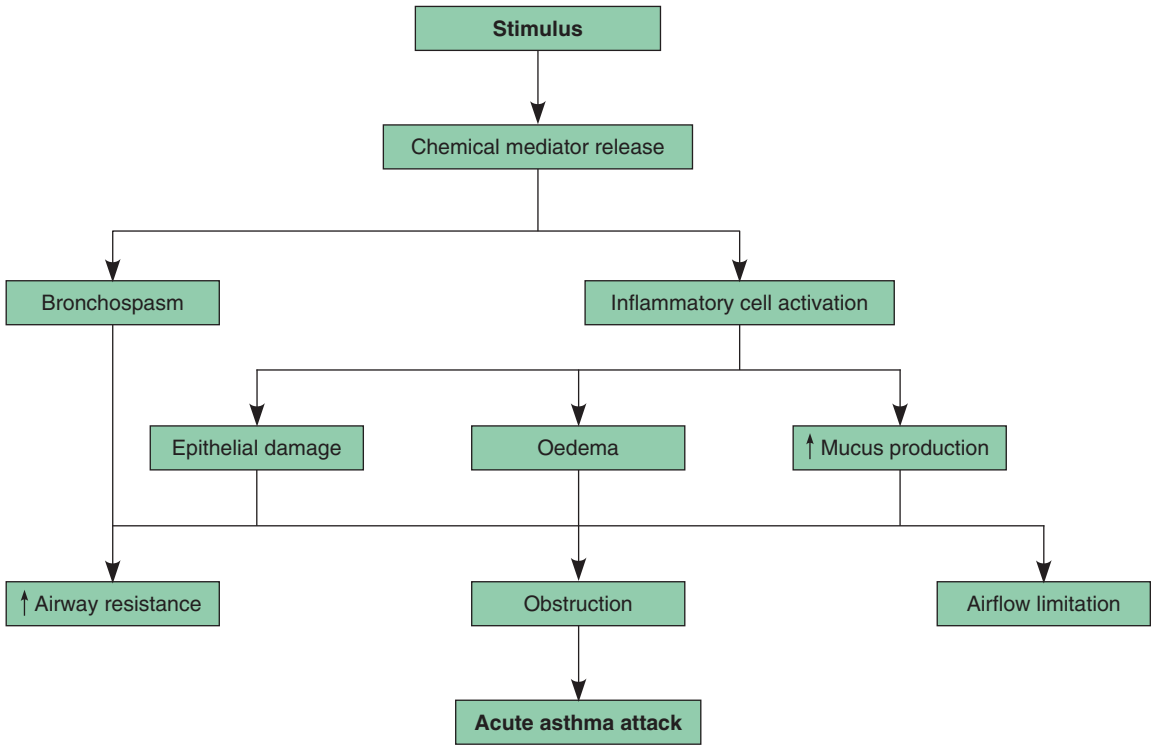

FIGURE 36.2 ■ Pathogenesis of an acute episode of asthma

The frequency of attacks and severity of symptoms vary greatly from person to person. Although some people have infrequent, mild episodes, others have nearly continuous manifestations of cough, dyspnoea on exertion and wheezing, with periodic severe exacerbations (see Table 36.1). **Status asthmaticus** is severe, prolonged asthma that does not respond to routine treatment. Without aggressive therapy, status asthmaticus can lead to respiratory failure with hypoxaemia, hypercapnia and acidosis. Endotracheal intubation, mechanical ventilation and aggressive drug treatment may be necessary to sustain life.

In addition to acute respiratory failure, other complications associated with acute asthma include dehydration, respiratory infection, atelectasis, pneumothorax and cor pulmonale.

Cough-variant asthma

A common symptom of asthma is a cough which is usually non-productive and non-paroxysmal (Morris, 2015). Cough can be initiated by either upper airway irritants (e.g. post nasal drip or gastro-oesophageal reflux disease) or by inflammation or constriction of the lower airways. Most commonly, cough associated with asthma is accompanied by classic asthma symptoms

TABLE 36.1 GINA assessment of asthma control in adults, adolescents and children 6–11 years

ASTHMA SYMPTOM CONTROL	CONTROLLED	PARTLY CONTROLLED	UNCONTROLLED
Daytime asthma symptoms more than twice a week? Any night waking due to asthma? Reliever needed for symptoms more than twice a week? Any activity limitation due to asthma?	None of these	1–2 of these	3–4 of these
Risk factors for poor asthma outcomes Assess risk factors at diagnosis and periodically, particularly for individuals experiencing exacerbations. Measure FEV_1 at start of treatment, after 3–6 months of controller treatment to record the individual's personal best lung function, then periodically for ongoing risk assessment.			Having one or more of the risk factors increases the risk of exacerbations even if symptoms are well controlled.

Source: Global Initiative for Asthma (GINA) (2015). *Global strategy for asthma management and prevention*. Retrieved from www.ginasthma.org/local/uploads/files/GINA_Report_2015_May19.pdf.

such as chest constriction, dyspnoea and wheezing. Individuals with *cough-variant asthma*, however, have persistent cough without wheezing or dyspnoea, often delaying diagnosis. These individuals do have significant airway inflammation and demonstrate the pathophysiological features of asthma.

INTERPROFESSIONAL CARE

The diagnosis of asthma is based primarily on the history and manifestations. Treatment goals are twofold. Daily management focuses on controlling symptoms and preventing acute attacks. During an acute attack, therapy is directed towards restoring airway patency and alveolar ventilation.

Diagnosis

Diagnostic tests are used to determine the degree of airway involvement during and between acute episodes, and to identify causative factors such as allergens. See Chapter 33 for more information about and the nursing care related to these diagnostic tests.

- *Respiratory function tests (RFTs)* are used to evaluate the degree of airway obstruction. Respiratory function testing done before and after use of an aerosolised bronchodilator helps determine the reversibility of airway obstruction. The residual volume of the lungs may be increased and the vital capacity decreased or normal even during periods of remission. The forced expiratory volume and peak expiratory flow rate are the most valuable respiratory function studies to evaluate the severity of an asthma attack and the effectiveness of treatment measures.
- *Challenge* or *bronchial provocation testing* uses an inhaled substance such as methacholine or histamine with RFTs to confirm the diagnosis of asthma by detecting airway hyperresponsiveness.
- *Arterial blood gases (ABGs)* are drawn during an acute attack to evaluate oxygenation, carbon dioxide elimination and acid–base status. ABGs initially show hypoxaemia with a low PaO_2 and mild respiratory alkalosis with an elevated pH and low $PaCO_2$ due to tachypnoea. Severe airflow obstruction causes significant hypoxaemia and respiratory acidosis ($pH < 7.35$ and $PaCO_2 > 42$ mmHg), indicative of respiratory failure and the need for mechanical ventilation. See Chapter 9 for more information about arterial blood gases and their interpretation.
- *Skin testing* may be done to identify specific allergens if an allergic trigger is suspected for asthma attacks.

Disease monitoring

Peak expiratory flow rate (PEFR) is used on a day-to-day basis to evaluate the severity of bronchial hyperresponsiveness. Small, inexpensive meters to measure PEFR are available. Readings taken at varying times of day over several weeks are used to establish the person's personal best or normal PEFR. This value is then used to evaluate the severity of airway obstruction. The National Asthma Council of Australia recommends that some people with asthma may benefit from regular peak flow monitoring, which enables not only the individual but also asthma healthcare professionals to monitor and recognise exacerbations early (NACA, 2015).

Preventive measures

Asthma attacks often can be prevented by avoiding allergens and environmental triggers. Modifying the home environment by controlling dust, removing carpets, covering mattresses and pillows to reduce dust mite populations and installing air-filtering systems may be useful. Pets may need to be removed from the household. Eliminating all tobacco smoke in the home is vital. Wearing a mask that retains humidity and warm air while exercising in cold weather may help prevent attacks of exercise-induced asthma. Early treatment of respiratory infections is vital to prevent asthma exacerbations. National guidelines recommend that all individuals with asthma have a written asthma action plan. Despite the recommendation being in place for over 20 years, the majority of people with asthma in Australia do not have a plan. Healthcare professionals should work towards ensuring that all individuals in their care have a written asthma action plan.

Asthma first aid

Friends and family should be aware of how to manage an individual who is having an asthma attack. The National Asthma Council Australia advocates a four-step plan for acute asthma management. The First Aid for Asthma chart (see Figure 36.3) clearly identifies steps to assist an individual who is having an asthma attack.

Medications

Medications are used to prevent and control asthma symptoms, reduce the frequency and severity of exacerbations, and reverse airway obstruction. Drugs used for long-term control of asthma are taken daily to maintain control of the disease. The primary drugs in this group are anti-inflammatory agents, long-acting bronchodilators and leukotriene receptor antagonists. Quick-relief medications provide prompt relief of bronchoconstriction and airflow obstruction with associated wheezing, cough and chest tightness. Short-acting adrenergic stimulants (rapid-acting bronchodilators), anticholinergic drugs and methylxanthines fall into this category.

A step-wise approach for managing asthma is recommended (see Figure 36.4). For all individuals, a short-acting inhaled β_2-agonist is recommended for quick relief of acute symptoms. Up to three treatments at 20-minute intervals or a single nebuliser treatment may be used as needed. Strategies for long-term control may need to be modified if a short-acting bronchodilator is needed more than twice a week (NACA, 2015).

Many of the drugs used for continued asthma management and relief of an acute attack can be administered by a metered-dose inhaler (MDI), dry powder inhaler (DPI) or nebuliser. The advantages of administering medications locally by inhalation include rapid onset and reduced systemic effects of the drugs. In an MDI, a chemical propellant is used to deliver the medication when the canister is depressed. In contrast, DPI contains no propellant. Instead, the medication is released by inhaling rapidly through the mouthpiece.

Nursing implications for medications used to treat asthma are outlined in the 'Medication administration' box below.

First Aid for Asthma

1

Sit the person comfortably upright.
Be calm and reassuring.
Don't leave the person alone.

2

Give 4 puffs of a blue/grey reliever
(e.g. Ventolin, Asmol or Airomir)
Use a spacer, if available.
Give 1 puff at a time with 4 breaths after each puff
Use the person's own inhaler if possible.
If not, use first aid kit inhaler or borrow one.

OR

Give 2 separate doses of a Bricanyl or Symbicort inhaler
If a puffer is not available, you can use Symbicort **(people over 12)** or Bricanyl, even if the person does not normally use these.

3

Wait 4 minutes.
If the person still cannot breathe normally, **give 4 more puffs.**

Wait 4 minutes.
If the person still cannot breathe normally, **give 1 more dose.**

4

If the person still cannot breathe normally,
CALL AN AMBULANCE IMMEDIATELY (DIAL 000)
Say that someone is having an asthma attack.

Keep giving reliever.
Give 4 puffs every 4 minutes until the ambulance arrives.
Children: 4 puffs each time is a safe dose.
Adults: For a severe attack you can give up to 6–8 puffs every 4 minutes

If the person still cannot breathe normally, **CALL AN AMBULANCE IMMEDIATELY (DIAL 000)** Say that someone is having an asthma attack.

Keep giving reliever while waiting for the ambulance:
For Bricanyl, give 1 dose every 4 minutes
For Symbicort, give 1 dose every 4 minutes (up to 3 more doses)

HOW TO USE INHALER

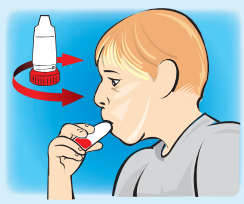
WITH SPACER

- **Assemble spacer**
- **Remove puffer cap** and **shake well**
- Insert puffer upright into spacer
- Place mouthpiece between teeth and seal lips around it
- **Press once firmly** on puffer to fire one puff into spacer
- **Take 4 breaths** in and out of spacer
- Slip spacer out of mouth
- **Repeat** 1 puff at a time until 4 puffs taken – remember to shake the puffer before each puff
- **Replace cap**

WITHOUT SPACER

- **Remove cap** and **shake well**
- **Breathe out** away from puffer
- Place mouthpiece between teeth and seal lips around it
- **Press once firmly** on puffer while breathing in slowly and deeply
- Slip puffer out of mouth
- **Hold breath** for 4 seconds or as long as comfortable
- Breathe out slowly away from puffer
- **Repeat** 1 puff at a time until 4 puffs taken – remember to shake the puffer before each puff
- **Replace cap**

BRICANYL OR SYMBICORT



- **Unscrew cover** and remove
- **Hold inhaler upright and twist grip** around and then back
- **Breathe out** away from inhaler
- Place mouthpiece between teeth and seal lips around it
- **Breathe in forcefully and deeply**
- Slip inhaler out of mouth
- Breathe out slowly away from inhaler
- **Repeat** to take a second dose – remember to twist the grip both ways to reload before each dose
- **Replace cover**

Not Sure if it's Asthma?
CALL AMBULANCE IMMEDIATELY (DIAL 000)
If a person stays conscious and their main problem seems to be breathing, follow the asthma first aid steps. Asthma reliever medicine is unlikely to harm them even if they do not have asthma.

Severe Allergic Reactions
CALL AMBULANCE IMMEDIATELY (DIAL 000)
Follow the person's Action Plan for Anaphylaxis if available. If the person has known severe allergies and seems to be having a severe allergic reaction, use their adrenaline autoinjector (e.g. EpiPen, Anapen) before giving asthma reliever medicine.

ICS: inhaled corticosteroid; SABA: short-acting $beta_2$ agonist; LABA: long-acting $beta_2$ agonist

* Reliever: Short-acting $beta_2$ agonist (or low-dose budesonide/eformoterol combination for patients using this combination as both maintenance and reliever).

§ In addition, manage flare-ups with extra treatment when they occur, and manage exercise-related asthma symptoms as indicated.

† Montelukast can be added to inhaled corticosteroid as an alternative to switching to ICS/LABA, but is less effective.

Note: PBS status as at April 2015: Montelukast treatment is not subsidised by the PBS for people aged 15 years or over. Special Authority is available for DVA gold card holders, or white card holders with approval for asthma treatments.

FIGURE 36.4 ■ Stepped approach to adjusting asthma medication in adults

BRONCHODILATORS Most asthmatics need bronchodilator therapy to control their symptoms (see Table 36.2). Inhalation of nebulised medication is the preferred means of administration. The primary bronchodilators used include adrenergic stimulants and anticholinergic agents. These drugs often are administered in combination with an anti-inflammatory agent.

Adrenergic stimulants (β_2-agonists) affect receptors on smooth muscle cells of the respiratory tract, causing smooth muscle relaxation and bronchodilation. Long-acting adrenergic stimulants such as inhaled salmeterol and oral sustained-release salbutamol are used in conjunction with anti-inflammatory drugs to control symptoms, but are not appropriate to treat an acute episode of asthma. Inhaled short-acting beta-adrenergic agonists such as salbutamol and terbutaline, administered by MDI or DPI, are the treatment of choice for quick relief. They act within minutes, but their duration generally is short, lasting only 4 to 6 hours. Tachycardia and muscle tremors, common side effects of adrenergic agonists, are minimal with inhalation therapy.

Anticholinergic medications prevent bronchoconstriction by blocking parasympathetic input to bronchial smooth muscle. Ipratropium bromide, an anticholinergic drug administered by MDI, is useful when asthma symptoms are poorly controlled by adrenergic stimulants alone. Anticholinergic drugs act more slowly than adrenergic stimulants, requiring up to 60 to 90 minutes to achieve maximal effect.

ANTI-INFLAMMATORY AGENTS Corticosteroids and two non-steroidal anti-inflammatory agents, cromolyn sodium and

TABLE 36.2 Asthma medications and delivery devices

GENERIC NAME	COMMON TRADE NAMES	DEVICE OR PRESENTATION	ROUTE OF DELIVERY	CLASS
RELIEVERS				
Salbutamol	Airomir Asmol Butamol Epaq Ventolin	Autohaler MDI Nebulising solution Syrup Injection *(Often for obstetric purposes)*	Inhaled Oral Subcutaneous injection Intramuscular injection Intravenous injection	SAßa
Terbutaline	Bricanyl	Turbuhaler Elixir Solution for injection	Inhaled Oral Subcutaneous injection	
PREVENTERS				
Ciclesonide	Alvesco	MDI	Inhaled	ICS

Budesonide	Pulmicort	Turbuhaler Nebulising suspension	Inhaled	ICS
Beclomethasone dipropionate	Qvar	MDI Autohaler	Inhaled	OCS
Sodium cromoglycate	Intal Forte	Nebulising solution	Inhaled	Mast cell stabiliser
Nedocromil sodium	Tilade	MDI	Inhaled	Mast cell stabiliser
Montelukast	Singulair	Tablet	Oral	LTRA
SYMPTOM CONTROLLERS				
Eformoterol fumarate dehydrate	Oxis Foradile	Turbuhaler	Inhaled	LAßa
Salmeterol xinafoate	Serevent	Accuhaler	Inhaled	LAßa
COMBINATION MEDICATIONS				
Fluticasone and salmeterol	Seretide	Accuhaler MDI	Inhaled	LAßa + ICS
Budesonide and eformoterol	Symbicort	Turbuhaler	Inhaled	LAßa + ICS

ICS = inhaled corticosteroids; LAßa = long-acting, selective beta$_2$-adrenoreceptor agonist; MDI = metered dose inhaler; SAßa = short-acting beta agonist; LTRA = leukotriene receptor antagonist.

nedocromil, are used to suppress airway inflammation and reduce asthma symptoms.

Corticosteroids block the late response to inhaled allergens and reduce bronchial hyper-responsiveness. The preferred route of administration is by MDI or DPI to minimise systemic absorption and reduce the adverse effects of prolonged steroid use (cushingoid effects). For a severe acute attack, corticosteroids may be given systemically to alleviate symptoms and induce remission.

Cromolyn sodium and nedocromil are used to prevent acute episodes of asthma. They reduce airway hyper-reactivity and inhibit the release of mediator substances. These drugs are used for long-term control of asthma, not quick relief. They have a wide margin of safety and few side effects.

LEUKOTRIENE ANTAGONISTS Leukotriene modifiers, montelukast (Singulair) and zafirlukast (Accolate), are oral medications that reduce the inflammatory response in asthma. They appear to improve lung function, diminish symptoms and reduce the need for short-acting bronchodilators. These drugs affect the metabolism and excretion of other medications such as warfarin and theophylline and may cause liver toxicity.

METHYLXANTHINE Theophylline is an old drug of the methylxanthine class, which is used less commonly nowadays

MEDICATION ADMINISTRATION Asthma

ADRENERGIC STIMULANTS

Adrenergic stimulants affect sympathetic receptors in the respiratory tract. Administered by metered-dose inhalers or dry powder inhalers, these drugs are the treatment of choice for acute bronchial asthma. Nearly all of the drugs in this class (adrenaline and isoprenaline being the exceptions) selectively activate β_2-receptors at the doses typically used to treat asthma. β_2-receptor activation results in smooth muscle relaxation and bronchodilation. Salmeterol and eformoterol are highly selective to β_2-receptors, resulting in fewer adverse effects. However, they have been shown to increase the risk of serious asthma exacerbations and death by masking the symptoms of worsening inflammation. Salmeterol (or eformoterol) should be used with concomitant corticosteroid therapy to prevent rapid deterioration from serious bronchospasm (MIMS, 2015a).

Oral forms of adrenergic agonists may be used for prophylaxis but are not effective in treating an acute attack because of their slow onset. When administered orally or parenterally, their effect on sympathetic nervous system receptors can produce undesirable side effects, such as nervousness, irritability, tachycardia and cardiac arrhythmias.

Nursing responsibilities

- Use with caution in individuals with hypertension, cardiovascular disease or arrhythmias, hyperthyroidism or diabetes.
- When given to a person who is hypoxaemic and acidotic, these drugs may cause potentially dangerous cardiac stimulation.
- Observe for desired effect of reduced dyspnoea and wheezing. Central nervous system stimulation (anxiety, irritability and insomnia) and tremor are common side effects.

Health education for the person and family

- Follow the First Aid for Asthma chart (see Figure 36.3).
- Use the prescribed inhaler or nebuliser as directed.
- If taking a bronchodilator along with another medication by inhalation, use the bronchodilator first to open airways and enhance the effectiveness of the second medication.
- Rinse mouth after using inhalers to reduce systemic absorption of the medication.
- Keep a log to track bronchodilator use. If the drug becomes less effective or if higher doses are needed, contact a doctor.
- Report palpitations, irregular pulse and other side effects to the doctor.

ANTICHOLINERGICS

Anticholinergics are potent bronchodilators, blocking muscarinic receptors of the parasympathetic nervous system. Activation of muscarinic receptors produces smooth muscle contraction and bronchoconstriction; blockade of these receptors facilitates smooth muscle relaxation and bronchodilation. Atropine is used infrequently because of its tendency to dry secretions of the mucous membranes and other side effects. Ipratropium and tiotropium bromide are available as inhalers and have fewer side effects than atropine.

Nursing responsibilities

- Assess for possible contraindications to the drug, including hypersensitivity, glaucoma, prostatic hypertrophy or bladder-neck obstruction.
- Assess for desired and/or adverse effects: improving or worsening symptoms; nausea, vomiting, abdominal cramping, anxiety, dizziness; headache.
- Provide ice chips or sips of clear fluid to relieve dry mouth.

Health education for the person and family

- To prevent overdose, take no more than the prescribed number of doses per day.
- If the drug becomes less effective over time, notify the doctor; an adjustment in dosage may be needed.

CORTICOSTEROIDS

The anti-inflammatory effect of corticosteroids helps both prevent and treat acute episodes. Corticosteroids are used to reduce the frequency and severity of asthma attacks and allow reduced dosages of other drugs. The beneficial effects of corticosteroids for asthma result from their ability to decrease the synthesis and release of inflammatory mediators (such as histamine and leukotrienes), reduce inflammatory cell activation and infiltration and decrease airway oedema. Corticosteroids also increase the number and receptivity of β_2-receptors (Chetta & Olivieri, 2012). The cushingoid side effects of corticosteroids, always a major concern with their use, are minimised when they are inhaled. Note that the combination product salmeterol/fluticasone is associated with an increased risk of serious asthma exacerbations and death. It is a second-line drug, recommended for use only when asthma is inadequately controlled using other preparations (MIMS, 2015b).

Nursing responsibilities

- Administer inhaler doses after bronchodilators to facilitate transit of the medication to distal airways.
- Assess for common side effects: sore throat; hoarseness; and oropharyngeal or laryngeal *Candida albicans* infection.
- Administer antifungal medications or gargles as ordered.

Health education for the person and family

- Rinse the mouth after using the inhaler and maintain good oral hygiene to reduce the risk of fungal infections.
- These medications should not be used to alleviate the symptoms of an acute attack.
- Several weeks of continued therapy may be required before a beneficial effect is noticed.
- Notify the doctor if you develop weight gain, fluid retention, muscle weakness, redistribution of fat or mood changes.

MAST CELL STABILISERS

Cromolyn sodium and nedocromil inhibit inflammatory cells in the airway, blocking early and late responses to inhaled antigens. Both drugs also prevent bronchoconstriction in response to inhaling cold air. These drugs act primarily by stabilising the cytoplasmic membrane of mast cells, preventing the cells from releasing inflammatory mediators

MEDICATION ADMINISTRATION Asthma (continued)

such as histamine. These drugs are used only for preventing asthma attacks, not to treat an acute attack. They are administered by metered-dose inhaler and have a wide margin of safety. Individuals using nedocromil may complain of an unpleasant taste.

Nursing responsibilities

- Evaluate for potential adverse effects of wheezing and bronchoconstriction.

Health education for the person and family

- Gargling or sipping water can decrease the throat irritation associated with nebuliser treatment.
- Use appropriate technique. Inhale deeply with head tipped back to open airways, hold breath and then exhale. Repeat until all the drug dose has been inhaled.
- These drugs are used only to prevent asthma attacks; they are not effective in treating an acute attack.
- Several weeks may be required before a beneficial effect is noted.

LEUKOTRIENE RECEPTOR ANTAGONISTS

Leukotriene receptor antagonists interfere with the inflammatory process in the airways by suppressing the effects of leukotrienes, a group of inflammatory mediators. Leukotrienes are powerful bronchoconstrictors and vasodilators; blocking their synthesis or binding to their receptors improves airflow, decreases symptoms and reduces the need for short-acting bronchodilators. They are used for maintenance therapy in adults and children over the age of 12 as an alternative to inhaled corticosteroid therapy. They are not used to treat an acute attack.

Nursing responsibilities

- Administer at least 1 hour before or 2 hours after meals.
- These drugs inhibit some liver enzymes, affecting the metabolism of warfarin and possibly terfenadine and theophylline. Monitor prothrombin times and theophylline blood levels.
- Monitor liver enzymes, because these drugs may be hepatotoxic.

Health education for the person and family

- Take the drugs as prescribed on an empty stomach.
- Notify the doctor if a change in colour of stools or urine is noted or if jaundice develops.

METHYLXANTHINES

The methylxanthines are central nervous system (CNS) stimulants chemically related to caffeine. These drugs produce bronchodilation through relaxation of bronchial smooth muscle. As CNS stimulants, they produce adverse effects such as nervousness, insomnia and tremors. When administered in large doses, convulsions may result.

Once the drugs of choice for preventing and treating asthma attacks, they are now used primarily to prevent nocturnal asthma. Theophylline has a narrow margin of safety and high potential for toxicity. Because the metabolism and excretion of theophylline vary significantly from person to person—affected by such factors as age, smoking, genetic factors, alcoholism and other chronic diseases—monitoring of serum levels is vital.

Nursing responsibilities

- The therapeutic blood level for theophylline is 10 to 20 mg/L.
- Monitor for manifestations of toxicity. Anorexia, nausea, vomiting, restlessness, insomnia, cardiac arrhythmias and seizures are early manifestations. Other manifestations include epigastric pain, haematemesis, diarrhoea, headache, irritability, muscle twitching, palpitations, tachycardia, flushing and circulatory failure.
- Administer with meals or a full glass of water or milk to minimise gastric irritation.
- Monitor effect closely when administering concurrently with medications such as barbiturates, anticonvulsants, thyroid hormone, β-blockers, bronchodilators and others.

Health education for the person and family

- Oral methylxanthines are ineffective to treat an acute asthma attack; do not delay other treatment by using these drugs.
- Check with the doctor before taking any over-the-counter (OTC) medications or other prescription drugs while on theophylline.
- Do not smoke while using this drug.
- Report adverse effects to the doctor.

CONSIDERATION FOR PRACTICE

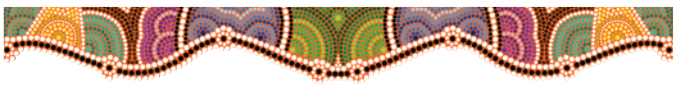
The treatment of chronic health conditions becomes complicated in women of child-bearing age. Before administering *any* medication, the pregnancy category should be assessed (see table below).

PREGNANCY CATEGORY FOR COMMON MEDICATIONS USED IN ASTHMA

Drug	Category	Drug	Category
acetylcysteine	B2	methylprednisolone (IV)	A
beclomethasone	B3	montelukast	B1
budesonide	A	nedocromil	B1
ciclesonide	B3	omalizumab	B1
dexamethasone	A	prednisolone	A
dornase alfa	B1	prednisone	A
eformoterol	B3	salbutamol (MDI)	A
fluticasone	B3	salmeterol	B3
hydrocortisone	A	sodium cromoglycate	A
ipratropium bromide	B1	terbutaline	A
isoprenaline	A	zafirlukast	B1

Reproduced with permission from MIMS Australia, please visit www.tga.gov.au to view its copyright and disclaimer policies; Prescribing medicines in pregnancy database (2015), Therapeutic Goods Administration, used by permission of the Australian Government www.tga.gov.au/hp/medicines-pregnancy.htm.

because of its frequent adverse effects. Many other drugs available have more efficiency and fewer adverse effects attributed to their use. Theophylline should never be used as a first-line drug for the treatment of asthma, but is occasionally used as adjunctive treatment. It relaxes bronchial smooth muscle, inhibits the release of chemical mediators of the inflammatory response and increases diaphragmatic contractility. Theophylline has significantly more adverse effects associated with its use (NACA, 2015).



Nursing care

Nurses encounter individuals with asthma both in the acute care setting during an acute exacerbation and as outpatients or in homes. The priority nursing care needs differ with each setting.

Health promotion

Although specific measures to prevent asthma have not yet been identified, the link between parental smoking and childhood asthma is strong. Discuss this link with young people and families with children. Encourage all individuals to avoid ever starting smoking and, if they already do smoke, to quit. Provide referrals to smoking cessation clinics, help groups or a care provider for nicotine patches as needed to facilitate quitting.

Assessment

Assessment of the person experiencing an acute asthma attack must be very focused and timely.

- *Health history:* current symptoms, including chest tightness, dyspnoea; duration of current attack; measures used to relieve symptoms and their effect; identification of precipitating factors for the attack; frequency of attacks; current medications; known allergies.
- *Physical examination:* apparent level of distress; colour; vital signs; respiratory rate and excursion, breath sounds throughout lung fields; apical pulse.
- *Diagnostic tests:* forced expiratory volume, peak expiratory flow rate; arterial blood gases.

Nursing diagnoses and interventions

An acute asthma attack causes fear as breathing becomes increasingly difficult and hypoxaemia develops. Anxiety in turn tends to increase the severity and manifestations of the attack. Priority nursing care needs during an acute attack focus on improving airway clearance and reducing fear and anxiety. Teaching about prevention of future attacks and home management must be postponed until adequate ventilation is restored.

Ineffective airway clearance

Bronchospasm and bronchoconstriction, increased mucus secretion and airway oedema narrow the airways and impair airflow during an acute attack of asthma. Both inspiratory and expiratory volumes are affected, decreasing the oxygen available at the alveolus for the process of respiration. Narrowed air passages increase the work of breathing, increasing the metabolic rate and tissue demand for oxygen.

- Monitor skin colour and temperature and level of consciousness (LOC). *Cyanosis, cool clammy skin and changes in LOC (agitation, lethargy or confusion) indicate worsening hypoxia.*

CONSIDERATION FOR PRACTICE

Assess respiratory status at least every 1 to 2 hours. Observe respiratory rate and depth, chest movement or excursion, breath sounds and peak expiratory flow rate. Respiratory status can change rapidly during an acute asthma attack and its treatment. Decreasing PEFRs indicate worsening airflow restriction. Slowed, shallow respirations with significantly diminished breath sounds and decreased wheezing may indicate exhaustion and impending respiratory failure. Immediate intervention is necessary.

- Assess ABG results and pulse oximetry readings; notify the doctor of abnormal values or changes in status. *These values provide information about gas exchange and the adequacy of alveolar ventilation. A fall in oxygen saturation levels is an early indicator of impaired gas exchange.*

CONSIDERATION FOR PRACTICE

Assess cough effort and sputum for colour, consistency and amount. Ineffective cough may also signal impending respiratory failure.

- Place in Fowler's, high-Fowler's or orthopnoeic (with head and arms supported on the over-bed table) position to facilitate breathing and lung expansion. *These positions reduce the work of breathing and increase lung expansion, especially of basilar areas.*
- Administer oxygen as ordered. If a mask is used, monitor closely for feelings of claustrophobia or suffocation. *Supplemental oxygen reduces hypoxaemia. Although the mask is a very effective oxygen delivery system, it may increase anxiety.*
- Administer nebuliser treatments and provide humidification as ordered. *Nebuliser treatments are used to administer bronchodilators and other medications; humidity helps loosen secretions.*
- Initiate or assist with chest physiotherapy, including percussion and postural drainage. *Percussion and postural drainage facilitate the movement of secretions and airway clearance.*
- Increase fluid intake. *Increasing fluids helps reduce the viscosity of the secretions.*
- Provide endotracheal suctioning as needed. *Endotracheal suctioning may be necessary to remove secretions and improve ventilation if the person is unable to clear secretions by coughing.*

Ineffective breathing pattern

The physiological changes in lung ventilation that occur during an acute asthma attack impair both lung expansion

and emptying. Anxiety caused by hypoxia and dyspnoea compounds the problem by increasing the respiratory rate. Collaborative and nursing interventions can help restore a more normal breathing pattern and adequate lung ventilation.

- Monitor vital signs and laboratory results. *Tachypnoea, tachycardia, an elevated blood pressure and increasing hypoxaemia and hypercapnia are signs of compromised respiratory status.*

CONSIDERATION FOR PRACTICE

Frequently assess respiratory rate, pattern and breath sounds. Note manifestations of ineffective breathing, including rapid rate, shallow respirations, nasal flaring, use of accessory muscles, intercostal retractions and diminished or absent breath sounds. Early identification of ineffective respirations allows timely initiation of interventions.

- Assist with ADLs as needed. *This conserves energy and reduces fatigue.*
- Provide rest periods between scheduled activities and treatments. *Scheduled rest is important to prevent fatigue and reduce oxygen demands.*
- Teach and assist to use techniques to control breathing pattern:
  a. pursed-lip breathing
  b. abdominal breathing
  c. relaxation techniques, including visualisation and meditation.

  Pursed-lip breathing helps keep airways open by maintaining positive pressure and abdominal breathing improves lung expansion. Relaxation techniques reduce anxiety and its effect on the respiratory rate.
- Administer medications, including bronchodilators and anti-inflammatory drugs, as ordered. Monitor for desired and possible adverse effects. *Medications are used to improve airway status and facilitate breathing.*

Anxiety

Acute exacerbations of asthma can produce significant anxiety. Fear of being unable to breathe and feelings of suffocation associated with acute asthma are significant. Financial or other concerns may cause the person to want to avoid hospitalisation. Increasingly frequent and severe episodes may cause fear for the future. Hypoxia contributes to anxiety as well, stimulating the sympathetic nervous system and the fight-or-flight response.

- Assess level of anxiety. *Interventions for severe anxiety or panic differ from those for mild or moderate anxiety.*
- Assist to identify coping skills that have been successful in the past. *Successful coping helps the person to regain control of the situation, reducing anxiety.*
- Listen actively to concerns; do not deny or negate the fear of dying or of being unable to breathe. *Active listening promotes trust and helps the person express concerns.*
- Include the person in care planning and decisions as appropriate, without making excessive demands. *Participating in decision making increases the person's sense of control. Because high levels of anxiety interfere with the ability to make decisions, it is important to avoid placing demands on the person that may further increase the level of anxiety.*
- Reduce excessive environmental stimuli and maintain a calm demeanour. *This promotes rest.*

CONSIDERATION FOR PRACTICE

Provide physical and emotional support. Remain with the person during episodes of severe anxiety; schedule time every 1 to 2 hours to be with the mildly or moderately anxious person. Answer call lights promptly. The severely anxious person may fear being alone or believe that they will die if someone is not on hand. Knowing that the nurse is readily available and will return quickly reduces anxiety.

CONSIDERATION FOR PRACTICE

Provide clear, concise directions and explanations about procedures. Avoid presenting more information than the person is able to assimilate. Anxiety interferes with the ability to learn. Explanations may need to be repeated frequently.

- Allow supportive family members to remain with the person. *Significant others provide additional support and can help reduce anxiety.*
- Assist to use relaxation techniques, such as guided imagery, muscle relaxation and meditation. *These techniques help restore psychological balance and reduce sympathetic stimulation and responses.*

Ineffective therapeutic regimen management

Once acute asthma is under control and effective respirations have been re-established, it is important to help the person identify contributing factors to the attack. This helps the person prevent future episodes.

- Assess level of understanding about asthma and the prescribed treatment regimen. Provide additional information and teaching as indicated. *Assessment helps to identify and clarify misperceptions and difficulties with disease management.*
- Discuss the person's perception of the illness and its effect on their lifestyle. *Open discussion can help identify conflicts between lifestyle and the treatment regimen.*
- Assist the person and significant others to identify problems or difficulties integrating the treatment regimen into their lifestyle. *Asthma and its management may necessitate lifestyle modifications to prevent acute exacerbations. This can significantly impact on family members—for example, eliminating cigarette smoking or pets from the household, removing carpets or daily damp dusting to remove dust mites.*
- Assess knowledge and understanding of prescribed medications and use of OTC preparations. *This is important to determine misperceptions or possible misuse of medications.*
- Provide verbal and written instructions. *Written instructions reinforce teaching and allow future reference.*

CONSIDERATION FOR PRACTICE

Assist to identify factors that contributed to the acute episode. Identifying contributing factors increases the person's awareness of the disease and of strategies to prevent future exacerbations.

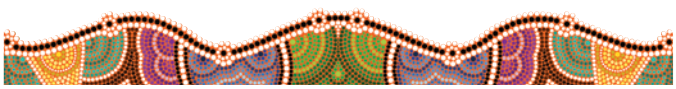
- Refer to counselling, support groups or self-help organisations. *These can help the person and family adapt to living with asthma and the treatment regimen.*

Community-based care

Asthma is a chronic disease that is best managed by the person with assistance from medical personnel. Teaching for home care focuses on promoting the highest level of wellness and preventing and managing acute episodes and exacerbations of the disease. Topics to include in teaching are as follows:

- Suggestions for lifestyle changes to avoid specific triggers for asthma attacks—for example:
  - Warm up slowly before exercising in cold weather; wear a special mask or scarf to retain air warmth and humidity while exercising.
  - Substitute indoor exercises during cold, dry weather.
  - Reduce the risk of respiratory infections (e.g. adequate rest, good nutrition and stress management to maintain immune function, yearly influenza vaccines and immunisation against pneumococcal pneumonia).
  - Use techniques to reduce or manage physical and psychological stress.
- Using peak expiratory flow rate (PEFR) meter to monitor airway status; how to manage the disease based on results.
- Using prescribed medications, including:
  - name, frequency, dose and desired effect
  - potential adverse effects and their management, including effects to report to the doctor
  - potential interactions with other drugs (including OTC herbal preparations) or foods
  - if tolerance is a potential risk, how to identify it and steps to take.

Provide referrals to local or regional resources for further teaching and support as needed. Consider the need for community-based services, home respiratory care services and others as needed.



CHRONIC OBSTRUCTIVE PULMONARY DISEASE

Individuals with chronic airflow obstruction due to chronic bronchitis and/or emphysema are said to have **chronic obstructive pulmonary disease (COPD)**.

Incidence and risk factors

In 2013, approximately 6434 Australians died of COPD (4% of all deaths). Males accounted for 55% of deaths and females 45% (ABS, 2015b). More than one in 20 Australians over 55 years of age has COPD and the financial burden is calculated to cost Australians approximately $929 million annually (AIHW, 2015d). Prevalence data in Australia is under-reported and COPD is thought to be under-diagnosed.

FAST FACTS

- In 2012 in Australia, COPD was the fifth leading cause of death.
- In 2013 in Australia, 52% of all respiratory deaths were from COPD.
- The average length of stay in hospital for COPD-associated issues is 5 days for people aged 55–69 years and 6 days for people over 85 years of age, compared with 3 days for individuals with respiratory tract infections without complications and/or co-morbidities.

Sources: ABS (2015b); AIHW (2015d); Lung Foundation Australia (2015).

Obstructive lung disease typically affects middle-aged and older adults. Cigarette smoking is clearly implicated as the primary cause of COPD. It is estimated that over 70% of deaths in people with COPD are attributed to smoking (Scollo & Winstanley, 2012). Cigarette smoke and the irritants it contains impair ciliary movement, inhibit the function of alveolar macrophages and cause mucus-secreting glands to hypertrophy. Smoke also produces emphysema or airway destruction and constricts smooth muscle, increasing airway resistance. Other contributing factors include air pollution, occupational exposure to noxious dusts and gases, airway infection and familial and genetic factors (see the accompanying 'Genetic considerations' box).

Pathophysiology

COPD is characterised by slowly progressive obstruction of the airways. The disease is one of periodic exacerbations, often related to respiratory infection, with increased symptoms of dyspnoea and sputum production. Unlike acute processes in which lung tissues recover, airways and lung parenchyma do not return to normal following an exacerbation; instead, they demonstrate progressive destructive changes.

Although one or the other may predominate, COPD typically includes components of both chronic bronchitis and emphysema, two distinctly different processes. Small airways disease, narrowing of small bronchioles, is also part of the COPD complex. Through different mechanisms, these processes cause airways to narrow, resistance to airflow to increase and expiration to become slow or difficult (see Figure 36.5). The result is a mismatch between alveolar ventilation and blood flow or perfusion, leading to impaired gas exchange.

Chronic bronchitis

Chronic bronchitis is a disorder of excessive bronchial mucus secretion. It is characterised by a productive cough lasting 3 or more months in 2 consecutive years (Bullock & Hales, 2012). Cigarette smoke is the main factor implicated in the development of chronic bronchitis.

Inhaled irritants lead to a chronic inflammatory process with vasodilation, congestion and oedema of the bronchial mucosa. Goblet cells increase in size and number, and mucous glands enlarge. Thick, tenacious mucus is produced in increased amounts (Mosenifar, 2015). Changes in bronchial squamous cells impair the ability to clear mucus. Narrowed airways and excess secretions

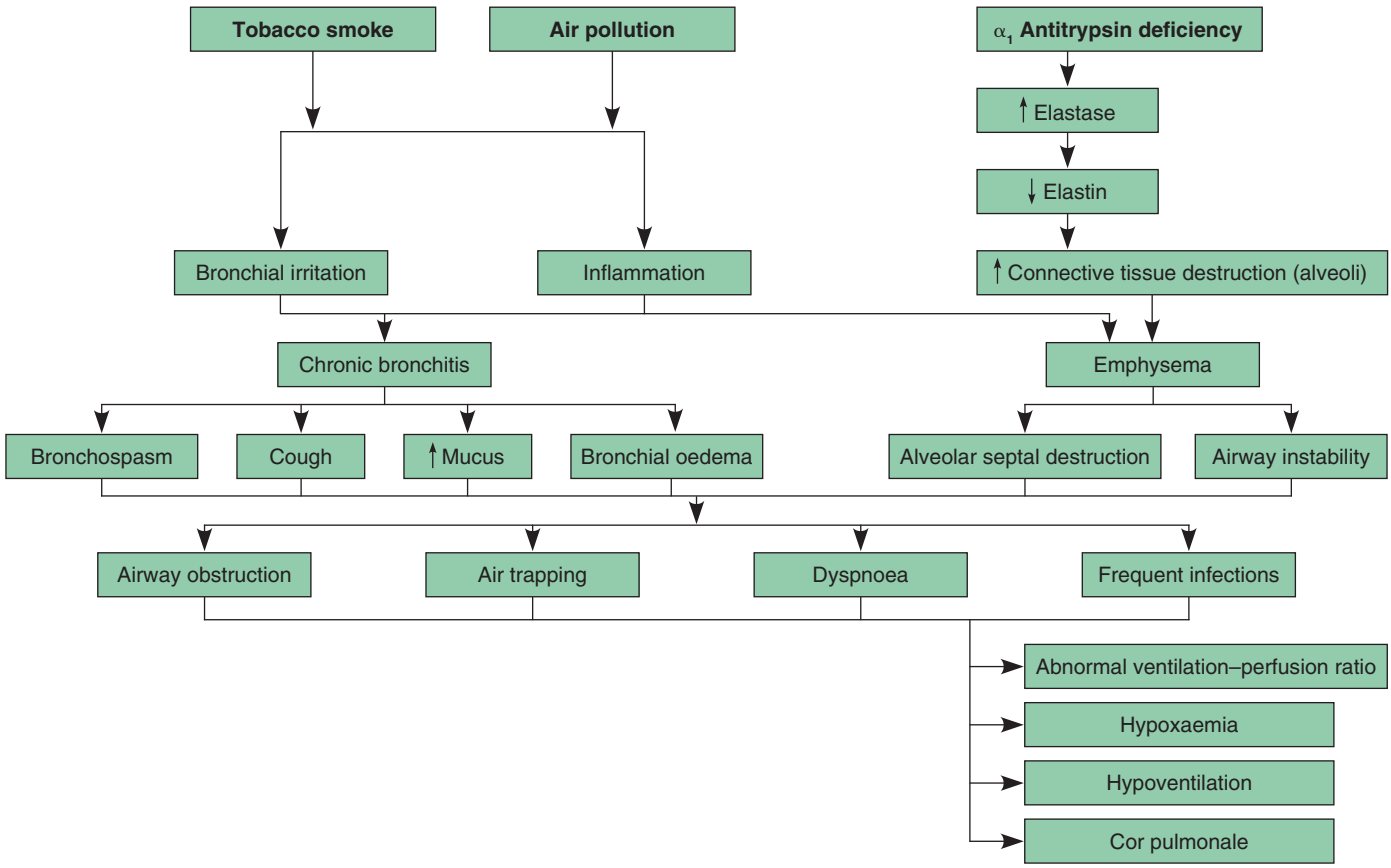


FIGURE 36.5 ■ Pathogenesis of chronic obstructive pulmonary disease

obstruct airflow; expiration is affected first, then inspiration. Because ciliary function is impaired, normal defence mechanisms are unable to clear the mucus and any inhaled pathogens. Recurrent infection is common in chronic bronchitis (Mosenifar, 2015). An imbalance between ventilation and perfusion leads to hypoxaemia, hypercapnia and pulmonary hypertension. Pulmonary hypertension often leads to right-sided heart failure.

Emphysema

Emphysema is characterised by destruction of the walls of the alveoli, with resulting enlargement of abnormal air spaces. As in chronic bronchitis, cigarette smoking is strongly implicated as a causative factor in most cases of emphysema. Deficiency of α_1-antitrypsin, an enzyme that normally inhibits the activity of proteolytic enzymes and tissue destruction in the lungs, contributes to the development of emphysema, especially when combined with exposure to cigarette smoke.

Inflammatory cells that collect in distal airway tissues appear to lead to destruction of elastic fibres in the respiratory bronchioles and alveolar ducts. Alveolar wall destruction causes alveoli and air spaces to enlarge, with loss of corresponding portions of the pulmonary capillary bed. As a result, the surface area for alveolar–capillary diffusion is reduced, affecting gas exchange. Elastic recoil is lost, reducing the volume of air that is passively expired. The loss

GENETIC CONSIDERATIONS Emphysema

Severe α_1-antitrypsin (alpha-1 antitrypsin or ATT) deficiency, present in about 2% of people with COPD, is a proven risk factor for COPD. Normal alpha-1 antitrypsin levels are associated with the common M allele. Two other alleles, the S allele and the Z allele, lead to reduced alpha-1 antitrypsin levels. An estimated one in 2500 Australians carries a single gene associated with alpha-1 antitrypsin deficiency and can pass that gene on to their offspring (Lung Foundation Australia, 2014a). Different concentrations of alpha-1 antitrypsin can be produced, depending on the inherited phenotype (observable characteristic or trait). Approximately 1 in 2500 people in Australia inherits severe alpha-1 antitrypsin deficiency (see Table 36.3).

TABLE 36.3 Concentration of alpha-1 antitrypsin related to phenotype inherited

PHENOTYPE INHERITED	ALPHA-1 ANTITRYPSIN CONCENTRATION
MM	normal
MS	80% of normal
MZ	60% of normal
SZ	40% of normal
ZZ	10% of normal

Source: Lung Foundation Australia (2012a). *Alpha-1 antitrypsin deficiency and lung disease*. Retrieved from http://lungfoundation.com.au/wp-content/uploads/2013/12/Alpha-1-Antitrypsin-Deficiency-and-Lung-Disease1.pdf. Reproduced with permission from Lung Foundation Australia.

of support tissue also affects airways, increasing the risk of expiratory collapse and further air trapping. Anatomically, either respiratory bronchioles or alveoli may be the primary tissue involved.

To summarise, COPD is a progressive, non-reversible process of airway narrowing and loss of supporting tissue. Three separate processes typically are involved:

- chronic bronchitis with persistent airway oedema, excessive mucus production and impaired airway clearance
- emphysema with loss of interstitial membranes and airway support tissue, resulting in airway collapse and loss of alveolar surface area for gas exchange
- small airways disease with bronchoconstriction.

The result of these processes and their combined effects is increased work of breathing, impaired expiration with air trapping and impaired gas exchange.

Manifestations

The clinical presentation of COPD varies from simple chronic bronchitis without disability to chronic respiratory failure and severe disability. Table 36.4 outlines the classifications of COPD severity.

Manifestations are typically absent or minor early in the disease. When the person finally seeks care, productive cough, dyspnoea and exercise intolerance often have been present for as long as 10 years. The cough typically occurs in the mornings and often is attributed to 'smoker's cough'. Initially, dyspnoea occurs only on extreme exertion; as the disease progresses, dyspnoea becomes more severe and accompanies mild activity. Manifestations characteristic of chronic bronchitis and emphysema develop. The clinical features and manifestations of COPD are summarised in Table 36.5.

TABLE 36.4 Classification of COPD by severity

		FEV_1 (% PREDICTED)	SYMPTOMS	HISTORY OF EXACERBATIONS	CO-MORBID CONDITIONS*
COPD SEVERITY	MILD	60–80	Breathlessness on moderate exertion Recurrent chest infections Little or no effect on daily activities	Frequency may increase with severity	Present across all severity groups
	MODERATE	40–59	Increasing dyspnoea Breathlessness walking on level ground Increasing limitation of daily activities Cough and sputum production Exacerbations requiring corticosteroids and/or antibiotics		
	SEVERE	40	Dyspnoea on minimal exertion Daily activities severely curtailed Experiencing regular sputum production Chronic cough		

FEV_1 = forced expiratory volume in 1 second.
*Common co-morbid conditions include cardiovascular disease, skeletal muscle dysfunction, metabolic syndrome, osteoporosis, anxiety or depression, lung cancer, peripheral vascular disease and sleep apnoea.
Source: Lung Foundation Australia (2014b). *The COPD-X: Concise Guide for Primary Care*. Retrieved from http://lungfoundation.com.au/wp-content/uploads/2015/06/LFA-COPD-X-Concise-Guide-for-Primary-Care.pdf. Reproduced with permission from Lung Foundation Australia.

TABLE 36.5 Clinical features and manifestations of COPD

	FEATURE	CHRONIC BRONCHITIS	EMPHYSEMA
History	Onset	After age 35; recurrent respiratory infections	After age 50; insidious progressive dyspnoea
	Smoking	Usual	Usual
	Cough	Persistent, productive of copious mucopurulent sputum	Absent or mild with scant clear sputum, if any
Physical examination	Appearance	Often obese; oedematous and cyanotic; distended neck veins and other symptoms of right-sided heart failure	Usually thin and cachectic; barrel chest; prominent accessory muscles of respiration
	Chest	Adventitious sounds with wheezing and rhonchi; normal percussion note	Distant or diminished breath sounds; hyper-resonant percussion note
Other features	Blood gases	Hypercapnia and hypoxaemia; respiratory acidosis	Normal or mild hypoxaemia; normal pH
	Pulmonary function studies	Normal or decreased total lung capacity; moderately increased residual volume	Increased total lung capacity; markedly increased residual volume
	Pulmonary hypertension	May be severe	Only when advanced

Manifestations of chronic bronchitis are a productive cough with copious amounts of thick, tenacious sputum, cyanosis and evidence of right-sided heart failure, including distended neck veins, oedema, liver engorgement and an enlarged heart. Adventitious lung sounds, including loud rhonchi and possible wheezes, are prominent on auscultation.

Emphysema is insidious in onset. Dyspnoea is the initial symptom. Initially occurring only with exertion, dyspnoea may progress to become severe even at rest. Cough is minimal or absent. Air trapping and hyperinflation increase the anterior–posterior chest diameter, causing *barrel chest*. The person often is thin, tachypnoeic, uses accessory muscles of respiration and often assumes a position of sitting and leaning forward (see Figure 36.6). The expiratory phase of the respiratory cycle is prolonged. On auscultation, breath sounds are diminished and the percussion tone is hyper-resonant.

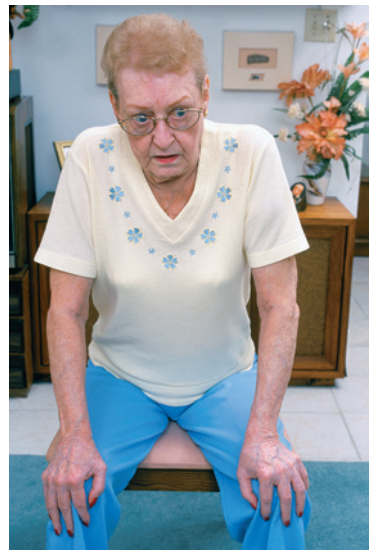

FIGURE 36.6 ■ Typical appearance of a person with emphysema. Note the person's anxious expression and assumption of the tripod position, leaning forward with the hands on the knees

INTERPROFESSIONAL CARE

Although COPD can be prevented in most people, it cannot be cured. Smoking abstinence is the only certain way to prevent COPD and to slow its progression. To a certain extent, airway obstruction can be reversed and disability minimised early in the disease. Treatment generally focuses on relieving symptoms, minimising obstruction and slowing disability.

Diagnosis

Diagnostic tests are used to help establish the diagnosis of chronic obstructive pulmonary disease and identify the predominant component, emphysema or chronic bronchitis. These procedures also are used to assess respiratory status and monitor treatment effectiveness. See Chapter 33 for more information about these diagnostic procedures and related nursing care.

- *Respiratory function testing* is performed to establish the diagnosis and evaluate the extent and progress of COPD (see Box 33.1). Results are based on calculated norms for each person by age, height, sex and weight; note these as well as all current medications on the requisition. In COPD, the total lung capacity and residual volume typically are increased. The forced expiratory volume (FEV_1) and forced vital capacity (FVC) are decreased due to narrowed airways and resistance to airflow (see Figure 36.7).
- *Ventilation–perfusion scanning* may be performed to determine the extent of ventilation–perfusion mismatch—that is,

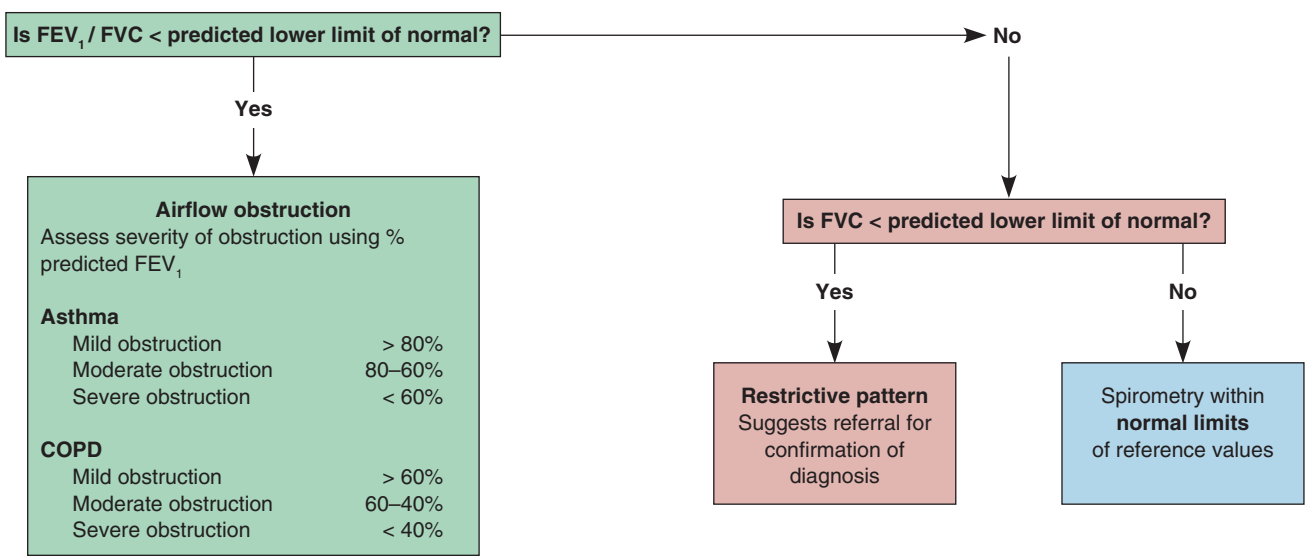

FIGURE 36.7 ■ Guideline for spirometry interpretation

Source: Johns, D., Burton, D. & Swanney, M. (2015). *Spirometer users' and buyers' guide.* Melbourne: National Asthma Council Australia. © National Asthma Council Australia. Retrieved from www.nationalasthma.org.au/uploads/content/209-Spirometer-Users-and-Buyers-Guide-2015-updated.pdf.

the extent to which lung tissue is ventilated but not perfused (dead space) or perfused but inadequately ventilated (physiological shunting) (see Figure 36.8). A radioisotope is injected or inhaled to illustrate areas of shunting and absent capillaries.

- *Serum α_1-antitrypsin (alpha-1 antitrypsin) levels* may be drawn to screen for deficiency, particularly in people with a family history of obstructive airway disease, those with an early onset, women and non-smokers. Normal adult serum alpha-1 antitrypsin levels range from 90 to 200 mg/dL. Fasting is not required prior to this test.
- ABGs are drawn to evaluate gas exchange, particularly during acute exacerbations of COPD. Individuals with predominant emphysema often have mild hypoxaemia and normal or low carbon dioxide tension. Respiratory alkalosis may be present due to an increased respiratory rate. Predominant chronic bronchitis and airway obstruction may cause marked hypoxaemia and hypercapnia with respiratory acidosis. Oxygen saturation levels are low due to marked hypoxaemia.
- *Pulse oximetry* is used to monitor oxygen saturation of the blood. Marked airway obstruction and hypoxaemia often cause oxygen saturation levels of less than 95%. Pulse oximetry may be continuously monitored to assess the need for supplemental oxygen.
- *Exhaled carbon dioxide (capnogram* or $ETCO_2$) may be measured to evaluate alveolar ventilation. The normal $ETCO_2$ reading is 35 to 45 mmHg; it is elevated when ventilation is inadequate and decreased when pulmonary perfusion is impaired. $ETCO_2$ monitoring can reduce the frequency of ABG determinations.
- *Full blood count (FBC) with white blood cell (WBC) differential* often shows increased red blood cells (RBCs) and haematocrit (erythrocytosis) as chronic hypoxia stimulates increased erythropoiesis to improve the oxygen-carrying capacity of the blood. *Polycythaemia*, increased numbers of all blood cells, may be evident. Increased WBC count and a higher percentage of immature WBCs (bands) are often indicative of bacterial infection.
- *Chest x-ray* may show longer lung fields and flattening of the diaphragm due to hyperinflation and evidence of pulmonary infection if present. The anterior–posterior (AP) diameter is wider (see Figure 36.9).

CONSIDERATION FOR PRACTICE

Hypercapnia (elevated $PaCO_2$ levels) is often chronic in individuals with COPD (CO_2 retainers). In these individuals, administering excessive oxygen flows can actually reduce respiratory rate which results in increased $PaCO_2$, potentially leading to somnolence and acute respiratory failure. While oxygen is the drug of choice for treating individuals with COPD, close monitoring is necessary during oxygen therapy.

Quitting smoking

Smoking cessation can not only prevent COPD from developing, but can also improve lung function once the disease has

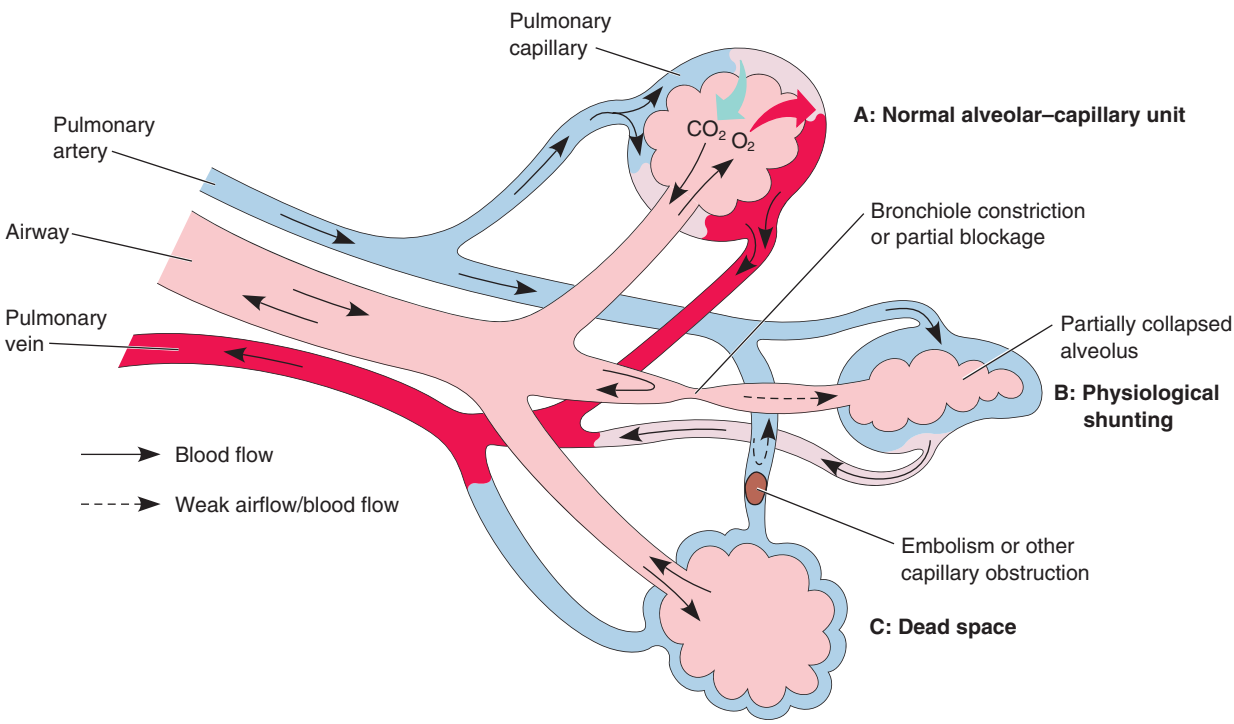

FIGURE 36.8 ■ Ventilation–perfusion relationships. *A*, Normal alveolar–capillary unit with an ideal match of ventilation and blood flow. Maximal gas exchange occurs between alveolus and blood. *B*, Physiological shunting: a unit with adequate perfusion but inadequate ventilation. *C*, Dead space: a unit with adequate ventilation but inadequate perfusion. In the latter two cases, gas exchange is impaired

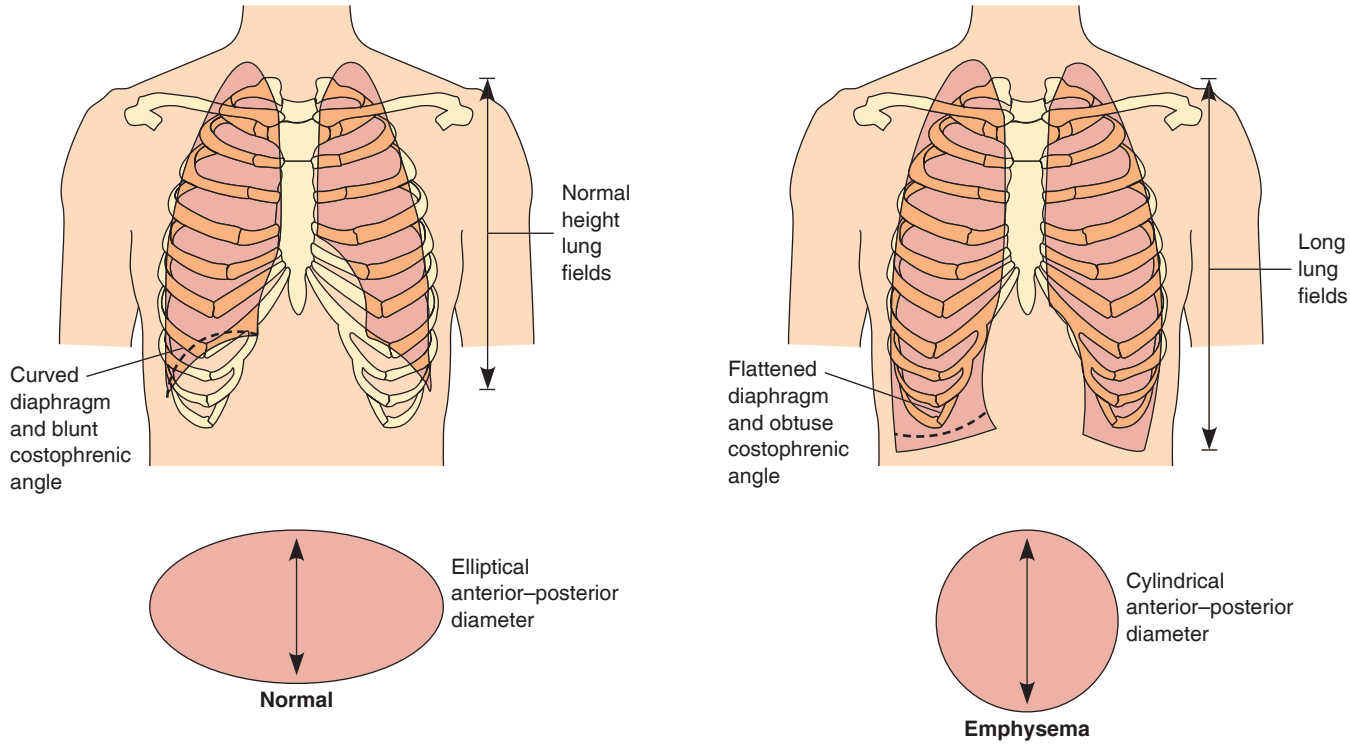

FIGURE 36.9 ■ Anatomical changes related to emphysema

been diagnosed. FEV_1 improves and survival is prolonged, largely due to lower rates of lung cancer and heart disease. Sustained quitting is difficult; however, various methods may assist people.

- Nicotine replacement therapy can increase the rate of quitting by up to 70%.
- Partial nicotine agonists such as varenicline can increase the rate of quitting by up to 50%.
- The non-nicotine oral therapy bupropion can improve the rate of quitting more than a placebo but less successfully than varenicline.
- Group counselling can improve quitting success above minimal support.
- Brief motivational advice from healthcare professionals has a success rate of 3–6%.
- Interventions such as hypnotherapy, acupuncture, naltrexone, aversive smoking, biomedical feedback, electronic cigarettes, physical activity, the Alan Carr method or the consumption of St John's wort (*Hypericum perforatum*) herb extract do not currently demonstrate sufficient good-quality empirical evidence to support their success (Zwar et al., 2014).

Medications

Immunisation against pneumococcal pneumonia and influenza is recommended yearly to reduce the risk of respiratory infections. If the infection is considered to be bacterial, a broad-spectrum antibiotic is prescribed. Antibiotics should be administered in times of exacerbation. However, prophylactic antibiotics, although they have a statistically significant reduction in number of sick days experienced, do not have a place in routine medication regimens as the risk of increasing antibiotic resistance is too great (Abramson et al., 2014).

Bronchodilators improve airflow and reduce air trapping in COPD, resulting in improved dyspnoea and exercise tolerance. Bronchodilators may be given by MDI, DPI, nebuliser or orally. Oral administration may promote adherence, but is associated with much higher rates of adverse effects. A spacer may facilitate effective use of an MDI. Ipratropium bromide, an anticholinergic agent administered by MDI, is frequently prescribed. It has a longer duration of action than the short-acting β_2-adrenergic stimulant bronchodilators and few side effects. Salmeterol, a longer-acting β_2-agonist, may be used in combination therapy. Bronchodilators are discussed in further detail in the section on asthma and their nursing implications are outlined in the 'Medication administration' box earlier in this chapter.

Corticosteroid therapy may be used when asthma is a major component of COPD. It also improves symptoms and exercise tolerance and may reduce the severity of exacerbations and the need for hospitalisation. Oral corticosteroids, such as prednisone, are used initially. If a beneficial response occurs, the amount is reduced to the lowest effective dose. Every-other-day dosing or administration by inhaler is preferred to minimise steroid side effects, such as cushingoid effects and an increased risk of osteoporosis and vertebral fractures.

Alpha-1 antitrypsin replacement therapy is not common practice in Australia.

Treatments

In addition to refraining from smoking, exposure to other airway irritants and allergens should be avoided. The person should remain indoors during periods of significant air pollution to prevent exacerbations of the disease. Air-filtering systems or air conditioning may be useful.

Respiratory hygiene measures, including hydration, effective coughing, percussion and postural drainage, are used to improve clearance of airway secretions. Maintaining adequate systemic hydration is essential to keep secretions thin. Forceful coughing is often less effective than leaning forward and repeatedly 'huffing', with relaxed breathing between huffs. Percussion and postural drainage may be necessary if the person is unable to clear secretions by usual means. Cough suppressants and sedatives generally are avoided because they may cause retention of secretions.

Unless disabling cardiac disease is present, a regular exercise program is beneficial for:

- improving exercise tolerance
- enhancing ability to perform ADLs
- preventing deterioration of physical condition.

A program of regular aerobic exercise designed to gradually increase exercise tolerance is recommended. Activities that strengthen the muscles used for breathing and ADLs, such as swimming and golf, also are beneficial.

Breathing exercises are used to slow the respiratory rate and relieve accessory muscle fatigue. Pursed-lip breathing slows the respiratory rate and helps maintain open airways during exhalation by keeping positive pressure in the airways. Abdominal breathing relieves the work of accessory muscles of respiration.

OXYGEN Long-term oxygen therapy is used for severe and progressive hypoxaemia. Oxygen therapy improves exercise tolerance, mental functioning and quality of life in advanced COPD. It also reduces the rate of hospitalisation and increases length of survival. Oxygen may be used intermittently, at night or continuously. For severely hypoxaemic individuals, the greatest benefit is seen with continuous oxygen. Home oxygen may be supplied as liquid oxygen, compressed gas cylinders or oxygen concentrators.

An acute exacerbation of COPD may necessitate oxygenation and inspiratory positive-pressure assistance with a face mask or intubation and mechanical ventilation. Oxygen administered without intubation and mechanical ventilation requires caution: administering oxygen to individuals with chronic elevated carbon dioxide levels in the blood can actually increase the $PaCO_2$, leading to increased somnolence and even respiratory failure. Close monitoring of LOC and ABGs during oxygen therapy is vital (Mosenifar, 2015).

Surgery

When medical therapy is no longer effective, lung transplantation may be an option; however, it has been shown to have limited survival benefit (Abramson et al., 2014). Lung reduction surgery is an experimental surgical intervention for advanced diffuse emphysema and lung hyperinflation. The procedure reduces the overall volume of the lung, reshapes it and improves elastic recoil. As a result, respiratory function and exercise tolerance improve and dyspnoea is reduced. See the box in Chapter 35 for nursing care of the person undergoing lung surgery. Special nursing care considerations related to lung or heart–lung transplant are summarised in Box 36.2.

Nursing care

Health promotion

Not smoking—never starting or quitting—is the best preventive measure for chronic obstructive pulmonary disease. Even in individuals with COPD, smoking cessation improves lung function and increases survival. Educate all individuals, including preschool and school-aged children, about the risks of smoking (see Box 36.3).

Assessment

Focused assessment for the person with chronic obstructive pulmonary disease includes:

- *Health history:* current symptoms, including cough, sputum production, dyspnoea, activity tolerance; frequency of respiratory infections and most recent episode; previous diagnosis of emphysema, chronic bronchitis or asthma; current medications; smoking history (in pack years—packets per day times number of years smoked), history of exposure to second-hand smoke, occupational or other pollutants.
- *Physical examination:* general appearance, weight for height, mental status; vital signs, including temperature; skin colour and temperature; anterioposterior and lateral chest diameter, use of accessory muscles, nasal flaring or pursed-lip breathing; respiratory excursion and diaphragmatic excursion; percussion tone; breath sounds throughout; neck veins, apical pulse and heart sounds, peripheral pulses, oedema.
- *Diagnostic tests:* FVC and FEV_1, ABGs, haematocrit.

Nursing diagnoses and interventions

Individuals with chronic obstructive pulmonary disease, whether hospitalised or in the community, have multiple nursing care needs. Because of the obstructive nature of the disease, airway clearance is a high priority. Nutritional deficit is common, particularly when emphysema is predominant. Because this chronic disease affects all functional health patterns, psychosocial issues are also of concern in planning nursing care. In addition to the nursing diagnoses presented here, see the nursing care plan that follows.

Ineffective airway clearance

Both chronic bronchitis and emphysema affect the ability to maintain open airways. In chronic bronchitis, copious amounts of thick, tenacious mucus are produced. Ciliary action is impaired, making it difficult to clear mucus from the airways.

BOX 36.2 Nursing considerations related to lung transplant

While immediate postoperative care for individuals undergoing lung or heart–lung transplant is provided by specially trained interprofessional teams in transplant centres, increased survival following transplant means that these individuals are more commonly seen in community-based settings, non-transplant units and on general nursing care wards. An understanding of common post-transplant complications and care needs of the person following transplant facilitates appropriate nursing care.

Common post-transplant complications

In the early post-transplant period, the most common complications relate to the surgical procedure itself or to rejection of the transplanted organ(s).

- *Rejection*. Acute organ rejection can occur at any time following the transplant. An acute change in FEV_1 and FVC on home spirometry is often the first indication of acute rejection. Other manifestations of rejection include fever, dyspnoea and an elevated WBC count. Because these manifestations are similar to those of infection, the person is instructed to contact their doctor or transplant coordinator for further investigation. Acute rejection is treated with increased corticosteroids and adjustment of the immunosuppressive regimen (see Chapter 12). Chronic rejection is less amenable to therapy, ultimately necessitating retransplant.
- *Infection*. Prevention of infection is vital in a person following lung transplantation. Individuals are encouraged to reduce their risk of infection by avoiding contact with people who have an infectious disease (e.g. upper respiratory tract infection (URTI), shingles, diseases of childhood). The transplant recipient may not have typical manifestations of infection due to immunosuppression. Any vague symptoms with or without fever or leucocytosis are investigated. Recurrent viral infections such as cytomegalovirus have been associated with chronic rejection; hence, they are aggressively treated with antiviral therapy. Treatment of other infections is targeted to the infectious organism.

Nursing considerations for the person following transplant

Reverse isolation procedures are not necessary unless the neutrophil count is very low ($< 500/mm^3$). Use good handwashing and standard precautions at all times and aseptic technique for dressing changes, IV starts and site care, and other invasive procedures (such as urinary catheterisation). Do not allow caregivers or visitors with URTI to have contact with the person; a mask may be provided for short visits if contact is unavoidable. Skin surveillance and care is vital following transplant. Intact skin reduces the risk of infection; however, corticosteroid therapy increases the risk of skin tears and breakdown.

The effect of all medications on immunosuppressive therapy and the transplanted organ(s) should be carefully investigated prior to administration. Some antibiotics and other drugs can affect blood levels of immunosuppressants.

Particular attention must be paid to respiratory hygiene. Denervation of the transplanted lung eliminates the usual cough stimuli (Whitson, 2015). Regularly scheduled coughing and deep breathing, and the use of vibration, percussion and postural drainage, are important to prevent accumulation of secretions (Goodman & Fuller, 2015).

BOX 36.3 Cigarette smoking and tobacco use

The use of tobacco reaches back to early civilisations when it was used in religious ceremonies and as an offering of friendship. At one time tobacco was thought to have medicinal qualities effective against all common diseases. Widespread use of tobacco in the male population of the industrialised world began during World War I.

Tobacco is now recognised as the leading cause of preventable illness in the world. Diseases directly related to tobacco use are responsible for the deaths of more than 19 000 Australians every year (Department of Health and Ageing, 2012). In spite of this knowledge, aggressive marketing of the product continues and its worldwide use is increasing, especially in developing countries.

The link between tobacco use and lung cancer was reported as early as 1912. Today, 90% of lung cancer in men and 65% in women is considered to be caused by smoking tobacco (Cancer Australia, 2015). The World Health Organization (WHO) reported that tobacco smoke contributes to the death of 6 million people a year worldwide (WHO, 2015).

Cigarette smoke contains over 4000 chemicals (more than 50 of which are known to cause cancer), including nicotine (WHO, 2015). Nicotine is a highly addictive psychoactive substance that is relatively cheap and readily available. It produces euphoria, which acts as a positive reinforcer for continued use.

Tar is the particulate matter in cigarette smoke that is responsible for most of its carcinogenic and pathological effects on the lungs. Smoke also paralyses the cilia, reducing their ability to remove the tar. The risk of cancer and other lung diseases is dose related, affected by the age at which smoking began, the number of cigarettes smoked per day and the number of years smoked. Smoking cessation reduces the risks associated with tobacco use. For some, such as those at risk of coronary heart disease, quitting smoking yields rapid benefits. For others, the degree of risk reduction is less immediate, but still significant.

Nurses need to do more than simply advise individuals to quit smoking and talk about the risks of smoking. Nurses can take an active role in smoking cessation. Identify smoking habits, smoking-related illnesses and previous efforts to

(continued)

BOX 36.3 Cigarette smoking and tobacco use (continued)

quit. Work with the person to identify barriers and obstacles to quitting. Educate about the addictive nature of nicotine and explain the manifestations of nicotine withdrawal (anxiety, irritability, headache and disturbed sleep). Develop a plan with the individual that specifies a target date to quit and includes ways to deal with obstacles to quitting, withdrawal symptoms and the temptation to resume smoking. Offer self-help material at an appropriate reading level. Refer to a counsellor, doctor, self-help group or smoking cessation clinic. If a relapse occurs, accept it as a normal part of rehabilitation from any addictive substance. Continue to provide support and encouragement, helping the person to avoid further relapses.

Nurses can be especially effective in primary prevention of cigarette smoking and the diseases associated with it. Just as tobacco companies direct advertising at women and teens, nurses can target these populations and younger children for programs to prevent smoking. In addition, nurses need to become active in reducing minors' access to tobacco products, especially cigarettes.

Nursing diagnoses that may be appropriate related to smoking include the following:

- *Ineffective maintenance of health* related to tobacco use evidenced by cough, haemoptysis, or shortness of breath.
- *Decisional conflict* related to tobacco use evidenced by inability to determine a 'quit smoking date'.
- *Ineffective denial* related to substance abuse and dependence evidenced by statements discounting health concerns related to tobacco smoking.

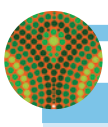
The loss of supporting tissue caused by emphysema increases the risk of airway collapse. In both cases, air is trapped distally and less oxygen is available to the alveoli for diffusion. Normal respiratory defence mechanisms are impaired and mucus-plugged airways provide an ideal environment for bacterial growth. Respiratory infection further impairs airway clearance and is often the cause of an acute exacerbation.

- Assess respiratory status every 1 to 2 hours or as indicated. Assess rate and pattern; cough and secretions (colour, amount, consistency and odour); and breath sounds, both normal and adventitious. *Frequent assessment is vital to monitor current status and response to treatment. Adventitious sounds should decrease with effective intervention. Diminished or absent breath sounds may indicate increasing airway obstruction and possible atelectasis.*

CONSIDERATION FOR PRACTICE

Promptly report changes in oxygen saturation, skin colour or mental status. A drop in oxygen saturation levels, increasing cyanosis or altered LOC indicate hypoxaemia, which may be related to airway obstruction.

- Monitor ABG results. *Increasing hypoxaemia, hypercapnia and respiratory acidosis may indicate increasing airway obstruction.*
- Weigh daily, monitor intake and output, and assess mucous membranes and skin turgor. *Dehydration causes respiratory secretions to become thicker, more tenacious and difficult to expectorate; fluid overload can further compromise respiratory status.*



TRANSLATION TO PRACTICE Evidence-based practice: community nurse mentoring improves self-management in people with COPD

A Tasmanian controlled study by Wood-Baker et al. in 2012 demonstrated that a community nurse can facilitate improved quality of life and early healthcare utilisation to reduce the risk of exacerbation in people with chronic obstructive pulmonary disease (COPD). The group investigated the effectiveness of a program including home visits, the development of a behaviour-specific, reasonable and measureable action plan, and telephone follow ups. People with COPD over 45 years of age without other lung diseases or unstable cardiac, renal or liver disease, and with an anticipated survival rate of greater than 12 months, were included. Results demonstrated that increased quality of life and reduced time to death and readmission can be achieved through well-designed community nurse mentoring programs.

IMPLICATIONS FOR NURSING

Years of life lost, readmission for exacerbation and reduced quality of life are serious social and financial costs of COPD. Programs which directly facilitate better outcomes in any of these factors should be considered beneficial in the management of individuals with COPD. It would be reasonable to consider that financial gains from reducing exacerbation and improving a person's quality of life would easily offset costs of such a program. Among other things, this study reaffirmed the fact that community nursing support appears to be an important factor in the risk of readmission for exacerbation.

CRITICAL THINKING IN PERSON-CENTRED CARE

1. Identify factors that may be important in such a program. Consider the practicalities of offering such a program including necessary content, volume and type of support, and logistical issues such as provision of support for individuals in rural and remote regions.
2. Which factors would be important to measure in order to determine an improvement in a person with COPD?
3. People with COPD generally have co-morbid issues. What implications would cardiac, renal or hepatic disease have on an individual with COPD?

- Encourage a fluid intake of at least 2000 to 2500 mL per day unless contraindicated. *Adequate fluid intake helps keep mucus secretions thin.*
- Place in Fowler's, high-Fowler's or orthopnoeic position; encourage movement and activity to tolerance. *Upright positions improve ventilation and reduce the work of breathing. Activity helps mobilise secretions and prevent them from pooling.*
- Assist with coughing and deep breathing at least every 2 hours while awake. Position seated upright, leaning forward during coughing. *The upright position promotes chest expansion, increasing the effectiveness of coughing and reducing the work involved.*
- Provide tissues and a paper bag to dispose of expectorated sputum. *This important infection control measure reduces the spread of respiratory organisms to other people.*
- Refer to a respiratory therapist and assist with or perform percussion and postural drainage as needed. *Percussion helps loosen secretions in airways; postural drainage facilitates movement of these secretions out of the respiratory tract.*
- Provide rest periods between treatments and procedures. *The person with COPD fatigues easily; adequate rest is important to conserve energy and reduce fatigue.*
- Administer expectorant and bronchodilator medications as ordered. Correlate timing with respiratory treatments. *Using expectorants and bronchodilators prior to coughing, percussion and postural drainage increases their effectiveness in clearing airways.*

CONSIDERATION FOR PRACTICE

Provide endotracheal, oral or nasopharyngeal suctioning as necessary. Suctioning may be necessary to stimulate cough and help clear secretions.

- Provide supplemental oxygen as ordered. *Supplemental oxygen helps maintain adequate blood and tissue oxygenation.*

CONSIDERATION FOR PRACTICE

Prepare for intubation and mechanical ventilation if respiratory status deteriorates (increasing hypoxaemia and hypercapnia, decreased LOC, cyanosis or worsening airway obstruction). Respiratory failure is a possible complication of an acute exacerbation of COPD and requires immediate intervention to preserve life.

NURSING CARE PLAN A person with COPD

Anna Mercurio is an 83-year-old widow who lives with her two adult sons. During the past 15 years, Mrs Mercurio has become increasingly short of breath while gardening and walking, two favourite activities. She also has developed a chronic cough that is particularly bad in the mornings. Ten years ago her family doctor told her that she had emphysema. She is admitted to the hospital with possible pneumonia and acute exacerbation of COPD.

ASSESSMENT

Mrs Mercurio was admitted to the medical unit. In the nursing history, the nurse notes that she denies ever smoking, but says that her husband and two sons have been smokers 'for practically their whole lives'. She says she lived an active life before developing lung disease, but her breathing difficulties and cough have progressed so that she now must rest after just a few minutes of housework or other activity. Her cough is productive of moderate to large amounts of sputum, particularly in the mornings. She developed increasing shortness of breath and sputum 2 days ago; this morning, she could not complete her morning activities without resting, so she contacted her doctor.

On physical examination, Mrs Mercurio demonstrated the following: skin very warm and dry, colour dusky. Pauses frequently while speaking to breathe. Respiratory rate 36, fairly shallow; coughs frequently, producing large amounts of thick, tenacious green sputum. Other vital signs: P 115 and irregular, BP 186/60, T 39°C. Appears very thin; weight 43.6 kg, height 160 cm. Anteroposterior and lateral chest diameter increased; moderate kyphosis noted. Chest hyperresonant to percussion. Auscultation reveals distant breath sounds with scattered wheezes and rhonchi throughout lung fields. Chest x-ray shows flattening of diaphragm, long lung fields, slight cardiac enlargement, prominent vascular and bronchial markings, and patchy infiltrates. Initial laboratory work reveals moderate erythrocytosis, leucocytosis and low serum albumin. Arterial blood gas results: pH 7.19; PaO_2 54 mmHg; $PaCO_2$ 59 mmHg; HCO_3^- 30 mg/dL and O_2 saturation 88%. Admitting orders include sputum specimen for culture; intravenous penicillin G, 2 million units every 4 hours; salbutamol/ipratropium inhaler, two puffs every 6 hours; salmeterol/fluticasone dry powder inhaler, twice a day; bed rest with bathroom privileges; oxygen per nasal prongs at 2 L/min continuously; and regular diet.

DIAGNOSES

- *Ineffective airway clearance* related to pneumonia and COPD evidenced by increased shortness of breath and respiration rate.
- *Impaired gas exchange* related to acute and chronic lung disease evidenced by low oxygen saturations.
- *Risk of impaired ventilation* related to loss of hypoxaemic respiratory drive and respiratory muscle fatigue evidenced by decreasing respiration rate and oxygen saturations.
- *Impaired home maintenance* related to activity intolerance evidenced by inability to undertake activities of daily living.

PLANNING

- Closely monitor response to oxygen therapy, including skin colour, oxygen saturation, sputum consistency and respiratory drive.

(continued)

NURSING CARE PLAN A person with COPD (continued)

- Assess respiratory status and LOC every 1 to 2 hours until stable, then at least every 4 hours.
- Contact respiratory therapy for percussion and postural drainage following inhaler treatments.
- Meet with Mrs Mercurio and her sons to develop a post-discharge care plan.
- Refer to home health department for nursing follow up.
- Refer to social services for possible assistance with home maintenance.

Expected outcomes

- Expectorate secretions effectively.
- Return to level of respiratory function prior to acute exacerbation.
- Demonstrate improved ABG and oxygen saturation values.
- Maintain spontaneous respirations without excess fatigue.
- Verbalise willingness to allow sons or a housekeeper to assist with daily household tasks.

IMPLEMENTATION

- Increase fluid intake to at least 2500 mL per day and provide bedside humidifier.
- Elevate head of bed to at least 30 degrees at all times.
- Teach 'huff' coughing technique.
- Administer medications as ordered, providing ipratropium inhaler before beclomethasone inhaler. Provide mouth care after inhalers.
- Provide for uninterrupted rest periods following treatments and procedures.

EVALUATION

After the first day in the hospital Mrs Mercurio's condition begins to improve slowly. On discharge 6 days later she is able to provide self-care with less fatigue and dyspnoea. She is using oxygen at night only, admitting that it is only for security. Although a few scattered wheezes and rhonchi are still present in her lungs, Mrs Mercurio's sputum is thinner, white and easily expectorated. She will continue taking oral penicillin V for an additional 10 days at home. She will also continue using the inhalers as prescribed. Although Mrs Mercurio's sons admit they will probably never be able to quit smoking, they have agreed to smoke only in the garage or outside. A community health nurse will initially evaluate Mrs Mercurio's progress three times weekly. Arrangements have been made for a housekeeper to come twice a week for cleaning and laundry. Mrs Mercurio is glad to be returning home and grateful for the arrangements that have been made.

CRITICAL THINKING IN THE NURSING PROCESS

1. Mrs Mercurio has never been a smoker but has had long-term exposure to second-hand smoke. How does second-hand smoke contribute to lung diseases in adults and children?
2. The nursing care plan included the nursing diagnosis *Risk of impaired ventilation* related to loss of hypoxaemic respiratory drive and respiratory muscle fatigue. Identify the normal physiological events that stimulate breathing and describe how these differ for the person with chronic hypoxaemia and hypercapnia.
3. The person with an acute exacerbation of COPD is at risk of respiratory failure. Which changes in Mrs Mercurio's assessment findings could indicate this complication?
4. Develop a nursing care plan for Mrs Mercurio for the nursing diagnosis *Deficient diversional activities* related to inability to continue preferred activities.

REFLECTION ON THE NURSING PROCESS

1. Outline what you have learned from this case study that you will take into your future practice.
2. In individuals experiencing acute exacerbations, extreme shortness of breath can result in an inability to speak in sentences of more than a couple of words. How might this impact on communication and the ability to collect an adequate detailed health history? How should you prioritise the information required at that point in time? Which techniques would you use to facilitate adequate communication without further compromising a person's oxygenation?

Inadequate nutrition

With advanced COPD, minimal activity, including eating, can cause fatigue and dyspnoea. The person may be unable to consume a full meal without resting. At the same time, the increased work of breathing increases metabolic demands and more kilojoules are required. The person may appear cachectic (thin and wasted). Poor nutritional status further impairs immune function and increases the risk of a complicating infection.

- Assess nutritional status, including diet history, weight for height (use reference tables of desired weights) and anthropometric (skinfold) measurements. *It is important to differentiate nutritional status from body type rather than assume a nutritional impairment.*
- Observe and document food intake, including types, amounts and kilojoule intake. *This information can provide direction for supplementation, if needed.*
- Monitor laboratory values, including serum albumin and electrolyte levels. *These values provide information about the adequacy of nutritional intake, including protein.*
- Consult with a dietitian to plan meals and nutritional supplements that meet kilojoule needs. More concentrated sources of high-energy foods may be required to maintain kilojoule intake without excess fatigue. *A diet high in proteins and fats without excess carbohydrates is recommended to minimise carbon dioxide production during metabolism. (Carbohydrates are metabolised to form CO_2 and water.)*
- Provide frequent, small feedings with between-meal supplements. *Frequent, small meals help maintain intake and reduce fatigue associated with eating.*

- Place seated or in high-Fowler's position for meals. *An upright position promotes lung expansion and reduces dyspnoea.*
- Assist to choose preferred foods from the menu; encourage family members to bring food from home if allowed. *Providing preferred foods encourages eating.*
- Keep snacks at the bedside. *Snacks provide additional kilojoule intake.*
- Provide mouth care prior to meals. *This helps enhance the appetite.*
- If unable to maintain oral intake, consult with the doctor about enteral or parenteral feedings. *Maintenance of kilojoule and nutrient intake is vital to prevent catabolism.*

Compromised family coping

Chronic illness affects the entire family structure. Roles and relationships change; additional demands are placed on the family. Family members may blame the person for causing the illness and may have distorted perceptions about it, even denying its existence. They may refuse to assist or participate in care. The person may develop an attitude of helplessness or dependence, or may demonstrate anger, hostility or aggression.

- Assess interactions between individuals and their family. *Assessment helps identify desired and potential destructive behaviours.*
- Assess the effect of the illness on the family. *Assessment of family interactions, roles and relationships assists in planning appropriate interventions.*
- Help the person and family identify strengths for coping with the situation. *Identifying personal and family strengths helps the family regain a sense of control.*
- Provide information and teaching about COPD. *Education helps the family gain an understanding of the individual's condition and needs.*
- Encourage expression of feelings. *Avoid judging feelings expressed by family members as 'good' or 'bad', 'right' or 'wrong'. It is important that the nurse remain objective to maintain the therapeutic relationship.*
- Help family members recognise behaviours and attitudes that may hinder effective treatment, such as continuing to smoke in the house. *Family members may be unaware of the effect of their behaviour on the person's ability to change habits and cope with a disabling disease.*
- Encourage family members to participate in care. *This helps develop skills for use at home.*
- Initiate a care conference involving the person, family and healthcare team members from a variety of disciplines. *A wide range of perspectives and areas of expertise aids in problem solving and facilitates communication.*
- If dysfunctional family relationships interfere with measures to enhance coping, advocate for the person, reaffirming his or her right to make decisions. *Dysfunctional family relationships are not likely to change simply because of illness. The nurse can better meet the person's needs by accepting their limitations in dealing with family members.*
- Refer the person and family to support groups and respiratory rehabilitation programs, as available. *Support groups and structured rehabilitation programs enhance coping abilities.*
- Arrange a social services consultation. *This can help the person and their family identify care and support service needs.*
- Refer community agencies or home services such as Meals on Wheels as appropriate. *Agencies or community services can provide additional support beyond the family's means or capability.*

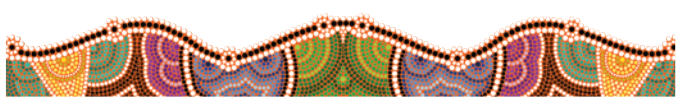
Conflict: smoking

Smoking is more than a habit; it is an addiction. The person who must quit is facing a significant loss, not only of nicotine but also of a lifestyle. Although the person may fully comprehend the consequences of continuing to smoke, the decision to give up a part of their life is not easy. This fear may be expressed in such concerns as 'I'll gain weight' or 'What will I do with my hands?' In addition to providing practical information, a plan and assistance with nicotine withdrawal, the nurse must support the person's decision-making process to comply with an order to stop smoking.

- Assess knowledge and understanding of the choices involved and possible consequences of each. *The decision to quit smoking ultimately belongs to the individual. They need a full understanding of the consequences of quitting or continuing to smoke.*
- Acknowledge concerns, values and beliefs; listen non-judgmentally. *The nurse needs to avoid imposing their own values and beliefs about smoking on the person.*
- Spend time with the person, encouraging expression of feelings. *This demonstrates acceptance of the person and their right to make the decision.*
- Help plan a course of action for quitting smoking and adapt it as necessary. *When the person develops the plan, they have more ownership in it and interest in making it work.*
- Demonstrate respect for decisions and the right to choose. *Respect supports self-esteem and the ability to cope.*
- Provide referral to a counsellor or other professional as needed. *Counsellors or other people trained to assist with smoking cessation can help with decision making.*

Community-based care

As with any chronic disease, the person and family will have primary responsibility for disease management. Teaching is vital to promote optimal health and slow disease progression. Teaching for home care focuses on effective coughing and breathing techniques (see Box 36.4), preventing exacerbations and managing prescribed therapies.



BOX 36.4 Person-centred teaching: effective coughing and breathing techniques

Pursed-lip and diaphragmatic breathing techniques help minimise air trapping and fatigue. Pursed-lip breathing helps maintain open airways by maintaining positive pressures longer during exhalation. Teach the person to:

1. Inhale through the nose with the mouth closed.
2. Exhale slowly through pursed lips, as though whistling or blowing out a candle, making exhalation twice as long as inhalation.

Diaphragmatic or abdominal breathing helps conserve energy by using the larger and more efficient muscles of respiration. Teach the person to:

1. Place one hand on the abdomen, the other on the chest.
2. Inhale, concentrating on pushing the abdominal hand outwards while the chest hand remains still.
3. Exhale slowly, while the abdominal hand moves inwards and the chest hand remains still.

Repeat these exercises as often as necessary until the techniques become incorporated into normal breathing.

Several different coughing techniques may be useful. For controlled cough technique, teach the person to:

1. Following prescribed bronchodilator treatment, inhale deeply and hold breath briefly.
2. Cough twice, the first time to loosen mucus, the second to expel secretions.
3. Inhale by sniffing to prevent mucus from moving back into deep airways.
4. Rest. Avoid prolonged coughing to prevent fatigue and hypoxaemia.

For 'huff' coughing, teach the person to:

1. Inhale deeply while leaning forwards.
2. Exhale sharply with a 'huff' sound to help keep airways open while mobilising secretions.

In addition, include the following topics when teaching for home care:

- maintaining adequate fluid intake (at least 2 L of fluid daily)
- avoiding respiratory irritants, including cigarette smoke, both primary and secondary, other smoke sources, dust, aerosol sprays, air pollution and very cold, dry air
- preventing exposure to infection, especially upper respiratory infections
- importance of pneumococcal vaccine and annual influenza immunisation
- prescribed exercise program, maintaining ADLs and balancing rest and exercise
- maintaining nutrient intake (e.g. eating small frequent meals and using nutritional supplements to provide adequate kilojoules)
- ways of reducing sodium intake if prescribed
- identifying early signs of an infection or exacerbation and the importance of seeking medical attention for the following: fever, increased sputum production, purulent (green or yellow) sputum, upper respiratory infection, increased shortness of breath or difficulty breathing, decreased activity tolerance or appetite, increased need for oxygen
- prescribed medications, including purpose, proper use and expected effects
- avoiding use of OTC medications unless approved by the doctor
- other prescribed therapies, such as use of home oxygen, percussion, postural drainage and nebuliser treatments
- use, cleaning and maintenance of any required special equipment
- importance of wearing an identification band and carrying a list of medications at all times in case of an emergency.

Provide referrals to home care services such as home health, assistance with ADLs as needed, home maintenance services, respiratory therapy and home oxygen services, and other agencies such as Meals on Wheels as indicated.

OTHER SELECTED LUNG DISEASES AFFECTING THE AIRWAY

THE PERSON WITH CYSTIC FIBROSIS

Cystic fibrosis (CF) is an autosomal recessive disorder that affects epithelial cells of the respiratory, gastrointestinal and reproductive tracts and leads to abnormal exocrine gland secretions. Although it can affect many organ systems, CF is particularly damaging to the lungs, leading to COPD in childhood and early adulthood. Respiratory manifestations of CF are the usual cause of morbidity and death from this disease. The gastrointestinal tract also is affected significantly; exocrine pancreatic insufficiency is characteristic of CF. Abnormally high sweat electrolytes also occur in CF.

Incidence and prevalence

In Australia, 34 people died from cystic fibrosis in 2013 (ABS, 2015c). As at 31 December 2013, 3235 people were recorded to have cystic fibrosis on the Australian Cystic Fibrosis Data Registry. Of the 92 new Australian CF diagnoses in 2013, 86% were diagnosed before 1 year of age. In 2001, the number of adults on the register was 35%; in 2013, 49.9% of the people on the CF register were adults. Due to advances in medical management, 22% of the people on the register are over 30 and 4% are over 60 years of age (Australian Cystic Fibrosis Data Registry (ACFDR), 2015).

Pathophysiology

The CFTR protein is involved in membrane transport of chloride and sodium in cells lining the ducts of exocrine glands (sweat glands, pancreas, liver and reproductive systems). The genetic abnormality of CF leads to a lack or abnormality of this protein, with resulting abnormal electrolyte transport across epithelial cell membranes (see the accompanying box).

GENETIC CONSIDERATIONS
Cystic fibrosis

The gene responsible for cystic fibrosis is at a single locus on the long arm of chromosome 7. This gene codes for a protein known as the *cystic fibrosis transmembrane conductance regulator (CFTR)*. More than 1000 mutations of this gene have been identified. The most common mutation, identified as ΔF508, accounts for about 66% of cystic fibrosis (Sharma, 2014). Cystic fibrosis is an autosomal recessive disorder: it is not transmitted as a sex-linked trait and the normal gene is dominant. People with one abnormal gene do not have the disorder but can transmit this abnormal gene to their offspring. When a child inherits an abnormal gene from both parents, the disorder is seen. Genetic screening of family members can detect 70–75% of carriers of the CF gene. Screening for the CF gene is not recommended for the general population.

Defective chloride transport causes more water and sodium reabsorption than normal. Secretions in affected organs become thick and viscous, obstructing glands and ducts. This obstruction causes dilation of secretory glands and damage to exocrine tissue. The hallmark pathophysiological effects of CF include:

- excess mucus production in the respiratory tract with impaired ability to clear secretions and progressive COPD
- pancreatic enzyme deficiency and impaired digestion
- abnormal elevation of sodium and chloride concentrations in sweat.

In the lungs, viscous mucus plugs small airways and impairs mucociliary clearance, leading to atelectasis, infection, bronchiectasis and dilation of distal airways. Lower respiratory infections with *Staphylococcus aureus* and *Pseudomonas, Haemophilus influenza and Escherichia coli* are common (ACFDR, 2015). A multidrug-resistant bacteria *Burkholderia cepacia* (previously *Pseudomonas cepacia*) is clinically significant as it may also hamper the potential for lung transplantation (Lubamba et al., 2012) Acute and chronic damage to lung parenchyma causes tissue loss and extensive scarring and fibrosis. The upper lobes are involved to a greater extent than the lower lobes. Severe airway obstruction and chronic hypoxaemia lead to pulmonary hypertension, right ventricular hypertrophy and eventual cor pulmonale. Death usually results from a combination of cardiovascular changes and respiratory failure.

Pancreatic insufficiency is a frequent component of CF. It can range from slight pancreatic dysfunction to complete absence of function due to obstruction of pancreatic ducts with thick mucus and degenerative and fibrotic changes. Pancreatic insufficiency and impaired enzyme secretion lead to impaired digestion and absorption of proteins, carbohydrates and fats.

About 8–12% of individuals with CF over 25 years of age develop diabetes mellitus. Liver failure is another potential complication of the disease (Sharma, 2014). Because the genetic defect also affects cells of the reproductive tract, males with CF usually are sterile. Although females may have difficulty conceiving, pregnancies are usually carried to term.

FIGURE 36.10 ■ Clubbing of fingers caused by chronic hypoxaemia

Source: © John Radcliffe Hospital/Science Source.

Depending on a women's pre-pregnancy health, pregnancy can be tolerated well despite at least a moderate decrease in lung function (Lau et al., 2011).

Manifestations

Manifestations of CF in a young adult include a history of chronic lung disease. Recurrent pneumonia, exercise intolerance and chronic cough are typical. Other pulmonary manifestations include *clubbing* of the fingers and toes (see Figure 36.10), increased anteroposterior chest diameter (barrel chest), hyperresonant percussion tone and basilar crackles on auscultation. Distended neck veins, ascites and peripheral oedema accompany right-sided heart failure. Abdominal pain and *steatorrhoea* (excess fat in the stools, causing frequent, bulky, foul-smelling stool) commonly result from associated pancreatic insufficiency. Growth and development are often retarded, resulting in small stature.

INTERPROFESSIONAL CARE

The treatment plan for cystic fibrosis is multidisciplinary, with the goals of preventing or treating respiratory complications and maintaining adequate nutrition. Psychosocial care is vital, as is genetic and occupational counselling.

Diagnosis

Although evidence of lung disease and pancreatic insufficiency suggests CF, analysis of Cl^- concentration in sweat is used to confirm the diagnosis. In CF, the Cl^- concentration is > 70 mEq/L. Pilocarpine (a parasympathomimetic agent) and a small electric current are used to increase sweat production on the forearm. Absorbent paper or gauze is used to collect the sweat for analysis.

ABGs and oxygen saturation levels show hypoxaemia. Pulmonary function studies reveal reduced airflow, reduced forced vital capacity (see Box 33.1) and reduced total lung capacity. Alveolar–capillary diffusion also is typically reduced.

Medications

Immunisation against respiratory infections is vital to promote optimal health. Yearly influenza vaccine is recommended, along with measles and pertussis boosters as needed.

Bronchodilator inhalers may be used to control airway constriction. Acute pulmonary infections are treated with appropriate antibiotic therapy as determined by sputum culture and sensitivity tests. A prolonged treatment course or multiple antibiotics may be required to eradicate pulmonary infections. Antibiotics may be administered by several routes, including inhalation, to achieve the desired concentration in large airways (Sharma, 2014). Dornase alfa, recombinant human DNase, breaks down the excess DNA in the sputum of individuals with CF, decreasing its viscosity and making it easier to clear. Dornase alfa, administered by aerosol, reduces the frequency of hospitalisations and the need for antibiotics for some individuals.

Treatments

Chest physiotherapy with percussion and postural drainage is used to promote airway clearance. Newer airway clearance techniques include the use of the 'huff' cough technique with specified breathing cycles or patterns. In one technique, a valved mask or mouthpiece is used to maintain positive expiratory pressure (PEP) for approximately 20 breaths, followed by three to five 'huff' coughs. This cycle is repeated for a total of 20 minutes. The autogenic drainage technique, a form of biofeedback, involves controlled breathing at specific lung volumes and patterns to facilitate the movement of mucus into larger airways, where it can be cleared with the 'huff' cough. A flutter valve device, which looks like a fat pipe, contains a steel ball within an inner cone. The weight of the ball provides intermittent PEP, which vibrates airway walls to loosen secretions.

Oxygen therapy may be required for hypoxaemia. A liberal fluid intake helps reduce the viscosity of mucus secretions. A diet high in protein, fat and kilojoules may be necessary to maintain weight. Vitamins and minerals are supplemented to counteract excess losses in the sweat and stools. Enteral or parenteral nutrition may be required during acute exacerbations of the disease.

Surgery

Lung transplantation currently offers the only definitive treatment for CF. Lung transplantation lengthens lifespan and improves quality of life. Single-lung, double-lung and heart–lung transplants have been successfully completed. Because the donor lungs do not have the CF gene, they do not develop the pathophysiological changes of CF. Although the other defects characteristic of CF remain, these can be managed with pharmacological therapy.

Nursing care

Nursing care for the person with cystic fibrosis is much the same as that for any chronic obstructive lung disease. Promoting airway clearance is the priority of nursing care. The genetic component of the disease and the person's age are important considerations. Adults with CF are just entering their productive years and face a lifespan that is likely to be shortened significantly. Females who do conceive face the prospect of transmitting the defective gene to their offspring.

Nursing diagnoses and interventions

Ineffective airway clearance

Bronchial hygiene measures, including vibration, percussion and postural drainage, are the mainstay of treatment for person with CF.

- Assess respiratory status, including vital signs, breath sounds, SpO_2 and skin colour, at least every 4 hours. *Early identification of respiratory compromise allows intervention before tissue hypoxia is significant.*
- Assess cough and sputum (amount, colour, consistency and possible odour). *Assessment of the cough and nature of sputum produced allows evaluation of the effectiveness of respiratory clearance and the response to therapy.*
- Monitor ABG results; report increasing hypoxaemia and other abnormal results to the doctor. *Blood gas changes may be an early indicator of impaired gas exchange due to airway obstruction.*
- Place in Fowler's or high-Fowler's position. Encourage frequent position changes and ambulation as allowed. *The upright position promotes lung expansion; position changes and ambulation facilitate the movement of secretions.*
- Assist to cough, deep breathe and use assistive devices. *Coughing and deep breathing help clear airways.*
- Provide a fluid intake of at least 2500 to 3000 mL per day. *A liberal fluid intake helps liquefy secretions, facilitating their clearance.*
- Work with the doctor and respiratory therapist to provide pulmonary hygiene measures, such as postural drainage, percussion and vibration. *These techniques help mobilise and clear secretions.*
- Administer prescribed medications as ordered and monitor their effects. If the infecting organism is resistant to the prescribed antibiotic, little improvement may be seen with treatment. *Bronchodilators help maintain open airways but may have adverse effects such as anxiety and restlessness.*

Anticipatory grieving

The person with CF and family members face the knowledge that their lifespan is likely to be short.

- Spend time with the person and family. *Time is necessary to develop a trusting, therapeutic relationship.*
- Answer questions honestly; do not deny the probable outcome of the disease. *Honesty reinforces reality and provides a sense of control over decisions to be made.*
- Encourage the person and family to express their feelings, fears and concerns. *Open expression of feelings helps to promote understanding and acceptance.*
- Assist with understanding the grieving process and acceptance of feelings as normal. *Feelings of guilt, anger or depression may cause the person to withdraw from others. Explanation of the grieving process enhances understanding and ability to cope.*

- Help the individual and their family make decisions regarding treatment and care. *This also is important to give them a sense of control.*
- Encourage use of other support systems, such as spiritual and social groups. Refer the person and their family to support groups, social support services and hospice care as indicated. *These support systems provide emotional support and help the person and family cope with the diagnosis.*
- Discuss advance directives (living wills) and power of attorney for healthcare with the person and their family. *These documents give the person and their family a sense of control over the medical care provided if the person is no longer able to express their own wishes.*

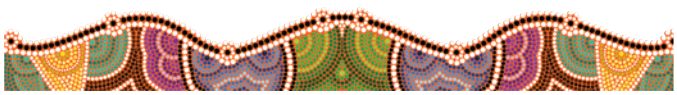
Community-based care

Education of the person and family affected by CF is essential to maintaining optimal health. The adult whose disease was diagnosed in infancy or childhood has grown up with the disease and often has a much greater knowledge level than many caregivers. However, when the initial diagnosis is made as an adolescent or young adult, teaching needs are significant. Include the following topics when teaching for home care:

- respiratory care techniques, including percussion, postural drainage and controlled cough techniques
- specific breathing and coughing exercises and procedures
- the importance of avoiding respiratory irritants, such as cigarette smoke, air pollution and occupational dusts and gases
- measures to prevent respiratory infection, such as maintaining immunisations and optimal general health and avoiding exposure to large crowds and infected people.

Refer to a dietitian for planning and teaching to maintain adequate nutrition and minimise gastrointestinal symptoms. Referral to community agencies and support groups is also helpful.

Discuss the genetic transmission of cystic fibrosis and refer for counselling and possible genetic testing. Help the individual and their family sort through the impact of the disease on future pregnancies and generations. Remember that the possibility of CF may present an ethical dilemma regarding future pregnancies. Provide support as needed.



THE PERSON WITH ATELECTASIS

Atelectasis is not a disease but a condition associated with many respiratory disorders. It is a state of partial or total lung collapse and airlessness. It may be acute or chronic. The most common cause of atelectasis is obstruction of the bronchus ventilating a segment of lung tissue. The affected segment may be small or an entire lobe. Other causes include compression of the lung by pneumothorax, pleural effusion or tumour; or loss of pulmonary surfactant and inability to maintain open alveoli.

The manifestations of atelectasis depend on its size. Diminished breath sounds over the affected area may be the only sign of a small atelectasis. If a large lung segment is affected, manifestations may include tachycardia, tachypnoea, dyspnoea, cyanosis and other signs of hypoxaemia. Chest expansion may be reduced and breath sounds absent on the affected side. Fever and other manifestations of infection may be present.

Chest x-ray shows an area of airless lung. Computed tomography (CT) scan may help determine the cause of atelectasis.

The primary therapy for atelectasis is prevention. Individuals with COPD, smokers undergoing surgery and people on prolonged bed rest or mechanical ventilation should have vigorous chest physiotherapy to maintain open airways as they are at high risk of atelectasis. Frequently assess respiratory status, including rate, breath sounds and spirometry readings, for early detection and treatment.

When atelectasis develops, treatment focuses on the underlying cause. Vigorous coughing and chest therapy may relieve obstruction by a mucus plug. Bronchoscopy may be necessary to remove the obstruction. Antibiotic therapy is ordered to treat infectious causes.

Nursing care to prevent and treat atelectasis is directed towards airway clearance. Position the person with atelectasis on the unaffected side to promote gravity drainage of the affected segment. Encourage frequent position changes, ambulation, coughing and deep breathing. Unless contraindicated, encourage fluids to help liquefy secretions. Teach the person at high risk of developing atelectasis about respiratory care measures, fluid intake and preventing respiratory infections.

THE PERSON WITH BRONCHIECTASIS

Bronchiectasis is characterised by permanent abnormal dilation of one or more large bronchi and destruction of bronchial walls. Infection often is present. The destructive process of bronchiectasis is initiated by inflammation, usually due to recurrent airway infections. About half of all cases of bronchiectasis are related to cystic fibrosis. Other causes include infections, such as severe pneumonia, tuberculosis or fungal infections; lung abscess; exposure to toxic gases; abnormal lung or immunological defences; and localised airway obstruction due to a foreign body or tumour. Inflammation and airway obstruction are common to all of these processes. Bronchial walls become weakened and dilated as a result, leading to pooling of secretions and further infection and inflammation.

A chronic cough productive of large amounts of mucopurulent sputum is characteristic. Other manifestations of bronchiectasis include haemoptysis, recurrent pneumonia, wheezing and shortness of breath, malnutrition, right-sided heart failure and cor pulmonale.

Collaborative care for bronchiectasis focuses on maintaining optimal pulmonary function and preventing progression of the disorder. The diagnosis is typically based on the history and physical examination. Chest x-ray and CT scan may be ordered to help confirm the diagnosis and determine the extent of lung damage.

Antibiotics are prescribed at the first indication of infection and may also be used prophylactically. Inhaled bronchodilators may be ordered. Chest physiotherapy is a vital component of continuing care for bronchiectasis. Percussion and postural

drainage help mobilise secretions. Oxygen may be prescribed. Bronchoscopy may be used to clear retained secretions or obstruction, or to evaluate haemoptysis. If lung destruction is localised and unresponsive to conservative management, surgical lung resection may be necessary.

Nursing care of the person with bronchiectasis is similar to that for individuals with other obstructive lung diseases. Airway clearance is a primary problem, as is ineffective breathing pattern. Other applicable nursing diagnoses may include *Impaired gas exchange*, *Inadequate nutrition* and *Self-care deficit*.

INTERSTITIAL PULMONARY DISORDERS

Many lung diseases damage the interstitial or connective tissue of the lung. Occupational lung diseases and sarcoidosis are interstitial lung diseases. Toxic drugs and radiation also cause interstitial damage. Table 36.6 identifies common causes of interstitial lung disorders. These disorders may be acute or insidious. Their rate of progression varies from person to person, as does the degree of disability they produce. Statistics are difficult to locate. However, in Australia, in 2013, 807 people died from lung diseases due to external agents, such as pneumoconiosis from asbestos or other mineral fibres, or pneumonitis due to organic substances, solids or liquids (ABS, 2015b).

THE PERSON WITH AN OCCUPATIONAL LUNG DISEASE

Occupational lung diseases are a diverse group of disorders directly related to inhalation of noxious substances in the work environment. There are two main classifications of occupational lung diseases:

- *Pneumoconiosis:* chronic fibrotic lung diseases caused by inhalation of inorganic dusts and particulate matter.
- *Hypersensitivity pneumonitis:* allergic pulmonary diseases caused by exposure to inhaled organic dusts.

Physiology review

Lung tissue contains elastin and collagen fibres. Elastin fibres are easily stretched, facilitating lung expansion. Collagen fibres, in contrast, resist stretching. This increases the work of breathing. Both elastin and collagen affect lung compliance or the ease with which the lungs are inflated (Caronia, 2014). Other factors affecting compliance include the water content of lung tissue and surface tension.

Pathophysiology and manifestations

When a noxious substance is inhaled, the response to that substance depends on:

- the size of particulates
- its nature (organic or inorganic)
- where it deposits in the respiratory tract
- the susceptibility of the individual.

Relatively large particles, larger than 6 μm, are too big to reach lower airways and often are deposited in the nose. Smaller particles can be carried with inspired air into the alveoli. Normal lung defences, including alveolar macrophages, lymph channels and the mucociliary escalator, attempt to remove particulate matter from the alveoli. Cigarette smoking, alcohol ingestion or hypersensitivity reactions can impair these defences.

The inhaled substance damages alveolar epithelium, leading to an inflammatory process of the alveoli and interstitial tissue of the lung. The inflammatory response produces further damage and abnormal fibrotic (scar) tissue replaces the elastin fibres of normal lung tissue. As a result, the lungs become stiff and non-compliant. Lung volumes decrease, the work of breathing increases and alveolar–capillary diffusion is impaired, leading to hypoxaemia.

Asbestosis

Inhalation of asbestos fibres is a common cause of occupational lung disease. *Asbestosis* is a diffuse interstitial fibrotic disease involving the terminal airways, alveoli and pleurae. Exposure to asbestos fibres occurs during mining, milling, manufacturing and application of asbestos products. Although symptoms may not become apparent until 20 years after exposure, they tend to progress, even when further exposure has been halted.

TABLE 36.6 Selected causes of interstitial lung disorders

CAUSE	EXAMPLES
Inorganic dusts	Silica (silicosis), asbestos (asbestosis), coal (coal worker's pneumoconiosis), talc (talcosis)
Organic dusts	Cotton (byssinosis), sugar cane (bagassosis), mouldy hay (farmer's lung)
Drugs	Antineoplastic agents, antibiotics, gold salts, phenytoin
Radiation	External radiation or inhaled radioactive materials
Infections	Widespread tuberculosis or fungal infections, viral or *Pneumocystis carinii* pneumonia
Poisons and noxious gases	Paraquat, nitrogen dioxide, chlorine, ammonia, sulfur dioxide
Systemic diseases	Uraemia, pulmonary oedema
Unknown causes	Sarcoidosis, idiopathic pulmonary fibrosis, connective tissue disorders

Asbestosis is also associated with an increased risk of bronchogenic carcinoma, especially in cigarette smokers. Mesothelioma, a rare cancer of the pleural membrane, is also associated with asbestos exposure. The period between asbestos exposure and tumour development in mesothelioma is long, ranging from 20 to 30 years. People exposed to asbestos prior to the imposition of strict environmental controls may only now be developing manifestations of this disease.

The manifestations of asbestosis include exertional dyspnoea, exercise intolerance and inspiratory crackles. Diffuse, small, irregular or linear opacities appear on chest x-ray, primarily in the lower lobes. As the disease progresses, respiratory failure and marked hypoxaemia may develop.

Silicosis

Inhalation of silica dust by hard-rock miners, foundry workers, sandblasters, pottery makers and granite cutters can lead to *silicosis*, a nodular pulmonary fibrosis (Varkey, 2013). In silicosis, macrophages are destroyed as they engulf silica particles, releasing substances that damage lung tissue and lead to fibrosis and scarring.

Simple silicosis is asymptomatic with no demonstrable respiratory impairment. Complicated silicosis, in contrast, is characterised by large conglomerate densities in the upper lungs. These individuals may be severely dyspnoeic and have a productive cough. Respiratory function testing shows both restrictive and obstructive changes. The increasing size of conglomerate masses can lead to severe disability, cor pulmonale and death.

Coal worker's pneumoconiosis

In the US, this occupational lung disease affects approximately 30% of all miners with 16% ultimately developing interstitial fibrosis (Khan, 2014). In 2012–2013 in Australia, 27 people were admitted for healthcare related to the effects of coal worker's pneumoconiosis (CWP) (AIHW, 2015a). Ingestion of coal dust by alveolar macrophages causes 'coal macules' to form, leading to *coal worker's pneumoconiosis* or *black lung disease*. Coal macules appear on chest x-ray as diffuse, small opacities primarily affecting the upper lungs.

Simple CWP generally is asymptomatic. A small percentage of individuals (1–2%) develop progressive massive fibrosis, which destroys the pulmonary vascular bed and airways of the upper lungs. This progressive form of the disease causes symptoms similar to those of complicated silicosis.

Hypersensitivity pneumonitis

Workers exposed to organic dusts and gases may develop *hypersensitivity pneumonitis*, an allergic pulmonary disease affecting the airways and alveoli. Byssinosis, resulting from cotton dust exposure; bagassosis, due to exposure to mouldy sugar cane fibre; farmer's lung and bird-fancier's lung are examples of hypersensitivity pneumonitis.

Either acute or subacute illness can occur. Acute illness occurs 4 to 8 hours after exposure and is heralded by sudden onset of malaise, chills and fever, dyspnoea, cough and nausea. The subacute syndrome is characterised by an insidious onset of chronic cough, progressive dyspnoea, anorexia and weight loss. Diffuse fibrosis occurs after repeated exposure to the organic material, leading to respiratory insufficiency.

INTERPROFESSIONAL CARE

Prevention is a key strategy for all occupational lung diseases. Containing dust and wearing personal protective devices that limit the amount of inhaled particles are essential for people who work in industries with known risks.

Investigations

Chest x-ray, pulmonary function studies, bronchoscopy and possibly lung biopsy are used to establish the diagnosis of pneumoconiosis. Characteristic patterns are seen for each disorder on x-ray. Pulmonary function testing shows restrictive impairment of lung ventilation, with reduced vital capacity and reduced total lung capacity. The diffusing capacity of the lungs is also decreased. Blood gas analysis reveals hypoxaemia, especially with exercise. Bronchoscopy may be performed to obtain tissue for biopsy. Specialised lung scans may be used to determine the extent of fibrosis.

Management

Eliminating further exposure to the offending agent is an important part of disease management. There is no specific therapy. Anti-inflammatory drugs, such as corticosteroids, may reduce the inflammatory response and slow the progression of the disease. Preventing exposure to other damaging substances such as cigarette smoke and pollution is vital. Pneumococcal vaccine and annual influenza immunisations are recommended to reduce the risk of lower respiratory infections. Other care is supportive, similar to that for COPD.

Nursing care

Health promotion

Teaching about the dangers of occupational lung diseases and ways to reduce their risks needs to begin early, before the disease develops. Nurses in industrial and public health settings can begin by recognising potential dangers and teaching workers about measures to reduce dust in their work area and the use of personal protective devices such as masks. Nurses working with affected families have an excellent opportunity to begin educating children about the risks associated with the occupation.

Nursing diagnoses and interventions

Nursing care for the person with occupational lung diseases is similar to that for those with COPD. Activity intolerance is a high-priority problem for many individuals. Severe dyspnoea can significantly interfere with ADLs. Nursing measures to reduce energy expenditures and provide for rest are essential. Caregiver role strain, either actual or potential, must be considered when the person with severe disability is being cared for at home.

Both the individual and their family coping may be compromised. Many of these diseases develop after 20 to 30 years of exposure to the hazardous material. Individuals who entered

the industry following high school may develop evidence of disease in their forties and face the possibility of changing their occupation or developing significant disability. The resulting role strain affects all members of the family.

Other nursing diagnoses to consider for the person with an occupational lung disease follow:

- *Ineffective oxygenation* related to restrictive lung disease evidenced by low oxygen saturations.
- *Situational low self-esteem* related to effects of ill heath, evidenced by reduced ability to maintain self-care.

Community-based care

The affected person and their family need teaching in preparation for home care, including:

- prevention of further lung damage—for example, avoiding cigarette smoke and heavy air pollution
- recommendations for pneumococcal and annual influenza immunisations; yearly tuberculin testing for individuals with silicosis
- respiratory hygiene measures, such as liberal fluid intake, coughing and deep-breathing exercises
- use and care of oxygen therapy equipment if required
- use and effects of any prescribed or recommended OTC medications.

THE PERSON WITH SARCOIDOSIS

Sarcoidosis is a chronic, multisystem disease characterised by an exaggerated cellular immune response in involved tissues. This abnormal immune response leads to granuloma formation in the lungs, lymph nodes, liver, eyes, skin and other organs. Its cause is unknown. Sarcoidosis primarily affects young adults between the ages of 20 and 40. In Australia in 2013, 35 people died of sarcoidosis (ABS, 2015c). The disease is unusual in Indigenous Australians and in individuals from an Asian background. Women are affected at a slightly higher rate than men. Approximately 1 in 10000 people in Australia have sarcoidosis (Allen, 2015).

In sarcoidosis, multiple granulomas form; these lesions may resolve spontaneously or proceed to fibrosis. The lungs are affected in most individuals with sarcoidosis. Sarcoidosis has a low mortality rate—less than 5% (Kamangar, 2015). Pulmonary haemorrhage and cardiac and respiratory failure from pulmonary fibrosis are the leading causes of death from sarcoidosis.

The manifestations of sarcoidosis vary depending on the organ system affected. It may be asymptomatic, diagnosed by characteristic findings on routine chest x-ray. Symptoms may be insidious, with anorexia, fatigue, weight loss, fever, dyspnoea, arthralgias and myalgias. Skin lesions, uveitis, lymphadenopathy, hepatomegaly or other manifestations may also develop.

Leucopenia, eosinophilia and an elevated erythrocyte sedimentation rate (ESR) typically are noted in sarcoidosis. The chest x-ray helps to determine the extent of pulmonary involvement. Biopsy of a granulomatous lesion may be required to confirm the diagnosis. Pulmonary function tests reveal decreased compliance and impaired diffusing capacity.

Sarcoidosis often resolves spontaneously; therefore, treatment is indicated only when symptoms are severe or disabling. Corticosteroid therapy is prescribed to suppress the inflammatory process when indicated. Relapse frequently occurs when corticosteroids are discontinued. Other anti-inflammatory or immune-modifier medications may also be used.

Nursing care for individuals with sarcoidosis is directed by involved organ systems and related manifestations. Respiratory care is supportive and includes avoiding respiratory irritants and maintaining adequate ventilation. Refer for smoking cessation assistance as needed.

Teach individuals about the disease and symptoms to report to a healthcare provider, including shortness of breath, tearing and eye inflammation, chest pain or irregular pulse, skin lesions and swollen and painful joints. If corticosteroid therapy is prescribed, teach the importance of taking the drug as prescribed and not stopping it abruptly. Include information about managing the side effects of corticosteroids by limiting sodium and increasing potassium in the diet, taking the medication with food or milk to minimise gastric irritation and identifying early signs of infection.

PULMONARY VASCULAR DISORDERS

The cardiovascular and respiratory systems are closely interrelated. As blood flows through the capillary network of the pulmonary vascular system, oxygen diffuses into it and carbon dioxide diffuses out. An effective match of alveolar ventilation and capillary perfusion is essential to maintain this process and, ultimately, tissue oxygenation and function of all organ systems. Both vascular and alveolar changes can alter gas exchange. Arteriosclerotic changes in pulmonary vasculature reduce blood flow to the alveolus. Nearly all lower respiratory system disorders potentially can affect ventilation. Many also have a secondary effect on lung perfusion, because breakdown or fibrosis of alveolar walls destroys the capillary network as well. This section focuses on primary disorders of the pulmonary vascular system.

THE PERSON WITH PULMONARY EMBOLISM

A **pulmonary embolism** (or *thromboembolism*) is obstruction of blood flow in part of the pulmonary vascular system by an embolus. *Thromboemboli*, or blood clots, that develop in the venous system (deep venous thrombosis, or DVT) or right side of the heart are the most frequent cause of pulmonary embolism. Other sources of emboli include tumours that

have invaded venous circulation, fat or bone marrow entering the circulation due to fracture or other trauma, amniotic fluid released into the circulation during childbirth and intravenous injection of air or other foreign substances.

Pulmonary embolism (PE) is a medical emergency. Most people who die from PE will generally die within the first few hours (Ouellette, 2015). In many cases, DVT has not been recognised or treated; often embolisation also goes undetected. Prevention is the most effective treatment strategy for PE.

Incidence and risk factors

In Australia, approximately 12 445 people were hospitalised for the treatment of PE in 2012–2013 (AIHW, 2015a). In 2013, pulmonary embolism caused 392 deaths in Australia (ABS, 2015c). Although many substances can become emboli, thrombus arising from the deep veins of the legs is the leading cause of PE. The risk factors for a pulmonary embolus are those for DVT: stasis of venous blood flow, vessel wall damage and altered blood coagulation.

Prolonged immobility; trauma, including hip and femur fractures; surgery (orthopaedic, pelvic and gynaecological surgery, in particular); myocardial infarction and heart failure; obesity; and advanced age are risk factors for DVT. Women who use oral contraceptives or oestrogen therapy are at risk, as are women during pregnancy and childbirth. See Chapter 31 for more information about DVT.

Physiology review

The right heart receives deoxygenated blood from the systemic venous circulation. The entire output of the right ventricle enters the pulmonary circulation via the pulmonary artery. This artery branches into successively smaller arteries, arterioles and capillaries of the pulmonary vascular system. Each alveolus of the lungs is surrounded by a meshwork of capillaries. Oxygen and carbon dioxide readily diffuse across the alveolar–capillary membrane, driven by a concentration gradient. The partial pressure of oxygen in the alveolus is greater than in the capillary; therefore, it diffuses into the blood. Carbon dioxide diffuses from the capillaries into the alveoli, driven by the higher pressure of dissolved carbon dioxide in venous blood.

A match between blood flow through the pulmonary vascular system (perfusion) and lung ventilation is necessary for effective *respiration* (gas exchange). Local factors regulate ventilation and perfusion to maintain this match. A low alveolar PO_2 constricts alveolar capillaries, directing blood flow to better-ventilated areas of the lung. High alveolar PCO_2 levels cause local bronchodilation, increasing airflow and eliminating excess carbon dioxide.

Pathophysiology

Thrombi affecting only the deep veins of the calf rarely embolise to the pulmonary circulation. However, thrombi often propagate proximally to the popliteal and ileofemoral veins. From there, they may break loose to become an embolus. As vessels of the venous system become progressively larger, the embolus moves freely until it enters the pulmonary arterial system, with its progressively smaller vessels leading to the pulmonary capillary beds (see Figure 36.11).

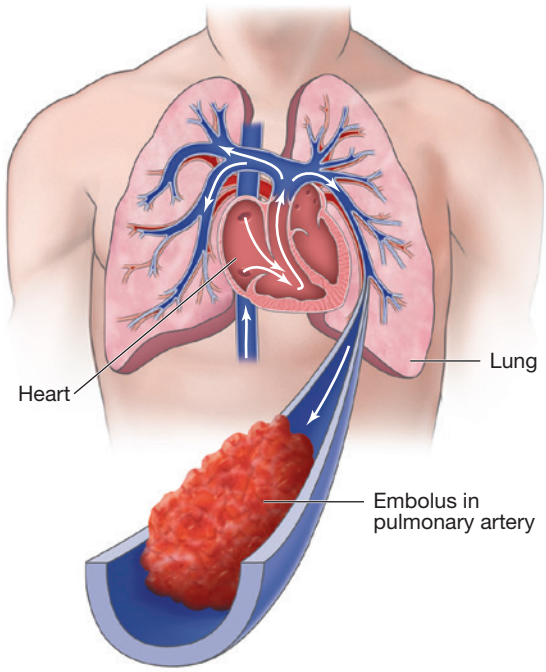


FIGURE 36.11 ■ A thromboembolism lodged in a pulmonary vessel

The impact of a pulmonary embolus depends on the extent to which pulmonary blood flow is obstructed, the size of the embolus, its nature and secondary effects of the obstruction. The effects can range widely:

- Occlusion of a large pulmonary artery with sudden death. Gas exchange is significantly reduced or prevented, and cardiac output falls dramatically as blood fails to move through the pulmonary vascular system and return to the left heart.
- Lung tissue infarction due to occlusion of a significant portion of pulmonary blood flow. Fewer than 10% of pulmonary emboli result in pulmonary infarction.
- Obstruction of a small segment of the pulmonary circulation with no permanent lung injury.
- Chronic or recurrent, possibly multiple, small emboli with recurring symptoms.

Obstruction of pulmonary blood flow by an embolus affects both perfusion and ventilation. Neurohumoral reflexes triggered by obstruction cause vasoconstriction, increasing pulmonary vascular resistance. In severe cases, this can lead to pulmonary hypertension and right ventricular heart failure. Systemically, hypotension and a drop in cardiac output may develop. Bronchoconstriction occurs in the affected area of lung. Dead space (areas of the lung that are ventilated but not perfused) increases. Alveolar surfactant decreases, increasing the risk of atelectasis.

If infarction does not occur, the thrombolytic system (see Chapter 28) ultimately dissolves the clot and pulmonary function returns to normal. Infarcted tissue becomes scarred and fibrotic.

Fat emboli are the most common non-thrombotic pulmonary emboli. A fat embolism usually occurs after fracture of long bone

(typically the femur) releases bone marrow fat into the circulation. Adipose tissue or liver trauma may also lead to fat emboli.

Manifestations

The manifestations of PE depend on its size and location. Small emboli may be asymptomatic. Manifestations usually develop abruptly, over a period of minutes. The most common symptoms are dyspnoea and pleuritic chest pain. Anxiety, a sense of impending doom and cough are also common (see box below). Diaphoresis and haemoptysis may develop. Massive pulmonary embolus can cause syncope and cyanosis. On examination, tachycardia and tachypnoea are noted. Crackles may be heard on auscultation of the chest and a cardiac gallop (S_3 and possibly S_4) may be noted. A low-grade fever may develop. It is difficult to differentiate pulmonary embolism from myocardial infarction or pneumonia by manifestations.

Characteristic manifestations of fat emboli include sudden onset of cardiopulmonary and neurological symptoms: dyspnoea, tachypnoea, tachycardia, confusion, delirium and decreased LOC. Petechiae often develop on the chest and arms.

MANIFESTATIONS Pulmonary embolism

COMMON
- Dyspnoea
- Chest pain
- Anxiety
- Cough
- Tachycardia and tachypnoea
- Crackles (rales)
- Low-grade fever

LESS COMMON
- Diaphoresis
- Haemoptysis
- Syncope
- Cyanosis
- S_3 and/or S_4 gallop

INTERPROFESSIONAL CARE

Because deep venous thrombosis may not be identified until pulmonary embolism occurs, prevention is the primary goal in treating PE.

Early ambulation is an effective means of preventing venous stasis and reducing the incidence of PE. External pneumatic compression of the legs is also effective for individuals undergoing neurosurgery, urological surgery or major surgery of the hip or knee or when anticoagulant therapy is contraindicated. Other preventive measures include elevating the legs and active and passive leg exercises.

When PE occurs, treatment is supportive. Oxygen therapy is initiated and analgesics may be ordered to relieve severe pleuritic pain and anxiety. Pulmonary artery and wedge pressures are monitored with a balloon (Swan–Ganz) catheter. Cardiac outputs also may be assessed. Cardiac rhythm is monitored to detect arrhythmias.

Diagnosis

The studies performed to identify DVT differ from those used to diagnose a PE. See Chapter 31 for diagnostic studies for venous thrombosis.

- *Plasma d-dimer levels* detect inflammation. A d-dimer is a fragment of fibrin formed during lysis of a blood clot; elevated blood levels indicate thrombus formation and lysis (e.g. DVT and PE).
- *Chest CT with contrast* is the principal test used to diagnose PE. Chest CT effectively shows large, central PE; newer-generation scanners also can detect peripheral emboli.
- *Lung scans*, including perfusion and ventilation scans, may be used. In a perfusion lung scan, radio-tagged albumin is injected intravenously and distributed in the lungs by the pulmonary blood flow. The lungs are then scanned for distribution of the isotope. An area of lung in which the isotope is undetectable is suggestive of occluded blood flow and PE. For a ventilation scan, a radio-tagged gas is inhaled and the lungs are scanned for gas distribution. Combined perfusion and ventilation scans allow identification of areas of the lungs that are ventilated but not perfused, a characteristic of PE.
- *Pulmonary angiography* is the definitive test for PE when other, less invasive tests are inconclusive. It is possible to detect very small emboli with angiography. A contrast medium injected into the pulmonary arteries illustrates the pulmonary vascular system on x-ray.
- *Chest x-ray* often shows pulmonary infiltration and occasionally pleural effusion.
- *Electrocardiogram (ECG)* is ordered to rule out acute myocardial infarction as the cause of symptoms. ECG findings commonly associated with PE include tachycardia and non-specific T-wave changes.
- *ABGs* usually show hypoxaemia (PaO_2 less than 80 mmHg) and often respiratory alkalosis (pH >7.45, $PaCO_2$ <38 mmHg) due to tachypnoea and hyperventilation.
- *$ETCO_2$* may be measured to evaluate alveolar perfusion. The normal $ETCO_2$ reading is 35 to 45 mmHg; it is decreased when pulmonary perfusion is impaired.
- *Coagulation studies* are ordered to monitor the response to therapy. The *activated partial thromboplastin time (aPTT* or *PTT*) is used to assess the intrinsic clotting pathway and the response to heparin therapy. Desired levels with anticoagulant therapy are 1.5 to 2 times the control value. The risk of recurrent thromboembolism is high at lower levels; the risk of bleeding increases at higher levels. The *International Normalized Ratio (INR)* is used to assess the extrinsic clotting system and oral anticoagulation with warfarin (Coumadin). The goal of anticoagulant therapy is to achieve a therapeutic range of 2.0 to 3.0.

Medications

Anticoagulant therapy is the standard treatment to prevent pulmonary emboli. It is often instituted in high-risk individuals who have no evidence of PE to prevent possible devastating effects. In the person with DVT or a pulmonary embolus, anticoagulants are administered to prevent further clotting and embolisation. See Chapter 31 for more information about anticoagulant therapy to prevent and treat DVT. See the ‘Medication

administration' box on anticoagulant therapy in Chapter 31 for the nursing implications for such therapy.

For PE, heparin therapy is initiated with an intravenous bolus of 5000 to 10 000 units of heparin, followed by continuous infusion at the rate of 1000 to 1500 units per hour. The aPTT or PTT is monitored frequently until stabilised. Heparin therapy is typically continued for about 5 days or until oral anticoagulant therapy has become fully effective.

Oral anticoagulant therapy with warfarin sodium is initiated at the same time as heparin. Warfarin alters the synthesis of vitamin-K-dependent clotting factors and requires 5 to 7 days to be fully effective. Anticoagulant therapy is continued for 2 to 3 months when few risk factors for thromboemboli exist; long-term therapy is used when chronic disorders that increase the risk of thromboemboli are present.

Bleeding is a risk associated with anticoagulant therapy. Although major haemorrhage is uncommon, it occurs in approximately 5% of individuals receiving intravenous heparin. Cardiac, hepatic and renal disease increase the risk of significant bleeding, as does age over 60 years. Protamine, a protein that combines with heparin to inactivate it, is used to stop its anticoagulant effect if major bleeding occurs. Vitamin K is given to treat bleeding associated with warfarin therapy.

Thrombolytic therapy may be used to treat massive pulmonary embolus and hypotension. Streptokinase, urokinase or tissue plasminogen activator (tPA) are used to *lyse* (disintegrate) the embolus, restore pulmonary blood flow and reduce pulmonary artery and right heart pressures. Although thrombolytic therapy may not reduce mortality associated with pulmonary embolus, it may reduce the incidence of pulmonary hypertension, which develops 3 to 5 years after an embolism. Thrombolysis significantly increases the risk of bleeding, particularly cerebral bleeding. Contraindications to thrombolysis include intracranial disease, recent stroke, active bleeding or a bleeding disorder, pregnancy, severe hypertension and recent surgery or trauma. Because of the increased risk of haemorrhage, invasive procedures are avoided after thrombolysis. See Chapter 29 for further discussion of thrombolytic therapy and its nursing implications.

Surgery

When anticoagulant therapy fails to prevent recurrent emboli or is contraindicated, an umbrella-like filter may be inserted into the inferior vena cava to trap large emboli while allowing continued blood flow. The filter usually is inserted percutaneously, via either the femoral or the jugular vein.

Nursing care

Health promotion

Nurses are pivotal in preventing pulmonary embolism. Encouraging individuals to ambulate after surgery or illness, applying compression stockings or pneumatic compression devices, teaching and encouraging leg exercises, discouraging the use of pillows under the knees—all of these measures help prevent DVT and subsequent PE.

Teach individuals to reduce the risks associated with long periods of immobility, stopping every 1 to 2 hours during long automobile trips for a brief stretch and walk, getting up every hour or so and doing leg exercises while seated during long flights and avoiding crossing the legs to prevent venous stasis and pooling. Regular exercise such as walking also reduces the risk of DVT. Instruct individuals who stand for long periods to use well-fitted elastic stockings, being careful to avoid hose that bind around the knee or thigh.

Assessment

Because pulmonary embolus can be a medical emergency, assessment may be very focused. In other instances, when emboli are small and not life threatening, a more extensive nursing assessment may be done.

- *Health history:* chest pain, dyspnoea, other symptoms, including onset, severity, precipitating factors; history of recent surgery, venous thrombosis or other risk factor such as childbirth or malignancy; current medications.
- *Physical examination:* level of consciousness, presence of respirations and pulse; colour, skin temperature and moisture; vital signs, including apical pulse and temperature; breath sounds and heart sounds; oxygen saturation level; neck vein distension, peripheral oedema.
- *Diagnostic tests:* plasma d-dimer levels, coagulation studies; chest x-ray and other imaging studies; oxygen saturation and ABGs; ECG.

Nursing diagnoses and interventions

A large pulmonary embolus can cause a significant mismatch between pulmonary ventilation and circulation. Impaired gas exchange is a priority problem and focus for interventions. Cardiac output may be significantly affected by obstructed pulmonary blood flow. Thrombolytic and anticoagulant therapy affect the clotting process, increasing the risk of bleeding. Anxiety accompanies PE almost universally.

Impaired gas exchange

Pulmonary embolism results in areas of the lung that are ventilated but not perfused; they receive no capillary blood flow. If the embolus is large and a major segment of the lung is not perfused, gas exchange is significantly affected. Nursing interventions are directed towards compensating for impaired gas exchange.

- Frequently assess respiratory status, including rate, depth, effort, lung sounds and oxygen saturation. *Impaired ventilation will further compromise gas exchange and worsen hypoxaemia. Oxygen saturation can be monitored continuously and non-invasively to evaluate gas exchange.*

CONSIDERATION FOR PRACTICE

Monitor and record LOC, mental status and skin colour. Hypoxaemia often causes confusion and agitation; hypercapnia may reduce LOC. Cyanosis indicates significant hypoxaemia.

- Place in Fowler's or high-Fowler's position, with the lower extremities dependent. *This position facilitates maximal lung expansion and reduces venous return to the right side of the heart, lowering pressures in the pulmonary vascular system.*

CONSIDERATION FOR PRACTICE

Start oxygen per nasal prongs or mask. Obtain a doctor's order if one has not been written. Supplemental oxygen increases alveolar and arterial oxygenation. Oxygen is a drug and must be prescribed by the doctor. It may, however, be initiated by the nurse in an emergency to prevent tissue hypoxia.

- Monitor ABG results, reporting abnormal findings as indicated. An arterial line may be inserted for monitoring arterial pressure and arterial blood sampling. *ABGs are used to assess gas exchange and tissue oxygenation.*
- Maintain bed rest. *Bed rest reduces metabolic demands and tissue needs for oxygen.*

Decreased cardiac output

The impact of a large pulmonary embolus on haemodynamic status can be significant. Pressures in the pulmonary vascular system and right heart increase; blood return to the left heart and cardiac output may significantly decrease. Nursing interventions focus on preserving an adequate blood pressure and organ function until cardiopulmonary status stabilises. A central line for haemodynamic monitoring may be instituted. (See Chapter 30 for nursing care related to haemodynamic monitoring.)

- Auscultate heart sounds every 2 to 4 hours, reporting any abnormalities. *Sounds such as an S3 or S4 gallop may indicate cardiac compromise.*

CONSIDERATION FOR PRACTICE

Assess and record vital signs and cardiopulmonary status every 15 to 30 minutes initially, then every 2 to 4 hours as condition stabilises. Frequent assessment facilitates timely interventions to maintain cardiovascular status and preserve organ function.

CONSIDERATION FOR PRACTICE

Record intake and output hourly. Decreased urinary output often is an early indicator of decreased cardiac output. Maintaining renal perfusion is vital to preserve renal function and prevent acute renal failure.

- Assess skin colour and temperature. *These assessments monitor tissue perfusion.*
- Monitor cardiac rhythm. *A drop in cardiac output and other haemodynamic alterations resulting from pulmonary embolism can precipitate arrhythmias. Arrhythmias, in turn, can further impair cardiac output.*
- Administer vasopressors and other medications as ordered. Carefully monitor the response to prescribed medications. *Drugs may be prescribed to maintain adequate arterial pressure and tissue perfusion. Potent drugs such as vasopressors require careful monitoring for desired and adverse effects.*
- Monitor pulmonary artery pressures, neck vein distension and peripheral oedema. Report findings as indicated. *Right-sided heart failure is a potential complication of PE because of increased pulmonary artery pressures.*
- Maintain intravenous and arterial access sites as well as central lines. *The person may be in an unstable and critical condition, potentially needing immediate interventions to maintain life.*
- Instruct to report chest pain or other symptoms. *Decreased cardiac output and an increased workload due to pulmonary hypertension may cause anginal pain.*

CONSIDERATION FOR PRACTICE

Provide frequent skin care. Impaired tissue perfusion and oxygenation increase the risk of skin and tissue breakdown.

Ineffective protection

Thrombolytics and anticoagulant therapy impair normal clotting mechanisms, increasing the risk of bleeding and haemorrhage. This risk is particularly acute during the first 24 to 48 hours following thrombolytic drug administration.

- Assess frequently for overt and covert signs of bleeding: bleeding gums; haematuria; obvious or occult blood in stool or vomitus; incisional bleeding, bleeding or bruising of injection sites or with minor trauma; joint pain or immobility; abdominal or flank pain. *Careful monitoring is necessary to identify early signs of abnormal bleeding and prevent potential haemorrhage.*
- Report coagulation study results outside the desired range for anticoagulant therapy. *Levels less than the target range may indicate an increased risk of further clot development and pulmonary emboli; levels above the target range indicate an increased risk of bleeding.*

CONSIDERATION FOR PRACTICE

Promptly report changes in neurological status. Although cerebral bleeding is not evident externally, changes in LOC and other neurological signs suggest it and should be reported immediately.

- Keep protamine sulfate available for heparin therapy and vitamin K available for warfarin therapy. *Bleeding or haemorrhage due to excess anticoagulant may require antidote administration to rapidly reverse anticoagulant effects.*
- Assess medication regimen for possible drug interactions that could potentiate or inhibit anticoagulant effects. *Drug interactions can increase the risk of haemorrhage or further embolus formation.*
- Avoid invasive procedures, injections and venipunctures when possible, particularly during and following thrombolytic therapy. *Invasive procedures increase the risk of tissue trauma and bleeding.*

- Maintain firm pressure on injection and venipuncture sites. Maintain pressure for 30 minutes following arterial puncture. *Firm pressure reduces the risk of bleeding into the tissues.*
- Maintain adequate fluid intake. Administer stool softeners as ordered. *These measures help prevent constipation and straining, which may precipitate bleeding of haemorrhoids.*

CONSIDERATION FOR PRACTICE

Use an infusion device to administer heparin infusion. Using an infusion pump or device helps prevent administration of excess medication.

Anxiety

Pulmonary embolism is a physiological and psychological threat to safety and integrity. It is a major physiological stressor, eliciting a strong neuroendocrine stress response. The feeling of suffocation and inability to catch one's breath that accompanies a pulmonary embolus is also a strong psychological stressor. Fear and anxiety are common responses.

- Assess anxiety level. *Appropriate interventions are determined by the level of anxiety.*

CONSIDERATION FOR PRACTICE

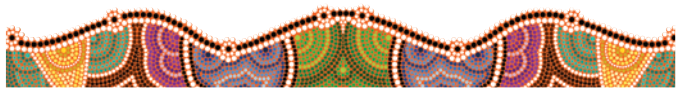
Provide reassurance and emotional support, listening to fears. Do not negate the fear of dying, but reassure that treatment usually restores effective respiratory function. The fear of death is very real and must not be discounted; however, it is important to provide reassurance to alleviate excess anxiety.

- Remain with the person as much as possible. *The presence of a caring nurse helps reduce fear.*
- Explain procedures and treatments, using short, simple sentences. *Providing clearly understood, simple instructions reduces fear of the unknown.*
- Reduce environmental stimuli and use a calm, reassuring manner. *These measures help reduce anxiety (for both the nurse and the individual).*
- Allow supportive family members to remain with the person as much as possible. *Calm, supportive family members provide further reassurance.*
- Administer morphine sulfate as ordered. *Morphine is given to reduce pain and anxiety.*

Community-based care

Discuss the following topics when preparing the person with pulmonary embolism and family members for home care:

- use of prescribed anticoagulant, including drug interactions, scheduled laboratory testing and manifestations of bleeding to report to the primary care provider
- using a soft toothbrush and electric razor to reduce the risk of bleeding
- avoiding aspirin (unless prescribed) and other OTC medications unless approved by the doctor
- importance of wearing a MedicAlert® tag for anticoagulant use
- health-promotion measures to reduce the risk of recurrent PE
- symptoms of recurrent PE, such as sudden chest pain, shortness of breath and, possibly, bloody sputum.



THE PERSON WITH PULMONARY HYPERTENSION

The pulmonary vascular system is normally a high-flow, low-pressure, low-resistance system that can accommodate large increases in blood flow when necessary (e.g. during exercise). The normal mean arterial pressure in the pulmonary system is 12 to 15 mmHg (25 to 28 systolic/8 diastolic). **Pulmonary hypertension** is abnormal elevation of the pulmonary arterial pressure. In Australia, approximately 3 to 10 people per million have idiopathic pulmonary hypertension. A family history is present in 10–12% of cases (PHA Australia, 2015). In 2012–2013 in Australia, 1581 people were admitted to hospital for management of either primary (idiopathic) or secondary hypertension (AIHW, 2015a).

Pathophysiology

Pulmonary hypertension can develop as a primary disorder, but usually occurs secondarily to another condition. In both instances, changes in the pulmonary artery lead to abnormal growth and remodelling of pulmonary vessels. Smooth muscle cells and fibroblasts proliferate, leading to abnormal vasoconstriction and fibrosis of pulmonary vessels. Once initiated, pulmonary vascular changes are progressive and non-reversible. Vasoconstrictive substances such as endothelin 1 and thromboxane A_2 are produced in excess, while the production of vasodilating substances such as nitric oxide is reduced. This further contributes to vasoconstriction and increased pulmonary artery pressures. Thromboxane A_2 also stimulates platelet aggregation, promoting clot formation in pulmonary vessels. Inflammation may contribute to progression of the disease. Vasoconstriction and increased pressures in the pulmonary system increase the workload of the right ventricle, ultimately leading to right ventricular failure (Oudiz, 2014; Kamangar, 2014).

Primary pulmonary hypertension

Primary pulmonary hypertension is an uncommon disorder without identified cause. It occurs in both familial and sporadic patterns. In the familial form, a gene transmitted in an autosomal dominant pattern affects a protein receptor in the walls of pulmonary arteries, leading to abnormal vessel growth and remodelling. Primary pulmonary hypertension mainly affects women in their thirties or forties.

Secondary pulmonary hypertension

Secondary pulmonary hypertension is more common than primary. HIV infection and collagen diseases (e.g. scleroderma and lupus) may lead to secondary pulmonary hypertension. However, its usual cause is the reduced size of the pulmonary vascular bed, which may be due to vasoconstriction or widespread vessel destruction or obstruction. Hypoxaemia is a potent pulmonary vasoconstrictor and common initiating

factor in pulmonary hypertension. Chronic lung diseases, sleep apnoea and hypoventilation due to obesity or neuromuscular disease can lead to hypoxaemia. Alveolar wall destruction associated with emphysema leads to loss of pulmonary capillaries. Large or multiple pulmonary emboli may cause vessel obstruction. Left ventricular failure or mitral stenosis also can lead to elevated pulmonary pressures. Once initiated, pulmonary hypertension becomes self-sustaining, as pulmonary vessels undergo changes that further narrow the pulmonary bed.

Manifestations

The manifestations of pulmonary hypertension are progressive dyspnoea, fatigue, angina and syncope with exertion. In secondary pulmonary hypertension, the signs and symptoms often are masked by those of the underlying disease. Dull, retrosternal chest pain may occur in addition to the manifestations of the primary disease. Primary pulmonary hypertension is a progressive disorder that generally causes a steady decline to death within 3 to 4 years.

Complications

Cor pulmonale is a condition of right ventricular hypertrophy and failure resulting from long-standing pulmonary hypertension. Chronic obstructive pulmonary disease is the most common cause of cor pulmonale.

The manifestations of cor pulmonale are those of the underlying pulmonary disorder and right-sided heart failure. Chronic productive cough, progressive dyspnoea and wheezing are common. With right-sided heart failure, peripheral oedema and distended neck veins are seen. Skin is warm, moist and cyanotic because of increased numbers of RBCs and hypoxaemia.

INTERPROFESSIONAL CARE

An FBC commonly shows *polycythaemia*, increased numbers of red blood cells. ABGs and oxygen saturation measurements reveal hypoxaemia. A chest x-ray shows right heart enlargement and dilation of central pulmonary arteries. Typical ECG changes are those of right ventricular hypertrophy. An echocardiogram may be done to identify cardiac changes occurring either as a cause or a result of pulmonary hypertension. Doppler ultrasonography is a non-invasive means of estimating pulmonary artery pressure, but cardiac catheterisation may be required for definitive diagnosis. See Chapter 28 for nursing care of the person undergoing cardiac catheterisation.

Treatment for pulmonary hypertension focuses on slowing the course of the disease, preventing thrombus formation and reducing pulmonary vasoconstriction. Oxygen is administered to reduce hypoxaemia and improve activity tolerance. If polycythaemia is present, venesection is performed to reduce the viscosity of the blood.

The calcium channel blockers nifedipine or diltiazem may be given to reduce pulmonary vascular resistance and improve cardiac output. Short-acting direct vasodilators such as intravenous epoprostenol or oral bosentan may be used for individuals who do not respond to calcium channel blockers. An oral anticoagulant (warfarin) is given to prevent clotting (Oudiz, 2014; Kamangar, 2014).

Bilateral lung or heart–lung transplant is the most effective long-term treatment for primary pulmonary hypertension.

When cor pulmonale is present, salt and water restrictions as well as diuretic therapy are added to the above regimen to manage the right-sided heart failure.

Nursing care

Nursing care for the person with pulmonary hypertension or cor pulmonale is largely supportive. The focus is on the underlying lung disease. Impaired gas exchange due to contraction of the pulmonary vascular system is a significant problem that causes many secondary problems, such as activity intolerance, anxiety and fatigue. Nursing interventions for impaired gas exchange are directed towards maintaining adequate alveolar ventilation, oxygenation and perfusion. The following measures may be included:

- monitoring breath sounds, respiratory rate, skin colour and use of accessory muscles
- positioning for optimal lung expansion
- coughing, deep breathing and chest physiotherapy
- administering prescribed vasodilators.

It is important to assess fatigue and dyspnoea with activities and to plan frequent rest periods. Assist with self-care as needed to conserve energy.

With primary pulmonary hypertension, *Anticipatory grieving* and *Hopelessness* are additional potential nursing diagnoses. When cor pulmonale is present, *Decreased cardiac output*, *Excess fluid volume* and *Ineffective individual coping* must be considered.

Community-based care

Most care for these chronic conditions is provided in the home and community settings. Teaching is directed both at the underlying lung disease, if present, and the resulting hypertensive process. Refer to the section on COPD for teaching related to this disease, the most frequent underlying cause of cor pulmonale. In addition, provide teaching about the following topics for the person and their family:

- disease process, its management and the prognosis
- manifestations or changes in condition to report to the doctor, such as a change in activity tolerance, increased oedema and signs of respiratory infection or exacerbation
- importance of planned rest periods between activities and measures to conserve energy, such as using a shower chair
- importance of not smoking due to its irritant and vasoconstrictive effects
- prescribed medications, including their use and effects.

RESPIRATORY FAILURE

Many of the conditions discussed in this chapter and in Chapter 35, from pneumonia to acute respiratory distress syndrome, can lead to respiratory failure. In **respiratory failure**, the lungs are unable to oxygenate the blood and remove carbon dioxide adequately to meet the body's needs, even at rest.

THE PERSON WITH ACUTE RESPIRATORY FAILURE

Respiratory failure is not a disease but a consequence of severe respiratory dysfunction. It is often defined by ABG values. An arterial oxygen level (PaO_2) of less than 50 to 60 mmHg and an arterial carbon dioxide level ($PaCO_2$) of greater than 50 mmHg are generally accepted as indicators of respiratory failure. However, individuals with advanced COPD may be alert and functional with blood gas values that would indicate respiratory failure in someone whose respiratory function was previously normal. In people with COPD, respiratory failure is indicated by an acute drop in blood oxygen levels along with increased carbon dioxide levels.

Respiratory failure can result from inadequate alveolar ventilation (hypoventilation), impaired gas exchange or a significant ventilation–perfusion mismatch. COPD is the most common cause of respiratory failure. Other lung diseases, chest injury, inhalation trauma, neuromuscular disorders and cardiac conditions can also lead to respiratory failure. Selected causes of acute respiratory failure are identified in Table 36.7.

Pathophysiology

Respiratory failure may be characterised by primary hypoxaemia or a combination of hypoxaemia and hypercapnia (see Figure 36.12). In hypoxaemic respiratory failure, PaO_2 is significantly reduced, whereas $PaCO_2$ remains normal or is low due to stimulation of the respiratory centre and tachypnoea. Impaired diffusion across the alveolar–capillary membrane and a ventilation–perfusion

TABLE 36.7 Selected causes of respiratory failure

TYPE OF DYSFUNCTION	EXAMPLES
Impaired ventilation	
• Airway obstruction	Laryngospasm, foreign body aspiration, airway oedema
• Respiratory disease	Asthma, COPD
• Neurological causes	Spinal cord injury, poliomyelitis, Guillain–Barré syndrome, drug overdose, stroke
• Chest wall injury	Flail chest, pneumothorax
Impaired diffusion	
• Alveolar disorders	Pneumonia, pneumonitis, COPD
• Pulmonary oedema	Heart failure, ARDS, near-drowning
Ventilation–perfusion mismatch	Pulmonary embolism

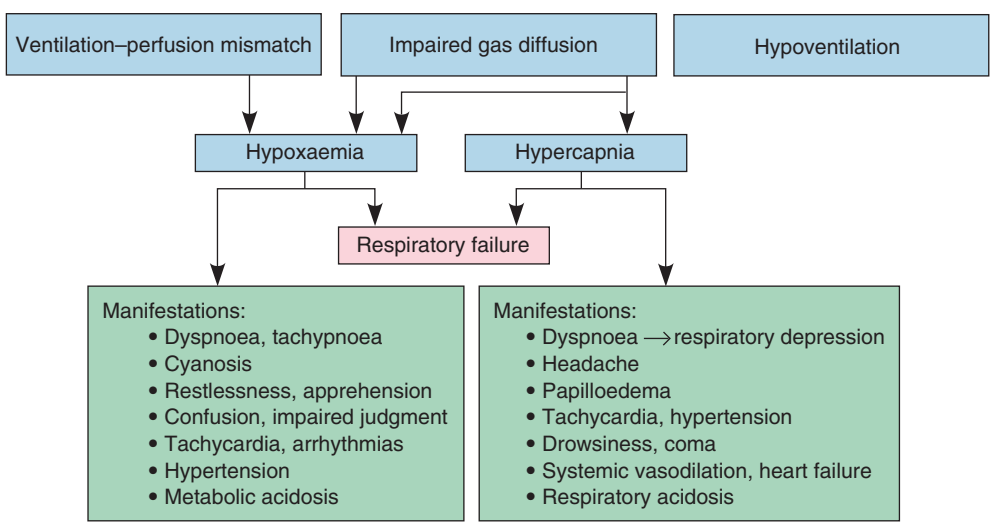


FIGURE 36.12 ■ Causes and manifestations of respiratory failure

mismatch can cause a drop in arterial oxygen levels that is more rapid than the rise in carbon dioxide. Metabolic acidosis results from tissue hypoxia. The increased work of breathing can eventually lead to respiratory muscle fatigue and hypoventilation.

Hypoventilation, or reduced movement of air into and out of the lung, causes carbon dioxide retention. With significant hypoventilation, the carbon dioxide level in the blood rises rapidly, leading to respiratory acidosis. Hypoxaemia develops more slowly and responds readily to administration of oxygen unless gas exchange also is impaired.

In summary, hypoxaemia without a corresponding rise in carbon dioxide levels indicates a failure of oxygenation; hypoxaemia with hypercapnia is the result of lung hypoventilation.

See the accompanying 'Pathophysiology illustrated' feature.

Manifestations and course

The manifestations of respiratory failure are caused by hypoxaemia and hypercapnia, as well as the underlying disease process. Hypoxaemia causes dyspnoea and neurological symptoms such as restlessness, apprehension, impaired judgment and motor impairment. Tachycardia and hypertension develop as the cardiac output increases in an effort to bring more oxygen to the tissues. Cyanosis is present. As hypoxaemia progresses, arrhythmias, hypotension and decreased cardiac output may develop.

Increased carbon dioxide levels depress CNS function and cause vasodilation. Dyspnoea and headache are early signs. Other manifestations include peripheral and conjunctival vasodilation, papilloedema, neuromuscular irritability and decreased LOC. As hypercapnia worsens, the respiratory centre may be depressed, reducing dyspnoea and slowing respirations. Increased carbon dioxide and hydrogen ion concentrations no longer stimulate the respiratory centre; hypoxaemia provides the primary active breathing stimulus. Administering oxygen without ventilatory support may further reduce the drive to breathe, leading to respiratory arrest.

The prognosis for acute respiratory failure varies, depending on the underlying disease process. Respiratory failure resulting from uncomplicated drug overdose generally resolves quickly without long-term effects. When respiratory failure results from underlying lung disease, the course may be prolonged and the outcome less favourable.

INTERPROFESSIONAL CARE

Treatment of respiratory failure focuses on correcting the underlying cause or disease, supporting ventilation and correcting hypoxaemia and hypercapnia. Care related to disorders that can precipitate respiratory failure is discussed in the sections specific to each disorder.

Diagnosis

Exhaled carbon dioxide and ABGs are used to diagnose and monitor treatment of respiratory failure.

- *$ETCO_2$* is used to evaluate alveolar ventilation. The normal $ETCO_2$ is 35 to 45 mmHg; it is elevated when ventilation is inadequate and decreased when pulmonary perfusion is impaired.
- *ABGs* also are used to evaluate alveolar ventilation and gas exchange. With hypoxaemic respiratory failure, the $PaCO_2$ may be normal, 38 to 42 mmHg, or even low due to tachypnoea. A pH of less than 7.35 and low bicarbonate levels indicate metabolic acidosis, typical of hypoxaemic respiratory failure.

  In respiratory failure due to hypoventilation, the $PaCO_2$ is elevated, usually greater than 50 mmHg. The pH is low due to respiratory acidosis. Acidosis develops rapidly in hypoxaemia and hypercapnia because of increased acid production (metabolic) and decreased acid elimination (respiratory).

Medications

Drugs used in treating respiratory failure depend on the underlying cause of the failure and the need for intubation and mechanical ventilation.

Beta-adrenergic (sympathomimetic) or anticholinergic medications may be administered by inhalation to promote bronchodilation. If mechanical ventilation is required, the drugs may be given by nebuliser attached to the ventilator. See 'Medication administration: Asthma' on pages 1318–1319 and the asthma section of this chapter for more information about bronchodilators and their nursing implications. Corticosteroids, administered by inhalation or intravenously, may be ordered to reduce airway oedema. Antibiotics are given to treat any underlying infection.

Sedation and analgesia often are required during mechanical ventilation to decrease pain and anxiety. Benzodiazepines such as diazepam, lorazepam or midazolam may be used for sedation and to inhibit the respiratory drive. Intravenous morphine or fentanyl provides analgesia and also inhibits the respiratory drive, allowing more effective mechanical ventilation. Occasionally, the person's respiratory drive competes with the ventilator despite sedation, decreasing its effectiveness and increasing the work of breathing. A neuromuscular blocking agent may be necessary to induce paralysis and suppress the ability to breathe. Nursing implications of neuromuscular blockers are described in the 'Medication administration' box below.

Oxygen therapy

Oxygen is administered to reverse hypoxaemia in acute respiratory failure. In general, the goal is to achieve an oxygen saturation of 90% or greater without oxygen toxicity. A PaO_2 of about 60 mmHg usually is adequate to meet the oxygen needs of body tissues. Higher levels do not significantly increase oxygen saturation and may lead to hypoventilation in individuals with chronic hypercapnia. As little as 1 to 3 L of oxygen per nasal prongs or 28% oxygen per Venturi mask may correct hypoxaemia in advanced COPD. Oxygen concentrations of 40–60% may be required when diffusion is impaired (e.g. in pneumonia or ARDS). High concentrations are used only for short periods to avoid oxygen toxicity. Both the oxygen concentration and duration of therapy contribute to oxygen toxicity. Continued high oxygen concentrations impair the synthesis of surfactant, reducing lung compliance (ease of inflation). ARDS or absorption atelectasis may develop.

When respiratory failure is caused by hypoventilation or usual oxygen delivery systems do not correct hypoxaemia, a tight-fitting mask to maintain *continuous positive airway pressure (CPAP)* may be used. CPAP increases lung volume,

MEDICATION ADMINISTRATION Neuromuscular blockers

NON-DEPOLARISING NEUROMUSCULAR BLOCKERS

Non-depolarising neuromuscular blockers competitively block the action of acetylcholine (ACh) at skeletal muscle receptors, preventing muscle depolarisation and contraction. Complete muscle paralysis is achieved within minutes. Facial muscles are affected first, followed by muscles of the limbs, neck and trunk. The muscles of respiration (the diaphragm and intercostal muscles) are least sensitive to the effects of neuromuscular blockers and are paralysed last. When the drug is discontinued or an antagonist is given, muscles recover in reverse order; respiratory function is recovered first.

Nursing responsibilities

- Prior to administering, assess endotracheal tube placement and ensure effective mechanical ventilator function. The risk of hypoxaemia and organ damage is significant if respiratory muscles are paralysed without adequate ventilatory support in place.
- Administer the drug by slow intravenous injection and/or intravenous infusion as prescribed.
- Keep an acetylcholinesterase (AChE) inhibitor such as neostigmine available at the bedside to rapidly reverse neuromuscular effects if needed.
- Administer morphine sulfate, diazepam, midazolam or other anti-anxiety agent or sedative as ordered. Neuromuscular blockers provide no sedation or pain relief; muscle paralysis in a conscious person produces extreme anxiety.
- Instil artificial tears every 2 to 4 hours.
- Suction oral cavity as needed to remove saliva.
- Ensure ventilator alarms are always on and appropriate for the person especially when administering neuromuscular blockers. Should the tubing become disconnected or plugged, the person is unable to breathe independently. Begin manual intermittent positive pressure ventilation with an air viva bag or bag/valve system and/or call for assistance.
- Treat the person as though awake and alert. Although unable to respond, mental function is unaffected.

Health education for the person and family

- Reassure that the ability to move and communicate will return when the drug is discontinued.
- Teach the family about the effects of the drug and the reason for its use. Explain that the person can hear and understand what is going on.

opening previously closed alveoli, improving ventilation of underventilated alveoli and ventilation–perfusion relationships.

Airway management

If the upper airway is obstructed or positive-pressure mechanical ventilation is necessary to correct hypoxaemia and hypercapnia, an endotracheal tube that extends from the mouth or nose into the trachea is inserted (see Figure 36.13). To maintain positive-pressure ventilation, the tube is cuffed with an air-filled balloon just above the end of the tube. When the cuff is inflated it obstructs the upper airway, preventing air from escaping back into the nose or mouth. Excess pressure from the cuff can cause tissue ischaemia and necrosis of the trachea. To minimise this risk, high-volume, low-pressure ('floppy') cuffs are used. Tubes with low-pressure cuffs may be left in place for 3 to 4 weeks.

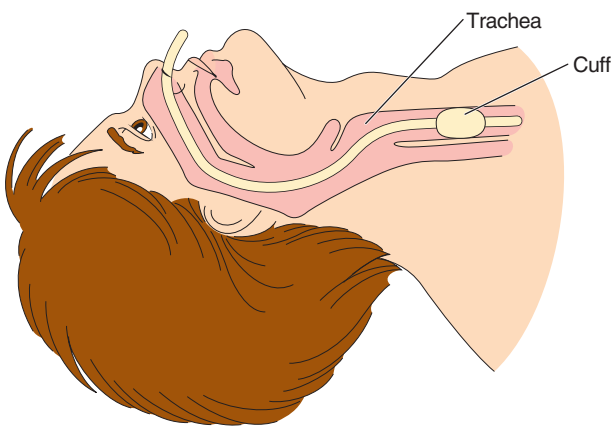

FIGURE 36.13 ■ Nasal endotracheal (nasotracheal) intubation

A tracheostomy may be performed if long-term ventilatory support is required. Although a tracheostomy is more comfortable and easier to secure in place, complications such as cuff necrosis and increased risk of infection are associated with tracheostomy as well as endotracheal intubation. Table 36.8 compares the advantages, disadvantages and possible complications of endotracheal tubes and tracheostomy.

When the person is able to maintain effective respirations and ventilatory support is no longer required, the endotracheal tube is removed (*extubation*). Gag, cough and swallow reflexes must be intact to prevent aspiration. After oxygenation and suctioning, the cuff is deflated and the tube removed. Humidified oxygen is provided immediately following removal. Close observation for respiratory distress is vital following extubation. Inspiratory stridor within the first 24 hours indicates laryngeal oedema, which may necessitate re-intubation. Sore throat and a hoarse voice are common after extubation. Oral intake is reinitiated slowly, with careful assessment of swallowing.

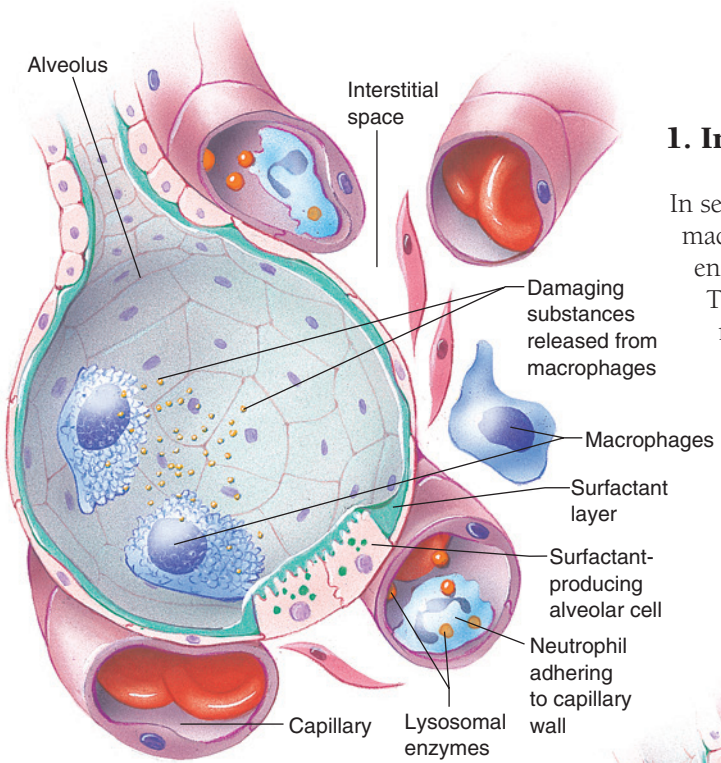
Mechanical ventilation

Mechanical ventilation is indicated when alveolar ventilation is inadequate to maintain blood oxygen and carbon dioxide levels. Specific indications for mechanical ventilation include:

- apnoea or acute ventilatory failure
- hypoxaemia unresponsive to oxygen therapy alone
- increased work of breathing with progressive fatigue.

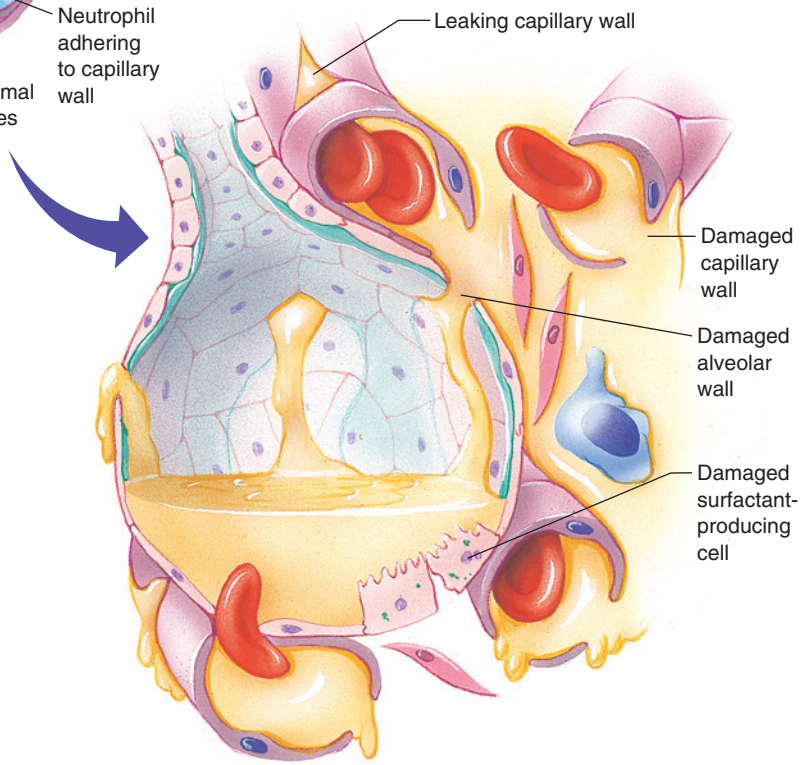
Acute respiratory distress syndrome

Acute respiratory distress syndrome (ARDS) is a severe form of acute respiratory failure that occurs in response to pulmonary or systemic insults. ARDS is characterised by non-cardiogenic pulmonary oedema caused by inflammatory damage to alveolar and capillary walls. Many disorders may precipitate ARDS, although sepsis is the most common.



1. Initiation of ARDS

In sepsis-induced ARDS, bacterial toxins cause macrophages and neutrophils to adhere to endothelial surfaces of the alveoli and capillaries. The macrophages release oxidants, inflammatory mediators, enzymes and peptides that damage the capillary and alveolar walls. In response, neutrophils release lysosomal enzymes, causing further damage.

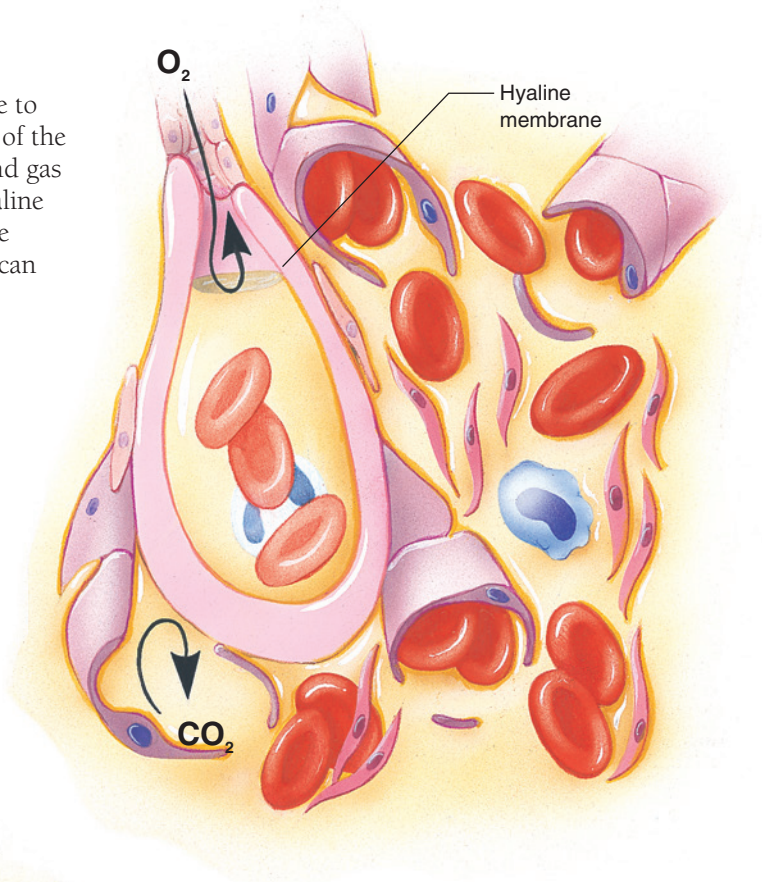


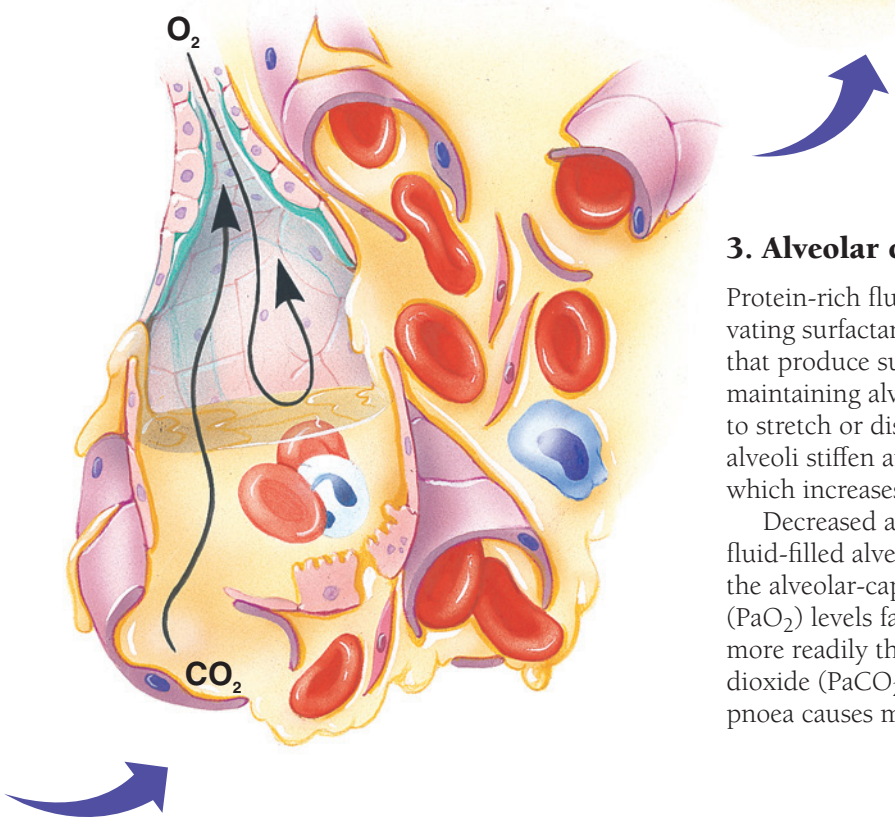
2. Onset of pulmonary oedema

The damaged capillary and alveolar walls become more permeable, allowing plasma, proteins and erythrocytes to enter the interstitial space. As interstitial oedema increases, pressure in the interstitial space rises and fluid leaks into alveoli. Plasma proteins accumulating in the interstitial space lower the osmotic gradient between the capillary and interstitial compartments. As a result, the balance is disrupted between the osmotic force that pulls fluid from the interstitial space into the capillaries and the normal hydrostatic pressure that pushes fluid out of the capillaries. This imbalance causes even more fluid to enter alveoli.

4. End-stage ARDS

Fibrin and cell debris from necrotic cells combine to form hyaline membranes, which line the interior of the alveoli and further reduce alveolar compliance and gas exchange. Because CO_2 cannot diffuse across hyaline membranes, $PaCO_2$ levels now begin to rise while PaO_2 levels continue to fall. Rising $PaCO_2$ levels can lead to respiratory acidosis. Without respiratory support, respiratory failure will develop.
Even with aggressive treatment, almost 50% of people with ARDS die.





3. Alveolar collapse

Protein-rich fluid accumulates in the alveoli, inactivating surfactant and damaging type II alveolar cells that produce surfactant. (Surfactant is important in maintaining alveolar compliance—the ability of tissue to stretch or distend.) As active surfactant is lost, the alveoli stiffen and collapse, leading to atelectasis, which increases breathing effort.

Decreased alveolar compliance, atelectasis and fluid-filled alveoli interfere with gas exchange across the alveolar-capillary membrane. Blood oxygen (PaO_2) levels fall. Because carbon dioxide diffuses more readily than oxygen, however, blood carbon dioxide ($PaCO_2$) levels also fall initially as tachypnoea causes more CO_2 to be expired.

TABLE 36.8 A comparison of endotracheal tubes and tracheostomy

	ADVANTAGES	DISADVANTAGES	POTENTIAL COMPLICATIONS
Oral endotracheal tube	• More easily inserted • Larger tube can be used, facilitating work of breathing, suctioning	• More difficult to secure • Can be obstructed by biting • Communication and mouth care more difficult • Increased risk of lower respiratory infection	• Obstruction or displacement • Pressure necrosis of lip • Tracheo-oesophageal fistula
Nasal endotracheal tube	• More easily secured and stabilised • Well tolerated • Facilitates communication and oral hygiene	• Necessitates smaller tube, which may impede removal of secretions • Increased risk of lower respiratory infection	• Obstruction or displacement • Pressure necrosis of nares • Obstruction of sinus drainage, possible sinusitis • Tracheo-oesophageal fistula
Tracheostomy	• Easily secured and stabilised • Enables swallowing, speech and oral hygiene • Avoids upper airway complications	• Requires surgical incision • Increased risk of lower respiratory infection	• Haemorrhage due to incision or vessel erosion by tube • Wound infection • Subcutaneous emphysema • Tracheo-oesophageal fistula • Tracheal infarction and stenosis

One of the most common indicators for ventilatory support is respiratory muscle fatigue or its potential. Drug overdose, neural disorders, chest wall injury and airway problems such as severe asthma or COPD can lead to acute ventilatory failure. Disorders that affect alveolar–capillary diffusion, such as pulmonary contusion, pneumonia and ARDS, may necessitate mechanical ventilation to attain adequate oxygenation. Positive-pressure ventilation increases lung volume, helps redistribute fluid from the alveolar to the interstitial space and helps reduce the oxygen demand caused by increased work of breathing.

TYPES OF VENTILATORS Two broad general classifications of mechanical ventilators are available. Negative-pressure ventilators create negative (subatmospheric) pressure externally to draw the chest outwards and air into the lungs, mimicking spontaneous breathing. The iron lung and cuirass ventilator are examples of negative-pressure ventilators. Negative-pressure ventilators are rarely used nowadays.

Positive-pressure ventilators are used more often than negative-pressure ones, especially in treating acute respiratory failure (see Figure 36.14). These ventilators push air into the lungs, rather than drawing it in like negative-pressure ventilators. Either invasive ventilation using an endotracheal tube or tracheostomy or non-invasive positive-pressure ventilation may be used. Increasingly, non-invasive techniques, which use a nasal or face mask, nasal plugs or an oral mouthpiece, are being used with various levels of success (Byrd, 2015).

Non-invasive ventilation (NIV) provides ventilator support using a tight-fitting face mask, thus avoiding intubation. Its primary use is to support individuals with obstructive sleep apnoea, neuromuscular disease or impending respiratory failure (e.g. advanced COPD). NIV also may be used for individuals in respiratory failure who refuse intubation. The degree of success varies, primarily limited by the person's intolerance due to the physical and psychological discomfort of wearing a mask when dyspnoeic (Soo Hoo, 2014). NIV tends to be more successful in individuals without significant underlying lung disease (e.g. respiratory failure related to neuromuscular disease).

Several variables are used to trigger, cycle and limit airflow with positive-pressure ventilators. The *trigger* prompts the ventilator to deliver a breath. The individual's inspiratory effort triggers ventilator-assisted breaths. *Ventilator-controlled breaths* usually are triggered by a preset time interval (e.g. a breath is delivered every 5 seconds for a rate of 12 breaths per minute). The *ventilator cycle*, or duration of inspiration, can be limited by volume, pressure, flow or time. *Volume-cycled ventilators* deliver air until a preset volume is delivered. *Pressure-cycled ventilators* cycle off when a preset pressure is achieved within the airways. *Flow-cycled ventilators* are cycled by a preset inspiratory flow rate, and *time-cycled ventilators* deliver air for a set time interval. Airflow delivered by the ventilator also can be limited by factors such as airway pressure (e.g. a volume-cycled ventilator can be set to immediately stop inspiratory flow if airway pressure exceeds a preset value).

MODES OF VENTILATION A number of different *modes* or patterns of ventilation may be used with positive-pressure ventilators. The mode determines whether a breath is initiated by the person or the ventilator and the pattern of airway support provided by the ventilator. CPAP, bi-level airway pressure support, assist-control mode ventilation, synchronised intermittent mandatory ventilation, positive end-expiratory pressure, pressure support ventilation and pressure-control ventilation are common modes of ventilation in use today (see Table 36.9).

Continuous positive airway pressure applies positive pressure to the airways of a person who is spontaneously breathing. CPAP may be used with either endotracheal intubation or a tight-fitting face mask. All breathing is spontaneous (triggered by the person) and pressure controlled. CPAP is used to help maintain open airways and alveoli, decreasing the work of breathing. *Bi-level ventilators (BiPAP)* provide inspiratory positive airway pressure as well as airway support during expiration. Bi-level ventilation is primarily used at night with a tight-fitting mask (nasal, facial

FIGURE 36.14 ■ *A*, Positive-pressure ventilator. *B*, Control panel used to set the mode, rate, limits and percentage of oxygen delivered

or oral). Three modes of ventilation can be used with BiPAP: spontaneous breathing (S); timed mode (T), in which pressure-supported breaths are delivered at a predetermined rate; and spontaneous/timed (S/T), in which the ventilator switches to timed mode if spontaneous breathing falls below a preset rate (International Ventilator Users Network, 2015).

Assist-control mode ventilation (ACMV or AC) is frequently used to initiate mechanical ventilation and when the person is at risk of respiratory arrest (e.g. overdose or head injury). Assisted breaths are triggered by inspiratory effort; however, if the respiratory rate falls below a preset number (e.g. 14 per minute), ventilator-controlled breaths are delivered. All breaths, assisted and controlled, are delivered at a specific tidal volume or pressure and inspiratory flow rate.

Synchronised intermittent mandatory ventilation (SIMV) allows the person to breathe spontaneously, without ventilator assistance, between delivered ventilator breaths. Mandatory or ventilator-controlled breaths are delivered at a preset rate, volume and/or pressure, coordinated with the individual's inspiratory efforts. New evidence appearing suggests that respiratory muscles may not be able to rest between mandatory breaths and, therefore, this mode may result in fatigue which actually prolongs the need for ventilation (Byrd, 2015).

Positive end-expiratory pressure (PEEP) requires intubation and can be applied to any of the previously described ventilator modes. With PEEP, a positive pressure is maintained in the airways during exhalation and between breaths. Keeping alveoli open between breaths improves ventilation–perfusion relationships and diffusion across the alveolar–capillary membrane. This reduces hypoxaemia and allows use of lower percentages of inspired oxygen. PEEP is particularly useful for treating ARDS.

In *pressure support ventilation (PSV)*, ventilator-assisted breaths are delivered when the person initiates an inspiratory effort. The cycle is flow limited; inspiration is terminated when inspiratory airflow falls below a preset rate. This mode decreases the work of breathing. It can be used in combination with SIMV when the respiratory drive is depressed. Ventilator support can be gradually withdrawn during weaning.

Pressure-control ventilation (PCV), in contrast, controls pressure within the airways to reduce the risk of airway trauma (e.g. following thoracic surgery). Ventilation is time triggered and time cycled, but pressure is limited. The ventilator maintains a preset airway pressure throughout inspiration. Because all breaths are controlled by the ventilator, heavy sedation may be required to prevent competition between inspiratory effort and ventilator control.

Pressure-regulated volume control (PRVC) is a newer mode. It enables the desired tidal volume to be preset and permits the ventilator to deliver a pressure-limited (controlled) breath. Some benefits include automatic breath-to-breath

TABLE 36.9 Modes of positive-pressure ventilator operation

MODE	DESCRIPTION	PATTERN
Spontaneous breathing	Person has full control of rate, tidal volume, pressures.	Assist-control mode ventilation (ACMV)	Person can trigger ventilator to deliver breaths at preset volume or pressure and inspiratory flow rate; breaths will be delivered at preset rate if person does not initiate.	Synchronised intermittent mandatory ventilation (SIMV)	Mandatory breaths delivered by ventilator are synchronised with person's inspiratory effort.	Continuous positive airway pressure (CPAP)	Positive pressure is maintained in airways; all breaths are spontaneous.	Positive end-expiratory pressure (PEEP)	Used in conjunction with other ventilator modes; positive airway pressure is maintained throughout respiratory cycle.	Pressure support ventilation (PSV)	Pressurised inspiratory flow supports the person's inspiratory effort, decreasing the work of breathing.	
adjusting according to the individual's lung compliance, resulting in the lowest peak inspiratory pressure needed to achieve a preset tidal volume.

VENTILATOR SETTINGS In addition to choosing the mode of ventilation, other parameters are set to meet individual's needs when positive-pressure ventilation is used (see Table 36.10).

For most adults, the rate is initially set between 12 and 15 breaths per minute. With ACMV or SIMV, the person's respiratory rate often is higher than the ventilator setting due to spontaneous breathing. Exhaled carbon dioxide ($ETCO_2$) or the $PaCO_2$ may be used to determine the rate. A $PaCO_2$ of less than 38 mmHg indicates hyperventilation and respiratory alkalosis; the set rate is reduced. A $PaCO_2$ above 42 mmHg or an $ETCO_2$ greater than 45 mmHg indicates hypoventilation and a need to increase the rate.

The tidal volume setting controls the amount of gas delivered with each ventilator breath. Depending on various factors, an average normal adult tidal volume at rest may range between 5 and 10 mL/kg of body weight. The tidal volume delivered by mechanical ventilation is slightly higher to compensate for tubing dead space. Higher tidal volumes can cause lung tissue trauma.

The percentage of oxygen delivered with ventilator breaths is adjusted to maintain the oxygen saturation and PaO_2 within acceptable ranges. Because prolonged delivery of high oxygen concentrations increases the risk of oxygen toxicity and pulmonary fibrosis, the FiO_2 is set at the lowest possible level for adequate tissue oxygenation. For most individuals, the goal is to maintain an oxygen saturation level of greater than 90%. Lower oxygen saturation levels may be appropriate for individuals with longstanding COPD.

COMPLICATIONS Although endotracheal intubation and mechanical ventilation can be lifesaving in respiratory failure, they are not without risk. Improper endotracheal tube placement or advancement of the tube into a mainstem bronchus can result in ventilation of one lung only. The inflated lung becomes over-distended and traumatised and the uninflated lung develops atelectasis. In non-invasive ventilation, associated complications include gastric dilation, aspiration, facial skin necrosis, drying of the eyes and mucous membranes, stress and claustrophobia (Soo Hoo, 2014).

Healthcare-associated pneumonia Infection is a significant risk associated with intubation and mechanical ventilation. Normal upper respiratory tract defence mechanisms are bypassed, with loss of air humidification and trapping of pathogens. Oral secretions and gastric contents can enter the respiratory tree through the open epiglottis. Frequent, meticulous oral hygiene, upright positioning with the head of the bed elevated >30 degrees, gastric ulcer prophylaxis, minimised ventilator time, removal of condensate from circuits and frequent and thorough hand hygiene from the healthcare professionals are vital interventions in reducing the risk of ventilator-associated pneumonia (Elliot, Aitken & Chaboyer, 2012). Often the cough reflex is inhibited or impaired by the underlying disease process and the continued presence of the endotracheal tube. Secretions often become thick and tenacious, increasing the risk of atelectasis.

Barotrauma *Barotrauma* (also called *volutrauma*) is lung injury due to alveolar over-distension. Both the volume of delivered gas and the pressures under which it is delivered can contribute to barotraumas. As a result, over-distended alveoli rupture, allowing air to escape into the pulmonary interstitial spaces and the mediastinum, pleural space and other tissues. Subcutaneous emphysema, pneumothorax and pneumomediastinum are possible results of barotrauma.

Subcutaneous emphysema, or air in the subcutaneous tissue, causes tissue swelling of the chest, neck and face. A 'crackling' or air-bubble-popping sensation is felt on palpation of subcutaneous emphysema. Swelling may be massive. Once the cause is corrected, the air is gradually reabsorbed.

Pneumothorax is identified by signs of unequal chest expansion, a sudden loss or significant decrease in breath sounds on the affected side and a hyper-resonant percussion tone. Rapid chest tube insertion is necessary to prevent tension pneumothorax and cardiovascular compromise.

Pneumomediastinum is the presence of air in the mediastinum, the space between the lungs that contains the heart, great vessels, trachea and oesophagus. Air in the mediastinal space can interfere with the function of all of these organs and lead to such complications as pneumopericardium (air in the pericardial sac). Pneumomediastinum may have few manifestations, but the chest x-ray shows widening of the mediastinal space.

Cardiovascular effects Positive-pressure ventilation increases intrathoracic pressure, which can interfere with venous return

TABLE 36.10 Ventilator settings

PARAMETER	DESCRIPTION
Rate (*f*)	Number of ventilator-delivered breaths per minute: usually 10 to 15 in adults using ACMV; may be lower in SIMV
Tidal volume (*VT*)	Amount of gas delivered with each ventilator breath: usually 8 to 10 mL/kg of body weight
Oxygen concentration (FiO_2)	Percentage of oxygen delivered with ventilator breaths; can be set between 21% (room air) and 100%
I:E ratio	Duration of inspiration to expiration: usually 1:2 to 1:1.5
Flow rate	Speed at which air is delivered
Sensitivity	Effort required to initiate a ventilator-assisted breath
Pressure limit	Maximal pressure within airways that will terminate a ventilator breath

to the heart and ventricular filling. As a result, cardiac output falls. Use of PEEP increases the effects of mechanical ventilation on cardiac output. The decreased cardiac output can affect liver and kidney function secondarily.

Gastrointestinal effects Gastrointestinal complications are commonly associated with prolonged mechanical ventilation. Stress ulcers (erosive gastritis) may develop, leading to painless gastrointestinal haemorrhage. Histamine H_2-receptor blockers are often used to prevent stress ulcers. Air leaks around the endotracheal tube can cause gastric distension; a nasogastric tube is inserted to prevent vomiting. Sedation and other medications used during mechanical ventilation can slow intestinal motility, leading to constipation.

WEANING The process of removing ventilator support and re-establishing spontaneous, independent respirations is called **weaning**. Weaning begins only after the underlying process causing respiratory failure has been corrected or stabilised. The process and time required for weaning depend on factors such as pre-existing lung condition, duration of mechanical ventilation and the person's general condition, both physical and psychological. In all cases, the vital signs, respiratory rate, extent of dyspnoea, blood gases and clinical status are used to evaluate weaning and its progress. More rapid weaning protocols are common in people with no underlying pulmonary condition who have only been ventilated for a short period of time. In this situation, care must be taken to avoid failed extubation (Elliot et al., 2012).

Following a brief period of mechanical ventilation, a T-piece or CPAP may be used for weaning. In T-piece weaning, the ventilator is removed for brief periods during which oxygen is delivered using a T-piece (see Figure 36.15). The duration of periods off the ventilator is gradually increased until the person can maintain adequate independent respirations for several hours. Vital signs, oxygen saturation, $ETCO_2$ and PaO_2 are carefully monitored during the process. The person is placed back on the ventilator at previous settings if signs of respiratory distress develop. When mechanical ventilation is no longer needed, the endotracheal tube is removed. CPAP weaning follows a similar process, with trials of spontaneous breathing supported by the ventilator in CPAP mode.

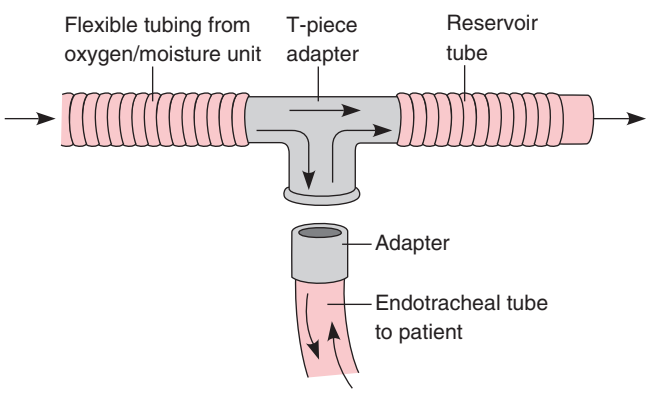

FIGURE 36.15 ■ A T-piece for weaning from mechanical ventilation

SIMV and PSV are used for weaning when the duration of mechanical ventilation has been longer and reconditioning of respiratory muscles is needed. When SIMV is used, the number of mandatory ventilator-assisted breaths is gradually decreased as ABGs, $ETCO_2$ and the respiratory rate are monitored.

Weaning is the primary use for pressure-support ventilation. Initially, PSV is set slightly below the peak inspiratory pressures required during volume-cycled ventilation. Pressure support levels are gradually decreased, often in a cyclical pattern of periods of minimal support alternating with higher support to recondition respiratory muscles. Various weaning protocols exist; however, some parameters used identify an individual's readiness for extubation including a respiratory rate of less than 25 breaths per minute, a tidal volume of greater than 5 mL/kg and a PaO_2 of greater than 80 mmHg (Byrd, 2015).

Terminal weaning When an illness is terminal or irreversible with a poor prognosis, terminal weaning may be requested by the person or their family. *Terminal weaning* is the gradual withdrawal of mechanical ventilation when survival without assisted ventilation is not expected. Unlike weaning when recovery is expected, which usually occurs in a critical care unit, the person is moved to a quiet critical care or hospice room or even home prior to initiating terminal weaning. Family members are encouraged to remain with the person throughout the process. If possible, decisions about sedation and analgesia prior to and during weaning are made with the person, as are decisions about hydration and nutritional support following weaning. Ventilator support is gradually withdrawn using the same modes described earlier (SIMV, PSV). Analgesia and sedation are given to promote comfort during weaning.

Nutrition and fluids

Attention also must be paid to fluid and electrolyte status and adequate nutrition. Mechanical ventilation promotes sodium and water retention due to its effects on cardiac output. Renal perfusion is decreased, stimulating the renin–angiotensin–aldosterone system to retain sodium and water. A Swan–Ganz catheter is often inserted to monitor pulmonary artery pressures and cardiac output. An arterial line allows repeated blood gas analysis and continuous arterial pressure monitoring. Serum electrolytes are drawn frequently and intake, output and daily weight are carefully monitored.

Enteral or parenteral nutrition are provided during mechanical ventilation because the endotracheal tube prohibits eating. A nasogastric, gastrostomy or jejunostomy feeding tube is placed for enteral nutrition. A jejunostomy tube may be used to reduce the risk of regurgitation and aspiration.

Nursing care

Health promotion

Education is a primary strategy to prevent respiratory failure. Teach all individuals and the public about the risks of smoking,

water safety, the value of a working smoke detector and measures to prevent smoke inhalation in a fire. Discuss the importance of pneumococcal vaccine and annual influenza immunisations for people who are at high risk, including those over age 65 and people with chronic diseases. Teach individuals with spinal cord injury or neuromuscular disease to use effective breathing and coughing techniques to maintain airway patency. Work with individuals addicted to narcotic drugs to attain and maintain drug-free status. Teach individuals with COPD about measures to reduce their risk of respiratory infection and symptoms to report to the doctor.

Assessment

Focused assessment data related to respiratory failure include the following:

- *Health history:* current manifestations, their duration and identified precipitating factors (may need to be obtained from family members if mental status is affected); history of previous episodes; chronic diseases such as COPD, occupational lung disease; current medications.
- *Physical examination:* LOC, mental status; vital signs; colour and oxygen saturation; respiratory assessment, including rate and depth, use of accessory muscles, respiratory excursion, auscultation; cardiovascular assessment, including heart rate and sounds, neck vein distension, peripheral pulses, evidence of clubbing.
- *Diagnostic tests*: ABGs, chest x-ray, pulmonary artery pressure and wedge pressure readings, cardiac output.

Nursing diagnoses and interventions

Individuals in respiratory failure are often unstable and critically ill. They require both intensive medical care and intensive nursing care. Priority nursing needs relate to maintaining ventilation and a patent airway. Perhaps less obvious, but no less critical, nursing care needs to relate to preventing injury and managing anxiety.

Impaired spontaneous ventilation

In acute respiratory failure, fatigue from the work of breathing may impair the ability to maintain adequate ventilation. This is a concern both prior to initiation of mechanical ventilation and during the weaning process.

- Assess and document respiratory rate, vital signs and oxygen saturation every 15 to 30 minutes. *Close monitoring is vital to detect early signs of increasing respiratory distress and inability to sustain adequate breathing.*

CONSIDERATION FOR PRACTICE

Promptly report signs of respiratory distress, including tachypnoea, tachycardia, nasal flaring, use of accessory muscles, intercostal retractions, cyanosis, increasing restlessness, anxiety or decreased LOC. These may be early manifestations of respiratory failure and inability to maintain ventilatory effort.

- Promptly report worsening ABGs and oxygen saturation levels. *Close assessment of these values allows timely intervention as needed.*
- Administer oxygen as ordered, monitoring response. Observe closely for respiratory depression, especially in the person with COPD. *Oxygen administration reduces the hypoxic respiratory drive. Chronically high $PaCO_2$ levels depress the respiratory centre; hypoxaemia may provide the only respiratory drive.*
- Place in Fowler's or high-Fowler's position. *Sitting positions decrease pressure on the diaphragm and chest, improving lung ventilation and decreasing the work of breathing.*
- Minimise activities and energy expenditures by assisting with ADLs, spacing procedures and activities, and by allowing uninterrupted rest periods. *Rest is vital to reduce oxygen and energy demands.*

CONSIDERATION FOR PRACTICE

Avoid sedatives and respiratory depressant drugs. These medications can further depress the respiratory drive, worsening respiratory failure.

- Prepare for endotracheal intubation and mechanical ventilation:
  a. Obtain an intubation tray with a selection of sterile endotracheal tubes and laryngoscope with a variety of adult blades.
  b. Check laryngoscope bulb; replace battery or bulb as needed.
  c. Set up for endotracheal suction, bringing suction equipment and gloves to the bedside.
  d. Set up the ventilator.
  e. Notify radiology that a portable chest x-ray will be needed on completion of intubation to verify correct placement of the endotracheal tube.

  Intubation and mechanical ventilation may be required to maintain ventilation and gas exchange.
- Explain the procedure and its purpose to the person and their family, providing reassurance that this is a temporary measure to reduce the work of breathing and allow rest. Inform the person and their significant others that talking is not possible while the endotracheal tube is in place and establish a means of communication. *Thorough explanation is important to relieve anxiety.*

Ineffective airway clearance

Ineffective airway clearance may either cause respiratory failure or occur as a result of interventions. Impaired ventilation frequently leads to acute respiratory failure, particularly in a person with COPD or asthma. Chest trauma also can impair airway patency as a result of pulmonary contusion and ineffective cough. Although intubation and mechanical ventilation can be lifesaving measures, they also increase the risk of respiratory infection and ineffective secretion management.

- Suction as needed to maintain a patent airway. Indicators for suctioning include crackles and rhonchi on auscultation, frequent coughing or setting off of the high-pressure alarm, and increasing restlessness or anxiety. Procedure 36.1 outlines endotracheal suctioning. *Although individuals with a tracheostomy can usually cough up secretions, the length and diameter of endotracheal tubes*

PROCEDURE 36.1 Endotracheal suctioning

GATHER SUPPLIES

- Suction unit with connecting tubing and connector at the bedside
- If an in-line suction catheter is not present:
  a. sterile suction catheter (a simple formula for sizing is:
     if ETT < 6 mm (Fr = ETT size (mm) x 2)
     if ETT ≥ 6 mm (Fr = ETT size (mm) – 2 x 2)
  b. a solution (e.g. water) to clean suction tubing following intervention
- Personal protective devices as indicated: goggles, mask, gown

BEFORE THE PROCEDURE

Explain the procedure and why it is being done. Tell the person that although suctioning is not painful, it is uncomfortable. While suction is being applied, breathing is difficult but these periods last only 10 seconds. Stress that suctioning allows removal of secretions and stimulates coughing, and helps clear secretions. Establish a means of communicating; for example, tell the person to raise a finger or rapidly blink if unable to tolerate suctioning.

DURING THE PROCEDURE

1. Use standard precautions.
2. Prepare the suction unit by turning it on and regulating it to no more than –80 to –120 mmHg.
3. Open sterile saline bottle and pour approximately 50 mL of saline into the opened sterile container.

With an in-line catheter

- Wearing exam gloves, attach the catheter to the suction tubing.
- Adjust the oxygen (FiO_2) to 100%; allow three breaths.
- Manipulating the catheter through the plastic shield (to maintain its sterility), insert the catheter without applying suction until resistance is met; apply suction while slowly withdrawing the catheter with a twirling motion (see photograph).
- Suction for no longer than 10 seconds (count the seconds or watch the clock—the time passes more quickly than you think. Holding your own breath during this time also gives you an indication of how quickly the technique needs to be completed), then allow to rest for three to five breaths. Repeat the procedure as needed for a total of no more than three times.
- Remove suction tubing from the catheter, clear the tubing, turn off suction and remove and discard gloves.

Endotracheal suctioning

Source: © Ansell Horn/Phototake.

As an open suction technique

- Open suction catheter. Ensure that there is water to clean the catheter between attempts.
- With a non-touch technique, attach catheter to suction tubing, keeping dominant hand clean; remove the outside package with the non-dominant hand and take the sterile catheter with the dominant hand.
- Use the non-dominant hand to adjust oxygen (FIO_2) to 100%; allow three breaths.
- Using the non-dominant hand, disconnect ventilator tubing from the endotracheal tube. Manipulating the suction catheter with the dominant hand and the suction control valve with the non-dominant hand, insert the catheter, without applying suction, until resistance is met. Then, apply suction intermittently while slowly withdrawing the catheter, using a twirling motion.
- Suction for no longer than 10 seconds. Reconnect the ventilator and allow the person to rest for three to five breaths; clear suction tubing as per protocol.
- Repeat the preceding two steps as needed for a total of three times.
- Reconnect ventilator tubing to the endotracheal tube.
- Clear suction tubing, turn off suction and remove the catheter, discarding it with the gloves.

4. Provide three additional breaths at 100% oxygen and then readjust to the previous ordered level.
5. Note colour, quantity, consistency and odour of sputum.
6. Assess lung sounds and tolerance of the procedure.
7. Wash hands.

AFTER THE PROCEDURE

Document results of suctioning procedure, along with the character of the sputum and the person's tolerance of the procedure. Report changes in sputum character, such as purulence or an odour that may indicate infection.

make this extremely difficult. Even with humidification, secretions often become thick and tenacious, further inhibiting their removal.

CONSIDERATION FOR PRACTICE

Frequently assess respiratory rate, chest movement, lung sounds, oxygen saturation, $ETCO_2$ and ABGs. Intubation and mechanical ventilation do not ensure adequate oxygenation and ventilation. Displacement of the endotracheal tube or obstruction by respiratory secretions impairs ventilation.

- Obtain sputum for culture if it appears purulent or is odorous. *Culture is necessary to identify pathogens and guide antibiotic therapy.*
- Perform percussion, vibration and postural drainage as required. *These techniques help loosen secretions and move them into larger airways for removal by coughing or suctioning.*

CONSIDERATION FOR PRACTICE

Evaluate endotracheal tube cuff pressure by measurement (no more than 20 to 25 mmHg of pressure). The minimum effective cuff pressure to maintain alveolar ventilation is used to reduce the risk of tracheal ischaemia and necrosis.

- Firmly secure endotracheal or tracheostomy tube. Provide adequate slack on ventilator tubing to prevent tension on the tube when turning, positioning or transferring to chair or stretcher. *These measures are important to ensure proper airway placement and prevent its inadvertent removal.*
- Assess fluid balance and maintain adequate hydration. *Adequate hydration helps liquefy secretions.*

Risk of injury

Many factors increase the risk of injury in acute respiratory failure. Hypoxaemia and hypercapnia affect the level of consciousness and may impair mental status. Endotracheal intubation and mechanical ventilation carry risks of tracheal damage and trauma to the lungs. Neuromuscular blockade, if used, presents a significant risk of injury as the person is unable to breathe spontaneously, communicate and move.

- Assess frequently, noting the following:
  a. LOC, orientation and awareness
  b. condition of mucosa of mouth and nose
  c. respiratory: lung sounds, chest excursion and ventilator pressures
  d. cardiovascular: vital signs, skin colour, capillary refill and peripheral pulses
  e. gastrointestinal: bowel sounds; test gastric secretions and faeces for occult blood
  f. genitourinary: urine output, daily weight
  g. skin and extremities.

  Complications associated with respiratory failure and mechanical ventilation can affect many body systems. Frequent assessment allows early detection and intervention.
- Report condition changes such as increasing air leak around the cuff and decreased breath sounds or chest movement. *These may be manifestations of a complication of intubation and ventilation, such as tracheal necrosis, displacement of the endotracheal tube into the right mainstem bronchus, pneumothorax or atelectasis.*

CONSIDERATION FOR PRACTICE

Do not bypass or turn off any ventilator alarms. A person who is intubated is unable to communicate verbally and cannot call for help. If neuromuscular blockers are used, the person is also unable to breathe without ventilator support.

- Turn and reposition frequently, taking care to stabilise endotracheal tube during movement. *Repositioning helps maintain tissue perfusion and prevent skin and tissue breakdown.*
- Keep skin and bed linen clean, dry and wrinkle-free. Protect pressure areas with padding, egg crate or heel and elbow protectors. *The person may not be able to perceive and report pain and move voluntarily to reduce pressure, necessitating excellent skin care.*
- Perform passive range-of-motion exercises every 4 to 8 hours. *These exercises maintain joint flexibility and help prevent contractures associated with long-term immobility.*
- Keep side rails up and use soft restraints as needed. *These safety measures are important to prevent falls, inadvertent disconnection of the ventilator or dislodging of the endotracheal tube.*
- Administer histamine H_2-blockers as ordered. *Stress gastritis and possible gastrointestinal haemorrhage are common, preventable complications of mechanical ventilation.*

Anxiety

Critical illness creates anxiety for any person. In acute respiratory failure, this anxiety is compounded by the presence of an endotracheal tube or tracheostomy, mechanical ventilator, numerous monitors and equipment, and, potentially, neuromuscular blockade and paralysis of voluntary muscles. Fear of continued dependence on the mechanical ventilator and inability to return to a normal life may compound this anxiety.

CONSIDERATION FOR PRACTICE

Frequently monitor anxiety level. High levels of anxiety increase oxygen use and often interfere with the ability to work with the respirator. This can increase hypoxaemia and further increase anxiety; intervention is necessary to break this cycle.

TRANSLATION TO PRACTICE Evidence-based practice for the person who is intubated

Individuals who are intubated cannot communicate verbally. In a cross-sectional, correlational study by Khalaila et al. (2011), 65 critically ill people who were intubated for at least 24 hours and extubated in the preceding 72 hours were investigated. The study measured communication difficulties and psychoemotional distress (involving fear and anger) related to endotracheal intubation. The researchers found that communication difficulties were a positive predictor for psychological distress. Stressful experiences were positively related to feelings of anger, and the number of different communication methods was negatively associated with feelings of fear and anger.

IMPLICATIONS FOR NURSING

People who are intubated and receiving mechanical ventilation are critically ill. Stress can contribute to physical deterioration; therefore, identifying and attempting to remove stressors can have a positive effect on a person's recovery. This research reinforces the need to ensure that methods to reduce frustration and fear related to communication difficulties from endotracheal intubation should be instigated.

CRITICAL THINKING IN PERSON-CENTRED CARE

1. Why is a person who is mechanically ventilated unable to communicate verbally?
2. What tools are available to assist the nurse in facilitating improved communication skills with people who are unable to communicate verbally?
3. Is there any way that a person who is undergoing neuromuscular blockade and mechanical ventilation can communicate with the nurse? Which factors need to be considered in this circumstance?
4. How can a nurse be sure that the information the person is trying to express is the same information that is being received by the nurse?

See the accompanying 'Translation to practice' box for information about assessing and managing pain in individuals who are intubated.

- Remain with the person as much as possible. *The frequent and continuing presence of a caregiver provides reassurance that help is readily available.*
- Explain all monitors, procedures, unusual sounds and machinery. *Understanding of the environment and various sounds and alarms reduces anxiety.*
- Provide a simple means of communication, such as a slate, picture board or alphabet board. Reassure that endotracheal tube removal restores the ability to speak. *The inability to speak and call out for help is frightening for the person. Providing an alternate means of communication helps reduce anxiety.*
- Encourage frequent family visits, especially if the time of visitations is being limited. Encourage family participation in care. *Family visits help reduce anxiety and feelings of abandonment. Allowing family members to participate in care helps reduce their anxiety as well.*
- Explain to the family that the person can hear and understand. Emphasise the importance of talking to the person, not over or about the person. *The family may not understand that the person may be mentally alert although unable to respond. Talking to the person about everyday things reduces the person's sense of isolation and fear.*
- Provide distraction with radio or television if available. *Distraction helps reduce the focus on machines and unusual sounds of monitors and alarms.*
- Attend to physical needs promptly and completely. *This provides reassurance that needs will be met even though the person is unable to ask for assistance.*
- Reassure that intubation and mechanical ventilation are temporary measures to allow the lungs to rest and heal. Reinforce that the person will be able to breathe independently again. *The person may fear continued dependence on mechanical ventilation.*

CONSIDERATION FOR PRACTICE

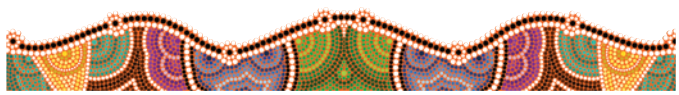
Provide sedation and anxiolytic medications as needed, especially when neuromuscular blockade is used. Although neuromuscular blockade paralyses voluntary muscles, the level of consciousness is unimpaired.

Community-based care

Prior to hospital discharge, teach the person and their family about the following topics:

- factors that precipitated respiratory failure and measures to prevent it in the future (e.g. the impact of respiratory irritants on compromised lungs)
- measures to prevent future episodes, such as remaining indoors with an air filter or air conditioning when pollution levels are high, obtaining influenza and pneumonia immunisations, and avoiding exposure to cigarette smoke
- effective coughing and pulmonary hygiene measures such as percussion, vibration and postural drainage.

Acute respiratory failure resulting from an acute insult such as pneumonia or near-drowning often resolves with few long-term sequelae. When respiratory failure results from an underlying disease such as COPD, the prognosis is less optimistic. Individuals with end-stage COPD may have repeated episodes of respiratory failure, with a gradual loss of respiratory function and reserve. These individuals may choose terminal weaning rather than a future of increasing disability. Discuss what to expect during the terminal weaning process with the person and their family. Discuss use of sedation prior to and during the weaning process. Explain that medications are used to reduce respiratory distress and dyspnoea during weaning. Assure the person and family that nursing support is continuously available during the weaning process and that family and other supporters such as clergy are allowed to remain with the person.



THE PERSON WITH ACUTE RESPIRATORY DISTRESS SYNDROME

Acute respiratory distress syndrome (ARDS) is characterised by non-cardiac pulmonary oedema and progressive refractory hypoxaemia. First identified in 1967, ARDS has been known by various names, such as shock lung and adult hyaline membrane disease. It is widely recognised as a severe form of acute respiratory failure. In Australia, 12 people died of ARDS in 2013 (ABS, 2015c).

Although the exact cause of ARDS is unclear, it is known that ARDS does not occur as a primary process but may follow a number of diverse conditions producing direct or indirect lung injury (see Table 36.11). Individuals who develop ARDS as a complication of an acute lung injury or condition are more likely to fully recover than individuals with chronic conditions.

Pathophysiology

The underlying pathology in ARDS is acute lung injury resulting from an unregulated systemic inflammatory response to acute injury or inflammation. Inflammatory cellular responses and biochemical mediators damage the alveolar–capillary membrane. This damage develops rapidly, often within 90 minutes of the systemic inflammatory response and within 24 hours of the initial insult. Damaged capillary membranes allow plasma and blood cells to escape into the interstitial space. Increased interstitial pressure and damage to the alveolar membrane allow fluid to enter the alveoli. Within the alveolus, the fluid dilutes and inactivates surfactant. Surfactant-producing cells are damaged by the inflammatory process, leading to a deficit of surfactant, increased alveolar surface tension and alveolar collapse with atelectasis. The lungs become less compliant and gas exchange is impaired. As the syndrome progresses, hyaline membranes form, further reducing gas exchange and compliance. Finally, fibrotic changes occur in the lungs. Intra-alveolar septa thicken and alveolar surface area for gas exchange is reduced. Hypoxaemia becomes refractory or resistant to improvement with supplemental oxygen and the $PaCO_2$ rises as diffusion is further impaired. Figure 36.16 illustrates the pathogenesis of ARDS.

TABLE 36.11 Conditions associated with the development of ARDS

CONDITIONS	EXAMPLES
Shock	Haemorrhagic shock, septic shock
Inhalation injuries	Aspiration of gastric contents, smoke and toxic gases, near-drowning, oxygen toxicity
Infections	Gram-negative sepsis, viral pneumonias, *Pneumocystis carinii* pneumonia
Drug overdose	Heroin, methadone, aspirin
Trauma	Burns, head injury, lung contusion, fat emboli
Other	Disseminated intravascular coagulation, pancreatitis, uraemia, amniotic fluid and air emboli, multiple transfusions, open heart surgery with cardiopulmonary bypass

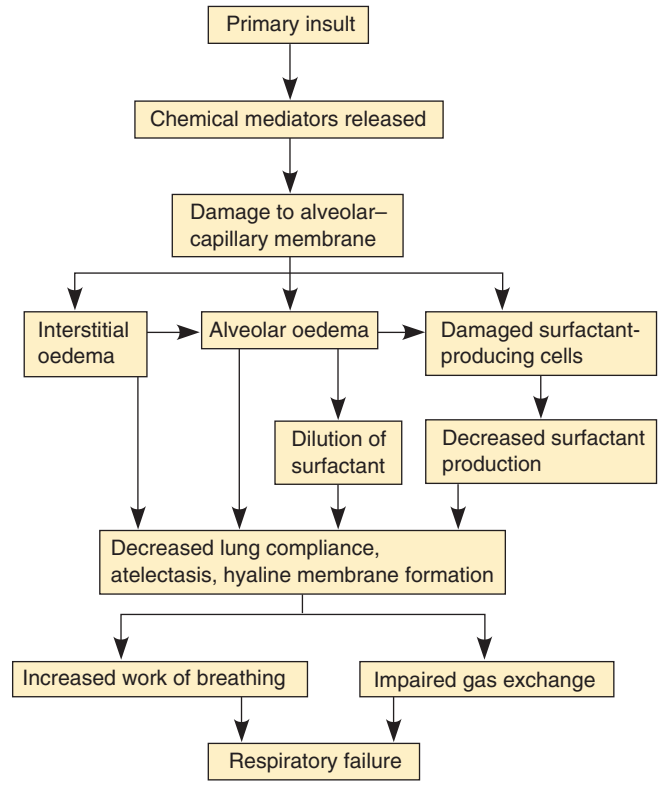


FIGURE 36.16 ■ The pathogenesis of ARDS

As ARDS progresses, tissue hypoxia becomes significant and metabolic acidosis develops. Carbon dioxide exchange is impaired as well as oxygen exchange, leading to combined respiratory and metabolic acidosis. Sepsis and multiple-organ-system dysfunction of the kidneys, liver, gastrointestinal tract, CNS and cardiovascular system are the leading causes of death in ARDS. If the process is halted before this occurs, the long-term prognosis for recovery is good.

Manifestations

Initial manifestations of ARDS typically develop 24 to 48 hours after the initial insult. Dyspnoea, tachypnoea and anxiety are early manifestations. Progressive respiratory distress develops, with increasing respiratory rate, intercostal retractions and use of accessory muscles of respiration. Cyanosis develops that may not improve with oxygen administration. Breath sounds are initially clear, but crackles (rales) and rhonchi develop later. As respiratory failure progresses, mental status changes such as agitation, confusion and lethargy occur.

INTERPROFESSIONAL CARE

ARDS management is directed towards identifying and treating its underlying cause and providing aggressive respiratory support.

- *ABGs* initially show hypoxaemia with a PaO_2 of less than 60 mmHg and respiratory alkalosis due to tachypnoea.

- *Chest x-ray* changes may not be evident for as long as 24 hours after the onset of ARDS. Diffuse infiltrates are seen initially, progressing to a 'white out' pattern. Chest CT scan provides a better illustration of the pattern of alveolar consolidation and atelectasis in ARDS (Horlander, 2014).
- *Pulmonary function testing* shows decreased lung compliance with reduced vital capacity, minute volume and functional vital capacity (see Box 33.1).
- *Pulmonary artery pressure monitoring* shows normal pressures in ARDS, helping distinguish ARDS from cardiogenic pulmonary oedema.

Medications

Although there is no definitive drug therapy for ARDS, a number of medications may be used. Inhaled nitric oxide reduces intrapulmonary shunting and improves oxygenation by dilating blood vessels in better ventilated areas of the lungs. Surfactant therapy may be prescribed. Surfactant is a complex mixture of phospholipids, neutral lipids and proteins that forms a thin layer atop a thin layer of water on the inner surface of the alveolus, reducing the surface tension within the alveoli. Surface tension tends to pull the walls of the alveoli together, increasing the likelihood of collapse during exhalation. Surfactant, by reducing surface tension, helps maintain open alveoli, decreasing the work of breathing, improving compliance and gas exchange, and preventing atelectasis.

Diagnosis

Refractory hypoxaemia (hypoxaemia that does not improve with oxygen administration) is the hallmark of ARDS.

Interventions to block the inflammatory response are under investigation, such as using non-steroidal anti-inflammatory agents and corticosteroids. Corticosteroids may be used late in the course of ARDS to improve oxygenation and lung mechanics when fibrotic changes occur.

Mechanical ventilation

The mainstay of ARDS management is endotracheal intubation and mechanical ventilation. With ARDS, it is rarely possible to maintain adequate tissue oxygenation with oxygen therapy alone.

With mechanical ventilation, the FiO_2 is set at the lowest possible level to maintain a PaO_2 higher than 60 mmHg and oxygen saturation of approximately 90%. When the PaO_2 cannot be maintained with less than 50% inspired oxygen, there is a risk that oxygen toxicity will accentuate ARDS. Often it is necessary to add CPAP, BiPAP or PEEP to mechanical ventilation settings to maintain blood and tissue oxygenation. Maintaining open airways and alveoli enhances gas diffusion and reduces ventilation–perfusion mismatch. PEEP decreases cardiac output and increases the risk of barotrauma, necessitating close monitoring. Either assist-control or SIMV may be used along with PEEP or CPAP in treating ARDS.

It is important to remember that mechanical ventilation does not cure ARDS; it simply supports respiratory function while the underlying problem is being identified and treated.

Treatments

Atelectasis frequently occurs in dependent lung regions in ARDS. Prone positioning in conjunction with mechanical ventilation reduces the pressure of surrounding tissue on dependent regions and improves oxygenation.

Other management strategies include careful fluid replacement, attention to nutrition, treatment of any infection and correction of the underlying condition. A Swan–Ganz line may be placed to monitor pulmonary artery pressures and cardiac output. Fluid replacement is carefully tailored to these measurements to avoid fluid imbalances, which may worsen hypoxia and ARDS. Enteral or parenteral feeding is necessary to maintain nutritional status and prevent tissue catabolism. Infections are treated with intravenous antibiotic therapy tailored to the causative organism. Low-molecular-weight heparin may be ordered to prevent thrombophlebitis and possible pulmonary embolus or disseminated intravascular coagulation, a possible complication of ARDS.

Nursing care

The nursing care needs of the person with ARDS are very similar to those of any individual with acute respiratory failure. Maintaining adequate ventilation and respirations is of highest priority, along with preventing injury and managing anxiety. See the section on acute respiratory failure for nursing care related to these diagnoses. Additional high-priority nursing care concerns for the person with ARDS are related to the effects of PEEP on cardiac output and potential problems of weaning ventilatory support. See the nursing care plan that follows for additional nursing interventions for the person with ARDS.

Nursing diagnoses and intervention

Decreased cardiac output

With positive-pressure ventilation, increased intrathoracic pressure decreases cardiac output. When PEEP is applied, intrathoracic pressure increases further; this can significantly decrease venous return, ventricular filling, stroke volume and cardiac output. Manifestations of decreased cardiac output include hypotension and compensatory tachycardia as the heart attempts to maintain cardiac output despite decreased stroke volume. In the person who is already hypoxic because of ARDS, this drop in cardiac output can increase tissue damage. Urine output falls and arrhythmias may develop.

- Monitor and record vital signs, including apical pulse, at least every hour; more frequently immediately following initiation of mechanical ventilation or the addition of PEEP. *Frequent assessment is vital to detect early signs of decreased cardiac output.*
- Assess level of consciousness at least every 4 hours. *Altered LOC, confusion and restlessness are early signs of cerebral hypoxia due to decreased cardiac output.*

- Monitor pulmonary artery pressures, central venous pressure and cardiac output readings every 1 to 4 hours. *Changes in these measurements may indicate worsening cardiac status.*
- Assess heart and lung sounds frequently. *Increasing crackles or abnormal heart sounds may indicate heart failure.*
- Weigh daily at the same time. *Accurate daily weights are the best indicator of fluid volume status.*
- Frequently provide good skin care, keeping skin clean and dry and protecting pressure points. *Tissue hypoxia increases the risk of skin breakdown, which in turn increases the risk of infection and sepsis.*
- Maintain intravenous fluids as ordered. *Intravenous fluids are given to maintain vascular volume and prevent dehydration.*
- Administer analgesics, sedatives and neuromuscular blockers as needed. *These medications may be prescribed to decrease cardiac workload.*

Dysfunctional ventilatory weaning response

The person with dysfunctional ventilatory weaning response has difficulty adjusting to reduced mechanical ventilator support, prolonging the weaning process. Airway congestion, inadequate rest or nutrition, pain, anxiety and a non-supportive environment are factors that can contribute to difficulty weaning. With ARDS, the pathological processes of the disease and its effects on gas exchange may be responsible for a prolonged or ineffective weaning process.

Assessment findings indicative of dysfunctional weaning include:

- dyspnoea, apprehension or agitation
- decreasing oxygen saturation level
- cyanosis or pallor, diaphoresis
- increased blood pressure, pulse and respiratory rate
- diminished or adventitious breath sounds, use of accessory muscles
- decreased LOC
- deteriorating ABG values
- shallow, gasping breaths or paradoxical abdominal breathing.

Nursing interventions for dysfunctional weaning include the following:

- Observe the person closely following changes in ventilator settings and during T-piece trials. *Vital signs—heart and respiratory rates, in particular—can provide early signs of hypoxaemia and poor tolerance of the weaning process.*

CONSIDERATION FOR PRACTICE

Frequently monitor oxygen saturation, $ETCO_2$ and ABGs following changes in ventilator settings. These values are used to assess the adequacy of ventilation and gas exchange during the weaning process.

- Place in Fowler's or high-Fowler's position. *Fowler's position facilitates lung expansion and reduces the work of breathing.*
- Fully explain all weaning procedures, along with expected changes in breathing. *Adequate explanations help reduce anxiety and improve the ability to cooperate.*
- Remain with the person during initial periods following changes of ventilator settings or T-piece trials. *This provides reassurance and allows close monitoring of the response.*
- Limit procedures and activities during weaning periods. *Reducing energy expenditures and cardiac work facilitates the weaning process.*
- Provide diversion, such as television or radio. *Diversion helps distract the focus from breathing.*
- Begin weaning procedures in the morning, when the person is well rested and alert; weaning may be discontinued overnight to provide rest. *The work of breathing increases during the weaning process; adequate rest is important.*
- Avoid administering drugs that may depress respirations during the weaning process (except as ordered at night to facilitate rest when ventilator support is provided). *Sedatives or analgesics that depress respirations can impair the weaning process.*
- Keep oxygen at the bedside following weaning and extubation. *Supplemental oxygen may be necessary to maintain adequate blood and tissue oxygenation.*

CONSIDERATION FOR PRACTICE

Frequently assess respiratory status following weaning and extubation. Keep an intubation kit readily available following extubation; be prepared for emergency re-intubation.

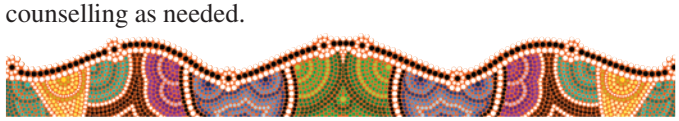
- Provide pulmonary hygiene with percussion and postural drainage. *Maintaining patent airways and adequate alveolar ventilation is vital during the weaning process.*

Community-based care

When preparing the person who has recovered from ARDS and the family for home care, discuss the following topics:

- ARDS did not result from something they did or did not do, but developed as a consequence of serious illness. Provide factual information about ARDS.
- Maximal respiratory function following ARDS is usually achieved within 6 months; respiratory function may remain significantly impaired. This may necessitate changes in occupation, lifestyle and family roles.
- Avoiding smoking and exposure to second-hand smoke and environmental pollutants is vital to prevent further lung damage.
- Obtain immunisation for pneumococcal pneumonia and annual influenza immunisations to prevent further episodes of serious respiratory disease.

Provide referrals to community health and respiratory care services as indicated, as well as for occupational therapy and counselling as needed.



NURSING CARE PLAN A person with ARDS

Peggy Adamson is a 36-year-old single woman (75 kg) admitted to the hospital following a near drowning at the local lake. On admission to the emergency department, Ms Adamson is alert and oriented, having been rescued and resuscitated within 2 minutes of the accident. Rescuers report that she seemed to have aspirated 'a lot' of water as she was water-skiing when the accident occurred. She is admitted to the critical care unit for observation. Oxygen is started per nasal prongs at 6 L/min, intravenous fluids are administered to correct electrolyte imbalances and 40 mg of frusemide is given intravenously for hypervolaemia.

ASSESSMENT

Throughout her stay, Ms Adamson has remained alert and oriented with stable vital signs. Her respiratory rate has been 20 to 24 per minute, with scattered crackles, oxygen saturations of around 94%, and a PaO_2 of 75 to 80 mmHg on 6 L/min of oxygen. Her pulse has been 96 to 100 and regular. On her initial assessment, the nurse notes that Ms Adamson seems apprehensive and anxious. Although her blood pressure is 116/74, unchanged from previous levels, her heart rate is up to 106 and respiratory rate is 28 per minute. Her lungs have scattered crackles but good breath sounds throughout, unchanged from previous assessments. Ms Adamson's oxygen saturation has dropped to 84%, her oxygen is increased to 8 L/min. ABG results show PaO_2, 65 mmHg; respiratory alkalosis, pH, 7.48; and $PaCO_2$, 32 mmHg.

Portable chest x-rays were ordered. The doctor orders a non-rebreather mask at 8 L/min and repeat ABGs in 1 hour. The chest x-ray reveals scattered infiltrates and a normal heart size.

Ms Adamson's oxygen saturation continues to fall and subsequent blood gases show a PaO_2 of 55 mmHg. The attending doctor diagnoses probable ARDS. Ms Adamson is intubated via endotracheal tube and is commenced on mechanical ventilation.

DIAGNOSES

- *Impaired gas exchange* related to effects of near drowning evidenced by increased respiration rate and decreasing oxygen saturations.
- *Anxiety* related to hypoxaemia evidenced by decreasing oxygen saturations.
- *Risk of decreased cardiac output* related to mechanical ventilation evidenced by decreasing blood pressure and increasing heart rate.
- *Risk of injury* related to endotracheal intubation evidenced by haemoptysis.

PLANNING

- Obtain all necessary supplies and radiology in preparation for intubation and mechanical ventilation.
- Explain the purpose and procedure of intubation.
- Provide an opportunity to express fears related to intubation and mechanical ventilation; answer questions and provide reassurance.
- Discuss communication strategies while intubated; obtain a magic slate.

Expected outcomes

- Breathe effectively with the mechanical ventilator.
- Demonstrate improved oxygen saturation, $ETCO_2$ and ABG values.
- Express fears related to intubation and mechanical ventilation.
- Demonstrate reduced anxiety levels (relaxed facial expression, ability to rest).
- Maintain adequate cardiac output and tissue perfusion.
- Tolerate endotracheal intubation and mechanical ventilation without evidence of infection or barotrauma.

IMPLEMENTATION

- Administer analgesics and/or sedatives as ordered.
- Monitor oxygen saturation and $ETCO_2$ levels every 30 to 60 minutes initially after mechanical ventilation is commenced; report changes to the doctor.
- Obtain ABGs as ordered or indicated; monitor and report results.
- Suction via endotracheal tube as needed to maintain clear airways.
- Provide periods of uninterrupted rest.
- Monitor vital signs every 1 to 2 hours.
- Assess skin colour, capillary refill and the presence of oedema every 4 hours.
- Monitor urine output hourly; report output of less than 30 mL per hour.
- Assess lung sounds and chest excursion every 1 to 2 hours.

EVALUATION

Ms Adamson is intubated and placed on a volume-cycled ventilator at 50% FiO_2 and a tidal volume of 730 mL in the assist-control mode at 16 breaths per minute. She has difficulty working with the ventilator initially, so morphine and midazolam are ordered to reduce her anxiety. Ms Adamson's oxygen saturation, $ETCO_2$ and ABG results do not begin to improve until 5 mmHg of PEEP is added to ventilator settings. After 3 days of mechanical ventilation with PEEP and aggressive fluid and diuretic therapy, Ms Adamson begins to improve. She is placed on SIMV and, over the course of another 3 days, is gradually weaned off the ventilator to a face mask with CPAP. She eventually recovers fully, with minimal apparent long-term effects.

CRITICAL THINKING IN THE NURSING PROCESS

1. Endotracheal intubation and mechanical ventilation were effective in supporting Ms Adamson's respiratory status as she recovered from ARDS. Discuss a possible sequence of events had it not been possible to wean her from the ventilator.
2. How might the presentation and management of an acute episode of respiratory failure due to ARDS differ from respiratory failure related to COPD?
3. What measures can nurses take to prevent the development of ARDS?
4. Develop a nursing care plan for Ms Adamson for the nursing diagnosis *Powerlessness* related to endotracheal intubation and mechanical ventilation.

REFLECTING ON THE NURSING PROCESS

1. Outline what you have learned from this case study that you will apply to your future practice.
2. Communication from the nurse to the individual and their significant others is important. Given Ms Adamson's diagnosis of ARDS, what information and education should be communicated to both Ms Adamson and her significant others? Create a different list for both.

CHAPTER HIGHLIGHTS

- Obstructive disorders of the lower respiratory system, including asthma, COPD and cystic fibrosis, impair airflow into and out of the lungs, often affecting outflow of air to a greater extent than inflow. As a result, air trapped in the alveoli increases the residual volume of the lungs and reduces functional residual capacity. Alveolar ventilation is reduced as well. The net result is less available oxygen in the alveoli and impaired gas exchange.
- In many instances, acute episodes of asthma can be avoided through the use of inhaled steroids to reduce airway inflammation, inhaled long-acting bronchodilators and frequent self-monitoring of expiratory flow rate. Nursing care focuses on teaching for self-management and providing care during acute episodes of airway constriction.
- Chronic obstructive pulmonary disease (COPD) is a long-term process of progressive lung dysfunction. COPD involves two different disease processes: chronic bronchitis, characterised by airway oedema; and excessive mucus production and emphysema, characterised by destruction of supporting tissue with enlargement of respiratory bronchioles and alveolar spaces and loss of surface area for gas exchange.
- Smoking and exposure to tobacco smoke is the single greatest risk factor for COPD. A small percentage of cases result from an inherited deficiency of α_1-antitripsin, an enzyme that inhibits lung tissue destruction. Although smoking cessation does not reverse COPD, it does slow the progress of the disease.
- Cystic fibrosis, inherited as an autosomal recessive disorder, causes thick, viscous secretions in affected organs, primarily the lungs, pancreas, sweat glands and reproductive tract. In the lungs, small airway clearance is impaired, leading to atelectasis, bronchiectasis, infection and dilation of distal airways with air trapping and impaired gas exchange. Chest physiotherapy and early treatment of respiratory infections are key components of disease management. Ultimately, lung or heart–lung transplant may be required.
- Occupational lung diseases, pneumoconiosis and hypersensitivity pneumonitis damage interstitial tissues of the lungs, leading to fibrosis and scarring that causes the lungs to become stiff and non-compliant. Lung volumes decrease, the work of breathing increases and gas diffusion is impaired. Most occupational lung diseases are progressive and non-reversible. Interprofessional care is similar to that provided for individuals with COPD.
- Pulmonary vascular disorders affect blood flow through the pulmonary vascular system and gas exchange. Pulmonary embolism, obstruction of pulmonary blood flow, is a potentially critical condition usually resulting from deep venous thrombosis. Sudden onset of chest pain and dyspnoea with changes in haemodynamic status are possible manifestations of pulmonary embolism. Prevention through early ambulation, lower extremity exercises and sequential compression devices is the most effective treatment for pulmonary embolism.
- In primary and secondary forms of pulmonary hypertension, constriction of pulmonary vessels and remodelling of the pulmonary vascular bed increase pressure in the pulmonary system and right heart, ultimately leading to right-sided heart failure (cor pulmonale). Treatment focuses on slowing disease progression through oxygen therapy, administration of vasodilators and anticoagulants, and supporting function.
- Hypoventilation, impaired gas exchange and significant ventilation–perfusion mismatch (e.g. pulmonary embolism) can lead to respiratory failure. Hypoventilation leads to hypoxaemia and hypercapnia, whereas in impaired gas exchange or ventilation–perfusion mismatch, hypoxaemia predominates.
- The manifestations of respiratory failure relate directly to the effects of hypoxaemia (dyspnoea, restlessness, apprehension, impaired judgment, motor impairment, tachycardia, hyper- or hypotension, and cyanosis) and hypercapnia (dyspnoea, headache, peripheral and conjunctival vasodilation, papilloedema, neuromuscular irritability and decreased LOC).
- Respiratory support often is required, using positive-pressure ventilators. Variables of mechanical ventilation include the mode or cycle of ventilation, the flow rate and amount, pressures delivered and the oxygen concentration. Either invasive or non-invasive techniques may be used.
- Complications of mechanical ventilation include lung and mucous membrane trauma and infection, reduced cardiac output, gastric dilation, impaired communication and stress.
- ARDS is non-cardiac pulmonary oedema caused by a diffuse inflammatory response with increased pulmonary capillary permeability leading to interstitial and alveolar oedema and impaired gas exchange. As the process continues, lung compliance decreases, increasing the work of breathing, and atelectasis and consolidation of lung tissue develop. Respiratory failure with refractory hypoxaemia results.
- Mechanical ventilation and measures to support physiological function are the primary treatments for ARDS. The mortality rate, however, remains high at about 50%.

CONCEPT CHECK

1 All of the following nursing diagnoses are appropriate for a person with an acute asthma attack. Which is of highest priority?

1 *Anxiety* related to difficulty breathing
2 *Ineffective airway clearance* related to bronchoconstriction and increased mucus production
3 *Ineffective breathing pattern* related to anxiety
4 *Ineffective health maintenance* related to lack of knowledge about attack triggers and appropriate use of medications

2 The nurse caring for a person with asthma notices that the individual's respirations have slowed and he is no longer coughing. Breath sounds are diminished throughout his lung fields and absent in the bases. The nurse should:

1 notify the doctor
2 allow the person to rest undisturbed
3 obtain a chest x-ray
4 ask family members to leave

3 When teaching use of a metered-dose inhaler (MDI), the nurse's instruction should be:

1 take quick shallow breaths in rapid succession while holding the canister down
2 use the inhaler containing the anti-inflammatory drug first, then the bronchodilator
3 use the anti-inflammatory drug as needed to treat acute episodes of wheezing
4 rinse the mouth after using the inhaler to reduce systemic absorption of the drug

4 Which of the following would be an expected assessment finding in a person admitted with chronic obstructive airway disease?
1 AP chest diameter equal to or greater than lateral chest diameter
2 mental confusion and lethargy
3 3+ pitting oedema of ankles and lower legs
4 oxygen saturation readings of 85% or less

5 An appropriate goal for a person admitted with an acute exacerbation of COPD would be:
1 will verbalise self-care measures to regain lost lung function
2 arterial blood gases will be within normal limits by discharge
3 will maintain SpO_2 (saturation or peripheral oxygen) of 90% or higher
4 will identify strategies to help reduce number of cigarettes smoked per day

6 Which of the following statements best represents a nurse's understanding of use of supplemental oxygen in individuals with COPD?
1 The individual should not smoke because oxygen supports combustion.
2 Oxygen is used only at night for individuals with COPD.
3 Oxygen is never used for individuals with COPD because they may become dependent on it.
4 The person needs to be closely monitored for signs of respiratory depression.

7 The community health nurse working with a person who has cystic fibrosis specifically directs the home care aide to report which of the following? (Select all that apply.)
1 thick, tenacious milky white sputum
2 fever
3 bulky, fatty stools
4 difficulty clearing mucus secretions
5 increasing shortness of breath and fatigue

8 A person in skeletal traction suddenly develops right-sided chest pain and shortness of breath. The nurse should:
1 check for Homans' sign
2 start oxygen per nasal prongs
3 administer the prescribed analgesic
4 elevate the head of the bed to 45 degrees

9 The nurse caring for a person with COPD recognises which of the following as an early sign of possible respiratory failure?
1 restlessness and tachypnoea
2 deep coma
3 hypotension and tachycardia
4 decreased urine output

10 The nurse caring for a person undergoing mechanical ventilation for acute respiratory failure plans and implements which of the following measures to help maintain effective alveolar ventilation?
1 keeps the person in supine position
2 increases the tidal volume on the ventilator
3 maintains ordered oxygen concentration
4 performs endotracheal suctioning as indicated

UNIT 9 BUILDING CLINICAL COMPETENCE

Responses to altered respiratory function

CLINICAL SCENARIO

You have been assigned to work with the following individuals on a respiratory unit. Significant data obtained during report are as follows:

- Jack Holt, a 65-year-old male, has bacterial pneumonia. Vital signs are T 38.3°C, P 94, R 30, BP 146/88. He is complaining of chest pain with breathing and has a productive cough of rusty-coloured sputum. His SpO_2 is 90% in room air.
- Maggie Sawyer, an 82-year-old female, is being discharged today following treatment for a deep venous thrombosis. She has congestive obstructive pulmonary disease. Suddenly she complains of difficulty breathing, chest pain, coughing, restlessness and a feeling that she is going to die.
- James Mohr, a 25-year-old male, sustained head, neck and chest injuries, and has a tracheostomy, from a motor vehicle crash. His vital signs were stable at the last assessment. He begins coughing and puts on his call light.
- Amy Campbell, a 30-year-old female, is being treated after having a severe asthma attack. Her current vital signs are T 37.2°C, P 64, R 26, BP 124/84. She has inspiratory and expiratory wheezing. Her SpO_2 is 94% on 4 L/min O_2 via nasal prongs.

Critical thinking questions

1 In what order would you visit these individuals after report?

1 _____
2 _____
3 _____
4 _____

2 Which top two priorities would you choose for each of the individuals presented above? Can you explain, if asked, the rationale for your choices?

	Priority #1	Priority #2
Jack Holt		
Maggie Sawyer		
James Mohr		
Amy Campbell		

3 The older adult is prone to respiratory problems due to which age-related changes in the respiratory system? (Select all that apply.)

1. loss of skeletal muscle strength in the thorax
2. increased elastic recoil of lungs during expiration
3. alveoli that are less elastic and more fibrotic
4. decreased residual volume of lung
5. decreased effectiveness of coughing

4 Bacterial pneumonia is spread by droplets. When using standard precautions, which equipment is necessary to prevent its spread?

1. Wear a gown when providing hygiene care for the person.
2. Wear a gown and gloves when touching the person.
3. Wear a mask and gloves when suctioning the person.
4. Wear a cap to keep hair from touching the individual.

5 For the individual receiving percussion and vibration with postural drainage for left lower lobe pneumonia, which position most facilitates removal of secretions?

1. semi-Fowler's position with arms elevated
2. right Sims' position with head in Trendelenberg
3. high-Fowler's position leaning on a bedside tray
4. left Sims' position with head flat

6 On discharge, the nurse teaches Mrs Sawyer ways to prevent pulmonary embolism. Which instruction is appropriate?

1. Use pillows under the knees when in bed.
2. Apply knee-high elastic stockings when ambulating.
3. Exercise the legs vigorously to encourage blood flow.
4. Stop every 1 to 2 hours to stretch legs when travelling.

7 Mr Mohr will be discharged with a tracheostomy. What should the nurse teach him about tracheostomies?

1. The tracheostomy will not interfere with lifting when returning to work.
2. Water-skiing is allowed, but swimming in a pool or lake is not allowed.
3. Showering is allowed as long as the tracheostomy is covered with a washcloth.
4. A small amount of alcohol is allowed but smoking is not allowed.

8 When admitted to the emergency department, which laboratory studies would you expect to obtain on a person with an inhalation injury?

1. arterial blood gases, carboxyhaemoglobin levels, electrolytes
2. sputum cultures and sensitivity, serology testing, sputum Gram stain
3. methaemoglobin levels, venous blood gases, white blood cell count
4. full blood cell count, oxygen saturation, sputum specimen

9 Arterial blood gases results are ordered on a person with acute respiratory distress. The results are: pH, 7.22; PaO_2, 50 mmHg; $PaCO_2$, 58 mmHg; HCO_3^-, 29 mEq/L. How would a nurse interpret these results?

1. respiratory acidosis
2. respiratory alkalosis
3. metabolic acidosis
4. metabolic alkalosis

10 Corticosteroids are ordered to decrease the inflammatory process of asthma. Which comment indicates the person understands how to take corticosteroids?

1. 'Corticosteroids have very few side effects to worry about.'
2. 'I understand that I cannot stop taking the medication abruptly.'
3. 'I can stop taking the corticosteroids as soon as I feel better.'
4. 'I can take an over-the-counter medication if I develop a cold.'

11 Which are early manifestations of pulmonary tuberculosis?

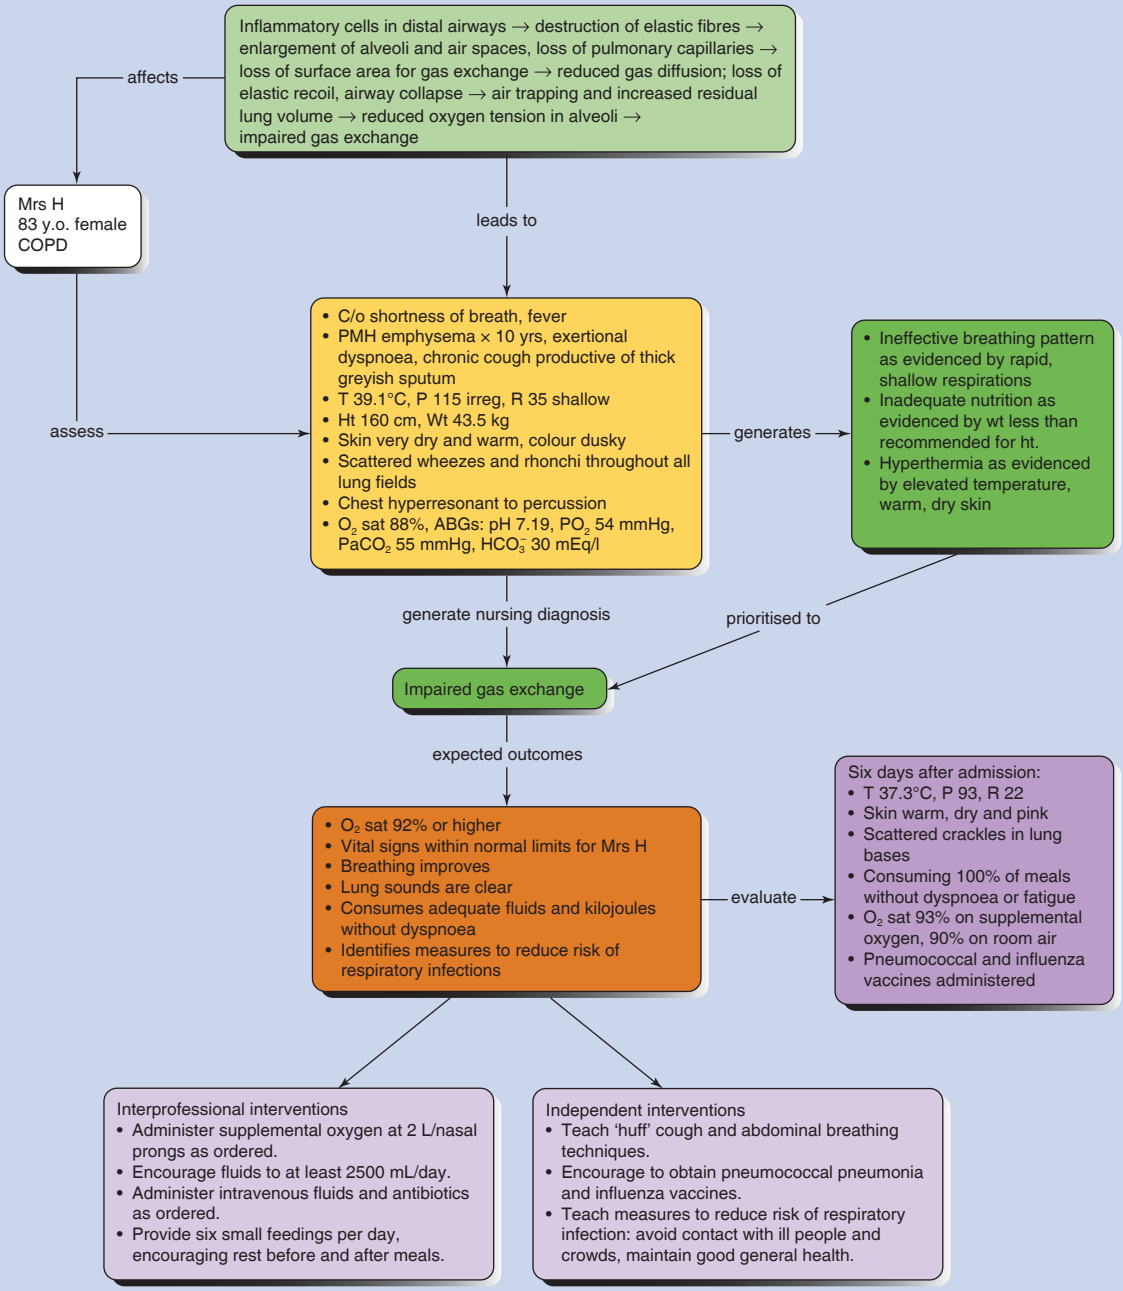
1. tachypnoea, tachycardia, activity intolerance
2. bradypnoea, foul-smelling sputum, weight gain
3. blood-tinged sputum, high-grade fever, fatigue
4. low-grade fever, night sweats, dry cough

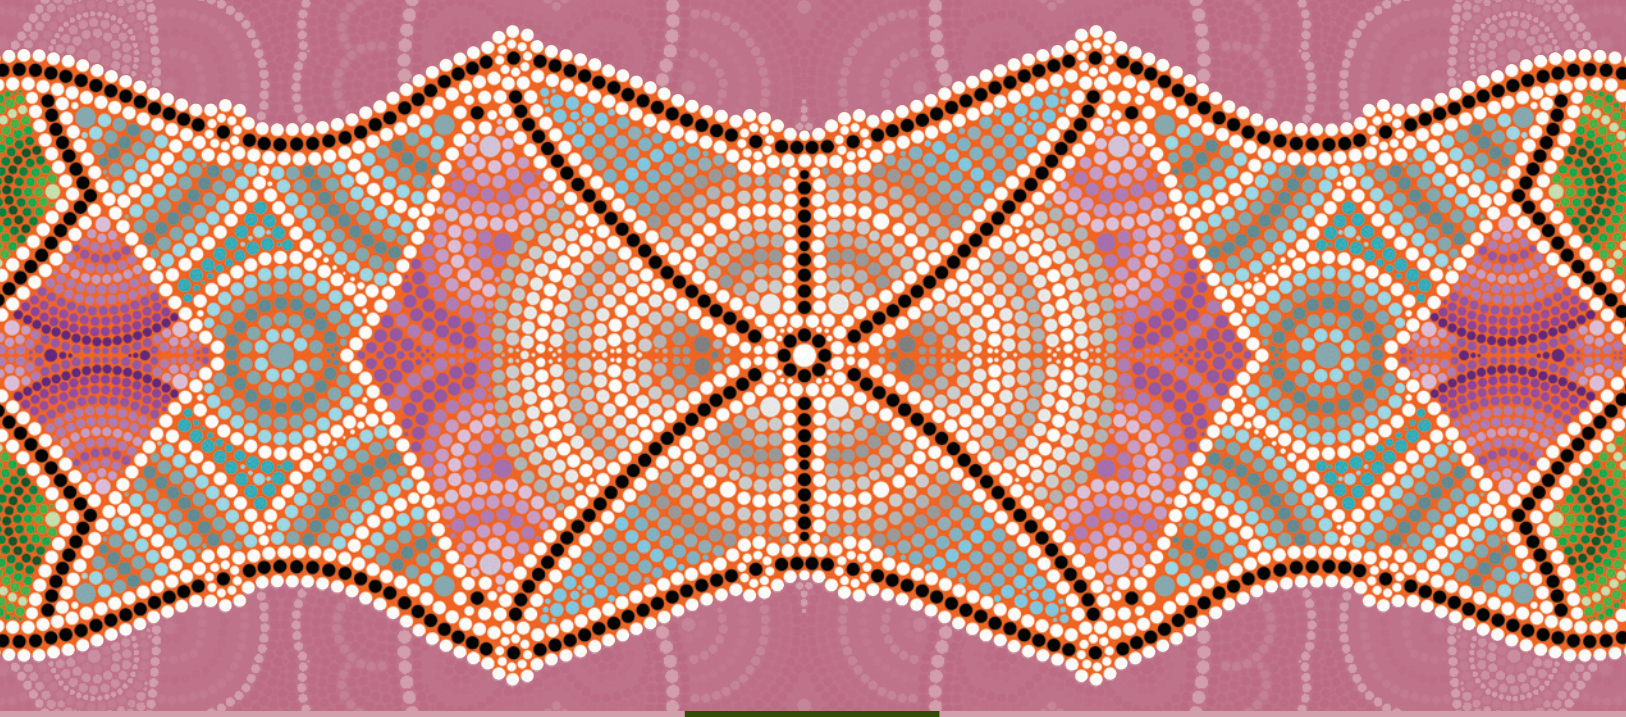
CASE STUDY

Gladys Hamer is an 83-year-old female who is seen in the emergency department with complaints of shortness of breath and fever. Her vital signs are T 39.1°C, P 115 and irregular, R 35 and shallow, BP 168/66. Her height is 160 cm and weight is 43.5 kg. On assessment, her skin is very dry and warm. Her colour is dusky. Scattered wheezes and rhonchi are heard throughout all lung fields. Her chest is hyper-resonant to percussion. A pulse oximeter is applied and the O_2 sat reading is 88%. Mrs Hamer has a past medical history of emphysema for 10 years, complaints of shortness of breath on exertion and has a chronic cough productive of thick, greyish sputum. Her spouse died 5 years ago and she has lived with her two adult sons since then.

Blood is drawn for arterial blood gases and results are pH, 7.19; PaO_2, 54 mmHg, $PaCO_2$, 55 mmHg; HCO_3^-, 30 mEq/L. These results indicate respiratory acidosis. Based on her current assessment, arterial blood gas results and past medical history, a medical diagnosis of chronic obstructive pulmonary disease (COPD) is determined.

When planning nursing care for Mrs Hamer, the nursing diagnosis of *Impaired gas exchange* related to acute and chronic lung disease is appropriate for implementing nursing interventions.





UNIT 10

RESPONSES TO ALTERED MUSCULOSKELETAL FUNCTION

CHAPTER 37

A PERSON-CENTRED APPROACH TO ASSESSING THE MUSCULOSKELETAL SYSTEM

DEBRA RAYMOND

LEARNING OUTCOMES

- Describe the anatomy, physiology and functions of the musculoskeletal system.
- Explain the normal movements allowed by synovial joints.
- Identify specific topics for consideration during a health history interview of the person with health problems involving the musculoskeletal system.
- Describe normal variations in assessment findings for the older adult.
- Identify manifestations of impairment of the musculoskeletal system.

CLINICAL COMPETENCIES

- Conduct and document a health history for people who have or are at risk of alterations in the musculoskeletal system.
- Conduct and document a physical assessment of musculoskeletal structures and functions.
- Monitor the results of diagnostic tests and report abnormal findings.

EQUIPMENT NEEDED

- Tape measure
- Goniometer

KEY TERMS

The tissues and structures of the musculoskeletal system perform many functions, including support, protection and movement. The musculoskeletal system has two subsystems: the bones and joints of the skeleton, and the skeletal muscles. These subsystems work together to allow the body to perform both gross and simple movements, such as closing a door, and fine, complex movements, such as repairing a watch.

ANATOMY, PHYSIOLOGY AND FUNCTIONS OF THE MUSCULOSKELETAL SYSTEM

The musculoskeletal system is composed of bones of the skeletal system; ligaments, tendons and muscles of the muscular system; and joints. The bones serve as the framework for the body and for the attachment of muscles, tendons and ligaments. Innervated by the nervous system, contraction and relaxation of muscles permit movement at joints.

The skeleton

Bones form the body's structure and provide support for soft tissues. They also protect vital organs from injury and serve to move body parts by providing points of attachment for muscles. Bones also store minerals and serve as a site for **haematopoiesis** (blood cell formation).

The human skeleton is made up of 206 bones (see Figure 37.1). Bones of the skeletal system are divided into the axial skeleton and the appendicular skeleton. The axial skeleton includes the bones of the skull, ribs, sternum and vertebral column. The appendicular skeleton consists of all the bones of the upper and lower limbs, shoulder girdles and pelvic girdle.

Bone structure

Bone cells include osteoblasts (cells that form bone), osteocytes (cells that maintain bone matrix) and osteoclasts (cells that resorb bone). Bone matrix is the extracellular element of bone tissue; it consists of collagen fibres, minerals (primarily calcium and phosphate), proteins, carbohydrates and ground substance. Ground substance is a gelatinous material that facilitates diffusion of nutrients, wastes and gases between the blood vessels and bone tissue. Bones are covered with periosteum, a double-layered connective tissue. The outer layer of the periosteum contains blood vessels and nerves; the inner layer is anchored to the bone.

Bones consist of a rigid connective tissue called osseous tissue of which there are two types: compact bone is smooth and dense; spongy bone contains spaces between meshworks of bone. Both types contain the same elements and are found in almost all bones of the body.

The basic structural unit of compact bone is the Haversian system (also called an osteon). The Haversian system consists of a central canal, called the Haversian canal; concentric layers of bone matrix, called lamellae; spaces between the lamellae, called lacunae; osteocytes within the lacunae; and small channels, called canaliculi (see Figure 37.2).

Spongy bone has no Haversian systems. Instead, the lamellae are arranged in concentric layers called trabeculae that branch and join to form meshworks. The spongy sections of long bones and flat bones contain tissue for haematopoiesis. In the adult, these sections, called red marrow cavities, are present in the spongy centre of flat bones (especially the sternum) and in only two long

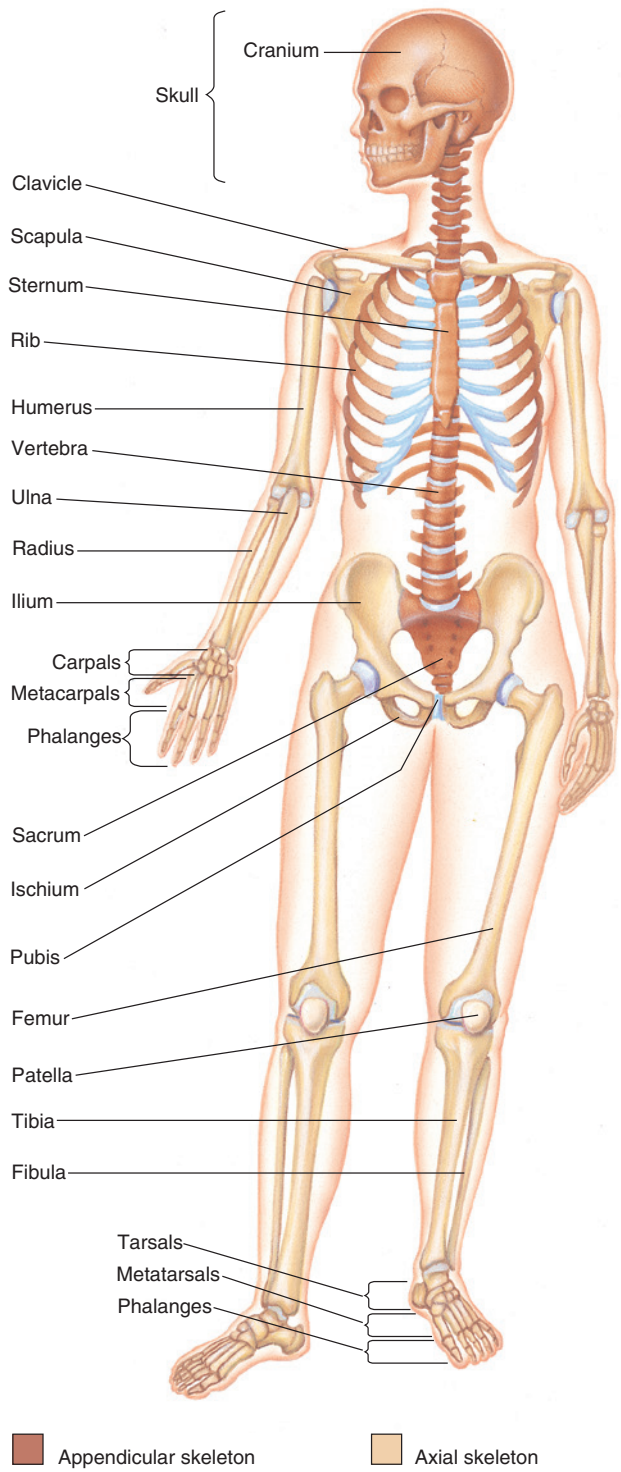


FIGURE 37.1 ■ Bones of the human skeleton

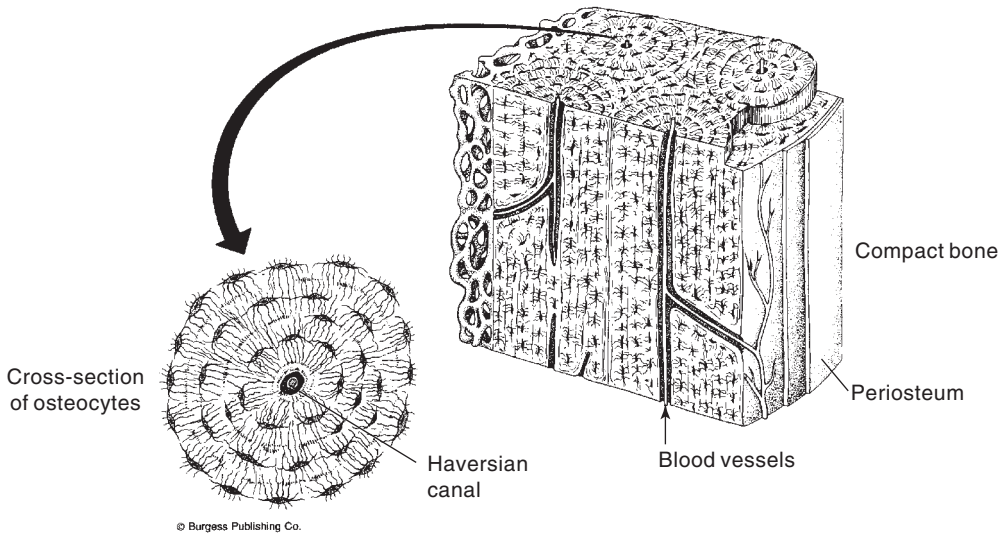

FIGURE 37.2 ■ The microscopic structure (Haversian system) of compact bone

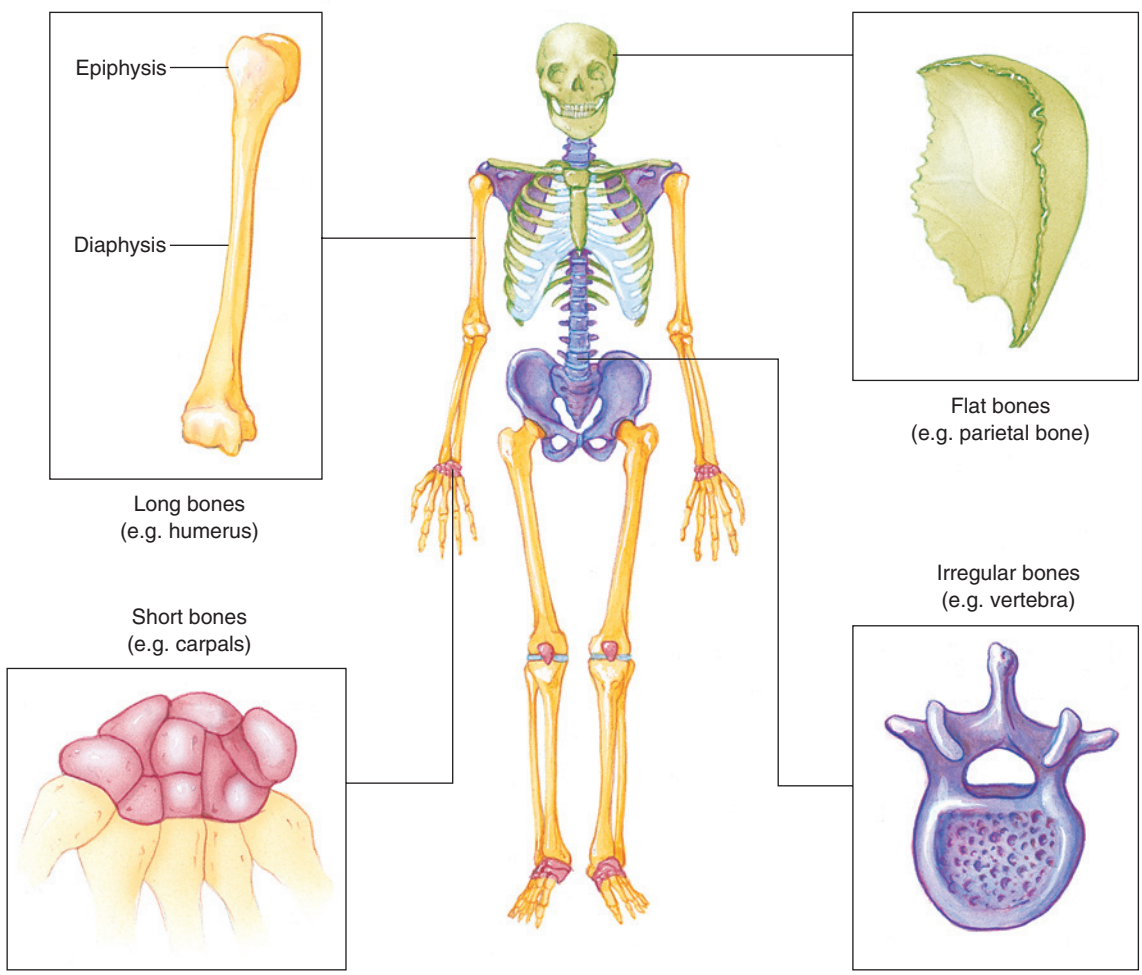

FIGURE 37.3 ■ Classification of bones according to shape

bones: the humerus and the head of the femur. This red marrow is active in haematopoiesis in adults.

Bone shapes

Bones are classified by shape (see Figure 37.3).

- *Long bones* are longer than they are wide. They have a midportion or shaft, called a diaphysis, and two broad ends, called epiphyses (see Figure 37.4). The diaphysis is compact bone and contains the marrow cavity, which is lined with endosteum. Each epiphysis is spongy bone covered by a thin layer of compact bone. Long bones include the bones of the arms, legs, fingers and toes.
- *Short bones*, also called cuboid bones, are spongy bone covered by compact bone. They include the bones of the wrist and ankle.
- *Flat bones* are thin and flat and most are curved. Their disc-like structure consists of a layer of spongy bone between two thin layers of compact bone. Flat bones include most bones of the skull, the sternum and the ribs.
- *Irregular bones* are of various shapes and sizes and, like flat bones, are plates of compact bone with spongy bone between. Irregular bones include the vertebrae, the scapulae and the bones of the pelvic girdle.

Bone remodelling in adults

Although the bones of adults do not normally increase in length and size, constant remodelling of bones, as well as repair of damaged bone tissue, occurs throughout life. In the bone remodelling process, bone resorption and bone deposit occur at all periosteal and endosteal surfaces. Hormones and forces that put stress on the bones regulate this process, which involves a combined action of the osteocytes, osteoclasts and osteoblasts. Bones that are in use, and are therefore subjected to stress, increase their osteoblastic activity to increase **ossification** (the development of bone). Bones that are inactive undergo increased osteoclast activity and bone resorption.

The hormonal stimulus for bone remodelling is controlled by a negative feedback mechanism that regulates blood calcium levels. This stimulus involves the interaction of parathyroid hormone (PTH) from the parathyroid glands and calcitonin from the thyroid gland. When blood levels of calcium decrease, PTH is released; PTH then stimulates osteoclast activity and bone resorption so that calcium is released from the bone matrix. As a result, blood levels of calcium rise and the stimulus for PTH release ends. Rising blood calcium levels stimulate the secretion of calcitonin, inhibit bone resorption and cause the deposit of calcium salts in the bone matrix. Thus, bones are necessary to regulate blood calcium levels.

Calcium ions are necessary for the transmission of nerve impulses, the release of neurotransmitters, muscle contraction, blood clotting, glandular secretion and cell division. Of the body's 1200 to 1400 g of calcium, over 99% is present as bone minerals.

Bone remodelling is also regulated by the response of bones to gravitational pull and to mechanical stress from the pull of muscles. Although the exact mechanism is not fully understood, it is known that bones that undergo increased stress are heavier and larger. This finding supports Wolff's law, which states that bone develops and remodels itself to resist the stresses placed on it.

The process of bone repair following a fracture is discussed in Chapter 38.

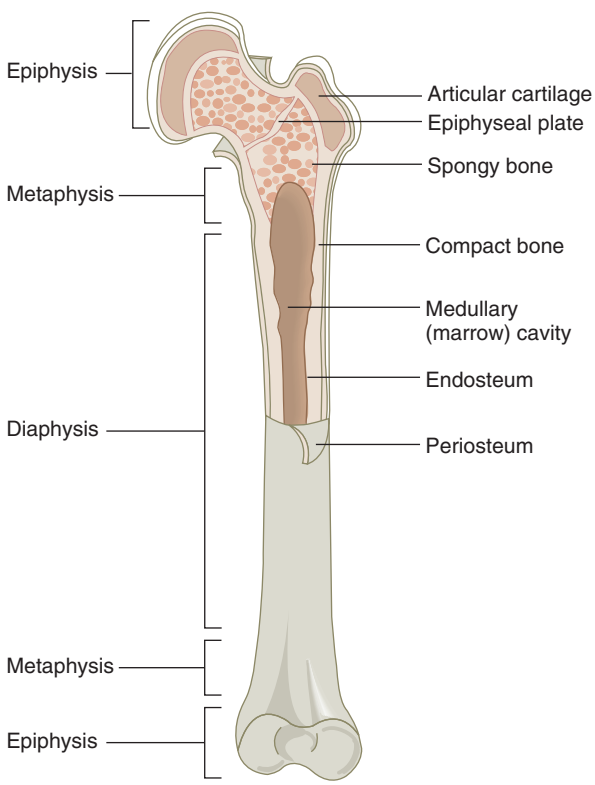

FIGURE 37.4 ■ Parts of a long bone

Muscles

The three types of muscle tissue in the body are skeletal muscle, smooth muscle and cardiac muscle (see Table 37.1). This discussion focuses on skeletal muscle, the only muscle that allows musculoskeletal function. Skeletal muscles attach to and cover the bones of the skeleton. Skeletal muscles promote body movement, help maintain posture and produce body heat. They may be moved by conscious, voluntary control or by reflex activity. The body has approximately 600 skeletal muscles (see Figure 37.5).

Skeletal muscles are thick bundles of parallel multinucleated contractile cells called fibres. Each single muscle fibre is itself a bundle of smaller structures called myofibrils. The myofibrils have alternating light and dark bands that give skeletal muscle

TABLE 37.1 Types of body muscle

TYPE	DESCRIPTION	EXAMPLES
Skeletal	Striated, voluntary muscle (can consciously move) can contract rapidly and vigorously, and is adaptable	Biceps, triceps, deltoid, gluteus maximus
Smooth	Non-striated, involuntary muscle (cannot consciously move)	Muscles in the walls of the bladder, stomach and bronchi
Cardiac	Striated, involuntary muscle	Heart muscle

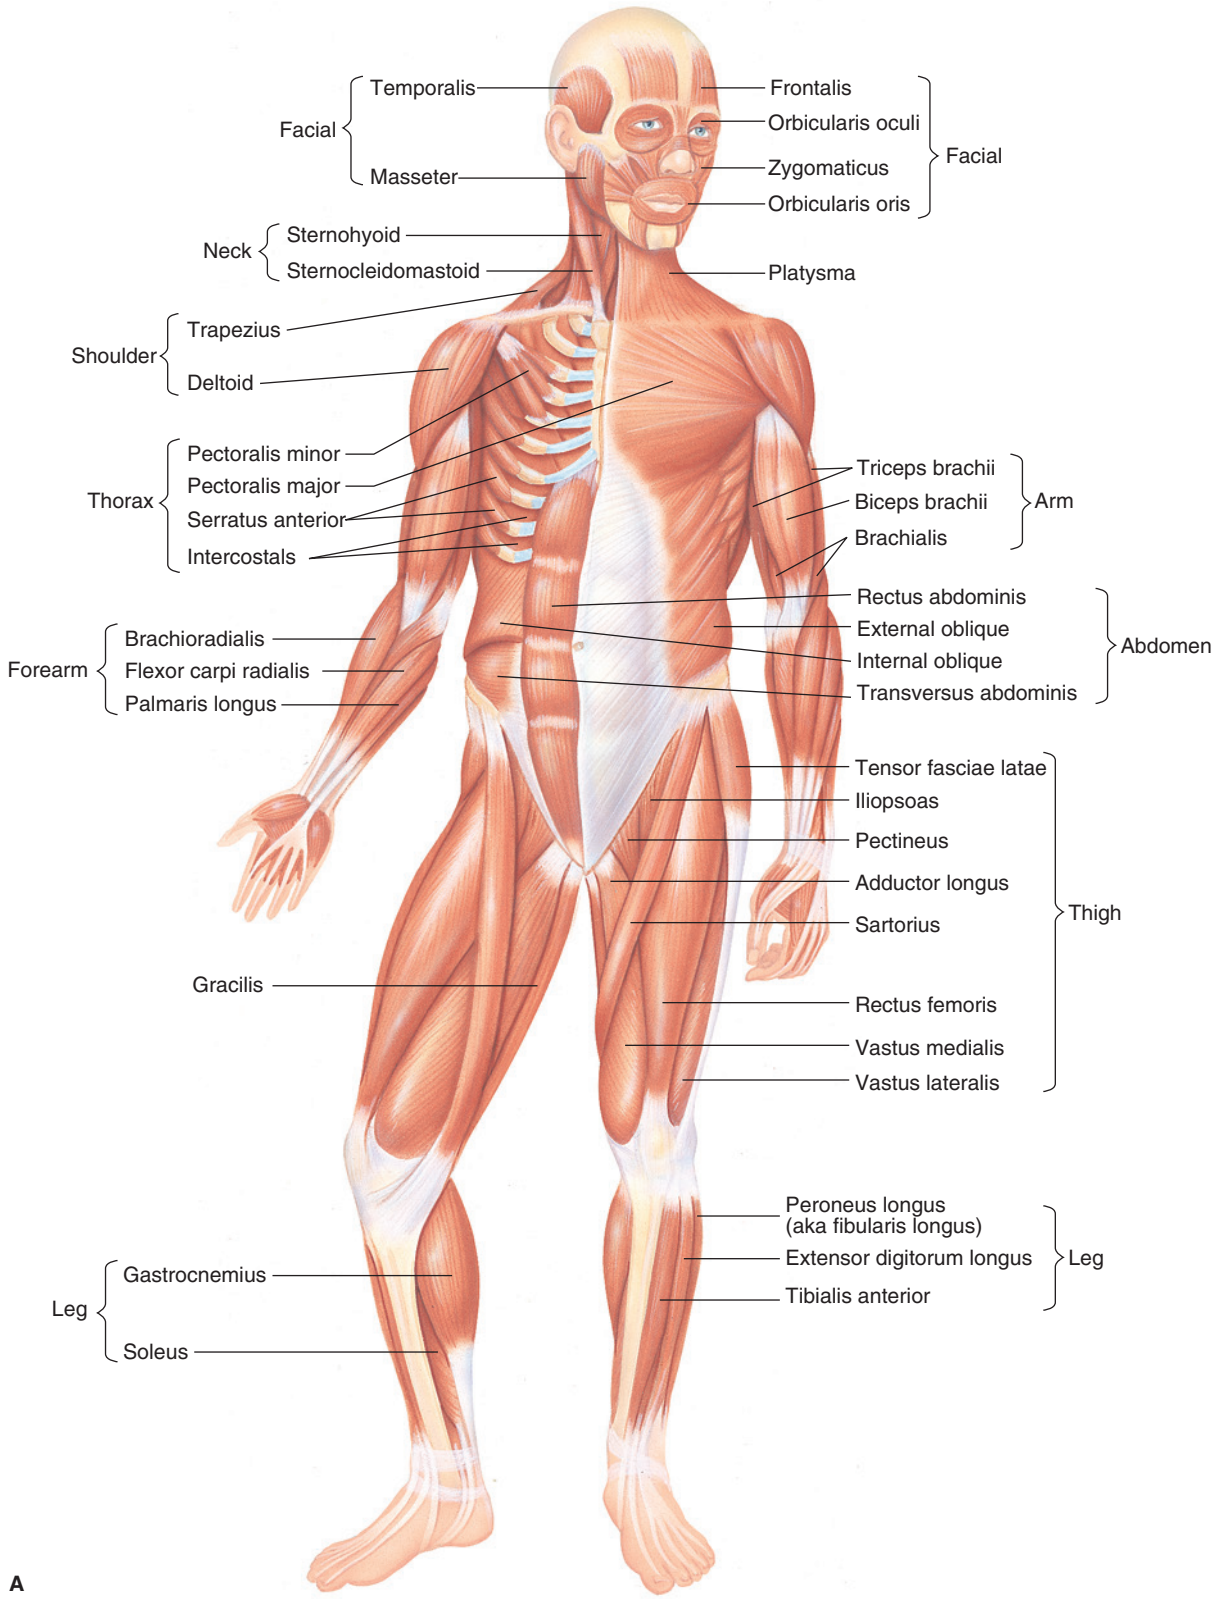

FIGURE 37.5 ■ *A*, Muscles of the anterior body

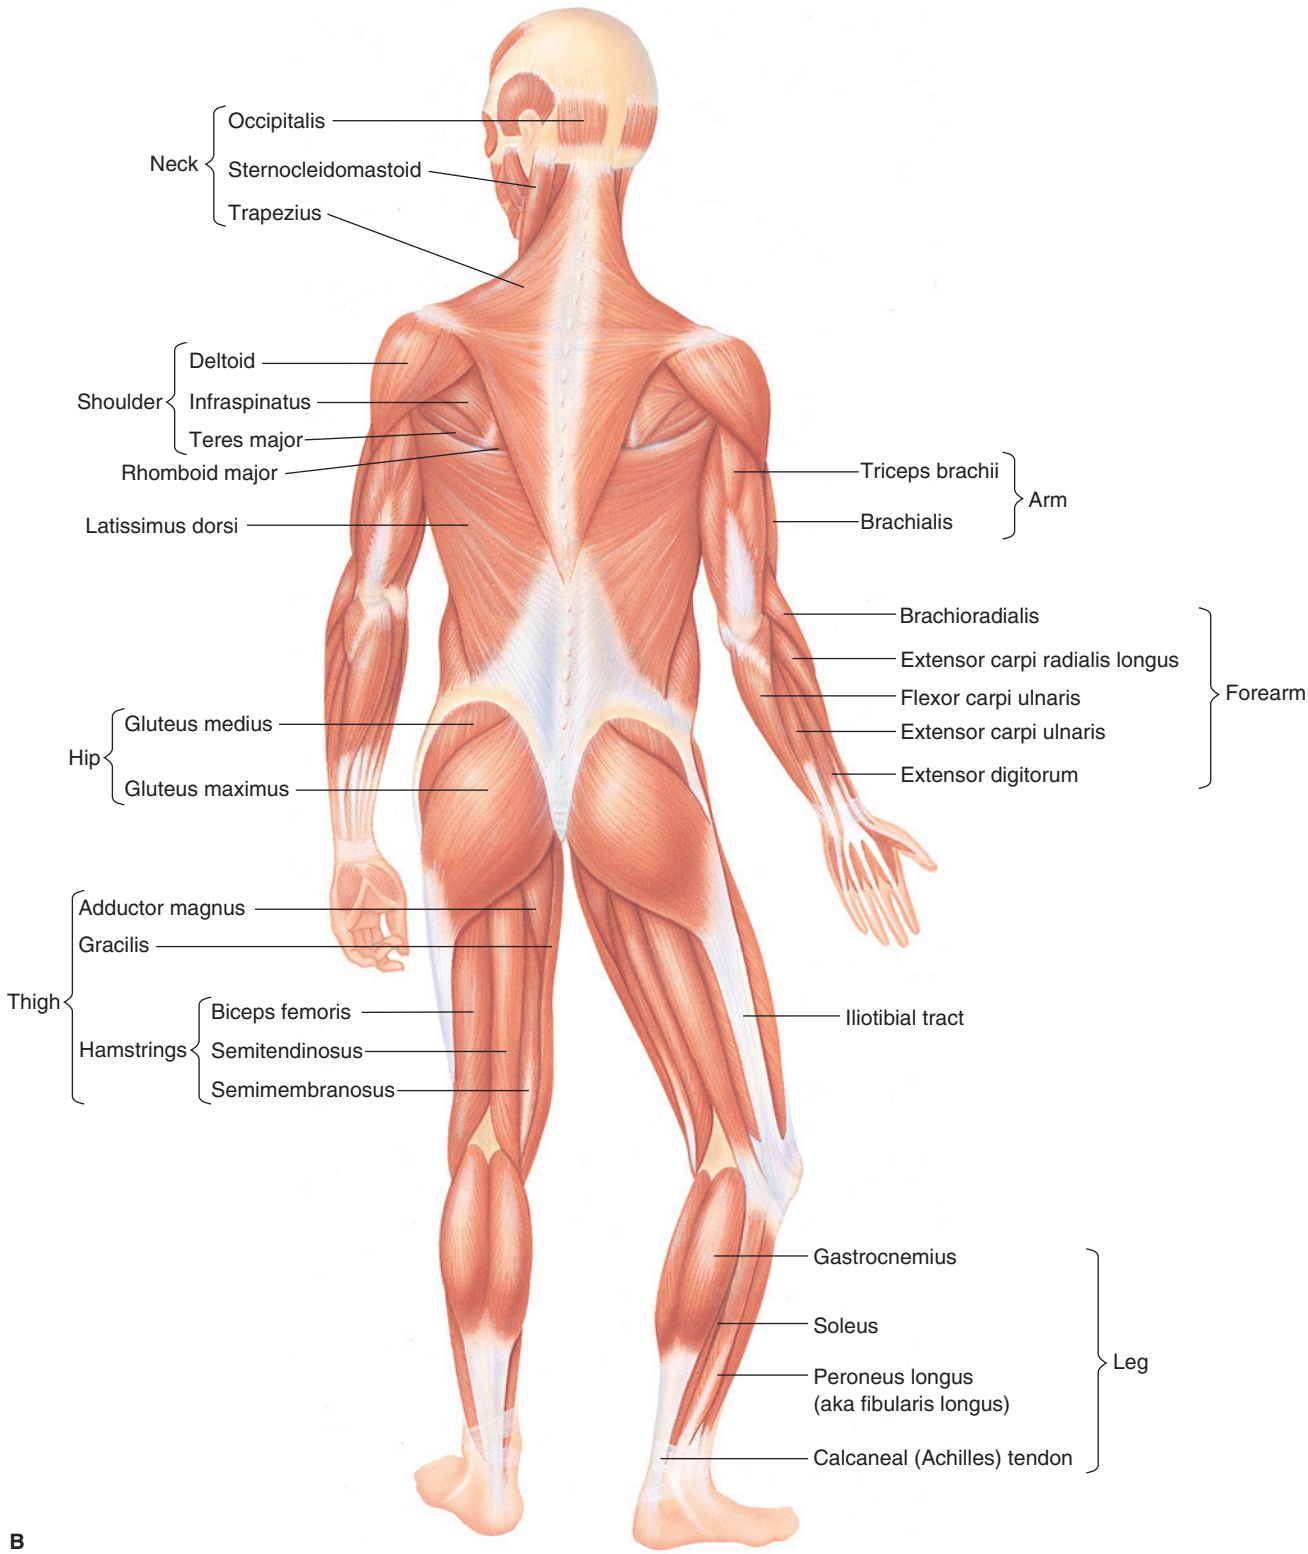

FIGURE 37.5 ■ *B*, Muscles of the posterior body

its striated (striped) appearance under an electron microscope. Myofibrils are strands of smaller repeating units called sarcomeres, which consist of thick filaments of myosin and thin filaments of actin, proteins that contribute to muscle contraction.

Skeletal muscle cells have typical functional properties:

- *Excitability:* the ability to receive and respond to a stimulus. The stimulus is usually a neurotransmitter released by a neuron and the response is the generation and transmission of an action potential along the plasma membrane of the muscle cell.
- *Contractibility:* the ability to respond to a stimulus by forcibly shortening.
- *Extensibility:* the ability to respond to a stimulus by extending and relaxing; muscle fibres shorten when they contract and extend when they relax.
- *Elasticity:* the ability to resume its resting length after it has shortened or lengthened.

Skeletal muscle movement is triggered when motor neurons release acetylcholine, a neurotransmitter that crosses the neuromuscular junction and alters the permeability of the muscle fibre. Sodium ions enter the fibre, producing an action potential that causes muscle contraction. The more fibres that contract, the stronger the contraction of the entire muscle.

Prolonged strenuous activity causes continuous nerve impulses and eventually results in a build-up of lactic acid and reduced energy in the muscle, or muscle fatigue. However, continuous nerve impulses are also responsible for maintaining muscle tone. Lack of use results in muscle atrophy, whereas regular exercise increases the size and strength of muscles.

Joints, ligaments and tendons

Joints, or articulations, are regions where two or more bones meet. Joints hold the bones of the skeleton together while allowing the body to move. Joints may be classified by function as synarthroses, amphiarthroses or diarthroses. Table 37.2 describes each of these types. Joints are also classified by structure as fibrous, cartilaginous or synovial.

Fibrous joints

Fibrous joints permit little or no movement because the articulating bones are joined either by short connective tissue fibres that bind the bones together, as with the sutures of the skull, or by short cords of fibrous tissue called ligaments, which permit slight give but no true movement.

Cartilaginous joints

Some cartilaginous joints, such as the sternocostal joints of the rib cage, are composed of hyaline cartilage growths that fuse together the articulating bone ends. These joints are immobile. In other cartilaginous joints, such as the intervertebral discs, the hyaline cartilage fuses to an intervening plate of flexible fibrocartilage. This structural feature accounts for the flexibility of the vertebral column.

Synovial joints

Bones in synovial joints are enclosed by a cavity that is filled with synovial fluid, a filtrate of blood plasma (see Figure 37.6). Synovial joints are freely movable, allowing many kinds of movements, as listed and described in Table 37.3. Synovial joints are found at all articulations of the limbs.

They have several characteristics:

- The articular surfaces are covered with articular cartilage.
- The joint cavity is enclosed by a tough, fibrous, double-layered articular capsule; internally, the cavity is lined with a synovial membrane that covers all surfaces not covered by the articular cartilage.
- Synovial fluid fills the free spaces of the joint capsule, enhancing the smooth movement of the articulating bones.

Bursae are small sacs of synovial fluid that cushion and protect bony areas that are at high risk of friction, such as the knee and the shoulder. Tendon sheaths are a form of bursae, but they are wrapped around tendons in high-friction areas.

The fibrous capsules that surround synovial joints are supported by ligaments, dense bands of connective tissue that connect bones

TABLE 37.2 Functional classification of joints

TYPE	DESCRIPTION	EXAMPLES
Synarthrosis	Immovable joint	Skull sutures Epiphyseal plates Joint between first rib and manubrium of sternum
Amphiarthrosis	Slightly movable joint	Vertebral joints Joint of the pubic symphysis
Diarthrosis	Freely movable joint	Joints of the limbs Shoulder joints Hip joints

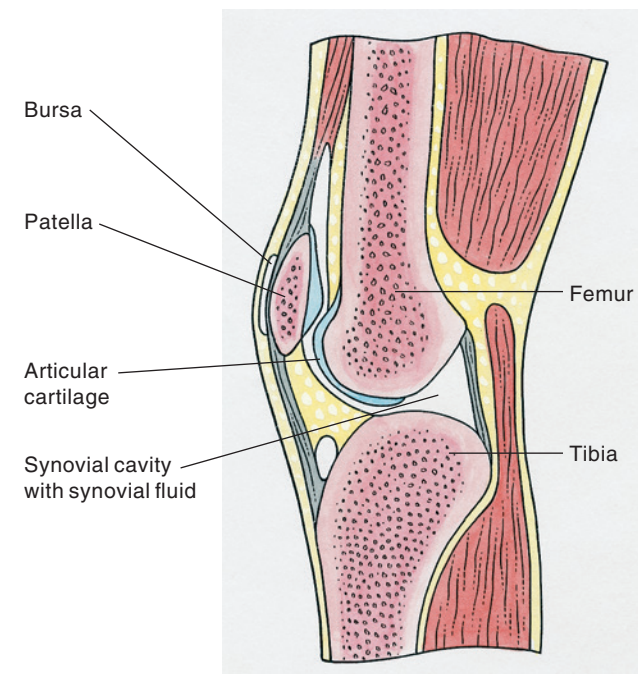

FIGURE 37.6 ■ Structure of a synovial joint (knee)

Source: DK Images.

TABLE 37.3 Movements allowed by synovial joints

TYPE	DESCRIPTION
Abduction	Move limb away from body midline
Adduction	Move limb towards body midline
Extension	Straighten limbs at joint
Flexion	Bend limbs at joint
Dorsiflexion	Bend ankle to bring top of foot towards shin
Plantar flexion	Straighten ankle to point toes down
Pronation	Turn forearm to place palm down
Supination	Turn forearm to place palm up
Eversion	Turn out
Inversion	Turn in
Circumduction	Move in circle
Internal rotation	Move inwards on a central axis
External rotation	Move outwards on a central axis
Protraction	Move forwards and parallel to ground
Retraction	Move backwards and parallel to ground

to bones. Ligaments limit or enhance movement, provide joint stability and enhance joint strength. Tendons are fibrous connective tissue bands that connect muscles to the periosteum of bones and enable the bones to move when skeletal muscles contract. When muscles contract, increased pressure causes the tendon to pull, push or rotate the bone to which it is connected.

ASSESSING MUSCULOSKELETAL FUNCTION

Structures and functions of the musculoskeletal system are assessed by a health assessment interview to collect subjective data, a physical assessment to collect objective data and findings from diagnostic tests. Sample documentation of an assessment of the musculoskeletal system is given in the accompanying box.

Health assessment interview

A health assessment interview to determine problems with musculoskeletal structure and/or function may be conducted during a health screening, and may focus on a chief complaint (such as joint pain) or may be part of a total health assessment. Health problems affecting the neurological system may manifest as problems with musculoskeletal function, and an assessment of both systems may be necessary. (See Chapter 40 for assessment of the neurological system.) If the person has problems with musculoskeletal structure or function, analyse its onset, characteristics, course, severity, precipitating and relieving factors, and any associated symptoms, noting the timing and circumstances. For example, ask the person:

- Describe the pain you have had in your elbow. Does the pain increase with movement? Have you noticed any redness or swelling?
- Did you injure your ankle before you began to experience difficulty walking?
- Is your pain worse in the morning or does it get worse throughout the day?

The primary manifestations of altered function of the musculoskeletal system are pain and limited mobility. Specific descriptors of the pain, its location and its nature are important. Other significant information includes associated manifestations, such as fever, fatigue, changes in weight, rash and/or swelling. Also collect information about the person's lifestyle: type of employment, ability to carry out activities of daily living (ADLs) and provide self-care, exercise or participation in sports, use of alcohol or drugs, and nutrition. Explore past injuries and measures to self-treat pain (such as over-the-counter (OTC) medications, prescribed medications, application of heat or cold, splinting, wrapping or rest).

Interview questions categorised by functional health patterns are listed in the Functional health pattern interview box below.

SAMPLE DOCUMENTATION

Assessment of the musculoskeletal system

7/4/2015
NURS
0900

58-year-old Caucasian male, employed as a roofer, comes to the orthopaedic clinic for evaluation of chronic knee pain. The person states, 'The pain in my knees is worse when I get up in the morning and when I carry something heavy at work.' Posture erect, gait even without obvious limp. Bones of lower extremities appear equal in size and shape bilaterally. No swelling noted, bulge test negative for fluid around knee. Crepitus heard in both knees during flexion and extension. Range of motion (ROM) in both knees slightly decreased. No obvious decrease in muscle mass. The person states that his knee pain during ROM is a 3 on a 1 to 10 scale. Referred to clinic physician for further evaluation, including x-rays of both knees.

———— R. Coleman

R. COLEMAN RN

Physical assessment

Physical assessment of the musculoskeletal system may be performed either as part of a total assessment or alone for a person with known or suspected problems. The techniques used to assess the musculoskeletal system are inspection, palpation and measurement of muscle mass and range of motion (ROM). The person should be comfortably dressed in clothing that lets you see the movement of all joints clearly. The person may be standing, sitting or lying down; the sequence of the examination should be such that the person does not have frequent position changes. An assessment of the older adult, the person in pain or the person who is weak may take extra time. Normal age-related findings for the older adult are summarised in Table 37.4.

FUNCTIONAL HEALTH PATTERN INTERVIEW Musculoskeletal system

FUNCTIONAL HEALTH PATTERN	INTERVIEW QUESTIONS AND LEADING STATEMENTS
Health perception–Health management	■ Have you ever had any muscle or bone diseases or injuries? If so, describe them. ■ Describe any surgery, physical therapy, heat or other treatments you have received for problems with your muscles or bones. ■ List any medications, such as muscle relaxants or prescribed or over-the-counter (OTC) medications and ointments you use for musculoskeletal problems. ■ Do you take any herbal or nutritional supplements for musculoskeletal problems? If so, what and how often?
Nutritional–Metabolic	■ Describe your dietary intake in a typical 24-hour period. Does your diet include milk, cheese, cottage cheese and vegetables? If so, how often? ■ Do you take vitamins and/or additional calcium supplements? If so, what type and how often? ■ Have you had a recent weight gain or loss? What do you see as your ideal weight? ■ Have you had any redness or swelling in your joints?
Elimination	■ Does your musculoskeletal problem make it difficult for you to get to the bathroom?
Activity–Exercise	■ Describe your usual activities for a 24-hour period. ■ Describe any musculoskeletal problems (such as weakness, stiffness, pain) that limit your activities of daily living (ADLs), such as driving, gardening, dressing, bathing, walking, climbing stairs, cooking or cleaning. ■ Has there been a change in your usual ability to move around? Describe. ■ Do you regularly exercise or take part in strenuous activities such as heavy lifting? Describe. If you have to lift heavy objects at work, do you use any type of special equipment? Describe. ■ Do you use any assistive devices (such as a cane or walker) to help move around?
Sleep–Rest	■ Does having this problem with your musculoskeletal system interfere with your ability to rest and sleep? If so, how, and what do you do?
Cognitive–Perceptual	■ Describe any muscle, bone or joint pain that you have. What relieves it or makes it worse? ■ Describe any changes in the colour, temperature or sensations in your extremities. ■ Describe any muscle weakness you are experiencing. ■ Do you have stiffness in your joints when you wake up? Does it get better with movement? ■ Do you ever have muscle cramps?
Self-perception–Self-concept	■ How does having this condition make you feel about yourself?
Role–Relationships	■ How has having this condition affected your relationships with others? ■ Has having this condition interfered with your ability to work? Explain. ■ Has anyone in your family had problems with bone, joint or muscle disease? Explain.
Sexuality–Reproductive	■ Has this condition interfered with your usual sexual activity?
Coping–Stress–Tolerance	■ Has having this condition created stress for you? ■ Have you experienced any kind of stress that makes the condition worse? Explain. ■ Describe what you do when you feel stressed.
Value–Belief	■ Describe how specific relationships or activities help you cope with this problem. ■ Describe specific cultural beliefs or practices that affect how you care for and feel about this problem. ■ Are there any specific treatments that you would not use to treat this problem?

TABLE 37.4 Age-related changes in the musculoskeletal system

AGE-RELATED CHANGE	SIGNIFICANCE
Bones and joints: • ↓ bone mass and minerals. • ↓ calcium reabsorption, a slow resorption of the interior of long bones and slower production of new bone on the outside surface of bones. • Vertebrae shorten and intervertebral discs thin, and kyphosis often occurs. • Cartilage on bone surfaces in joints deteriorates and bone spurs may occur.	Decreased bone mass as well as decreased calcium absorption contributes to bones that are often thinner and weaker, with an increased risk of fractures with trauma. As the spinal column shortens, height decreases. Loss of joint cartilage and formation of bone spurs makes movement more painful and may even limit mobility. Especially common in older adults.
Muscles: • Muscle fibres atrophy and fibrous tissue slowly replaces muscle tissue. • ↓ muscle mass and strength. • ↓ muscle movements, especially in the arms and legs. • Range of motion decreases. • Tendons shrink and harden. • Muscle cramping is common.	Regular exercise is very important in decreasing the loss associated with ageing in terms of maintaining muscle mass, strength and agility.

Prior to the examination, collect all equipment and explain the techniques to decrease the person's anxiety. The sequence for a musculoskeletal examination follows:

1. Begin the examination with an assessment of gait and posture. Observe how the person walks, sits and/or moves about in bed.
2. Inspect and palpate the bones for any obvious deformity or changes in size or shape. Palpation also will elicit tenderness or pain.
3. Measure the extremities for length and circumference. Before taking measurements, make sure the person is lying in a comfortable position. Remember to compare limbs bilaterally.
4. Assess muscle mass by first inspecting for obvious increase or decrease in size. Assess and document muscle strength on a scale of 0 to 5 (see Table 37.5). Box 37.1 provides instructions for testing the strength of various muscles.
5. Assess joints for swelling, pain, redness, warmth, crepitus and ROM. Only assess the ROM of every joint if the person has a specific musculoskeletal problem; however, assessing one or more joints is a common part of nursing care. Use a goniometer for precise measurements of joint ROM (see Figure 37.7). This device has a pointer joined to a protractor at 0 degrees. The two arms are placed along articulating bones and the angle of joint movement is recorded in degrees.

BOX 37.1 Guidelines for assessing muscle strength

In adults, muscles are usually strong and equally strong bilaterally. However, neuromuscular diseases, disuse, metabolic disorders or infections can cause muscle weakness. Muscle strength is expected to be greater in the dominant arm and leg. In most instances (and especially when moving digits and extremities), the nurse provides resistance by pushing in the opposite direction.

The muscles listed below are routinely tested. Instructions for the person are also provided.

MUSCLE	INSTRUCTIONS FOR THE PERSON
Ocular muscles and lids	Close eyes tightly.
Finger muscles	Shake hands.
	Make a fist.
	Spread fingers.
Facial muscles	Blow out cheeks.
	Stick out tongue.
Hip muscles	Raise straight leg while supine.
Neck muscles	Bend head forwards and backwards.
Gluteal and leg muscles	Alternately cross legs while sitting.
Deltoid muscles	Hold arms up.
Biceps muscle	Bend the arm.
Quadriceps muscle	Straighten leg.
Triceps muscle	Straighten the arm.
Wrist muscles	Bend hand forwards and backwards.
Ankle and foot muscles	Bend foot up and down.

TABLE 37.5 Muscle grading scale

GRADE	ASSESSMENT DESCRIPTION
0	(No visible) contraction; paralysis
1	Can feel contraction of muscle but there is no movement of limb
2	Passive ROM
3	Full ROM against gravity
4	Full ROM against some resistance
5	Full ROM against full resistance

Diagnostic tests

The results of diagnostic tests of musculoskeletal structure and function are used to support the diagnosis of a specific injury or disease, to provide information to identify or modify the appropriate medications or therapy used to treat the disease, and to help nurses monitor the person's responses to treatment and nursing care interventions. Diagnostic tests to assess the structures and functions of the musculoskeletal system are described in the table below and summarised in the following

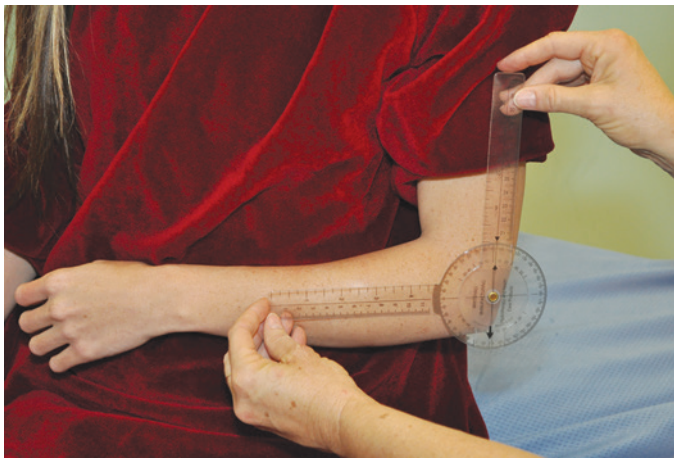

FIGURE 37.7 ■ Using a goniometer to measure joint ROM

bulleted list. More information is included in the discussion of specific injuries or diseases in Chapters 38 and 39.

- Blood tests are used to monitor levels of alkaline phosphatase, calcium, uric acid and creatine kinase, which are commonly increased in bone and joint diseases and muscle trauma (see Table 37.6).
- Radiological examinations, including x-rays, CT scans, MRIs and bone scans, are done to identify and evaluate bone density and structure in conditions such as arthritis, intervertebral disc disease, musculoskeletal trauma, muscle tears, osteomyelitis and bone tumours.
- Bone density examinations (dual energy x-ray absorptiometry (DEXA), quantitative ultrasound (QUS) and bone mineral density (BMD)) are done to evaluate bone mineral density and evaluate the degree of osteoporosis.
- An arthroscopy uses a fibre-optic endoscope to examine the joint interior, to diagnose diseases and to perform surgery. An arthrocentesis is done to withdraw fluid from a joint by needle aspiration.
- Both an electromyogram (EMG) and a somatosensory evoked potential (SSEP) are tests of the electrical activity of skeletal muscle.

Regardless of the type of diagnostic test, the nurse is responsible for explaining the procedure and any special preparation needed, for assessing for medication use that may affect the outcome of the tests, for supporting the person during the examination as necessary, for documenting the procedures as appropriate, and for monitoring the results of the tests.

Genetic considerations

When conducting a health assessment interview and a physical assessment, it is important for the nurse to consider genetic influences on the health of the adult. During the health assessment interview, ask about family members with health problems affecting musculoskeletal structure or function. In addition, ask about a family history of arthritis, abnormally long bones, muscular dystrophy and motor neurone disease. During the physical assessment, assess for any manifestations that might indicate a genetic disorder (see the box below). If data are found to indicate genetic risk factors or alterations, ask about genetic testing and refer for appropriate genetic counselling and evaluation. Chapter 7 provides further information about genetics in medical–surgical nursing.

TABLE 37.6 Blood tests with purposes specific to the musculoskeletal system

NAME OF TEST	PURPOSE	NORMAL VALUE
Alkaline phosphatase (ALP)	To identify bone diseases. Increased in bone cancer, Paget's disease, healing fractures, rheumatoid arthritis and osteoporosis	Neonate: 50–300 U/L Growing child: 70–350 U/L Adult, non-pregnant: 25–100 U/L Higher levels are seen in the third trimester of pregnancy and in individuals over 50 years of age
Calcium (Ca)	To monitor calcium levels and detect calcium imbalances. Decreased with lack of calcium and vitamin D intake and malabsorption from the gastrointestinal tract. Increased in bone cancer and multiple fractures	4.5–5.5 mEq/L or 9–11 mg/dL (serum) Total calcium: 2.10–2.60 mmol/L Corrected calcium: 2.15–2.60 mmol/L Ionised calcium: 1.16–1.30 mmol/L
Phosphorus (P), phosphate (PO_4)	To assess phosphorus levels. Increased with bone tumours and healing fractures	1.7–2.6 mEq/L or 2.5–4.5 mg/dL Adult: 0.8–1.5 mmol/L Levels are slightly higher in children
Rheumatoid factor (RF)	To diagnose rheumatoid arthritis (RA) (positive for RA at > 1:80 titre). Also increased in lupus erythematosus and scleroderma	< 1:20 titre < 30 IU/L
Uric acid	To diagnose and monitor the treatment of gout. Panic level considered > 12 mg/dL	Male: 3.5–8.0 mg/dL Female: 2.8–6.8 mg/dL
Human leucocyte antigen (HLA)	To diagnose diseases such as juvenile rheumatoid arthritis or ankylosing spondylitis	Match or no match; no normal values
Creatine kinase (CK)	To diagnose muscle trauma or disease. Increased in muscular dystrophy and traumatic injuries (specifically, CPK-MM isoenzyme)	Neonate: 70–380 U/L Adult female: 30–180 U/L Adult male: 60–220 U/L

DIAGNOSTIC TESTS The musculoskeletal system

NAME OF TEST Blood chemistry

PURPOSE AND DESCRIPTION See Table 37.6

RELATED NURSING CARE No special preparation is needed.

NAME OF TEST X-ray

PURPOSE AND DESCRIPTION X-rays are done to identify and evaluate bone density and structure. Injection of contrast medium with an accompanying x-ray may be done to visualise joint structures, intervertebral discs and wounds deep in muscle.

RELATED NURSING CARE No special preparation needed for standard x-rays. If contrast medium is used, assess for allergy to shellfish, iodine or contrast medium used in previous tests. If allergy is present, test will not be performed.

NAME OF TEST Computed tomography (CT) scan

PURPOSE AND DESCRIPTION Provides a three-dimensional picture used to evaluate musculoskeletal trauma and bony abnormalities.

RELATED NURSING CARE No special preparation is needed.

NAME OF TEST Magnetic resonance imaging (MRI)

PURPOSE AND DESCRIPTION Used in diagnosis and evaluation of avascular necrosis, osteomyelitis, tumours, disc abnormalities and tears in ligament or cartilage. Uses radiowaves and magnetic fields; gadolinium may be injected to increase visualisation of bony or muscular structures.

RELATED NURSING CARE Assess for metallic implants or metal on clothing. (Metallic implants, such as clips on aneurysms, pacemakers or shrapnel, will prohibit having an MRI.)

NAME OF TEST Bone scan

PURPOSE AND DESCRIPTION Degree of uptake of a radioisotope (based on blood supply to bone) is measured with a Geiger counter and recorded on paper. Uptake is increased in osteomyelitis, osteoporosis, cancers of the bone and in some fractures. Uptake is decreased in avascular necrosis.

RELATED NURSING CARE No special preparation is needed; tell the person to increase oral fluids after the test to aid in excretion of the radioisotope.

NAME OF TEST Bone density (BD)

- Dual energy x-ray absorptiometry (DEXA)
- Quantitative ultrasound (QUS)
- Bone mineral density (BMD)
- Bone absorptiometry

PURPOSE AND DESCRIPTION Bone density examinations are done to evaluate bone mineral density and to evaluate degree of osteoporosis. DEXA can calculate the size and thickness of bone and detect even a 1% loss of bone mass. Osteoporosis is diagnosed if the peak bone mass level is below > 2.5 standard deviations.

Normal value: 1 standard deviation below peak bone mass.

RELATED NURSING CARE No special preparation is needed. Assess for previous fractures, which may increase bone density.

NAME OF TEST Arthroscopy

PURPOSE AND DESCRIPTION An endoscopic examination of the interior surfaces of a joint, used to perform surgery and diagnose diseases of the patella, meniscus and synovial and extrasynovial membranes. In addition, fluid may be drained from the joint and tissue removed for biopsy. A fibre-optic endoscope is inserted into the joint, with either local or general anaesthesia.

RELATED NURSING CARE If general anaesthesia is used, the person is nil by mouth at least 6–8 hours prior to surgery. Following the procedure, assess for bleeding and swelling, apply ice to the area if prescribed and teach the person to avoid excessive use of the joint for 2 to 3 days.

NAME OF TEST Arthrocentesis

PURPOSE AND DESCRIPTION Done to obtain synovial fluid from a joint for diagnosis (such as infections) or to remove excess fluid. A needle is inserted through the joint capsule and fluid is aspirated.

RELATED NURSING CARE No special preparation is needed. Apply compression dressing and assess for bleeding and leakage of fluid following the procedure.

DIAGNOSTIC TESTS The musculoskeletal system (continued)

NAME OF TEST Electromyogram (EMG)

PURPOSE AND DESCRIPTION Measures the electrical activity of skeletal muscles at rest and during contraction; useful in diagnosing neuromuscular diseases. Needle electrodes are inserted into skeletal muscle (as on the legs) and electrical activity can be heard, viewed on an oscilloscope and recorded on graph paper. Normally, there is no electrical activity at rest.

RELATED NURSING CARE Tell the person not to drink fluids containing caffeine or to smoke for 3 hours before the test and not to take medications such as muscle relaxants, anticholinergics or cholinergics.

NAME OF TEST Somatosensory evoked potential (SSEP)

PURPOSE AND DESCRIPTION Measures nerve conduction along pathways to evaluate evoked potential of muscle contractions. Used to identify dysfunction of lower motor neurons as well as muscle disease. Transcutaneous or percutaneous electrodes are applied to the skin and provide recordings.

RELATED NURSING CARE No special preparation is needed.

GENETIC CONSIDERATIONS Musculoskeletal disorders

- Myotonic dystrophy is an inherited disorder in which the muscles become weak, have a decreased ability to relax and eventually waste away. Other effects are mental deficiency, hair loss and cataracts. Although rare, the disease does increase in severity with each successive generation.
- Marfan syndrome, an autosomal dominant disorder of connective tissue, affects the bones, lungs, eyes, heart and blood vessels. It is characterised by abnormally long extremities and is believed to have affected Abraham Lincoln. The aspect of the disease that is most life threatening is the effect on the cardiovascular system. With advances in the diagnosis, evaluation and management of the organ abnormalities associated with Marfan syndrome, the life expectancy for a person with the disease has nearly doubled in the past 25 years. Today, individuals with Marfan syndrome can expect to live about 70 years (National Marfan Foundation, 2013).
- Ellis–van Creveld syndrome is a rare genetic disorder characterised by a variety of physical alterations, including short-limb dwarfism, additional fingers or toes, malformed wrists, cardiac abnormalities and partial tooth eruption.
- Duchenne muscular dystrophy, an X-linked disorder, primarily affects males. It is one of the most common muscular dystrophies and is characterised by rapid muscle degeneration early in life.
- Motor neurone disease is a neurological disease that affects the motor neurons in the spinal cord and brain, eventually resulting in paralysis and death.
- Other musculoskeletal diseases believed to have a genetic component include rheumatoid arthritis, osteoarthritis, gout, muscular dystrophy, ankylosing spondylitis, lupus erythematosus and scleroderma.

MUSCULOSKELETAL ASSESSMENTS

Technique/normal findings	Abnormal findings
Gait and body posture	
Inspect body posture and gait. *Body posture should be upright; gait should be smooth and steady.*	■ Joint stiffness, pain, deformities and muscle weakness can cause changes in gait and posture.
Inspect the spine for curvature. Ask the person to stand and bend back slowly as far as possible, bend slowly to the right and then to the left as far as possible, turn slowly to the right and left in a circular motion, and bend forwards slowly and try to touch fingers to toes. *When viewed from the back, the cervical and lumbar spine are concave, the thoracic spine is convex and the spine is straight.*	■ With herniated lumbar discs, the lumbar curve flattens and spinal mobility is decreased. ■ An increased lumbar curve, called **lordosis**, may be seen in obesity or pregnancy. ■ A lateral, S-shaped curvature of the spine is called **scoliosis**. Functional scoliosis usually is a compensatory response to painful paravertebral muscles, herniated discs or discrepancy in leg length. It disappears with forward flexion. Structural scoliosis is often congenital and tends to appear during adolescence. It is accentuated with forward bending. ■ **Kyphosis** is an exaggerated thoracic curvature of the spine common in older adults.

Technique/normal findings	Abnormal findings
Joints	
Inspect the joints for deformity, swelling and redness. *There should be no visible deformity, swelling or redness of joints.*	■ Diseases of the joints may be manifested by such deformities as tissue loss, tissue overgrowth or contractures or irreversible shortenings of muscles and tendons. ■ Disease in a joint may cause obvious bulging. ■ Redness, swelling and pain are evidence of an inflammation or infection in the joint. ■ Inflammation and injury cause joint pain. ■ Arthritis, bursitis, tendonitis and osteomyelitis (infection of a bone) result in painful, hot joints. ■ **Crepitation** (a grating sound) is present in a joint when the articulating surfaces have lost their cartilage, such as in arthritis.
Palpate the joints for tenderness, warmth, crepitation, consistency and muscle mass. *Joints should be non-tender and consistent bilaterally and without visible or palpable excess warmth, crepitation or masses.*	
Range-of-motion	
Assess joint ROM by asking the person to perform activities specific to each joint, as described below. *All bilateral joints should move through full range of motion.*	
Temporomandibular joint: 'Open your mouth wide and then close your mouth.' (As the person opens and closes the mouth, palpate the temporomandibular joints with your index and middle fingers, as shown in Figure 37.8.)	■ Clicking or popping noises, decreased ROM, pain and swelling may indicate temporomandibular joint syndrome or, in rare cases, osteoarthritis.
Cervical spine: 45-degree flexion: 'Touch your chin to your chest.' 55-degree extension: 'Look at the ceiling.' 40-degree lateral bending: 'Try to touch your right ear to your right shoulder.' Repeat with the left side. 70-degree rotation: 'Try to touch your chin to each shoulder.'	■ Neck pain and limited extension with lateral bending are seen with herniated cervical discs and in cervical spondylosis. ■ An immobile neck with head and neck thrust forwards is seen with ankylosing spondylitis.
Lumbar spine: 75- to 90-degree flexion: 'Touch your toes with your fingers' (see Figure 37.9A). 30-degree extension: 'Bend backwards slowly.' 35-degree lateral bending: 'Bend right and left' (see Figure 37.9B). 30-degree rotation: 'Twist your shoulders right and left' (see Figure 37.9C).	■ Decreased movement or pain with movement may indicate an abnormal spinal curvature, arthritis, herniated disc or spasm of paravertebral muscles.

FIGURE 37.8 ■ Palpating the temporomandibular joints

Technique/normal findings	Abnormal findings

A

B

C

FIGURE 37.9 ■ *A*, Forward flexion of spine. *B*, Lateral flexion of spine. *C*, Rotation of spine

Fingers: Flexion: 'Make a fist.' Extension: 'Open your hand.' Abduction: 'Spread your fingers.' Adduction: 'Close your fingers.'	■ Flexion and extension of fingers are decreased in arthritis. ■ Heberden's nodes and Bouchard's nodes are hard, non-tender nodules on the dorsolateral parts of the distal and proximal interphalangeal joints, respectively. They are common in osteoarthritis. ■ Stiff, painful, swollen finger joints are seen in acute rheumatoid arthritis. ■ Boutonnière and swan-neck deformities are seen in chronic rheumatoid arthritis. ■ Swollen finger joints with a white chalky discharge may be seen in chronic gout.
Wrists: 90-degree flexion: 'Bend wrist down.' 70-degree extension: 'Bend wrist up.' 55-degree ulnar deviation: 'Bend wrist towards little finger.' 20-degree radial deviation: 'Bend wrist towards thumb.'	■ Bilateral chronic swelling in the wrist is seen in arthritis.
Elbows: 160-degree flexion: 'Touch your hands to your shoulders.' 180-degree extension: 'Straighten your elbows.' 90-degree supination: 'Bend your elbows 90 degrees and turn hands palm up.' 90-degree pronation: 'Bend your elbows 90 degrees and turn fists down.'	■ Swollen, tender, inflamed elbows are apparent in gouty arthritis and rheumatoid arthritis. ■ Pain and tenderness at the lateral epicondyle occur in tennis elbow.

Technique/normal findings	Abnormal findings
Shoulders: 180-degree flexion: 'Hold your arms straight up and out.' 50-degree hyperextension: 'Put your straight arm behind your back.' 90-degree internal rotation: 'Put your forearm behind your lower back.' 180-degree abduction: 'Raise your straight arm up and out to your side.' 50-degree adduction: 'Put your straight arm across your chest.'	■ Pain and tenderness over the biceps tendon occurs with **tendonitis** (inflammation of a tendon). ■ The arm cannot be abducted fully when the supraspinatus tendon of the shoulder is ruptured. ■ Pain and limited abduction is also seen with **bursitis** (inflammation of a bursa) and calcium deposits in this area.
Toes: 90-degree flexion: 'Walk on your toes.'	■ The great toe is excessively abducted in hallux valgus. ■ The joint above the great toe is swollen, inflamed and painful in gouty arthritis. ■ There is hyperextension of the metatarsophalangeal joint and flexion of the proximal interphalangeal joint with hammer toes.
Ankles: 20-degree dorsiflexion: 'Point your foot to the ceiling.' 45-degree plantar flexion: 'Point your foot to the floor.' 30-degree inversion: 'Walk on the outside of your feet.' 20-degree eversion: 'Walk on the inside of your feet.'	■ Contractures of the Achilles tendon may occur in people with rheumatoid arthritis or following prolonged bed rest.
Knees: 130-degree flexion: 'Do a deep knee bend.' 180-degree extension: 'Sit down and hold your legs straight out in front of you.'	■ Swelling over the suprapatellar pouch is seen with inflammation and fluid in the articular capsule of the knee. **Synovitis** is inflammation of the synovial membrane lining the articular capsule of a joint. It is common with knee trauma. ■ Swelling over the patella is seen in bursitis.
Hips: (The person is lying down.) 120-degree flexion: 'Bring bent knee up to your chest.' 30-degree hyperextension: 'Lie on your abdomen and lift up one leg at a time.' 45-degree abduction: 'Hold your leg straight and move it out to the side.' 40-degree internal rotation: 'Bend your knee and swing it towards your other leg.' 45-degree external rotation: 'Bend your knee and swing it out to the side.'	■ Movement of the hip is limited and/or painful in arthritis.

Technique/normal findings	Abnormal findings
Special assessments	
Perform Phalen's test. Ask the person to hold the wrist in acute flexion for 60 seconds (see Figure 37.10). *There should be no tingling, numbness or pain.*	■ Numbness and burning in the fingers during Phalen's test may indicate carpal tunnel syndrome.

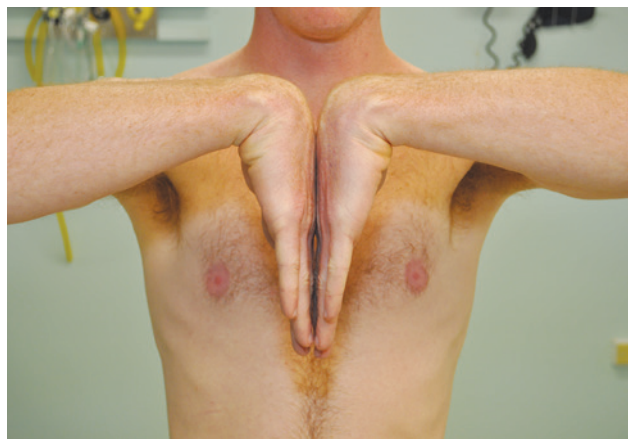

FIGURE 37.10 ■ Phalen's test

Check for small amounts of fluid on the knee by conducting the bulge test. Milk upwards on the medial side of the knee and then tap the lateral side of the patella (see Figure 37.11). *No bulge of fluid should appear on the medial side of the knee.*	■ A fluid bulge indicates increased fluid in the knee joint rather than soft tissue swelling.

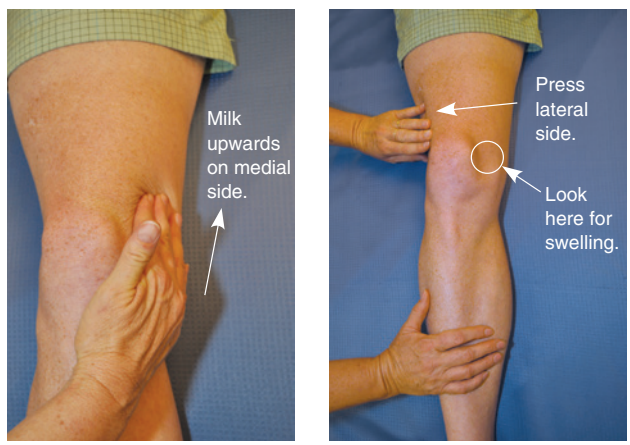

FIGURE 37.11 ■ Checking for the bulge sign

Conduct the ballottement test to detect large amounts of fluid in the knee. Apply downward pressure on the knee with one hand while pushing the patella backwards against the femur with the other hand (see Figure 37.12). *There should be no movement of the patella. The patella should rest firmly over the femur.*	■ Increased fluid will cause a tapping sound as the patella displaces the fluid and hits the femur.

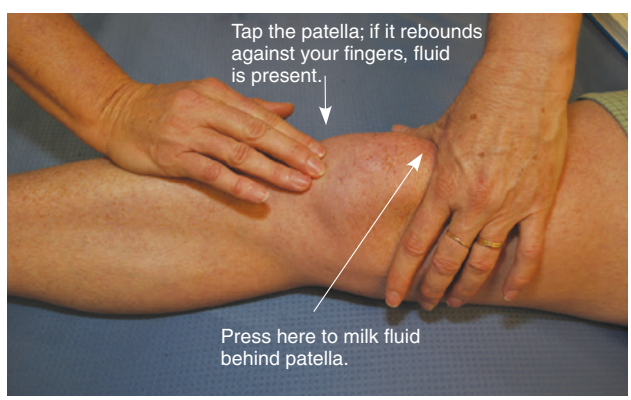

FIGURE 37.12 ■ Checking for ballottement

Technique/normal findings	Abnormal findings
Perform McMurray's test. While reclining, ask the person to turn the flexed knee towards the centre of the body. Stabilise the knee with one hand and apply pressure on the lower leg with the other hand (see Figure 37.13). *There should be no pain or clicking.*	■ Pain, locking (inability to fully extend the knee) or a popping sound may indicate an injury to a meniscus, a disc of cartilaginous tissue in the knee.

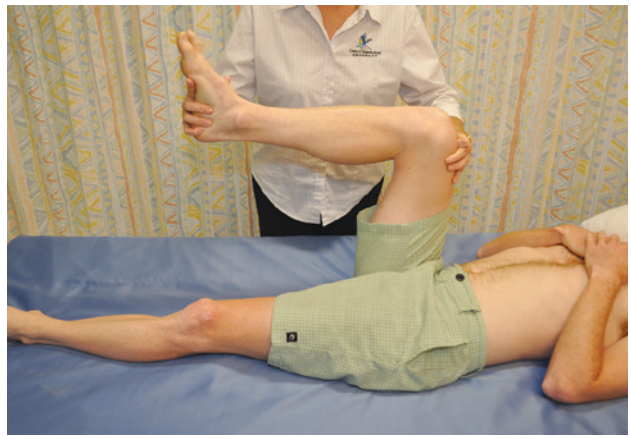

FIGURE 37.13 ■ McMurray's test

Perform the Thomas test. Ask the person to lie down and extend one leg while bringing the knee of the opposite leg to the chest (see Figure 37.14). *The extended leg should not rise off the table.*	■ A hip flexion contracture will cause the extended leg to rise off the table.

FIGURE 37.14 ■ Thomas test for hip contracture

CONCEPT CHECK

1 A person you are caring for has an epiphyseal fracture. Based on this information, which classification of bone is involved?
1 irregular
2 flat
3 long
4 short

2 When asking a person to move an extremity away from the body midline, you are assessing:
1 abduction
2 adduction
3 extension
4 flexion

3 A person you are caring for asks you, 'Why is blood being examined for uric acid?' What would be your most accurate response?
1 'A uric acid test is done to see if your gout medication is effective.'
2 'A uric acid test is done to diagnose rheumatoid arthritis.'
3 'Do you have a family history of muscle or bone disease?'
4 'Tell me how you got that big bruise on your hip.'

4 At what age would a woman be most likely to have a bone density examination?
1 as a teenager
2 in her twenties
3 in her forties
4 in her sixties

5 With ageing, bone mass and calcium absorption decrease. Which risk is increased as a result?
1 obesity
2 weakness
3 fractures
4 deformity

6 What would you ask the person to do in order to assess facial muscle strength?
1 'Close your eyes tightly.'
2 'Stick out your tongue.'
3 'Bend your head forwards.'
4 'Open your eyes wide.'

7 Which term is used to document a grating sound when a joint is moved?
1 crackles
2 arthritis
3 synovitis
4 crepitation

8 While conducting the ballottement test, you note the patella rebounds against your fingers. What does this finding indicate?
1 deformity of the elbow
2 infection of the metatarsals
3 fluid in the knee joint
4 crepitus in the hip joint

9 During the physical assessment of a young adult, you note a lateral, S-shaped curve of the spine. What is the name of this condition?
1 lordosis
2 scoliosis
3 kyphosis
4 musclosis

10 What are the most common manifestations of musculoskeletal disorders?
1 pain and limited mobility
2 swelling and exaggerated reflexes
3 cyanosis and decreased pulses
4 pallor and decreased ROM

CHAPTER 38

NURSING CARE OF PEOPLE WITH MUSCULOSKELETAL TRAUMA

ANN-MARIE BROWN

KEY TERMS

LEARNING OUTCOMES

- Compare and contrast the causes, risk factors, pathophysiology, manifestations, interprofessional care and nursing care of contusions, strains, sprains, joint dislocations and fractures.
- Describe the stages of bone healing.
- Explain the pathophysiology, manifestations and related treatment for complications of bone fractures: compartment syndrome, fat embolism syndrome, deep venous thrombosis, infection, delayed union and non-union, and reflex sympathetic dystrophy.
- Discuss the purposes and related nursing interventions for casts, traction and stump care.
- Explain the causes, levels, types and potential complications (infection, delayed healing, chronic stump pain, phantom pain and contractures) of an amputation.
- Describe the pathophysiology, interprofessional care and nursing care for repetitive use injuries: carpal tunnel syndrome, bursitis and epicondylitis.

CLINICAL COMPETENCIES

- Assess functional health status of people with musculoskeletal injuries and monitor, document and report abnormal manifestations.
- Use evidence-based research to plan and implement nursing care for people with skeletal pin sites.
- Determine priority nursing diagnoses, based on assessed data, to select and implement individualised nursing interventions for people with musculoskeletal injuries.
- Provide skilled cast care, traction care and stump care.
- Integrate interprofessional care into care of people with musculoskeletal trauma.
- Provide teaching appropriate for prevention and self-care of traumatic injuries of the musculoskeletal system.
- Revise the plan of care as needed to provide effective interventions to promote, maintain or restore functional health status to people with traumatic injuries of the musculoskeletal system.

Musculoskeletal trauma is an injury to muscle, bone or soft tissue that results from excessive external force. The external force transmits more kinetic energy than the tissue can absorb and injury results. The severity of the trauma depends not only on the amount of force but also on the location of the impact, because different parts of the body can withstand different amounts of force. A wide variety of external forces can cause trauma and the force involved can vary in severity (e.g. a step off the curb, a fall, being tackled in a football game and a motor vehicle crash). See Chapter 10 for a detailed discussion of the results of different forces and types of injury from trauma.

Traumatic musculoskeletal injuries include blunt tissue trauma, alterations in tendons and ligaments, and fractures of bones. Various forces that cause musculoskeletal trauma are typical for a specific environment, activity or age group. For example, motorcycle accidents resulting in fractures of the distal tibia, midshaft femur and radius are common in young men. Sports injuries, resulting from either overuse or acute trauma, are seen more often in adolescents and young adults. Falls are the most common cause of injury in people age 65 or older, with fractures of the vertebrae, proximal humerus and hip seen most often (Porth & Matfin, 2014). Regardless of the cause, the injury may require rehabilitation and temporary or permanent changes in lifestyle.

Musculoskeletal trauma can result in mild or severe injuries. A person may experience a soft tissue injury, a fracture and/or a complete amputation. In addition, trauma to one part of the musculoskeletal system often produces dysfunction in adjacent structures. For example, a fracture of the femur prevents the adjacent muscles from abducting and adducting. Nursing care helps minimise the effects of trauma, prevents complications and hastens restoration of function. This chapter discusses fractures, amputations, soft tissue injuries, dislocations and repetitive use injuries.

TRAUMATIC INJURIES OF THE MUSCLES, LIGAMENTS AND JOINTS

THE PERSON WITH A CONTUSION, STRAIN OR SPRAIN

Contusions, strains and sprains are among the most commonly reported injuries. They account for about 50% of work-related injuries, with lower back injuries being the most commonly reported occupational injury. However, many sprains and strains are not work related and often are not reported. The lower back and cervical region of the spine are the most common sites for muscle strains; the ankle is the most commonly sprained joint, usually caused by forced inversion of the foot.

Pathophysiology and manifestations

A contusion, the least serious form of musculoskeletal injury, is bleeding into soft tissue that results from a blunt force, such as a kick or striking a body part against a hard object. The skin remains intact, but small blood vessels rupture and bleed into soft tissues. A contusion with a large amount of bleeding is referred to as a *haematoma*. The manifestations of a contusion include swelling and discolouration of the skin. The blood in the soft tissue initially results in a purple-blue colour commonly referred to as a *bruise*. As the blood begins to reabsorb, the area involved becomes brown and then yellow until it disappears.

A **strain** is a stretching injury to a muscle or a muscle–tendon unit caused by mechanical overloading. A muscle that is forced to extend past its elasticity will become strained. Lifting heavy objects without bending the knees or a sudden acceleration–deceleration, as in a motor vehicle crash, can cause strains. The most common sites for a muscle strain are the lower back and cervical regions of the spine. The manifestations of a strain include pain, limited motion, muscle spasms, swelling and possible muscle weakness. Severe strains that partially or completely tear the muscle or tendon are painful and disabling.

A **sprain** is a stretch and/or tear of one or more ligaments surrounding a joint. Forces going in opposite directions cause the ligament to overstretch and/or tear. The ligaments may be partially or completely torn. Although any joint may be involved, sprains of the ankle and knee are most common. Manifestations include loss of the ability to move or use the joint, a feeling of a 'pop' or tear, discolouration, pain and rapid swelling. Motion increases the joint pain. The intensity of the manifestations depends on the severity of the sprain. A comparison of sprains and strains is presented in Box 38.1.

INTERPROFESSIONAL CARE

The goal of the initial stage of treating soft tissue trauma is to reduce swelling and pain. People should follow a regimen of rest, ice, compression and elevation (RICE) for the first 24 to 48 hours (see Table 38.1 for RICE therapy). Severe sprains may require surgical repair. Ankle sprains may be immobilised with an air cast, with no limitations on weight bearing. A knee injury often requires a knee immobiliser, such as a knee brace (e.g. Zimmer brace). If an upper extremity is injured, a sling is provided. Physical therapy may be recommended for rehabilitation. Time required for healing depends on the severity of the injury; for example, a mild ankle sprain may require up to 3 to 6 weeks

BOX 38.1 Comparison of sprains and strains

Sprain
- Defined as an injury to a ligament that results from a twisting motion.
- Can cause joint instability.
- Pain, oedema and swelling are present.
- Motion increases the joint pain.

Strain
- Defined as a microscopic tear in the muscle.
- Sharp or dull pain is present.
- Pain increases with isometric contraction of the muscle.
- Swelling and local tenderness are present.

TABLE 38.1 RICE therapy for musculoskeletal injuries

ACTION	HEALTH EDUCATION FOR THE PERSON AND FAMILY
Rest	• Decrease regular activities of daily living and exercise as needed. • If advised by your healthcare provider, do not put weight on the injured area for 48 hours. • Crutches may help if you can't put weight on an ankle or knee. • If you use a cane or crutch for an ankle injury, use it on the uninjured side so you can lean away from and relieve weight on the injured ankle.
Ice	• Apply an ice pack to the injured area for 20 minutes at a time, four to eight times a day. • An ice bag, cold pack, plastic bag filled with ice or a bag of frozen peas may be used. • Do not apply the ice pack for longer than 20 minutes to avoid cold injury and frostbite.
Compression	• Compression often helps reduce swelling. The kind you use will depend on the recommendation of your healthcare provider. • Examples of compression bandages include special boots, air casts and splints.
Elevation	• Keep the injured extremity elevated on a pillow above heart level, to help reduce swelling and pain.

of rehabilitation, whereas a severe sprain may require up to 8 to 12 months to return to full activities (National Institute of Arthritis and Musculoskeletal and Skin Diseases, 2015).

When soft tissue trauma is suspected, x-rays are taken to rule out soft tissue injury and magnetic resonance imaging (MRI) may be done if further assessment is necessary. Medications used to treat soft tissue trauma include non-steroidal anti-inflammatory drugs (NSAIDs) and analgesics.

Nursing care

The nursing care of each person is individualised. A strain or sprain may not be as devastating to a person with a desk job as it would be to a professional athlete; therefore, the nurse should determine what the injury means to the particular person.

Nursing diagnoses and interventions

Nursing diagnoses focus on providing information about self-care to decrease pain and return physical mobility to pre-injury levels.

Acute pain

The pain that results from soft tissue trauma is due primarily to the injury to the muscle or ligament and secondarily to bleeding and oedema at the injury site.

- Teach the person to use RICE (rest, ice, compression, elevation) therapy to care for the injury. *The interventions included in RICE therapy allow the injured muscle, ligament or tendon to heal (rest), cause vasoconstriction and reduce pain (ice), decrease oedema formation and pain (compression), and promote venous return to decrease oedema and pain (elevation).*

Impaired physical mobility

Pain causes the person to avoid using or bearing weight on the injured extremity. Always observe the person's use of assistive devices; if the device is inappropriate, the person can face a greater risk of falling. Also consider that the device may be appropriate but the person may not be using it correctly or safely. As a person ages, muscle mass in the upper extremities declines. As a result, the older person with a sprained ankle may not be able to use crutches because crutches require that the person distribute body weight along the upper extremities. Older people may therefore find a walker more useful.

- Teach the correct use of crutches, walkers, canes or slings if prescribed. *Use of the correct technique increases safety and encourages use of these devices.*
- Encourage follow-up care. *Severe sprains may require further evaluation to determine if surgical intervention is indicated.*

THE PERSON WITH A JOINT DISLOCATION

A **dislocation** is an injury of a joint in which the ends of bones are forced from their normal position. Dislocations usually follow trauma such as a fall or blow, with the bone ends displaced or separated from their normal position in the joint capsule. They commonly are seen in people who take part in contact sports such as football or from falls during activities such as skiing. Although dislocations may occur in any joint, they occur most frequently in the shoulder and acromioclavicular joints. Dislocations may also result from a disease such as rheumatoid arthritis. A **subluxation** is a partial dislocation in which the bone ends are still partially in contact with each other.

Pathophysiology

Dislocations may be congenital, traumatic or pathological. Congenital dislocations are present at birth and are seen in the hip and knee. Traumatic dislocations result from falls, blows or rotational injuries. Pathological dislocations result from disease of the joint, including infection, rheumatoid arthritis, paralysis and neuromuscular diseases.

Manifestations

The manifestations of a dislocation include pain, deformity and limited motion.

INTERPROFESSIONAL CARE

Care of the person with a dislocation focuses on relieving pain, correcting the dislocation and preventing complications. The dislocation is diagnosed by physical examination and x-rays. The joint is most often reduced (bone ends realigned) by means of manual traction.

Treatment of a shoulder joint dislocation depends on the severity of the dislocation. Reduction of shoulder dislocations may be undertaken in the emergency department or on occasions in the operating theatre. Immobilisation is no longer recommended and only the most severe dislocations are surgically reduced. A dislocated hip requires immediate reduction in the emergency room under sedation to prevent necrosis of the femoral head and injury to the sciatic and femoral nerves. After reduction, the person is placed on bed rest. In some cases, traction is needed for several weeks. If a hip dislocation is accompanied by a fracture, the person will undergo surgery to increase mobility, decrease complications and rapidly stabilise the joint.

Children, generally between the ages of 1 and 4 years, often have common injuries such as a pulled elbow. This is a result of the radius slipping out of its normal position at the elbow joint. It is usually caused by a sudden yank or pull on the child's lower arm or wrist (e.g. when a child is being lifted up). The child presents as distressed and is unable to use the arm, with the elbow in the extension and the forearm in the pronation position. This can be reduced with manipulation of the elbow (Royal Children's Hospital Melbourne, 2015a).

Nursing care

Nursing care of the person with a dislocation or subluxation is individualised to the cause of injury, the type of dislocation and the age of the person. It is important to teach people to seek immediate medical attention, to splint the joint to prevent further damage and to put ice on the injured joint (Mayo Clinic, 2015). Assessment of the affected limb is required to observe for changes in movement, sensation, colour, warmth and increased pain. These changes need to be reported and documented.

Nursing diagnoses and interventions

Nursing diagnoses focus on relieving pain and preventing complications.

Risk of injury

The person with a dislocation requires frequent assessments to ensure that neurovascular compromise does not develop.

- Monitor neurovascular status by assessing the '5 Ps': pain, pulses, pallor, paralysis and paraesthesia. *Neurovascular compromise is indicated by increased pain, decreased or absent pulses, pale skin, inability to move a body part or extremity, and changes in sensation (such as 'pins and needles' sensations or loss of sense of sharp/dull touch).*
- Maintain immobilisation after reduction. *Immobilisation prevents the joint from dislocating again.*

Community-based care

Joint dislocations often tend to be recurring injuries for people actively participating in contact sports and other vigorous physical activities. Prolonged immobilisation (for several weeks after the injury) and aggressive rehabilitation following the initial dislocation can reduce the risk of recurrent dislocation. The following topics should be addressed in preparing the person for community-based care:

- importance of complying with the prescribed length of immobilisation
- skin care and ways to prevent skin-to-skin contact, particularly in the axillary area
- prescribed rehabilitation exercises that will strengthen muscles and other supportive structures in the shoulder, decreasing the risk of future dislocations
- alternatives to activities that precipitate recurrent dislocations
- instructions or referrals to physical therapy if needed for further teaching about using assistive devices
- referrals to physical and occupational therapy and community-based services as needed.

TRAUMATIC INJURIES OF BONES

THE PERSON WITH A FRACTURE

A **fracture** is any break in the continuity of a bone. Fractures vary in severity according to the location and the type of fracture. Although fractures occur in all age groups, they are more common in people who have sustained trauma and in older people.

Pathophysiology

Any of the 206 bones in the body can be fractured. A fracture occurs when the bone is subjected to more kinetic energy than it can absorb. Fractures may result from a direct blow, a crushing force (compression), a sudden twisting motion (torsion), a severe muscle contraction or disease that has weakened the bone (called a *stress* or *pathological fracture*). Two basic mechanisms produce fractures: direct force and indirect force. With direct force, the kinetic energy is applied at or near the site of the fracture. The bone cannot withstand the force. With indirect force, the kinetic energy is transmitted from the point of impact to a site where the bone is weaker. The fracture occurs at the weaker point.

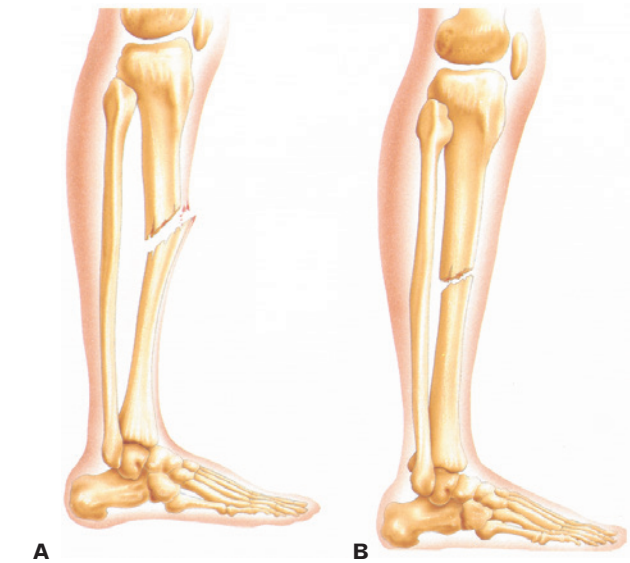

FIGURE 38.1 ■ *A*, An open fracture. *B*, A closed fracture

Fractures in adults are classified in the following ways:

- If the skin is intact, the fracture is considered a *closed* (*simple*) *fracture*. If the skin integrity is interrupted, the fracture is considered an *open* (*compound*) *fracture* (see Figure 38.1). An open fracture allows bacteria to enter the injured area and increases the risk of complications.
- The fracture line may be *oblique* (at an angle to the bone) or *spiral* (curved around the bone). An *avulsed* fracture occurs when the fracture pulls bone and other tissues away from the point of attachment. It may also be described as *comminuted* (the bone breaks in many pieces), *compressed* (the bone is crushed), *impacted* (the broken bone ends are forced into each other) or *depressed* (the broken bone is forced inwards) (see Figure 38.2).
- *Complete fractures* involve the entire width of the bone, whereas incomplete fractures involve only a part of the width of the bone.
- A *stable* (non-displaced) *fracture* is one in which the bones maintain their anatomical alignment. An *unstable* (displaced) *fracture* occurs when the bones move out of correct anatomical alignment. If a fracture is displaced, immediate interventions are required to prevent further damage to soft tissue, muscle and bone.

Fractures may also be classified by point of reference on the bone, such as midshaft, middle third and distal third. The point of reference may also be specific, such as intra-articular or diaphyseal.

Fracture healing

Regardless of classification or type, fracture healing progresses over three phases: the inflammatory phase, the reparative phase and the remodelling phase (see 'Pathophysiology illustrated' below). The bleeding and inflammation that develop at the site of the fracture initiate the inflammatory phase. A haematoma forms between the fractured bone ends and around the bone surfaces. The osteocytes at the bone ends die as the haematoma clots, obstructing blood flow and depriving them of oxygen and nutrients. Necrosis of the cells heightens the inflammatory response, which in turn leads to vasodilation and oedema. In addition, fibroblasts, lymphocytes, macrophages and even osteoblasts from the bone migrate to the fracture site. Fibroblasts form a fibrin meshwork and promote the growth of granulation tissue and capillary buds. The lymphocytes and macrophages wall off the area, localising and containing the inflammation. The capillary buds invade the fracture site and supply a source of nutrients to promote the formation of collagen. The collagen allows calcium to be deposited.

Once calcium is deposited, a callus begins to form. In this reparative phase, osteoblasts promote the formation of new bone and osteoclasts destroy dead bone and assist in the

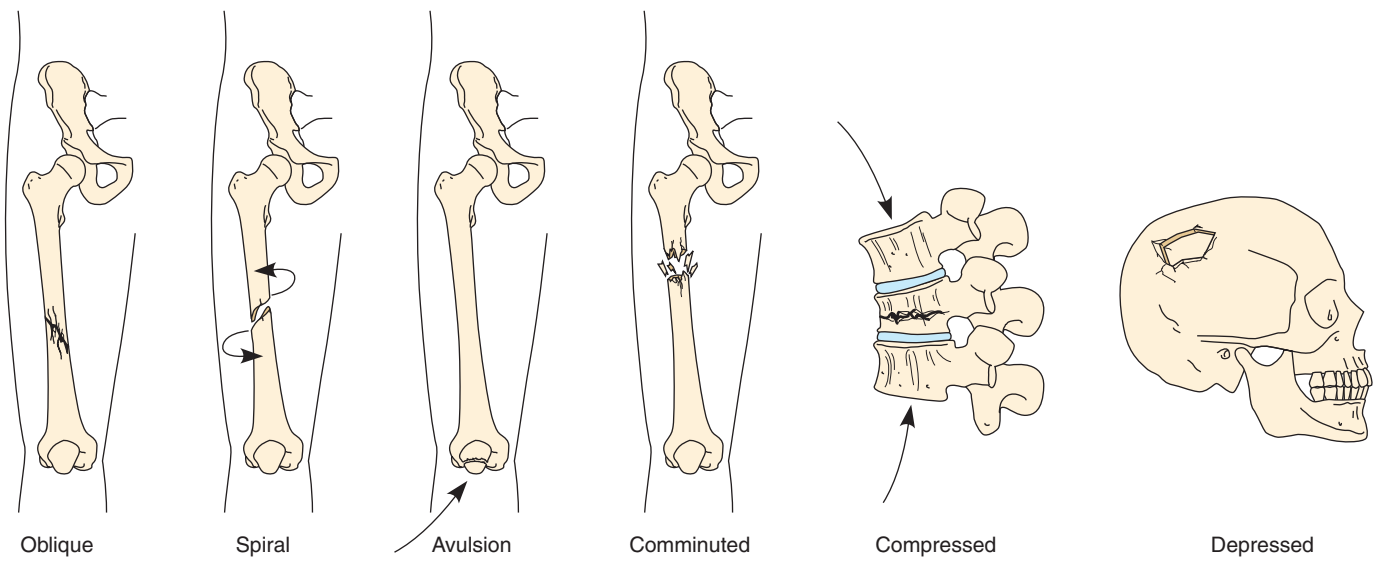

FIGURE 38.2 ■ Types of fractures

synthesis of new bone. Collagen formation and calcium deposition continue. During the remodelling phase, excess callus is removed and new bone is laid down along the fracture line. Eventually, the fracture site is calcified and the bone is reunited.

The age, physical condition of the person and the type of fracture sustained influence the healing of fractures. Other factors influence bone healing either positively or negatively and may be grouped according to their local or systemic influence (see Box 38.2). Healing time varies with the individual. An uncomplicated fracture of the arm or foot can heal in 6 to 8 weeks. A fractured vertebra will take at least 12 weeks to heal. Healing of a fractured hip may take from 12 to 16 weeks.

Manifestations

Fractures are often accompanied by soft tissue injuries that involve muscles, arteries, veins, nerves or skin. The degree of soft tissue involvement depends on the amount of energy or force transmitted to the area. Fracture manifestations and their causes are outlined in the 'Manifestations' box below.

Complications

Complications of musculoskeletal trauma are associated with pressure from oedema and haemorrhage, development of fat emboli, deep venous thrombosis, infection, loss of skeletal integrity or involvement of nerve fibres. Bone fragments may also result in further injury or complications.

BOX 38.2 Factors influencing bone healing

Positive factors

Local:

- Immobilisation
- Timely correction of displacement
- Application of ice
- Electrical stimulation

Systemic:

- Adequate amounts of growth hormone, vitamin D and calcium
- Adequate blood supply
- Absence of infection or diseases
- Younger age
- Moderate activity level prior to injury

Negative factors

Local:

- Delay in correction of displacement
- Open fracture (increases risk of infection)
- Presence of foreign body at fracture site

Systemic:

- Immunocompromised status
- Decreased circulation (as in diabetes or peripheral vascular disease)
- Malnutrition
- Osteoporosis
- Advanced age

Compartment syndrome

A compartment is a space enclosed by a fibrous membrane, or fascia. The fascia lines the compartment within the limbs and is non-expandable. Compartments within the limbs may enclose and support bones, nerves and blood vessels. **Compartment syndrome** occurs when excess pressure in a limited space constricts the structures within a compartment, reducing circulation to muscles and nerves. Acute compartment syndrome may result from haemorrhage and oedema within the compartment following a fracture or from a crush injury, or from external compression of the limb by a cast that is too tight. Increased pressure within the confined space of the compartment results in entrapment of nerves, blood vessels and muscles.

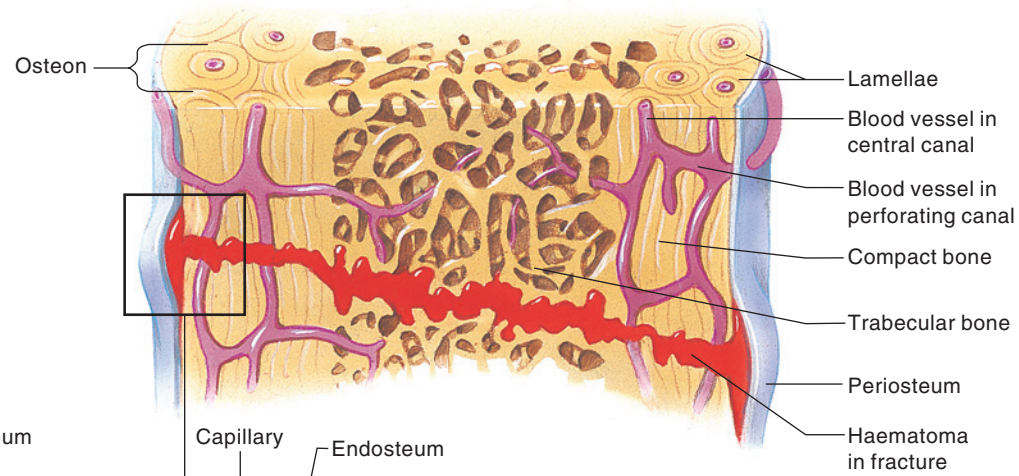
Entrapment of blood vessels limits tissue perfusion, beginning a cycle of events that may result in the loss of the limb. Inadequate oxygen supply causes cellular acidosis, which intensifies as cellular energy requirements are met through anaerobic metabolism. The capillaries inside the compartment dilate in an attempt to increase the supply of blood and oxygen. Additional blood and oxygen are not available and plasma proteins leak out into the interstitial tissues. The interstitial tissue then pulls fluid in to balance the protein load. As a result, oedema within the compartment increases. The oedema causes further compression of the vascular network and the cycle continues. Uninterrupted, this cycle threatens the person's limb and increases the risk of sepsis. Compartment syndrome usually develops within the first 48 hours of injury, when oedema is at its peak. Manifestations of compartment syndrome are listed in the box below. It is important to note that arterial pulses may remain normal, even when pressure within the compartment is high enough to significantly impair tissue perfusion.

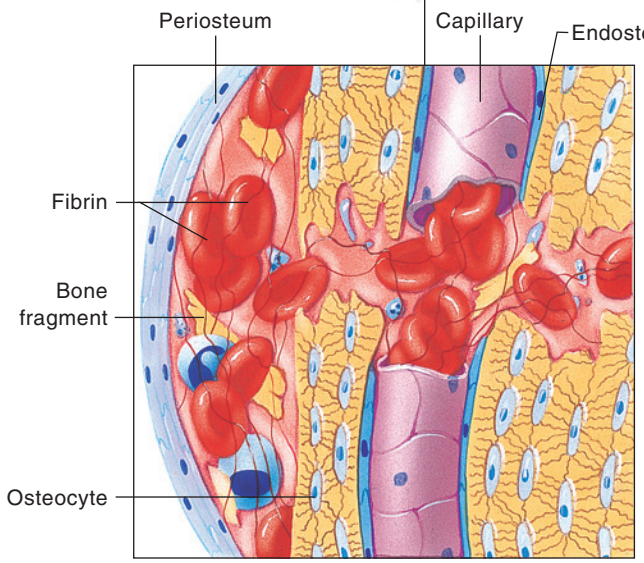
If compartment syndrome develops, interventions to alleviate pressure will be implemented; these may include removal of a tightly fitting cast. If the pressure is internal, a *fasciotomy*,

MANIFESTATIONS Fracture

MANIFESTATION	CAUSE
Deformity	Abnormal position of bones secondary to fracture and muscles pulling on fractured bone
Swelling	Oedema from localisation of serous fluid and bleeding
Pain/tenderness	Muscle spasm, direct tissue trauma, nerve pressure, movement of fractured bone
Numbness	Nerve damage or nerve entrapment
Guarding	Pain
Crepitus	Grating of bones or entrance of air in an open fracture. *Note:* Do not manipulate the extremity to elicit crepitus; doing so may cause additional damage.
Hypovolaemic shock	Blood loss or associated injuries
Muscle spasms	Muscle contraction near the fracture
Ecchymosis	Extravasation of blood into the subcutaneous tissue

Bone healing





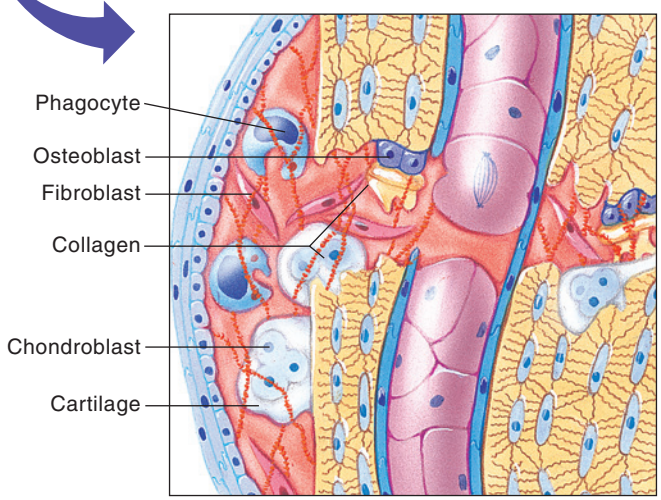
1. Bone injury

When a bone fractures, blood vessels within the bone and surrounding soft tissues tear and begin to bleed, forming a haematoma. Necrotic bone tissue adjacent to the fracture causes an intense inflammatory response characterised by vasodilation, exudate formation and white cell migration to the fracture site.

2. Fibrocartilaginous callus formation

Clotting factors within the haematoma form a fibrin meshwork. Within 48 hours, fibroblasts and new capillaries growing into the fracture form granulation tissue that gradually replaces the haematoma. Phagocytes begin to remove cell debris.

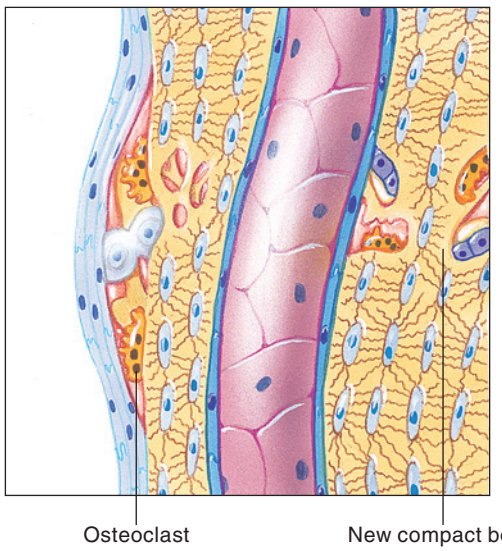
Osteoblasts, bone-forming cells, proliferate and migrate into the fracture site, forming a fibrocartilaginous callus. The osteoblasts build a web of collagen fibres from both sides of the fracture site that eventually unites to connect bone fragments, thus splinting the bone. Chondroblasts lay down patches of cartilage that provide a base for bone growth.

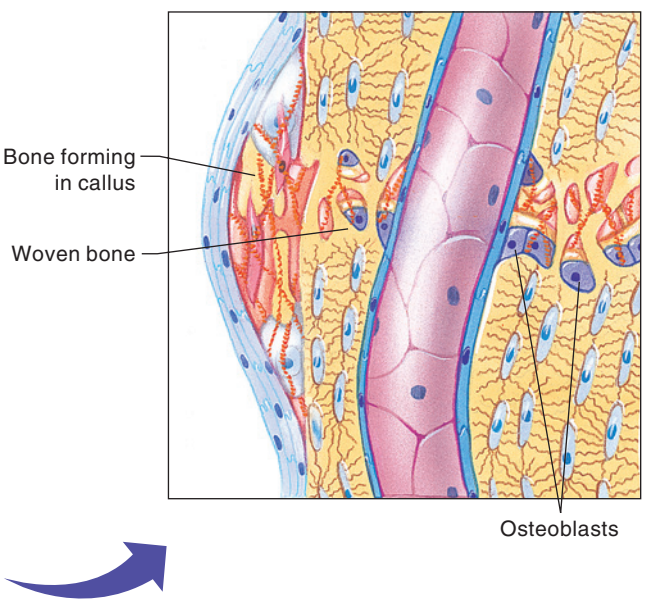


4. Bone remodelling

Osteoblasts continue to form new woven bone, which is in turn organised into the lamellar structures of compact bone. Osteoclasts resorb excess callus as it is replaced by mature bone.

As the bone heals and is subjected to the mechanical stress of everyday use, osteoblasts and osteoclasts respond by remodelling the repair site along the lines of force. This ensures that the repaired section of bone eventually resembles the structure of the uninjured part.





3. Bony callus formation

Osteoblasts continue to proliferate and synthesise collagen fibres and bone matrix, which are gradually mineralised with calcium and mineral salts to form a spongy mass of woven bone. The trabeculae of woven bone bridge the fracture. Osteoclasts migrate to the repair site and begin removing excess bone in the callus. Bony callus formation usually continues for 2 to 3 months.

a surgical intervention in which muscle fascia is cut to relieve pressure within the compartment, may be necessary. After a fasciotomy, the incision is left open and passive ROM exercises are performed on the extremity.

Volkmann's contracture, a common complication of elbow fractures, can result from unresolved compartment syndrome. Arterial blood flow decreases, leading to ischaemia, degeneration and contracture of the muscle. Arm mobility is impaired and the person is unable to completely extend the arm.

Fat embolism syndrome

Fat emboli occur when fat globules lodge in the pulmonary vascular bed or peripheral circulation. **Fat embolism syndrome (FES)** is characterised by neurological dysfunction, pulmonary insufficiency and a petechial rash on the chest, axilla and upper arms. Long bone fractures and other major trauma are the principal risk factors for fat emboli; hip replacement surgery also poses a risk of FES.

When a bone is fractured, pressure within the bone marrow rises and exceeds capillary pressure; as a result, fat globules leave the bone marrow and enter the bloodstream. Another contributing factor may be the stress-induced release of catecholamine, which causes the rapid mobilisation of fatty acids. Once the fat globules are released, they combine with platelets and travel to the brain, lungs, kidneys and other organs, occluding small blood vessels and causing tissue ischaemia.

Manifestations usually develop within a few hours to a week after injury. The manifestations result from the occlusion of the blood supply and the presence of fatty acids. Altered cerebral blood flow causes confusion and changes in level of consciousness. Pulmonary circulation may be disrupted and free fatty acids damage the alveolar–capillary membrane. Pulmonary oedema, impaired surfactant production and atelectasis can result in significant respiratory insufficiency and manifestations of acute respiratory distress syndrome (see Chapter 36). Fat droplets activate the clotting cascade, causing thrombocytopenia. Petechiae (pin-sized purplish areas from bleeding under the skin) appearing on the skin, buccal membranes and conjunctival sacs are thought to result from either microvascular clotting or the accompanying thrombocytopenia.

MANIFESTATIONS Compartment syndrome

EARLY MANIFESTATIONS
- Pain
- Normal or decreased peripheral pulse

LATER MANIFESTATIONS
- Cyanosis
- Tingling, loss of sensation (paraesthesias)
- Weakness (paresis)
- Severe pain, especially when the extremity is passively flexed
- Eventual renal failure (due to release of myoglobin into the bloodstream; myoglobin molecule is too large for effective filtration and excretion by kidney, and renal failure results)

Early stabilisation of long bone fractures is preventive for FES. Prompt identification and treatment of the syndrome are necessary to maintain adequate pulmonary function. In severe cases, the person may require intubation and mechanical ventilation to prevent hypoxaemia. Fluid balance is closely monitored. Corticosteroids may be administered to decrease the inflammatory response of lung tissues, stabilise lipid membranes and reduce bronchospasm (Porth & Matfin, 2014).

Deep venous thrombosis

A *deep venous thrombosis (DVT)* is a blood clot that forms along the intimal lining of a large vein. Three precursors linked to DVT formation are: (1) venous stasis or decreased blood flow; (2) injury to blood vessel walls; and (3) altered blood coagulation (see Table 38.2). Any or all of these precursors can cause a DVT to form. Damage to the lining of the vein causes the platelets to aggregate or clump together, forming the thrombus. Fibrin, white blood cells (WBCs) and red blood cells (RBCs) begin to cling to the thrombus and a tail forms. This tail or the entire thrombus may dislodge and move to the brain, lungs or heart. Five per cent of DVTs dislodge and enter the pulmonary circulation to form a pulmonary embolus. If the thrombus remains in the vein, venous insufficiency may result from scarring and valve damage.

If a DVT is present, there may be swelling, leg pain, tenderness or cramping. Not all people experience manifestations, however. For this reason diagnostic tests, such as a venogram or Doppler ultrasound of lower extremities, may be required. A venogram requires intravenous administration of dye in the radiology department, whereas a Doppler ultrasound study is non-invasive and can be performed at the person's bedside. Doppler ultrasonography uses sound waves to form an image on a computer screen.

The best treatment for DVT is prevention. Early immobilisation of the fracture and early ambulation of the person are imperative. The extremity should be elevated above the level of the heart. Frequent assessments of the injured extremity may lead to early recognition of DVT and prevent the formation of pulmonary embolus. Prophylactic anticoagulant administration is beneficial. Anti-embolism stockings and compression boots increase venous return and prevent stasis of blood. Constrictive clothing should be avoided.

The diagnosis of DVT requires rapid intervention. Fibrinolytic agents, which dissolve the clot, may be administered.

TABLE 38.2 Precursors of deep venous thrombosis

PRECURSOR	IMPLICATIONS FOR FRACTURES
Decreased blood flow	Common in people with a fracture who are immobilised and less active. Bed rest alone can decrease venous flow by 50%.
Injury to blood vessel wall	May occur as a direct result of the force that caused the fracture or from surgical manipulation.
Altered blood coagulation	May result from active blood loss. The body's attempt to maintain homeostasis leads to increased production of platelets and clotting factor

Heparin may be administered intravenously or subcutaneously, to prevent more clots from forming. Prophylactic warfarin, rivaroxaban or low-molecular-weight heparin (e.g. enoxaparin (Clexane)) may also be administered to prevent DVT (Hirsch et al., 2008; NPS MedicineWise, 2013). A vena cava filter may be placed to prevent the existing clot from entering the pulmonary circulation and forming a pulmonary embolus. In extreme cases in which anticoagulation therapy is contraindicated, a thrombectomy (surgical removal of the clot) may be necessary. See Chapter 31 for further discussion of DVT.

Infection

Infection is more likely to occur in an open fracture than a closed fracture, but any complication that decreases blood supply increases the risk of infection. Infection may result from contamination at the time of injury or during surgery. *Pseudomonas*, *Staphylococcus* or *Clostridium* organisms may invade the wound or bone. *Clostridium* infection is particularly serious because it may lead to severe gas gangrene and cellulitis, but any infection may delay healing and result in osteomyelitis—infection within the bone that can lead to tissue death and necrosis. (See Chapter 39 for a discussion of osteomyelitis.)

Delayed union and non-union

Delayed union is the prolonged healing of bones beyond the usual period. Many factors may inhibit bone healing, including poor nutrition, inadequate immobilisation, prolonged reduction time, infection, necrosis, age, immunosuppression and severe bone trauma resulting in multiple fragments. Delayed union is diagnosed by means of serial x-ray studies. It is important to note that x-ray findings may lag 1 to 2 weeks behind the healing process; for example, a person may be completely healed by week 13, but this fact may not be apparent on the x-ray until week 14.

Delayed union may lead to **non-union**, which can cause persistent pain and movement at the fracture site. Non-union may require surgical interventions, such as internal fixation and bone grafting. If infection is present, the bones are surgically debrided. Electrical stimulation of the fracture site may be as effective as bone grafting.

Reflex sympathetic dystrophy

Reflex sympathetic dystrophy may occur after musculoskeletal or nerve trauma. This term refers to a group of poorly understood post-traumatic conditions involving persistent pain, hyperaesthesias, swelling, changes in skin colour and texture, changes in temperature and decreased motion. Diagnosis is made by the person's history and physical examination. X-rays may demonstrate spotty osteoporosis and bone scans may reveal increased uptake of radionuclide. Treatment with a sympathetic nervous system blocking agent often alleviates the manifestations.

INTERPROFESSIONAL CARE

A fracture requires treatment to stabilise the fractured bone(s), maintain bone immobilisation, prevent complications and restore function. The diagnosis of a fracture is primarily based on physical assessments and x-rays.

Emergency care

Emergency care of the person with a fracture includes immobilising the fracture, maintaining tissue perfusion and preventing infection. In the case of serious trauma, normal body alignment must be maintained and may involve cervical immobilisation. Once the person is in a secure location, they are assessed for instability or deformity of the bone. If any deformity or instability is detected, the extremity is rapidly immobilised. Open wounds are covered with sterile dressings and bleeding may be controlled with a pressure dressing. The extremities are assessed for the presence of pulses, movement and sensation. The joints above and below the deformity are immobilised. Pulses, movement and sensation are re-evaluated after splinting.

The fracture is splinted to maintain normal anatomical alignment and prevent the fracture from dislocating. Splinting relieves pain and prevents further damage to the arteries, nerves and bones. Splinting can be accomplished with air splints. If equipment is not available, the limb may be secured to the body. For example, an arm may be secured to the torso with a sling or one leg may be strapped to the other leg.

Diagnosis

Diagnosis of a fracture begins with the history and initial assessment and usually is confirmed by radiographical tests. X-rays and bone scans are used to identify fractures (see Figure 38.3). Blood chemistry studies, full blood count (FBC), group and hold and coagulation studies may be used to assess blood loss, renal function, muscle breakdown and the risk of excessive bleeding or clotting. Diagnostic tests are described in Chapter 37.

Medications

Most people with a fracture require pharmacological interventions. The priority intervention focuses on relieving pain. In the case of multiple fractures or fractures of large bones, narcotics are administered initially. As healing progresses, the person begins to take oral medication for pain. Pain management for the person with a fracture is described in Box 38.3.

Stool softeners may be administered to decrease the risk of constipation secondary to narcotics and immobility. People who have sustained trauma are often placed on anti-ulcer medications or antacids. NSAIDs may be prescribed to decrease inflammation. Antibiotics may be administered prophylactically, particularly to people with open or complex fractures. Anticoagulants may be prescribed to prevent DVT.

Treatments

Fracture treatment may involve a closed reduction and the application of a cast, or may include one or more of the following: traction, casts, surgery and electrical bone stimulation.

TRACTION Muscle spasms usually accompany fractures and may pull bones out of alignment. Traction is the application of a straightening or pulling force to return the factured bones to or maintain them in normal anatomical position. Weights are applied to maintain the necessary force (see Figure 38.4). Traction is not used often in orthopaedic management due to the advancement of orthopaedic implant technologies and operative techniques. It may be used in the short term for the individual awaiting operative fixation.

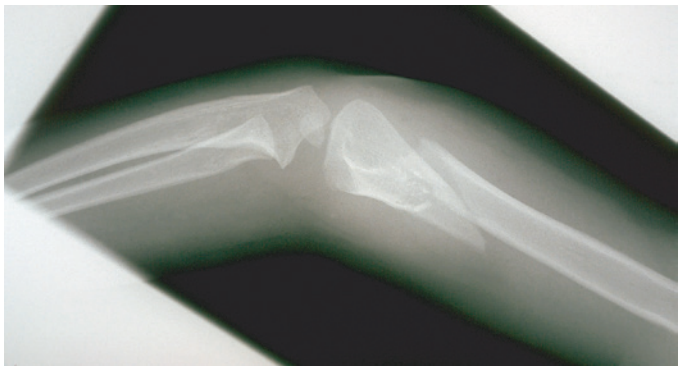


FIGURE 38.3 ■ X-ray of an oblique fracture of the femur

Source: © Charles Stewart and Associates.

Types of traction are as follows:

- In *manual traction*, the hand directly applies the pulling force.
- *Skin traction* (also called straight traction) is used to control muscle spasms and to immobilise a part of the body before surgery, with traction exerting its grabbing and pulling force through the person's skin. The most common type of skin traction is Buck's traction, in which traction tape or a foam boot is applied to the lower portion of a person's leg and a free-hanging weight is attached to the taped or booted area (see Figure 38.4A). Buck's traction is used to immobilise the leg before surgery to repair a fracture of the proximal femur. The advantage of skin traction is the relative ease of use and ability to maintain comfort. The disadvantage is that the weight required to maintain normal body alignment or fracture alignment cannot exceed the tolerance of the skin—about 13.2 kg per extremity. It is important to ensure that the weights remain hanging freely; they should never rest on the bed or the floor. The nurse may have to reposition the person or the weights if this occurs.
- *Balanced suspension traction* involves more than one force of pull. Several forces work in unison to raise and support the person's injured extremity off the bed and pull it in a straight line away from the body (see Figure 38.4B). The advantage of this type of traction is that it increases mobility without threatening joint continuity. The disadvantage is that the increased use of multiple weights makes the person more likely to slide down in the bed.
- *Skeletal traction* is the application of a pulling force through placement of pins into the bone (see Figure 38.4C). The person may receive a local, spinal or general anaesthetic, and the pins are inserted into the bone. This type of traction must be applied under sterile conditions because of the increased risk of infection. One or more pulling forces may be applied with skeletal traction. The advantage of this type of traction is that more weight can be used to maintain the proper anatomical alignment if necessary. The disadvantages include increased anxiety, increased risk of infection and increased discomfort. The weights used for skeletal traction are not removed by the nurse.

Nursing interventions for people in traction are described in Box 38.4.

CASTS

A cast is a rigid device applied to immobilise the injured bones and promote healing. The cast immobilises the joints above and below the fractured bone so that the bone will not move during healing. A fracture is first reduced manually (by hand) and a cast is then applied. Casts are applied on people who have relatively stable fractures.

BOX 38.3 Pain management in the person with a fracture

The person who has had musculoskeletal trauma experiences pain from many different causes:

- the interruption in the continuity of the bone itself
- damage to ligaments and tendons
- swelling of tissues around the trauma site
- muscle spasms
- tissue anoxia from swelling inside a cast, splint or the muscle fascia sheath
- haematoma formation
- pressure over bony prominences from casts or splints.

The pain is often severe and may be described as sharp, aching or burning. Carefully assess any complaint of pain; pain may be an indication of a serious complication, such as compartment syndrome, decreased tissue perfusion and neurovascular impairment, or pressure ulcers. Do not administer analgesics until the location, character and duration of pain have been carefully assessed. After the cause of the pain has been identified, the following nursing interventions may be implemented:

1. Administer prescribed analgesics, which may include NSAIDs and narcotic analgesics. For serious fractures or following orthopaedic surgery, patient-controlled analgesia (PCA) or epidural methods of providing pain relief may be used. If medications are used on an as-needed basis, tell the person to request the medication before the pain is severe; alternatively, offer the medications at regular intervals for the first 24 to 48 hours. Reassure the person that addiction does not result from taking medications to relieve fracture or surgical pain. Most people require only oral analgesics by the third or fourth day after orthopaedic surgery.
2. Elevate the involved extremity and apply cold (if prescribed) to help decrease swelling.
3. Monitor and drain the accumulated fluids in any drainage devices to ensure patency and to decrease the possibility of haematoma formation.
4. Encourage the person to wiggle fingers or toes on an extremity in a cast or traction to improve venous return and decrease oedema.
5. Assist the person to change positions to relieve pressure and use pillows to provide support.
6. Teach the person alternative methods of pain management, such as relaxation and guided imagery.
7. Notify the doctor of unrelieved pain, which may indicate a serious complication such as compartment syndrome or neurovascular impairment.

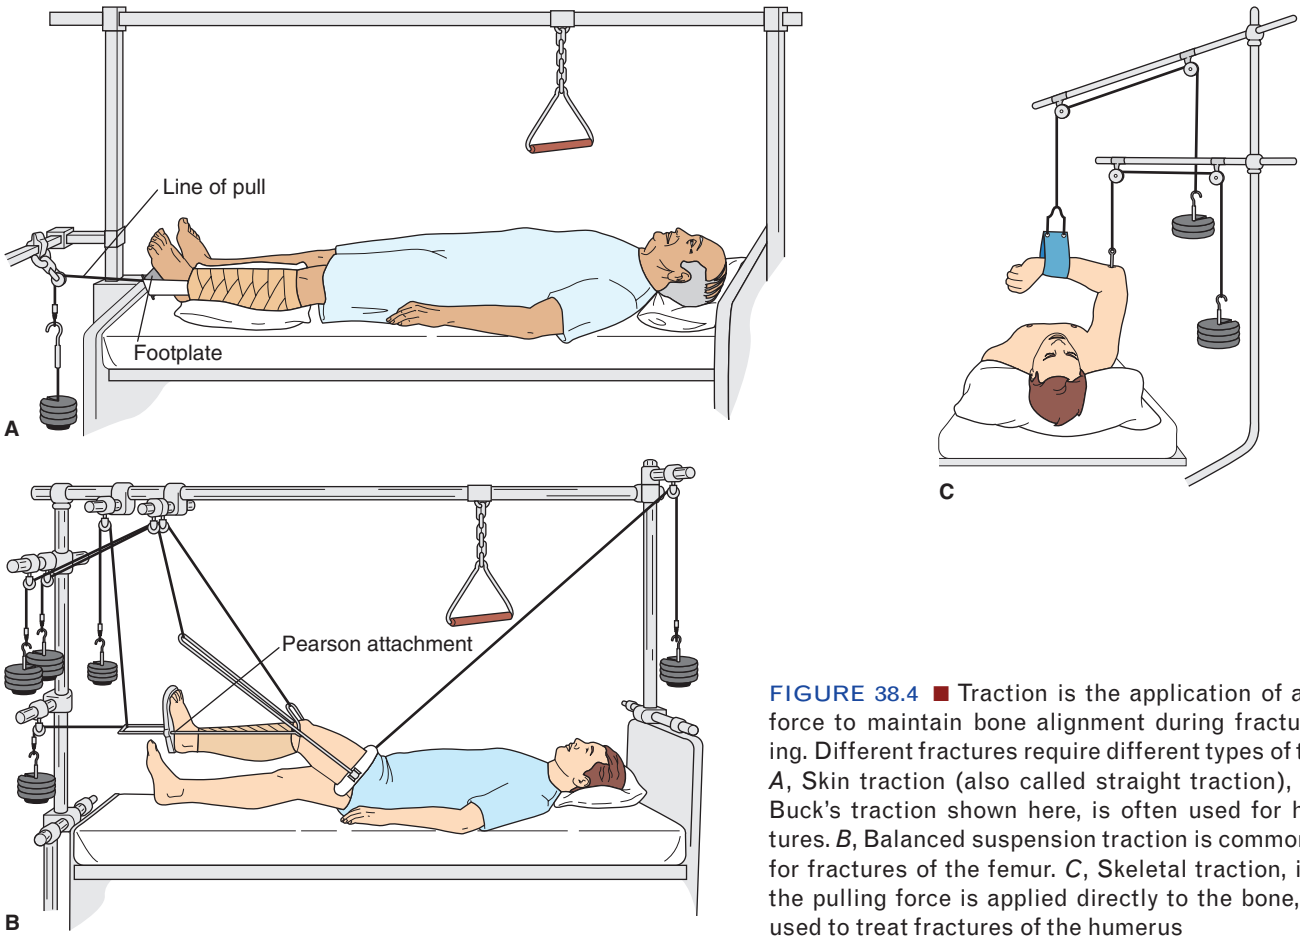

FIGURE 38.4 ■ Traction is the application of a pulling force to maintain bone alignment during fracture healing. Different fractures require different types of traction. *A*, Skin traction (also called straight traction), such as Buck's traction shown here, is often used for hip fractures. *B*, Balanced suspension traction is commonly used for fractures of the femur. *C*, Skeletal traction, in which the pulling force is applied directly to the bone, may be used to treat fractures of the humerus

The cast, which may be composed of plaster or fibreglass, is applied over a thin cushion of padding and moulded to the normal contour of the body. The cast must be allowed to dry before any pressure is applied to it; simply palpating a wet cast with the fingertips will leave dents that may cause pressure ulcers. A plaster cast may require up to 48 hours to dry, whereas a fibreglass cast dries in less than 1 hour. The type of cast applied is determined by the location of the fracture (see Figure 38.5). Nursing care of the person with a cast is discussed in the box below. During follow-up appointments,

BOX 38.4 Nursing interventions for people in traction

- In skeletal traction, never remove the weights.
- In skin traction, remove weights only when intermittent skin traction has been ordered to alleviate muscle spasm.
- For traction to be successful, countertraction is necessary. In most instances, the countertraction is the person's weight. Therefore, do not wedge the person's foot or place it flush with the footboard of the bed.
- Maintain the line of pull:
  a. Centre the person on the bed.
  b. Ensure that weights hang freely and do not touch the floor.
- Ensure that nothing is lying on or obstructing the ropes. Do not allow the knots at the end of the rope to come into contact with the pulley.
- If a problem is detected, assist in repositioning. The area of the fracture must be stabilised when the person is repositioned.
- In skin traction:
  a. Frequently assess skin for evidence of pressure, shearing or pending breakdown.
  b. Protect pressure sites with padding and protective dressings as indicated.
- In skeletal traction:
  a. Frequent skin assessments should include pin care per policy.
  b. Report signs of infection at pin sites, such as redness, drainage and increased tenderness.
  c. The person may require more frequent analgesic administration.
- Perform neurovascular assessments frequently.
- Assess for common complications of immobility, including formation of pressure ulcers, formation of renal calculi, deep venous thrombosis, pneumonia, paralytic ileus and loss of appetite.
- Teach the person and family about the type and purpose of the traction.

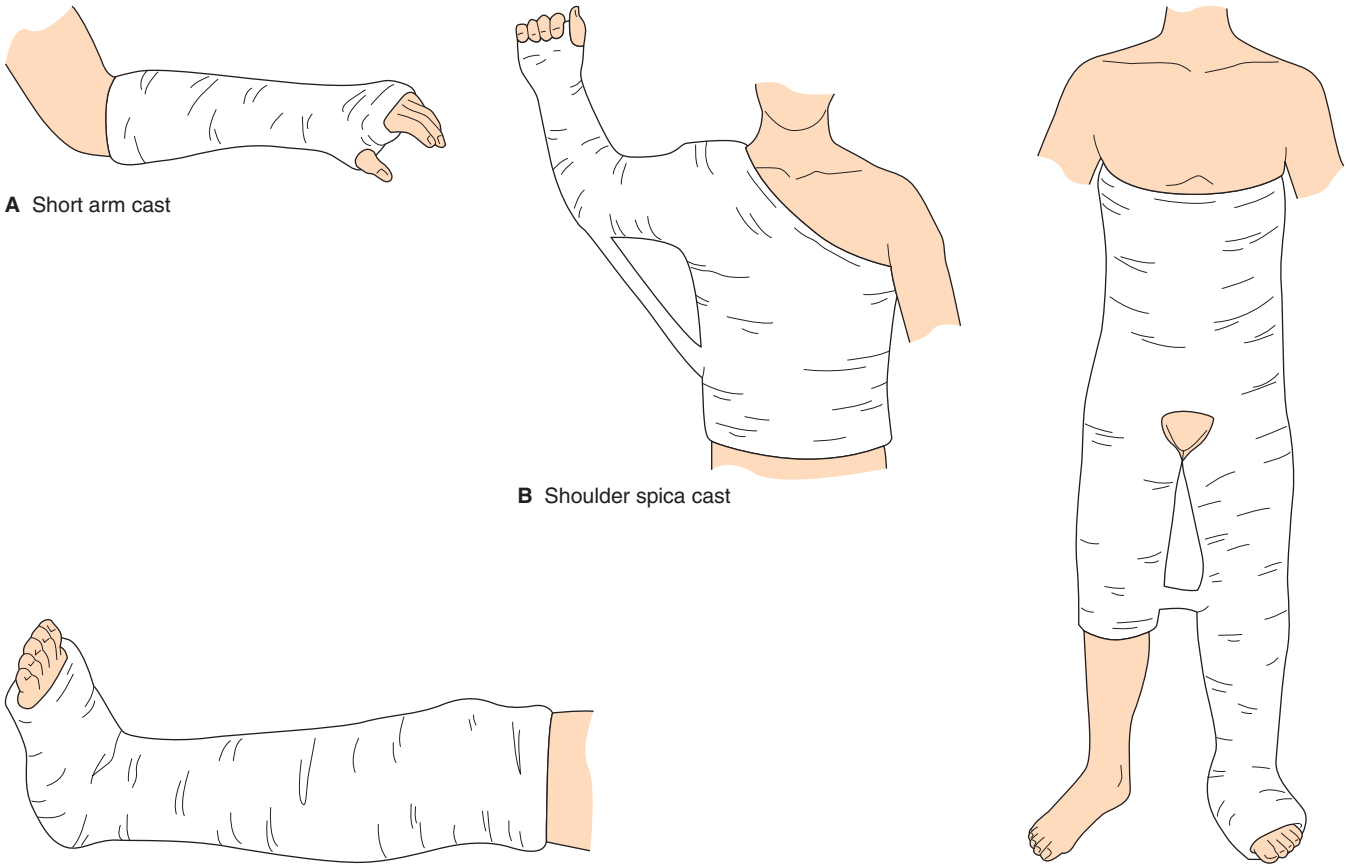

FIGURE 38.5 ■ Examples of types of casts used to immobilise fractures

the doctor may x-ray the bone to assess alignment and healing and possibly remove the cast for skin assessment.

SURGERY Surgery is indicated for a fracture that requires direct visualisation and repair, a fracture with common long-term complications or a fracture that is severely comminuted and threatens vascular supply.

The simplest form of surgery is done by external fixation with an external fixator device. An external fixator consists of a frame connected to pins that are inserted perpendicular to the long axis of the bone (see Figure 38.6). The number of pins inserted varies with the type and site of the fracture, but in all cases the same number of pins are inserted above and below the fracture line. The pins require care similar to that of skeletal traction pins. The person is monitored for infection, and frequent neurovascular assessment is performed. The fixator increases independence while maintaining immobilisation.

NURSING CARE OF THE PERSON with a cast

NURSING INTERVENTIONS

- Perform frequent neurovascular assessments.
- Palpate the cast for 'hot spots' that may indicate the presence of underlying infection.
- Report any drainage promptly.
- Assess the injured extremity for coolness, changes in colour, increased pain, increased swelling and/or loss of sensation.
- Use a blow dryer on the cool setting to relieve itching by blowing cool air into the cast.
- If a sling is used, it should distribute the weight of the cast evenly around the neck. Do not roll the sling; this can impair circulation to the neck.
- If crutches are used, arrange for a physiotherapist to teach correct crutch walking.
- When the cast is removed, an oscillating cast remover will be used. A guard prevents the cast remover from penetrating past the depth of the cast, so it will not cut the person. It is noisy and the person will feel vibration.

HEALTH EDUCATION FOR THE PERSON AND FAMILY

- Do not place any objects in the cast.
- If the cast is made of plaster, keep it dry.
- If the cast is made of fibreglass, dry it with a blow dryer on the cool setting if it becomes wet. Be aware that some padding is not waterproof and therefore will need to be checked prior to the person showering or swimming.

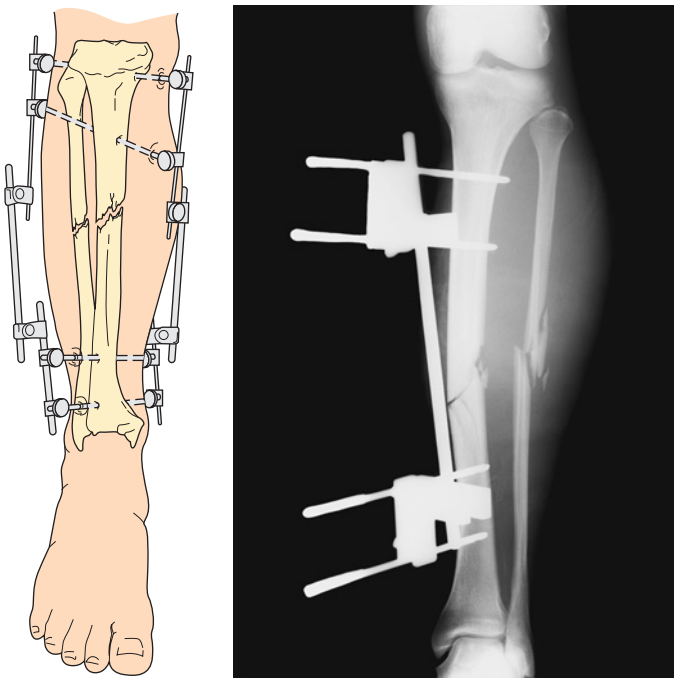

FIGURE 38.6 ■ In external fixation, pins are placed through the bone above and below the fracture site to immobilise the bone. External fixation rods hold the pins in place

Source: Image from SPL/Science Source.

Internal fixation can be accomplished through a surgical procedure called an *open reduction and internal fixation (ORIF)*. In this procedure, the fracture is reduced (placed in correct anatomical alignment) and nails, screws, plates or pins are inserted to hold the bones in place (see Figure 38.7). Open fractures of the arms and legs are most commonly repaired in this way. Hip fractures in older people are almost always repaired with ORIF to prevent complications and to allow early rehabilitation. Interventions for postoperative nursing care are presented in Box 38.5.

BOX 38.5 Nursing interventions for people with internal fixation

- Expect the person to have sutures and at least one drain (the type depends on the surgeon's choice).
- Perform neurovascular assessments frequently.
- Assess the following:
  a. wounds for drainage
  b. drainage device for the removal of serosanguineous fluid
  c. bowel sounds
  d. lung sounds.
- Administer medications, such as analgesics and antibiotics, per doctor's orders.
- In hip fractures, place an abductor pillow between the legs to prevent dislocation of the hip joint.
- Arrange for physical and occupational therapy, as ordered.
- Assist with weight-bearing program, if ordered.
- Encourage early mobilisation, coughing and deep breathing, as appropriate, to help prevent complications.

ELECTRICAL BONE STIMULATION Electrical bone stimulation is the application of an electrical current at the fracture site. It is a painless method of treating fractures that are not healing appropriately. The electrical stress increases the migration of osteoblasts and osteoclasts to the fracture site. Mineral deposition increases, promoting bone healing. Electrical bone stimulation can be accomplished invasively or non-invasively. In invasive stimulation, the surgeon inserts a cathode and a lead wire at the fracture site. The lead wire is attached to an internal or external generator, which delivers electricity through the lead wire to the cathode 24 hours a day. In non-invasive inductive stimulation, a treatment coil encircles the cast or skin directly over the fracture site. The coil is attached to an external generator that runs on batteries. The electricity goes through the skin to the fracture site. The time period for external stimulation can vary from 3 to 10 hours per day. The person may be taught to self-administer the non-invasive electrical stimulation. Electrical

bone stimulation is contraindicated in the presence of infection and for upper extremities if the person has a pacemaker.

Fractures of specific bones or bony areas

Causes, manifestations, complications, treatment and selected nursing interventions are described for the following fractures: skull, face, spine, clavicle, humerus, elbow, radius/ulna, wrist/hand, ribs, pelvis, femur, hip, tibia/fibula and ankle/foot.

Fracture of the skull

The skull may be fractured as a result of either a fall or a direct blow. The person must be assessed for neurological damage and any loss of consciousness (LOC) must be documented. A complete neurological assessment is conducted: pupillary reaction to light; movement and strength of all extremities; complaints of nausea and vomiting; LOC and orientation to person, place and time are noted. A displaced skull fracture, which is referred to as depressed, may press on the brain and cause neurological damage. Brain injuries related to skull fractures are discussed in Chapter 41.

Fracture of the face

Fracture of the facial bones may result from a direct blow. The person presents with haematomas, pain, oedema and bony deformity. Non-displaced fractures are monitored to ensure the airway is not compromised. The person is observed for any neurological deficits. Severely displaced or multiple facial fractures are treated with ORIF with wires or plates.

Nursing care focuses on maintaining the airway by helping the person clear secretions from the oropharynx. The nurse monitors the person's breathing for increased effort or tachypnoea and notifies the doctor immediately if these findings are noted. Pain is treated with analgesics and body image disturbances are addressed. If the person asks to see their face, the nurse should plan to stay with the person and answer questions while the person looks in a mirror.

Fracture of the spine

The spine can be injured in many ways, including sports injuries, falls and motor vehicle accidents. The spine can be fractured in the cervical, thoracic, lumbar or sacral area. The most severe complication of spine fracture is injury to the spinal cord (discussed in Chapter 42). A fracture to the vertebrae may cause the bones to become displaced and apply pressure on the spinal cord which may in turn result in permanent paralysis.

A non-displaced cervical spinal fracture may be treated with a cervical collar or a halo immobilising brace. The displaced cervical fracture is reduced by manual or skeletal traction and, eventually, application of a brace and/or surgical stabilisation of the bones with plates and screws. Immobilisation after a spinal fracture may last as long as 6 months.

Fracture of the clavicle

A fracture of the clavicle commonly results from a direct blow or a fall. The most common location is midclavicular. A person with a midclavicular fracture typically assumes a protective slumping position to immobilise the arm and prevent shoulder movement. A less common fracture occurs along the distal third of the clavicle. This type of fracture may be associated with ligament damage. Injuries to the clavicle may be associated with skull or cervical fractures. The fractured bone, if displaced, may lacerate the subclavian vessels and result in haemorrhage. The fractured bone may also puncture the lung, resulting in a pneumothorax. Malunion may occur at the fracture site and result in asymmetry of the clavicles. Injury to the brachial plexus may result in numbness and decreased movement of the arm on the affected side.

A deformity may be observed or palpated along the clavicle. Treatment focuses on immobilising the fractured bone in normal anatomical position by applying a clavicular strap, or a surgical repair may be necessary.

Fracture of the humerus

The exact location of the fracture, the presence of displacement and the results of the neurovascular examination determine the severity of a fracture of the humerus and the appropriate interventions. Treatment focuses on immobilising the fractured bone in normal anatomical position. Common complications of humeral fracture include nerve and ligament damage, frozen or stiff joints, and malunion. Early interventions may prevent permanent damage.

Fractures of the proximal humerus are common in older adults. A simple non-displaced fracture of the proximal humerus (near the humeral head) with a normal neurovascular assessment can be safely treated with immobilisation. A more complicated displaced fracture of the proximal humerus with bone fragmentation requires surgical intervention. The more severe the fracture and damage to soft tissue, the more likely it is that the range of motion (ROM) of the shoulder will be impaired. Rehabilitative measures focus on increasing ROM.

The humerus may also fracture along the shaft, usually as a direct result of trauma. If the humeral shaft fracture is simple and non-displaced, a hanging arm cast is applied. This cast maintains alignment of the fracture by using the pulling force of gravity; therefore, the person must be instructed not to rest the cast on anything to alleviate the weight. If the person is on bed rest, a hanging arm cast is not applied because the arm would not be able to hang freely. Instead, the fracture is immobilised with external skeletal traction. This traction places the injured arm in an upright position over the face and weights are hung off the distal portion of the humerus (see Figure 38.4C). Nursing interventions for people with fractures of the humerus are presented in Box 38.6.

Fracture of the elbow

The most common location of an elbow fracture is the distal humerus. Elbow fractures usually result from a fall or a direct blow to the elbow. The person guards the injured extremity, holding the arm rigidly in a flexed position or an extended position. Because the radius, ulna or humerus may be involved in the elbow fracture, all three bones must be visualised by x-ray.

Complications of an elbow fracture include nerve or artery damage and haemarthrosis, a collection of blood in the elbow joint. The most serious complication of an elbow fracture is Volkmann's contracture, which results from arterial occlusion and muscle ischaemia. The person complains of forearm pain, impaired sensation and loss of motor function. Rapid

BOX 38.6 Nursing interventions for people with fractures of the humerus

- Perform neurovascular assessments frequently.
- Administer prescribed medications to alleviate pain.
- Encourage exercises for people with a hanging cast:
  a. finger exercises: move each finger of the affected arm through complete range of motion
  b. pendulum shoulder exercises: dangle the affected arm at the side and move it forwards and backwards about 30 degrees in each direction.
- If the person is discharged, instruct the person and family in cast care and sling application, neurovascular assessments, exercises, prescribed pain medications and manifestations of complications.
- If the person is admitted to the hospital, provide preoperative teaching.

interventions are aimed at relieving pressure on the brachial artery and nerve, and preventing muscle atrophy.

Non-displaced elbow fractures are treated by immobilising the fracture with a posterior splint or cast. The displaced fracture is first reduced and then immobilised. Nursing interventions focus on alleviating pain, maintaining immobilisation and educating people in neurovascular assessments.

Fracture of the radius and/or ulna

Fractures of the radius and ulna may occur as a result of either indirect injury, such as twisting or pulling on the arm, or direct injury, such as that resulting from a fall. The usual treatment of radius fractures depends on the location. The proximal radial head may be fractured from a fall on an outstretched hand. Blood commonly collects in the elbow joint and must be aspirated. If the fracture is non-displaced, a sling is applied. If the fracture is displaced, surgical intervention is required. After surgical repair of a displaced fracture, the arm is splinted with a posterior plaster splint. The person avoids movement for the first week and then initiates movement gradually.

When both bones are broken, the fracture is usually displaced. The person complains of pain and inability to turn up the palm of the hand. A non-displaced fracture is casted for about 6 weeks and either a shorter cast or a brace is then applied for 6 more weeks. If the fracture is displaced, surgical intervention is performed. The doctor reduces the fracture and may insert pins or screws to keep the bones in alignment. After the surgery, a cast is applied and the person is encouraged to exercise the fingers.

Complications after a radius and/or ulnar fracture include compartment syndrome, delayed healing and decreased wrist and finger movement. After surgery, the person also has an increased risk of infection. Nursing interventions focus on alleviating pain, maintaining immobilisation and educating people in neurovascular assessments, the importance of elevation and the need to inform the doctor of changes in sensation or an increase in pain.

Fractures in the wrist and hand

Wrist fractures often result from a fall onto an outstretched hand or onto the back of the hand. A common type of wrist fracture is *Colles' fracture*, in which the distal radius fractures after a fall onto an outstretched hand. The person with a wrist fracture presents with a bony deformity, pain, numbness, weakness and decreased ROM of the fingers. The capillary refill and sensation of the hand must be assessed.

The hand is composed of many bones. Most commonly, the metacarpals and phalanges are involved in a hand fracture. The injuring mechanism in a hand fracture varies from striking an object with a closed fist to closing a hand in a door. The person presents with complaints of pain, oedema and decreased ROM.

Comparative x-rays may be obtained to compare left and right wrists and hands. Complications of wrist and hand fractures are compartment syndrome, nerve damage, ligament damage and delayed union. A wrist fracture is commonly treated with closed reduction, cast application and elevation of the injured extremity. A hand fracture is splinted and elevated.

Nursing interventions focus on alleviating pain and educating the person in neurovascular assessments, the importance of elevation and how to exercise the fingers to prevent stiffness. If the dominant hand is injured, the person will require assistance in performing activities of daily living (ADLs).

Fracture of the ribs

Rib fractures commonly result from blunt chest trauma. The location of the fracture and involvement of underlying organs determine the severity of the injury. Fractures of the first through to third ribs may result in injury to the subclavian artery or vein. Fractures of the lower ribs may result in spleen and liver injuries.

The person presents with a history of recent chest trauma. Typically, the person complains of pain along the lateral portion of the rib. Palpation of the rib reveals a bony deformity and increases pain. Deep inspiration also increases pain. The skin over the fracture site may be ecchymotic (bruised).

A complication of rib fractures is a flail chest, which results from the fracture of two or more adjacent ribs in two or more places and the formation of a free-floating segment that moves in the opposite direction to the rib cage. The bony instability impairs respirations. Treatment is aimed at stabilising the flail segment and supporting respirations. Other complications of rib fractures include pneumothorax and/or haemothorax. The fractured rib may pierce and injure the lung. The lower ribs may pierce the liver or spleen, resulting in intra-abdominal bleeding. Pneumonia may also develop from ineffective clearing of respiratory secretions.

A simple rib fracture is treated with pain medication and instructions for coughing, deep breathing and splinting. The person is also instructed to return to the emergency room if shortness of breath develops. Nursing interventions focus on alleviating pain and teaching the person about splinting. Because deep inspiration increases pain, people frequently avoid it. The person may be instructed to splint the injured rib with the hand or a pillow, and to take deep breaths and cough to decrease the chance of developing pneumonia and/or atelectasis. Incentive spirometry is encouraged.

Fracture of the pelvis

Pelvic fractures are often caused by trauma, such as a fall or a motor vehicle crash. The person with a pelvic fracture presents with pain in the back or hip area. A single fracture in the pelvis

is treated conservatively with bed rest on a firm mattress. Log-rolling increases person comfort. A pelvic fracture with two fracture sites is considered unstable and treated with surgery. An external fixator may be applied to stabilise the pelvis. In the person who is not stable for surgery, a pelvic sling may be used. The pelvic sling stabilises the pelvis and allows the person to move in bed with less pain. Common complications include hypovolaemia, spinal injury, bladder injury, urethral injury, kidney damage and gastrointestinal trauma.

Nursing care focuses on alleviating discomfort, maintaining immobilisation and preparing the person for surgery if necessary. The nurse monitors the person for increased heart rate, decreased blood pressure and decreasing haemoglobin levels. These findings may indicate impending hypovolaemia due to bleeding into the pelvis. Any blood in the urine should be reported to the doctor; this may indicate kidney, bladder or urethral damage.

Fracture of the shaft of the femur

A large amount of force, such as from motor vehicle crashes, falls or acts of violence, is required to fracture the shaft of the femur. People with femoral shaft fractures often have associated multiple traumas. A fracture of the femoral shaft is manifested by an oedematous, deformed, painful thigh. The person is unable to move the hip or knee. Initial assessment focuses on the circulation and sensation present in the affected extremity. Pedal pulses and capillary refill in the affected extremity are compared to the unaffected extremity. Complications of a femoral shaft fracture include hypovolaemia due to blood loss (which may be as great as 1.0 to 1.5 L), fat embolism, dislocation of the hip or knee, muscle atrophy and ligament damage.

Treatment of fractures of the shaft of the femur initially includes skeletal traction to separate the bony fragments and reduce and immobilise the fracture. Depending on the location and severity of the fracture, traction may be followed by either external or internal fixation. Strength in the affected extremity is maintained through gluteal and quadricep exercises. ROM exercises for unaffected extremities are critical in preparation for ambulation. Although full weight bearing is usually restricted until x-rays demonstrate bone union, the person may be allowed to carry out non-weight-bearing activities with an assistive device.

The nurse assesses pulses in the extremity and compares them bilaterally. Sensation is evaluated by asking whether the person can feel touch and discriminate sharp from dull objects. Nursing interventions include providing pain medication, providing reassurance and decreasing anxiety, and assisting with exercises of the lower legs, feet and toes.

Fracture of the hip

A hip fracture refers to a fracture of the femur at the head, neck or trochanteric regions (see Figure 38.8). Hip fractures are classified as intracapsular or extracapsular. *Intracapsular fractures* involve the head or neck of the femur; *extracapsular fractures* involve the trochanteric region. The majority of hip fractures involve the neck or trochanteric regions. The femoral head and neck lie within the joint capsule and are not covered in periosteum; thus, they do not have a large blood supply. Fractures at this location usually fragment, further decreasing blood supply and increasing the risk of non-union and avascular necrosis. The trochanteric region is covered in periosteum and therefore has more blood supply than the head or neck.

Hip fractures are a common clinical issue in the older adult in both Australia and New Zealand. It is predicted that by the age of 90, 33% of all women and 19% of all men will have had a hip fracture (Agency for Clinical Innovation (ACI), 2014). In adults of both countries, hip fractures are more prevalent in women than in men, due to osteoporosis. The mortality rate for people with hip fractures also increases by 25% (Australian Institute of Health and Welfare (AIHW), 2015). Hip fractures cause a decrease in mobility and independence. Factors contributing to falls include problems with gait and balance,

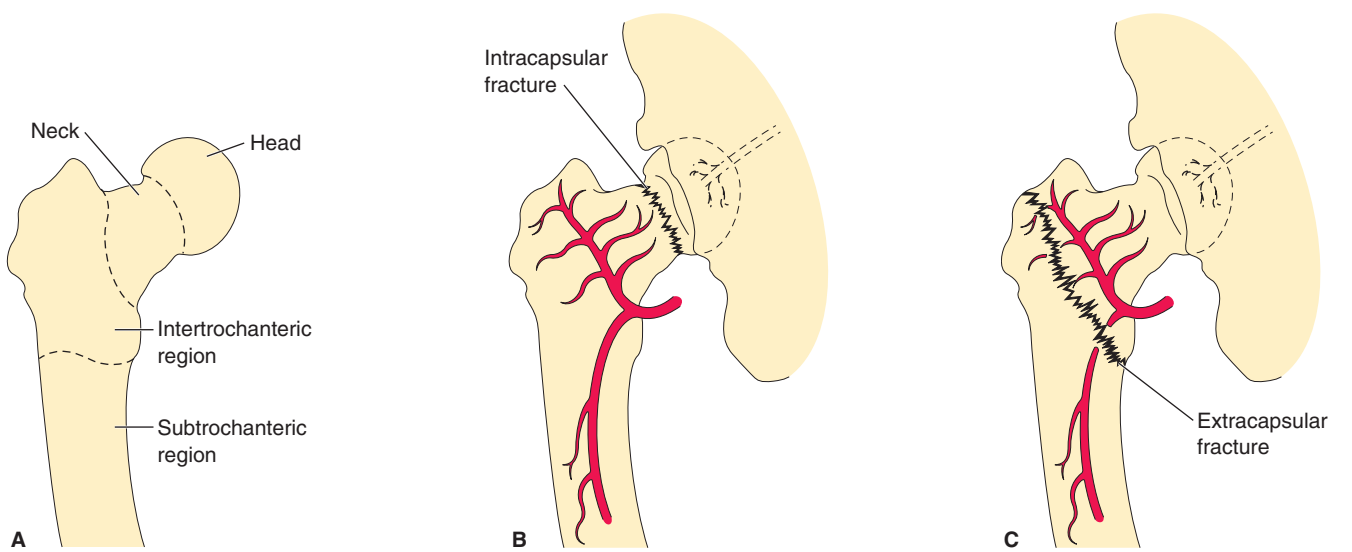

FIGURE 38.8 ■ Regions where hip fractures may occur: *A*, The head of the femur, the neck of the femur and the trochanteric regions of the femur. *B*, Intracapsular fractures occur across the head or neck of the femur. *C*, Extracapsular fractures occur across the trochanteric regions. Note how both intracapsular and extracapsular fractures disrupt the blood supply to the bone

neurological and musculoskeletal impairments, dementia, psychoactive medications and visual impairments. Modifiable risk factors, identified through research, include lower body weakness, problems with walking and balance, and taking four or more medications or any psychoactive medications.

Hip fractures occur in older adults as a result of decreases in bone mass and the increased tendency to fall. Whether the femur breaks spontaneously and causes the fall, or whether the fall causes the fracture, is not always clear; regardless of the cause of the fracture, rapid interventions are required to prevent bone necrosis. Assessment findings commonly associated with a hip fracture are pain, inability to walk and shortening and external rotation of the affected lower extremity. Rarely, the fracture dislocates posteriorly; if that occurs, the extremity may internally rotate. However, some people with a hip fracture have only vague pain in the buttocks, knees, thighs, groin or back, and their ability to walk is unaffected. If the fracture is not visible on x-ray, a bone scan or MRI may be done to confirm the presence of the fracture.

A hip fracture may be treated with traction to decrease muscle spasms, followed by surgery (however, this is being used less) (ACI, 2014); or surgery may be performed immediately or within the first 24 hours. The goal of surgery is to reduce and stabilise the fracture, thereby increasing mobility, decreasing pain and preventing complications. Surgery usually consists of ORIF of the fracture. Fixation is accomplished by securing the femur in place with pins, screws, nails or plates (see Figure 38.9A). An ORIF works well for fractures in the trochanteric area. Fractures of the femoral neck frequently disrupt blood supply to the femoral head. If blood supply is disrupted, the surgeon will replace the femoral head with a prosthesis (see Figure 38.9B). If the acetabulum has been damaged, the surgeon may insert a metal cup. Replacement of either the femoral head or the acetabulum with a prosthesis is called a *hemiarthroplasty*. Replacement of both the femoral head and the acetabulum is a *total hip arthroplasty (THA)*, discussed in Chapter 39.

Nursing care for a person with a hip fracture focuses on maintaining skin integrity, preventing infection, alleviating pain, maintaining circulation to the injured extremity and increasing mobility, and is discussed in more detail in the following 'Nursing care' section.

FAST FACTS

Hip fracture in older adults

- Almost one in three older Australians has a fall each year.
- Over 40% have multiple falls.
- Over 30% require medical attention after a fall.
- Hip fracture in older adults is most often the result of a fall; in contrast, car crashes are the most common cause of a hip fracture in young and middle-aged adults.
- The risk of a fractured hip increases with each decade of life, especially in Caucasian postmenopausal women, who have the highest incidence of osteoporosis. Women have about 80% of all hip fractures. Women who smoke are at greater risk because smoking reduces bone density in menopausal women.
- Complications are related both to the fracture and to the resulting treatment. Only a small number of people retain their previous mobility, while about 20% require nursing home care.
- Half of all older adults hospitalised for a hip fracture cannot return home or live independently after the fracture.

Sources: Data from Australian Commission on Safety and Quality in Health Care (ACSQHC) (2015); Centers for Disease Control and Prevention (2012); Queensland Health (2015).

Fracture of the tibia and/or fibula

Fractures of the lower extremities often result from a fall on a flexed foot, a direct blow or a twisting motion. The person presents with oedema, pain, bony deformity and a haematoma at the level of injury.

Circulation and sensation are assessed to rule out common complications of the fracture, including damage to the peroneal nerve or tibial artery, compartment syndrome, haemarthroses and ligament damage. Peroneal nerve damage may be indicated by the person's inability to point the toe upwards on the affected side. Tibial artery damage may be the cause of an absent dorsalis pedis pulse on the affected side. Compartment syndrome may be present if the person develops pain on passive movement and paraesthesias. An oedematous knee may indicate a collection of blood in the knee joint. Ligament damage may be present if the person cannot move the knee and/or ankle.

If the fracture is closed, a closed reduction and casting are frequently performed. A long leg cast that allows for partial weight bearing is used. Partial weight bearing usually is prescribed by the doctor within 10 days of the fracture. A short leg cast will be applied in 3 to 4 weeks. If the fracture is open, either external fixation or ORIF will be performed. After surgery, a cast may be applied and weight bearing begins according to the doctor's orders, usually in about 6 weeks.

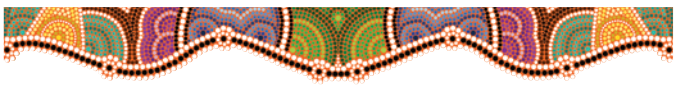
Nursing care is designed to increase comfort, monitor neurovascular status and prevent complications. The nurse instructs the person in cast care, on the use of assistive devices, how to perform neurovascular assessment and when to follow up with the doctor.

Fracture in the ankle and foot

The person with an ankle fracture presents with pain, limited ROM, haematoma, oedema and difficulty ambulating. Most ankle fractures are treated by closed reduction and casting. Open fractures are treated by surgical intervention and splinting.

The person with a foot fracture presents with similar symptoms; however, ROM of the ankle is not usually affected. Most foot fractures are non-displaced and treated with closed reduction and casting. More severe displaced foot fractures may require surgery and the placement of wires to maintain reduction of the fracture.

Nursing care focuses on increasing comfort, increasing mobility and educating the person. Analgesia is given for pain. The extremity should be elevated and ice can be applied. The person is taught cast care, neurovascular assessment and crutch walking.



Nursing care

In planning and implementing nursing care for the person with fractures, the nurse should consider the person's response to the traumatic experience. Although each person has individual needs, nursing care commonly focuses on the person's problems with pain, impaired physical mobility, impaired tissue perfusion and neurovascular compromise.

Health promotion

Trauma prevention can save lives. Many communities are educating people of all ages, from primary school students to older adults, in trauma prevention. Young adults face a high risk of sustaining trauma. They need to be taught the importance of safety equipment—such as automobile seat belts, bicycle and motorised vehicle helmets, shin guards, proper footwear, protective eyewear and hard hats—in preventing or decreasing the severity of injury from trauma. Older adults should have regular screenings for osteoporosis (with a bone density test), activity levels, cognitive and affective disorders, vision impairments and risk of falls. Older adults can reduce their risk of falling by increasing lower body strength and balance through regular physical activity and by asking their healthcare provider or pharmacist to review their medications. Educational programs about workplace and farm safety, including information about ergonomic principles, can also help prevent musculoskeletal injuries.

Having a regular exercise program and avoiding obesity are important factors in maintaining good bone health in all adults. An adequate intake of calcium is essential to ensure proper growth, development and maintenance of strong bones throughout life. It is important that women ensure good bone health prior to menopause, because the loss of oestrogen during and after menopause decreases calcium use and increases the risk of osteoporosis. Strong bones are formed by calcium intake and weight-bearing exercise, both of which are equally important in the postmenopausal woman.

Older people are at higher risk of musculoskeletal trauma due to falls. For these people, home assessments must be performed and potential hazards removed. Specific teaching topics for preventing falls in older adults are outlined in the 'Nursing care of the older adult' box below.

Assessment

Collect the following data through the health history and physical examination (see Chapter 37).

- *Health history:* age, history of traumatic event, history of chronic illnesses, history of prior musculoskeletal injuries, medications. (Ask the older adult specifically about anticoagulants and calcium supplements.)
- *Physical assessment:* pain with movement, pulses, oedema, skin colour and temperature, deformity, range of motion, touch. These assessments include the 5 Ps of neurovascular assessment, as follows, in both the initial assessment and ongoing focused assessments:
  1. *Pain*. Assess pain in the injured extremity by asking the person to grade it on a scale of 0 to 10, with 10 as the most severe pain.
  2. *Pulses*. Assess distal pulses, beginning with the unaffected extremity. Compare the quality of pulses in the affected extremity to those of the unaffected extremity.
  3. *Pallor*. Observe for pallor and skin colour in the injured extremity. Paleness and coolness may indicate arterial compromise, whereas warmth and a bluish tinge may indicate venous blood pooling.

NURSING CARE OF THE OLDER ADULT Teaching older adults to prevent falls

- Begin a regular exercise program; lack of exercise leads to weakness and an increased chance of falling. Exercises that improve balance and coordination (such as tai chi) are the most helpful.
- Make your home safer:
  - Remove any items in your pathway, including from stairs, to avoid tripping.
  - Remove small throw rugs or use double-sided tape to keep rugs from slipping.
  - Place frequently used items within easy reach to avoid use of a step-ladder.
  - Install grab bars next to your toilet and in the bath or shower.
  - Use non-slip mats in the bathtub and on shower floors.
  - Improve lighting, using lamp shades or frosted bulbs to reduce glare.
  - Install handrails and lights in all staircases.
  - Wear shoes that give good support and have thin, non-slip soles. Avoid wearing slippers and athletic shoes with deep treads.
- Ask your doctor to review your medications, including prescriptions and over-the-counter medications. Some medications, or a combination of medications, may cause dizziness or drowsiness, leading to falls.
- Have your vision checked by an eye doctor. Your glasses may no longer have the correct prescription or you may have developed an eye condition such as cataracts or glaucoma that limits your vision (ACI, 2014).

4 *Paralysis/Paresis*. Assess ability to move body parts distal to the fracture site. Inability to move indicates paralysis. Loss of muscle strength (weakness) when moving is paresis. A finding of limited range of motion may lead to early recognition of problems such as nerve damage and paralysis.
5 *Paraesthesia*. Ask the person if any change in sensation, such as burning, numbness, prickly feeling or stinging (all these are paraesthesias) has occurred.

Nursing diagnoses and interventions

Nursing care for people with fractures ranges from teaching for home care treatments provided in the emergency or urgent care department (such as manual reduction and cast application) to providing interventions to maintain health and decrease the risk of complications in people with complex or multiple fractures. Teaching is also necessary for caregivers of the older adult who is discharged home or to a long-term care or rehabilitation facility following a fractured hip. A nursing care plan is included below.

Acute pain

Pain is caused by soft tissue damage and is compounded by muscle spasms and swelling.

- Monitor vital signs. *Some analgesics decrease respiratory effort and blood pressure.*
- Ask the person to rate the pain on a scale of 0 to 10 (with 10 as the most severe pain) before and after any intervention. *This facilitates objective assessment of the effectiveness of the chosen pain relief strategy. Pain that increases in intensity or remains unrelieved with analgesics can indicate compartment syndrome.*
- For the person with a hip fracture, apply Buck's traction per doctor's orders. Keep the traction weights hanging freely. *Buck's traction immobilises the fracture and decreases pain and additional trauma.*
- Move the person gently and slowly. *Gentle moving helps prevent the development of severe muscle spasms.*

CONSIDERATION FOR PRACTICE
Do not let weights lie on the bed or the floor. The weights can be removed long enough to move the person up or down in bed to ensure freely hanging weights.

- Elevate the injured extremity above the level of the heart. *Elevating the extremity promotes venous return and decreases oedema, which decreases pain.*
- Encourage distraction or other non-invasive methods of pain relief, such as deep breathing and relaxation. *Distraction, deep breathing and relaxation help decrease the focus on the pain and may lessen the intensity of pain.*
- Administer pain medications as prescribed. For home care, explain the importance of taking pain medications before the pain is severe. *Analgesics alleviate pain by stimulating opiate receptor sites.*

CONSIDERATION FOR PRACTICE
In the case of fracture in an extremity, supporting the extremity above and below the fracture can also decrease pain and muscle spasms.

Risk of peripheral neurovascular dysfunction

In the person with a fracture, compartment syndrome or deep venous thrombosis can impair circulation and, in turn, tissue perfusion.

- Assess the 5 Ps every 1 to 2 hours. Report abnormal findings immediately. *Unrelenting pain, pallor, diminished distal pulses, paraesthesias and paresis are strong indicators of compartment syndrome.*

NURSING CARE PLAN A person with a hip fracture

Barbara Wallace, aged 74, has a history of osteoporosis. She is a widow and lives alone in a two-storey terrace house. Mrs Wallace is retired and depends on a pension and social security for her income. She takes pride in making all her own meals from scratch.

While walking to the shopping centre one day, Mrs Wallace trips and falls up the gutter and fractures her left hip. She is transported by ambulance to the nearest hospital emergency department.

ASSESSMENT

During the initial assessment at the ED, abnormal findings are that Mrs Wallace's left leg is shorter than her right leg and is externally rotated. Distal pulses are present and bilaterally strong; both legs are warm. Mrs Wallace complains of severe pain in her hip but states that no numbness or burning is present. She is able to wiggle the toes on her left leg and has full movement of her right leg. Initial vital signs are as follows: T 36.6°C, P 100 and regular, R 18, BP 120/58. Diagnostic tests include FBC, blood chemistry, cross-match and x-ray studies of the left hip and pelvis. The FBC reveals a haemoglobin of 11.0 g/dL and a normal WBC count. Blood chemistry findings are within normal limits. The x-ray reveals a fracture of the left femoral neck. Mrs Wallace is admitted to the hospital. She is given a femoral block and ordered regular analgesia. An open reduction and internal fixation (ORIF) is planned for the following day.

DIAGNOSES

- *Acute pain* related to fractured left femoral neck and muscle spasms.
- *Impaired physical mobility* related to bed rest and fractured left femoral neck.
- *Risk of ineffective tissue perfusion* related to unstable bones and swelling.
- *Risk of disturbed tactile sensory perception* related to the risk of nerve impairment.

PLANNING

- Identify and manage pain.
- Monitor changes in neurovascular status.
- Monitor postoperative complications.

(continued)

NURSING CARE PLAN A person with a hip fracture (continued)

Expected outcomes

- Mrs Wallace will verbalise a decrease in pain.
- Improved comfort for Mrs Wallace.
- Maintain normal neurovascular status.
- Prevention of postoperative complications including DVT, pressure areas, atelectasis, urinary stasis and constipation.

IMPLEMENTATION

- Assess pain on a scale of 0 to 10 before and after implementing measures to reduce pain.
- Administer narcotics per the doctor's order.
- Position Mrs Wallace so as to reduce pain.
- Perform neurovascular assessment every 2 to 4 hours and document findings.
- Encourage deep breathing and relaxation techniques.
- Demonstrate postoperative exercises.
- Teach the purpose of and the procedure for performing isometric and flexion/extension exercises.

EVALUATION

Three days after surgery, Mrs Wallace is out of bed and in a chair. She verbalises a decrease in pain. There have been no abnormal neurovascular assessments. She is able to independently perform isometric and flexion/extension exercises in both lower extremities. Safe discharge planning includes explaining the benefits to Mrs Wallace of going to a rehabilitation facility before going directly home, and referrals for home care. A community nurse will visit and the discharge planner at the hospital has organised review by the physiotherapist and the occupational therapist to order a trapeze for her bed, an elevated toilet seat, an elevated cushion for her chair and a walker.

CRITICAL THINKING IN THE NURSING PROCESS

1. What factors placed Mrs Wallace at risk of a hip fracture?
2. Identify the preoperative management and how you can explain this to Mrs Wallace. Explain the reason for the femoral block and why she needs to remain in bed.
3. Describe how each of the following, if manifested by Mrs Wallace, would increase her risk of postoperative complications: urinary incontinence; weight more than 20% under normal for her height; chronic constipation. Which nursing diagnoses and interventions would you include in her plan of care to decrease the risk?

REFLECTION ON THE NURSING PROCESS

1. Outline what you have learned from this case study that you will take into your future practice.
2. Which education requirements would the nurse need to implement prior to Mrs Wallace being discharged?

CONSIDERATION FOR PRACTICE

Pulses may remain strong, even in the presence of compartment syndrome.

- Assess nail beds for capillary refill. If nails are too thick or discoloured, assess the skin around the nail. *Delayed capillary refill may indicate decreased tissue perfusion.*

CONSIDERATION FOR PRACTICE

It may not be possible to accurately assess capillary refill in older adults, who often have thickened, discoloured nails. If so, test nearby skin.

- Monitor the extremity for oedema and swelling. *Excessive swelling and haematoma formation can compromise circulation.*
- Assess for deep, throbbing, unrelenting pain. *Pain that is not relieved by analgesics may indicate neurovascular compromise.*
- Monitor the tightness of the cast. *Oedema can cause the cast to become tight; a tight-fitting cast may lead to compartment syndrome or paralysis.*
- If cast is tight, be prepared to assist the doctor with bivalving (see Figure 38.10). *Bivalving, the process of splitting the cast down both sides, alleviates pressure on the injured extremity.*
- If compartment syndrome is suspected, assist the doctor in measuring compartment pressure. Normal compartment pressure is 10 to 20 mmHg. *Compartment pressure greater than 30 mmHg indicates compartment syndrome.*
- Elevate the injured extremity above the level of the heart. *Elevating the extremity increases venous return and decreases oedema.*
- Administer anticoagulant per doctor's order. *Prophylactic anticoagulation decreases the risk of clot formation.*

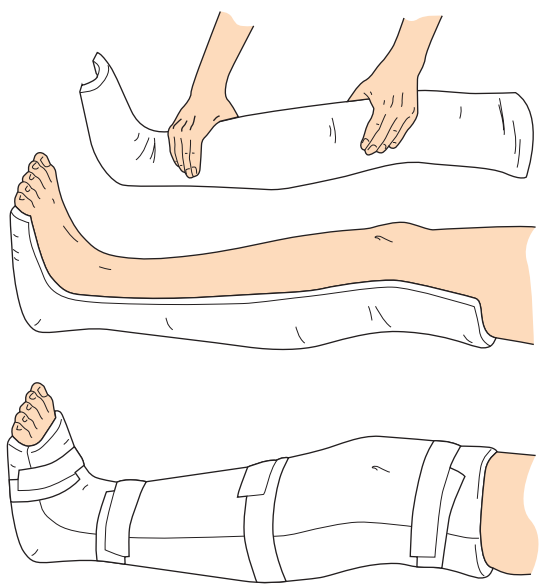


FIGURE 38.10 ■ Bivalving is the process of splitting the cast down both sides to alleviate pressure on or allow visualisation of the extremity

Risk of infection

The person who undergoes surgical repair will have a postoperative wound. Any break in skin integrity must be monitored for infection. Wound healing in an orthopaedic person is affected by the cause of the wound, as well as by the therapies used to repair musculoskeletal structures. It is important for nurses to understand normal wound healing processes; characteristics of musculoskeletal wounds, contamination and drainage; and potential complications, in order to plan for and implement appropriate interventions (Royal Children's Hospital Melbourne, 2015b).

- For people with skeletal pins, follow established guidelines for skeletal pin site care, as outlined in the 'Translation to practice' box below. *Pins or wires attached to traction, casts or external fixators stabilise a segment of bone so that optimal healing can occur. However, pin infections of varying severity do occur* (Holmes & Brown, 2005).
- Monitor vital signs and lab reports of WBCs. *Increases in pulse rate, respiratory rate, temperature and WBCs may indicate infection.*
- Use sterile technique for dressing changes. *The initial postoperative dressing will be changed by the surgeon. The nurse must change all subsequent dressings without introducing organisms into the operative site.*
- Assess the wound for size, colour and the presence of any drainage. *Redness, swelling and purulent drainage indicate infection.*
- Administer antibiotics per doctor's orders. Prophylactic antibiotic administration inhibits bacterial reproduction and thereby helps prevent skin flora from entering the wound. *In the case of 'dirty wounds', such as those occurring from vehicular crashes, antibiotics are routinely administered.*

Impaired physical mobility

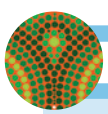
The person who has experienced a fracture requires immobilisation of the fractured bone(s). Immobilisation alters normal gait and mobility. The person will need to use assistive devices such as crutches, canes, slings or walkers.

- Teach or assist the person with ROM exercises for the unaffected limbs. *ROM exercises help prevent muscle atrophy and maintain strength and joint function. Flexion and extension exercises prevent the development of foot drop, wrist drop or frozen joints.*
- Teach isometric exercises and encourage the person to perform them every 4 hours. *Isometric exercises help prevent muscle atrophy and force synovial fluid and nutrients into the cartilage.*
- Encourage ambulation when able; provide assistance as necessary. *Ambulation maintains and improves circulation, helps prevent muscle atrophy and helps maintain bowel function.*
- Teach and observe the person's use of assistive devices (such as canes, crutches, walkers, slings) in conjunction with the physical therapist. *Proper use of devices is necessary for safe ambulation and helps prevent the loss of joint function secondary to complications and falls.*
- Turn the person on bed rest every 2 hours. If the person is in traction, teach the person to shift his or her weight every hour. *Turning and shifting weight increase circulation and help prevent skin breakdown.*

Risk of disturbed tactile sensory perception

The person who has sustained a fracture is at risk of nerve injury from the initial trauma, as well as from complications such as compartment syndrome.

- Assess the ability to differentiate between sharp and dull touch and the presence of paraesthesias and paralysis every



TRANSLATION TO PRACTICE Evidence-based practice for the person with skeletal pins

Clinical guidelines for specific person care interventions, such as skeletal pin care, should be based on research in order to provide the most appropriate evidence-based practice. Management of people with an external fixation device will depend on the surgeon. Each surgeon has their own protocol for pin care cleaning (Lethaby, Temple & Santy-Tomlinson, 2013).

- Pins located in areas with considerable soft tissue should be considered at greater risk of infection.
- People and their families should be taught pin site care before discharge from the hospital. They should be required to demonstrate whatever care needs to be done and should be provided with written instructions that include signs and symptoms of infection—such as exudate, erythema, tenderness and pain—which may require removal of the pins (Holmes & Brown, 2005).

IMPLICATIONS FOR NURSING

Evaluation of the literature by the systematic review of Lethaby et al. (2013) found that the preference of the surgeon determined the care required for external pin sites.

CRITICAL THINKING IN PERSON-CENTRED CARE

1. List the factors that may increase the risk of infection of skeletal pin sites. Which nursing interventions may be used to reduce this risk?
2. You are caring for a person with skeletal pins for external fixation of a fracture of bones of a lower extremity. There is dried yellow drainage around the pin site. Based on clinical decision making without research to support your actions, would you remove the crusts? Why or why not?
3. You are teaching a person how to undertake pin care at home. Make a list of manifestations of infection the person may experience. What would you recommend if any of these manifestations occur?

Source: Data from Lethaby, A., Temple, J. & Santy-Tomlinson, J. (2013). Pin site care for preventing infections associated with external bone fixators and pins. *Cochrane Database of Systematic Reviews*, Issue 4.

1 to 2 hours. *Paraesthesias develop as a result of pressure on nerves and may indicate compartment syndrome.*

CONSIDERATION FOR PRACTICE

Paralysis is a late sign of nerve entrapment and requires that the healthcare provider be notified immediately.

- Elevate the injured extremity above the level of the heart. *Elevating the extremity decreases swelling and the risk of compartment syndrome and nerve entrapment.*
- Check the cast for fit. *A tightly fitting cast can decrease blood flow to distal tissues, compress nerves and cause compartment syndrome.*
- Support the injured extremity above and below the fracture site when moving the person. *Such support helps prevent displacement of bony fragments and decreases the risk of further nerve damage.*

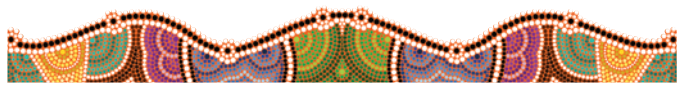
Community-based care

Person and family teaching focuses on individualised needs. The type of fracture and its location determine how much teaching the person and family will require. For example, a person who has a simple non-displaced tibial fracture may need to be taught only cast care and crutch walking. An older person who has sustained a hip fracture and requires surgical intervention, by contrast, has a wider array of teaching needs, including the use of an abduction pillow, proper bending and proper sitting. Address the following topics for home care of the person who has fractured a hip:

- Encourage independence in ADLs:
  - Explain that the person should sit only on high chairs to prevent excess flexion of the hip; a high toilet seat can be added to a regular toilet seat.
  - Encourage the person and family to equip the shower with a rail to aid stability and prevent falls.
  - If a walker is needed, teach the person its proper use: do not carry the walker, but lift it, advance it and then take two steps, or use a rolling walker.
  - If a walking stick is needed, instruct the person to use it on the affected side.
  - Stress the importance of well-balanced meals and explain all prescribed medications.

People who have experienced a fracture or have had orthopaedic surgery often have a cast and require an extended period of immobilisation or limited activities. Address the following topics for home care:

- Do not try to scratch under a cast with a sharp object.
- Do not get a plaster cast wet.
- Follow the doctor's order for weight bearing.
- Physiotherapy departments or offices can often evaluate the home environment for safety and suggest modifications as needed. Physiotherapists also teach crutch walking, limited weight bearing, transferring and other activities.
- Home care agencies can teach wound care and provide ongoing monitoring of wound healing.
- Local medical equipment and supply sources rent or sell durable equipment such as crutches, walkers, wheelchairs, overhead trapeze units, shower chairs, elevated toilet seats, grab bars and bedside commodes. Slings or braces may be purchased through medical equipment dealers.
- Local pharmacies are good resources for dressing supplies such as antiseptic solutions or ointments, dressings and tape.
- Fitness equipment suppliers may be able to provide rehabilitation equipment such as hand or ankle weights for strengthening exercises.



THE PERSON WITH AN AMPUTATION

An **amputation** is the partial or total removal of an extremity. Amputation may be the result of an acute process, such as a traumatic event, or a chronic condition, such as peripheral vascular disease or diabetes mellitus. Regardless of the cause, an amputation is devastating to the person.

The loss of all or part of an extremity has a significant physical and psychosocial effect on the person and family. Adaptation may take a long time and require much effort. Interprofessional healthcare is always important, but is especially necessary to meet the person's physical, spiritual, cultural and emotional needs after an unexpected or planned amputation.

Causes of amputation

Peripheral vascular disease (PVD) is the major cause of amputation of the lower extremities (see Chapter 31). Common risk factors for the development of PVD include hypertension, diabetes, smoking and hyperlipidaemia. Peripheral neuropathy also places the person with diabetes at risk of amputation. In peripheral neuropathy, loss of sensation frequently leads to unrecognised injury and infection. Untreated infection may lead to gangrene and the need for amputation. These risks are discussed in Chapter 19.

The incidence of traumatic amputations is highest in young men. Most amputations in this group result from motor vehicle crashes or accidents involving machinery at work. The person presents to the trauma centre with an injury that may be life threatening; significant loss of blood and tissue may have already occurred and shock may develop. (See Chapter 10 for a discussion of shock and trauma.) Other traumatic events that may necessitate an amputation are frostbite, burns or electrocution.

Amputations result from or are necessitated by interruption in blood flow, either acute or chronic. In acute trauma situations, the limb is partially or completely severed and tissue death ensues. However, replantation of fingers, small body parts and entire limbs has been successful. In chronic disease processes, circulation is impaired, venous pooling begins, proteins leak into the interstitium and oedema develops. Oedema increases the risk of injury and further decreases circulation. Stasis ulcers develop and readily become infected because impaired healing and altered immune processes allow bacteria to proliferate. The presence of progressive

FAST FACTS

- Males are at higher risk of amputations and are three times more likely to suffer an amputation than females.
- The middle and older age groups have the highest incidence of amputation. This is generally due to peripheral vascular disease, atherosclerosis and changes due to diabetes mellitus. In Australia, the most common causes of lower extremity amputations are disease, trauma and thermal injuries, congenital or birth defects, and tumours.
- Upper extremity amputation is usually due to trauma or birth defect.
- Demographics show that amputees represent 1 per 1000 individuals across Australia, and subsequently there are in excess of 20 000 amputees living in Australia.

Source: Australian Physiotherapists in Amputee Rehabilitation (2015). Retrieved from www.austpar.com/index.html.

infection further compromises circulation and ultimately leads to gangrene (tissue death), which requires amputation.

Levels of amputation

The level of amputation is determined by local and systemic factors. Local factors include ischaemia and gangrene; systemic factors include cardiovascular status, renal function and severity of diabetes mellitus. The goals are to alleviate symptoms, to maintain healthy tissue and to increase functional outcome. When possible, the joints are preserved because they allow greater function of the extremity. Figure 38.11 illustrates common sites of amputation.

Types of amputation

Amputations may be open (*guillotine*) or closed (*flap*). Open amputations are performed when infection is present. The wound is not closed but remains open to drain. When infection is no longer present, surgery is performed to close the wound. In closed amputations, the wound is closed with a flap of skin that is sutured in place over the stump. Terms used to refer to amputations are defined in Table 38.3.

Amputation site healing

For the prosthesis to fit well, the amputation site must heal properly. To promote healing, a rigid or compression dressing is applied to prevent infection and minimise oedema. A compression bandage is usually applied immediately after surgery to support the soft tissues. The bandage may be elastic and is applied to the residual limb. The compression bandage is worn at all times, except for showering and physiotherapy. Bandages are reapplied several times a day to ensure a snug fit, but not to interfere with circulation.

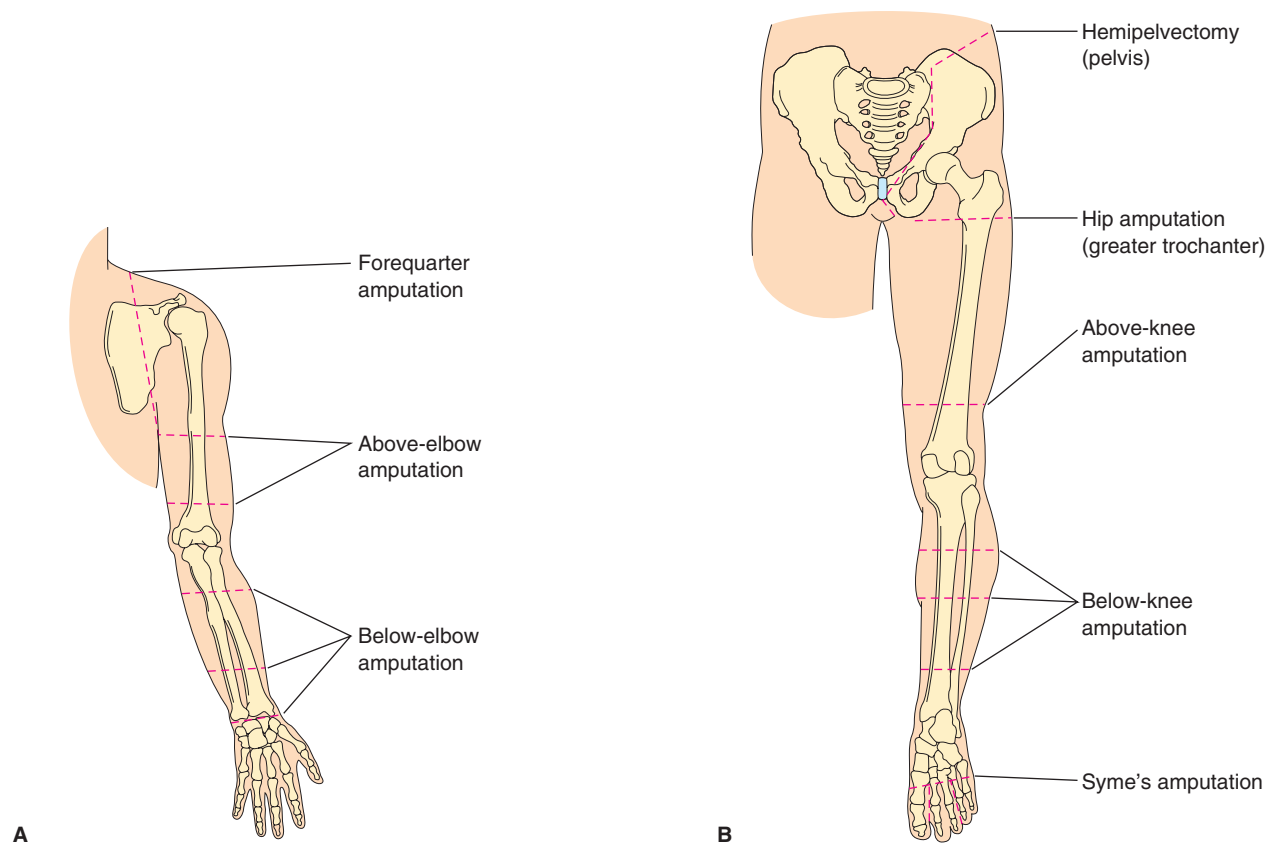


FIGURE 38.11 ■ Common sites of amputation. *A*, The upper extremities. *B*, The lower extremities. The surgeon determines the level of amputation based on blood supply and tissue condition

TABLE 38.3 Amputation terms

TERM	MEANING
Arm	Amputation of a portion of the arm, either above or below the elbow
Disarticulation	Amputation through a joint
Forequarter	Removal of the entire arm and disarticulation of the shoulder
Closed (flap)	Amputation in which a flap of skin is formed to cover the end of the wound
Open (guillotine)	Perpendicular cutting of the extremity in which the wound is left open; used when infection is present
Leg	Amputation below the knee (BK)
Thigh	Amputation above the knee (AK)
Finger or toe	Amputation of one or all of the fingers or toes
Syme	Modified disarticulation of the ankle
Foot	Amputation of part of the foot and toes

Once the wound has healed, the compression bandage need only be worn when the prosthesis is not worn. The bandage is applied from the distal to the proximal extremity (see Figure 38.12).

Complications

Complications that may occur after an amputation include infection, delayed healing, chronic stump pain and phantom pain, and contractures.

Infection

Generally, the person who suffers a traumatic amputation has a greater risk of infection than the person who has a planned amputation. However, even planned amputations carry a risk of infection. The person who is older, has diabetes mellitus or suffers peripheral neurovascular compromise is at a particularly high risk of infection. Infection may present itself locally or systemically. Local manifestations of infection include drainage, odour, redness and increased discomfort at the suture line. Systemic manifestations include fever, an increased heart rate, a decrease in blood pressure, chills and positive wound or blood cultures.

Delayed healing

If infection is present, or if the circulation remains compromised, delayed healing (occurring at a slower rate than expected) will result. In older people, other pre-existing conditions can increase the risk of delayed healing. In people of any age, electrolyte imbalances can contribute to delayed healing processes, as can a diet that lacks the proper nutrients to meet the body's increased metabolic demands during healing. Smoking compromises healing by causing vasoconstriction and decreasing blood flow to the stump. Deep venous thrombosis and compromised venous return, which may result from prolonged immobilisation, are other potential factors. Decreased cardiac output decreases blood flow and thus also delays healing.

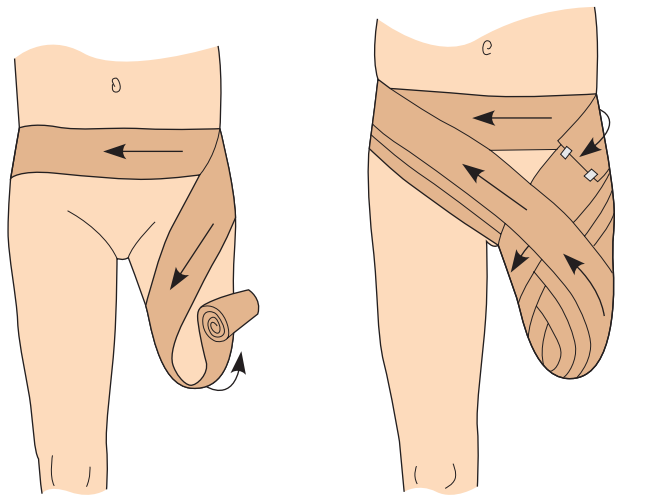

FIGURE 38.12 ■ Stump dressings increase venous return, decrease oedema and help shape the stump for a prosthesis. With an above-knee amputation, a figure-eight bandage is started by bringing the bandage down over the stump and back up around the hips

Chronic stump pain and phantom pain

Chronic stump pain is the result of neuroma formation, causing severe burning pain. Interventions to relieve this pain include medications, nerve blocks, transcutaneous electrical nerve stimulation (TENS) and surgical stump reconstruction. Phantom limb pain is not the same as phantom limb sensation. A majority of amputees experience phantom limb sensation (sensations such as tingling, numbness, cramping or itching in the phantom foot or hand) early in the postoperative period. It is often self-limiting, but may last for decades in some people. When phantom limb sensation is painful, it is referred to as **phantom limb pain**. Although various theories have been proposed, the exact cause of this experience is unknown. Treatments include pain management, TENS and a variety of surgical procedures. The management of phantom limb pain is difficult for both people and healthcare professionals. People with phantom limb pain often benefit from referral to a pain clinic for a comprehensive pain management program.

Contractures

A contracture is an abnormal flexion and fixation of a joint caused by muscle atrophy and shortening. Contracture of the joint above the amputation is a common complication. The person needs to be taught to extend the joint. The person with an above-the-knee amputation should lie prone for periods throughout the day. The person with a below-the-knee amputation should elevate the stump, keeping the knee extended. The same principles apply to the upper extremities. All joints should receive either active or passive ROM exercises every 2 to 4 hours. A trapeze frame should be added to the bed to encourage the person to change position every 2 hours. The person who has an upper extremity amputation should exercise both shoulders. Postural exercises can help prevent the person from hunching over secondary to the loss of weight on the affected side. The person with an above-the-knee amputation should not sit for prolonged periods of time; prolonged sitting can lead to hip contracture.

INTERPROFESSIONAL CARE

Interprofessional care is essential for the person who has sustained an amputation. Physiotherapy and occupational retraining are necessary and the person may also benefit from the presence of clergy. The entire healthcare team must view both the positive and the negative effects of amputation; that is, they must see amputation as a means to increase the person's independence and to relieve symptoms. The person should be able to become familiar with the members of the healthcare team and their roles; this allows the person greater control over their care and rehabilitation and promotes independence.

Diagnosis

Preoperatively, the person has routine laboratory and diagnostic tests (see Chapter 3 for care of the person having surgery). Preoperative tests, including Doppler flowmetry, segmental blood pressure determination, transcutaneous partial pressure oxygen readings and angiography, are performed to assess the circulation present in the limb at different levels and to determine the level of viable tissue. Postoperative tests include FBC to monitor for haemorrhage, WBC count to monitor for infection, blood chemistries to evaluate electrolytes and fluid balance, and a vascular Doppler ultrasonography if a DVT is suspected.

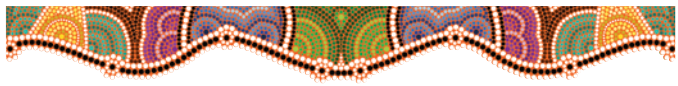
Medications

The person receives medications preoperatively, intraoperatively and postoperatively. Preoperatively, the doctor may prescribe intravenous antibiotics. Intraoperatively, anaesthetic agents are administered. It also may be necessary to administer agents to control blood pressure during the surgery. Postoperatively, the person resumes any routinely prescribed medications and in addition may receive antibiotics and analgesics. Steroids may be administered to decrease swelling. A protein pump inhibitor (PPI) antagonist may also be ordered to decrease the risk of peptic ulcer formation. Stool softeners may be administered to prevent constipation.

Prosthesis

The type of prosthesis selected for the person with an amputation depends on the level of the amputation as well as the person's occupation and lifestyle. Each prosthesis is based on a detailed prosthetic prescription and is custom made for the person based on the specific characteristics of the stump. Most are made of plastic and foam materials. Many factors influence the person's use of the prosthesis, including the status of the remaining limb, cognitive status, cardiovascular status, preoperative activity level and motivation to use the prosthesis.

People with a lower extremity amputation are often fitted with early walking aids. Pneumatic devices that fit over the stump are used in the immediate postoperative period to allow early ambulation, decreased postoperative swelling and improved morale. People may begin weight bearing as soon as 2 weeks after surgery. People with upper extremity amputations may be fitted for a prosthesis immediately after surgery. Rehabilitation of the person with an amputation is a team effort, involving the person, nurse, doctor, physical therapist, occupational therapist, social worker, prosthetist and vocational counsellor.



Nursing care

Health promotion

The goals of health promotion activities focus on preventing the progression of chronic diseases such as peripheral vascular disease and diabetes mellitus and on safety. People with PVD from any cause need education about foot care and early recognition of decreased circulation. Education within both urban and rural populations should provide knowledge about working safely with lawn care equipment as well as farm and occupational machinery.

In addition, it is important that the public know what to do if a traumatic amputation occurs in the home, community or workplace. The following guidelines may help preserve the amputated part until it can be surgically reattached:

- Keep the person in a prone position with the legs elevated.
- Apply firm pressure to the bleeding area, using a towel or article of clothing.
- Wrap the amputated part in a clean cloth. If possible, soak the cloth in saline (such as contact lens solution).
- Put the amputated part in a plastic bag and put the bag on ice. Do not let the amputated part come into direct contact with the ice or water.
- Send the amputated part to the emergency department with the injured person and be sure the emergency personnel know what it is.

Assessment

Collect the following data through the health history and physical examination. Further focused assessments are described in the following nursing interventions sections.

- *Health history:* mechanism of injury, current and past health problems, pain, occupation, ADLs, changes in sensation in the feet, cultural and/or religious guidelines for handling the amputated part.
- *Physical examination:* bilateral neurovascular status of the extremities, bilateral capillary refill time, skin over the lower extremities (discolouration, oedema, ulcerations, hair, gangrene).

Nursing diagnoses and interventions

The goals of nursing care for a person with an amputation are to relieve pain, promote healing, prevent complications, support the person and family during the process of grieving and adaptation to alterations in body image, and restore mobility. Care is individualised and the circumstances that led to the amputation (e.g. traumatic injury or disease) must also be addressed. (See the accompanying nursing care plan.) Applying rehabilitation principles to nursing care is also important.

Acute pain

Pain from the surgical procedure can be compounded by muscle spasms, swelling and phantom limb pain.

- Ask the person to rate the pain on a scale of 0 to 10 (with 10 as the most severe pain) before and after any intervention. *This facilitates objective assessment of the effectiveness of the chosen pain relief strategy. Pain that increases in intensity or remains unrelieved with analgesics can indicate compartment syndrome.*
- Splint and support the injured area. *Splinting prevents additional injury by immobilising the stump and decreasing oedema while moulding the stump for a good prosthetic fit.*
- Unless contraindicated, elevate the stump on a pillow for the first 24 hours after surgery. *Elevating the stump promotes venous return and decreases oedema, which will decrease pain.*
- Move and turn the person gently and slowly. *Gentle moving and turning prevents the development of severe muscle spasms.*
- Administer pain medications as prescribed. A PCA pump may be ordered by the doctor. *Analgesics alleviate pain by stimulating opiate receptor sites. PCA pumps increase person control over and allow early relief of pain before it intensifies.*
- Encourage deep breathing and relaxation exercises. *These techniques increase the effectiveness of analgesics and modify the pain experience.*
- Reposition the person every 2 hours; turn from side to side and onto abdomen. *Repositioning alleviates pressure from one area and distributes it throughout the body, and helps prevent cramping of muscles.*

CONSIDERATION FOR PRACTICE

Lying prone prevents hip contracture.

Risk of infection

The person who has an amputation is at risk of wound infection. Early recognition of infection can lead to early treatment and prevent wound dehiscence.

- Assess the wound for redness, drainage, temperature, oedema and suture line approximation. *Redness is normal in the immediate postoperative period; if it persists, however, it can indicate infection. A hot area that is palpated over the incision or increased drainage may also indicate infection.*
- Take the person's temperature every 4 hours. *Increased body temperature may indicate infection.*
- Monitor WBC count. *The WBC count rises in the presence of infection.*
- Use aseptic technique to change the wound dressing. *Aseptic technique prevents contamination of the wound with bacteria.*
- Administer antibiotics as ordered. *Antibiotics inhibit bacterial cell replication and help prevent or eradicate infection.*
- Teach the person stump-wrapping techniques. *Correctly wrapping the stump from the distal to the proximal extremity increases venous return and prevents pooling of fluid, thereby reducing the chance of infection.*

Risk of impaired skin integrity

Stump care is essential, not only in the postoperative healing period but also throughout life with a prosthesis. A variety of skin problems may be caused by a prosthesis, including epidermoid cysts, abrasions, blisters and hair follicle infections. The person must be taught stump care prior to discharge.

- Each day, preferably at night, wash the stump with soap and warm water, and dry thoroughly. *Inspect the stump for redness, irritation or abrasions. It is essential to maintain intact skin to ensure successful use of the prosthesis.*
- Massage the end of the stump, beginning 3 weeks after surgery. *Massage helps desensitise the remaining part of the limb and prevents scar tissue formation. If the skin adheres to the underlying tissue, it will tear when stressed from wearing a prosthesis.*
- Expose any open areas of skin on the remaining part of the limb for 1 hour four times a day. *Air exposure promotes healing.*
- Change stump socks and elastic wraps each day. Wash these in mild soap and water and allow to completely dry before using again. *Stump socks and elastic wraps must be kept clean and dry to prevent skin breakdown.*

Risk of dysfunctional grieving

The person who has lost an extremity is at risk of dysfunctional grieving. Denial of the need for surgery and the inability to discuss feelings compound this risk.

- Encourage verbalisation of feelings, using open-ended questions. *Asking open-ended questions allows the person to discuss feelings and communicates the listener's willingness to listen.*
- Actively listen and maintain eye contact. *Active listening and eye contact communicate respect for what the person is expressing.*
- Reflect on the person's feelings. *Reflection statements such as 'You seem angry' allow the person to recognise feelings and perhaps develop a plan for resolution.*

NURSING CARE PLAN A person with a below-the-knee amputation

John Rocke is a 45-year-old divorcee with no children. He has a history of type 2 diabetes mellitus and poor control of blood glucose levels. Mr Rocke is unemployed and currently receives unemployment benefits. He lives alone in a second-floor unit. Mr Rocke had developed gangrene in the foot and failed to seek prompt medical attention; as a result, a left below-the-knee amputation was necessary.

Mr Rocke is in his second postoperative day and his vital signs are stable. The stump is splinted and has a soft dressing. The wound is approximating well without signs of infection. He has not performed ROM exercises or turning since his surgery, complaining of severe pain. When the nurse goes into the room, he yells, 'Get out! I don't want anyone to see me like this.' No one has visited him since

NURSING CARE PLAN A person with a below-the-knee amputation (continued)

his hospitalisation. He is tolerating a diabetic diet and is using a urinal independently. He has an order for morphine, 5 mg IM/SC every 4 hours prn for pain and cephazolin, 1 g IV every 8 hours. He is on blood glucose coverage with regular insulin subcutaneously.

ASSESSMENT

Jane Simmons, RN, has just come on duty. She notes that Mr Rocke is upset and angry. He will not let anyone enter the room to give him medication or assess his vital signs.

DIAGNOSES

- *Disturbed body image* related to amputation of left lower leg.
- *Dysfunctional grieving* related to anger and loss of left lower leg.
- *Situational low self-esteem* related to appearance.
- *Risk of injury from infection and contractures* related to refusal of care.
- *Acute pain* related to surgery.

PLANNING

- Assess and manage Mr Rocke's pain related to the amputation.
- Ask a social worker to consult with Mr Rocke. Utilising a social worker may assist the person to discuss his current feelings about the amputation.
- Manage risk of contractures and infection.

Expected outcomes

- Verbalise his feelings about the amputation.
- Able to control his own analgesia and be pain free.
- Be allowed to control his pain with a PCA pump.
- Verbalise a decrease in pain.
- Verbalise the importance of turning.
- Turn every 2 hours.
- Allow the staff to monitor his vital signs and administer medications.

IMPLEMENTATION

- Actively listen to the person.
- Offer to arrange a visit with a fellow amputee.
- Assess pain and effectiveness of analgesia.
- Ask the doctor if the person can be placed on a PCA pump.
- Teach the person the importance of turning every 2 hours to prevent contractures.
- Encourage turning and lying prone.
- Teach the importance of antibiotics in preventing and treating infection.

EVALUATION

One week after his surgery, Mr Rocke is actively participating in his care. He has apologised for his behaviour and has explained to Ms Simmons that he was angry about the loss of his leg. He states, 'I thought I knew what to expect, but I didn't.'

CRITICAL THINKING IN THE NURSING PROCESS

1. Once Mr Rocke is ready to assist with his stump care, how would you proceed? Would you give him full responsibility for care and dressings, or would you gradually increase his participation? Why?
2. Which factors in Mr Rocke's home environment and medical history may make self-care more difficult? Do you expect Mr Rocke to follow up on care after his discharge? Why or why not?
3. Mr Rocke states, 'Why should I exercise this leg—it was already cut off!' How would you respond? What is the purpose of exercising the stump?

REFLECTION ON THE NURSING PROCESS

1. Identify the issues regarding the care of Mr Rocke that will be able to assist you with your future nursing care.
2. Looking back at the care you have given Mr Rocke, identify any issues that you feel that you could have seen earlier to improve Mr Rocke's outcome.

- Allow the person to have unlimited visiting hours, if possible. *Unlimited visiting hours allow increased social support.*
- If desired by the person, provide spiritual support by encouraging activities such as visits from a spiritual leader, prayer and meditation. *These activities often provide support during the grieving process.*

Disturbed body image

Although amputation is a reconstructive surgery, the person's body image will be disturbed. Risk of body image disturbance is higher in young people, in whom body image is a particularly important component of self-image.

- Encourage verbalisation of feelings. *This allows the person to communicate concerns and fears and lets the person know the nurse is willing to listen.*
- Allow the person to wear clothing from home. *Familiar clothing provides emotional comfort and helps the person retain a sense of his or her own identity.*
- Encourage the person to look at the stump. *Looking at and touching the stump helps the person face their fear of the unknown and move from denial to acceptance.*
- Encourage the person to care for the stump. *Active participation in care increases self-esteem and independence.*
- Offer to have a fellow amputee visit the person. *A support person who has experienced the same change gives the person the hope that they too can regain independence.*
- Encourage active participation in rehabilitation. *Active participation in rehabilitation increases independence and mobility.*

Impaired physical mobility

If time allows, the person should begin strengthening muscles preoperatively. If the amputation is the result of an emergency, exercises begin within 24 to 48 hours of surgery. The return of independent mobility boosts self-esteem and promotes adaptation to amputation.

- Perform ROM exercises on all joints. *ROM exercises help prevent the development of joint contractures that limit mobility.*
- Maintain postoperative stump shrinkage devices. These may be elastic bandages, shrinker socks, an elastic stockinette or a rigid plaster cast. *In order for the prosthetic limb to fit properly and as the wound heals, therapists will*

work with the person to wrap the stump with elastic wraps or stockings that minimise swelling and shape the stump for the best fit possible into a prosthetic limb.

- Turn and reposition the person every 2 hours. The person with a lower extremity amputation should lie prone every 4 hours, for up to 2 hours. *Repositioning increases blood flow to muscles, forces synovial fluid into joints and helps prevent contractures.*
- Reinforce teaching by the physical therapist in crutch walking or the use of assistive devices. *These devices increase mobility by balancing the person and facilitating ambulation.*
- Encourage active participation in physical therapy. *Physical therapy will fatigue the person in the early stage of healing. Encouragement may increase the person's participation in the physical therapy regimen and thereby increase activity tolerance.*

Community-based care

Person and family teaching includes stump care, prosthesis fitting and care, medications, assistive devices, exercises, rehabilitation, counselling, support services and follow-up appointments. The depth of teaching depends on the cause and site of the amputation and the needs of the person. See the 'Meeting individualised needs' box below.

Holistic nursing care is especially important for the older person with an amputation. The normal ageing process decreases renal and liver function; hence, medications have longer half lives. Altered circulation prolongs wound healing, and slowing of reflexes and alterations in gait may disrupt balance. A walker may be more appropriate than crutches because older people have less strength in the upper extremities. Safety issues, such as decreasing the risk of recurrent falls, must be addressed. The nurse should also assess the person's need for in-home assistance and make appropriate referrals to visiting nurses and home health aides.

MEETING INDIVIDUALISED NEEDS The person with an amputation

Amputation of a limb has significant long-term consequences for the person. The person will grieve the loss of a body part and must adjust to a new self-image. The person's ability to perform normal ADLs and to maintain their usual family and social roles may be significantly affected, at least initially. Depending on the person's occupation, job performance may be affected, necessitating a change of career.

The nurse may be responsible for involving multiple members of the healthcare team in the person's care and rehabilitation, and for coordinating their activities. Following an amputation, the person may need the services of any or all of the following:

- social services to help with rehabilitative and financial arrangements
- physiotherapists to teach ambulation techniques and to provide deep heat or massage
- occupational therapists to assist the person in developing adaptive techniques to deal with the loss of a limb
- prosthetists to develop a prosthesis for the missing limb that will meet the person's needs for ADLs and other activities
- home nursing services for nursing care such as assessments and wound care
- support group services to assist in adapting to the body image change and effects of amputation on ADLs.

Assessing for home care

Preparing the amputee for home care includes a careful assessment of the person's family and support services, and of the home for possible barriers to the person's safety and independence.

Assess the person's acceptance of the amputation and knowledge base about care needs, any activity restrictions or special needs and resources for home care. Discuss home management (i.e. who is responsible for household activities such as cleaning and cooking). Enquire about arrangements that have been made for home care activities and ADLs. Evaluate the person's use of prescription and non-prescription medications, paying particular attention to possible interactions and drugs that may affect the person's balance, mental alertness or appetite. Ask about social habits, such as cigarette smoking, alcohol use or other drug use, that may affect healing or the person's ability to provide self-care.

Assess the person's home environment for possible safety hazards or barriers to ambulation, such as:

- scatter rugs
- stairs between living areas of the house
- presence of grab bars to facilitate toileting and bathing
- access to clean water and other needs for wound care.

Health education for the person and family

The new amputee needs a great deal of teaching to learn to adapt to loss of a limb, whether it is an upper or lower extremity that has been lost. Because the person must be ready to learn before teaching can be effective, use therapeutic communication techniques to encourage the person to verbalise feelings about the amputation and its effects. Use active listening, and teach the person ways to reduce anxiety and deal with feelings of helplessness and loss. Encourage the person to participate in care of the stump to build self-esteem and reinforce teaching. Include the following in teaching for home care:

- Teach the person to wrap the stump appropriately in preparation for fitting the prosthesis.
- Discuss positioning of the stump. Contractures are a particular problem for people with an above-knee amputation and can interfere with the ability to use a prosthesis effectively.
- Teach the person how to perform stump exercises to maintain joint mobility and muscle tone of the affected limb.
- Encourage the person to resume physical activities as soon as possible. This improves the person's health and wellbeing, as well as the person's self-esteem.

MEETING INDIVIDUALISED NEEDS The person with an amputation (continued)

- Discuss household modifications to promote independence, such as grab bars in the bathroom, taps with single-handle controls for water flow and temperature, and handheld shower heads and shower chairs for bathing.

THE PERSON WITH A REPETITIVE USE INJURY

Repeatedly twisting and turning the wrist, pronating and supinating the forearm, kneeling or raising arms over the head can result in repetitive use injuries. People with repetitive use injuries pose a challenge to the healthcare team. Often these people appear puzzled as they relate a history of manifestations that have worsened over time. They deny abrupt trauma and often worry about the ability to return to work. Repetitive use injuries are common. The number of workers' compensation claims for repetitive use injuries is steadily growing. The increase is believed to be a result of technology advances in the workplace.

Pathophysiology

Common repetitive use injuries include carpal tunnel syndrome, bursitis and epicondylitis.

Carpal tunnel syndrome

The carpal tunnel is a canal through which flexor tendons and the median nerve pass from the wrist to the hand. The syndrome develops from narrowing of the tunnel and irritation of the median nerve. Carpal tunnel syndrome involves compression of the median nerve as a result of inflammation and swelling of the synovial lining of the tendon sheaths. The person complains of numbness and tingling of the thumb, index finger and lateral ventral surface of the middle finger. The person may also complain of pain in this area that interferes with sleep and is alleviated by shaking or massaging the hand and fingers. The affected hand may become weak and the person may be unable to hold utensils or perform activities that require precision.

Carpal tunnel syndrome is one of the three most common work-related injuries. The incidence is believed to be related directly to the number of people using computers. The incidence of carpal tunnel syndrome is higher in women, especially postmenopausal women.

Bursitis

Bursitis is an inflammation of a bursa. A bursa is an enclosed sac found between muscles, tendons and bony prominences. The bursae that commonly become inflamed are in the shoulder, hip, knee and elbow. Constant friction between the bursa and the musculoskeletal tissue around it causes irritation, oedema and inflammation. Manifestations develop as the sac becomes engorged. The area around the sac is tender and extension and flexion of the joint near the bursa produce pain. The inflamed bursa is hot, red and oedematous. The person guards the joint to decrease pain and may point to the area of the bursa when identifying joint tenderness.

Epicondylitis

Epicondylitis is inflammation of the tendon at its point of origin into the bone. Epicondylitis is also referred to as *tennis elbow* or *golfer's elbow*. The exact pathophysiology of epicondylitis is unknown. Current theories attribute inflammation of the tendon to microvascular trauma. Tears, bleeding and oedema are thought to cause avascularisation and calcification of the tendon. Manifestations of epicondylitis include point tenderness, pain radiating down the dorsal surface of the forearm and a history of repetitive use.

INTERPROFESSIONAL CARE

Medical management of repetitive use disorders focuses on relieving pain and increasing mobility. Once the diagnosis is made, treatment can range from conservative measures, such as rest and pharmacological agents, to aggressive measures such as surgery.

Diagnosis

Carpal tunnel syndrome is diagnosed by the person's history and physical examination. The history may reveal an occupation that involves areas such as computer work, jackhammer operation, mechanical work or gymnastics. History of a radial bone fracture or rheumatoid arthritis also increases the risk of carpal tunnel syndrome. Tests specific for carpal tunnel include Phalen's test (see Chapter 37). Bursitis and epicondylitis are diagnosed by history and physical examination.

Medications

The person with a repetitive use injury usually receives NSAIDs. Narcotics may also be administered for acute flare-ups and severe pain. For the person who has epicondylitis or carpal tunnel syndrome, corticosteroids may be injected into the joint.

Treatments

Treatment of repetitive use injuries is performed first by conservative management, followed, if necessary, by surgery.

CONSERVATIVE MANAGEMENT The first steps in the care of all repetitive use injuries are to immobilise and rest the involved joint. The joint may be splinted and ice may be applied (as described in Table 38.1) in the first 24 to 48 hours to decrease pain and inflammation. Ice application may be followed by heat application every 4 hours.

SURGERY Surgery is usually reserved for the person who does not obtain relief with conservative treatment. Surgery for carpal tunnel syndrome includes resection of the carpal ligament to enlarge the tunnel. In epicondylitis and bursitis, calcified deposits may be removed from the area surrounding the tendon or bursa.

Nursing care

The nursing care of a person with a repetitive use injury focuses on relieving pain, teaching about the disease process and treatment, and improving physical mobility.

Nursing diagnoses and interventions

Acute pain

Swelling and nerve inflammation cause pain in the person with a repetitive use injury.

- Ask the person to rate the pain on a scale of 0 to 10 (with 10 being the most severe pain) before and after any intervention. *This facilitates objective assessment of the effectiveness of the chosen pain relief strategy.*
- Encourage the use of immobilisers. *Splinting maintains joint alignment and prevents pain due to movement of inflamed tissues.*
- Teach the person to apply ice and/or heat as prescribed. *Ice causes vasoconstriction and decreases the pooling of blood in the inflamed area. Ice may also numb the tender area. Heat decreases swelling by increasing venous return.*
- Encourage use of NSAIDs as prescribed. *NSAIDs decrease swelling by inhibiting prostaglandins.*
- Explain why treatment should not be abruptly discontinued. *Abrupt discontinuation of treatment may cause reinflammation of the injured area.*

Impaired physical mobility

Joint pain and swelling can impair mobility.

- Suggest interventions to alleviate pain (such as using an immobiliser and taking pain medications). If the joint is pain free, the person will be more likely to take an active role in therapy.
- Refer to a physiotherapist for exercises. *The physiotherapist can assist the person with exercise to prevent joint stiffness.*
- Suggest consultation with an occupational therapist. *Occupational therapy can help the person learn new ways to perform tasks to prevent recurring symptoms.*

Community-based care

Address the following topics for home care:

- Causes of and treatments for repetitive use injury.
- Rehabilitation to allow the person to return to a state of independence.
- Ways to avoid unnecessary exposure to the activities that increase risk of redeveloping the injury. Suggest evaluation of the person's work environment by an environmental risk manager who can prescribe measures to reduce the risk of repetitive use injuries. Wrist supports or an ergonomic keyboard may be useful for the person who uses a computer extensively. Appropriate desk and chair height also are important in maintaining the correct anatomical position while working.
- Information about sources for braces or other assistive devices.

CHAPTER HIGHLIGHTS

- The most commonly reported musculoskeletal injuries are contusions, strains and sprains. Immediate treatment includes RICE (rest, ice, compression, elevation) therapy.
- Dislocations may be congenital, traumatic or pathological. Nursing assessments include monitoring neurovascular status by assessing for increased pain, decreased or absent pulses, pale skin, inability to move a body part or extremity, and changes in sensation.
- Any of the 206 bones of the body may sustain a fracture. Fractures are closed or simple (skin is intact) or open or compound (skin integrity is interrupted); open fractures are at risk of infection. Other fracture descriptors include oblique or spiral, avulsed, comminuted, compressed, impacted or depressed.
- Fractures heal through three phases: inflammatory, reparative and remodelling. Healing is influenced by the age and physical condition of the person and by the type of fracture.
- Fracture complications include compartment syndrome, fat embolism syndrome, deep venous thrombosis, infection, delayed union and non-union, and reflex sympathetic dystrophy.
- Fractures are treated with surgery, traction and/or casts to stabilise the fractured bone, maintain bone immobilisation, prevent complications and restore function.
- Fractures of the hip are most often sustained by older adult women and are usually the result of a fall. They are the most common injury in the older population, resulting in the greatest number of deaths, and cause the most serious health problems of all fractures for people aged 65 years and older.
- Nursing care for the person with a fracture focuses on interventions for acute pain, risk of peripheral vascular dysfunction, risk of infection, impaired physical mobility and risk of disturbed tactile sensory perception.
- An amputation is the partial or total removal of an extremity. This loss has a significant physical and psychosocial effect on the person and the family. The most common cause for amputation of a lower extremity is peripheral vascular disease. Trauma is the most common cause for upper extremity amputation.
- Complications that may follow an amputation include infection, delayed healing, chronic stump pain, phantom pain and contractures. Stump care is necessary to prevent complications and to prepare the stump for a prosthesis.
- Nursing care for the person with an amputation is provided as part of the interprofessional team and is focused on a return to functional health, with interventions to meet needs for acute pain, impaired skin integrity, grieving, disturbed body image and impaired physical mobility.
- Repetitive use injuries, especially common in the workplace, include carpal tunnel syndrome, bursitis and epicondylitis.

CONCEPT CHECK

1 You are teaching a young adult how to provide self-care for a sprained ankle. You explain that the reason for applying ice immediately after the injury is based on the principle that ice:
1 increases the diameter of blood vessels
2 decreases the diameter of blood vessels
3 is helpful in increasing white blood cells
4 lowers the blood pressure and pulse

2 A person with a compound, open fracture has been admitted to the emergency department and is scheduled for immediate surgery. Which of the following nursing diagnoses would be most appropriate in the immediate postoperative period?
1 *Risk of post-traumatic stress disorder (PTSD)*
2 *Impaired transfer ability*
3 *Risk of infection*
4 *Risk of falls*

3 While providing care to an older woman with a cast on her left lower arm (from below the elbow to above the fingers), you perform a neurovascular assessment. Which of the following assessments indicates a possible complication?
1 slightly oedematous fingers
2 warm, pink skin above the cast
3 pale, cold fingers
4 pain rating of 2 on a 1 to 10 scale

4 Which of the following minerals is essential to bone healing?
1 potassium
2 magnesium
3 sodium
4 calcium

5 You are assessing a young man with a newly applied long leg cast. He complains of extreme pain in his leg and his toes are cyanotic and lack sensation. What is your priority intervention?
1 Document the assessments carefully and accurately.
2 Notify the healthcare provider who applied the cast.
3 Elevate the leg on at least three pillows.
4 Apply an ice bag over the painful area.

6 Your assigned person has been diagnosed with DVT of the left lower extremity. What body system would require very careful monitoring?
1 haematological
2 respiratory
3 digestive
4 renal

7 Although nursing diagnoses are always individualised, what is one nursing diagnosis common to all musculoskeletal injuries?
1 *Disturbed body image*
2 *Acute pain*
3 *Chronic pain*
4 *Risk of infection*

8 At what position would you place the remaining extremity following a below-the-knee amputation during the first 24 hours after surgery?
1 elevated above the level of the heart
2 lower than the rest of the body
3 crossed over the intact extremity
4 level with the rest of the body

9 The day following a below-the-knee amputation, the person you are caring for tells you that he feels as though his toes are cramping in the amputated foot. What is this experience called?
1 chronic stump pain
2 contractures
3 attention seeking
4 phantom limb pain

10 A friend is cutting wood with a circular saw. He suddenly screams that he has cut off his finger. What would you do with the amputated finger?
1 Don't worry about it; the important thing is to get him to the hospital.
2 Put it in a storage bag filled with warm water.
3 Tape it to his hand so the emergency personnel will know where it is.
4 Wrap it in a towel, put it in a plastic bag and lay it on ice.

CHAPTER 39

NURSING CARE OF PEOPLE WITH MUSCULOSKELETAL DISORDERS

ANN-MARIE BROWN

KEY TERMS

LEARNING OUTCOMES

- Explain the pathophysiology, manifestations, complications, interprofessional care and nursing care of metabolic, degenerative, autoimmune, inflammatory, infectious, neoplastic, connective tissue and structural musculoskeletal disorders.
- Compare and contrast the pathophysiology, manifestations, diagnosis and treatments for osteoporosis, osteoarthritis, Paget's disease and rheumatoid arthritis.
- Discuss the purposes, nursing implications and health education for the person and family regarding medications used to treat osteoporosis, Paget's disease, gout, osteomalacia, osteoarthritis, rheumatoid arthritis, systemic lupus erythematosus, osteomyelitis, bone tumours, scleroderma and lower back pain.
- Describe the surgical procedures used to treat people with arthritis.

CLINICAL COMPETENCIES

- Assess functional status of people with musculoskeletal disorders and monitor, document and report abnormal manifestations.
- Use evidence-based research to assess people at risk of osteoporosis and to evaluate the effectiveness of internet use to teach older adults with rheumatoid arthritis.
- Determine priority nursing diagnoses, based on assessed data, to select and implement individualised nursing interventions for people with musculoskeletal disorders.
- Administer topical, oral and injectable medications used to treat musculoskeletal disorders knowledgeably and safely.
- Provide skilled care to people having a surgical debridement for osteomyelitis and a total joint replacement.
- Integrate interprofessional care into care of people with musculoskeletal disorders.
- Provide teaching appropriate for community-based self-care of musculoskeletal disorders.
- Revise the plan of care as needed to provide effective interventions to promote, maintain or restore functional health status to people with musculoskeletal disorders.

Various metabolic, degenerative, autoimmune, inflammatory, infectious, neoplastic, connective tissue and structural disorders may affect the musculoskeletal system. Many of these diseases have significant physical, psychosocial and financial consequences. When these problems occur, people experience a variety of individualised responses to their altered health status. Nursing care is directed towards meeting physiological needs, providing education and ensuring psychological support for the person and family.

Arthritis refers to inflammation of the joints, while **rheumatic disorders** refer to diseases of the muscles and bones as well as the joints. These diseases affect not only the joints but also the connective tissues of the body. The various types of arthritis are discussed in this chapter in different sections, depending on the primary aetiology of the disorder. Approximately 15% (3.3 million people) of all Australians had arthritis in 2011–2012 (Australian Bureau of Statistics (ABS), 2012). The two most prevalent forms of arthritis are osteoarthritis, which accounts for 51% of cases, and rheumatoid arthritis, which accounts for a further 14% of cases (ABS, 2012). According to the ABS, 37.3% of people who have arthritis don't know which type they have (ABS, 2012).

There are more than 100 different types of arthritis, but the most common are osteoarthritis, rheumatoid arthritis, systemic lupus erythematosus, ankylosing spondylitis and gout (Arthritis Australia, 2015). The aetiology of most rheumatic disorders is not clear; in many cases, the pathophysiological processes involved are often complex and poorly understood. Many are primary disorders; others occur as secondary processes associated with another disease. The wear and tear of ageing, autoimmune processes, metabolic disorders, genetic factors and infection are also implicated as causative factors in some forms of rheumatic disease.

Arthritic disorders are a leading cause of disability; however, their very prevalence may lead the public and healthcare professionals to treat them as normal ageing processes or to discount the validity of the pain and disability experienced by the person with arthritis.

METABOLIC BONE DISORDERS

Metabolic bone disorders originate in the bone remodelling process, which normally involves a sequence of events of bone reabsorption and formation. In the adult, this process is primarily internal remodelling through replacement of trabecular bone. Adults replace about 25% of trabecular bone every 4 months through reabsorption of old bone by osteoclasts and formation of new bone by osteoblasts (Porth & Matfin, 2014). Metabolic bone disorders may result from a variety of factors, including ageing, calcium and phosphate imbalances, genetics and changes in levels of hormones.

THE PERSON WITH OSTEOPOROSIS

Osteoporosis, literally defined as 'porous bones', is a metabolic bone disorder characterised by loss of bone mass, increased bone fragility and an increased risk of fractures. The reduced bone mass is caused by an imbalance of the processes that influence bone growth and maintenance. Although osteoporosis may result from an endocrine disorder or malignancy, it is most often associated with ageing.

In Australia, the number of people suffering from osteoporosis is increasing. Women over the age of 50 are at greatest risk of developing a fracture. In 2011–2012, the estimated prevalence of self-reported diagnosed osteoporosis was 15% of women and 3% of men (AIHW, 2014).

Risk factors

The risk of developing osteoporosis depends on how much bone mass is achieved between ages 25 and 35 and how much is lost later. Certain diseases, lifestyle habits and ethnic backgrounds increase the risk of developing osteoporosis (see the 'Focus on cultural diversity' box below). Different variables affect one's risk of osteoporosis—some can be modified and others cannot. The risk factors are summarised in Box 39.1.

BOX 39.1 Risk factors for osteoporosis

- A family history of osteoporosis
- Personal history of fracture after age 50
- Current low bone mass
- History of fracture in a first-degree relative
- Being female, especially Caucasian or Asian
- Being thin and/or having a small frame
- Menopause-associated low oestrogen levels
- Low testosterone levels in men
- Dietary: low lifetime calcium intake, vitamin D deficiency
- Medication use: anticonvulsants, corticosteroids
- Lifestyle: inactivity, cigarette smoking, excess alcohol
- Presence of certain chronic diseases

Unmodifiable risk factors

Both men and women are susceptible to osteoporosis as they age, because the osteoblasts and osteoclasts undergo alterations that diminish their activity. Women have a significantly higher risk of manifestations and complications of osteoporosis because their peak bone mass is 10–15% less than that of men. In addition, age-related bone loss begins earlier and proceeds more rapidly in women, beginning in their thirties and accelerating before menopause. Oestrogen in women and testosterone in men appear to help prevent bone loss; decreasing levels of these hormones associated with ageing contribute to bone loss. Age-related bone loss in men occurs 15 to 20 years later than in women and at a slower rate.

Indigenous people of both sexes are much more likely than non-Indigenous people to be hospitalised with a minimal hip trauma. Indigenous Australians were slightly more likely to

FOCUS ON CULTURAL DIVERSITY

The person with osteoporosis

- Significant risk is reported for people of all cultural backgrounds, but the highest percentage of cases are in European and Asian women aged 50 or older, with 20% estimated to have osteoporosis and 52% estimated to have low bone mass.
- When differences in age structure are taken into account, the prevalence of osteoporosis in Indigenous Australians is lower than for non-Indigenous Australians. About 2% (1.5% of men and 2.5% of women) of Indigenous Australians have doctor-diagnosed osteoporosis compared with about 3% of non-Indigenous Australians (0.9% of men and 4.7% of women).

Source: Australian Institute of Health and Welfare (2011). *A picture of osteoarthritis in Australia.* Retrieved from www.aihw.gov.au/WorkArea/DownloadAsset.aspx?id=10737418747.

report having arthritis than non-Indigenous Australians (18% compared to 15%) and back problems (18% compared to 16%). The proportion of Indigenous Australians reporting osteoporosis was similar to that for non-Indigenous Australians (2% compared to 3%) (ABS, 2011).

Premature osteoporosis is increasing in female athletes, who have a greater incidence of eating disorders and amenorrhoea. Poor nutrition and intense physical training can result in a deficient production of oestrogen. Decreased oestrogen, combined with a lack of calcium and vitamin D, results in a loss of bone density (Porth & Matfin, 2014).

People who have an endocrine disorder such as hyperthyroidism, hyperparathyroidism, Cushing's syndrome or diabetes mellitus are at high risk of osteoporosis. These disorders affect the metabolism, in turn affecting nutritional status and bone mineralisation.

Modifiable risk factors

Modifiable risk factors include behaviours that place a person at risk of developing osteoporosis, as well as physical changes such as menopause whose contribution to osteoporosis can be modified by preventive strategies. Calcium deficiency is an important modifiable risk factor contributing to osteoporosis. Calcium is an essential mineral in the process of bone formation and other significant body functions. When there is an insufficient intake of calcium in the diet, the body compensates by removing calcium from the skeleton, weakening bone tissue. Acidosis, which may result from a high-protein diet, contributes to osteoporosis in two ways. Calcium is withdrawn from the bone as the kidneys attempt to buffer the excess acid. Acidosis also may directly stimulate osteoclast function. A high intake of diet soda with a high phosphate content also can deplete calcium stores.

With menopause and decreasing oestrogen levels, bone loss accelerates in women. Oestrogen promotes the activity of osteoblasts, increasing new bone formation. In addition, oestrogen enhances calcium absorption and stimulates the thyroid gland to secrete calcitonin, a hormone that suppresses osteoclast activity and increases osteoblast activity.

Both cigarette smoking and excess alcohol intake are risk factors for osteoporosis. Smoking decreases the blood supply to bones. Nicotine slows the production of osteoblasts and impairs the absorption of calcium, contributing to decreased bone density. Alcohol has a direct toxic effect on osteoblast activity, suppressing bone formation during periods of alcohol intoxication. In addition, heavy alcohol use may be associated with nutritional deficiencies that contribute to osteoporosis. Interestingly, moderate alcohol consumption in postmenopausal women actually may increase bone mineral content, possibly by increasing levels of oestrogen and calcitonin.

Sedentary lifestyle is another modifiable risk factor that can cause osteoporosis. Weight-bearing exercise, such as walking, influences bone metabolism in several ways. The stress of this type of exercise causes an increase in blood flow to bones, which brings growth-producing nutrients to the cells. Walking causes an increase in osteoblast growth and activity.

Prolonged use of medications that increase calcium excretion, such as aluminium-containing antacids and anticonvulsants, increase the risk of developing osteoporosis. Heparin therapy increases bone resorption and its prolonged use is associated with osteoporosis. Antiretroviral therapy for people with AIDS or HIV infection may cause decreased bone density and osteoporosis (Porth & Matfin, 2014).

Anyone who takes a glucocorticoid medication for more than 3 months is at risk of glucocorticoid-induced osteoporosis. These medications, often prescribed to control many rheumatic diseases, include prednisolone (Prednisone) and dexamethasone (Decadron, Hexadrol). They can directly affect bone cells, slowing the rate of bone formation. They also interfere with how the body uses calcium and affect levels of sex hormones, leading to bone loss. Problems that result, such as an increased possibility of fractures, can be prevented by taking a daily regimen of calcium supplements with added vitamin D and one multivitamin (Mazziotti, Canalis & Giustina, 2010).

Pathophysiology

Although the exact pathophysiology of osteoporosis is unclear, it is known to involve an imbalance of the activity of osteoblasts that form new bone and osteoclasts that resorb bone. Until age 35, when peak bone mass occurs, formation occurs more rapidly than does reabsorption. After peak bone mass is achieved, slightly more is lost than is gained (about 0.3–0.5% per year); this loss is accelerated if the diet is deficient in vitamin D and calcium. In women, bone loss begins to increase to 1–2% per year from the age of 45 years, increases to 2–4% per year at the onset of menopause (with loss of oestrogen), then slows but does not stop at about age 60. In men, bone density tends to remain relatively stable until middle age, decreasing by about 0.5–1.0% per year from the age of 45–55 years (Osteoporosis Australia, 2012).

Osteoporosis affects the diaphysis (shaft of the bone) and the metaphysis (portion of the bone between the diaphysis and the epiphysis). The diameter of the bone increases, thinning the outer supporting cortex. As osteoporosis progresses, trabeculae are lost from cancellous bone (the spongy tissue of bone) and the outer cortex thins to the point that even minimal stress will fracture the bone (Porth & Matfin, 2014).

Manifestations

The most common manifestations of osteoporosis are loss of height, progressive curvature of the spine, lower back pain and fractures of the forearm, spine or hip. Osteoporosis is often called the 'silent disease' because bone loss occurs without symptoms.

The loss of height occurs as vertebral bodies collapse. Acute episodes generally are painful, with radiation of the pain around the flank into the abdomen. Vertebral collapse can occur with little or no stress; minimal movements such as bending, lifting or jumping may precipitate the pain. In some people, vertebral collapse may occur slowly, accompanied by little discomfort. Along with loss of height, characteristic dorsal kyphosis and cervical lordosis develop, accounting for the 'dowager's hump' often associated with ageing. The abdomen tends to protrude and the knees and hips to flex as the body attempts to maintain its centre of gravity (see Figure 39.1).

Complications

The most common fractures are vertebral, hips and wrists. There may be no obvious manifestations of osteoporosis until fractures occur. Some fractures are spontaneous; others may result from everyday activities. While wrist and vertebral fractures have not been shown to increase disability or mortality, persistent pain and associated posture changes may restrict the person's activities or interfere with activities of daily living (ADLs).

INTERPROFESSIONAL CARE

Care of the person with osteoporosis focuses on stopping or slowing the process, alleviating the symptoms and preventing complications. Proper nutrition and exercise are important components of the treatment program.

Diagnosis

The manifestations of osteoporosis can mimic those of other bone disorders, so diagnostic tests are needed to differentiate osteoporosis from other problems.

A bone mineral density (BMD) scan assesses the mass of bone per unit volume—how tightly the bone is packed. Dual-energy x-ray absorptiometry (DEXA) measures bone density in the lumbar spine or hip and is considered to be highly accurate. Ultrasound transmits painless sound waves through the heel of the foot to measure bone density. This 1-minute test is not as sensitive as DEXA, but is accurate enough for screening purposes. These tests are described in Chapter 37.

Laboratory tests include alkaline phosphatase (AST), which may be elevated following a fracture, and serum bone Gla protein (osteocalcin), which can be used as a marker of osteoclastic activity and therefore is an indicator of the rate of

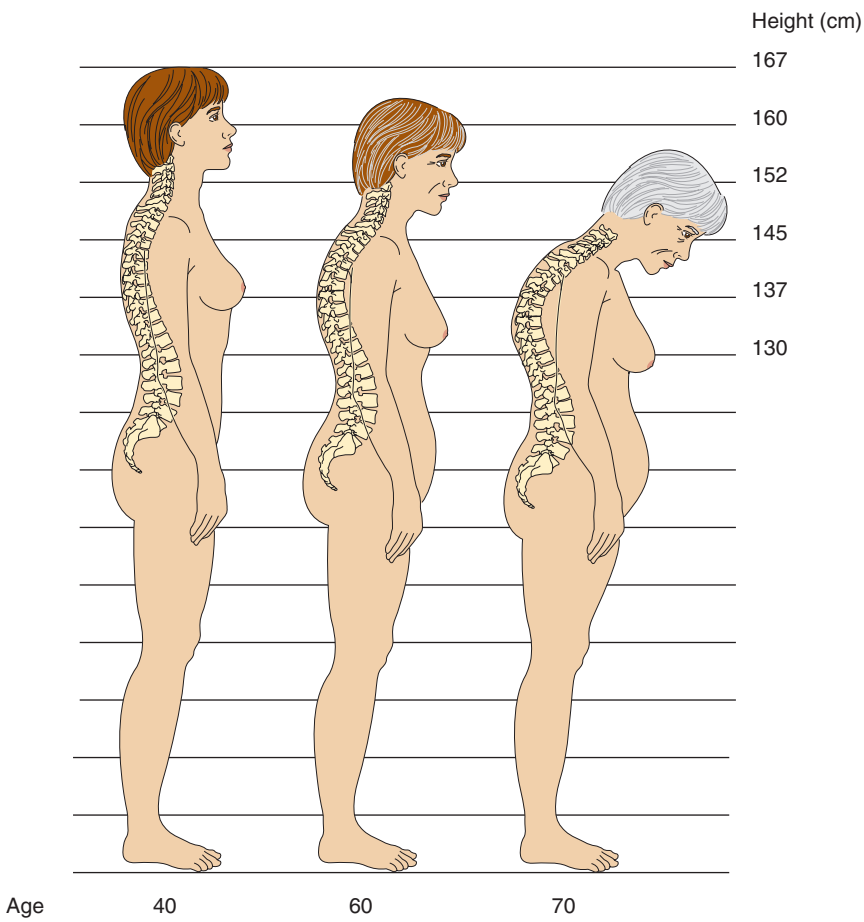

FIGURE 39.1 ■ Spinal changes caused by osteoporosis. As the condition progresses, height can be reduced by as much as 17 cm

TABLE 39.1 Differential features of osteoporosis, osteomalacia and Paget's disease

DIFFERENTIATING FEATURES	OSTEOPOROSIS	OSTEOMALACIA	PAGET'S DISEASE
Pathophysiology	Resorption greater than bone formation	Inadequate mineralisation of bone matrix	Excessive osteoclastic activity and formation of poor-quality bone
Calcium level (serum)	Normal	Low or normal	Normal or elevated (especially in immobilised people)
Phosphate level (serum)	Normal	Low or normal	Normal
Parathyroid hormone level (serum)	Normal	High or normal	Normal
Alkaline phosphatase level (serum)	Normal	Elevated	Increased; not a reliable test for people who have liver disease or are pregnant
Hydroxyproline (urine)	Not applicable	Not applicable	Increased
Radiographic findings	Osteopenia, fractures	Decreased bone density, radiolucent bands known as Looser's zones or pseudofractures	'Punched-out' appearance of bone, increase in bone thickness, linear fractures, mosaic pattern of bone matrix

bone turnover. This test is most useful to evaluate the effects of treatment, rather than as an indicator of the severity of the disease. A comparison of laboratory test results for metabolic bone diseases is outlined in Table 39.1.

Medications

Oestrogen replacement therapy reduces bone loss, increases bone density in the spine and hip, and reduces the risk of fractures in postmenopausal women. It is particularly recommended for women who have undergone surgical menopause before age 50 and is often prescribed for women with other osteoporosis risk factors. Oestrogen therapy alone is associated with an increased risk of endometrial cancer, so it usually is prescribed in combination with progestin (hormone replacement therapy, or HRT). The choice of using HRT to prevent osteoporosis is one that must be made between the woman and her healthcare provider.

Raloxifene (Evista) is a selective oestrogen receptor modulator (SERM) that appears to prevent bone loss by mimicking oestrogen's beneficial effects on bone density in postmenopausal women. It does not have the risks of oestrogen. Hot flushes are a common side effect and this drug should not be taken by a woman with a history of blood clots.

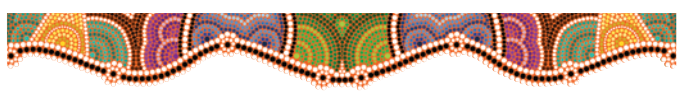
Alendronate (Fosamax) and risedronate (Actonel) are from the class of drugs known as bisphosphonates. Bisphosphonates are potent inhibitors of bone resorption that may be used to prevent and treat osteoporosis. They inhibit bone breakdown, preserve bone mass and increase bone density in the hip and vertebrae. Alendronate is especially useful for men and young adults and to prevent or treat glucocorticoid-induced osteoporosis. The nursing implications of bisphosphonates are found in the 'Medication administration' box on page 1432. Teriparatide (Forteo) is a synthetic parathyroid hormone, administered subcutaneously to stimulate new bone formation and mass. It is used to decrease the risk of bone fracture from osteoporosis in postmenopausal women and in men with primary or secondary hypogonadism.

Ibandronate sodium (Boniva) is the first monthly osteoporosis medication. It is used for both treatment and prevention of postmenopausal osteoporosis and reduces the number of vertebral fractures in women with osteoporosis, as well as increasing bone density in women who do not have the disease. It has been available in Australia since 2006 (Osteoporosis Australia, 2015). Ibandronate sodium needs to be taken on the same day of each month.

Calcitonin is a hormone that increases bone formation and decreases bone resorption. Calcitonin increases spinal bone density and reduces the risk of compression fractures; it may reduce the risk of hip fracture as well. Calcitonin usually is prescribed as a nasal spray, although it also is available in parenteral form. Because calcitonin is a protein, it can precipitate anaphylactic-type allergic responses.

Sodium fluoride stimulates osteoblast activity, increasing bone formation. When used to treat osteoporosis, bone mass of the spine increases and the risk of spinal fractures may be reduced. Fluoride therapy may, however, be associated with an increased risk of hip and other non-vertebral fractures.

Medications being investigated include vitamin D metabolites and other bisphosphonates. See the 'Medication administration' box below for information about calcium, calcitonin and fluoride.



Nursing care

Osteoporosis is both preventable and treatable; therefore, nursing care focuses primarily on planning and implementing interventions to prevent the disease, its manifestations and the resulting injuries. An important aspect of preventing osteoporosis is educating people under age 35. A nursing care plan for a person with osteoporosis is found below.

Health promotion

Health promotion activities to prevent or slow osteoporosis focus on calcium intake, exercise and health-related behaviours.

Nutrition

For people of all ages, stress the importance of maintaining a daily calcium intake that meets recommendations of the National

MEDICATION ADMINISTRATION The person with osteoporosis

CALCIUM

Postmenopausal women, regardless of whether they take replacement oestrogen, are encouraged to take calcium to prevent osteoporosis.

Nursing responsibilities

- Help the person to maintain an adequate dietary intake of calcium. The best dietary source is milk and other dairy products, including yoghurt.
- Postmenopausal women who take oestrogen need 1000 mg of calcium daily. Those who do not take oestrogen need about 1500 mg daily to minimise osteoporosis.
- Identify alternative sources, such as skim milk and low-fat yoghurt, oysters, canned sardines or salmon, beans, cauliflower and dark-green leafy vegetables.

Health education for the person and family

- Take calcium carbonate in divided doses 30 to 60 minutes before meals to allow for absorption.
- Take calcium citrate with meals to minimise gastrointestinal distress.

CALCITONIN

Calcitonin–salmon injection, synthetic Calcimar Miacalin (injection or nasal spray)

In postmenopausal osteoporosis, calcitonin prevents further bone loss and increases bone mass if the person consumes adequate amounts of calcium and vitamin D. Calcitonin may be used in postmenopausal women who cannot or will not take oestrogen.

Nursing responsibilities

- Calcitonin is protein in nature; both the parenteral form and the nasal spray forms may cause an anaphylactic-type allergic response. Observe the person for 20 minutes after administration; have appropriate emergency equipment and drugs available to treat anaphylaxis.
- Alternate nostrils daily when administering calcitonin nasal spray.
- Review medical history for conditions that contraindicate use of calcitonin products: hypersensitivity to salmon calcitonin and lactation (calcitonin is secreted in breast milk and may inhibit lactation).
- Observe for side effects: nausea and vomiting, anorexia, mild transient flushing of the palms of the hands and the soles of the feet, and urinary frequency.
- Teach the person the proper technique for handling and injecting the drug at home.

Health education for the person and family

- Take the medication in the evening to minimise side effects.
- Warm nasal spray to room temperature before using.
- Rhinitis (runny nose) is the most common side effect with calcitonin nasal spray. Other possible side effects include sores, itching or other nasal symptoms. Report nosebleeds to your healthcare provider.
- Nausea and vomiting may occur during initial stages of therapy; they disappear as treatment continues.
- While taking the medication, be sure to consume adequate amounts of calcium and vitamin D.

FLUORIDE

Fluoride is a mineral long recognised as essential for the normal formation of dentine and tooth enamel. Fluoride appears to decrease the solubility of bone mineral and therefore the rate of bone reabsorption. Its use in preventing and treating osteoporosis is relatively new but promising.

Nursing responsibilities

- Monitor serum fluoride levels every 3 months.
- Have bone mineral density studies conducted at 6-month intervals to document progress of bone growth.

Health education for the person and family

- Take sodium fluoride tablets after meals and avoid milk or dairy products; these reduce gastrointestinal absorption of the medication.
- While taking fluoride, be sure to maintain an adequate calcium intake.
- Use fluoride mouth rinse immediately after brushing teeth and just before retiring at night. Do not swallow the rinse and avoid eating or drinking for at least 30 minutes after use.
- Notify the healthcare provider if teeth become stained or mottled after repeated use of fluoride mouth rinse.

Institutes of Health (for Australia and New Zealand) and the National Health and Medical Research Council (NRMRC) and Ministry of Health (MoH) (2015). This is particularly important for adolescent girls and young adult women who may avoid eating many high-calcium foods such as dairy products because of concerns about weight. Optimal calcium intake before ages 30 to 35 probably increases peak bone mass. Emphasise that low-fat (or non-fat) dairy products also contain calcium, although some fat in the product may enhance calcium absorption.

Milk and milk products are the best sources of calcium. The lactose in milk facilitates calcium absorption as well. Other food sources of calcium include sardines, clams, oysters and salmon, as well as dark-green leafy vegetables such as broccoli, bok choy and spinach. For people who avoid dairy products because of lactose intolerance or a vegetarian diet, suggest alternative sources.

Calcium supplements are available in many forms. Most supplements provide calcium carbonate in the range of 200 to 600 mg per tablet. Other forms of calcium, including citrate, gluconate and lactate, generally provide a lower amount of elemental calcium per tablet. A combination of calcium with vitamin D is recommended, particularly for older adults who may have a vitamin D deficiency that impairs their ability to absorb and use calcium.

Exercise

Teach people the importance of physical activity and weight-bearing exercises in preventing and slowing bone loss. Suggest that people participate in regular exercise, such as walking for at least 20 minutes four or more times a week. Inform people that swimming and pool aerobic exercises are not as beneficial for maintaining bone density because of the lack of weight-bearing activity.

NURSING CARE PLAN A person with osteoporosis

Nancy Bauer is a 53-year-old school teacher. She has been married for 36 years and has two children. Mrs Bauer is 165 cm tall. She has smoked one packet of cigarettes a day for 30 years and drinks one to two glasses of wine with dinner each evening. She does not routinely exercise. Mrs Bauer has had symptoms of menopause for 8 years, including hot flushes in the early years and mood swings of late. She has never been on hormone replacement therapy.

Mrs Bauer is currently seeking medical advice for continuous lower back pain. The pain is not relieved with an over-the-counter analgesic and she frequently wakes up during the night because of the pain. She is diagnosed with osteoporosis.

ASSESSMENT

The nurse practitioner notes that Mrs Bauer's vital signs are within normal limits. She has full range of motion of all extremities and is able to stand and bend over, but she reports discomfort when returning to the upright position. Mrs Bauer has a slightly pronounced 'hump' on her upper back and is 2.5 cm shorter than her stated height on admission. Her muscle strength is symmetrical and strong.

DIAGNOSIS

- *Acute pain* of the lower spine related to vertebral compression.
- *Deficient knowledge* related to osteoporosis and treatment to prevent further damage.
- *Imbalanced nutrition: less than body requirements* related to inadequate intake of calcium.
- *Risk of injury* related to effects of change in bone structure secondary to osteoporosis.

PLANNING

Ensure Mrs Bauer is able to manage her pain and educate her regarding her osteoporosis and associated issues.

Expected outcomes

- Verbalise a decrease in back pain.
- Be able to describe ways to treat her osteoporosis and prevent further complications.
- Verbalise an understanding of the current research and treatment regarding osteoporosis.
- Verbalise safety precautions to prevent fractures due to falls.
- Seek consultation for supplements and medications to prevent further bone loss.
- Verbalise how stopping smoking can help prevent further progression of osteoporosis.
- Design a program of physical activity to prevent complications of osteoporosis.

IMPLEMENTATION

- Teach back-strengthening exercises.
- Refer to an osteoporosis support group, if available.
- Assess current knowledge base and correct misconceptions regarding treatment of osteoporosis.
- Provide current educational literature regarding treatment of osteoporosis.
- Review safety and fall precautions, and provide literature regarding how to create a safe home environment.
- Instruct in dietary and calcium supplements that help prevent effects of osteoporosis.
- Provide realistic, yet optimistic, feedback about loss of height and bone integrity and the potential outcomes of treatment.
- Discuss physical exercises that help prevent complications due to osteoporosis.

EVALUATION

On her return visit 6 months later, Mrs Bauer reports that she feels much better. She is no longer irritable and does not experience mood swings because she has been taking her prescribed hormone replacements for 6 months. She is eating products rich in calcium and taking a daily supplement of calcium with vitamin D. Mrs Bauer has reduced her wine intake to one glass in the evening and now drinks decaffeinated coffee and tea. She also states that since she stopped smoking, she has been walking 30 to 45 minutes every day.

CRITICAL THINKING IN THE NURSING PROCESS

1. What is the rationale for stopping smoking and limiting caffeine and alcohol intake in the treatment of osteoporosis?
2. Which foods would you encourage for people at high risk of osteoporosis whose serum cholesterol and LDL/HDL ratios indicate a high risk of cardiovascular disease?
3. Which physical activities would you consider beneficial in helping to prevent the effects of osteoporosis in the female person who is wheelchair bound or has limited mobility?
4. Develop a care plan for Mrs Bauer for the nursing diagnosis *Risk of trauma.*

REFLECTION ON THE NURSING PROCESS

1. Reflecting on the care for Mrs Bauer, identify the main issues you have learned from this case study that you will able to apply in future practice.
2. What type of health education is required for Mrs Bauer prior to discharge, and how would this be best delivered to her?

Healthy behaviours

Behaviours that help prevent osteoporosis include not smoking, avoiding excessive alcohol intake and limiting caffeine intake to two or three cups of coffee each day.

Assessment

Collect the following data through the health history and physical examination:

- *Health history:* age, risk factors, history of fractures, smoking history, alcohol intake, medications, usual diet, menstrual history including menopause, usual exercise/activity level, lower back pain (see the following 'Translation to practice' box).
- *Physical examination:* height, spinal curves.

Nursing diagnoses and interventions

Nursing care of people who have osteoporosis focuses on teaching about the disease process, helping maintain physical mobility and nutrition, and solving problems associated with pain and injury.

TRANSLATION TO PRACTICE Evidence-based practice for the person with osteoporosis

Osteoporosis is a major health problem in Australia and New Zealand. Risk factors for osteoporosis include being Caucasian, having a small body frame, not doing weight-bearing exercises and having a family history of osteoporosis. Nursing can do much to prevent the development of osteoporosis by assessing risk factors and teaching about diet, exercise and lifestyle.

IMPLICATIONS FOR NURSING

Assessment is a critical component of the nursing process, enabling nurses to identify people at risk of diseases, to monitor ongoing interventions and to design teaching specific to a person's needs. The risk factors for osteoporosis are genetics, calcium and vitamin D status, body mass index, previous fractures, recurrent falls, medical conditions such as malabsorption disorders, thyroid disease, diabetes, chronic kidney or liver disease, and medications such as antiepileptic drugs, antidepressants and long-term glucocortisoids (Osteoporosis Australia, 2014).

CRITICAL THINKING IN PERSON-CENTRED CARE

1. At what age do women develop maximum bone mass? (Review information in a text or on the internet.) Based on this information, what type of teaching would be most effective?
2. Compare and contrast your teaching for a 24-year-old Indigenous Australian woman who has a calcium-poor diet but is a non-smoker, and a thin, Caucasian, 64-year-old woman who is postmenopausal and smokes.
3. While screening people in a clinic for health risks, including osteoporosis, a man in his seventies says, 'Oh, I can't have bad bones . . . I'm a man!' How would you respond?

Health-seeking behaviours

At multiple points in the person's lifetime, nurses can provide vital information that will help people use self-care strategies to reduce their risk of developing osteoporosis:

- Assess the person's health habits, including diet, exercise, smoking and alcohol use. *The risk of developing osteoporosis in later life is affected by such things as diet, regular participation in weight-bearing exercise and personal habits such as smoking and alcohol consumption.*
- Teach women and men of all ages the importance of maintaining an adequate calcium intake. Provide a list of calcium-rich foods and discuss the use of calcium supplements with people who do not consume adequate dietary calcium. *Calcium needs vary during the course of a lifetime; however, many people never consume adequate amounts of calcium. This affects their peak bone mass and the rate of bone loss with ageing. Calcium in foods is more completely absorbed than that supplied by calcium supplements.*
- Discuss the importance of maintaining a regular schedule of weight-bearing exercise, either through an exercise program or regular physical activity. *Weight-bearing exercise promotes osteoblast activity, helping maintain bone strength and integrity.*
- Refer people to smoking-cessation programs and alcohol treatment programs as appropriate. *Smoking interferes with oestrogen's protective effects on bones, promoting bone loss. Excess alcohol intake affects the nutritional status of the person, increasing the risk of calcium and vitamin D deficiency.*
- Refer people with significant risk factors for osteoporosis to primary care providers or clinics for bone-density evaluation. *Early identification and treatment of osteoporotic changes in bones can reduce the risk and possible long-term consequences of falls and fractures.*

Risk of injury

Falls that would result in little or no injury in the healthy adult may cause fractures in the person with osteoporosis. Even normal movements such as twisting, bending, lifting or rising from bed can precipitate a vertebral fracture.

- Implement safety precautions as necessary for the person who is hospitalised or in a long-term care facility. Maintain the bed in a low position; use side rails if indicated to prevent the person from getting up alone; provide night-time lighting to toilet facilities. *Most falls are preventable, particularly in hospitals and long-term care facilities.*
- Avoid using restraints (if hospitalised or a resident in a long-term care facility) if at all possible. *Restraints may actually increase the person's risk of falling, as well as the risk of injury associated with a fall.*

CONSIDERATION FOR PRACTICE

People may fracture osteoporotic bones when pulling against restraints.

- Teach people who are able to participate in weight-bearing exercises to perform exercises at least three times a week for a sustained period of 30 to 40 minutes. *The mechanical force of weight-bearing exercises promotes bone growth. Bones weaken and demineralise without exercise. Walking is an easy, low-impact form of exercise. Swimming (including walking on the bottom of the pool) does not provide the needed weight-bearing activity.*
- Encourage older adults to use assistive devices to maintain independence in ADLs. *Walking sticks, canes and other assistive devices encourage independence and support activities that promote bone growth.*
- Teach older people about safety and fall precautions. *An assessment of the person's home for safety and fall risks may reduce the risk of fractures and, in turn, the cost of hospitalisation and potential disability and/or death.*

Imbalanced nutrition: less than body requirements

Most Australians do not maintain their recommended daily intake of calcium. People must therefore be made aware of the

relationship between an adequate calcium intake and maintaining strong bones. The recommendations for Australia and New Zealand are:

- 1300 mg/day for girls and boys aged 12 to 18 years
- 1000 mg/day for pregnant and lactating women over 19; 1300 mg/day for pregnant and lactating women under 18
- 1000 mg/day for women aged 19 to 50
- 1000 mg/day for men aged 19 to 70
- 1300 mg/day for women over 50 and men over 70 (NHMRC and MoH, 2015).

Teach people taking calcium supplements the importance of taking the medication at the proper time and the side effects that may occur. Free hydrochloric acid is needed for calcium absorption. Calcium carbonate supplement should be taken 30 to 60 minutes before meals to allow adequate absorption. Calcium citrate supplements should be taken with meals to prevent gastrointestinal distress.

CONSIDERATION FOR PRACTICE
Calcium supplements should be taken in divided doses (two to three times daily) for improved distribution.

Acute pain

Advanced stages of osteoporosis can result in pain and immobilisation. Acute pain usually results from a complicating fracture, especially a compression fracture of the vertebrae.

- Suggest anti-inflammatory pain medications for treatment of both acute and chronic phases of pain. People should be instructed in the amount and frequency as noted on the manufacturer's labels. *Continuous administration of ibuprofen or other non-steroidal anti-inflammatory drugs (NSAIDs) can be useful to provide relief from pain, but people must be cautioned not to exceed dosage recommendations.*

CONSIDERATION FOR PRACTICE
Teach people on long-term anti-inflammatory medications to watch for bright-red bleeding from the stomach (in vomitus) or black bowel movements.

- Suggest the application of heat to relieve pain. *A heating pad may offer temporary pain relief. To avoid the 'rebound effect', the heat should be removed every 20 to 30 minutes.*

Community-based care

The person who has osteoporosis needs education on safety and preventing falls. In addition to home safety, outdoor safety is important, too. People should be taught to use assistive devices for added stability, to wear rubber-soled shoes for traction and to walk on the grass when footpaths are slippery.

Address the following topics when discussing home care:

- resources for medical supplies and assistive devices
- diet, exercise and medications
- pain management
- maintaining good posture to help prevent stress on the spine

THE PERSON WITH PAGET'S DISEASE

Paget's disease, also called *osteitis deformans*, is a progressive metabolic skeletal disorder that results from excessive metabolic activity in bone, with excessive bone resorption followed by excessive bone formation. This chronic remodelling results in the affected bones being larger and softer, with manifestations of bone pain, arthritis, obvious skeletal deformities and fractures. The disorder affects bones of the axial skeleton, especially the femur, pelvis, vertebrae and skull. The disease may affect one bone or multiple bones. The cause is unknown; however, several theories have been proposed, including hormonal imbalance, vascular disorder, neoplasm, autoimmune disorder and inborn error of connective tissue. It affects up to 4% of Australians over the age of 55 years (Walsh, 2012).

Paget's disease occurs in both men and women, affecting 1.5–8% of the population over the age of 50 in many countries. It is less common in people of Asian, Indian and Scandinavian descent. It is more common in men—2:1 compared to women—and up to 40% of all people with Paget's disease have at least one other relative with the disorder. It has a familial tendency as a result of mutations in several genes. The measles virus has been found in bone lesions and the relevance of that finding is under investigation (Paget Foundation, 2015).

Pathophysiology

Paget's disease progresses slowly. It usually follows a two-stage process: an excessive amount of osteoclastic bone resorption followed by excessive osteoblastic bone formation. The initial phase presents with an abnormal increase in osteoclasts. The bones increase in size and thickness because of the acceleration in bone resorption and regeneration, resulting in a thick layer of coarse bone with a rough and pitted outer surface (Porth & Matfin, 2014). Resorption of cancellous bone occurs rapidly. As new bone tissue tries to replace the loss, fibrous tissue forms in the bone marrow. The bone is at first hyperaemic and soft, and bowing occurs. When this excessive bone cell activity decreases, the result is a gain in bone mass, but the newly formed bone becomes hard and brittle. This brittleness may lead to fractures.

Manifestations

Most people with Paget's disease are asymptomatic for years and the disease often is discovered when typical changes are seen on

an incidental x-ray. Manifestations are often vague and depend on the specific area involved (see the box below). The most common manifestation is localised pain of the long bones, spine, pelvis and cranium. The pain is described as a mild to moderate deep ache that is aggravated by pressure and weight bearing. It is more noticeable at night or when the person is resting. The pain usually is due to metabolic bone activity, secondary degenerative osteoarthritis, fractures or nerve impingement. Because of the increase in blood flow to pagetic bone, flushing and warmth of the overlying skin may be apparent.

MANIFESTATIONS Paget's disease

MUSCULOSKELETAL EFFECTS
- Pain (in the long bones of lower extremities or joints)
- Deformity (enlargement of skull, bowing of lower extremities and deformity of elbows and knees)
- Fractures of lower extremities
- Pathological fractures (especially of the tibia)
- Compression fractures
- Collapse of the vertebrae, resulting in kyphosis and loss of height
- Muscle weakness

NEUROLOGICAL EFFECTS
- Hearing loss
- Spinal cord injuries
- Dementia
- Pain from spinal stenosis
- Bladder and/or bowel dysfunction

CARDIOVASCULAR EFFECTS
- Congestive heart failure

METABOLIC EFFECTS
- Symptoms of hypercalcaemia in immobilised people
- Hypercalciuria and renal calculi
- Increased skin temperature over affected extremities

Complications

Complications of Paget's disease are as follows:
- nerve palsy syndromes from involvement of the upper extremities
- pathological fractures from loss of bone structure
- mental deterioration from compression of the brain when the skull is involved
- compression of the spinal cord from affected cervical vertebrae causing quadriplegia
- cardiovascular disease, resulting from vasodilation of the vessels in the skin and subcutaneous tissues overlying the affected bones
- osteogenic sarcoma, seen in 5–10% of people with severe disease (Porth & Matfin, 2014).

INTERPROFESSIONAL CARE

Care of the person with Paget's disease focuses on relieving pain, suppressing bone cell activity if necessary and preventing or minimising the effects of complications. Many people with Paget's disease are asymptomatic and do not require treatment. For more severely affected people, pharmacological agents are usually effective. Occasionally, surgery may be required.

Diagnosis

Many of the diagnostic tests that are useful for the diagnosis of osteoporosis are equally useful for people with Paget's disease (see Table 39.1). These include x-rays and bone scans to illustrate localised areas of demineralisation in the early stages, seen as 'punched-out' areas that lend a coarse, irregular appearance to the bone. In the later phase, x-rays show enlargement of the bones, tiny cracks in the long bones, and/or bowing of the weight-bearing bones. Computed tomography (CT) scans and magnetic resonance imaging (MRI) help identify possible causes of pain, including degenerative problems, spinal stenosis or nerve root impingement. Diagnostic tests are described in Chapter 37.

Laboratory tests used in diagnosis include a plasma alkaline phosphatase, which will show a steady rise as the disease progresses; the normal level (30 to 115 international units (IU)/L) may be elevated from high normal to more than 3000 international units/L. A urinary collagen pyridinoline test is a sensitive indicator of the rate of bone resorption. Liver function tests, isotope bone scans and vitamin D levels are also useful diagnostic tools (Walsh, 2012).

Medications

People who have mild symptoms often find relief using aspirin or NSAIDs such as ibuprofen and indomethacin. People who are experiencing manifestations and whose diagnostic test results are elevated are usually treated with an agent that retards bone resorption, such as calcitonin or a bisphosphonate.

Bisphosphonates such as alendronate, pamidronate and risedronate are the primary treatments used for severe Paget's disease. These drugs inhibit bone resorption, possibly by attaching to the surface of the calcium/phosphate phase of bone and inhibiting osteoclast activity. They are safe and usually are well tolerated by the person. Alendronate is available as an oral preparation and pamidronate is available for intravenous administration. Oral preparations are poorly absorbed from the GI tract and may cause gastric or oesophageal irritation. Alendronate should be given with a full glass of water on an empty stomach, at least 30 minutes before other medications or food. Pamidronate is given as an intravenous infusion in 5% dextrose or 0.9% sodium chloride. It is given for 3 successive days, generally promoting a rapid response with reduced urinary excretion of hydroxyproline and pyridinium and a fall in alkaline phosphatase. Intravenous pamidronate may cause flu-like symptoms, but these generally are brief. Calcium supplements also are prescribed for people receiving bisphosphonates. After bisphosphonate treatment, people often experience remission of symptoms for a year or more. See the 'Medication administration' box below for nursing implications.

Calcitonin inhibits osteoclastic resorption of bone and is secreted by the thyroid gland. It also works as an analgesic for bone pain. The two derivatives of this medication are salmon (fish) and human. Salmon calcitonin (Calcimar) is generally preferred because it is inexpensive and widely available. Human calcitonin (Cibacalcin) is derived from human thyroid glands, which makes

MEDICATION ADMINISTRATION The person with Paget's disease

BISPHOSPHONATES

Alendronate
Etidronate
Pamidronate
Risedronate
Tiludronate

The bisphosphonates inhibit bone resorption, increasing the mineral density of bones and reducing the incidence of fractures. They are also used in both the prevention and treatment of osteoporosis. When used for Paget's disease, bisphosphonates slow the accelerated bone turnover associated with this disease. Bone pain is relieved and the incidence of pathological fractures is reduced. Cardiac and vascular manifestations of the disease also improve.

Nursing responsibilities

- Administer alendronate with water 30 minutes before food or other medications due to its common side effect of nausea.
- Do not give foods high in calcium, vitamins with mineral supplements or antacids within 2 hours of administering alendronate as this may interfere with the absorption of the drug.
- Instruct the person to avoid lying down for 30 minutes after taking the drug as alendronate causes GI tract irritation and to facilitate delivery of the dose to the stomach (Bryant & Knights, 2014).
- Assess renal function studies before initiating therapy; alendronate is not recommended for use in people with renal insufficiency.
- Dilute the prescribed dose of pamidronate in 1000 mL of 5% dextrose or 0.9% sodium chloride; infuse over at least 4 hours. Do not add to calcium-containing solutions such as Hartmann's solution.
- Monitor the IV site for signs of thrombophlebitis.
- Assess the person for signs of electrolyte imbalance or other adverse responses such as a drug fever.

Health education for the person and family

- Take the medication as directed with clear water only. Consuming other beverages or food within 30 minutes of taking alendronate may interfere with its absorption and effectiveness.
- Do not lie down until after the person has eaten. Alendronate can irritate the oesophagus.
- Report symptoms such as new or worsening heartburn, difficulty swallowing or painful swallowing.
- Fever with or without chills may occur while receiving intravenous pamidronate; this will subside without treatment. Flu-like symptoms also may occur; these will subside within a week or so.
- Report any abnormal symptoms such as tingling around the mouth or numbness and tingling of the fingers or toes, which may indicate an imbalance of electrolytes in the blood.
- Take calcium and vitamin D supplements as instructed by the person's primary care provider.
- Response to these medications is gradual and continues for months after the drug is stopped.

it more expensive and difficult to obtain. The parenteral form of calcitonin is used in treating Paget's disease. (See the 'Medication administration' box on p. 1427 for nursing implications.)

Surgery

Different surgical interventions may be used to treat people with Paget's disease, such as repairing a complete fracture through pagetic bone, realigning a knee through tibial osteotomy to decrease pain or replacing a hip and/or knee for osteoarthritis. Because increased bleeding is a manifestation of Paget's disease, it is important to administer a potent bisphosphonate prior to surgery to decrease hypervascularity and reduce the risk of increased operative blood loss (Paget Foundation, 2015; Walsh, 2012).

Nursing care

Nursing diagnoses and interventions

The nursing interventions for the person with symptomatic Paget's disease focus on pain control, prevention of injury or fractures, and education regarding the disease process and prescribed therapies.

Chronic pain

The most common manifestation of Paget's disease is bone pain. This usually is the manifestation that prompts the person to seek healthcare.

- Assess the location and extent of the pain to determine the bone areas involved. *Bone pain in Paget's disease is poorly localised and is frequently described as 'aching and deep'.*
- Teach the person to take NSAIDs or aspirin on a regular basis as prescribed. *Pain is most noticeable at night or when the person is resting. The pain can become evident when it is aggravated by pressure and weight bearing.*
- Ensure correct placement of prescribed brace or corset. *The person may be required to wear a light brace or corset to relieve back pain and provide support when assuming an upright position. The person may need instruction in the correct application of the device and in the evaluation of pressure areas that may result from wearing the device.*
- Suggest referral for heat therapy and massage. *Heat therapy and massage can alleviate mild discomfort. Care should be taken when applying massage over areas prone to pathological fractures.*

Impaired physical mobility

People with Paget's disease need to maintain or improve mobility so that they can perform necessary self-care activities and prevent complications of immobility.

- Provide an assistive device for use when ambulating. *During the active phase of Paget's disease, the person is prone to fractures. Bone deformities, activity intolerance, fear of falling and pain are all factors that may make the person more prone to falls. An assistive device can provide both physical and psychological support during ambulation, permit the person to ambulate further and provide a device for resting during ambulation.*

CONSIDERATION FOR PRACTICE

Activities as seemingly simple as lifting a heavy box may result in a fracture in the person with Paget's disease.

- Teach good body mechanics. *The person with bone deformities should avoid activities that require lifting and twisting.*
- Reinforce information about exercise protocols and activity regimens. *Exercise and activity protocols should be planned carefully to prevent injury and to minimise fatigue.*

Community-based care

A diagnosis of Paget's disease can be frightening for the person and family. It is important that they understand that this is a treatable disease and that many manifestations of the disease will be relieved with treatment. Inform the person that remissions of the disease often last for a year or more after effective treatment. The Paget Foundation should be suggested as a resource. Discuss the following topics:

- the importance of following the prescribed treatment regimen and keeping scheduled follow-up appointments
- because it may take several weeks to notice a response to treatment, the importance of continuing therapy during this time and after a response is obtained
- if bisphosphonates such as alendronate or pamidronate are ordered, the importance of taking supplemental calcium to prevent low blood calcium levels
- the importance of remaining active
- safety in the home and outdoor environment to prevent falls
- the need to report to the primary care provider any sudden pain or disability, even if no trauma has occurred, because pathological fractures are possible.

THE PERSON WITH GOUT

Gout is a metabolic disease that occurs from an inflammatory response to the production or excretion of uric acid resulting in high levels of uric acid in the blood (hyperuricaemia) and in other body fluids, including synovial fluid. The disorder is characterised by deposits of urates (insoluble precipitates) in the connective tissues of the body. Gout has an acute onset, usually at night, and often involves the first metatarsophalangeal joint (great toe). The initial acute attack is usually followed by a period of months or years without manifestations. As the disease progresses, urates are deposited in various other connective tissues. Deposits in the synovial fluids cause acute inflammation of the joint (*gouty arthritis*). Over time, urate deposits in subcutaneous tissues cause the formation of small white nodules (called **tophi**). Deposits of crystals in the kidneys can form urate kidney stones and result in kidney failure.

Gout may occur as either a primary or a secondary disorder. Primary (inherited) gout is characterised by elevated serum uric acid levels resulting from either an inborn error of purine metabolism or a decrease in renal uric acid excretion due to an unknown cause. Purines are part of the structure of the nuclear compounds DNA and RNA; they also may be synthesised by the body. Impaired uric acid excretion leads to hyperuricaemia in the majority of people with primary gout. In secondary gout, hyperuricaemia occurs as a result of another disorder or treatment with certain medications. Disorders associated with rapid cell turnover, such as some malignancies (leukaemia, in particular), haemolytic anaemia and polycythaemia, can increase purine metabolism. Chronic renal disease, hypertension, starvation and diabetic ketoacidosis can interfere with uric acid excretion, as can certain drugs, including some diuretics (such as frusemide, ethacrynic acid and chlorothiazide), pyrazinamide, cyclosporin, ethambutol and low-dose salicylates. Alcohol ingestion appears to interfere with uric acid excretion and to accelerate its synthesis.

Gout occurs more often in men, usually after the age of 40. In women, attacks of gout are rarely seen until after menopause. The incidence and prevalence of gout are increasing in Australia and New Zealand (Robinson, Taylor & Merriman, 2012). A number of risk factors for gout have been identified (see Box 39.2). Of these, male gender and ageing cannot be modified; the others can be. Consumption of a diet rich in meat and seafood is associated with a higher risk of developing gout, whereas total protein intake and consumption of purine-rich vegetables have not been shown to contribute to its development (Terkeltaub, 2009; Shulten et al., 2009). While alcohol intake has long been known to increase the risk of hyperuricaemia and gout, recent studies have shown that consumption of soft drinks sweetened with sugar or fructose (corn syrup) also increases the risk of gout in men. Obesity and metabolic syndrome (abdominal obesity, hyperlipidemia, hypertension and insulin resistance) are strongly correlated with hyperuricaemia and gout (Rothschild, Francis & Miller, 2015).

Pathophysiology

Uric acid is the breakdown product of purine metabolism. Normally, a balance exists between its production and its

BOX 39.2 Risk factors for gout

- Male gender
- Age
- Diet: higher consumption of meat and seafood
- Alcohol intake, beer in particular
- Consumption of sugar- or fructose-sweetened soft drinks
- Obesity
- Medications: diuretics, aspirin

excretion, with approximately two-thirds of the amount produced each day excreted by the kidneys and the rest in the faeces. The normal serum urate levels for men and women vary, the normal range being 2–7 mg/dL (120–420 μmol/L) for men and 2–6 mg/dL (120–360 μmol/L) for women, although these figures may differ between laboratories or populations. Hyperuricaemia is therefore defined as serum urate levels > 7 mg/dL (> 420 μmol/L) for men and > 6 mg/dL (> 360 μmol/L) for women. Higher levels of uric acid are associated with increased incidence and prevalence rates for gout. Men have higher concentrations of uric acid and therefore a higher prevalence of gout, whereas premenopausal women and children have lower concentrations and therefore a lower prevalence of gout (Perez-Ruiz & Herrero-Beites, 2014).

At levels greater than 7.0 mg/dL, the serum is saturated and monosodium urate crystals may form. It is not known exactly how crystals of monosodium urate crystals are deposited in joints. Several mechanisms may be involved:

- Crystals tend to form in peripheral tissues of the body, where lower temperatures reduce the solubility of the uric acid.
- A decrease in extracellular fluid pH and reduced plasma protein binding of urate crystals are evident.
- Tissue trauma and a rapid change in uric acid levels may also lead to crystal deposition. A rapid increase in uric acid may occur with tissue trauma and release of cellular components.

The monosodium urate crystals may form in the synovial fluid or in the synovial membrane, cartilage or other joint connective tissues. They may also form in the heart, earlobes and kidneys. These crystals stimulate and continue the inflammatory process, during which neutrophils respond by ingesting the crystals. The neutrophils release their phagolysosomes, causing tissue damage, which perpetuates the inflammation.

Manifestations

The manifestations of gout are hyperuricaemia, recurrent attacks of inflammation of a single joint, tophi, kidney disease and kidney stones. Unless treated, the manifestations of gout appear in three stages: asymptomatic hyperuricaemia, acute gouty arthritis and tophaceous gout (see the 'Manifestations' box below).

MANIFESTATIONS Gout

ACUTE GOUTY ARTHRITIS
- Usually monoarticular, affecting metatarsophalangeal joint of great toe, instep, ankle, knee, wrist or elbow
- Acute pain
- Red, hot, swollen and tender joint
- Fever, chills, malaise
- Elevated WBC and erythrocyte sedimentation rate

TOPHACEOUS (CHRONIC) GOUT
- Tophi evident on joints, bursae, tendon sheaths, pressure points, helix of ear
- Joint stiffness, limited ROM and deformity
- Ulceration of tophi with chalky discharge

Asymptomatic hyperuricaemia

The first stage is asymptomatic hyperuricaemia, with serum levels averaging 9 to 10 mg/dL. Most people with hyperuricaemia do not progress to further stages of the disease.

Acute gouty arthritis

The second state is acute gouty arthritis. The acute attack (called a 'flare'), usually affecting a single joint, occurs unexpectedly, often beginning at night. It may be triggered by trauma, alcohol ingestion, dietary excess or a stressor such as surgery. It is often precipitated by an abrupt or sustained increase in uric acid levels. The affected joint becomes red, hot, swollen and exquisitely painful and tender.

Approximately 50% of initial attacks of acute gouty arthritis occur in the metatarsophalangeal joint of the great toe. Other sites for acute attacks include the instep of the foot, ankles, heels, knees, wrists, fingers and elbows. The pain, often intense, peaks within several hours and may be accompanied by fever and an elevated white blood cell (WBC) count and erythrocyte sedimentation rate (ESR). The affected joints are swollen and the skin over the joint is warm and dusky red.

Acute attacks of gouty arthritis last from several hours up to several weeks and typically subside spontaneously. There are no long-lasting sequelae and the person enters an asymptomatic period called the intercritical period. The intercritical period may last up to 10 years; however, approximately 60% of people experience a recurrent attack within 1 year. Successive attacks tend to last longer, occur with increasing frequency and resolve less completely than the initial attack.

Tophaceous (chronic) gout

Tophaceous (or chronic) gout occurs when hyperuricaemia is not treated. The urate pool expands and monosodium urate crystal deposits (tophi) develop in cartilage, synovial membranes, tendons and soft tissues. They are seen most often in the helix of the ear; in tissues surrounding joints and bursae (especially around the elbows and knees); along tendons of the fingers, toes, ankles and wrists; on ulnar surfaces of the forearms; along the shins of the legs; and on other pressure points. The skin over tophi may ulcerate, exuding chalky material containing inflammatory cells and urate crystals. Tophi can also develop in the tissues of the heart and spinal epidura. Although tophi themselves are not painful, they may restrict joint movement and cause pain and deformities of the affected joints. Tophi may also compress nerves and erode and drain through the skin.

Complications

Kidney disease may occur in people with untreated gout, particularly when hypertension is also present. Urate crystals are deposited in renal interstitial tissue. Uric acid crystals also form in the collecting tubules, renal pelvis and ureter, forming stones. The stones can range in size from a grain of sand to a massive structure filling the spaces of the kidney. Uric acid stones can potentially obstruct urine flow and lead to acute kidney failure.

INTERPROFESSIONAL CARE

The classic presentation of acute gouty arthritis is so distinctive that the diagnosis can often be based on the person's history

and physical examination. Treatment is directed towards terminating an acute attack, preventing recurrent attacks and reversing or preventing complications resulting from crystal deposition in tissues and formation of uric acid kidney stones.

Diagnosis

Diagnostic testing is performed to establish an accurate diagnosis and direct long-term therapy. Diagnostic tests are described in Chapter 37.

Serum uric acid is nearly always elevated (usually above 480 mmol/L). The WBC count shows significant elevation, reaching levels as high as 20 000/mm^3 during an acute attack. The ESR is elevated during an acute attack from the acute inflammatory process that accompanies deposits of urate crystals in a joint. In addition, a 24-hour urine specimen is analysed to determine uric acid production and excretion, and analysis of fluid aspirated from the acutely inflamed joint or material aspirated from a tophus shows typical needle-shaped urate crystals, providing the definitive diagnosis of gout.

Medications

Medications are used to terminate an acute attack, prevent further attacks and reduce serum uric acid levels to prevent long-term sequelae of the disease. It is important to treat the acute attack of gouty arthritis before initiating treatment to reduce serum uric acid levels, because an abrupt decrease in serum uric acid may lead to further acute manifestations. Pharmacological therapy is a mainstay of treatment in achieving these goals.

ACUTE ATTACK NSAIDs and colchinine are the treatment of choice for an acute attack of gout. Colchinine has known anti-inflammatory effects but no analgesic properties. That is why it is combined with an NSAID for analgesic effects. Indomethacin (Indocin) is the most frequently used NSAID for gout, although others are equally effective. Other NSAIDs that may be prescribed include ibuprofen (Nurofen), naproxen (Naprosyn, Anaprox), diclofenac (Voltaren) or ketorolac. Although extremely effective, NSAIDs are contraindicated for people with active peptic ulcer disease, impaired kidney function or a history of hypersensitivity reactions to the drugs. As with other anti-inflammatory drugs, people should be aware of possible risks and follow recommended doses carefully.

Colchicine can dramatically affect the course of an acute attack. Joint pain begins to diminish within 12 hours of the initiation of treatment and disappears within 2 days. Colchicine apparently acts by interrupting the cycle of urate crystal deposition and inflammation in an acute attack of gout. It has no anti-inflammatory effect in other forms of arthritis and its use is limited to gout. The use of colchicine is limited by significant side effects. When administered orally, many people develop abdominal cramping, diarrhoea, nausea or vomiting. Intravenous administration is limited by potential toxic effects, including local pain, tissue damage if extravasation occurs during injection, bone marrow suppression and disseminated intravascular coagulation (DIC). It is contraindicated for people who have significant gastrointestinal, kidney, hepatic or cardiac disease.

Corticosteroids may also be prescribed for the person with acute gouty arthritis. If possible, the intra-articular route is preferred for monoarticular arthritis to avoid the multiple systemic effects of steroid therapy. When gout is polyarticular, corticosteroids may be administered either orally or intravenously.

Analgesics may also be prescribed during an acute episode of gouty arthritis. Either codeine or pethidine may be administered to manage the person's pain. Aspirin is avoided because it may interfere with uric acid excretion.

PROPHYLACTIC THERAPY In people at high risk of future attacks of acute gout, prophylactic therapy with daily colchicine may be initiated. Prophylaxis is particularly useful during the first 1 to 2 years of treatment with antihyperuricaemic agents. Although colchicine does not affect the serum uric acid directly, it reduces the frequency of attacks by preventing crystal deposition within the joint. The doses required to achieve this effect are small and few side effects are associated with therapy.

Treatment to reduce serum uric acid levels is typically initiated for people with recurring gout, tophi or renal damage. Asymptomatic hyperuricaemic people require no treatment. Uricosuric agents are used for people who do not eliminate uric acid adequately; allopurinol is prescribed for people who produce excessive amounts of uric acid. Uricosuric drugs block the tubular reabsorption of uric acid, promoting its excretion and reducing serum levels. These drugs reduce the frequency of acute attacks, particularly when administered with colchicine. Probenecid lowers the serum concentration of uric acid by competitively inhibiting the reabsorption of urate at the proximal renal tubule, thus increasing urinary excretion of uric acid (Bryant & Knights, 2014).

Allopurinol (Zyloprim) is a xanthine oxidase inhibitor that lowers plasma uric acid levels and facilitates the mobilisation of tophi. Because of its effectiveness in lowering serum uric acid levels, it may trigger an attack of acute gout. The nursing implications for medications used to treat gout are included in the 'Medication administration' box on next page.

Complementary and alternative therapy

A variety of nutritional and herbal supplements may be used to help prevent gout or decrease the onset of manifestations. These include:

- Vitamin E and selenium may decrease tissue inflammation.
- Amino acids (alanine, aspartic acid, glutamic acid and glycine) increase the ability of the kidneys to excrete uric acid.
- Dark reddish-blue berries (such as cherries and blackberries) are good sources of flavonoids, which help lower uric acid levels, decrease inflammation and prevent or repair joint tissue damage.
- Acupuncture can provide pain relief.

Treatments

Treatments for gout, in addition to medications, include dietary management and rest.

NUTRITION Dietary purines contribute only slightly to uric acid levels in the body and no specific diet may be recommended. If a low-purine diet is recommended, the person should be taught that high-purine foods include all meats and seafood, yeast, beans, peas, lentils, oatmeal, spinach, asparagus, cauliflower and mushrooms. The obese person is advised to lose weight, but fasting is contraindicated for people with gout. Alcohol intake and specific foods that tend to precipitate attacks are avoided.

MEDICATION ADMINISTRATION The person with gout

COLCHICINE

Colchicine is used to terminate an acute attack of gouty arthritis and to prevent recurrent episodes of the disease. Colchicine does not alter serum uric acid levels, but appears to interrupt the cycle of urate crystal deposition and inflammatory response. It may be administered either by mouth or intravenously. Colchicine is also available as a fixed-dose combination with a uricosuric agent, probenecid. Only plain colchicine is used to treat an acute attack of gout; combination therapy is employed to prevent further attacks.

Nursing responsibilities

- Assess for possible contraindications to colchicine therapy, including serious gastrointestinal, renal, hepatic or cardiac disease.
- Administer the following as ordered:
  - *Intravenous doses:* give undiluted or diluted in up to 20 mL sterile 0.9% sodium chloride for injection. Administer over a period of 2 to 5 minutes.
  - *Oral doses:* give on an empty stomach to facilitate absorption.
- Evaluate for adverse effects, including abdominal cramping, nausea, vomiting and diarrhoea, and report promptly, because these side effects may necessitate discontinuation of the drug.

Health education for the person and family

- Drink 3 to 4 L of liquid per day.
- Report adverse responses, including gastrointestinal problems, fatigue, bleeding, easy bruising or recurrent infections, to the healthcare provider.
- Do not drink alcohol.

URICOSURIC DRUGS

Probenecid (Benemid)
Sulfinpyrazone (Anturane)

Probenecid inhibits the tubular reabsorption of urate, promoting the excretion of uric acid and decreasing serum uric acid levels. Sulfinpyrazone potentiates the renal excretion of uric acid, reducing serum uric acid levels. It is used to prevent recurrent attacks of acute gouty arthritis and to treat chronic gout.

Nursing responsibilities

- Assess for prior hypersensitivity responses to this drug.
- Administer after meals or with milk to minimise gastric distress.
- Increase fluid intake to at least 3 L/day to prevent the formation of uric acid kidney calculi.
- Administer sodium bicarbonate or potassium citrate as ordered to maintain an alkaline urine.
- Do not administer aspirin to people receiving probenecid because salicylates interfere with the action of the drug.
- Monitor people receiving the following drugs concurrently with probenecid for increased or toxic effects: penicillin and related antibiotics, indomethacin, paracetamol, naproxen, ketoprofen, lorazepam and rifampin.
- Monitor for possible adverse effects of probenecid, including headache, dizziness, hepatic necrosis, nausea and vomiting, renal colic, bone marrow depression, anaphylaxis, fever, hives and pruritus.
- Administer sulfinpyrazone with meals or antacid to minimise gastric distress.
- Monitor people taking sulfinpyrazone with other sulfa drugs for increased or toxic effects; monitor for hypoglycaemia when receiving insulin or oral hypoglycaemics concurrently; and monitor for bleeding or increased anticoagulant effect when receiving warfarin concurrently.
- Assess for contraindications to therapy with sulfinpyrazone, including active peptic ulcer disease, a history of hypersensitivity to phenylbutazone or other pyrazoles or blood dyscrasias.

Health education for the person and family

- Do not take aspirin or products containing aspirin while taking probenecid. Use paracetamol for relief of mild pain.
- Drink at least 3 L of fluids per day to minimise the risk of kidney stone formation.
- Take sulfinpyrazone with meals to minimise gastric distress and report epigastric pain, nausea or black stools to the healthcare provider promptly.

ALLOPURINOL (ZYLOPRIM)

Allopurinol acts on purine metabolism, reducing the production of uric acid and decreasing serum and urinary concentrations of uric acid. It is used for people with manifestations of primary or secondary gout, including acute attacks, tophi, joint destruction, urinary stones and nephropathy. It is not indicated for use in the treatment of asymptomatic hyperuricaemia.

Nursing responsibilities

- Monitor intake and output and increase fluid intake to approximately 3 L/day.
- Monitor for desired effect of decreased serum uric acid levels and for adverse effects such as nausea, diarrhoea and rash.
- Assess blood urea nitrogen (BUN) and creatinine levels prior to the initiation of and during treatment with allopurinol. Report signs of impaired kidney function such as an elevated BUN and creatinine, decreased urine output, and dilute or frothy urine to the healthcare provider.
- Administer with meals to minimise gastric distress.
- Monitor FBC periodically because allopurinol therapy may cause bone marrow depression.
- In people receiving warfarin concurrently, monitor prothrombin times and be alert to evidence of bleeding, because allopurinol prolongs the half life of warfarin.
- Monitor people receiving chlorpropamide, cyclophosphamide, hydantoin, theophylline, vidarabine or ACE inhibitors concurrently for increased drug effects.
- Discontinue the drug and notify the healthcare provider immediately if the person develops a rash. Rash and hypersensitivity responses occur more frequently in people receiving ampicillin, amoxicillin or thiazide diuretics.

Health education for the person and family

- Stop taking the drug and report any skin rash, painful urination, blood in the urine, eye irritation or swelling of the lips or mouth to the healthcare provider immediately.
- Take the medication after meals to minimise gastric distress.
- Drink 3 to 4 L of fluid daily to maintain a urinary output greater than 2 L/day.
- Acute gouty attacks may occur during the initial stages of allopurinol therapy; continue therapy prescribed for attacks (such as colchicine) to minimise acute episodes.
- Do not take a double dose of medication if you miss a dose.

A liberal fluid intake to maintain a daily urinary output of 2000 mL or more is recommended to increase urate excretion and reduce the risk of urinary stone formation. Urinary alkalinising agents, such as sodium bicarbonate or potassium citrate, may be prescribed as well to minimise the risk of uric acid stones. It is important to monitor people receiving these preparations carefully for signs of fluid and electrolyte or acid–base imbalances.

REST During an acute attack of gouty arthritis, bed rest is prescribed. It is continued for approximately 24 hours after the attack has subsided because early ambulation may bring about recurrence of acute manifestations (McPhee, Papadakis & Tierney, 2015). The affected joint may be elevated, and hot or cold compresses may be applied, for comfort.

Nursing care

People with gout provide self-care at home. Teaching focuses on self-management of pain and altered mobility.

Nursing diagnoses and interventions

Pain is a primary focus for nursing interventions in the person experiencing an acute attack of gout. The person's mobility is also impaired during an acute attack, because of both pain and prescribed activity limitations.

Acute pain

The pain associated with an attack of acute gouty arthritis is intense and accompanied by exquisite tenderness of the affected joint. Measures to alleviate the pain are vital in the initial period until anti-inflammatory medications become effective and the acute inflammatory response is relieved. The following are important in teaching about pain relief:

- Position the affected joint for comfort. Elevate the joint or extremity (usually the foot) on a pillow, maintaining alignment. *Elevation and normal body alignment facilitate blood return from the affected joint, alleviating some of the oedema.*
- Protect the affected joint from pressure, placing a foot cradle on the bed to keep bed covers off the foot. *A foot cradle keeps bed linen from applying pressure on the affected joint.*

CONSIDERATION FOR PRACTICE

The affected joints are so painful that even the weight of a sheet can be unbearable.

- Take anti-inflammatory and antigout medications as prescribed. In the initial period, colchicine may be given hourly. *These medications reduce the acute inflammatory response, gradually relieving discomfort.*
- Take analgesics as prescribed. *Supplemental analgesia may be necessary in the acute period until the inflammatory response is mediated.*
- Maintain bed rest. *It is important to immobilise the affected joint and promote rest to prevent exacerbation of joint inflammation.*

Community-based care

Discuss the following topics with the person:

- The disease and its manifestations. Tell the person that initial attacks cause no permanent damage but that recurrent attacks can lead to permanent damage and joint destruction. Discuss other potential effects of continued hyperuricaemia, including tophaceous deposits in subcutaneous and other connective tissues. Discuss the potential for kidney damage and kidney stones.
- The rationale for and use of prescribed medication. Stress the need to continue the medication until the healthcare provider discontinues it, even though the person is free of manifestations of gout. Tell the person to avoid drugs that increase uric acid blood levels: hydrochlorothiazide (HydroDiuril), cyclosporin (Neoral, Sandimmune), frusemide (Lasix) and high doses of aspirin. People who need to reduce their risk of heart attacks may safely take one baby aspirin each day.
- The importance of a high intake of fluids each day and avoiding the use of alcohol.

THE PERSON WITH OSTEOMALACIA

Osteomalacia, often referred to as *adult rickets*, is a metabolic bone disorder characterised by inadequate or delayed mineralisation of bone matrix in mature compact and spongy bone, resulting in softening of bones. Bone mineralisation requires adequate calcium and phosphate ions in extracellular fluid. When either of these ions is insufficient due to (1) inadequate calcium intake or decreased calcium absorption from the intestines because of insufficient vitamin D, or (2) increased renal losses or decreased intestinal absorption of phosphate, the bone matrix is not mineralised and cannot sustain weight bearing. Marked deformities of weight-bearing bone and pathological fractures occur. The primary causes of osteomalacia are vitamin D deficiency and hypophosphataemia. Osteomalacia can be corrected with treatment.

Osteomalacia has been almost non-existent in Australia and New Zealand because many foods are fortified with vitamin D, but its incidence is increasing among older adults and people who adhere to strict vegetarian diets. It is a significant health problem in cultures whose diets tend to be deficient in calcium and vitamin D. Women in northern China, Japan and northern India have a higher incidence of the disorder (Porth & Matfin, 2014).

The main risk factors for vitamin D deficiency are a diet low in vitamin D, decreased endogenous production of vitamin D because of inadequate sun exposure, impaired intestinal absorption of fats (vitamin D is a fat-soluble vitamin) and disorders that interfere with the metabolism of vitamin D to its active forms. Gastrectomy and small-bowel disorders may reduce the

absorptive surface of the bowel to the extent that nutrients are not completely or adequately absorbed. Both vitamin D and calcium absorption may be affected. Hepatobiliary disorders that interfere with bile production and release and chronic pancreatic insufficiency with inadequate pancreatic enzyme production can affect the absorption of fats and vitamin D from the bowel. Once absorbed, vitamin D is metabolised in the liver and the kidney to its active form; therefore, liver disorders such as cirrhosis and kidney disorders can affect this activation. Certain drugs, such as isoniazid, rifampicin and anticonvulsants, accelerate vitamin D metabolism, resulting in less availability to the tissues. Renal excretion of vitamin D is increased in some kidney disorders such as nephrotic syndrome. (See Box 39.3.)

Hypophosphataemia can be the result of insufficient dietary intake, excessive losses through the urine or stool, or a shift into the cells. Alcohol abuse is the most common cause of hypophosphataemia because of related dietary deficiencies, vomiting, antacid use and increased renal excretion of phosphate. Ingesting large amounts of non-absorbable antacids causes increased phosphate losses in the stool. Several acquired and genetic disorders cause increased losses of phosphate in the urine.

Pathophysiology

The two main causes of osteomalacia are insufficient calcium absorption in the intestine due to a lack of calcium or resistance to the action of vitamin D, and increased losses of phosphorus through the urine (Porth & Matfin, 2014). In its natural form, vitamin D is obtained from certain foods and ultraviolet radiation of the sun. Vitamin D maintains adequate serum levels of calcium and phosphate for normal mineralisation of the bone. Vitamin D deficiency, or resistance to its action, disrupts the normal mineralisation of the bone, causing softening of the bone.

Vitamin D is inactive when it is absorbed from the intestine or synthesised from exposure to ultraviolet light. For vitamin D to become active, a two-step process must occur: (1) vitamin D (and its metabolites) is transported in the blood to the liver, where it is converted to calcidiol, and (2) calcidiol is then transported to the kidney and transformed to an active form, calcitriol.

The active form of vitamin D is needed for optimal absorption of calcium and phosphorus from the intestine. Calcium and phosphorus are transported in the blood to the bones for normal mineralisation. If there is a lack of vitamin D, calcium and phosphorus are not absorbed from the intestine and serum calcium and phosphorus levels therefore fall. A deficiency in these minerals in turn activates the parathyroid glands, with loss of calcium and phosphorus from bone. The continued loss of calcium and phosphate in the bone disrupts bone mineralisation.

Impaired bone mineralisation causes abnormalities in both spongy and compact bone. The osteoid (the soft, non-calcified part of the matrix) continues to be produced but is not mineralised. This abnormal build-up of demineralised bone leads to gross deformities of the long bones, spine, pelvis and skull, because the bone is soft and unable to bear the weight and stress of body movement.

Manifestations

The manifestations of osteomalacia include bone pain and tenderness (see the box below). As the disease progresses, fractures occur. In contrast to osteoporosis, osteomalacia is not associated with a significant occurrence of hip fractures. Instead, pathological fractures occur in the commonly weakened areas (e.g. distal radius and proximal femur).

MANIFESTATIONS Osteomalacia

- Bone pain: may be vague and generalised at first, becoming more intense with activity as the disease progresses; occurs most frequently in the pelvis, long bones of the extremities, spine and ribs.
- Difficulty changing from lying to sitting position and sitting to standing position.
- Muscle weakness: frequently an early sign in severe cases.
- Waddling gait: may be due to pain and muscle weakness.
- Dorsal kyphosis: may occur in severe cases.
- Pathological fractures.

BOX 39.3 Causes of osteomalacia

Vitamin D deficiency
- Inadequate dietary intake
- Lack of sun exposure
- Malabsorption from intestines: gastrectomy, small-bowel disorders, gallbladder disease, chronic pancreatic insufficiency
- Kidney or liver disorders
- Drug effects: isoniazid, rifampicin, anticonvulsants

Phosphate depletion
- Inadequate intake
- Impaired absorption due to chronic antacid use
- Impaired renal tubular reabsorption due to either acquired or genetic disorders

Systemic acidosis
- Renal tubular acidosis
- Ureterosigmoidostomy
- Fanconi's syndrome

Mineralisation inhibitors
- Hypophosphatasia
- Sodium fluoride or disodium etidronate (Didronel)
- Aluminium intoxication

Chronic kidney failure
Calcium malabsorption

INTERPROFESSIONAL CARE

Osteomalacia may be difficult to differentiate from osteoporosis because the manifestations are very similar; however, once the specific cause is determined, appropriate therapy will correct the disorder.

Diagnosis

A history of inadequate dietary intake, kidney failure or some malabsorption states may suggest osteomalacia. Diagnostic tests are described in Chapter 37. Table 39.1 compares the diagnostic findings of osteomalacia with those of osteoporosis and Paget's disease. X-rays demonstrate the effects of generalised bone demineralisation: trabecular bone loss, cyst formation, compression fractures, bowing and bending deformities of the long bones, and osteoid deposits, particularly in the vertebral bodies and pelvis.

Laboratory tests include serum calcium, parathyroid hormone and alkaline phosphatase levels. Calcium may be normal or low, depending on the cause of the disease. Calcium levels may be reduced when calcium absorption is impaired or in severe vitamin D deficiency. Secondary hypoparathyroidism may shift calcium from the bone into extracellular fluid, maintaining a normal serum calcium level. Parathyroid hormone is frequently elevated as a compensatory response to hypocalcaemia in kidney failure or vitamin D deficiency. Alkaline phosphatase is usually elevated.

Medications

Therapeutic management of osteomalacia depends on the cause of the disease. Because the causes are so diverse, it is difficult to generalise treatment. Most people are placed on vitamin D therapy. Calcium and phosphate supplements may be indicated. Radiological evidence of healing often is apparent within weeks of initiating therapy.

Nursing care

Managing the person with osteomalacia includes assessing the person's current dietary intake of vitamin D, calcium and phosphorus, and exposure to ultraviolet light. It also includes managing the person's responses to bone pain and tenderness, fractures and muscle weakness.

Community-based care

Teaching is important not only for the person with osteomalacia, but also for people at risk of developing the disease. When milk and other dairy products began to be fortified with vitamin D, the incidence of childhood rickets decreased dramatically. Now many people are unaware of the importance of vitamin D, calcium and phosphorus to bone health.

Older adults as a group are at high risk of osteomalacia because of dietary deficiencies, age-related intestinal malabsorption and possible physical mobility limitations that restrict their exposure to sunlight. Teach older adults about the importance of maintaining an adequate intake of milk and other dairy products that are not only rich in calcium and phosphorus, but also are fortified with vitamin D. Few other food sources provide enough vitamin D to meet recommended levels. Cod liver oil may be used as a supplement because it contains significant amounts of vitamin D. Supplements are not recommended, however, for people who get adequate vitamin D through dietary sources and sun exposure, because this fat-soluble vitamin may become toxic at high levels. Instruct people who are taking supplements to report to their healthcare provider symptoms such as anorexia, nausea and vomiting, frequent urination, muscle weakness and constipation that may be indicative of hypervitaminosis D.

Teach the person with osteomalacia about safety measures to prevent falls. Discuss the importance of eliminating scatter rugs and clutter from living areas to prevent tripping. Teach the person to place a night-light in hallways and the bathroom to prevent falls associated with night-time toileting. Suggest installing grab bars in the shower and tub and next to the toilet for safety.

Teach people with bone pain and muscle weakness to use assistive devices such as walkers, canes or crutches when ambulating. Provide referrals to physical therapy for teaching people how to safely use these devices. Encourage people to participate in a supervised exercise program such as water aerobics or tai chi to improve muscle strength and balance.

DEGENERATIVE DISORDERS

Degenerative disorders, especially degenerative joint disease, are the most common forms of arthritis in the older adult. Both primary and secondary forms are seen in adults of all ages. Primary or idiopathic osteoarthritis, the most common type, occurs without a clear precipitating factor. Secondary osteoarthritis is associated with an identifiable cause. For instance, it may be related to trauma to a joint, inflammation, skeletal disorders such as congenital hip dysplasia or metabolic disorders. Regardless of cause, degenerative disorders of the joints and muscles can lead to impaired mobility and chronic pain. These problems may in turn cause disability, especially in the performance of ADLs by older adults.

THE PERSON WITH OSTEOARTHRITIS

Osteoarthritis (OA) (also labelled *degenerative joint disease*) is the most commonly occurring of all forms of arthritis and a leading cause of pain and disability in older adults (Porth & Matfin, 2014). This disease is characterised by loss of articular cartilage in articulating joints and hypertrophy of the bones at the articular margins. OA may be idiopathic (without known

FOCUS ON CULTURAL DIVERSITY
The person with osteoarthritis

- Indigenous Australians are more likely than other Australians to report having arthritis, but are much less likely to have hip or knee replacements.
- People in the most disadvantaged areas of Australia are less likely than those in the least disadvantaged areas to have a total hip replacement, but more likely to have a total knee replacement.
- People living in regional and remote areas are more likely to have hip or knee replacements than those living in major cities.

Source: Australian Institute of Health and Welfare (AIHW) (2015).

cause) or secondary (associated with known risk factors). OA affects more than 1.8 million Australians (over 8% of the total population) over the age of 45 years. Men are affected more than women at an earlier age, but the rate of OA in women exceeds men by the middle adult years. The joints most affected are in the hand, wrist, neck, lower back, hip, knee, ankle and feet. Men are more likely than women to have hip OA, whereas postmenopausal women more often have hand OA. In 2012–2013, 20% of Indigenous people reported having a musculoskeletal disease. The prevalence of long-term musculoskeletal diseases for Indigenous Australians was 1.1 times as high as for non-Indigenous Australians (AIHW, 2015).

The cultural and ethnic effects on the development of OA are outlined in the box above.

Localised OA affects only one or two joints. Generalised OA affects three or more joints. Generalised OA may also be classified as nodal (involving the hand) or non-nodal (no hand involvement). Nodal OA may also affect the knees, hips, cervical spine and lumbar spine. Idiopathic OA most commonly affects the terminal interphalangeal joints (*Heberden's nodes*) and less often the proximal interphalangeal joints (*Bouchard's nodes*) (see Figure 39.2), the joints of the thumb, the hip, the knee, the metatarsophalangeal joint of the big toe and the cervical and lumbar spine. Secondary OA may occur in any joint from an articular injury.

FIGURE 39.2 ■ Typical interphalangeal joint changes associated with osteoarthritis

Source: © L. Samsuri/Custom Medical Stock Photo, Inc.

Risk factors

Idiopathic OA is associated with increasing age. It has been suggested that OA may be inherited as an autosomal recessive trait, with genetic defects causing premature destruction of the joint cartilage. The causes of secondary OA include trauma, mechanical stress and inflammation of joint structures, joint instability, neurological disorders, endocrine disorders and selected medications.

Excessive weight contributes to the development of OA, especially in the hip, ankle and knee. Excess fat may have a direct metabolic effect in the development of the disease. Primary OA of the knee is almost four times more common in obese women and five times more common in obese men (AIHW, 2015). Inactivity is another risk factor. Moderate recreational exercise has been shown to decrease both the chance of developing OA and the progression of manifestations when OA is present. People involved in strenuous, repetitive exercise (such as participating in sports) have an increased risk of developing secondary OA.

Other risk factors that are linked to OA are hormonal factors such as decreased oestrogen in menopausal women, excessive growth hormone and increased parathyroid hormone.

Pathophysiology

The cartilage that lines joints provides a smooth surface, so that the bones of the joint glide over one another without friction, and it distributes the load from one bone to the next, dissipating the mechanical stress that occurs with joint loading. This cartilage normally contains more than 70% water. More than 90% of its dry weight is collagen, which provides strength, and proteoglycans, which provide elasticity and stiffness to compression. Cartilage cells, the chondrocytes, nest in this meshwork of collagen and proteoglycans. Normal articular cartilage exudes some of its water with compression, providing lubrication for joint surfaces. This water is reabsorbed during relaxation of the joint.

In OA, proteoglycans and collagen are lost from the cartilage as a result of enzymatic degradation. The water content of the cartilage increases as the collagen matrix is destroyed. With the loss of proteoglycans and collagen fibres, the cartilage becomes yellow or brownish grey and loses its tensile strength. Surface ulcerations occur and fissures develop in deeper layers of the cartilage. Eventually, large areas of articular cartilage are lost and underlying bone is exposed. The bone thickens in exposed areas, reducing its ability to absorb energy in joint loading. Cysts can also develop in the bone. *Cartilage-coated osteophytes* (bony outgrowths often called 'joint mice') change the anatomy of the joint. As these spurs or projections enlarge, small pieces may break off, leading to mild synovitis (inflammation of the synovial membrane).

Manifestations

The onset of OA is usually gradual and insidious, and the course slowly progressive. Pain and stiffness in one or more joints (usually weight bearing) are the first manifestations of OA. The pain is localised to the affected joints and may be described as a

deep ache. It typically is aggravated by use or motion of the joint and relieved by rest, although it may become persistent as the disease progresses. Pain at night may be accompanied by paraesthesias (numbness, tingling). Pain may also be referred to other parts of the body; for example, OA of the lumbosacral spine may cause severe pain along the path of the sciatic nerve. Following periods of immobility, such as sleeping all night or after a long automobile ride, involved joints may stiffen. Usually only a few minutes of activity are necessary to relieve the stiffness. Range of motion (ROM) of the joint decreases as the disease progresses and grating or crepitus may be noted during movement. Bony overgrowth may cause joint enlargement and flexion contractures may occur because of joint instability. In OA, enlarged joints are characteristically bony hard and cool on palpation. Manifestations specific to affected joints are outlined in the box below.

Complications

OA of the spine may involve the vertebral bodies and intervertebral discs, the diarthrodial joints, or both. *Spondylosis* is degenerative disc disease. As the intervertebral discs degenerate, disc space between the vertebrae is lost. Degenerative disc disease may be complicated by herniated disc, the protrusion of the nucleus pulposus of the disc. Herniation usually occurs in a lateral direction, potentially compressing nerve roots and causing radicular (distributed along the nerve) pain and muscle weakness. See Chapter 42 for further discussion of disc disorders.

Disc degeneration and joint space narrowing alter the mechanics of the spinal column, promoting osteoarthritic changes in the articular processes (the facet joints) of the vertebrae. The cartilage covering the inferior and superior articular processes degenerates, causing localised pain, stiffness, muscle spasm and limited range of motion. Osteophytes may form on articular processes, further contributing to pain and muscle spasm.

The presentation of OA in older people is similar to that in younger adults. However, in this population, the risk of debilitation because of OA is greater and the disease may progress faster. In addition, pain, stiffness and limited ROM increase the risk of falls and fractures in the older adult.

MANIFESTATIONS Osteoarthritis

AFFECTED SITE	MANIFESTATIONS
Interphalangeal joints	■ *Heberden's nodes*—bony enlargements of distal joints; may cause pain, redness, swelling ■ *Bouchard's nodes*—bony enlargement of proximal joints
First carpometacarpal	■ Swelling, tenderness at base of thumb ■ Crepitus with movement ■ 'Squared' appearance of joint
Spine	■ Localised pain and stiffness ■ Muscle spasm ■ Limited range of motion ■ Nerve root compression with radicular pain and motor weakness
Hips	■ Pain referred to inguinal area, buttock, thigh or knee ■ Loss of internal rotation ■ Limited extension, adduction and flexion
Knees	■ Pain and bony enlargement ■ Effusions ■ Crepitus ■ Instability and deformity with advanced disease

INTERPROFESSIONAL CARE

At this time, no treatment is available to arrest the process of joint degeneration. Appropriate management, however, is important to relieve pain and maintain the person's function and mobility. Research is also ongoing on a new class of medications called disease-modifying osteoarthritis drugs (DMOADs) and gene therapy. Vitamin D and chondroitin can slow the rate of degeneration of joints, especially knees (Arthritis Foundation, 2015).

Diagnosis

The diagnosis of OA is generally based on the person's history, physical examination and x-rays of affected joints. Diagnostic tests are described in Chapter 37.

Characteristic changes of OA are visible in x-ray studies of affected joints. Initially, irregular joint space narrowing is seen. Progressive changes include increased density of subchondral (under cartilage) bone, osteophyte formation at the joint periphery and the formation of cysts in the bone. In some cases, MRI or CT scan may be done to determine the extent of joint damage.

Examination of synovial fluid from involved joints can help rule out other types of arthritis (e.g. inflammatory arthritis, gout).

Medications

The pain of OA often can be managed through the use of analgesics such as aspirin. Paracetamol (Panadol) is generally preferred for use in older people because it has fewer toxic side effects. NSAIDs such as ibuprofen (Nurofen), naproxen (Naprosyn), indomethacin (Indocid) and diclofenac (Voltaren) may also be prescribed.

Topical medications include counterirritants, salicylates and capsaicin, sold without prescription as creams, gels, sprays, patches or ointments to relieve pain. Capsaicin, a topical agent, used alone or in conjunction with paracetamol is beneficial. The person should be taught to keep the medications away from their eyes, nose, mouth or any open skin, and not to bandage or apply heat to the treated area. The products should be used no more than three or four times a day and discontinued immediately if severe irritation occurs.

Medications that are effective in decreasing the pain and stiffness of OA are the NSAID COX-2 inhibitors. However, because of the increased risk of adverse cardiovascular (heart attack and strokes) and gastrointestinal (bleeding) effects of most drugs in this category, several were recalled by the Therapeutic Goods Administration (TGA) in 2004 (TGA, 2014). The only COX-2 inhibitor being prescribed as of 2006 was celecoxib (Celebrex).

Potent anti-inflammatory medications, such as systemic corticosteroids, are seldom prescribed for people with OA, although intra-articular corticosteroid injections may be used. With intra-articular injections, a long-acting corticosteroid medication, often mixed with a local anaesthetic such as lignocaine, is injected directly into the joint space of the affected joints. Although this procedure may provide marked pain relief, it can hasten the rate of cartilage breakdown if performed more frequently than every 4 to 6 months.

Treatments

OA is initially treated conservatively, but as pain increases and joint function decreases, surgery often becomes necessary.

CONSERVATIVE TREATMENT The goals of OA treatment are to relieve pain and maintain as much normal joint function as possible. Conservative treatment may include any or all of the following:

- ROM exercises, muscle-strengthening exercises, aerobic exercises
- heat and ice
- a balance between exercise and rest
- use of a cane, crutches or a walker
- weight loss, if indicated
- analgesic and anti-inflammatory medications.

VISCOSUPPLEMENTATION Viscosupplementation is a new treatment for OA of the knee. Hyaluronan, a natural component of synovial fluid, is injected directly into the knee joint. The injection may provide pain relief and improvement in knee function for up to 1 year, but its long-term effects are unknown (Hunter, 2015; NHMRC, 2009).

SURGERY Surgical procedures can provide dramatic results for people with significant chronic pain and loss of joint function. Although elective surgical procedures are frequently avoided in the older adult, even older people can benefit significantly if they do not have a chronic medical condition that contraindicates surgery.

ARTHROSCOPY An *arthroscopy* is a surgical procedure in which an arthroscope (a thin tube that is lit and has a camera in one end) is inserted into a joint. It may be done to diagnose the type of arthritis or to perform debridement by smoothing rough cartilage and flushing out the joint to remove debris. Although arthroscopic debridement and lavage of involved joints have been used, arthroscopy has not proven effective in the treatment of knee OA. It may be useful to remove large pieces of debris or repair a torn cartilage (Mayo Clinic, 2015).

OSTEOTOMY An *osteotomy*, an incision into or transection of the bone, may be performed to realign an affected joint, particularly when significant bony overgrowth or osteophyte formation has occurred. This procedure may also be used to shift the joint load towards areas of less severely damaged cartilage. Although osteotomy does not halt the process of OA, it may have a beneficial effect on joint function and pain, delaying the need for a joint replacement by several years.

JOINT ARTHROPLASTY A *joint arthroplasty* is the reconstruction or replacement of a joint. Arthroplasty is usually indicated when the person has severely restricted joint mobility and pain at rest. Pain is virtually eliminated and the function of the joint is generally improved. Arthroplasty may involve partial joint replacement or reshaping of the bones of a joint. For most people with OA, both surfaces of the affected joint are replaced with prosthetic parts in a procedure known as a *total joint replacement*. Joints that may be replaced include the hip, knee, shoulder, elbow, ankle, wrist and joints of the fingers and toes.

In a total joint replacement, some or all of the synovium, cartilage and bone on both sides of the joint are removed. A metallic prosthesis is inserted to replace one joint surface (generally the load-end or distal portion of a weight-bearing joint). The other joint surface is replaced by a silicone-lined ceramic or plastic prosthesis.

Most prosthetic joints are uncemented; that is, made of porous ceramic and metal components inserted so that they fit tightly into existing bone. The implant is secured by new bone growth into the prosthesis, a process that requires approximately 6 weeks. Although a longer non-weight-bearing period is necessary initially until the prosthesis is fixed in place by the bony growth, the implant appears to have a longer useful lifespan than cemented prostheses. In a cemented joint replacement, methyl methacrylate (a pliable polymer that hardens to hold the prosthesis in place) is used to secure the prosthesis to existing bone. Although the person is able to resume normal activities more rapidly following a cemented joint replacement, methyl methacrylate initiates an inflammatory response and the joint eventually loosens.

- In a *total hip replacement*, the articular surfaces of the acetabulum and femoral head are replaced. The entire head of the femur and part of the femoral neck are removed and replaced with a prosthesis (see Figure 39.3). The acetabulum is remodelled and a prosthesis of high-molecular-weight polyethylene is inserted. The success rate for total hip replacement is reported to be greater than 90%. Most hip replacements last 10 to 15 years, after which a second joint replacement, called

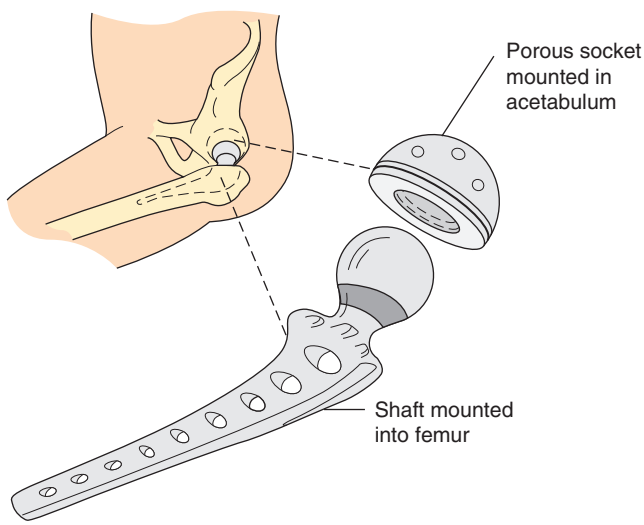

FIGURE 39.3 ■ Total hip prosthesis

a revision, can be performed. Potential problems associated with a total hip replacement include blood clots in leg veins, dislocation within the prosthesis, loosening of joint components from surrounding bone and infection. If recurrent or ineffectively treated, these complications may necessitate removal of the prosthesis, resulting in severe shortening of the extremity and an unstable hip joint.

- *Total knee replacement* is performed if the person has intractable pain and x-ray films show evidence of arthritis of the knee. Several prosthetic devices involving removal of varying amounts of bone are available for knee joint replacement (see Figure 39.4). The femoral side of the joint is replaced with a metallic surface and the tibial side with polyethylene. More than 80% of people obtain significant or total relief of pain with a total knee replacement. They must, however, engage in a vigorous program of rehabilitation to achieve the best results. Joint failure is more common with knee replacement than with a total hip replacement. Loosened joint components, often on the tibial side, are the most common cause of failure. The possible complications following a total knee replacement are the same as for a total hip replacement.
- *Total shoulder replacement* is indicated for unremitting pain and marked limitation of range of motion because of arthritic involvement of both the humeral and glenoid joint surfaces of the shoulder. The joint is immobilised in a sling or abduction splint for 2 to 3 weeks following arthroplasty. Dislocation, loosening of the prosthesis and infection are potential problems associated with total shoulder replacement.
- *Total elbow replacement* involves replacement of the humeral and ulnar surfaces of the elbow joint with a metal and polyethylene prosthesis. Pain and disabling stiffness of the joint are indications for an elbow arthroplasty. Complications, including dislocation, fracture, tricep weakness, loosening and infection, occur frequently.

Infection is the main complication associated with total joint replacement. Not only does infection interfere with healing and prolong recovery, but it may also necessitate removal of the prosthesis and may lead to loss of joint function. Other potential complications include circulatory impairment to the affected limb, thromboembolism, nerve damage and dislocation of the joint.

NURSING CARE OF THE PERSON having total joint replacement

PREOPERATIVE CARE

- Assess the person's knowledge and understanding of the planned operative procedure. Provide further explanations and clarification as needed. *It is important that the person have a clear and realistic understanding of the surgical procedure and expected results. Knowledge decreases anxiety and increases the person's ability to assist with postoperative care procedures.*
- Obtain a health history and physical assessment, including range of motion of the affected joints. *This information not only allows nurses to tailor care to the needs of the individual but also serves as a baseline for comparison of postoperative assessment data.*
- Explain necessary postoperative activity restrictions. Teach how to use the overhead trapeze for changing positions. *The person who learns and practises moving techniques before surgery can use them more effectively in the postoperative period.*
- Provide or reinforce teaching of postoperative exercises specific to the joint on which surgery is to be performed. *Exercises are prescribed postoperatively to: (a) strengthen muscles providing joint stability and support; (b) prevent muscle atrophy and joint contractures; and (c) prevent venous stasis and possible thromboembolism.*
- Teach respiratory hygiene procedures such as the use of incentive spirometry, coughing and deep breathing.

(continued)

NURSING CARE OF THE PERSON having total joint replacement (continued)

Adequate respiratory hygiene is imperative for all people undergoing joint replacement to prevent respiratory complications associated with immobility and the effects of anaesthesia. In addition, many people undergoing total joint replacement are older and may have reduced mucociliary clearance.

- Discuss postoperative pain control measures, including use of patient-controlled analgesia (PCA) or epidural infusion as appropriate. *It is important for the person to understand the purpose and use of postoperative pain control measures to allow early mobility and reduce complications associated with immobility.*
- Teach or provide prescribed preoperative skin preparation such as shower, shampoo and skin scrub with antibacterial solution. *These measures help reduce transient bacteria that may be introduced into the surgical site.*
- Administer intravenous antibiotic as ordered. *Antibiotic therapy is initiated before or during surgery and continued postoperatively to further reduce the risk of infection.*

POSTOPERATIVE CARE

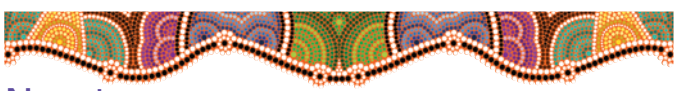
- Monitor vital signs, including temperature and level of consciousness, every 4 hours or more frequently as indicated. Report significant changes to the healthcare provider. *These routine assessments provide information about the person's cardiovascular status and can give early indications of complications such as excessive bleeding, fluid volume deficit and infection.*
- Perform neurovascular checks (colour, temperature, pulses and capillary refill, movement and sensation) on the affected limb hourly for the first 12 to 24 hours, then every 2 to 4 hours. Report abnormal findings to the healthcare provider immediately. *Surgery can disrupt the blood supply to or innervation of the affected extremity. If so, rapid intervention is important to preserve the function of the extremity.*
- Monitor incisional bleeding by emptying and recording suction drainage every 4 hours and assessing the dressing frequently. *Significant blood loss can occur with a total joint replacement, particularly a total hip replacement.*
- Reinforce the dressing as needed. *The dressing is usually changed 24 to 48 hours after surgery but may need reinforcement if excess bleeding occurs.*
- Maintain intravenous infusion and accurate intake and output records during the initial postoperative period. *The person is at risk of fluid volume deficit in the initial postoperative period because of blood and fluid loss during surgery, as well as the effects of the anaesthetic.*
- Maintain bed rest and prescribed position of the affected extremity using a sling, abduction splint, brace, immobiliser or other prescribed device. *Proper positioning of the affected extremity is vital in the initial postoperative period so that the joint prosthesis does not become dislocated or displaced.*
- Help the person shift position at least every 2 hours while on bed rest. *Shifting of position helps prevent pressure ulcers and other complications of immobility.*
- Remind the person to use the incentive spirometer, to cough and to breathe deeply at least every 2 hours. *These measures are important to prevent respiratory complications such as pneumonia.*
- Assess the person's level of comfort frequently. Maintain PCA, epidural infusion or other prescribed analgesia to promote comfort. *Adequate pain management promotes healing and mobility.*
- Help the person get out of bed as soon as allowed. Teach and reinforce the use of techniques to prevent weight bearing on the affected extremity, such as the overhead trapeze, pivot turning and toe touch. *Early mobility prevents complications such as pneumonia and thromboembolism, but appropriate techniques must be used to prevent injury to the operative site.*
- Initiate physical therapy and exercises as prescribed for the specific joint replaced, such as quadriceps setting, leg raising and passive and active ROM exercises. *These exercises help prevent muscle atrophy and thromboembolism and strengthen the muscles of the affected extremity so that it can support the prosthetic joint.*
- Use sequential compression devices or anti-embolism stockings, as prescribed. *These help prevent thromboembolism and pulmonary embolus for the person who must remain immobile following surgery.*
- For the person with a total hip replacement, prevent hip flexion of greater than 90 degrees or adduction of the affected leg. Provide a seat riser for the toilet or commode. *These measures prevent dislocation of the joint.*
- Assess the person with a total hip replacement for signs of prosthesis dislocation, including pain in the affected hip, or shortening and internal rotation of the affected leg.
- For the person with a total knee replacement, use a continuous passive range-of-motion (CPM) device or ROM exercises as prescribed. *Dislocation is not a problem with a knee replacement and more emphasis is placed on ROM exercises in the early postoperative period.*
- Maintain fluid intake and encourage a high-fibre diet. Administer stool softeners or rectal suppositories as needed. *Immobility contributes to the potential problem of constipation; these measures help maintain regular faecal elimination.*
- Encourage consumption of a well-balanced diet with adequate protein. *Adequate nutrition promotes tissue healing.*
- Teach or reinforce post-discharge exercises and activity restrictions. Emphasise the importance of scheduled follow-up physician visits. *People are discharged from the acute care facility before healing is complete. Exercises are prescribed and activities are resumed gradually to protect the integrity of the joint replacement and prevent contractures.*
- For those people needing additional direct care after discharge, arrange placement in a long-term care or rehabilitation facility. *Activity restrictions may preclude discharge to home for some people.*
- Make referrals as needed to community nursing and physiotherapy. *People often require home healthcare for both nursing care needs and continued physiotherapy following discharge from acute or long-term care.*

Nursing care for the person undergoing total joint replacement is outlined in the box below. Refer to Chapter 3 for further discussion of care for the person undergoing surgery.

PHYSICAL THERAPY AND REHABILITATION Recovery from all types of joint replacement requires postoperative physical therapy, focusing on building strength and regaining joint flexibility. Rehabilitation begins in the hospital, most often the day following surgery, and may be continued during home care. Recovery from a hip replacement is 80% complete in 4 weeks and 100% complete in 6 months. Recovery from a knee replacement is 80% complete in 4 weeks and 100% complete after 1 year. During rehabilitation, the person must follow a regimen of exercise, rest and medication (AIHW, 2013; 2015).

COMPLEMENTARY AND ALTERNATIVE THERAPIES The following complementary therapies are examples of those that may be used by people with OA to relieve pain and stiffness. These same therapies are also used by people with rheumatoid arthritis:

- biomagnetic therapy
- rest and joint protection
- weight loss
- acupuncture
- eliminating nightshade foods, such as potatoes, tomatoes, capsicum and eggplant, and tobacco
- taking nutritional supplements, such as glucosamine and chondroitin
- herbal therapy
- massage therapy
- osteopathic manipulation
- vitamin therapy
- yoga.



Nursing care

Osteoarthritis is a chronic process for which there is no cure. The focus of nursing care for the person with OA is providing comfort, helping maintain mobility and ADLs, and assisting with adaptations to maintain life roles. A nursing care plan for a person with OA is found below.

Health promotion

Although OA cannot be prevented, maintaining a normal weight and having a program of regular, moderate exercise will reduce risk factors. Glucosamine and chondroitin are nutritional supplements for OA that are increasingly popular and have been found to be of benefit in reducing manifestations. People should discuss these supplements with their healthcare provider before using them.

Assessment

Collect the following data through the health history and physical examination (see Chapter 37):

- *Health history:* family history of OA, occupation, recreational activities, joint pain and stiffness, ability to carry out ADLs and self-care activities.
- *Physical assessment:* height/weight; gait; joints: symmetry, size, shape, colour, appearance, temperature, pain, crepitus, range of motion, Heberden's nodes, Bouchard's nodes.

Nursing diagnoses and interventions

The priority nursing interventions for people with OA are directed towards managing chronic pain, facilitating physical mobility and improving ability to provide self-care.

Chronic pain

Pain is a primary manifestation of OA. As joint tissues degenerate and changes in joint structure occur, the amount of discomfort generally increases. The pain associated with OA increases with activity and tends to be relieved with rest. Non-pharmacological comfort measures are appropriate, with mild analgesics used to supplement these as needed.

- Monitor the level of pain, including intensity, location, quality and aggravating and relieving factors. *Accurate assessment of pain provides a basis for evaluation of the effect of interventions.*
- Teach people to take prescribed analgesic or anti-inflammatory medication as needed. Analgesics reduce the perception of pain and may decrease muscle spasm as well. *Anti-inflammatory medication may be ordered to decrease local inflammatory response in affected joints.*
- Encourage rest of painful joints. *The pain of OA is often relieved by joint rest.*
- Suggest applying heat to painful joints using the shower, a tub or sitz bath, warm packs, hot wax baths, heated gloves or diathermy, which uses high-frequency electrical currents to generate heat. *Heat application reduces accompanying muscle spasm, relieving pain. Moist heat penetrates deeper than dry heat; diathermy delivers heat directly to lesions in deeper body tissues.*
- Emphasise the importance of proper posture and good body mechanics for walking, sitting, lifting and moving. *Good body mechanics and posture reduce stress on affected joints.*
- Encourage the overweight person to reduce weight. *Excess weight places abnormal stress on joints, particularly the knees.*
- Encourage the use of non-pharmacological pain relief measures such as progressive relaxation, meditation, visualisation and distraction. *These adjunctive pain relief measures can reduce the person's reliance on analgesics and increase comfort.*

Impaired physical mobility

As intra-articular cartilage degenerates and joint structures are altered, the person with OA experiences pain, stiffness and decreased range of motion in affected joints. When the spine, large weight-bearing joints of the hips and knees, or the ankles and feet are affected, physical mobility can be significantly reduced.

- Assess the range of motion of affected joints. *Assessing joint mobility is important as a basis for planning appropriate interventions.*

- Perform a functional mobility assessment, evaluating gait, ability to sit and rise from sitting position, ability to step into and out of the tub or shower, and negotiation of stairs. *The functional assessment provides vital data about the person's ability to maintain ADLs.*
- Teach active and passive ROM exercises as well as isometric, progressive resistance and low-impact aerobic exercises. *Active ROM exercises help maintain muscle tone and mobility of affected joints and prevent contractures.*

Isometric and progressive resistance exercises improve muscle tone and strength; aerobic exercise improves endurance and cardiovascular fitness.

CONSIDERATION FOR PRACTICE

The older woman with OA may be more willing to take part in weight-bearing exercises if she does so as part of a group or organised activity.

NURSING CARE PLAN A person with osteoarthritis

Raymond Nasso is a 72-year-old retired commercial fisherman who has experienced arthritic pain in his hips for the past 10 to 15 years. During the past year, the pain in his right hip has become severe, prompting him to seek medical attention. Significant degenerative changes in both hip joints are noted on x-ray films. The physician recommends a total replacement of the right hip and total replacement of the left hip to follow in 6 to 12 months. Mr Nasso has preoperative teaching and tests the afternoon prior to his surgery, scheduled for 0800 the following morning.

ASSESSMENT

Christie Phlaugh, RN, completes a health history and examination of Mr Nasso on admission. Reviewing his medical record, she notes that Mr Nasso has mild Parkinson's disease and is taking carbidopa/levodopa (Sinemet 25-100) four times a day to control his symptoms. No other chronic medical conditions have been reported. Mr Nasso says he has been essentially healthy his entire life. He has no known allergies to medications, has never smoked and consumes only small amounts of alcohol.

On examination of Mr Nasso, Ms Phlaugh notes that he is alert and oriented. His vital signs are BP 116/64, P 68 regular, R 18, T 36.3°C PO. Peripheral pulses are strong and equal in the upper extremities and slightly weaker but equal in the lower extremities. His feet are cool to the touch but have immediate capillary refill. He has full ROM of his shoulders, elbows and wrists. The ROM of both hips is significantly restricted. Hip flexion beyond 90 degrees prompts pain on both sides. Both flexion and extension of the knees are limited slightly. Mr Nasso walks with a limp, favouring his right hip, and has a shuffling gait.

Preoperative laboratory studies including FBC, coagulation studies, chemistry panel and urinalysis show a serum creatinine of 1.7 mg/dL and BUN of 30 mg/dL, with no other abnormal values noted. His skin swabs, ECG and chest x-ray show no apparent pathologies. Cephazolin 500 mg is to be administered intravenously at 0600 prior to surgery and Mr Nasso is to shower and shampoo with antibacterial soap at bedtime. The physical therapist meets with Mr Nasso to evaluate his mobility and begin teaching him about postoperative weight-bearing restrictions.

DIAGNOSES (POSTOPERATIVE)

- *Acute pain* related to surgical incision.
- *Impaired physical mobility* related to activity and weight-bearing restrictions.
- *Risk of infection* related to disruption in skin integrity.
- *Risk of ineffective right leg tissue perfusion* related to vascular disruption and oedema.

PLANNING

Ensure Mr Nasso is able to manage his pain and prevent postoperative complications.

Expected outcomes

- Maintain an adequate level of comfort postoperatively as demonstrated by verbal expressions of comfort and the ability to move easily within restrictions.
- Remain free of infection.
- Maintain adequate perfusion of affected leg.
- Remain free of injury postoperatively.
- Comply with instructions to cough and breathe deeply.
- Remain free of adverse consequences of immobility such as pneumonia, pressure areas, thromboembolism or contracture.

IMPLEMENTATION

- Assess pain at least hourly during first 24 to 48 hours postoperatively and as needed thereafter.
- Instruct in the use of PCA and monitor its effectiveness.
- Help change position at least every 2 hours; encourage the use of the overhead trapeze to shift position frequently.
- Assess the surgical site frequently; report signs of excess bleeding or inflammation.
- Monitor temperature every 4 hours.
- Maintain sequential compression device and anti-embolic stocking as ordered; remove for 1 hour daily.
- Assist out of bed three times a day after the first 24 hours.
- Maintain abduction of the right hip with pillows.
- Perform passive ROM exercises of unaffected extremities every shift.
- Encourage frequent quadriceps-setting exercises and plantar and dorsiflexion of feet.
- Assess pulses, colour, movement and sensation of right foot hourly for the first 24 hours, then every 2 hours for 24 hours, then every 4 hours.
- Encourage the use of the incentive spirometer hourly for first 24 hours, then at least every 2 hours while awake.

EVALUATION

Mr Nasso returns to the orthopaedic unit from the recovery ward. For the first 36 hours after surgery he is confused and disoriented, but his orientation and thought processes gradually clear. His family has stayed with him and he has not experienced injury or other adverse consequences from his

NURSING CARE PLAN A person with osteoarthritis (continued)

confusion. Otherwise, Mr Nasso has had an uneventful postoperative recovery. Six days after surgery, he is transferred to an extended care rehabilitation facility for further therapy until he is able to ambulate with partial weight bearing on his affected leg. He returns home 5 weeks after surgery, able to use a walker for ambulation. Arrangements are made for an over-bed trapeze, elevated toilet seat and shower chair in his home. A community nurse and physiotherapist visit Mr and Mrs Nasso weekly for a month following his discharge. During this time Mr Nasso gradually resumes full weight bearing. Mr Nasso expresses pleasure with the relief of his hip pain and says he has no fear of having his left hip replaced in the future.

CRITICAL THINKING IN THE NURSING PROCESS

1 Mr Nasso's preoperative laboratory work showed a modest elevation in his serum creatinine and BUN. What do these studies indicate? How might these changes affect nursing responsibilities related to medication administration for Mr Nasso?
2 Mr Nasso became confused postoperatively. Which factors in his history might have alerted the nurses to this possibility? How might anaesthesia and postoperative analgesics have contributed to his confusion?
3 Develop a care plan for Mr Nasso using the nursing diagnosis of *Acute confusion*.

REFLECTION ON THE NURSING PROCESS

1 From caring for Mr Nasso, identify two key issues that you will be able to utilise for future practice.
2 Which health education and teaching techniques are required prior to Mr Nasso's discharge?

Self-care deficit

Just as OA of the lower extremities can reduce the person's mobility, OA of the upper extremities (the wrist, hand and finger joints, in particular) can significantly interfere with performance of ADLs such as cooking and brushing the hair. When the lower extremities are affected, bathing and toileting can be difficult.

- Perform a functional assessment of the upper and lower extremities. For upper extremities, assess the ability to touch the back of the head and to hold and use small items such as eating utensils. *The functional assessment provides important data about the person's ability to provide self-care.*
- Assess the home setting to determine the need for assistive devices such as handrails, grab bars, walk-in shower stall or shower chair, and handheld showerhead. *Many assistive devices are relatively easy and inexpensive to obtain and can significantly improve the person's independence in performing ADLs.*
- Assist in obtaining other assistive devices such as long-handled shoehorns, zipper grabbers, long-handled tongs or grippers for retrieving items from the floor, jar openers and special eating utensils. *These devices can prolong independence in performing ADLs.*

Community-based care

Because of the chronicity of OA, people and their families need appropriate teaching to manage the disease and its consequences effectively. Much of the teaching focus is on preservation of joint function and mobility. Discuss the following topics:

- Safeguard against hazards to safe mobility, such as scatter rugs. Encourage installation of safety devices such as handrails and grab bars.
- Understand the disease process and its chronic degenerative nature.
- Learn exercise techniques, including ROM, isometric, postural, stretching and strengthening, to maintain healthy cartilage, preserve ROM and develop supportive muscles and tendons. A walking program is beneficial for people with OA of the knee.
- Do not overuse or stress affected joints with heavy lifting, excessive stair climbing or bending, or other repetitive actions.
- Sit in a straight chair without slumping; avoid soft chairs or recliners, and sleep on a firm mattress or use a bed board.
- Use pain relief measures including prescribed or over-the-counter analgesic medications and non-pharmacological pain relief measures such as heat, rest, massage, relaxation and meditation.

For the person who has had a total joint replacement, discuss the following:

- use and weight bearing of the affected limb
- appropriate environmental modifications, such as an overhead trapeze for getting out of bed, elevated toilet seats and types of chairs to use and avoid when sitting
- prescribed exercises
- use of assistive devices for ambulation, such as crutches or a walker
- possible complications, including signs of infection or dislocation, and the need to notify the physician promptly if these occur.

Make referrals to home care, physical or occupational therapy, or other community agencies as indicated, and suggest the following resources:

- Arthritis Australia: www.arthritisaustralia.com.au
- Arthritis New Zealand: www.arthritis.org.nz
- Australian Rheumatology Association: http://rheumatology.org.au.

THE PERSON WITH MUSCULAR DYSTROPHY

Muscular dystrophy (MD) is a group of inherited muscle diseases that cause progressive muscle degeneration and wasting. The differences in the types of MD relate to the age at onset, the gender affected by the disorder, the muscles involved

TABLE 39.2 Types of muscular dystrophy

TYPE	SEX AND AGE AT ONSET	CLINICAL MANIFESTATIONS	PROGRESSION
Duchenne's	Males Ages 3 to 5	Weakness of pelvic and shoulder girdles Waddling gait Toe walking Lordosis Cardiac abnormalities Low IQ in 50% of cases	Rapid; person usually confined to wheelchair by age 15; death occurs by age 20
Myotonic	Males and females Any age	Myotonia of hand muscles Muscular weakness of arms and legs Cardiac abnormalities Endocrine abnormalities Mental retardation (common)	Slow; death usually occurs in early fifties
Becker's	Males Ages 5 to 20	Weakness of pelvic and shoulder girdles	Slow; person usually confined to wheelchair at 25 years after onset; normal lifespan
Facioscapulohumeral	Males and females Ages 10 to 20	Weakness of face and shoulder girdles	Slow; normal lifespan
Limb-girdle	Males and females Ages 20 to 40	Weakness of shoulder and pelvic girdles	Extremely variable; usually slow

and the rate at which the disease progresses. These factors are summarised in Table 39.2. In the majority of cases of MD, there is a positive family history.

The most common form of MD, Duchenne's muscular dystrophy, is inherited as a recessive single gene defect on the X chromosome (a sex-linked recessive disorder) and is transmitted from the mother to male children. This disorder affects males exclusively and occurs in 1 of 3500 live male births. It can be recognised early in pregnancy in about 95% of cases by genetic studies or in late pregnancy through amniocentesis. Genetic counselling cannot be reliably used to prevent this disease because there is no way to determine if the woman carries the defective gene. The manifestations appear in early childhood, with the average lifespan being about 15 years after onset (Porth & Matfin, 2014).

Other types of MD have an onset at any age and a slow progression with a normal lifespan.

Pathophysiology

The basic defect in MD is unknown; however, three theories have been proposed. The *vascular* and *neurogenic theories* suggest that the cause is a lack of blood supply to the muscle or a disturbance in the interaction between the nerve and muscle. The *membrane theory* suggests that an alteration in the cell membranes of the muscle causes them to degenerate. Recent genetic studies have shown a deficiency in the amount of dystrophin, a muscle membrane protein, in people with Duchenne's MD. Dystrophin plays an important role in protecting the muscle against mechanical stresses.

Manifestations

All forms of MD exhibit manifestations of muscle weakness. The specific muscles involved depend on the type of MD. As the disease progresses, the person develops difficulty with ambulation and eventually becomes wheelchair bound and finally bed bound. Cardiac abnormalities, endocrine abnormalities and mental retardation may also occur.

INTERPROFESSIONAL CARE

Because there is no cure or specific treatment for MD, care focuses on preserving and promoting mobility. An interdisciplinary approach, involving many members of the healthcare team, is necessary to meet the physical and psychological needs of these people and their families. Diagnosis and classification of the muscular dystrophies are most often based on the manifestations and the pattern of muscle involvement. Biochemical examination, muscle biopsy and electromyography confirm the diagnosis. Diagnostic tests are described in Chapter 37.

Tests include measuring creatine kinase (CK-MM, the isoenzyme found in skeletal muscle) which is elevated in the person with suspected MD; performing a muscle biopsy to identify fibrous connective tissue and fatty deposits that displace functional muscle fibres; and conducting an electromyogram (EMG), which will show a decrease in amplitude in MD.

Nursing care

Nursing care for a person with MD focuses on promoting independence and mobility, and providing psychological support for both the person and family. A holistic approach is essential in planning and implementing care.

Nursing diagnoses and interventions

Self-care deficit

The progressive muscle weakness that is associated with MD impairs the person's ability to perform self-care.

- Provide the person and their family with supportive care during the progress of the disease. The goal of treatment is to prolong each functional stage and delay or prevent deformity. *When transition from ambulation to a wheelchair occurs, depression and grief may occur.*
- Promote independence. Encourage tasks that can be accomplished rather than letting the person struggle with tasks that may prove frustrating. *All forms of MD result in progressive muscle weakness. Management of the disease is directed towards keeping the person as functional as possible while preventing any deformities.*

Community-based care

Teaching the person with MD focuses on maintaining function and independence and preventing deformities. Teach prescribed exercises such as stretching and counterposturing exercises. For the person with braces, discuss skin care and ways to prevent irritation under the brace. Because the person may have weakness involving muscles of respiration, teach the person how to prevent respiratory infections, such as avoiding crowds during flu season and being immunised against pneumococcal pneumonia and influenza. Provide information about support services and organisations such as the Muscular Dystrophy Association.

AUTOIMMUNE AND INFLAMMATORY DISORDERS

Autoimmune and inflammatory disorders of the musculoskeletal system are chronic systemic rheumatic disorders, characterised by diffuse inflammatory lesions and degenerative changes in connective tissues. The disorders have similar clinical features and may affect many of the same structures and organs.

THE PERSON WITH RHEUMATOID ARTHRITIS

Rheumatoid arthritis (RA) is a chronic systemic autoimmune disease that causes inflammation of connective tissue, primarily in the joints. Its course and severity are variable and the range of manifestations is broad. Manifestations of RA may be minimal, with mild inflammation of only a few joints and little structural damage, or relentlessly progressive, with multiple inflamed joints and marked deformity. Most people exhibit a pattern of symmetrical involvement of multiple peripheral joints and periods of remission and exacerbation.

The cause of RA is unknown. A combination of genetic, environmental, hormonal and reproductive factors is thought to play a role in its development. It is speculated that infectious agents, such as bacteria, mycoplasmas and viruses (especially Epstein–Barr virus), may play a role in initiating the autoimmune processes present in RA. Several studies have found that heavy smokers are at increased risk of developing RA. It is known that the incidence of RA has decreased during the past 40 years, supporting the theory that environmental factors may change and either promote or protect against RA (Arthritis Foundation, 2015; Grossman & Porth, 2013).

The course of RA is variable and fluctuating. Remissions are most likely to occur in the first year of the disease. The rate at which joint deformities develop is not constant. Disease progression is fastest during the first 6 years, slowing thereafter. RA contributes to disability and a tendency to shorten life expectancy. About 10% of people with RA go into long-term remission within 1 year; and another 50–60% go into remission within 2 years (Arthritis Foundation, 2015; Grossman & Porth, 2013).

FAST FACTS

- RA is found worldwide, affecting 0.3–2% of the total population and all races.
- RA affects three times as many women as men.
- The onset of RA occurs most frequently between the ages of 30 and 50 years.
- RA is less common than OA, with RA affecting around 400 000 Australians (AIHW, 2009).

The incidence of RA increases with age up to about 70 years. Although the onset and manifestations of RA are much the same in older and younger people, differentiating between RA and OA in the older adult may be difficult at times. It is important to establish an accurate diagnosis, however, because the management of these disorders differs significantly. Clinical features distinguishing RA from OA are listed in Table 39.3.

For older people, RA is managed much as it is for younger people. However, prolonged bed rest or inactivity is not prescribed for acute episodes because it may result in irreversible immobility in the older adult. Also, medications are used with greater caution because of the increased risk of toxicity. In many cases, emphasis is placed less on preventing joint deformity and more on maintaining functional status for the older person with RA.

Pathophysiology

It is believed that long-term exposure to an unidentified antigen causes an aberrant immune response in a genetically

TABLE 39.3 Comparison of the manifestations of rheumatoid arthritis and osteoarthritis

FEATURE	RHEUMATOID ARTHRITIS	OSTEOARTHRITIS
Onset	Usually insidious, may be abrupt	Insidious
Course	Generally progressive, characterised by remissions and exacerbations	Slowly progressive
Pain and stiffness	Predominant on arising, lasting > 1 hour; also occurs after prolonged inactivity	Pain with activity; stiffness following periods of immobility generally relieved within minutes
Affected joints	Appear red, hot, swollen; 'boggy' and tender to palpation; decreased ROM, weakness	Affected joints may appear swollen; cool and bony hard on palpation; decreased ROM
	Multiple joints affected in symmetrical pattern; PIP, MCP, wrists, knees, ankles and toes often involved	One or several joints affected including hips, knees, lumbar and cervical spine, PIP and DIP, wrist and 1st MTP joint
Systemic manifestations	Fatigue, weakness, anorexia, weight loss, fever; rheumatoid nodules; anaemia	Fatigue

susceptible host. As a result, normal antibodies (immunoglobulins) become autoantibodies and attack host tissues. These transformed antibodies, usually present in people with RA, are called *rheumatoid factors (RFs)*. The self-produced antibodies bind with their target antigens in blood and synovial membranes, forming immune complexes. (See Chapter 12 for further information about autoimmune processes.)

The damage to cartilage that occurs in RA is the result of at least three processes:

1. Neutrophils, T cells and other synovial fluid cells are activated and degrade the surface layer of the articular cartilage.
2. Cytokines, especially interleukin-1 (IL-1) and tumour necrosis factor alpha (TNF-α), cause the chondrocytes to attack the cartilage.
3. The synovium digests nearby cartilage, releasing inflammatory molecules containing IL-1 and TNF-α.

Leucocytes are attracted to the synovial membrane from the circulation, where neutrophils and macrophages ingest the immune complexes and release enzymes that degrade synovial tissue and articular cartilage. Activation of B and T lymphocytes results in increased production of rheumatoid factors and enzymes that increase and continue the inflammatory process.

The synovial membrane is damaged by the inflammatory and immune processes. It swells from infiltration of the leucocytes and thickens as cells proliferate and abnormally enlarge. The inflammation spreads and involves synovial blood vessels. Small venules are occluded and vascular flow to the synovial tissue decreases. As blood flow decreases and metabolic needs increase (from the increased number and size of cells), hypoxia and metabolic acidosis occur. Acidosis stimulates synovial cells to release hydrolytic enzymes into surrounding tissues, starting erosion of the articular cartilage and inflammation of the supporting ligaments and tendons.

The inflammation also causes haemorrhage, coagulation and deposits of fibrin on the synovial membrane, in the intracellular matrix and in the synovial fluid. Fibrin develops into *granulation tissue (pannus)* over denuded areas of the synovial membrane. The formation of pannus leads to scar tissue formation that immobilises the joint (see Figure 39.5).

Joint manifestations

The onset of RA is typically insidious, although it may be acute (precipitated by a stressor such as infection, surgery or trauma). Joint manifestations are often preceded by systemic manifestations of inflammation, including fatigue, anorexia, weight loss and non-specific aching and stiffness. People report joint swelling with associated stiffness, warmth, tenderness and pain. The pattern of joint involvement is typically polyarticular (involving multiple joints) and symmetrical. The proximal interphalangeal (PIP) and metacarpophalangeal (MCP) joints of the fingers, the wrists, the knees, the ankles and the toes are most frequently involved, although RA can affect any joint. Stiffness is most pronounced in the morning, lasting more than 1 hour. It may also occur with

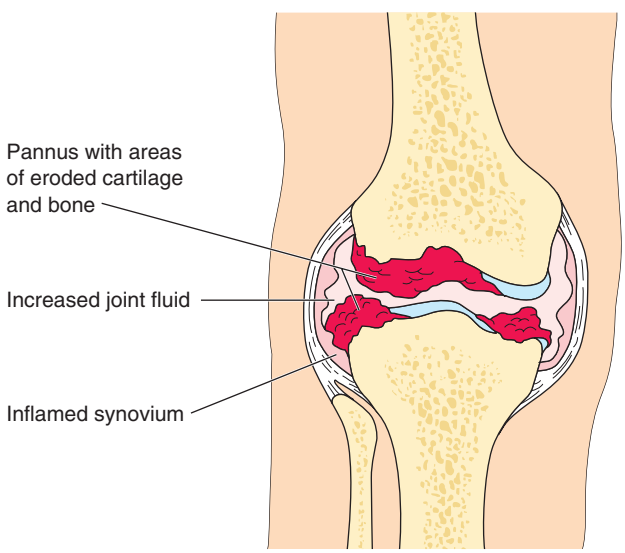


FIGURE 39.5 ■ Joint inflammation and destruction in rheumatoid arthritis. Note synovial inflammation with pannus formation and the erosion of cartilage and underlying bone

prolonged rest during the day and may be more severe following strenuous activity. Swollen inflamed joints feel 'boggy' or sponge-like on palpation because of synovial oedema. Range of motion is limited in affected joints and weakness may be evident.

The persistent inflammation of RA causes deformities of the joint itself and supporting structures such as ligaments, tendons and muscles. As the joint is destroyed, ligaments, tendons and the joint capsule are weakened or destroyed. Joint cartilage and bone are also destroyed. Weakening or destruction of these supporting structures results in lack of opposition to muscle pull, causing deformity.

Characteristic changes in the hands and fingers include ulnar deviation of the fingers and subluxation at the MCP joints. Swan-neck deformity is characterised by hyperextension of the PIP joint with compensatory flexion of the distal interphalangeal (DIP) joints (see Figure 39.6). A flexion deformity of the PIP joints with extension of the DIP joint is called a boutonnière deformity. The ability to effect a pinch is limited by hyperextension of the interphalangeal joint and flexion of the MCP joint of the thumb.

Wrist involvement is nearly universal, leading to limited movement, deformity and carpal tunnel syndrome. Inflammation of the elbows often causes flexion contracture.

The knees are frequently affected in RA, with visible swelling often obliterating normal contours. Instability of the knee joint along with quadriceps atrophy, contractures and valgus (knock-knee) deformities can lead to significant disability. Ambulation may be limited by pain and deformities when the ankles and feet are involved. Typical deformities of the feet and toes include subluxation, hallux valgus (deviation of the great toe towards the other digits of the foot), lateral deviation of the toes and cock-up toes (turned-up toes).

Spinal involvement is usually limited to the cervical vertebrae. Neck pain is common and neurological complications can occur.

Extra-articular manifestations

RA is a systemic disease with a variety of extra-articular manifestations. These are seen particularly in people with high levels of circulating rheumatoid factor. Fatigue, weakness, anorexia, weight loss and low-grade fever are common when the disease is active. Anaemia resistant to iron therapy frequently affects people with RA. Skeletal muscle atrophy is common, usually most apparent in the musculature around affected joints.

Rheumatoid nodules may develop, usually in subcutaneous tissue in areas subject to pressure: on the forearm, olecranon bursa, over the MCP joints and on the toes. Rheumatoid nodules are granulomatous lesions that are firm and either movable or fixed. They may also be found in viscera, including the heart, lungs, intestinal tract and dura.

Other possible extra-articular manifestations of RA include subcutaneous nodules, pleural effusion, vasculitis, pericarditis and splenomegaly (enlargement of the spleen). The multisystem effects of RA are illustrated overleaf.

Increased risk of coronary heart disease

People with rheumatoid arthritis have an increased risk of developing coronary heart disease (CHD). In turn, CHD increases the risk of myocardial infarction and death; in fact, RA is associated with a shortened life expectancy (Arthritis Foundation, 2015; Grossman & Porth, 2013). RA affects the heart by:

- direct effects on the blood vessels, with measures of C-reactive proteins (inflammatory markers) being more predictive of future cardiovascular disease than low-density lipoprotein (LDL) levels
- increased risk of having low high-density lipoprotein, high cholesterol and triglyceride levels, high blood pressure and high levels of homocysteine—all of which increase the risk of CHD
- the damaging side effects that many medications, such as methotrexate and steroids, often have on coronary vessels.

INTERPROFESSIONAL CARE

The diagnosis of RA is based on the person's history, physical assessment and diagnostic tests. Diagnostic criteria developed by the American Rheumatism Association (2015) are used as well (see Box 39.4). At least four of seven criteria must be present to establish the diagnosis. Positive RF occurs in approximately 80% of people and levels rise during active phases of the disease.

Once the diagnosis of RA has been established, the goals of therapy are to relieve pain, reduce inflammation, slow or stop joint damage, and improve wellbeing and ability to function. No cure currently exists for RA; the goal of treatment is to relieve its manifestations. An interprofessional approach is used, with a balance of rest, exercise, physical therapy and suppression of the inflammatory processes.

Because a cure is not available and traditional therapies are not always fully effective, the person with RA is vulnerable to

BOX 39.4 Diagnostic criteria for rheumatoid arthritis

- Morning stiffness lasting for at least 1 hour and persisting for at least 6 weeks
- Arthritis with swelling or effusion of three or more joints persisting for at least 6 weeks
- Arthritis of wrist, MCP or PIP joints persisting for at least 6 weeks
- Symmetrical arthritis with simultaneous involvement of corresponding joints on both sides of the body
- Rheumatoid nodules
- Positive serum rheumatoid factor
- Characteristic radiological changes of rheumatoid arthritis noted in hands and wrists (American Rheumatism Association, 2015).

quackery. Many non-traditional treatments, including diets, topical preparations, vaccines, hormones, plant extracts and copper bracelets, have been put forth. These treatments are often costly and none has been shown to be effective.

Diagnosis

Diagnostic tests are used to help establish the diagnosis of RA. Testing is also used to rule out other forms of arthritis and connective tissue disorders. Diagnostic tests are described in Chapter 37.

Laboratory tests are used to measure rheumatoid factors and the ESR, which is typically elevated. A full blood count (FBC) is done to identify anaemia. Diagnosing RA in the early stages is often difficult, but a new test is highly effective. In this blood test, people are tested for antibodies to cyclic citrullinated peptide (CCP) with accurate detection of early RA.

Synovial fluid examination will demonstrate changes associated with inflammation, including increased turbidity (cloudiness), decreased viscosity and increased protein and WBC levels. X-rays of affected joints are the most specific test for diagnosis of RA. Early in the disease, few changes may be evident other than soft tissue swelling and joint effusions. As the disease progresses, joint space narrowing and erosions are seen.

Medications

Four general approaches are used in the pharmacological management of people with RA:

1. Aspirin and other NSAIDs and mild analgesics are used to reduce the inflammatory process and manage the manifestation of the disease. Although these drugs may relieve manifestations of RA, they appear to have little effect on disease progression.
2. The second approach uses low-dose oral corticosteroids to reduce pain and inflammation. Recent studies suggest that low-dose oral corticosteroids also may slow the development and progression of bone erosions associated with RA.
3. A diverse group of drugs classified as disease-modifying or slow-acting antirheumatic drugs are employed in the third approach to treating RA. These drugs, which include gold compounds, D-penicillamine, antimalarial agents, infliximab and sulfasalazine, appear to alter the course of the disease, reducing its destruction of joints. Immunosuppressive and cytotoxic drugs are included in this category as well.
4. Intra-articular corticosteroids may be used to provide temporary relief in people for whom other therapies have failed to control inflammation.

ASPIRIN Aspirin is often the first drug prescribed in the treatment of RA unless its use is contraindicated for the person. Aspirin is an inexpensive and effective anti-inflammatory and analgesic agent. The dose of aspirin required to achieve a therapeutic blood level of 15 to 30 mg/dL and its full anti-inflammatory effect is approximately 4 g per day in divided doses (three or four 5 g (325 mg) tablets qid). This effective dose is just under the toxic dose, which produces tinnitus and hearing loss. The person may be instructed to increase the dose of aspirin gradually until either maximal improvement or toxicity occurs. If tinnitus develops, the person reduces the dose by two to three tablets per day until the tinnitus stops.

Gastrointestinal side effects and interference with platelet function are the greatest hazards of aspirin therapy. People are instructed to take aspirin with meals, milk or antacids to minimise gastrointestinal distress and reduce the risk of GI bleeding. Enteric-coated forms of aspirin and non-acetylated salicylate compounds produce less gastric distress than plain or buffered aspirin and reduce the risk of gastric ulceration, but they are more expensive. Salsalate (Disalcid, Mono-Gesic, Salflex) and choline magnesium trisalicylate (Trilisate, Tricosal) are examples of non-acetylated salicylate products. All salicylate products are contraindicated for people with a history of aspirin allergy.

OTHER NON-STEROIDAL ANTI-INFLAMMATORY DRUGS A number of other NSAIDs are available for use in the management of RA if aspirin is not tolerated or effective. All NSAIDs act by inhibiting prostaglandin synthesis. Although the efficacy of all NSAIDs, including aspirin, is equivalent, people's responses are individual. Several trials of different NSAIDs may be necessary to find the most effective drug.

Some NSAIDs are considerably more expensive than aspirin but may cause less gastrointestinal distress and require fewer doses per day. Gastric irritation, ulceration and bleeding remain the most common toxic effects of NSAIDs. They can also affect the lower intestinal tract, leading to perforation or aggravation of inflammatory bowel disorders. All NSAIDs can also be toxic to the kidneys.

NSAIDs commonly prescribed for people with RA are listed in Table 39.4. The TGA (2014) has issued planned regulatory actions for both prescription and over-the-counter (OTC) non-selective NSAIDs. These actions include increased label warnings about the potential serious adverse cardiovascular and gastrointestinal effects of these drugs; the non-prescription drugs include those containing ibuprofen, naproxen and ketoprofen. Nursing implications for the administration of NSAIDs are described in Chapter 11.

TABLE 39.4 Examples of non-steroidal anti-inflammatory drugs used to treat rheumatoid arthritis

DRUG	AVERAGE DOSE	COMMENTS AND PRECAUTIONS
Aspirin	600–900 mg 4 to 6 times daily	Least expensive NSAID; associated with risk of GI ulceration, bleeding and possible haemorrhage; may cause hepatotoxicity
Diclofenac (Voltaren)	50 mg tds or qid; or 75 mg bd	Expensive; risk of hepatotoxicity
Celecoxib	100 mg bd	GIT ulceration and bleeding. Adverse renal effects in some individuals
Flurbiprofen (Ansaid)	50–100 mg tds or qid, not to exceed 300 mg/day	Expensive
Ibuprofen (Nurofen, Advil others)	300 mg qid; 400–800 mg tds or qid	Available in prescription and OTC forms; less gastric distress reported than with aspirin or indomethacin; discontinue if visual disturbances develop
Indomethacin (Indocin)	25–50 mg bd or tds	A potent NSAID used for moderate to severe RA and acute episodes of chronic disease; higher incidence of adverse GI effects and CNS effects such as headache, dizziness and depression
Ketoprofen (Orudis)	50–75 mg tds or qid	Expensive; older adults and people with renal insufficiency require lower doses
Ketorolac	10 mg (max 40 mg)	Increased risk of GI bleeding and other severe effects increase with duration of treatment
Naproxen (Aleve, Anaprox, Naprosyn)	250–500 mg bd	Available in prescription and OTC preparations
Piroxicam (Feldene)	20 mg daily in a single or divided dose	Expensive; GI side effects including stomatitis, anorexia and gastric distress may occur more frequently than with other NSAIDs. Contraindicated in people with renal impairment
Sulindac (Clinoril)	150–200 mg bd	May be safer for use than other NSAIDs in people with chronic renal disease; rare fatal hypersensitivity reaction with fever, liver function abnormalities and severe skin reaction

bd = twice daily; qid = four times daily; tds = three times daily.

CORTICOSTEROIDS Systemic corticosteroids can dramatically relieve the symptoms of RA and appear to slow the progression of joint destruction. The long-term use of corticosteroids is associated with multiple side effects, such as poor wound healing, increased risk of infection, osteoporosis and gastrointestinal bleeding. Severe rebound manifestations can occur when these medications are discontinued. For these reasons, the use of systemic corticosteroids is limited to low dosages daily. The nursing implications for corticosteroid therapy are discussed in Chapter 12.

DISEASE-MODIFYING DRUGS Disease-modifying drugs are a diverse group of medications including drugs that modify immune and inflammatory responses, gold salts, antimalarial agents, sulfasalazine and D-penicillamine (see Table 39.5). They share characteristics that make them useful in the treatment of RA. Although beneficial effects are not apparent for several weeks or months following the initiation of therapy, they can produce not only clinical improvement but also evidence of decreased disease activity. Because their anti-inflammatory effect is minimal, NSAIDs are continued during therapy. As many as two-thirds of people taking disease-modifying drugs show improvement, although these drugs have not been shown to slow bone erosion or facilitate healing. All of these drugs are fairly toxic and close monitoring is necessary during the course of therapy.

Drugs that modify the autoimmune and inflammatory responses in people with RA include leflunomide (Arava) and etanercept (Enbrel). Leflunomide reversibly inhibits an enzyme involved in the autoimmune process and etanercept inhibits the binding of tumour necrosis factor to receptor sites. Infliximab (Remicade) is a biological response modifier and TNF-α receptor antagonist. Given by intravenous infusion, the drug is administered to reduce infiltration of inflammatory cells and TNF-α production. Adalimumab (Humira) is a biological response modifier that is given to people with RA to reduce the inflammatory events of polyarthritis and slow the progression of joint damage. Given by subcutaneous injection, the drug cannot be administered if the person has an acute or chronic infection in any part of the body. Prior to initiating the drug, the person should be tested for tuberculosis.

Gold salts may be administered by mouth but the intramuscular route is preferred because it is more effective. The mode of action of gold is unknown but it may produce clinical remission in some people and decrease new bony erosions. Weekly therapy is continued until significant improvement is noted unless toxic reactions occur. People experiencing benefit from gold therapy may be continued on monthly injections for several years. About one-third of people on gold therapy experience toxic reactions, including dermatitis, stomatitis, bone marrow depression and proteinuria. Mild skin reactions do not always necessitate discontinuation of therapy. FBC and

TABLE 39.5 Disease-modifying drugs used to treat rheumatoid arthritis

CLASS/MEDICATIONS	USUAL DOSE	ADVERSE EFFECTS	COMMENTS/NURSING RESPONSIBILITIES
Gold salts Gold sodium thiomalate (Myochrysine) Aurothioglucose (Solganal) Auranofin (Ridaura Capsules)	Parenteral: 1st dose 10 mg; 2nd dose 25 mg, then 50 mg weekly IM Oral: 6 mg daily	• Pruritus, dermatitis • Stomatitis, metallic taste • Renal toxicity • Blood dyscrasias • Gastrointestinal distress	• Frequent UA and FBC • Monitor the person after injection for flushing, fainting, dizziness, sweating, possible anaphylactic reaction
Antimalarial Hydroxychloroquine (Plaquenil)	200–600 mg daily with meals	• CNS reactions including irritability, nightmares, psychoses • Retinopathy • Alopecia, pruritus • Blood dyscrasias • GI disturbances	• Should not be used during pregnancy • Regular ophthalmological examination required
Other Sulfasalazine (Azulfidine)	2 g/day in divided doses with meals	• Anorexia, nausea, vomiting, gastric distress • Decreased sperm count • Headache • Rash • Blood dyscrasias • Hypersensitivity responses including Stevens–Johnson syndrome • CNS, liver and renal toxicity	• Administer in evenly divided doses • Maintain high fluid intake • May cause yellow-orange skin or urine discolouration • Regular FBC necessary
Penicillamine (Cuprimine, Depen Titratable)	125–250 mg/day initially, slowly increased to a total of 1000–1500 mg/day	• Skin rashes • Fever • Gastrointestinal distress • Oral ulcers, loss of taste • Fever • Bone marrow depression with thrombocytopenia, leucopenia, anaemia • Renal toxicity • May induce immune complex disorders such as Goodpasture's syndrome and myasthenia gravis	• Regular FBC and UA necessary • Administer on an empty stomach • Discontinue during pregnancy • May require 2 to 3 months of therapy before benefit is seen

CNS = central nervous system; FBC = full blood count; UA = urinalysis.

urinalysis are monitored throughout treatment with gold to assess for more severe toxic responses.

Hydroxychloroquine (Plaquenil) is an antimalarial agent sometimes employed in the treatment of RA. Three to 6 months of therapy is required to achieve the desired response and many people do not experience significant benefit. Although hydroxychloroquine has a relatively low toxicity, it can cause pigmentary retinitis and vision loss. People receiving this drug require a thorough vision examination every 6 months.

Sulfasalazine, a drug regularly prescribed for chronic inflammatory bowel disease, may also be prescribed for RA. See Chapter 23 for further discussion of this drug and its nursing implications.

For people not responding to the above preparations, penicillamine may be prescribed. Although this agent may be effective in the management of RA, toxic reactions are common and can be severe, including bone marrow suppression, proteinuria and nephrosis.

IMMUNOSUPPRESSIVE THERAPY Immunosuppressive or cytotoxic drugs are increasingly employed in the management of RA. Indeed, many now consider methotrexate the treatment of choice for people with aggressive RA. Methotrexate may be used along with NSAIDs in the initial treatment plan. A weekly dose can produce a beneficial effect in as few as 2 to 4 weeks. Gastric irritation and stomatitis are the most frequent side effects associated with methotrexate, but side effects may be better controlled if folic acid is taken at the same time. Alcoholism, diabetes, obesity, advanced age and renal disease increase the risk of toxic effects (hepatotoxicity, bone marrow suppression, interstitial pneumonitis).

Other immunosuppressive agents such as cyclosporin, azathioprine and monoclonal antibodies have also been employed in the treatment of people with severe, progressive, crippling disease who have failed to respond to other measures.

Treatments

The primary objectives in treating RA are to reduce pain and inflammation, preserve function and prevent deformity.

REST AND EXERCISE A balanced program of rest and exercise is an important component in the management of people with RA. During an acute exacerbation of the disease, the person may be hospitalised or a short period of complete bed rest may be prescribed. For most people, regular rest periods during the day are beneficial to reduce manifestations of the disease. Additionally, splinting of inflamed joints reduces unwanted motion and provides local joint rest. A variety of orthotic devices are available to reduce joint strain and help maintain function.

Rest must be balanced with a program of physical therapy and exercise to maintain muscle strength and joint mobility. ROM exercises are prescribed to maintain joint function and prevent contractures. Isometric exercises are used to improve muscle strength without increasing joint stress. Isotonic exercises also help improve muscle strength and preserve function. Low-impact aerobic exercises, such as swimming and walking, have been shown to benefit people with RA without adversely affecting joint inflammation or prompting acute episodes.

PHYSICAL AND OCCUPATIONAL THERAPY Physical and occupational therapists can design and monitor individualised activity and rest programs.

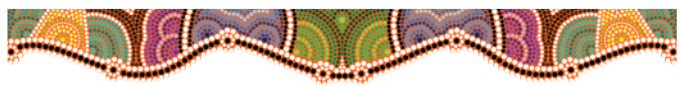
HEAT AND COLD Heat and cold are used for their analgesic and muscle-relaxing effects. Moist heat is generally the most effective and can be provided by a tub bath. Joint pain is relieved in some people through the application of cold.

ASSISTIVE DEVICES AND SPLINTS Assistive devices, such as a cane, walker or raised toilet seat, are most useful for people with significant hip or knee arthritis. Splints provide joint rest and prevent contractures. Night splints for the hands and/or wrists should maintain the extremity in a position of maximum function. The best 'splint' for the hip is lying prone for several hours a day on a firm bed. In general, splints should be applied for the shortest period needed, should be made of lightweight materials and should be easily removed to perform ROM exercises once or twice a day.

NUTRITION For most people with RA, an ordinary, well-balanced diet is recommended. Some people may benefit from substitution of usual dietary fat with omega-3 fatty acids found in certain fish oils.

SURGERY Surgical intervention may be employed for the person with RA at a variety of disease stages. Early in the course of the disease, synovectomy (excision of synovial membrane) can provide temporary relief of inflammation, relieve pain and slow the destructive process, helping to preserve joint function. Arthrodesis (joint fusion) may be used to stabilise joints such as cervical vertebrae, wrists and ankles. Arthroplasty, or total joint replacement, may be necessary in cases of gross deformity and joint destruction. Total joint replacement and nursing care of people undergoing this surgery are discussed in the preceding section on OA.

OTHER THERAPIES Several newer treatments that are not yet in widespread use may be employed in people with progressive RA. Plasmapheresis has been used to remove circulating antibodies, moderating the autoimmune response. Total lymphoid irradiation decreases total lymphocyte levels, although serious adverse effects are associated with this treatment and its continued efficacy has not been established.



Nursing care

People with chronic, progressive, systemic disorders such as RA have multiple nursing care needs involving many functional health patterns. Physical manifestations of the disease often result in acute and chronic pain, fatigue, impaired mobility and difficulty performing routine tasks. The disease also has many psychosocial effects. The person has an incurable chronic disease that may lead to severe crippling. Pain and fatigue can interfere with the person's ability to perform expected roles, such as home maintenance or job responsibilities. Even though the person's hands may appear swollen or deformed, other people may not understand the systemic nature of the disease or appreciate the difference between RA and OA. A nursing care plan for a person with RA is found below.

Health promotion

People with RA have control of their lives by becoming arthritis self-managers. They can help prevent deformities and the effects of arthritis by following prescriptions for exercise, rest, weight management, posture and positioning. The following suggestions are recommended:

- Respect pain as a warning signal. When pain is experienced, change the method of doing things, use equipment or tools if necessary and take intermittent rest periods. Prolonged rest may lead to decreased range of motion.
- A structured exercise program greatly improves the wellbeing of RA sufferers. Stretching, strengthening and aerobic conditioning are all important in the rehabilitation of RA.
- Superficial heat has great effect on hands and feet due to less subcutaneous tissues in these areas. Heat packs and hydrotherapy are excellent for prevention of pain.
- Use adaptive equipment to assist with functional independence (Johns Hopkins Arthritis Center, 2016).

Assessment

Collect the following data through the health history and physical examination (see Chapter 37):

- *Health history:* pain, stiffness, fatigue, joint problems: location, duration, onset, effect on function, fever, sleep patterns, past illnesses or surgery, ability to carry out ADLs and self-care activities.

- *Physical assessment:* height/weight; gait; joints: symmetry, size, shape, colour, appearance, temperature, range of motion, pain; skin: nodules, purpura; respiratory: cough, crackles; cardiovascular: pericardial friction rub, apical bradycardia, S_3.

Nursing diagnoses and interventions

Many nursing diagnoses may be appropriate for the person with RA. This section focuses on those related to its predominant manifestations and their effect on the person's life.

Chronic pain

Pain is a constant feature of RA when the disease is active. Pain accompanies both acute inflammation and lower levels of chronic inflammation. Some people say the pain in joints and surrounding tissue is like a deep, constant toothache. Pain can significantly affect the person's ability to provide self-care and maintain daily activities. It also contributes to the person's fatigue.

- Monitor the level of pain and duration of morning stiffness. *Pain and morning stiffness are indicators of disease activity. Increased pain may necessitate changes in the therapeutic treatment plan.*
- Encourage the person to relate pain to activity level and adjust activities accordingly. Teach the importance of joint and whole-body rest in relieving pain. *Pain is an indicator of excess stress on inflamed joints. Increasing pain indicates a need to decrease activity levels.*
- Teach the use of heat and cold applications to provide pain relief. The person may apply heat by showering or taking tub baths or using warm compresses or other local applications such as paraffin dips. *For people who find that heat increases pain and swelling during periods of acute inflammation, cold packs may be more effective. Both heat and cold have analgesic effects and can help relieve associated muscle spasms.*
- Teach about the use of prescribed anti-inflammatory medications and the relationship of pain and inflammation. *Anti-inflammatory agents reduce chemical mediators of inflammation and swelling, relieving pain.*
- Encourage using other non-pharmacological pain relief measures such as visualisation, distraction, meditation and progressive relaxation techniques. *These techniques can reduce muscle tension and help the person focus away from the pain, decreasing the intensity of the pain experience.*

Fatigue

The pain and chronic inflammatory processes associated with RA lead to fatigue. Other factors contribute as well. Discomfort often disrupts the person's sleep patterns. Anaemia, muscle atrophy and poor nutrition also play a role in the development of fatigue. The person with RA may experience depression or hopelessness, with associated manifestations of fatigue.

- Encourage a balance of periods of activity with periods of rest. *Both joint and whole-body rest are important to reduce the inflammatory response.*
- Stress the importance of planned rest periods during the day. *Rest is vital during acute exacerbations of the disease but also important to maintain the person in remission.*
- Help in prioritising activities, performing the most important ones early in the day. *Assigning priorities helps the person avoid performing relatively unimportant activities at the expense of more meaningful and important ones.*
- Encourage regular physical activity in addition to prescribed ROM exercises. *Aerobic exercise promotes a sense of wellbeing and restful sleep patterns.*
- Refer to counselling or support groups. *Counselling and support groups can help the person develop effective coping strategies and deal with depression and hopelessness.*

NURSING CARE PLAN A person with rheumatoid arthritis

Joanne James is a 42-year-old high school science teacher who began noticing vague joint pain, fatigue, poor appetite and general malaise, which she initially attributed to a case of the flu. However, her symptoms continued and she reports feeling very stiff in the mornings, often taking until 10 or 11 am to begin to feel 'normal'. She then began to notice aching in her hands and wrists, which she attributed to the quilting she loves to do in the evenings. She made an appointment with her family GP when she noticed that her knuckles and finger joints were not just achy but also swollen and hot. Noting that Mrs James has lost 5 kg since her last visit and has mild anaemia and a significantly elevated ESR, the GP referred her to the rheumatology clinic for further evaluation. Following examination, laboratory and radiological testing, the rheumatologist established a diagnosis of rheumatoid arthritis and initiated a multidisciplinary team conference to plan the management of Mrs James's condition.

ASSESSMENT

Cathy Greenstein, RN, completes an assessment of Mrs James. She notes that Mrs James is well groomed and answers questions readily but appears fatigued and ill. Mrs James relates that her job has been extremely stressful because teacher layoffs have resulted in larger class sizes and fewer teaching assistants. Despite her symptoms, she continues to teach full time, but says she feels unable to keep up with all her responsibilities due to her fatigue.

Mrs James states that she is allergic to penicillin. Her past medical history reveals only the usual childhood diseases and three uncomplicated pregnancies, resulting in the births of her children, aged 14, 11 and 9. Physical assessment findings include BP 124/78, P 82 regular, R 18, T 37.8°C PO. Hands: swelling of the proximal interphalangeal (PIP) and metacarpophalangeal (MCP) joints of both hands; second and third PIP and second MCP joints on right hand are red, shiny, hot, spongy and tender to palpation; able to extend fingers to

(continued)

NURSING CARE PLAN A person with rheumatoid arthritis (continued)

180 degrees but cannot make a complete fist with either hand, with flexion limited to less than 90 degrees; grip strength is weak bilaterally; wrist ROM is limited in all directions. Knees are swollen and flexion is slightly limited; positive bulge sign in the right knee. Diagnostic findings are an ESR of 52 mm/h, a haematocrit of 30% and positive for rheumatoid factor. Few changes other than soft tissue swelling are evident on hand and wrist x-rays.

DIAGNOSES

- *Chronic pain* related to joint inflammation.
- *Impaired home maintenance* related to fatigue.
- *Activity intolerance* related to the effects of inflammation.
- *Deficient knowledge of therapeutic regimen*.

PLANNING

Manage Mrs James's pain and educate her in relation to how to manage her condition and continue to undertake her usual activities.

Expected outcomes

- Verbalise effective pain management strategies:
  - Verbalise a plan to reduce responsibilities for home maintenance.
  - Express a willingness to plan rest breaks during the day.
- Demonstrate understanding of the prescribed therapeutic regimen and its importance for both short- and long-term benefit.

IMPLEMENTATION

- Use assistive devices to minimise joint stress with ADLs.
- Teach techniques for relieving pain and morning stiffness, including:
  - Schedule NSAIDs at equal intervals throughout the day.
  - Take morning NSAID dose with milk and crackers approximately 30 minutes before rising.
  - Perform ROM exercises in shower or bathtub.
  - Apply local heat with paraffin dip or compress, use cold packs as needed.
  - Teach techniques to minimise joint stress while performing ADLs.
  - Discuss ways to delegate household tasks to other family members.
  - Explore ways to incorporate 30-minute rest breaks into work schedule.
  - Provide arthritis literature and information.
  - Provide information about the disease process and its manifestations, prescribed medications with desired and adverse effects, and the importance of balancing rest and activity.

EVALUATION

The initial treatment regimen of aspirin, rest, exercise and physical therapy succeeded in partially relieving the acute manifestations of rheumatoid arthritis in Mrs James. However, complete remission has not been achieved. She has had difficulty scheduling rest periods at work and has had to struggle to delegate household tasks. 'I don't look sick to the kids and they seem to think housecleaning is a terrible imposition on their time. It's often easier to just do it myself than to fight about it. Besides, that way it gets done right.' Mrs James has faithfully followed the prescribed medication regimen and exercise routines and she has kept her scheduled appointments and maintained contact with the treatment team.

CRITICAL THINKING IN THE NURSING PROCESS

1. Mrs James is 42 years old. Would your nursing interventions differ if she were 72 years old? If so, how?
2. Rheumatoid arthritis is a chronic illness. What are the physical, emotional and economic implications of a chronic illness that results in chronic pain and deformity?
3. Develop a nursing care plan for Mrs James using the nursing diagnosis of *Ineffective role performance*.

REFLECTION ON THE NURSING PROCESS

1. Identify issues from this case study that would enable you to care for people with rheumatoid arthritis in your future practice.
2. For a person newly diagnosed with rheumatoid arthritis, which education strategies would be appropriate when caring for this person?

Ineffective role performance

Fatigue, pain and the crippling effects of RA can interfere with the person's ability to pursue a career and fill other life roles, such as parent, spouse or homemaker. As the person's role changes, so must the roles of other family members. This can contribute to changes in family processes, increased stress in the family and further difficulty coping with the effects of the disease.

- Discuss the effects of the disease on the person's career and other life roles. Encourage the person to identify changes brought on by the disease. *Discussion helps the person to accept the changes and begin to identify strategies for coping with them.*
- Encourage the person and family to discuss their feelings about role changes and grieve lost roles or abilities. *Verbalisation allows family members to validate and accept feelings about losses and changes, thus helping them to move into new roles.*
- Listen actively to concerns expressed by the person and family members; acknowledge the validity of concerns about the disease, prescribed treatment and the prognosis. *Demonstrating acceptance of these feelings and concerns promotes trust and validates their reality.*

CONSIDERATION FOR PRACTICE

Remember that grief resolution takes time and that people may respond to loss with anger.

- Help the person and family identify strengths they can use to cope with role changes. *Identifying strengths helps the*

person and family to consider role changes that maintain self-esteem and dignity.

- Encourage the person to make decisions and assume personal responsibility for disease management. *People who assume a personal and active role in managing their disease maintain a greater sense of self-control and self-esteem.*

Disturbed body image

The acute and long-term effects of RA can affect the person's body image, leading to feelings of hopelessness and powerlessness, social withdrawal and difficulty adapting to changes. When inflammation and joint deformity occur despite compliance, the person may have difficulty accepting the need to continue therapeutic measures, particularly those that have side effects or are costly or time consuming. In addition, unproven alternative treatment strategies and quackery may become increasingly attractive to the person.

- Demonstrate a caring, accepting attitude towards the person. *This attitude helps the person accept the physical changes brought on by the disease.*
- Encourage the person to talk about the effects of the disease—both physical effects and effects on life roles. *Verbalisation helps the person identify feelings and gives the nurse an opportunity to validate these feelings.*
- Encourage the person to maintain self-care and usual roles to the extent possible. *Discuss the use of clothing and adaptive devices that promote independence. Independence enhances the person's self-esteem.*
- Provide positive feedback for self-care activities and adaptive strategies. *Positive reinforcement encourages the person to continue adaptive measures and maintain independence.*
- Refer to self-help groups, support groups and other agencies that provide assistive devices and literature. *These groups and agencies can help the person develop adaptive strategies to cope with the effects of RA, enhancing the person's self-concept, body image and independence.*

Community-based care

RA is typically a chronic, progressive disease. As with most diseases of this nature, involvement of the person and family in its management is vital. Education is an important nursing role in caring for people with RA and their families. Address the following topics for home care of the person and for family members:

- disease process and treatments, including rest and exercise
- medications
- management of stiffness and pain
- energy conservation
- use of assistive devices to maintain independence, including self-care aids such as handheld showers, long-handled brushes and shoehorns, and eating utensils with oversized or special handles
- clothing options such as elastic waist pants without zippers, Velcro closures, zippers with large pull-tabs and slip-on shoes
- how to apply splints and take care of skin
- home and equipment modifications, such as a raised toilet seat, grab bars in the bathroom, a bath chair or adapted counter heights for people in a wheelchair
- physical therapy, occupational therapy, community services and home care services
- helpful resources:

THE PERSON WITH ANKYLOSING SPONDYLITIS

Ankylosing spondylitis (AS) is a chronic inflammatory arthritis that primarily affects the axial skeleton, leading to pain and progressive stiffening and fusion of the spine. The typical age of onset is between 15 and 45. The incidence is greater in men than women and men have more severe disease. AS is difficult to diagnose in the early stages, but may be a major cause of persistent back pain in young adults.

The cause of ankylosing spondylitis is unknown. As with the other spondyloarthropathies, there is a strong genetic component. Approximately 90% of people with AS have the HLA-B27 antigen; about 8% of the general population have this antigen (Porth & Matfin, 2014).

Pathophysiology

Early inflammatory changes are often first noted in the sacroiliac joints. As the cartilage erodes, joint margins ossify and are replaced by scar tissue. The joints of the spine are also affected, with inflammation of the cartilaginous joints and gradual calcification and ossification that leads to ankylosis or joint consolidation and immobility. Other organ systems may be affected as well, including the eyes, lungs, heart and kidneys.

Manifestations

The onset of ankylosing spondylitis is usually gradual and insidious. People may have persistent or intermittent bouts of lower back pain. The pain is worse at night, followed by morning stiffness that is relieved by activity. Pain may radiate to the buttocks, hips or down the legs. As the disease progresses, back motion becomes limited, the lumbar curve is lost and the thoracic curvature is accentuated. In severe cases, the entire spine becomes fused, preventing any motion. People with AS may also experience peripheral arthritis, primarily affecting the hip, shoulders and knee joints. Systemic manifestations include anorexia, weight loss, fever and fatigue. Many people develop uveitis (inflammation of the iris and the middle, vascular layer of the eye).

For most people with AS, the disease is intermittent with mild to moderate acute episodes. These people have a good prognosis with little risk of severe disability.

INTERPROFESSIONAL CARE

Diagnostic testing shows an elevated ESR during periods of active disease and typically a positive HLA-B27 antigen. The diagnosis of ankylosing spondylitis is usually confirmed with x-ray examination of the sacroiliac joints and spine. The sacroiliac joint becomes blurred and gradually obliterated. As the disease progresses, vertebrae become squared and disc spaces narrow.

As with other forms of arthritis, the management of AS is multidimensional. Physiotherapy and daily exercises are important to maintain posture and joint ROM. NSAIDs relieve pain and stiffness and allow the person to perform necessary exercises. Indomethacin (Indocin) is the NSAID most commonly used to treat AS. It may, however, have many adverse effects, including headache, nausea and vomiting, depression and psychosis. Other drugs that may be prescribed include sulfasalazine (Azulfidine) and topical or intra-articular corticosteroids. Severe hip joint arthritis may necessitate total hip arthroplasty.

Nursing care

The primary nursing role in ankylosing spondylitis is to provide supportive care and education. To promote mobility, teach the person to take NSAIDs at regular intervals throughout the day with food, milk or antacid. Encourage the person to maintain a fluid intake of 2500 mL or more per day. Suggest that the person perform exercises in the shower because warm, moist heat prompts mobility. Stress the importance of following the prescribed physical therapy and exercise program to maintain mobility.

Teach the person that proper positioning and posture are important. When sleeping, a bed board may be used to provide firmness and the person should sleep in the supine position using either no pillow or only one small pillow. Other important self-care activities include losing weight if applicable, avoiding smoking and using muscle-strengthening exercises. Suggest occupational counselling if pain and deformity are severe enough to cause work-related problems.

THE PERSON WITH REACTIVE ARTHRITIS

Reactive arthritis (ReA) (*Reiter's syndrome*) is an acute, non-purulent inflammatory arthritis that is believed to be a response to an exposure or infection with certain types of bacteria, including *Chlamydia* (a bacterium contracted during sexual activity) or *Salmonella*, *Shigella*, *Yersinia* or *Campylobacter* (which cause dysentery from contaminated or spoiled food). This type of arthritis most often affects young men who have an inherited HLA-B27 antigen. Reactive arthritis is often found in people with HIV infection, although the reason for the association is not clear. Reactive arthritis is typically self-limited, although it can be recurrent or progressive. About 15–20% of people with ReA develop a chronic arthritis or spondylitis (Spondylitis Association of America, 2009).

Manifestations

Non-bacterial urethritis is often the initial manifestation of Reiter's syndrome. In women, urethritis and cervicitis may be asymptomatic. Conjunctivitis and inflammatory arthritis follow. The arthritis is usually asymmetric, affecting large weight-bearing joints such as the knees and ankles, the sacroiliac joints or the spine. Mouth ulcers, inflammation of the glans penis and skin lesions may occur. The heart and aorta may also be affected.

INTERPROFESSIONAL CARE

The diagnosis of reactive arthritis is based on the person's history and presenting symptoms. Manifestations of ReA typically occur 2 to 4 weeks after the infection and subside in 3 to 12 months. The condition has a tendency to recur. No test is specific for the disorder. Urethral or cervical cultures are obtained to rule out gonococcal infection. When *Chlamydia* is suspected, the person and sexual partner are treated with tetracycline or erythromycin. Reactive arthritis is treated symptomatically, usually with NSAIDs.

Nursing care

People with reactive arthritis usually are seen in primary care settings such as a clinic or GP's office, making the nursing role primarily one of education. Teach the person about the association of the arthritis with the precipitating infection (if identified). Stress the importance of treating the infection effectively if it is still present. Use this opportunity to provide information about sexually transmitted infections and protective measures to prevent their transmission (see Chapter 49). Discuss the usual self-limiting nature of ReA, the appropriate use of prescribed NSAID preparations and symptomatic relief measures such as application of heat and rest.

THE PERSON WITH SYSTEMIC LUPUS ERYTHEMATOSUS

Systemic lupus erythematosus (SLE) is a chronic inflammatory connective tissue disease. It affects almost all body systems, including the musculoskeletal system. The manifestations of SLE are widely variable and are thought to result from cell and tissue damage caused by deposition of antigen–antibody complexes in connective tissues. SLE affects multiple body systems and can range from a mild, episodic disorder to a rapidly fatal disease process.

Although the exact aetiology of SLE is unknown, genetic, environmental and hormonal factors play a role in its development. Twin studies and a familial pattern of the disease point to a genetic component, as does an increased incidence of other connective tissue diseases in relatives of people with SLE. Certain human leucocyte antigen (HLA) genes are seen more frequently in people with SLE. Environmental factors such as viruses, bacterial antigens, chemicals, drugs or ultraviolet light may play a role in activation of the pathological mechanisms of the disease. In addition, it is felt that sex hormones may influence the development of SLE. Women with SLE have reduced levels of several active androgens that are known to inhibit antibody responses. Oestrogens have been shown to enhance antibody responses and have an adverse effect in people with SLE.

The course of SLE is mild in most people, with periods of remission and exacerbation. The number and severity of exacerbations tend to decrease with time. In some people, however, SLE is a virulent disease with significant organ system involvement.

People with active disease have an increased risk of infections, which are often opportunistic and severe. Infections such as pneumonia and septicaemia are the leading cause of death in people with SLE, followed by the effects of renal or central nervous system (CNS) involvement. See the multisystem effects of SLE overleaf.

Pathophysiology

The pathophysiology of SLE involves the production of a large variety of autoantibodies against normal body components such as nucleic acids, erythrocytes, coagulation proteins, lymphocytes and platelets. Autoantibody production results from hyper-reactivity of B cells (humoral response) because of disordered T-cell function (cellular immune response). The most characteristic autoantibodies in SLE are produced in response to nucleic acids, including DNA, histones, ribonucleoproteins and other components of the cell nucleus.

SLE autoantibodies react with their corresponding antigen to form immune complexes, which are then deposited in the connective tissue of blood vessels, lymphatic vessels and other tissues. The deposits trigger an inflammatory response leading to local tissue damage. The kidneys are a frequent site of complex deposition and damage; other tissues affected include the musculoskeletal system, brain, heart, spleen, lung, GI tract, skin and peritoneum. The autoantibodies produced and their target tissue determine the manifestations of SLE.

A number of drugs can cause a syndrome that mimics lupus in people with no other risk factors for the disease. Procainamide (e.g. Procan-SR, Pronestyl) and hydralazine (Apresoline, Hydralyn) are the most common drugs implicated, along with isoniazid (INH).

Renal and CNS manifestations of SLE rarely occur with drug-induced lupus, but arthritic and other systemic symptoms are common. Manifestations of drug-induced lupus usually resolve when the medication is discontinued.

FAST FACTS

- Approximately 1 person in 3500 is affected by SLE in Australia and New Zealand, with women predominating by a ratio of 9:1 over men.
- SLE usually affects women of childbearing age (when the incidence is 30 times greater than in men) but it can occur at any age.
- SLE is more common in Polynesians in New Zealand (3.5 times greater than Europeans), with similar numbers in Indigenous Australians (Porth & Matfin, 2014).
- The incidence of SLE is higher in some families.

Manifestations

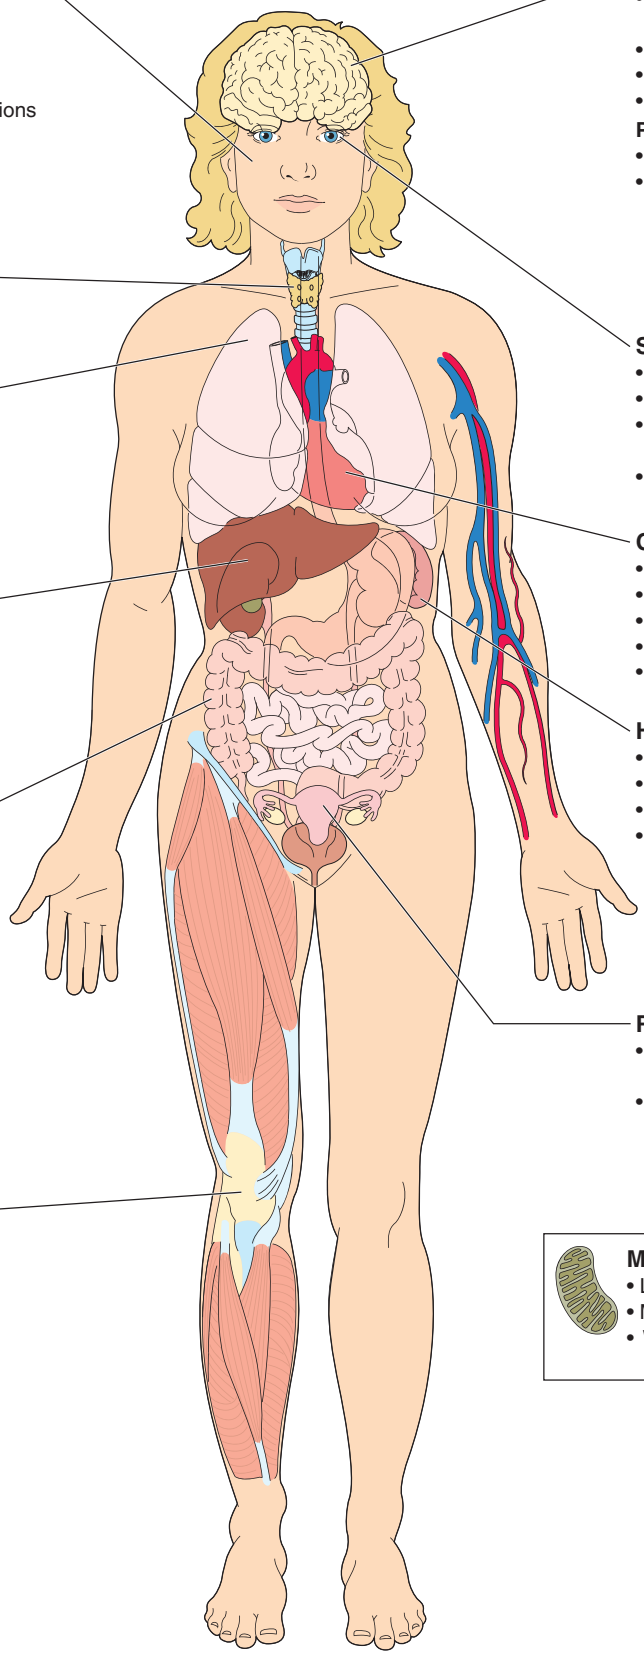
Typical early manifestations of SLE mimic those of rheumatoid arthritis, including systemic manifestations of fever, anorexia, malaise and weight loss, and musculoskeletal manifestations of multiple arthralgias and symmetric polyarthritis. Joint symptoms affect more than 90% of people with SLE. Although synovitis may be present, the arthritis associated with SLE is rarely deforming.

Most people affected by SLE have skin manifestations at some point during their disease. In fact, SLE was originally described as a skin disorder and named for the characteristic red butterfly rash across the cheeks and bridge of the nose (see Figure 39.7). Many people with SLE are photosensitive; a diffuse maculopapular rash on skin exposed to the sun is common. Other cutaneous manifestations include discoid lesions (raised, scaly, circular lesions with an erythematous rim), hives, erythematous fingertip lesions and splinter haemorrhages. Alopecia is common in people with SLE, although the hair usually grows back. Painless mucous membrane ulcerations may occur on the lips or in the mouth or nose. Common manifestations of SLE are listed in the box below.

Approximately 50% of people with SLE experience renal manifestations of the disease, including proteinuria, cellular casts and nephrotic syndrome. Up to 10% develop renal failure as a result of the disease.

Haematological abnormalities such as anaemia, leucopenia and thrombocytopenia are common with SLE. Cardiovascular disorders such as pericarditis, vasculitis and Raynaud's phenomenon often occur. Less frequently, myocarditis, endocarditis and venous or arterial thrombosis may develop.

MULTISYSTEM EFFECTS OF SYSTEMIC LUPUS ERYTHEMATOSUS



Integumentary
- Butterfly rash on face
- Photosensitivity
- Maculopapular rash on exposed body surfaces
- Discoid lesions
- Erythematous fingertip lesions
- Splinter haemorrhages
- Alopecia
- Ulcers (lip, mouth, nose)

Endocrine
- Thyroid abnormalities
- Hyperparathyroidism
- Glucose intolerance

Respiratory
- Pleurisy
- Pleural effusion
- Pneumonitis
- Interstitial fibrosis

Urinary
- Proteinuria
- Cellular casts

Potential complications
- Nephrotic syndrome
- Kidney failure

Gastrointestinal
- Anorexia
- Nausea
- Abdominal pain
- Diarrhoea
- Hepatomegaly

Musculoskeletal
- Arthralgias
- Symmetric polyarthritis
- Joint swelling and effusion
- Morning stiffness

Neurological
- Neuropathies (peripheral and central)
- Seizures
- Depression
- Psychosis

Potential complications
- Stroke
- Organic brain syndrome
  - Intellectual impairment
  - Memory loss
  - Personality changes
  - Disorientation

Sensory
- Conjunctivitis
- Photophobia
- Retinal vasculitis with transient blindness
- Cotton-wool spots on retina

Cardiovascular
- Pericarditis
- Myocarditis
- Endocarditis
- Vasculitis
- Venous or arterial thrombosis

Haematological
- Anaemia
- Leukopaenia
- Thrombocytopaenia
- Splenomegaly

Reproductive
- Pregnancy-induced hypertension, oedema and proteinuria
- Foetal loss

Metabolic processes
- Low-grade fever
- Malaise
- Weight loss

FIGURE 39.7 ■ The butterfly rash of systemic lupus erythematosus

Source: Wellcome Trust/Custom Medical Stock Photo.

Pleurisy, pleural effusions and lupus pneumonitis are common pulmonary manifestations of SLE.

Many people with SLE develop transient nervous system involvement, often within the first year of the disease. Organic brain syndrome manifestations include decline in intellect, memory loss and disorientation. Other possible neurological manifestations include psychosis, seizures, depression and stroke. Ocular manifestations of SLE include conjunctivitis, photophobia and transient blindness due to retinal vasculitis.

Gastrointestinal manifestations of SLE, such as anorexia, nausea, abdominal pain and diarrhoea, may affect up to 45% of people with the disease. The liver may be enlarged and liver function tests may yield abnormal results.

MANIFESTATIONS SLE

- Painful or swollen joints and muscle pain
- Unexplained fever
- Red rash, especially on the face
- Unusual loss of hair
- Pale, cyanotic fingers or toes
- Sensitivity to the sun
- Oedema in legs and around eyes
- Ulcers in the mouth
- Enlarged glands
- Extreme fatigue

INTERPROFESSIONAL CARE

Because of the diversity of organ system involvement and manifestations of SLE, diagnosis can be difficult. No one specific test is available to confirm the presence of this disease in all people suspected of having it. Instead, the diagnosis is based on the person's history and physical assessment, as well as laboratory studies.

As with rheumatoid arthritis, effective management of SLE requires teamwork, with active participation by both the person and members of the healthcare team. Although there is no cure for SLE, the 10-year survival rate is greater than 70% for people with this disease, which was once considered fatal in most cases.

Diagnosis

The multiple autoantibodies produced in SLE cause a number of abnormalities in laboratory tests. Diagnostic tests for the musculoskeletal system are described in Chapter 37.

- *Anti-DNA antibody testing* is a more specific indicator of SLE, because these antibodies are rarely found in any other disorder.
- *ESR* is typically elevated, occasionally to > 100 mm/h.
- *Serum complement levels* are usually decreased as complement is consumed or 'used up' by the development of antigen–antibody complexes.
- *FBC* abnormalities include moderate to severe anaemia, leucopenia and lymphocytopenia, and possible thrombocytopenia.
- *Urinalysis* (*UA*) shows mild proteinuria, haematuria and blood cell casts during exacerbations of the disease when the kidneys are involved. Renal function tests including *serum creatinine* and *blood urea nitrogen (BUN)* may also be ordered to evaluate the extent of kidney disease.
- *Kidney biopsy* may be performed to assess the severity of renal lesions and guide therapy (see Chapter 25).

Medications

The person with mild or remittent SLE may need little or no therapy other than supportive care. Arthralgias, arthritis, fever and fatigue can often be managed with aspirin or other NSAIDs. Aspirin is particularly beneficial for people with SLE because its antiplatelet effects help prevent thrombosis. It may, however, cause liver toxicity and hepatitis.

Skin and arthritic manifestations of SLE may be treated with antimalarial drugs such as hydroxychloroquine (Plaquenil). Hydroxychloroquine has also been shown to be effective in reducing the frequency of acute episodes of SLE in people with mild or inactive disease. Retinal toxicity and possibly irreversible blindness are the primary concerns with this drug. For this reason, the person taking hydroxychloroquine undergoes ophthalmological exam every 6 months.

People with severe and life-threatening manifestations of SLE (such as nephritis, haemolytic anaemia, myocarditis, pericarditis or CNS lupus) require corticosteroid therapy in high doses. Such people may require 40 to 60 mg of prednisone per day initially. The dosage is tapered as rapidly as the person's

MEDICATION ADMINISTRATION Immunosuppressive agents for SLE

CYTOTOXIC AGENTS

Azathioprine (Imuran)
Cyclophosphamide (Cytoxan)
Cyclosporin (Sandimmune)

Certain cytotoxic or antineoplastic drugs are effective as immunosuppressive agents. They act by decreasing the proliferation of cells within the immune system and are widely used to prevent rejection following a tissue or organ transplant. They are usually administered concurrently with corticosteroid therapy, allowing lower doses of both preparations and resulting in fewer side effects.

Nursing responsibilities

- Monitor blood count, with particular attention to the WBC and platelet counts. Notify the healthcare provider if WBCs fall below 4000 or platelets below 75 000.
- Monitor kidney and liver function studies, including BUN, creatinine, creatinine clearance and liver enzyme levels. Report any abnormal levels to the healthcare provider.
- Oral preparations should be administered with food to minimise gastrointestinal effects. Antacids may be ordered.
- Increase fluids to maintain good hydration and urinary output.
- Monitor intake and output.
- Monitor for signs of abnormal bleeding: bleeding gums, bruising, petechiae, joint pain, haematuria and black or tarry stools.
- Use meticulous handwashing and other appropriate measures to protect the person from infection. Assess for signs of infection.
- Pulmonary fibrosis is a potential adverse effect of cyclophosphamide. Therefore, monitor the results of pulmonary function studies and be alert to clinical signs of dyspnoea or cough.

Health education for the person and family

- Avoid large crowds and situations where you might be exposed to infections.
- Report signs of infection such as chills, fever, sore throat, fatigue or malaise to the healthcare provider.
- Use contraceptive measures to prevent pregnancy while you are taking these drugs because they cause birth defects.
- Avoid the use of aspirin or ibuprofen while taking these drugs. Report any signs of bleeding to the healthcare provider.
- You may stop menstruating while you are taking cyclophosphamide. The menses will resume after the drug is discontinued.
- If you are taking cyclophosphamide, be sure to report difficulty breathing or cough to the healthcare provider.

disease allows, although lowering the dosage may precipitate an acute episode. Some people with SLE require long-term corticosteroid therapy to manage symptoms and prevent major organ damage. These people are at increased risk of corticosteroid side effects, such as cushingoid effects, weight gain, hypertension, infection, accelerated osteoporosis and hypokalaemia.

Immunosuppressive agents such as cyclophosphamide or azathioprine may be used, alone or in combination with corticosteroids, to treat people with active SLE or lupus nephritis (see the 'Medication administration' box above). When these agents are used in combination, lower, less toxic doses of each drug can be used. The person receiving immunosuppressive agents is at increased risk of infection, malignancy, bone marrow depression and toxic effects specific to the drug prescribed.

Treatments

Because of the photosensitivity associated with SLE, the person should be cautioned to avoid sun exposure. People should use sunscreens with a sun protection factor (SPF) rating of 15 or higher when outdoors. Topical corticosteroids may be used to treat skin lesions. Some healthcare providers recommend avoiding the use of oral contraceptives, because oestrogen can trigger an acute episode.

People with lupus nephritis who progress to develop end-stage kidney disease are treated with dialysis (haemodialysis or peritoneal dialysis) and kidney transplantation.

Nursing care

Nursing care for the person with mild SLE may be limited to teaching. The person with severe disease, however, has many diverse nursing needs, which vary according to the organ systems involved. Because of the close link between rheumatoid arthritis and SLE, many of the nursing diagnoses and interventions identified for the person with arthritis may be appropriate for the person with lupus. The person with lupus nephritis or end-stage kidney disease has the nursing care needs related to glomerulonephritis and chronic kidney failure. This section focuses on the needs of the person related to the dermatological manifestations of lupus, an increased risk of infection and health maintenance.

Nursing diagnoses and interventions

The priority nursing interventions for the person with SLE are focused on problems with impaired skin integrity, ineffective protection and impaired health maintenance.

Impaired skin integrity

Skin lesions are a common manifestation of SLE. A rash or discoid lesion interrupts the integrity of the skin and the first line of protection against infection, increasing the person's already high risk of infection. These lesions, which usually appear on exposed parts of the skin, can also be disfiguring and cause the person emotional distress.

- Assess knowledge of SLE and its possible effects on the skin. *Assessment allows the nurse to base teaching and information on the person's existing knowledge, improving learning and retention.*
- Discuss the relationship between sun exposure and disease activity, both dermatological and systemic. *It is important for the person to understand that sun exposure may not only cause dermatological manifestations but also trigger an acute episode.*
- Suggest the following strategies to limit sun exposure:
  - Avoid being outdoors during hours of greatest sun intensity (10 am to 3 pm).
  - Use sunscreen with an SPF of 15 or higher when sun exposure cannot be avoided. Apply it 30 minutes before going out into the sun.
  - Reapply sunscreen after swimming, exercising or bathing.
  - Wear loose clothing with long sleeves and wide-brimmed hats when outdoors.

  These strategies can help the person maintain a normal lifestyle while helping to prevent acute episodes.
- Keep skin clean and dry; apply therapeutic creams or ointments to lesions as prescribed. *These measures promote healing and reduce the risk of infection.*

Ineffective protection

Ineffective protection can be a problem for the person with SLE, who is at increased risk of infection and multiple organ system problems because of the disease. In addition, treatment with corticosteroids or immunosuppressive agents further impairs immune responses and the ability to fight infection. The following interventions are for the person who is hospitalised.

- Wash hands before and after providing direct care. *Handwashing removes transient organisms from the skin, reducing the risk of transmission to the person.*

CONSIDERATION FOR PRACTICE

Hands must be washed before and after providing direct care, even if gloves are worn. A decrease in this type of medical asepsis is contributing to the increasing number of hospital-acquired infections that are resistant to antibiotics.

- Use strict aseptic technique in caring for intravenous lines and indwelling urinary catheters or performing any wound care. *Aseptic technique offers protection against external and resident host microorganisms.*
- Assess frequently for infection. Monitor temperature and vital signs every 4 hours. Assess for signs of cellulitis, including tenderness, redness, swelling and warmth. Report signs of infection to the healthcare provider promptly. *Therapy can suppress usual responses, such as elevated temperature and inflammation. The fever of infection may be mistaken for the fever commonly associated with lupus. The person receiving immunosuppressive therapy for the disease has an even higher risk of infection.*
- Monitor laboratory values, including FBC and tests of organ function; report changes to the healthcare provider. *An elevation in the WBC count with a shift to the left (increased numbers of immature leucocytes in the blood) may be an early indication of infection. Changes in liver function studies, renal function studies, myocardial enzymes or other laboratory values may indicate organ system involvement.*
- Initiate reverse or protective isolation procedures as indicated by the person's immune status. *These procedures provide further protection from infection for the severely immunocompromised person.*
- Ensure an adequate nutrient intake, offering supplementary feedings as indicated or maintaining parenteral nutrition if necessary. *Adequate nutrition is important for healing and immune system function.*
- Teach the person the importance of good handwashing after using the bathroom and before eating. *Handwashing reduces the risk of infection with endogenous organisms.*
- Monitor for potential adverse effects of medications, including thrombocytopenia and possible bleeding, fluid retention with oedema and possible hypertension, loss of bone density, osteoporosis and possible pathological fractures, renal or hepatic toxicity, and cardiac effects, particularly in the person with fluid retention and hypervolaemia. *Medications used to treat SLE have many potential adverse effects that can impair normal protective and homeostatic mechanisms.*

Impaired health maintenance

As with other chronic diseases, much of the responsibility for maintaining optimal health rests with the person. Disease manifestations such as fatigue, arthralgias, arthritis and increased risk of infection can interfere with the person's ability to maintain health. Psychosocial issues can also be a significant factor in health maintenance for the person with lupus. These issues may include denial of the significance of the disease, poor coping, lack of financial and other resources, and an inadequate support system.

- Assess the ability to maintain optimal health, identifying physical and psychosocial factors that may affect health maintenance. *Before intervening to improve the person's health maintenance, the nurse must identify and understand factors affecting it.*
- Provide care and teaching in a non-judgmental manner. *To intervene effectively, the nurse must accept the person and family as they are.*
- Encourage the person and family members to discuss the effect of the disease on their lives. *Open discussion helps the person and the nurse identify barriers to health maintenance and begin exploring alternative strategies.*
- Initiate an interprofessional care conference with the person and family. *In this care conference, a number of perspectives can be expressed, improving the planning of strategies for health maintenance activities.*
- Refer the person and family to counselling as needed. *Counselling may help the person and family develop the necessary coping skills to accept and deal with the disease.*

- Refer the person and family to community and social service agencies and local support groups. *These groups and agencies are valuable resources for the person and family.*

Community-based care

Teaching is a critical factor in preparing people with SLE for self-care at home. Address the following topics:

- the disease and its potential effects. Promote an optimistic outlook, stressing that the majority of people do not require long-term corticosteroid therapy and that the disease may improve over time
- the importance of skin care
- the importance of avoiding exposure to infection
- the need to follow the prescribed treatment plan, including rest and exercise, medications and follow-up appointments. Discuss manifestations of an acute episode (often called a flare) and stress the importance of contacting the healthcare provider promptly if any of these manifestations occur.

CONSIDERATION FOR PRACTICE

Warning signs of a flare-up

- Increased fatigue
- Pain, abdominal discomfort
- Rash
- Headache
- Fever
- Dizziness

- The significance of wearing a MedicAlert® tag identifying the condition and therapy such as corticosteroids or immunosuppressives.
- Family planning with the person and spouse. The use of oral contraceptives may be contraindicated for the person; if appropriate, provide information about alternative means of birth control. Pregnancy is not contraindicated for most women with lupus. However, the pregnant person requires close monitoring because acute episodes sometimes accompany pregnancy.
- The need for preventive healthcare for both men and women with SLE. Women should have gynaecological and breast examinations, and men should have prostate examinations, each year. Both men and women should have regular screenings for cholesterol and blood pressure. Annual influenza vaccinations are important, as is pneumococcal vaccinations for older people. If people are taking corticosteroids or antimalarial medications, annual eye examinations should be conducted to screen for and treat any eye problems.

THE PERSON WITH POLYMYOSITIS

Polymyositis is a systemic connective tissue disorder characterised by inflammation of connective tissue and muscle fibres leading to muscle weakness and atrophy. When muscle fibre inflammation is accompanied by skin lesions, the disease is known as dermatomyositis. Polymyositis is an autoimmune disorder of unknown cause that affects more women than men. The onset of the disease typically occurs between the ages of 40 and 60 years, although a childhood-onset form is also seen.

The immune mechanism causing the inflammatory response in polymyositis is not clear, but autoantibodies can be identified in the majority of people with the disease. The activation of complement is thought to contribute to the inflammatory process. Inflammation leads to muscle fibre necrosis and degeneration.

Manifestations

Initial manifestations of polymyositis include muscle pain, tenderness and weakness; rash; arthralgias; fatigue; fever; and weight loss. Skeletal muscle weakness is the predominant manifestation. Its onset may be either insidious or abrupt. Muscle weakness tends to progress over weeks to months. Muscles of the shoulder and pelvic girdles are particularly affected, making it difficult for the person to get out of chairs, climb stairs and reach overhead. Weakness of neck flexor muscles may make it difficult to raise the head from a pillow. Affected muscles may also be tender and painful. A characteristic dusky red rash may be present on the face and upper trunk. Other manifestations include Raynaud's phenomenon, dysphagia, dyspnoea and cough (due to interstitial pneumonitis). The risk of malignancy is increased, particularly in people with dermatomyositis.

INTERPROFESSIONAL CARE

There is no specific test to diagnose polymyositis. Autoantibodies may be identified in blood serum. Serum levels of muscle enzymes are elevated, particularly creatine kinase (CK) and aldolase levels. Biopsy of involved muscle shows patchy muscle fibre necrosis and the presence of inflammatory cells.

A combination of rest and corticosteroid therapy is prescribed for the person with polymyositis. Long-term corticosteroid therapy may be necessary to manage the disease. Immunosuppressive agents such as methotrexate, cyclophosphamide and azathioprine may be used for people who do not respond well to treatment with corticosteroids.

Nursing care

The nursing role in caring for the person with polymyositis is supportive. Measures to promote comfort are important. Muscle weakness may interfere with the person's ability to provide self-care and manage health and home. The person may have difficulty with speech because of pharyngeal muscle weakness. Provide alternate means of communication as needed and use patience in listening. Observe closely while the person eats, because aspiration is a potential problem. Modify the person's diet as needed to maintain nutrition and safety.

Educating the person and their family is an important component of care. Emphasise the need to balance periods of rest and activity. Discuss skin care to prevent dryness and infection. Teach the person about prescribed medications and their short- and long-term side effects. Provide information about safety measures while eating. Encourage family members to become trained in performance of CPR. Discuss signs of respiratory infection and other possible complications of polymyositis, including kidney failure and malignancy.

THE PERSON WITH OSTEOMYELITIS

Osteomyelitis is an infection of the bone. Osteomyelitis may occur as an acute, subacute or chronic process. It occurs as a consequence of bacteraemia (haematogenous osteomyelitis), invasion from a contiguous focus of infection or skin breakdown in the presence of vascular insufficiency (McPhee et al., 2015).

Osteomyelitis can occur at any age, but adults over age 50 are more commonly affected. The older adult is at risk of osteomyelitis for several reasons. Immune function tends to decline with ageing; the older adult also is more likely to have a chronic disease process that affects immune function. Circulatory status in older adults often is compromised by atherosclerotic processes, impairing blood flow to the bone. Older adults have a higher risk of pressure ulcers because of circulatory, skin, sensation and mobility changes associated with ageing. Pressure ulcers that cannot be staged and treated because of eschar formation pose a particular risk. In addition, the older adult may not demonstrate the typical signs of infection and inflammation, thus allowing an infectious process to become well established before it is detected.

Pathophysiology

The cause of osteomyelitis is usually bacterial; however, fungi, parasites and viruses can also cause bone infection. *Staphylococcus aureus* is the most common infecting organism. Other organisms include *Escherichia coli*, *Pseudomonas*, *Klebsiella*, *Salmonella* and *Proteus*.

Direct contamination of bone from an open wound, such as an open fracture or a gunshot or puncture wound, is the most common cause of osteomyelitis; osteomyelitis also may occur as a complication of surgery. The third mode of entry for microorganisms that invade bone tissue is the extension from adjacent soft tissue infection. People with venous stasis or arterial ulcers of the lower extremities or long-term complications of diabetes mellitus are at risk of this type of bacterial invasion.

After entry, bacteria lodge and multiply in the bone, resulting in the inflammatory and immune system response. Phagocytes attempt to contain the infection, releasing enzymes in the process that destroy bone tissue. Pus forms, followed by oedema and vascular congestion. The Haversian canals in the medullary (marrow) cavity of the bone allow the infection to travel to other segments of the bone. If the infection reaches the outer margin of the bone (see Figure 39.8), it raises the periosteum of the bone, spreading along the surface. Lifting of the periosteum from the cortex disrupts the blood vessels that enter the bone. Pressure increases, further compromising the vascular supply and leading to ischaemia and eventual necrosis of the bone. Blood and antibiotics cannot reach the bone tissue once the pressure compromises the vascular and arteriolar systems. In addition, bacteria adhere to damaged bone, coating the underlying bone with a protective film that further impedes host defences.

Haematogenous osteomyelitis

Haematogenous infections are caused by pathogens that are carried in the blood from sites of infection elsewhere in the body. Haematogenous osteomyelitis primarily affects older adults, people with sickle cell anaemia and intravenous drug users. The spine is the usual site of infection in adults. Pathogens enter the well-perfused vertebral bodies of adults via the spinal arteries. From there, the infection spreads into the disc space. The lumbar spine is involved more frequently than the thoracic or cervical spine. Urinary tract infections, soft tissue infection, endocarditis and infected intravenous sites are sources of pathogens.

People with acute haematogenous osteomyelitis experience an acute onset of pain, tenderness and fever. Soft tissue swelling over the affected bone may be noted. The course of vertebral osteomyelitis in intravenous drug users often is subacute, with vague, dull pain in the affected region and a normal or low-grade fever. The pain intensifies over 2 to 3 months and is accompanied by tenderness, muscle spasm and limited range of motion.

Osteomyelitis from a contiguous infection

Infections caused by an extension of infection from adjacent soft tissues fall into this category of osteomyelitis. The infection is a result of or a complication of direct penetrating wounds, joint replacements, decubitus ulcers and neurosurgery. This is the most common cause of osteomyelitis in adults.

The diagnosis of osteomyelitis often is not made until the infection has become chronic because the signs of acute infection may be masked by local tissue inflammation. Failure to heal a surgical wound or fracture or a developing sinus tract may be initial indicators of a bone infection.

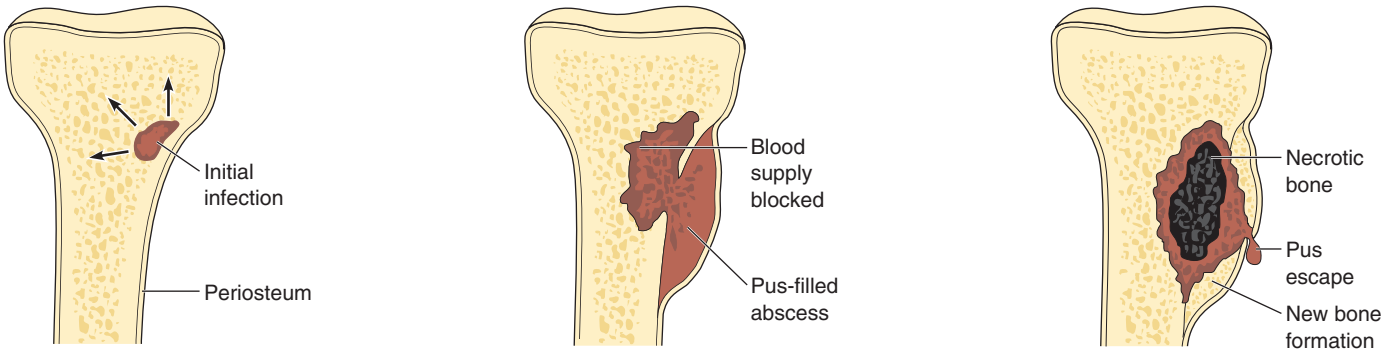

FIGURE 39.8 ■ Osteomyelitis. *A*, Site of initial infection. Bacteria enter and multiply in the bone and the inflammatory response is initiated. *B*, Acute phase, in which infection spreads to other parts of the bone. Pus forms, oedema occurs and the vascular supply is compromised. If the infection reaches the outer margin of the bone, the periosteum is lifted and ischaemia and necrosis eventually occur. *C*, Chronic phase. Necrotic bone separates, a new layer of bone forms around the necrotic bone and a sinus develops to allow the wound to drain

Osteomyelitis associated with vascular insufficiency

People with diabetes and peripheral vascular disease are at risk of developing osteomyelitis involving the feet. Diabetic neuropathy exposes the foot to trauma and pressure ulcers. The person may be unaware of the infection as it spreads into the bone. When tissue perfusion is poor, normal inflammatory responses and wound healing are impaired. The infection often is diagnosed when the person seeks treatment for a non-healing sore, swollen toe or acute cellulitis.

Manifestations

Manifestations of osteomyelitis vary according to the age of the person, the cause and site of involvement, and whether the infection is acute, subacute or chronic (see the box below).

MANIFESTATIONS Osteomyelitis

CARDIOVASCULAR EFFECTS
- Tachycardia

GASTROINTESTINAL EFFECTS
- Nausea and vomiting
- Anorexia

MUSCULOSKELETAL EFFECTS
- Limp in involved extremity
- Localised tenderness, especially in epiphyseal area

INTEGUMENTARY EFFECTS
- Drainage and ulceration at involved site
- Swelling, erythema and warmth at involved site
- Lymph node involvement, especially in the involved extremity

OTHER EFFECTS
- High temperature with chills
- Abrupt onset of pain
- Malaise

INTERPROFESSIONAL CARE

The care of the person with osteomyelitis focuses on relieving pain, eliminating the infection and preventing or minimising complications. Early diagnosis is important to prevent bone necrosis by early administration of the appropriate antibiotic. Most people require both debridement of bone and a long period of antibiotic administration.

Diagnosis

The diagnosis of osteomyelitis is based on bone scans, MRI, blood tests and biopsy. As described in Chapter 37, an MRI, CT scan and bone scan may be conducted to identify abscesses, sinus tracts and bone changes. An ultrasound can detect subperiosteal fluid collections, abscesses and periosteal thickening and elevation associated with osteomyelitis. During an acute infection, ESR and WBC are elevated. Blood and tissue cultures (from affected bone or soft tissue) are obtained to identify the infecting organism and direct antibiotic therapy.

Medications

Antibiotic therapy is mandatory to prevent acute osteomyelitis from progressing to the chronic phase. Parenteral antibiotic therapy begins as soon as cultures (blood and/or wound) are obtained. A penicillinase-resistant semisynthetic penicillin may be given until the culture and sensitivity results are known. These antibiotics are used initially because many cases of osteomyelitis are caused by *Staphylococcus aureus*. When the detailed sensitivity report is obtained from the cultures, more definitive antibiotics are prescribed.

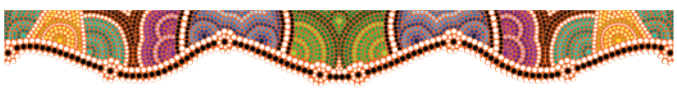
For the person with acute or chronic osteomyelitis, antibiotics are continued for 4 to 6 weeks. Intravenous antibiotic administration or oral therapy is common. Oral therapy with twice-daily ciprofloxacin has been shown to be as effective as parenteral therapy for treating adult people with chronic osteomyelitis caused by susceptible organisms

(McPhee et al., 2015). People can be treated as 'hospital in the home' with long-term IV antibiotics via PICC (peripherally inserted central venous catheter) for up to 6 months if needed.

Surgery

Surgical debridement is the primary treatment for the person with chronic osteomyelitis. The periosteum is excised and the cortex is drilled to release the pressure from accumulated pus. During this procedure, cultures may be obtained and sent to the laboratory for analysis. The wound holes are irrigated and the wound is then closed. The cavity may be kept clean by inserting drainage tubes that are connected to an irrigation and suction system. Postoperatively, the nurse is responsible for instilling and removing diluted antibiotic solutions through the drainage tubes. See the box below for related nursing care.

A musculocutaneous (myocutaneous) flap is another approach used for the treatment of the dead space caused by extensive debridement of the infected site. The procedure involves moving or rotating a muscle and the section of skin fed by the arteries from that muscle into the cavity created by the surgery. A skin graft is performed later.



Nursing care

The person with chronic osteomyelitis faces frequent and lengthy hospitalisations and/or treatment modalities. The prognosis is uncertain and functional deficits and amputation are a constant concern. The ongoing expenses, loss of financial support and role changes within the family are also concerns for the person.

Nursing diagnoses and interventions

Nursing diagnoses associated with acute osteomyelitis focus on preventing the transmission of infection and problems due to immobility. Providing comfort and person teaching are also very important.

Risk of infection

Compromised immune status places the person with osteomyelitis at risk of superinfection. An inadequate kilojoule intake is an additional factor that contributes to the risk.

- Maintain strict handwashing practices. *Meticulous handwashing helps prevent the spread of infection by minimising the entry of organisms into susceptible people.*

CONSIDERATION FOR PRACTICE

Careful handwashing before and after direct care is essential even if gloves are worn.

- Administer antimicrobial therapy at specified time intervals. *Optimal blood levels of antibiotic therapy are mandatory in people with infectious processes.*
- Maintain the person's optimal dietary kilojoule and protein intake. *High kilojoule and protein intake provides the person with sufficient nutritional support for the body's needs during the stressful event of the inflammatory process.*

Hyperthermia

The infection and associated inflammatory process can cause fever in the person with osteomyelitis.

- Monitor temperature every 4 hours and when the person reports chills and/or fever. *Blood cultures are frequently ordered when an acute elevation of temperature occurs. A sudden rise in temperature in people with either acute or chronic osteomyelitis may indicate inadequate antimicrobial management.*
- Maintain a cool environment and provide light clothing and bedding during temperature elevation. *Proper environmental conditions and clothing enhance the evaporative process during acute temperature elevation and promote comfort.*
- Ensure a daily fluid intake of 2000 to 3000 mL. *Dehydration may result from evaporative fluid losses during acute temperature elevations. Furthermore, people taking large doses of antibiotic therapy may experience fluid loss through excessive diarrhoea as a side effect of the therapy. Fluid replacement is necessary during this time to prevent further dehydration.*

Impaired physical mobility

Pain, infection, inflammation and the use of immobilisers can all impair the mobility of the person with osteomyelitis.

- Maintain the affected limb in functional position when immobilised. *The person may hesitate to move the involved extremity because of continuous pain; therefore, the extremity must be maintained in functional position to avoid flexion contracture.*
- Maintain rest and avoid subjecting the affected extremity to weight-bearing activities. *The involved extremity must be immobilised to avoid pathological fractures caused by stress on the weakened bone.*
- Ensure active or passive ROM exercises every 4 hours. *Flexion contracture occurs when the person remains immobile or when there is only minimal joint movement. Consult a physical therapist for plan of exercises to avoid contracture.*

Acute pain

The person with osteomyelitis experiences pain due to swelling.

- Use a splint or immobiliser when the person experiences acute pain from swelling. *Splinting or immobilising the involved extremity provides support and reduces pain caused by movement.*
- Ask the doctor to order scheduled administration of narcotic and non-narcotic analgesics on a 24-hour basis rather than as needed. *The use of 24-hour administration allows blood levels of pain-relieving medications to remain constant.*

NURSING CARE OF THE PERSON undergoing surgical debridement for osteomyelitis

PREOPERATIVE CARE

- Discuss the impending surgery, the person's concerns regarding surgery and its risks, and what steps will be taken if surgery is ineffective. *Open discussion and active listening are important means of gaining the person's trust and encouraging the person to express concerns about the outcome of the surgery. Surgery is frequently performed when 36 to 48 hours of antimicrobial therapy yields no improvement and when prolonged bacteraemia and evidence of an abscess formation are present. The periosteum is excised, allowing access to the purulent material in the infected area. If pus is not apparent, several holes may be drilled into the bone. In some cases, irrigation tubes are inserted and connected to an elaborate system for postoperative antimicrobial therapy.*
- People may need extensive antimicrobial treatment postoperatively if an irrigation system is surgically implanted. Before the procedure, explain to the person that bed rest and an extended period of treatment in the hospital are imperative. *People who understand the events that may occur postoperatively may be more accepting of the required restrictions.*

POSTOPERATIVE CARE

- Provide meticulous care of the dressing and/or irrigation setup. Frequently, the irrigation tubes are connected to a three-way stopcock, which allows irrigation and drainage of the debrided area without separating the tube from the collection device. *Nurses need to be extremely cautious and adhere to strict sterile technique.*
- Assess the person for manifestations of further infection. *Although the person will receive antimicrobial agents, it is important to monitor the person continually for sudden spikes in temperature, pain at the involved site and other indications of superinfection.*

HEALTH EDUCATION FOR THE PERSON AND FAMILY

- While receiving antimicrobial agents, be sure to drink adequate amounts of fluid and eat a high-kilojoule diet to minimise the risks of damage to the kidneys, yeast infection and adverse gastrointestinal effects.

CONSIDERATION FOR PRACTICE

People are often reluctant to ask for a prn pain medication, allowing the pain to reach a level that is difficult to manage.

- Use non-pharmacological strategies (e.g. heat, distraction, relaxation techniques) for pain management. *Pain of the muscles and joints may be controlled through non-pharmacological interventions. Warm moist packs, warm baths or heating pads to the involved extremity provide comfort due to vasodilation.*
- Avoid excessive manipulation of the involved area; handle the area gently. Carefully assess the person for guarding, limping or unwillingness to move the affected part. Communicate to other healthcare professionals the person's preferences for assistive devices and means of manipulating the involved area. *Gentle handling and minimal manipulation help reduce pain.*

Community-based care

Although people may be hospitalised for acute treatment and surgery, most care is provided at home. Community health services can provide intravenous medications, if prescribed. Discuss the following topics for home care:

- the importance of careful handwashing, especially after toileting and dressing changes
- the importance of taking all antibiotics as prescribed. Include information about helping prevent the yeast infections (of the mouth or vagina) often associated with prolonged antibiotic therapy by eating 1 cup (250 mL) of live-culture yoghurt each day
- the need to take pain medications on a regular basis to prevent pain from becoming severe. Provide information about how to deal with side effects, such as constipation, by increasing fluid and fibre intake
- how to perform wound care and sources for needed equipment and supplies
- rest or limited weight bearing for the affected extremity or body part. Teach how to avoid complications associated with prolonged immobilisation, such as frequently shifting position, keeping skin and linens clean and dry, and doing active ROM exercises for unaffected joints
- the importance of maintaining good nutrition. An adequate supply of kilojoules, protein and other nutrients is necessary for immune function and healing. Suggest frequent small meals and using nutritional supplements such as Ensure to help maintain nutritional intake.

THE PERSON WITH SEPTIC ARTHRITIS

Septic arthritis can develop if a joint space is invaded by a pathogen. The primary risk factors for septic arthritis are persistent bacteraemia (bacteria in the blood) (e.g. due to use of injectable drugs, endocarditis) and previous joint damage (e.g. due to trauma or rheumatoid arthritis). Arthroscopic surgery and total joint replacements that allow potential direct contamination of the joint are additional risk factors (McPhee et al., 2015).

Pathophysiology

The most common bacteria implicated in septic arthritis include gonococci, *S. aureus* and streptococci. Infections by Gram-negative bacteria such as *E. coli* and *Pseudomonas* are seen with

increasing frequency, particularly in people who inject recreational drugs or are immunocompromised (McPhee et al., 2015).

Infection of the joint leads to inflammation with resulting synovitis and joint effusion. Abscesses may form in synovial tissues or bone underlying joint cartilage. If not treated promptly and effectively, septic arthritis can lead to destruction of the affected joint. A single joint, often the knee, is usually affected. Septic arthritis may also affect other joints such as the shoulder, wrist, hip, fingers or elbow.

Manifestations

The onset of septic arthritis is typically abrupt, marked by pain and stiffness of the infected joint. The joint appears red and swollen and is hot and tender to the touch. Effusion (increased fluid within the joint space) is usually present. Systemic manifestations of infection, such as chills and fever, often accompany local manifestations, although these may be muted if the person is taking anti-inflammatory medications.

INTERPROFESSIONAL CARE

Septic arthritis is a medical emergency requiring prompt treatment to preserve joint function. When it is suspected, fluid from the affected joint is aspirated and sent for Gram stain and culture. Cultures also are obtained from all likely sources of the infection, including blood, sputum or wounds. The synovial fluid culture is always positive in non-gonococcal septic arthritis but often is negative for bacteria in early gonococcal arthritis. Infected synovial fluid usually is cloudy, with a high WBC count and a low glucose level. Joint x-ray films are often normal in the initial stages, but soon show demineralisation, bony erosions and joint space narrowing.

The infected joint is treated with rest, immobilisation, elevation and systemic antibiotics. Treatment with a broad-spectrum parenteral antibiotic is initiated before the results of culture are obtained. The medication may be changed or adjusted once the organism has been identified. Antibiotic therapy is continued for at least 2 weeks after inflammatory manifestations have abated. Frequent joint aspirations may be performed to remove excess fluid and pus and to evaluate for the continued presence of bacteria. Surgical drainage may be performed if the hip joint is involved (because of the difficulty of aspirating this joint) or when medical therapy does not rapidly eliminate bacteria from the synovial fluid. Physical therapy is implemented during the recovery period to ensure maintenance of optimal joint function.

Nursing care

Septic arthritis can be frightening to the person who experiences a sudden onset of joint pain and swelling and is faced with the possibility of rapid functional loss of movement. Nursing care is both supportive and educative. People may be hospitalised for initial treatment with intravenous antibiotics. It is important to monitor the person's response to therapy, including systemic manifestations such as fever. Position the affected joint appropriately, using pillows to elevate it as needed. Splints or traction may be used to immobilise the joint. Warm compresses may be ordered for comfort. Active ROM exercises preserve joint mobility and should be initiated as soon as the doctor allows.

The person with septic arthritis needs information about the disorder, its aetiology and its treatment. Teach the person how organisms may gain entry into the joint space. Discuss the role that the use of injected drugs and sexually transmitted infections play in septic arthritis and means to prevent infection as appropriate (e.g. using clean 'works', practising safer sex). Refer the person to a drug treatment program if necessary. Emphasise the importance of complying with all aspects of the treatment plan to prevent joint destruction and disability.

NEOPLASTIC DISORDERS

Bone tumours may be either primary (arising in the bone itself) or metastatic (seeded from a tumour elsewhere in the body). Like other tumours, bone tumours can be either benign or malignant.

THE PERSON WITH BONE TUMOURS

Benign bone tumours tend to grow slowly and do not often destroy surrounding tissues. Primary malignant tumours of the bone are rare, accounting for only about 1% of all adult cancers (Porth & Matfin, 2014). Malignant tumours grow rapidly and metastasise. Virtually every malignant tumour can metastasise to bone. However, the most common metastatic bone tumours originate from primary tumours of the prostate, breast, kidney, thyroid and lung.

Primary bone tumours arise from bone tissue itself—that is, cartilage (chondrogenic), bone (osteogenic), collagen (collagenic) and bone marrow cells (myelogenic). The tissue type, neoplasm classification, sites and incidence of the most common primary bone tumours are summarised in Table 39.6. The focus for discussion in this section is care of the person with a primary bone tumour.

TABLE 39.6 Description of common primary bone tumours

TISSUE TYPE	BENIGN	MALIGNANT	SITE	INCIDENCE
Chondrogenic (cartilage-forming tumours)	Osteochondroma—most common benign tumour		Pelvis, scapula, ribs	Higher in males
	Chondroma		Hands, feet, ribs, spine, sternum or long bones	Ages 30 to 50 Higher in males
		Chondrosarcoma	Femur, pelvis, ribs, head (epiphysis) of long bones	13% of malignant bone tumours Middle age and older Higher in males
Osteogenic (bone-forming tumours)	Osteoid Osteoma		Shaft (diaphysis) of long bones (i.e. femur, tibia)	Ages 20 to 30 Higher in males
		Osteosarcoma—most common malignant tumour	Long bones, knee	38% of malignant bone tumours Predominant in adolescents and people aged 50 to 60
Collagenic (collagen-forming tumours)		Fibrosarcoma	Femur, tibia	4% of malignant bone tumours Wide age distribution, but usually occurs in people aged 40 to 50 Higher in females
Myelogenic (tumours of bone marrow cells)	Giant cell tumour		Shaft (diaphysis) of long bones (i.e. femur, tibia, radius, humerus)	4–5% of bone tumours Wide age distribution Higher in females

Pathophysiology

The aetiology of bone tumours is unknown but there is a connection between increased bone activity and the development of primary bone tumours. Bone tumours frequently occur when primary bone growth is at its peak in adolescence or is overstimulated during disease, such as Paget's disease.

Primary tumours cause bone breakdown, called *osteolysis*, which weakens the bone, resulting in bone fractures. Normal bone adjacent to the tumour responds to tumour pressure by altering its normal pattern of remodelling. The bone's surface becomes altered and the contours enlarge in the area of the tumour growth.

Malignant bone tumours invade and destroy adjacent bone tissue by producing substances that promote bone resorption or by interfering with a bone's blood supply. Benign bone tumours, unlike malignant ones, have a symmetrical, controlled growth pattern. As they grow, they push against neighbouring bone tissue. This weakens the bone's structure until it becomes unable to withstand the stress of ordinary use and frequently causes pathological fracture.

Manifestations

The three main manifestations of bone tumours are pain, a mass and impaired function. Bone pain usually comes on slowly and lasts for as long as a week, is constant or intermittent, and may be worse at night. The mass is described as a swelling or lump on the bones that is firm, slightly tender and may be felt through the skin. The mass may interfere with normal movement and/or cause the bone to break. The manifestations of bone tumours are usually associated with a history of a fall or blow to the extremity that brings the mass to the person's attention. The injury, rather than the growth itself, usually causes the person to seek medical attention. Manifestations of bone tumours are listed in the box below.

INTERPROFESSIONAL CARE

Treatment and care of the person with a bone tumour focuses on prompt diagnosis, removal of the tumour, prevention of complications and education.

Diagnosis

The diagnosis of a bone tumour is critical to the survival of the person and possible preservation of the affected limb. Diagnostic tests are described in Chapter 37.

Radiological studies include x-rays, CT scans and MRI. X-rays show the location of the tumours and the extent of bone involvement. Benign tumours are characterised by sharp margins that are clearly separate from the surrounding normal bone. Metastatic bone destruction has a characteristic 'moth-eaten' pattern in which the growth has a less defined margin that cannot be separated from the normal bone. CT scan and MRI are useful in evaluating the extent of tumour invasion into bone, soft tissues and neurovascular structures. Percutaneous needle biopsy or needle biopsy at the time of surgery is used to determine the exact type of bone tumour.

Laboratory tests include an alkaline phosphatase (elevated with malignant bone tumour) and a calcium level (increased with massive bone destruction).

Treatments

As with other malignant tumours, bone tumours are treated with chemotherapy, radiation therapy and surgery.

MANIFESTATIONS Neoplasms of the musculoskeletal system

	MANIFESTATIONS
BONY SARCOMAS SITE	
Upper or lower extremity or pelvis	■ Worsening deep bony pain ■ Pain at night or during rest that may radiate and become severe ■ Muscular weakness or atrophy
Metaphysis of distal femur, proximal tibia, proximal humerus and pelvis	■ Soft tissue mass extending from bone with erythematous or warm skin over tissue mass ■ Change in ability to perform ADLs ■ Fever
SOFT TISSUE SARCOMAS SITE	
Upper or lower extremity and pelvis	■ Enlarging firm mass with irregular borders, which causes pain in surrounding soft tissue structures
Thigh; shoulder and pelvis	■ Erythema or warmth and venous dilation over skin ■ Muscular weakness and atrophy with limited range of motion change in ability to perform ADLs and change in gait ■ Paraesthesia with neurological involvement and distal swelling ■ Palpable local lymph nodes
Pelvis	■ Altered bowel and bladder habits or pain with intercourse

CHEMOTHERAPY Chemotherapeutic agents are administered to shrink the malignant tumour before surgery, to control recurrence of tumour growth after surgery or to treat metastasis of the tumour. Chemotherapeutic agents used to treat bone tumours are listed in Box 39.5. See Chapter 13 for further discussion of chemotherapy and its nursing implications.

RADIATION THERAPY Radiation therapy may be used in combination with chemotherapy. Radiation therapy is frequently applied to metastatic bone carcinomas as a method of pain control. It is also used to eliminate bony tumours or any remaining tumour after a surgical procedure. Radiation therapy is discussed in Chapter 13.

SURGERY The goal of surgery for the treatment of primary bone tumours is to eliminate the tumour completely. Tumours are removed either by excising the tumour itself or by amputating the affected limb. The type of procedure varies: removal of the tumour only, removal of the tumour along with a small margin of normal tissue surrounding the tumour, removal of the tumour and a wide zone of normal tissue, or removal of the tumour and part or all of the bone in which it lies. Cadaver allografts or metal prostheses often are used to replace missing bone, avoiding amputation. Care of the person undergoing amputation is discussed in Chapter 38.

BOX 39.5 Chemotherapeutic agents used for musculoskeletal neoplasms

Alkylating agents
Ifosfamide
Cyclophosphamide

Antibiotics
Doxorubicin
Bleomycin

Antimetabolites
Methotrexate

Plant alkaloids
Vincristine

Synthetic agents
Cisplatin

Nursing care

Nursing care for the person with bone tumours requires innovative interventions from the time of diagnosis through the rehabilitation phase. In the acute phase, problems associated with pain, lack of knowledge, immobility, coping and anxiety are foremost. If the person develops complications from treatment or if a malignancy metastasises, problems related to home health maintenance management, self-concept and prevention of further complications take priority.

Nursing diagnoses and interventions

The person with a bone tumour requires nursing care to meet many health problems, including prevention of injury, relief of pain, assistance with mobility and teaching about the disease process and treatment.

Risk of injury

In the person with a bone tumour, changes in bone tissue can cause pathological fractures.

- Teach how to avoid falls or injury to the tumour site, such as by using assistive devices when walking and ensuring the home environment is not conducive to falling (e.g. remove throw rugs and use night lights). *Pathological fractures may occur at the tumour site because bone destruction can weaken the area.*

- Provide referral to physical or occupational therapy for fitting of and teaching about assistive devices for ambulating, such as a cane, crutches or a walker. *Assistive devices can reduce the risk of falling when the person has significant weakness of an extremity or when balance has been affected by treatment of the disease.*

Acute pain, chronic pain

In the person with a bone tumour, pain may be related to direct invasion of the tumour or to pathological fractures. People may experience both acute and chronic pain.

- Develop strategies for controlling both acute pain (from surgery, fracture or inflammation) and chronic pain (from progression of the disease). *Analgesics combined with non-pharmacological methods of pain control provide optimum relief of pain. Chronic pain, when mild in nature, is best managed with NSAIDs or aspirin. Moderate pain is best managed with a combination of codeine and NSAIDs. Severe pain is best relieved with long-acting or sustained-relief narcotic analgesics.*
- Provide assistive devices (e.g. canes, walkers, crutches) when the person ambulates. *Assistive devices lessen the pain by supporting weight bearing during ambulation.*

Impaired physical mobility

Pain, muscle wasting or surgical procedures can impair the physical mobility of the person with a bone tumour.

- Begin muscle-strengthening and active and passive ROM exercises immediately after surgery. A continuous passive motion (CPM) machine may be used after surgical procedures to either upper or lower extremities. *Muscle-strengthening exercises must be encouraged as soon as possible to prevent muscle wasting and shorten the rehabilitation period.*
- Encourage exercises that help strengthen the triceps muscles. *The triceps are the major muscles in the arms and must be strengthened to assist in use of crutches or other assistive devices.*
- For the person who has undergone an amputation of a lower extremity, encourage quadriceps and gluteal setting exercises and leg raises. *These exercises will benefit the person when the rehabilitation period begins.*

Decisional conflict

A lack of knowledge about the diagnosis and treatment regimen can impair the person's ability to make informed decisions about the treatment plan.

- Discuss issues related to diagnosis, radiological evaluation, biopsy, surgery, chemotherapy, radiation therapy, potential complications, alternative therapies, risks, benefits, nursing management, discharge plans, home care and long-term treatment and follow up. *The person requires this information in order to make informed decisions about treatment.*

Community-based care

The person with a primary bone tumour needs information about the disease, its potential consequences and treatment options. Present information in a matter-of-fact manner, taking time to listen to and address the person's and family's concerns. Discuss expected effects and potential side effects of surgery, chemotherapy and radiation therapy. Provide information about how to minimise side effects. Teach the postsurgical person about wound care, demonstrating dressing changes and stump care (if amputation has occurred). Provide the person with a list of local resources for obtaining supplies. Discuss activity and weight-bearing restrictions. Refer the person to physical therapy for teaching about ambulation and appropriate muscle-group-strengthening exercises. Ensure that the person who has experienced an amputation is working with or has a referral to a prosthetic specialist. For the person with metastatic disease, discuss hospice services and support groups for people with cancer.

CONNECTIVE TISSUE DISORDERS

Connective tissue is the most abundant and widely distributed body tissue. It not only connects body parts but also provides support; forms bones, cartilage and the walls of blood vessels; and attaches muscles to bones. Connective tissue consists of three elements: (1) long fibres embedded in a (2) non-cellular ground substance and (3) cells specific to the class of connective tissue. Fibres made up primarily of collagen, a protein, are the most abundant in connective tissue.

Connective tissue disorders, also known as collagen diseases, are a group of immune-mediated disorders. Although they appear to have a genetic component, their cause is unknown. Because connective tissue and collagen are widely distributed in many varied tissues, these are systemic diseases with diverse manifestations.

THE PERSON WITH SYSTEMIC SCLEROSIS (SCLERODERMA)

Systemic sclerosis, also known as **scleroderma** ('hardening of the skin'), is a chronic disease characterised by the formation of excess fibrous connective tissue and diffuse fibrosis of the skin and internal organs. The cause of scleroderma is unknown, but genetic, immune and environmental factors are thought to play a role. Although this uncommon disease is distributed worldwide, a higher incidence is noted in coal and gold miners and in people exposed to certain chemicals such as polyvinyl chloride, epoxy resins and aromatic hydrocarbons.

Pathophysiology

Abnormalities in cellular immune function are believed to contribute to the development of scleroderma. Abnormal proliferation of fibrous connective tissue occurs in affected tissues, including the skin, blood vessels, lungs, kidneys and other organs.

Scleroderma may be either localised, affecting the skin only, or generalised (systemic sclerosis), with both skin and visceral organ involvement. Localised involvement may occur as irregularly shaped patches of skin (morphea) or a line of disease on the arm, leg or side of the face (linear scleroderma) (International Scleroderma Network, 2015). Eighty per cent of people with generalised disease have limited involvement, frequently manifested by CREST syndrome, a combination of calcinosis (abnormal calcium salt deposition in the tissues), Raynaud's phenomenon, oesophageal dysfunction, sclerodactyly (localised scleroderma of the fingers) and telangiectasia (dilated, superficial blood vessels). The remainder of people with generalised systemic sclerosis have a diffuse form of the disease and a higher risk of visceral organ involvement. Infections and diseases of the cardiovascular, renal, pulmonary and central nervous systems are the most common causes of death in people with systemic sclerosis.

FAST FACTS

- Scleroderma affects over 5000 people in Australia (Scleroderma Australia, 2015).
- Scleroderma affects women more often than men by a ratio of approximately 3:1.
- Although it can occur at any age from infancy to older adulthood, the onset of scleroderma typically occurs between the ages of 25 and 55 years (Scleroderma Foundation, 2015).

Manifestations

The initial manifestations of systemic sclerosis are usually noted in the skin, which thickens markedly. Diffuse, non-pitting swelling also is noted. As the disease progresses, the skin begins to atrophy, becoming taut, shiny and hyperpigmented (see Figure 39.9). Facial skin tightening leads to loss of skin lines and a pursed-lip appearance. Skin tightness may limit mobility, particularly of the face and hands. Other skin manifestations include telangiectasias (flat, red areas caused by dilation of small blood vessels, usually noted on the face, hands and in the mouth) and calcium deposits, usually noted around joints.

Arthralgias and Raynaud's phenomenon are common early manifestations of systemic sclerosis. Raynaud's phenomenon (intermittent attacks of small-artery vasospasm) is characterised by pallor of the fingers followed by cyanosis and then reactive hyperaemia with redness. Attacks are usually triggered by cold temperatures.

The person with visceral organ involvement may have varied symptoms. Dysphagia is common, because the motility of the oesophagus is affected. Pulmonary involvement can lead to exertional dyspnoea due to impaired gas exchange and right-sided heart failure due to pulmonary hypertension. Involvement of the heart may cause manifestations of pericarditis and arrhythmias. Diarrhoea or constipation, abdominal cramping and malabsorption can occur when the GI tract is affected. Renal effects can lead to proteinuria, haematuria, hypertension and kidney failure.

FIGURE 39.9 ■ Characteristic skin changes of scleroderma

Source: Joubert/Photo Researchers, Inc.

The prognosis for localised and limited scleroderma is good; many people have a normal lifespan. The course of diffuse systemic sclerosis is highly variable. This disease is usually progressive; complete remission is rare.

INTERPROFESSIONAL CARE

The manifestations of systemic sclerosis often allow diagnosis with little or no testing. No cure is currently available; treatment is symptomatic and supportive.

Diagnosis

No single diagnostic test is specific for systemic sclerosis, although a titre of 1:40 or higher for antinuclear antibody (ANA) is the most sensitive for diagnosis. Other laboratory studies that are done include an ESR, which is typically elevated from the chronic inflammatory process and an FBC, which will demonstrate anaemia. A skin biopsy may be done to confirm the diagnosis.

Medications

Medications to treat systemic sclerosis are chosen based on the person's symptoms. Immunosuppressive agents and corticosteroids are of limited benefit, but may be used to slow or prevent pulmonary fibrosis and in life-threatening disease. Penicillamine may be used to treat scleroderma and pulmonary fibrosis. Calcium channel blockers such as nifedipine or alpha-adrenergic blockers such as prazosin (Minipress) may be prescribed for people with Raynaud's phenomenon. When manifestations of oesophagitis accompany systemic sclerosis, H_2-receptor blockers

such as cimetidine (Tagamet) or ranitidine (Zantac), antacids or omeprazole (Losec; protein pump inhibitor), which block all gastric secretion, may be ordered. Tetracycline or another broad-spectrum antibiotic may be prescribed to suppress intestinal flora and relieve symptoms of malabsorption. People with kidney disease are usually treated with angiotensin-converting enzyme (ACE) inhibitors such as captopril (Capoten) to control hypertension and preserve kidney function. End-stage kidney disease is managed with dialysis and transplantation.

Physical therapy

Physical therapy is an important part of the management of systemic sclerosis to maintain mobility of affected tissues—the hands and face, in particular. Because the mouth opening, if involved, becomes increasingly smaller as the disease progresses, stretching and strengthening of facial muscles can be vital to maintaining oral food intake.

Nursing care

Nursing care needs of people with systemic sclerosis are individualised to the effects and manifestations of the disease, with interventions summarised in the following section.

Nursing interventions

Skin manifestations are present to some degree in nearly all people with scleroderma. Nursing care related to the skin focuses on maintaining skin integrity and flexibility. Measures to maintain supple skin are important because elasticity cannot be regained once it is lost. Apply moisturisers to prevent dryness and cracking. Protect the skin where it is stretched taut over joints or bony prominences. Perform ROM exercises to help prevent joint contractures due to increasingly tight skin.

Difficulty swallowing and recurrent oesophagitis may interfere with the person's nutritional status. Provide small, frequent meals. Consult with the dietitian and the person to determine which foods are easy to swallow. Keep the person in a sitting or Fowler's position after meals and elevate the head of the bed at night to minimise oesophageal reflux.

The dermatological and systemic effects of the disease may have significant psychological effects on the person, leading to feelings of helplessness and hopelessness and self-esteem disturbance. Establish an atmosphere of trust with the person. Listen actively and acknowledge concerns about the disease and its effects on the person's life and appearance. Encourage the person to share these concerns with family members and significant others. Provide referral to social services or counselling as appropriate.

The person with predominant pulmonary disease has nursing care needs similar to those of other people with restrictive respiratory disorders. If the person with systemic sclerosis has impaired renal function, nursing care is similar to that for people with chronic renal failure (see Chapter 27).

Community-based care

Teach the person with systemic sclerosis about the disease and introduce measures to help manage its effects. Stress the importance of good skin care and physical therapy exercises to maintain mobility, particularly of the hands and face. Discuss the need to avoid chilling (local and whole body) to prevent episodes of Raynaud's phenomenon. Teach the role of proper dress in the winter: loose, warm clothing, gloves and warm stockings. If needed, stress the need to stop smoking because of the vasoconstrictive effect of nicotine and the respiratory effects of the disease. Provide the person with information about manifestations of disease progression and organ involvement. Teach the person to report new or worsening symptoms to the doctor. In addition, suggest the following resources:

- Scleroderma Australia: www.sclerodermaaustralia.com.au
- Scleroderma New Zealand: http://scleroderma.org.nz.

THE PERSON WITH SJÖGREN'S SYNDROME

Sjögren's syndrome is an autoimmune disorder that causes inflammation and dysfunction of exocrine glands throughout the body. Sjögren's syndrome primarily affects women, with a ratio of women to men at 9:1. The highest incidence is between the ages of 40 and 60 years. Although it can occur as a primary disorder, Sjogren's syndrome is often associated with other rheumatic disease, including rheumatoid arthritis, SLE, primary biliary cirrhosis, scleroderma, Hashimoto's thyroiditis and interstitial pulmonary fibrosis (McPhee et al., 2015).

Pathophysiology

In this disease, exocrine glands in many areas of the body are destroyed by infiltration of lymphocytes and deposits of immune complexes. The salivary and lacrimal glands are particularly affected, leading to the characteristic manifestations of *xerophthalmia* (dry eyes) and *xerostomia* (dry mouth). People often experience dry, gritty-feeling eyes and may develop corneal ulcerations. Mucosal dryness affects taste, smell, chewing and swallowing and leads to increased dental caries. Parotid gland enlargement is common. Excess dryness can also affect the nose, throat, larynx, bronchi, vagina and skin. Systemic effects of Sjögren's syndrome include arthritis, dysphagia, pancreatitis, pleuritis, neurological manifestations including migraine and vasculitis. Nephritis may occur, but kidney failure rarely results. People with Sjögren's syndrome have a greatly increased risk of developing malignant lymphoma.

INTERPROFESSIONAL CARE

The diagnosis of Sjögren's syndrome is often based on the person's history and clinical presentation. Schirmer's test, which measures the quantity of tears secreted in a 5-minute period in response to irritation, ocular staining and slit-lamp examination

of the eye may be performed. A definitive diagnosis can be made by biopsy of either the lacrimal or the salivary gland.

Treatment is supportive. Artificial tears are used to decrease eye irritation and dryness. The person can keep the mouth moist by drinking fluids, using a saliva substitute and chewing sugarless gum. Medications that increase mouth dryness, such as atropine and decongestants, should be avoided.

Nursing care

Nurses caring for people with Sjögren's syndrome need to teach measures to protect the person's eyes and oral mucosa. Instil artificial tears as needed. Encourage the person to sip fluids throughout the day. Provide frequent oral hygiene, particularly before and after meals. Ensure that the person has sufficient fluids to drink during meals, because fluids help with chewing and swallowing.

THE PERSON WITH FIBROMYALGIA

Fibromyalgia is a common rheumatic syndrome characterised by musculoskeletal pain, stiffness and tenderness. The cause is unknown, but possible aetiologies include sleep disorders, depression, infections and an altered perception of normal stimuli. Fibromyalgia can be a complication of hypothyroidism, rheumatoid arthritis or (in men) sleep apnoea. It closely resembles chronic fatigue syndrome, except that musculoskeletal pain is predominant in fibromyalgia whereas fatigue is a more significant feature of chronic fatigue syndrome.

Pathophysiology

No inflammatory, structural or physiological muscle changes have been demonstrated in fibromyalgia. A connection between fibromyalgia and the central nervous system is being studied.

Manifestations

A gradual onset of chronic, achy muscle pain is typical, although the onset may be sudden, occasionally following a viral illness. The pain may be localised or involve the entire body. The neck, spine, shoulders and hips are often affected. Pain is produced by palpating localised 'tender points' (see Figure 39.10). Local tightness or muscle spasm may also occur. Systemic manifestations of fibromyalgia include fatigue, sleep disruptions, headaches, morning stiffness, painful menstrual periods and problems with thinking and memory (called the 'fibro fog'). Pain and fatigue are aggravated by exertion.

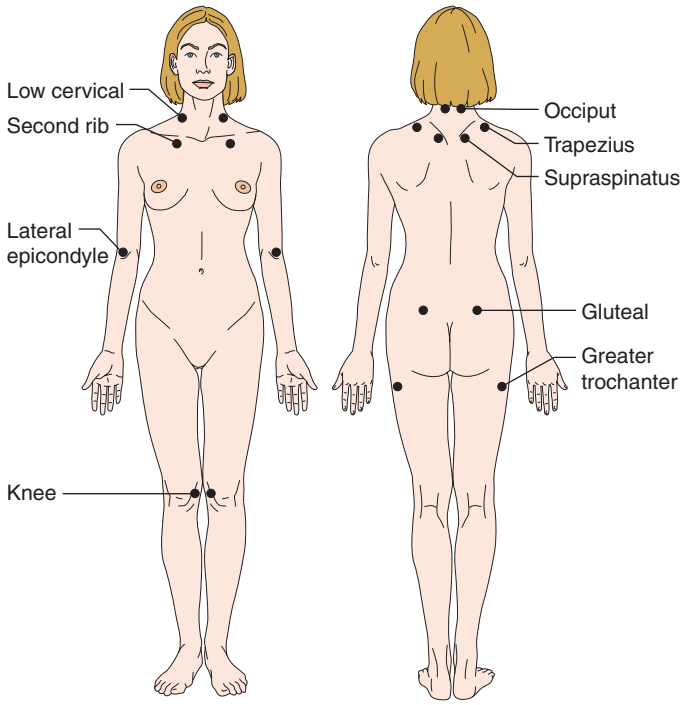


FIGURE 39.10 ■ Location of 'tender points' in fibromyalgia

INTERPROFESSIONAL CARE

The diagnosis of fibromyalgia is based on the history and physical assessment. The criteria—developed by the American College of Rheumatology and used in Australia and New Zealand—that are used for diagnosis are a history of widespread pain that has been present for at least 3 months, and pain at 11 of the 18 tender points on palpation. There are no laboratory or diagnostic tests for the disorder, although tests may be performed to rule out other rheumatic disorders, such as rheumatoid arthritis or SLE. Fibromyalgia also may occur as a complication of hypothyroidism, so thyroid function studies are performed.

Acknowledgement of the person's symptoms and the chronic but treatable nature of this disease is important (Huynh, Yanni & Morgan, 2008). Therapeutic measures include a program of structured aerobic exercise for conditioning, as well as stretching exercises.

Heated pool treatments with or without exercise have been shown to be beneficial. Evidence to support other treatments, such as cognitive behavioural therapy, hypnotherapy, biofeedback and acupuncture, is mixed (Huynh et al., 2008).

There are no medicines currently registered specifically for the treatment of fibromyalgia in Australia. Medical treatments regularly used in the treatment of fibromyalgia in Australia include tricyclic antidepressants (TCAs) which promote better sleep, paracetamol, non-steroidal anti-inflammatories (NSAIDs) and stronger analgesics as required (TGA, 2012). Milnacipran capsules have been listed for the management of fibromyalgia. Milnacipran assists in the treatment of chronic pain and fatigue. It is currently listed as restricted benefit in Australia.

Nursing care

Nursing care for people with fibromyalgia is supportive and educational, and provided in community settings such as clinics and other primary care settings. It is important to validate people's concerns and reassure them that their symptoms are not 'all in the head'. This syndrome is recognisable and manageable; its course is not progressive. Teach people about the disorder and reassure them that it resolves uneventfully in most instances. Provide verbal and written instructions about the use of heat, exercise, stress-reduction techniques and prescribed medications to relieve manifestations. In addition, suggest the following resources:

- Arthritis Australia: www.arthritisaustralia.com.au
- Fibromyalgia SA: sacfs.asn.au/download/fm_overview.pdf.

STRUCTURAL DISORDERS

Structural disorders of the musculoskeletal system most commonly affect the spine. The disorders discussed in this section are spinal deformities and lower back pain.

THE PERSON WITH SPINAL DEFORMITIES

Scoliosis and kyphosis are the two most common deformities of the spinal column. *Scoliosis* is a lateral curvature of the spine. *Kyphosis* is excessive angulation of the normal posterior curve of the thoracic spine. (See Figure 39.11.)

An estimated 1 in 10 people in Australia are affected by scoliosis (Scoliosis Association of Australia, 2015). It usually is diagnosed in adolescence, with girls more affected than boys by a ratio of 8:1. Idiopathic scoliosis is the most common form of the disorder, accounting for approximately 75% of cases. Congenital and neuromuscular disorders such as cerebral palsy, poliomyelitis and muscular dystrophy account for the rest (Porth & Matfin, 2014; Scoliosis Association of Australia, 2015).

Pathophysiology

Detailed discussions of the causes and treatment of scoliosis and kyphosis in younger people can be found in paediatric nursing textbooks. This discussion focuses on the nursing care of adults with these disorders. The manifestations of scoliosis and kyphosis are listed in the box below.

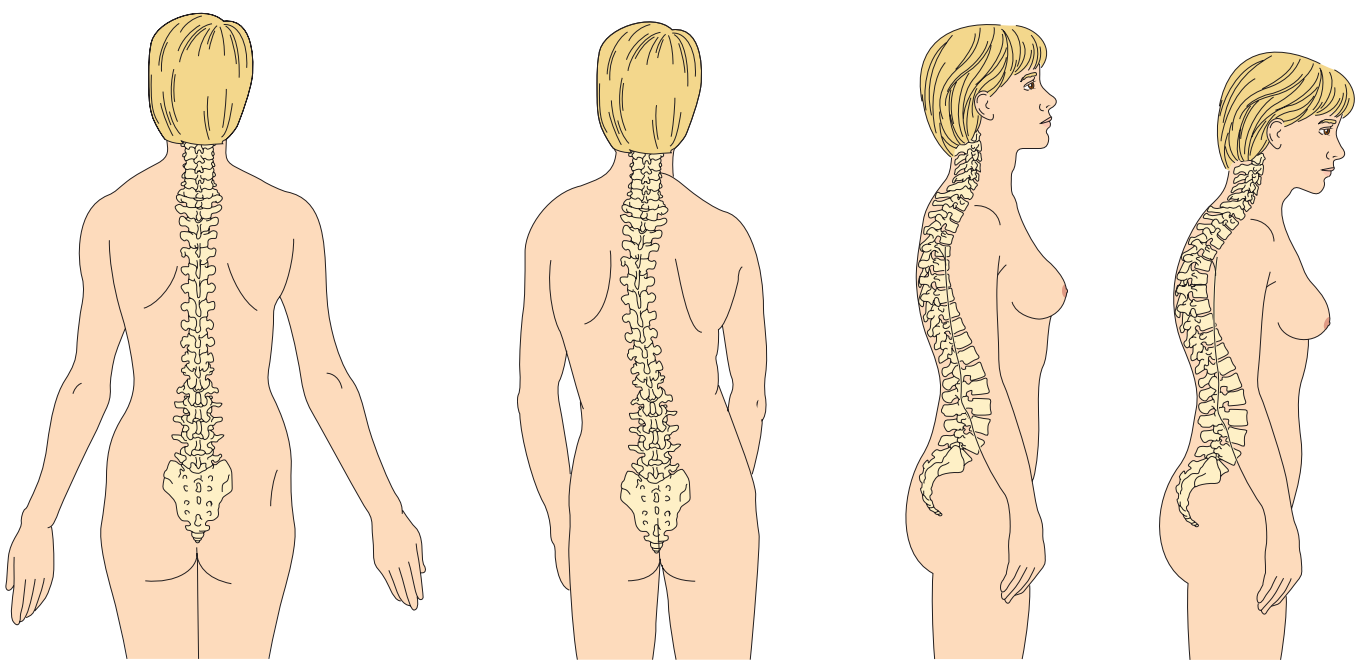

FIGURE 39.11 ■ Common deformities of the spinal column. *A*, Scoliosis is a lateral curvature of the spine. *B*, Kyphosis is an exaggerated posterior curvature of the thoracic spine

MANIFESTATIONS Scoliosis and kyphosis

SCOLIOSIS
- Asymmetry of shoulders, scapulae, waist creases
- Prominence of the thoracic ribs or paravertebral muscles on forward bend
- Lateral curvature and vertebral rotation on posteroanterior x-ray film

SEVERE SCOLIOSIS
- Back pain
- Shortness of breath
- Anorexia, nausea

KYPHOSIS
- Posterior rounding at the thoracic level
- Kyphotic curve of over 45 degrees on x-ray film

Scoliosis

Scoliosis is classified as *postural* when the small curve corrects with bending, and *structural* when the curve does not correct with bending (Porth & Matfin, 2014). Most people requiring treatment have structural scoliosis, a curve caused by a fixed deformity.

The lateral curve that occurs in scoliosis is usually evident in the thoracic, lumbar or thoracolumbar regions of the spine. The vertebral bodies in these spinal regions can be rotated as well as curved to one side or the other.

As scoliosis emerges, the soft tissues (muscles and ligaments) shorten on the concave side of the curvature. Over time, progressive deformities of the vertebral column and ribs develop, causing one-sided compression of the vertebral bodies. The degree of compression and twisting varies according to the location of each vertebra within the curved portion of the spine.

If the lateral curvature is less than 40 degrees when the person's spine reaches maturity, the risk of further progression during adult life is small. However, the spine becomes unstable if the lateral curvature is greater than 50 degrees and curvature likely will worsen throughout the person's lifetime.

Scoliosis is usually first noted by the deformity it causes, such as one shoulder that is higher than the other, a prominent hip or a projecting scapula. Pain is present in severe cases, usually in the lumbar region. Pain also may be caused by pressure on the ribs or the crest of the ilium. Shortness of breath may result from diminished chest expansion and gastrointestinal disturbances may occur because of crowding of the abdominal organs.

Kyphosis

Like scoliosis, kyphosis is classified as postural or structural. Postural kyphosis is caused by a slumping posture. Structural kyphosis may result from congenital malformations or paediatric disorders such as rickets or poliomyelitis. However, kyphosis also may occur during adulthood from vertebral tuberculosis and Paget's disease, or from metabolic disorders such as osteoporosis and osteomalacia. The condition can also result from the surgical removal or radiation of intervertebral discs for the treatment of spinal cord tumours or cysts.

The manifestations of kyphosis include moderate back pain and increased curvature of the thoracic spine as viewed from the side ('hunchback'). Impaired mobility and respiratory problems may occur in cases of severe curvature.

INTERPROFESSIONAL CARE

Diagnosis of scoliosis and kyphosis is important to prevent severe spinal deformity in the adult. The person stands with the arms relaxed and hanging freely at the sides while the examiner evaluates the person from both the back and the front for symmetry of the shoulders, scapulae, waist creases and the length of the arms. The person then bends forwards and the examiner observes for prominence of the thoracic ribs or vertebral muscles. The person is then viewed from the side while the screener looks for increased thoracic rounding or lumbar swayback.

A scoliometer is used to quantify the prominence of any curvatures noted during the examination. The scoliometer is placed at the apex of the curvature. A reading of greater than 10 degrees requires referral to a doctor (Porth & Matfin, 2014).

Diagnosis

Upright posteroanterior and lateral x-rays are used to confirm the diagnosis of curvature of the spine. For the person with scoliosis, the degree of curvature is measured by determining the amount of lateral deviation to the left or right. For the person with kyphosis, anteroposterior and lateral views typically reveal wedging of the vertebrae.

Treatments

Scoliosis and kyphosis may be treated conservatively or with surgery.

CONSERVATIVE TREATMENT Braces, electrical stimulation and traction may be used to prevent progression of scoliosis and kyphosis in younger people whose skeletons have not yet matured. Unfortunately, these approaches are ineffective in adults. Conservative treatment for adults with scoliosis and kyphosis may include weight reduction, active and passive exercises, and the use of braces for support.

SURGERY The use of surgery to correct spinal deformities depends on factors such as the degree of curvature and the person's overall physical, emotional and neurological status. Even with surgery, it is not possible to correct the abnormal curvature completely. The surgical procedure involves attaching metal reinforcing rods to the vertebrae and is usually performed using an anterior approach, although more severe curvature may require both an anterior and a posterior approach. The types of straightening devices used most frequently use bilateral rods with wire hooks or screws that stabilise the spine and correct the deformity.

Nursing care

Nursing diagnoses and interventions

Nursing interventions focus on minimising the risk of injury and neurological impairment.

Risk of injury

People with spinal deformities are at risk of injury from several sources, including structural aspects of bracing both before and after surgical intervention, dislocation of hooks and rods resulting from improper alignment or movement of the back and changes in body position after prolonged immobilisation.

- Assess the environment for safety hazards. *The person needs to learn to use handrails on stairways and take precautions when walking on slippery surfaces or areas with throw rugs.*

CONSIDERATION FOR PRACTICE

Some braces do not allow the person to flex or hyperextend the spinal column.

- Teach the person ways to reduce irritation of skin surfaces beneath the brace: wearing a smooth cotton T-shirt or cotton tube under the brace at all times, changing undergarments at least once daily and washing them with a mild soap. Undergarments should be changed more frequently in warmer weather. *The person wearing a brace is especially prone to skin breakdown and must take precautions to prevent it.*

CONSIDERATION FOR PRACTICE

Teach the person to avoid lotion and body powders; they may irritate the skin.

- Teach the person to loosen the brace during meals and for the first 30 minutes after each meal. *People have difficulty eating if the brace is tight. Loosening the brace during and after each meal will allow adequate nutritional intake and promote comfort.*
- Teach people how to apply the brace and explain ambulatory restrictions. *People requiring a brace need to learn how to apply the brace prior to ambulating. Ambulation is frequently restricted to walking rather than sitting for long periods.*
- Turn people who have undergone spinal surgery by using the log-rolling technique. *People require a position change at least every 2 hours. The use of a turn sheet and sufficient assistance allow the nurse to maintain the person's proper body alignment during the turning procedure.*
- Use a fracture bedpan following surgery. *The fracture bedpan provides minimal misalignment of spine and is more comfortable.*

Risk of peripheral neurovascular dysfunction

Surgical procedures can lead to neurological impairment in the person with a spinal deformity.

- Monitor the movement and sensation of lower extremities every 2 hours for the first 8 hours, then every shift and as needed. *Neurological assessment related to sensation and movement of the lower extremities is necessary because the surgical procedure is in close proximity to spinal nerves. Swelling of the surgical site can impinge on the spinal nerves and cause a loss of sensation and movement.*

Community-based care

People with structural scoliosis or kyphosis need reassurance that the condition was not caused by poor posture. If a brace is prescribed to relieve pain and other symptoms associated with the disorder, provide verbal and written instructions for wearing the brace, such as the number of hours per day it is to be worn and activity restrictions to follow when wearing or not wearing the brace. Teach the person how to protect and care for skin under the brace.

Surgical people need postoperative teaching regarding site care and activities. People who have spinal surgery often are allowed to ambulate fairly soon after surgery, but sitting may be restricted because of the stresses it places on the spine. Instruct the person to notify the healthcare provider if numbness, tingling, pain or weakness of an extremity develops after surgery.

Discuss the importance of not smoking and of avoiding respiratory infections for people with scoliosis or kyphosis that restricts respiratory excursion. Encourage these people to obtain pneumococcal pneumonia and influenza immunisations.

THE PERSON WITH LOWER BACK PAIN

Acute or chronic lower back pain involves the lumbar, lumbosacral or sacroiliac areas of the back. In most cases, lower back pain is due to strains in the muscles and tendons of the back caused by abnormal stress or overuse. Lower back pain caused by degenerative disc disease and herniated vertebral discs is covered in Chapter 42.

Pathophysiology

The pathophysiology of back pain varies with its many causes (see Box 39.6). In general, the five causes and types of back pain are as follows:

1. Local pain is caused by compression or irritation of sensory nerves. Fractures, strains and sprains are common causes of local pain; tumours also may press on pain-sensitive structures.
2. Referred pain may originate from abdominal or pelvic viscera.

BOX 39.6 Factors associated with back pain

Mechanical injury or trauma
- Muscle strain or spasm
- Compression fracture
- Lumbar disc disease

Degenerative disorders
- Spondylosis
- Spinal stenosis
- Osteoarthritis

Systemic disorders
- Osteomyelitis
- Osteoporosis or osteomalacia
- Neoplasms, primary or metastatic

Referred pain
- Gastrointestinal disorders
- Genitourinary disorders
- Gynaecological disorders
- Abdominal aortic aneurysm
- Hip pathology

Other
- Fibromyalgia
- Psychiatric syndromes
- Chronic anxiety
- Depression

3. Pain of spinal origin (i.e. pain associated with pathology of the spine such as disc disease or arthritis) may be referred to other structures such as the buttocks, groin or legs.
4. Radicular back pain is sharp, radiating from the back to the leg along a nerve root. This pain may be aggravated by movements such as coughing, sneezing or sitting.
5. Muscle spasm pain is associated with many spine disorders, although its origin may be unclear. This type of back pain is dull and may be accompanied by abnormal posture and taut spinal muscles.

MANIFESTATIONS Lower back pain

ALTERATIONS IN GAIT AND FLEXION
- Walking in a stiff, flexed state
- Inability to bend at waist
- Limp, which may indicate impairment of the sciatic nerve

NEUROLOGICAL INVOLVEMENT
- When tested for light and deep touch with a pin and cotton ball, may feel sensations in both limbs but experience a stronger sensation in the unaffected side
- Loss of both bowel and bladder control due to involvement of the sacral nerve

PAIN
- Pain in the affected leg when walking on heel or toes
- Continuous, knife-like localised pain in muscles close to the affected disc
- Pain that radiates down posterior of leg
- Sharp, burning pain in the posterior thigh or calf
- Pain in middle of buttock
- Tenderness when muscle close to the affected disc is palpated
- Severe pain with straight leg-raising manoeuvre

Manifestations

People with lower back pain report pain ranging from mild discomfort lasting a few hours to chronic debilitating pain. Acute pain is usually caused when the person participates in an activity that is not usually pursued, such as unusual lifting or bending or playing an active sport. Manifestations are presented in the accompanying box.

INTERPROFESSIONAL CARE

Care of the person with lower back pain focuses on relieving pain, correcting the condition if possible, preventing complications and educating the person.

Diagnosis

The choice of diagnostic tests for the person with low back pain depends on the suspected diagnoses, clinical findings and history. Current guidelines for care recommend that radiography, CT scans and MRI be used only with clinical signs of a potentially serious underlying condition. Diagnostic testing may be considered if pain and other manifestations continue to limit the person after 4 weeks of conservative treatment. Diagnostic tests are described in Chapter 37.

Medications

The medications of choice for lower back pain include NSAIDs and analgesics. NSAIDs block prostaglandin production and reduce inflammation, thus relieving the pain. Muscle relaxants, such as cyclobenzaprine (Flexeril), methocarbamol (Robaxin) or carisoprodol (Soma), may be used, but little evidence supports their efficacy.

Epidural steroid injections may be used to help reduce intense, intractable pain. A steroid solution is injected into the epidural space, which helps decrease the swelling and inflammation of the spinal nerves.

Conservative treatment

The majority of people with acute lower back pain need only a short-term treatment regimen. Limited rest, combined with appropriate exercise and education, is often the primary method of treatment. There is no evidence that activity is harmful or aggravating to the source of pain. In fact, activity promotes bone and muscle strength and may increase endorphin levels. Therefore, active rehabilitation helps to restore function and reduce pain.

Pain may be relieved by an ice bag or hot water bottle (or heating pad) applied to the back. Exercise programs are helpful provided that the person begins gradually and increases activity gradually as the recovery process continues. Physical therapy procedures include diathermy (deep heat therapy), ultrasonography, hydrotherapy and transcutaneous electrical nerve stimulation (TENS) units. These therapies reduce the muscle spasms and pain temporarily. They are frequently used in combination with exercise to provide early mobilisation for the person.

Nursing care

Nursing care of the person with lower back pain focuses on relieving the pain. In addition, most people have very little understanding of the anatomy of the spine, the reasons for the pain, the choices for treatment and the importance of self-management. Therefore, education is another essential aspect of treating lower back pain.

Health promotion

Recommendations for preventing back pain from the National Institute of Neurological Disorders and Stroke (2015) include the following:

- Have a regular exercise program.
- Stretch before working in the garden, jogging and playing sports.
- Quit smoking.
- Lose weight, if needed.
- Maintain a correct posture.
- Use supportive seats when driving.
- Lift by bending at the knees rather than at the waist.
- Reduce emotional stress that causes muscle tension.

In industrial and work settings, nurses should be alert for situations that increase the risk of back pain and injury. Office workers should have chairs with appropriate seat height and length and back support. Modifications of work space or machinery may be necessary for industrial workers to avoid excess stresses on back muscles. Finally, it is important to remember that back pain is a leading cause of lost work time for nurses themselves. Remind co-workers to use good body mechanics and to seek help when lifting or moving people.

Nursing diagnoses and interventions

Nursing interventions for the person with lower back pain are based on problems with acute pain, deficient knowledge and risk of impaired adjustment.

Acute pain

Muscle spasms and inflammation are among the contributing factors of lower back pain.

- Teach the person appropriate comfort measures. *People with lower back pain have discomfort due to muscle spasms and/or inflammation due to nerve compression, surgery or irritation from a brace.*
- Instruct the person to take NSAIDs or analgesics on a routine schedule rather than as needed. *Maintaining a constant blood level of the NSAIDs or analgesics reduces inflammation and provides continuous pain relief.*

Deficient knowledge

The person with lower back pain requires information regarding treatment modalities.

- Encourage the person to stay active. *There is little scientific evidence to show that bed rest is beneficial, but there is ample evidence about the adverse effects of bed rest. Staying in bed for more than 1 to 2 days can actually increase pain and cause joint stiffness and muscle weakness.*
- Teach the person about the 'rebound phenomenon' of prolonged heat or ice therapy. *Ice remaining on the skin longer than 15 minutes or heat longer than 30 minutes causes a reverse effect known as the rebound phenomenon. For example, heat produces maximum vasodilation in 20 to 30 minutes. Continuation of the application beyond 30 to 45 minutes causes tissue congestion and the blood vessels constrict. Likewise, with cold application, maximum vasoconstriction occurs when the skin reaches a temperature of 15°C. Prolonged cold can create a drop in temperature, at which time vasodilation occurs.*
- Provide instructions about appropriate back exercises such as partial sit-ups with the knees bent and knee–chest exercises to stretch hamstrings and spinal muscles. Each exercise should be done 5 times and gradually increased to 10 times. Advise the person to discontinue any exercise that is painful and to seek professional advice before continuing the exercise. *Repetition of prescribed back exercises, such as the pelvic tilt, partial sit-ups and back rolls, will strengthen the muscles that protect the spine and thus prevent back strain.*

Risk of impaired adjustment

The need for lifestyle changes may lead to impaired adjustment in people with back pain.

- Teach the use of appropriate body mechanics in lifting and reaching. The person should be instructed to plan the lift, keep the object being lifted close to the body and avoid twisting when lifting. Encourage the person to obtain help when lifting. *An item is considered excessively heavy if it equals 35% of the lifter's body weight.*
- Instruct the person to modify the workplace or environment to minimise stress to the lower back. *Lumbar supports in chairs, adjustment of chair or table height, and rubber floor mats help prevent back strain or injury.*
- Encourage obese people to lose weight. The trunk of the body must carry excess weight when the person is obese. *Obese people are further away from the objects they lift because of their greater abdominal girth. They may also have more difficulty squatting to lift. The greater the distance between an object and the person's centre of gravity, the higher the risk of straining the lower back.*

Community-based care

Back pain is a common problem in Australia and other industrialised countries. Nurses can have an effect on this significant problem by teaching health practices to prevent back injury to people of all ages. Teach people how to safely lift, bend and turn when engaging in physical activity. Stress the importance of using the large muscle groups of the legs to lift rather than bending and lifting with the smaller muscles of the back. Teach other aspects of good body mechanics, including posture, sleeping on a firm mattress and sitting in chairs that provide good support. Discuss the positive effect of maintaining optimal body weight and good physical fitness.

THE PERSON WITH COMMON FOOT DISORDERS

Hallux valgus, hammer toe and Morton's neuroma are common foot disorders that cause pain or difficulty in walking. All three disorders may be caused by wearing poorly fitting or confining shoes. These disorders are more prevalent among women.

Pathophysiology

Hallux valgus

Hallux valgus, commonly called a *bunion*, is the enlargement and lateral displacement of the first metatarsal (the great toe) (see Figure 39.12). Hallux valgus develops when chronic pressure against the great toe causes the connective tissue in the sole of the foot to lengthen so that the stabilising action of the great toe is gradually lost. The toe bends laterally away from the midline of the body and the metatarsophalangeal joint (MTP) is exposed to friction during walking and becomes enlarged. As the deformity progresses, calluses form over the metatarsal head and bursitis develops in the MTP. In severe cases, the lateral displacement of the great toe may approach 70 to 90 degrees and the second toe may be forced upwards, causing hammer toe. Although bunions may be a congenital disorder, most are caused by wearing pointed, narrow-toed shoes or high heels.

Hallux valgus is obvious on physical examination of the foot. The person may report an inability to fit into shoes. Often, the person may report joint pain or pain around calluses. In advanced or severe cases, the first metatarsal joint may have limited range of motion, particularly in dorsiflexion, and crepitus (crackling or popping) may occur during joint movement.

Hammer toe

Hammer toe (claw toe) is the dorsiflexion of the first phalanx with accompanying plantar flexion of the second and third phalanges. The condition may affect any toe, but the second toe is most commonly affected. People initially experience mild inflammation of the synovial membranes of the involved joints. As the deformity progresses, the dorsiflexed joint rubs against the overlying shoe, causing painful corns to develop.

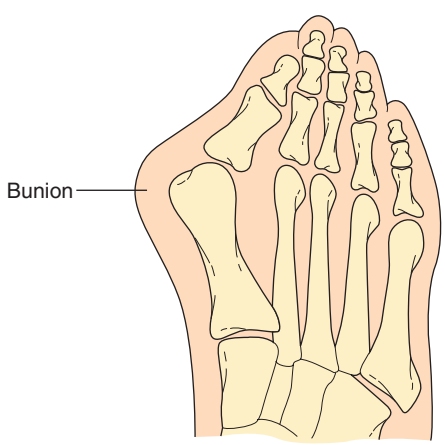

FIGURE 39.12 ■ Hallux valgus (bunion)

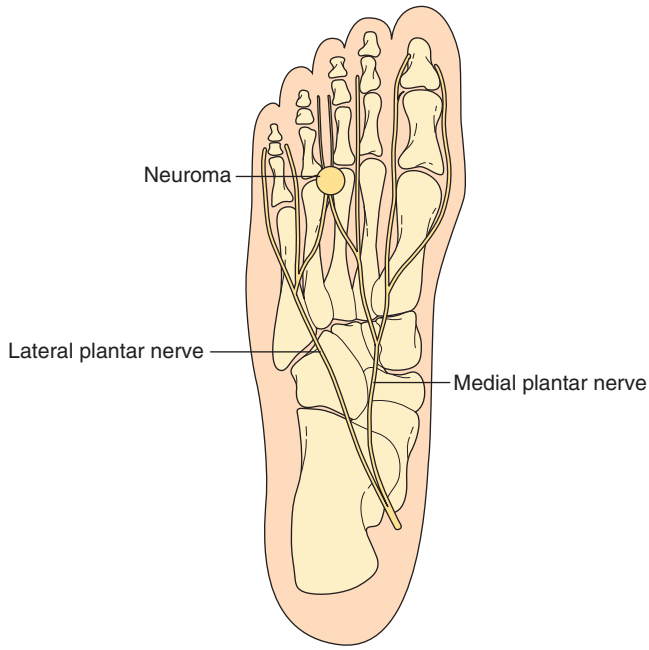

FIGURE 39.13 ■ Morton's neuroma

Morton's neuroma

Morton's neuroma is a tumour-like mass formed within the neurovascular bundle of the intermetatarsal spaces (see Figure 39.13). The neuromas usually occur in only one foot, most frequently in the third web space. Like other common foot disorders, Morton's neuroma usually is caused by wearing tight, confining shoes. The condition develops when repeated compression of the toes causes irritation and scarring of tissues surrounding the plantar digital nerve. The affected nerve becomes inflamed and swells. After repeated episodes of inflammation, the nerve fibres become fibrotic and a neuroma forms.

Manifestations include a burning pain at the web space of the affected foot that radiates into the tips of the involved toes. Weight bearing usually worsens any symptoms; removing the shoe and massaging the foot often relieves the pain. The neuroma may present as a palpable mass between the affected toes. The area over the neuroma usually is tender.

INTERPROFESSIONAL CARE

Care of the person with common foot disorders such as hallux valgus, hammer toe and Morton's neuroma focuses on relieving pain, correcting the structural deformity and preventing re-occurrence. In most cases, all three conditions are diagnosed by inspection. X-ray films of the affected foot are taken if the need for surgery arises.

Conservative treatment for common foot disorders usually involves the use of corrective shoes. Orthotic devices that cushion and stretch the affected joints may be placed within shoes or between the person's toes. For Morton's neuroma, metatarsal pads are used to spread the person's toes and

decompress the affected nerve. Analgesics may be prescribed to relieve pain and inflammation. In severe cases, corticosteroid drugs may be injected into the affected joints or surrounding tissue to relieve acute inflammation.

Surgery is reserved for people with intractable toe deformities or pain. Hallux valgus is treated with bunionectomy; ligaments are lengthened or shortened as needed, and pins are drilled into place so the toe remains in position. Similarly, the correction of hammer toe also involves straightening the affected toe and inserting pins to retain the correction. A cast may be applied over the foot following surgery to correct toe deformities. Surgery for Morton's neuroma causes loss of sensation to a portion of the foot because removing the neuroma involves cutting out a portion of the plantar nerve.

Nursing care

Nursing care for people with these foot deformities focuses on the same areas because the conservative treatment and preoperative and postoperative interventions are similar.

Nursing diagnoses and interventions

Pain relief, prevention of infection and person education are important components of the nursing care of people with foot disorders.

Chronic pain

In the person with a foot deformity, constant pressure of footwear over the involved joint can cause pain.

- Instruct people to wear corrective footwear to assist in the conservative treatment of foot problems. *Pain related to foot problems can result from improper footwear that does not provide proper toe room; in addition, heels higher than 2.5 cm can cause constant flexion and hyperextension problems. In some instances, the person must purchase special shoes or orthotics to ensure correct fit and relief of symptoms.*
- Suggest purchasing appropriate pads to wear over painful bunions, calluses/corns and the ball of the foot. *Protective pads are manufactured for specific foot problems; these include bunion pads, corn pads and metatarsal pads.*
- Instruct people to remove pads and inspect the skin every other day. *People who have difficulty reaching or observing the involved foot should ask another person to do the inspection for them. It is especially important to emphasise the need for inspection to people who have experienced loss of sensation of the feet due to such disorders as diabetes and chronic peripheral vascular disease.*

Risk of infection

Like all surgeries, foot surgery carries a risk of infection. This risk may be increased because of impaired peripheral circulation and exposure of the feet to the environment.

- Teach people proper care and cleaning of exposed pins implanted during the surgical procedure. *Pins inserted into soft tissue of the toes and bones are prone to becoming infected and can potentially result in osteomyelitis.*
- Teach people how to keep pins and casts dry while bathing or ambulating in inclement weather. *People must wear a plastic bag over the cast or pins when bathing or walking in rain or snow. When casts or pins are exposed in water, infection may result.*

Community-based care

For people in all age groups, teach the importance of well-fitting footwear. Discuss the long-term effects of wearing high-heeled shoes with constricting toes, with women in particular. Suggest alternatives for stylish footwear and encourage people to wear supportive and non-restrictive footwear at all times. Discuss the possible effects of bunions on balance and talk about safety measures to prevent falls and injury. Teach people techniques to relieve pressure on affected joints.

CHAPTER HIGHLIGHTS

- Metabolic bone disorders begin in the bone remodelling process and may result from ageing, calcium and phosphate imbalances, genetics and changes in hormone levels. The disorders include osteoporosis, Paget's disease, gout and osteomalacia.
- Osteoporosis is a major health problem in Australia, with fractures being the most common complication. Health promotion activities to prevent development of the disease include a calcium-rich diet, weight-bearing exercise and a healthy lifestyle.
- Gout is characterised by hyperuricaemia and the deposit of tophi in the subcutaneous tissues. Attacks of the disease typically begin with an acutely painful inflammation of the first joint of the great toe.
- Degenerative musculoskeletal disorders include osteoarthritis (OA) and muscular dystrophy (MD). OA is the most commonly occurring of all forms of arthritis and a leading cause of pain and disability in older adults. The disease is characterised by loss of cartilage in articulating joints and hypertrophy of bone at the articular margins. Pain and inflammation are most often conservatively managed with NSAIDs.
- If pain and disability are not controlled in people with arthritis, total joint replacements may be performed.
- Autoimmune and inflammatory disorders of the musculoskeletal system include rheumatoid arthritis (RA), ankylosing spondylitis (AS), reactive arthritis (ReA), systemic lupus erythematosus (SLE) and polymyositis.
- Although the cause of RA is unknown, it is believed to be a combination of genetic, environmental, hormonal and reproductive factors. RA is a systemic disease, affecting one or many joints with the risk of severe contractures and deformity and also causes fatigue, weakness, anorexia,

weight loss and fever. The primary objectives of treatment and care are to reduce pain and inflammation, preserve function and prevent deformity.

- SLE is a chronic inflammatory connective tissue disease, affecting almost all body systems, including the musculoskeletal system. Skin lesions are a common manifestation, exhibited by a characteristic rash on the face. The person with SLE is at increased risk of infection.
- Osteomyelitis and septic arthritis are infectious musculoskeletal disorders. Osteomyelitis may be the result of a blood-borne pathogen, a contiguous infection or a complication of vascular insufficiency. Septic arthritis is a medical emergency, requiring immediate treatment to preserve joint function.
- Bone tumours may be benign or malignant, primary or metastatic. The primary manifestations of a bone tumour are pain, a mass and impaired function. Nursing care is directed towards teaching to prevent injury and interventions to relieve pain.
- Scleroderma is a chronic disease characterised by the formation of excess connective tissue and diffuse fibrosis of the skin and internal organs. It may be either localised or generalised. Other connective musculoskeletal disorders are Sjögren's syndrome and fibromyalgia.
- Structural musculoskeletal disorders affecting the spine are manifested by scoliosis, kyphosis and lower back pain. Those commonly affecting the feet are hallux valgus, hammer toe and Morton's neuroma.

CONCEPT CHECK

1 Although all of the following nursing diagnoses are important when planning care for the person with osteoporosis, which is most significant in terms of long-term disability?
1 *Chronic pain*
2 *Risk of falls*
3 *Activity intolerance*
4 *Acute pain*

2 You are preparing a teaching plan for a woman with osteoarthritis. Which group of medications should you prepare to discuss?
1 opioids
2 antibiotics
3 hormones
4 NSAIDs

3 You are monitoring the laboratory reports for a person with an acute attack of gout. Which of the following measurements would you expect to be increased?
1 haematocrit
2 uric acid
3 alkaline phosphatase
4 creatinine

4 What is a potential complication of both osteoporosis and osteomalacia?
1 infection
2 blood clots
3 fractures
4 contractures

5 You are assessing a woman who has come to an orthopaedic clinic complaining of knee pain. Which of the following assessments you made would indicate an increased risk of osteoarthritis?
1 being overweight by 15 kg
2 having a history of falls
3 eating a diet high in calcium
4 walking 30 minutes each day

6 A postoperative nursing care plan for a person who has had a total knee replacement includes monitoring vital signs and laboratory results. The rationale for these interventions is to:
1 teach the person the importance of these assessments
2 promote rapport between the person and the healthcare providers
3 ensure adequate circulation to the involved extremity
4 prevent the progression of infection

7 When comparing osteoarthritis and rheumatoid arthritis, what assessment finding would be different in the person with rheumatoid arthritis?
1 Health history includes weight loss and fever.
2 Abnormal joint findings are limited to the hands.
3 Stiffness is relieved by activity.
4 Heberden's nodes are located on the finger joints.

8 *Ineffective protection* is an appropriate nursing diagnosis for the person with SLE. What would be your most important intervention for the hospitalised person?
1 Monitor laboratory findings.
2 Provide appropriate skin care.
3 Practise careful handwashing.
4 Administer prescribed medications.

9 Of the different types of arthritis, which one is considered a medical emergency, requiring immediate diagnosis and treatment?
1 osteoarthritis
2 septic arthritis
3 reactive arthritis
4 gouty arthritis

UNIT 10 BUILDING CLINICAL COMPETENCE

Responses to altered musculoskeletal function

CLINICAL SCENARIO

- You have been assigned to work with the following four people for the 0700 shift on an orthopaedic unit. Significant data obtained during report are as follows:
- Barry Drummond is a 70-year-old Indigenous man with type 2 diabetes mellitus who is 3 days postoperative with bilateral below-the-knee amputations. Vital signs are T 37.2°C, P 88, R 24, BP 150/92. He is complaining of feeling pain in his feet.
- Joyce Stevens is an 84-year-old who is 2 days postoperative for hip replacement surgery. Her vital signs are T 37.5°C, P 100, R 30 and shallow, BP 110/86. She is confused when spoken to. Petechiae have been noted on her arms and legs. She is complaining of difficulty breathing.
- James Gunning, a 21-year-old, was admitted with osteomyelitis of the upper right leg. He has a history of a gunshot wound to the leg. Vital signs are T 39.2°C, P 98, R 22, BP 138/80. He is scheduled for surgical debridement of the wound this morning. He is complaining of pain and requesting pain medication.
- Kim Wong is a 30-year-old who was admitted with manifestations of painful and swollen joints, muscle pain, pale and cyanotic fingers and toes and oedema of the legs and periorbital areas. Her vital signs are T 38.1°C, P 78, R 16, BP 108/72. She is complaining of extreme fatigue. She is to have blood drawn for complete blood count (FBC), anti-DNA antibody testing and serum complement levels.

Critical thinking questions

1 In what order would you visit these people after report?

1.
2.
3.
4.

2 What top two priority nursing diagnoses would you choose for each of the people presented above? Can you explain, if asked, the rationale for your choices?

	Priority Nursing Diagnosis #1	Priority Nursing Diagnosis #2
Barry Drummond		
Joyce Stevens		
James Gunning		
Kim Wong		

3 After the amputation wound is dressed, what is the person taught to do to toughen the stump?

1. Dangle the stump for 20 minutes every hour while awake.
2. Push the stump into soft and then harder surfaces.
3. Elevate the stump on two pillows, keeping the knee straight.
4. Apply prosthesis over the compression dressing.

4 To prevent hip contractures in the person with an above-the-knee amputation, what does the nurse instruct the person to do?

1. Lie supine for short periods throughout the day.
2. Elevate the stump above the level of the heart.
3. Perform active range-of-motion exercises every 8 hours.
4. Avoid sitting in a chair for prolonged periods of time.

5 The nurse explains to the person with gout that a low-purine diet is recommended. The person understands a low-purine diet when which meal is ordered?

1. ham and asparagus casserole
2. chicken and potatoes
3. chilli and spinach salad
4. prawn and scallop pasta

6 The person's laboratory results are haematocrit of 28%, haemoglobin of 8 g/dL, WBC count of 4000/mm^3, platelet count of 98 000/mL, eosinophil sedimentation rate of 100 mm/h, positive anti-DNA antibodies. What medical diagnosis is supported by these lab values?

1. systemic lupus erythematosus
2. rheumatoid arthritis
3. ankylosing spondylitis
4. polymyositis

7 People who have autoimmune diseases such as systemic lupus erythematosus are at increased risk of developing what disease?

1. chronic renal failure
2. hypertension
3. liver insufficiency
4. coronary heart disease

8 A prescription for ibuprofen (Nurofen) is given on discharge to the person with rheumatoid arthritis. Which toxic effects of the medication does the nurse instruct the person about?

1. diarrhoea, nausea and vomiting
2. blurred vision, tinnitus and headache
3. gastric irritation, ulceration and bleeding
4. dizziness, dry mouth and abdominal cramps

9 When performing a neurovascular assessment, which are included in the initial and focused assessments? (Select all that apply.)

1. pain
2. paroxysm
3. pallor
4. pulses
5. paresis
6. pallaesthesia
7. paraesthesia

10 Which person is at greatest risk of developing osteoporosis?

1. menopausal, Caucasian woman who smokes one packet of cigarettes a day
2. menopausal, Indigenous Australian woman who has diabetes and hypertension
3. premenopausal, underweight Asian woman who is allergic to dairy products
4. premenopausal, obese Indigenous woman who has a sedentary lifestyle

11 An older adult sprained an ankle after tripping on an uneven footpath. Which is the most important intervention?

1. Use a walker when ambulating.
2. Take anti-inflammatory and pain medications to reduce ankle pain.

3. Follow a regimen of rest, ice, compression and elevation.
4. Immobilise the ankle with an air splint.

12 Which actions by the nurse need to be followed when caring for the person with osteomyelitis?

1. Place the person in a private room and use gloves and gown with wound care and good handwashing.
2. Place the person in a semiprivate room with another infected person and use isolation precautions for both people.
3. Place the person near the nurse's station and use standard precautions when caring for the person.
4. Place the person at the end of the hall away from other people to prevent spread of infection and teach the person to use good handwashing.

CASE STUDY

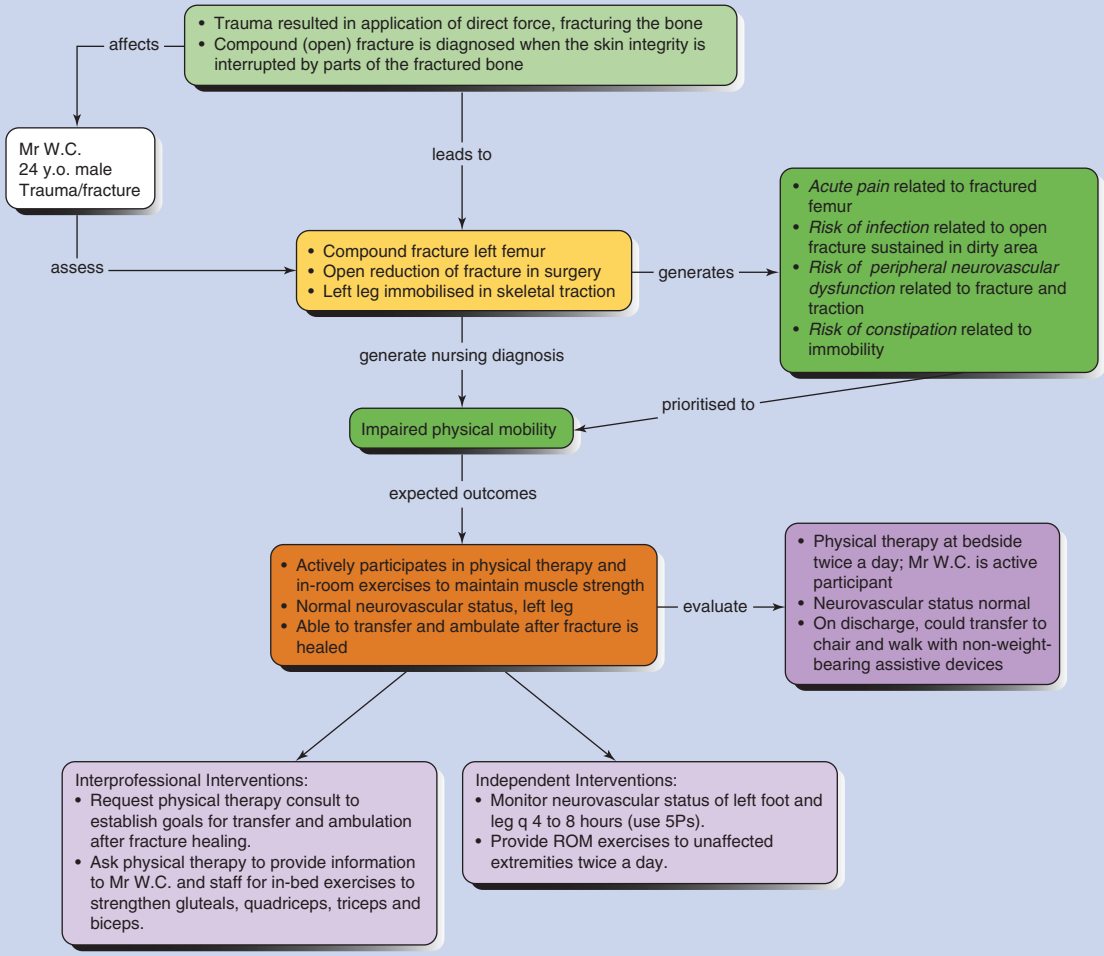
William Comfort is a 24-year-old Caucasian male admitted with a compound fracture of the left femur. He states he was quad biking on a hillside footpath and was thrown from the vehicle. He slid approximately 30 metres down the hill on his left side. His fall was stopped when his foot became tangled in some bushes. On admission, his vital signs were T 37.7°C, P 100 and thready, R 24, BP 116/70. His height is 1.88 m and weight is 89 kg. Assessment revealed an open fracture of the left leg with bleeding and oedema around the open site and severe pain on movement of the leg. Popliteal and pedal pulses are difficult to palpate. His left leg is pale and cool to touch with a capillary refill of 4 seconds. He states his leg feels numb. Multiple lacerations and abrasions are noted on his left trunk and arm. He states he does not have any medical problems and has not seen a doctor in the past 5 years. He is employed as a computer technician. He lives in an apartment with two friends.

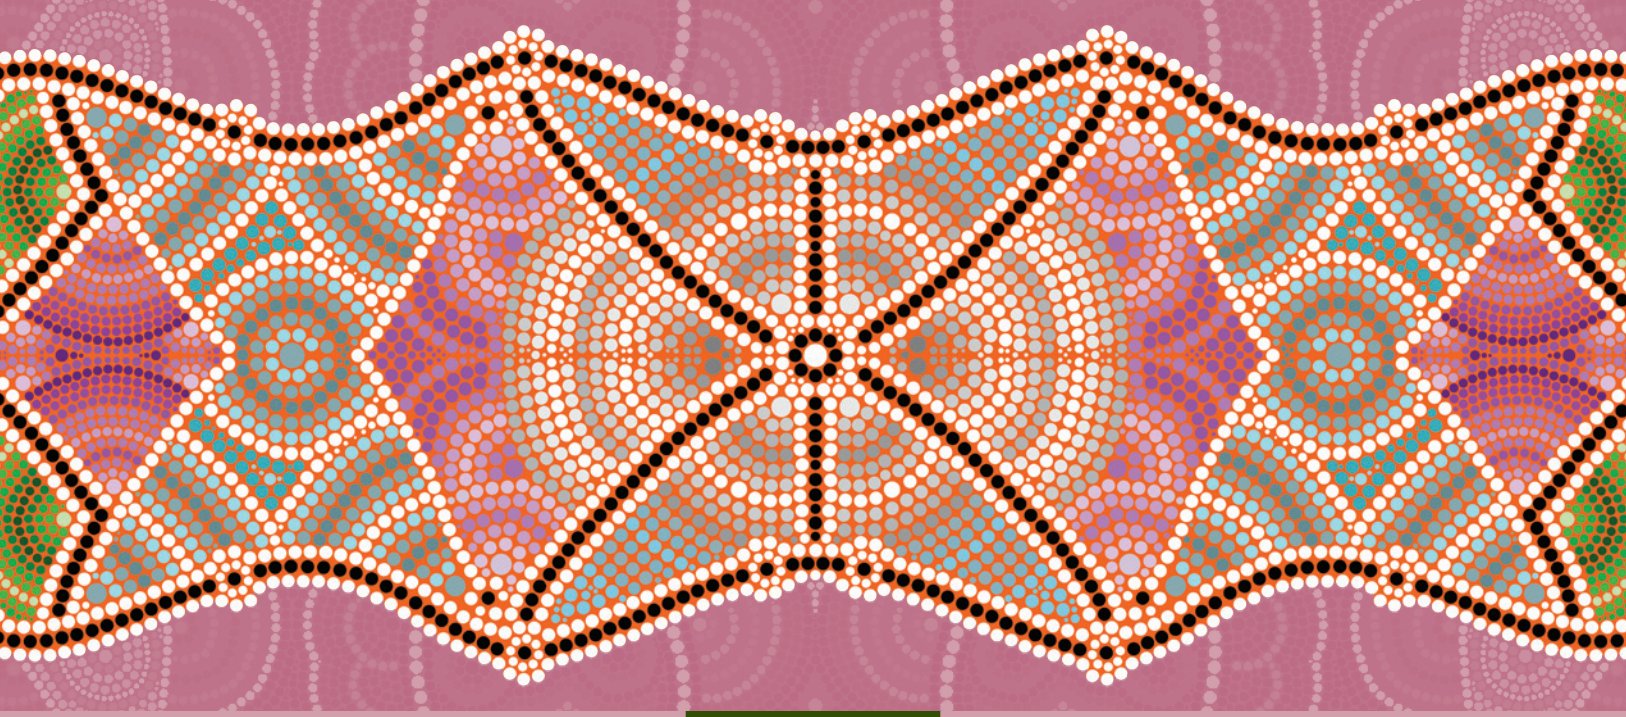
Blood is drawn for a baseline compete blood count (FBC) and urine is obtained for a urinalysis. An intravenous line is started in the right arm with Hartmann's solution infusing at 150 mL/h. He is given a tetanus toxoid immunisation and is medicated with morphine sulfate for pain. X-rays are taken of the left leg, left arm and abdomen. The wounds are cleansed with an antibacterial solution and antibiotic ointment is applied. He went to surgery for an open reduction of the left leg fracture and has been placed in skeletal traction to separate the bony fragments and reduce and immobilise the left leg fracture.

The pathophysiology of a femur fracture is a large amount of force applied to the shaft of the femur, resulting in breaking of the bone. An open fracture is diagnosed when the bone is broken with bone fragments protruding through the skin. Manifestations of a femur fracture are oedema and a deformed and painful thigh. The person is unable to move the hip or knee. Popliteal and pedal pulses are difficult to palpate. Capillary refill time is increased. Pallor and coolness indicate arterial compromise. Sensations to the leg may be burning, numbness, prickly feeling or stinging. Complications of a femur fracture include hypovolaemia, fat embolism, dislocation of the hip or knee, muscle atrophy and ligament damage.

Skeletal traction is the application of a pulling force through placement of pins into the bone. Pins are inserted under sterile conditions into the bone. One or more pulling forces may be applied to maintain alignment of the femur fracture. The disadvantages of skeletal traction are increased anxiety, increased risk of infection and increased discomfort.

When planning nursing care for Mr Comfort, the nursing diagnosis of *Impaired physical mobility* related to fracture of the left femur with skeletal traction is appropriate for implementing nursing interventions.





UNIT 11

RESPONSES TO ALTERED NEUROLOGICAL FUNCTION

CHAPTER 40

A PERSON-CENTRED APPROACH TO ASSESSING THE NERVOUS SYSTEM

DEBRA RAYMOND

KEY TERMS

LEARNING OUTCOMES

- Describe the anatomy, physiology and functions of the nervous system.
- Identify specific topics for consideration during a health history assessment interview of a person with a neurological disorder.
- Explain techniques for assessment of neurological function, including examinations of mental status, cranial nerves, sensory nerves, motor nerves, cerebellar function and reflexes.
- Identify manifestations of impairment of neurological function.
- Describe normal variations in assessment findings for the older adult.

CLINICAL COMPETENCIES

- Conduct and document a health history for a person with or at risk of alterations in the neurological system.
- Conduct and document a physical assessment of neurological structures and functions.
- Perform specific neurological assessments for people with suspected meningeal irritation and for people who are disoriented or comatose.
- Monitor the results of diagnostic tests and report abnormal findings.

EQUIPMENT NEEDED

- Cotton balls
- Safety pin
- Tongue depressor
- Tuning fork
- Reflex hammer
- Pencil and paper
- Penlight
- Printed materials
- Substances to test the senses of smell and taste

The nervous system regulates and integrates all body functions, muscle movements, senses, mental abilities and emotions. It collects information from the internal and external environments as sensory input, processes and interprets the input and causes responses that are manifested as motor or sensory output.

ANATOMY, PHYSIOLOGY AND FUNCTIONS OF THE NERVOUS SYSTEM

The nervous system is divided into two regions: the central nervous system (CNS), which consists of the brain and spinal cord; and the peripheral nervous system (PNS), which consists of the cranial nerves, the spinal nerves and the autonomic nervous system.

Nerve cells, action potentials and neurotransmitters

The highly integrated CNS and PNS consist of only two types of cells: neurons, which receive impulses and send them on to other cells; and neuroglia, which protect and nourish the neurons.

Neurons

Each neuron consists of a dendrite, a cell body and an axon (see Figure 40.1). The dendrite is a short process (projection) from the cell body that conducts impulses towards (afferent) the cell body. Cell bodies, most of which are located within the CNS, are clustered in ganglia or nuclei. The cell bodies and dendrites comprise what is often called the grey matter of the CNS. The axon, a long process, conducts impulses away (efferent) from the cell body. Many axons are covered with a myelin sheath, a white lipid substance. It is interrupted at intervals in unmyelinated areas called nodes of Ranvier, which allow movement of ions between the axon and the extracellular fluid. The myelin sheath serves to increase the speed of nerve impulse conduction in axons and is essential for the survival of larger nerve processes. Myelinated nerve fibres comprise the white matter of the brain and spinal cord.

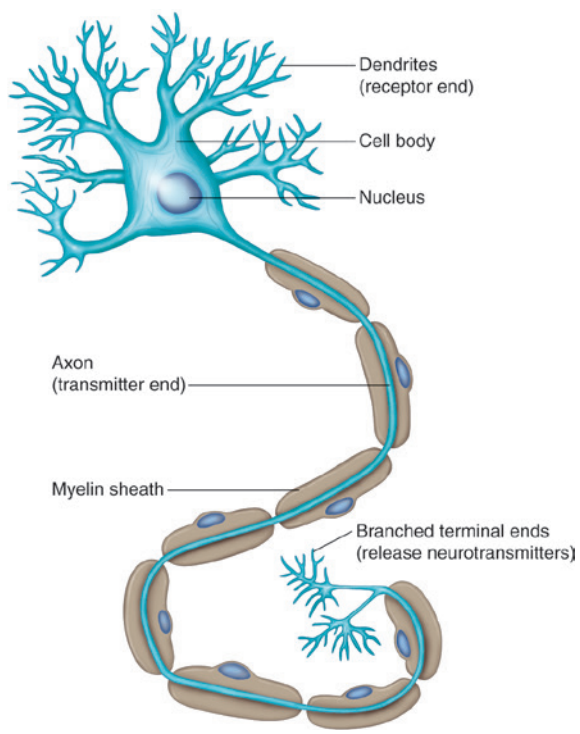


FIGURE 40.1 ■ A typical neuron

Neuroglia

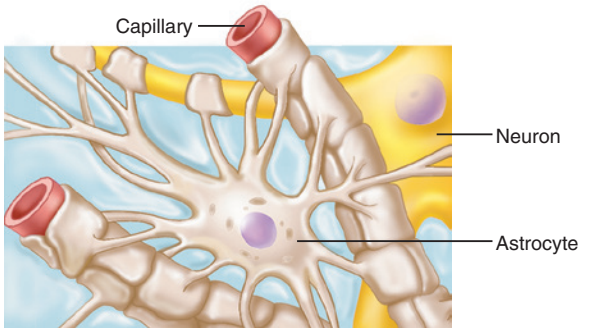
Neuroglia or glia cells are divided into six types of neuroglia—two in the PNS, which are *satellite cells* which surround neuron cell bodies with ganglia, and *Schwann cells* which surround and form myelin sheaths around the larger nerve fibres in the PNS (see Figure 40.2). The four types of neuroglia cells in the CNS are: *astrocytes* which support and bind and nourish the neurons; *oligodendrocytes* that produce myelin that surrounds axons within the CNS forming the myelin sheath; *ependymal cells* that line the central cavities of the brain and the spinal cord and function in the production of cerebral spinal fluid (CSF); and *microglia* which have a phagocytic function and assist in the removal of microorganisms or neuronal debris (Marieb & Hoehn, 2015).

Action potentials

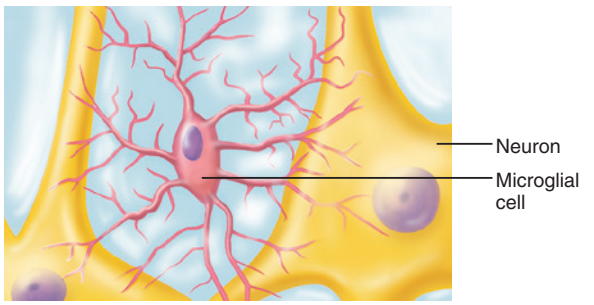
Action potentials are impulses (movements of electrical charge along an axon membrane) that allow neurons to communicate with other neurons and body cells. They are initiated by stimuli and propagated by the rapid movement of charged ions through the cell membrane. When a neuron reaches a certain level of stimulation, an electrical impulse is generated and conducted along the length of its axon. The movement of impulses to and from the CNS is made possible by afferent and efferent neurons. Afferent, or sensory, neurons have receptors in skin, muscles and other organs and relay impulses to the CNS. Efferent, or motor, neurons transmit impulses from the CNS to cause some type of action.

Nerve impulses occur when a stimulus reaches a point great enough to generate a change in electrical charge across the cell membrane of a neuron. A neuron that is not involved in impulse conduction is in a resting, or polarised, state, in which the number of positive ions in the fluid outside the cell membrane is greater than in the fluid within the cell. The chief regulators of membrane potential are sodium and potassium: sodium is the main positive ion in the extracellular fluid and potassium is the main positive ion in the intracellular fluid. In response to an electrical stimulus, the cell membrane becomes permeable to sodium, which moves into the cell. This changes the polarity of the cell membrane and the neuron is said to depolarise. This event stimulates an action potential, or a nerve impulse, to travel down the axon. When the charges and ions return to their original resting state, the neuron is repolarised. The events in an action potential are as follows:

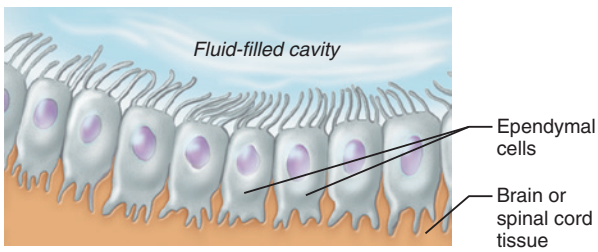
1. Initially, sodium permeability increases. As the membrane is depolarised, sodium channels open and sodium rushes into the cell to a point of depolarisation. (The inside of the cell becomes less negative in comparison to the outside of the cell.)



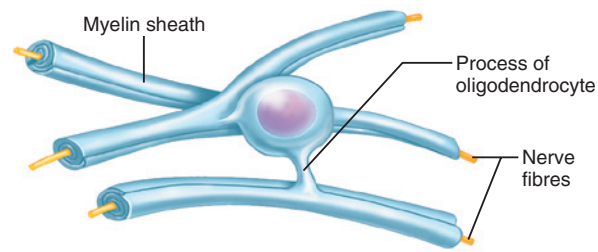
(A) Astrocytes are the most abundant CNS neuroglia



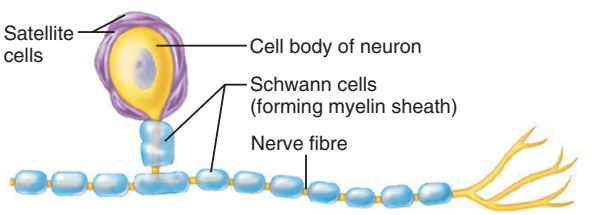
(B) Microglial cells are defensive cells in the CNS



(C) Ependymal cells line cerebrospinal-fluid-filled cavities



(D) Oligodendrocytes have processes that form myelin sheaths around CNS nerve fibres



(E) Satellite cells and Schwann cells (which form myelin) surround neurons in the PNS

FIGURE 40.2 ■ Neuroglia. *A–D*, Supporting cells of the CNS. *E*, Supporting cells of the PNS

Source: E. N. Marieb & K. N. Hoehn (2015). *Human anatomy and physiology* (10th ed.). Upper Saddle River, NJ: Pearson Education. © 2015. Printed and electronically reproduced by permission of Pearson Education, Inc.

2. This is followed by a decrease in sodium permeability, lasting only about 1 millisecond. The sodium gates close and the sodium influx stops.
3. The final event is an increase in potassium permeability. The potassium gates open, potassium rushes out of the cell and the cell interior becomes progressively less positive. The membrane potential moves back to its resting state and is repolarised.

The action potential is generated only at the point of the stimulus; but, once generated, it is propagated along the entire length of the axon regardless of whether the stimulus continues. Conduction of the impulse is rapid in myelinated fibres, with the action potential 'jumping' from one node of Ranvier to the next. The conduction of the impulse is slower in unmyelinated fibres.

Neurotransmitters

Neurotransmitters are the chemical messengers of the nervous system. When the action potential reaches the end of the axon at the presynaptic terminal, a neurotransmitter is released and travels across the synaptic cleft to bind with receptors in the postsynaptic neuron dendrite or cell body. The neurotransmitter may either be inhibitory or excitatory. The excitatory neurotransmitter is almost always acetylcholine (ACh), which is rapidly degraded by the enzyme acetylcholinesterase. Noradrenaline (NA), which may be either excitatory or inhibitory, is another major neurotransmitter.

Nerves that transmit impulses through the release of ACh are called *cholinergic*. Receptors that bind ACh are found in the viscera, skeletal muscle cells and the adrenal medulla (where they stimulate the release of adrenaline). The effect of ACh binding may be either to stimulate or to inhibit a response.

Nerves that transmit impulses through the release of NA are called *adrenergic*. Receptors that bind NA are found in the heart, lungs, kidneys, blood vessels and all target organs stimulated by the sympathetic division except the heart. Adrenergic receptors are further divided into alpha and beta types. Alpha-adrenergic receptors help control such varied functions as arterial vasoconstriction and pupil dilation. Beta-adrenergic fibres may be either $beta_1$- or $beta_2$-receptors. $Beta_1$-receptors are found in the heart, where they regulate the rate and force of contraction. $Beta_2$-receptors are found in receptor cells of the lungs, arteries, liver and uterus; they help regulate bronchial diameter, arterial diameter and glycogenesis. Generally, binding of NA to alpha-receptors stimulates a response, whereas binding to beta-receptors inhibits a response.

Other neurotransmitters include gamma aminobutyric acid (GABA), which inhibits CNS function; dopamine, which may be inhibitory or excitatory and helps control fine movement and emotions; and serotonin, which is usually inhibitory and controls sleep, hunger and behaviour and also affects consciousness.

The central nervous system

The central nervous system consists of the brain and spinal cord, highly evolved clusters of neurons that act to accept, interconnect, interpret and generate a response to nerve impulses originating throughout the body.

The brain

The brain is the control centre of the nervous system and also generates thoughts, emotions and speech. Males and females have equivalent brain sizes, averaging 1450 g in weight for a female and 1600 g for a male. The brain is surrounded by the skull, a bony structure that provides support and protection. The brain has four main regions: the cerebrum, the diencephalon, the brainstem and the cerebellum (see Figure 40.3). The general functions of these regions are summarised in Table 40.1.

The two hemispheres of the cerebrum account for almost 60% of brain weight. The surface of the cerebrum is folded into elevated ridges of tissue called gyri, which are separated by shallow grooves called sulci. Deep grooves, called fissures, further divide the surface of the cerebrum. The longitudinal fissure separates the hemispheres and the transverse fissure separates the cerebrum from the cerebellum. In addition, each cerebral hemisphere is divided into frontal, parietal, temporal and occipital lobes (see Figure 40.4).

The cerebral hemispheres are connected by a thick band of nerve fibres called the corpus callosum, which allows communication between the two hemispheres. Each hemisphere receives sensory and motor impulses from the opposite side of the body. One of the cerebral hemispheres tends to develop more than the other. Most people have a more highly developed left hemisphere, which is responsible for the control of language. The right hemisphere has greater control over nonverbal perceptual functions.

The cerebral cortex is the outer surface of the cerebrum. It consists of neuron cell bodies, unmyelinated fibres, neuroglia and blood vessels. The functions of the different lobes of the cerebrum and the specific areas of the cerebral cortex are shown in Figure 40.4 and listed in Table 40.2.

The diencephalon is embedded in the cerebrum superior to the brainstem. It consists of the thalamus, hypothalamus and epithalamus (see Figure 40.3). The thalamus begins to process sensory impulses before they ascend to the cerebral cortex. It serves as a sorting, processing and relay station for input into the cortical region. The hypothalamus, located inferior to the thalamus, regulates temperature, water metabolism, appetite, emotional expressions, part of the sleep–wake cycle and thirst. The epithalamus forms the dorsal part of the diencephalon and includes the pineal body, which is part of the endocrine system that affects growth and development.

BRAINSTEM The brainstem consists of the midbrain, pons and medulla oblongata (see Figure 40.3). The midbrain is a centre for auditory and visual reflexes. In addition, it functions

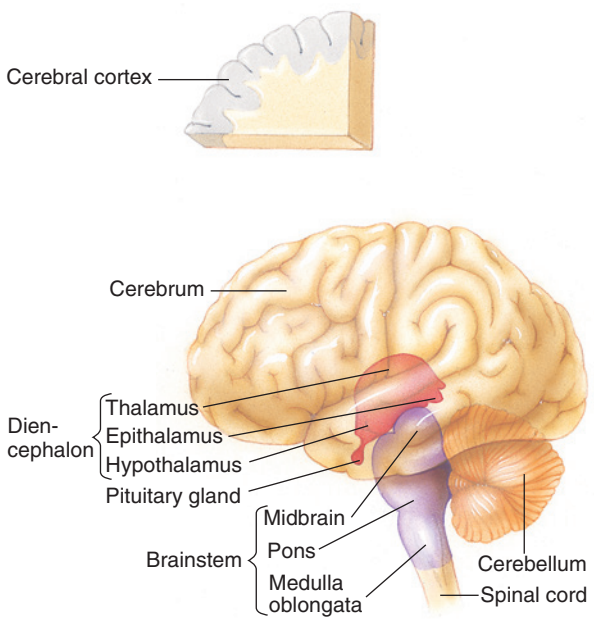


FIGURE 40.3 ■ The four main regions of the brain

TABLE 40.1 General functions of the four regions of the brain

REGION	FUNCTIONS
Cerebrum	Interprets sensory input. Controls skeletal muscle activity. Processes intellect and emotions. Contains skills memory.
Diencephalon	Conducts sensory and motor impulses. Regulates autonomic nervous system. Regulates and produces hormones. Mediates emotional responses.
Brainstem	Serves as conduction pathway. Serves as site of decussation of tracts. Contains respiratory nuclei. Helps regulate skeletal muscles.
Cerebellum	Processes information. Provides information necessary for balance, posture and coordinated muscle movement.

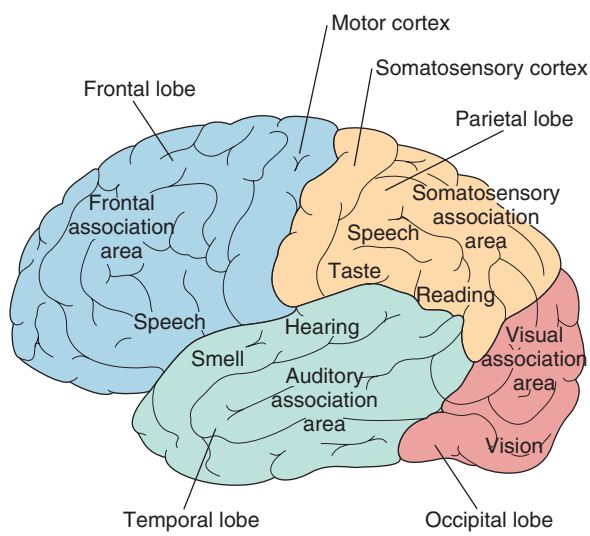

FIGURE 40.4 ■ Lobes of the cerebrum and functional areas of the cerebral cortex

TABLE 40.2 Functions of lobes of the cerebrum and areas of the cerebral cortex

AREA	FUNCTIONS
Parietal lobe (somatic sensory area of cerebral cortex)	Promotes recognition of pain, temperature and light touch. The left side receives input from the right side of the body, and vice versa.
Occipital lobe	Receives and interprets visual stimuli.
Temporal lobe	Receives and interprets olfactory and auditory stimuli.
Frontal lobe	Controls movements of voluntary muscles.
Primary motor area	Facilitates voluntary movement of skeletal muscles.
Speech area	Promotes understanding of spoken and written words.
Motor speech area (Broca's area)	Promotes vocalisation of words.

as a nerve pathway between the cerebral hemispheres and lower brain. The pons is located just below the midbrain. It consists mostly of fibre tracts, but it also contains nuclei that control respiration. The medulla oblongata, located at the base of the brainstem, is continuous with the superior portion of the spinal cord. Nuclei of the medulla oblongata play an important role in controlling cardiac rate, blood pressure, respiration and swallowing.

The cerebellum is connected to the midbrain, pons and medulla. Its functions include coordinating skeletal muscle activity, maintaining balance and controlling fine movements.

VENTRICLES The brain contains four ventricles, which are chambers filled with cerebrospinal fluid (CSF). They are linked by ducts that allow the CSF to circulate. One lateral ventricle is located within each hemisphere. These communicate with the third ventricle through the foramen of Monro. The third ventricle communicates with the fourth ventricle through the cerebral aqueduct that runs through the midbrain. The cerebral aqueduct is continuous with the central canal of the spinal cord.

CEREBROSPINAL FLUID Cerebrospinal fluid, a clear and colourless liquid, is formed by the choroid plexus, which are groups of specialised capillaries located in the brain ventricles. Derived from blood plasma, CSF consists of 99% water and contains protein, sodium, chloride, potassium, bicarbonate and glucose. (See Table 40.3 for normal laboratory values for CSF.) The usual amount of CSF ranges from 80 to 200 mL, averaging about 150 mL, and is replaced several times each day. It is absorbed by arachnoid villi. CSF is normally produced and absorbed in equal amounts. CSF circulates from the lateral ventricles of the cerebral hemispheres into the third ventricle, through the midbrain and into the fourth ventricle. Some CSF flows down the centre of the spinal cord as the rest of it circulates into the subarachnoid space and returns to the blood through the arachnoid villi. CSF forms a cushion for the brain tissue, protects the brain and spinal cord from trauma, helps provide nourishment for the brain and removes waste products of cerebrospinal cellular metabolism.

TABLE 40.3 Normal laboratory values for cerebrospinal fluid

COMPONENT	NORMAL VALUE
Appearance	Clear and colourless
pH	7.35
Specific gravity	1.007
WBCs	0–8 mm^3
Protein	0.15–0.45 g/L
Glucose	2.8–4.4 mmol/L
Chloride	118–132 mEq/L
Pressure	< 200 mmH_2O

MENINGES The brain and spinal cord are covered and protected by three connective tissue membranes called meninges. The meninges form divisions within the skull, enclose venous sinuses and contain CSF. The meninges have three layers (see Figure 40.5). The outermost double layer, the dura mater, is attached to the inner surface of the skull. The middle layer is the arachnoid mater, which encloses the entire CNS. It forms the subarachnoid space that contains CSF. The innermost layer, the pia mater, clings to the brain, spinal cord and segmental nerves and is filled with small blood vessels.

CEREBRAL CIRCULATION AND THE BLOOD–BRAIN BARRIER The brain receives about 750 mL of blood each minute and uses 20% of the body's total oxygen uptake.

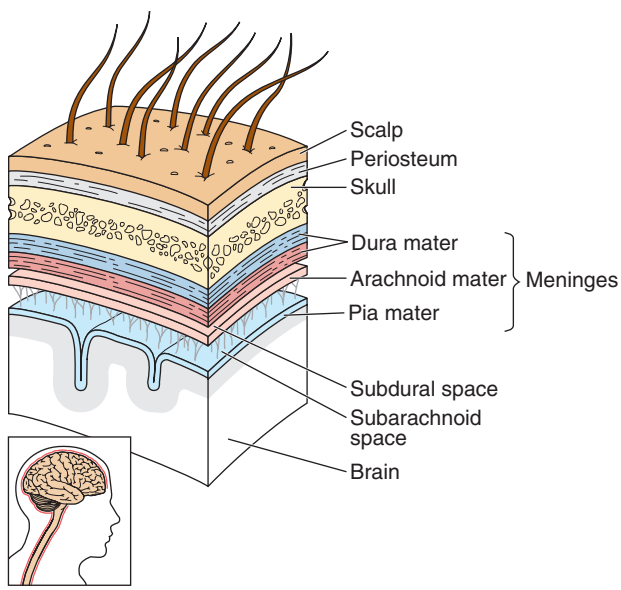

FIGURE 40.5 ■ Anatomy of the meninges

The large amount of oxygen is necessary for metabolism of glucose, which is the brain's sole source of energy. Blood flow to the brain is mostly controlled by autoregulatory or local mechanisms that respond to the brain's metabolic needs. Autoregulation is defined as the ability of the brain to maintain constant cerebral blood flow despite changes in systemic blood pressure. At least three metabolic factors affect cerebral blood flow: carbon dioxide, hydrogen ion and oxygen concentrations. Of these, increased carbon dioxide is the main stimulus for vasodilation with resultant increased cerebral blood flow.

The anterior part of the brain is supplied with blood by the two internal carotid arteries, and the posterior part of the brain is supplied with blood by the vertebral arteries. The internal carotid artery branches into further arteries: the ophthalmic, posterior communicating, anterior choroidal, anterior cerebral and middle cerebral. The brainstem and cerebellum receive their blood supply from the basilar artery. These main arteries are connected by small anterior and posterior communicating arteries, which form a circle of connected blood vessels called the circle of Willis (see Figure 40.6). This circle serves as a protective device, providing alternative routes for brain tissues to receive their blood supply.

The capillaries in the brain have low permeability because the cells that compose their walls join at very tight junctions and are surrounded by a basement membrane and by the processes of supporting cells in the brain (called astrocytes). As a result, the brain is protected from many harmful substances in the blood. This blood–brain barrier allows lipids, glucose, some amino acids, water, carbon dioxide and oxygen to pass through it, thus maintaining a controlled environment. Substances such as urea, creatinine, proteins, some toxins and most antibiotics cannot pass this barrier and enter brain tissue. However, injury to or infection of the brain may cause increased permeability of the blood–brain barrier, altering concentrations of proteins, water and electrolytes.

THE LIMBIC SYSTEM AND THE RETICULAR FORMATION The limbic system and the reticular formation are functional brain systems. These systems, made of networks of neurons, communicate across areas of the brain.

The limbic system consists of structures that form a ring of tissue in the medial side of each hemisphere, surrounding the upper portion of the brainstem and corpus callosum. The limbic system integrates and modulates input to make up the affective part of the brain, providing emotional and behavioural responses to environmental stimuli.

The reticular formation is located through the central core of the medulla oblongata, pons and midbrain. This system has widespread connections throughout the brain and relays sensory input from all body systems to all levels of the brain. The reticular formation includes the reticular activating system (RAS). The RAS is a stimulating system for the cerebral cortex, keeping it alert and responsive to incoming sensory stimuli while filtering out repetitive or unwanted stimuli. The sleep centre inhibits activity of the RAS, and drugs and alcohol may depress it. Other parts of the reticular formation include motor nuclei that help maintain muscle tone and coordinated movements through interconnections with spinal nerves and the vasomotor and cardiovascular regulatory centres, which are part of autonomic regulation of the cardiovascular system.

The spinal cord

The spinal cord extends from the medulla to the level of the first lumbar vertebra (see Figure 40.7). It serves as a centre for conducting messages to and from the brain and as a reflex centre. The spinal cord is about 42 cm long and 1.8 cm thick. The cord is protected by the vertebrae, the meninges and CSF. The grey matter of the cord is on the inside and the white matter is on the outside (the reverse of the arrangement in the brain).

The spinal cord is surrounded and protected by 33 vertebrae: 7 cervical, 12 thoracic, 5 lumbar, 5 sacral and 4 fused

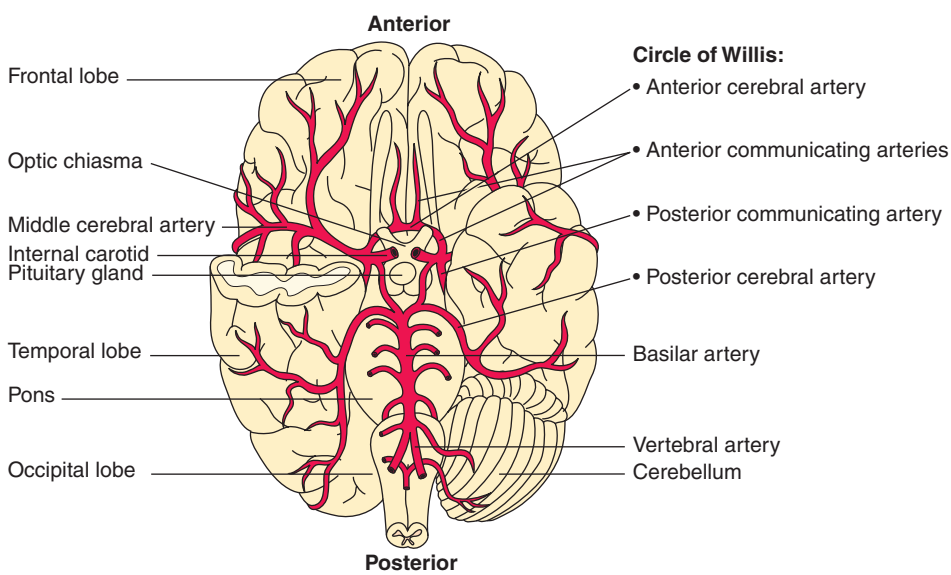

FIGURE 40.6 ■ The main arteries serving the brain and the circle of Willis

vertebrae, which form the coccyx. Each vertebra consists of a body and a vertebral arch formed by projections from the body. This arch encloses a space called the vertebral foramen. The vertebral foramina of all the vertebrae form the vertebral canal through which the spinal cord passes. Intervertebral foramina are spaces between the vertebrae through which spinal nerve roots pass as they exit the vertebral column.

Intervertebral discs are located between each of the movable vertebrae. Each disc is made of a thick capsule surrounding a gelatinous core called the nucleus pulposus. Ligaments that provide mobility and protection surround the vertebral column.

The roots of 31 pairs of spinal nerves, divided into the cervical, thoracic, lumbar, sacral and coccygeal nerves, arise from the cord (see Figure 40.7). Each separates into posterior (sensory) and anterior (motor) roots. Damage to the posterior roots results in loss of sensation, whereas damage to the anterior roots results in flaccid paralysis.

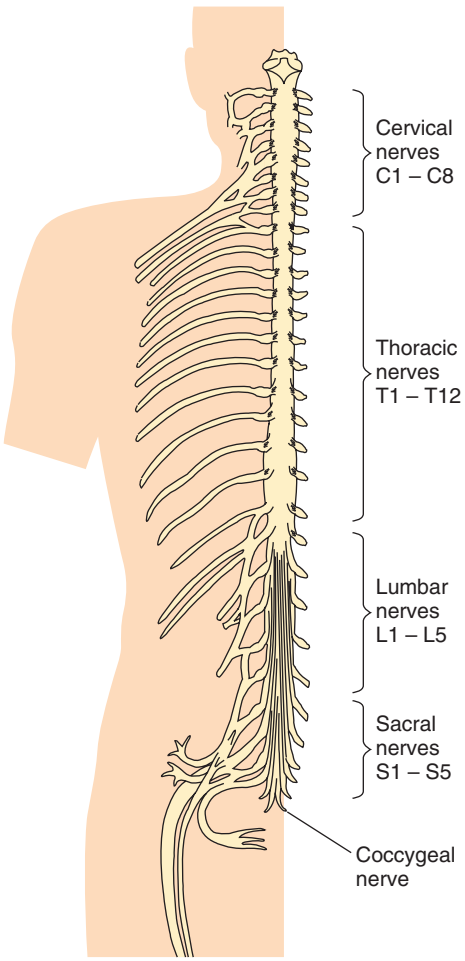

FIGURE 40.7 ■ Distribution of spinal nerves

FUNCTIONS OF THE SPINAL CORD AND SPINAL ROOTS Messages to and from the brain are conducted via ascending (sensory) pathways and descending (motor) pathways (see Figure 40.8). The main ascending tracts are the lateral and anterior spinothalamic tracts, which carry sensations for pain, temperature and crude touch; and the posterior tracts, which carry sensations for fine touch, position and vibration. The lateral and anterior corticospinal (pyramidal) tracts are descending tracts consisting of fibres that originate in the motor cortex of the brain and travel to the brainstem and then down the spinal cord. They mediate voluntary purposeful movements and stimulate certain muscular actions while inhibiting others. They also carry fibres that inhibit muscle tone. The rubrospinal, anterior and lateral reticulospinal and tectospinal (extrapyramidal) tracts include the pathways between the cerebral cortex, basal ganglia, brainstem and spinal cord outside the pyramidal tract. They maintain muscle tone and gross body movements.

UPPER AND LOWER MOTOR NEURONS Upper motor neurons, such as those of the corticospinal and extrapyramidal tract, carry impulses from the cerebral cortex to the anterior grey column of the spinal cord. Damage to upper motor neurons results in increased muscle tone, decreased muscle strength, decreased coordination and hyperactive reflexes. Lower motor neurons

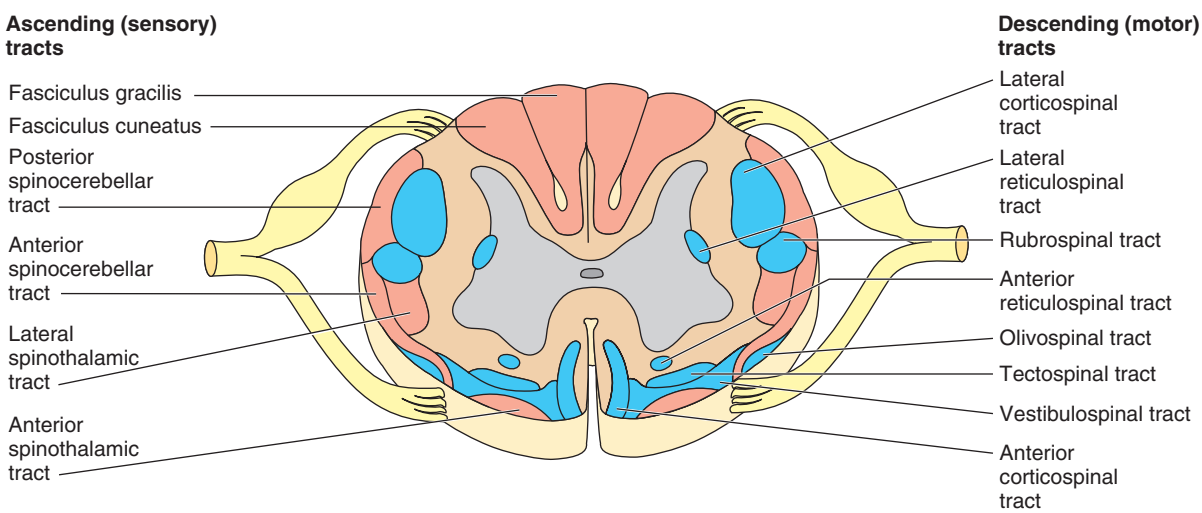

FIGURE 40.8 ■ Ascending and descending tracts of the spinal cord

begin in the anterior grey column of the spinal cord and end in the muscle. Damage to lower motor neurons results in decreased muscle tone, muscle atrophy, fasciculations and loss of reflexes.

The peripheral nervous system

The peripheral nervous system links the CNS with the rest of the body. It is responsible for receiving and transmitting information from and about the external environment. The PNS consists of nerves, ganglia (groups of nerve cells) and sensory receptors located outside—or peripheral to—the brain and spinal cord. The PNS is divided into a sensory (afferent) division and a motor (efferent) division. Most nerves of the PNS contain fibres for both divisions and all are classified regionally as either spinal nerves or cranial nerves.

Spinal nerves

The 31 pairs of spinal nerves (see Figure 40.7) are named by their location:

- cervical nerves: 8 pairs
- thoracic nerves: 12 pairs
- lumbar nerves: 5 pairs
- sacral nerves: 5 pairs
- coccygeal nerves: 1 pair.

Spinal nerves exit the vertebral column through intervertebral foramina to travel to the body regions they serve. The spinal cord does not reach the end of the vertebral column; as a result, the lumbar and sacral nerve roots travel inferiorly through the vertebral canal for some distance before exiting the vertebral column through their associated intervertebral foramina. This collection of descending nerve roots is called the cauda equina.

Each spinal nerve contains both sensory and motor fibres. The sensory fibres are located in the dorsal root and their cell bodies are located within the dorsal root ganglion. The motor fibres are located in the ventral root and their cell bodies are located within the spinal cord. The dorsal and ventral roots merge outside the vertebral canal just past the dorsal root ganglion, forming a spinal nerve. Each spinal nerve further divides into branches called rami.

The ventral rami of the cervical, brachial, lumbar and sacral regions form complex clusters of nerves called plexuses. The main spinal nerve plexuses innervate the skin and the underlying muscles of the arms and legs. For example, the cervical plexus innervates the diaphragm through the phrenic nerve; the brachial plexus innervates the upper extremities through the median, ulnar and radial nerves; and the lumbar plexus innervates the anterior thigh through the femoral nerve.

An area of skin innervated by cutaneous branches of a single spinal nerve is called a dermatome. The dorsal roots of the spinal nerves carry sensations from these specific dermatomes. Dermatomes provide anatomical landmarks that are useful for locating neurological lesions (see Figure 40.9).

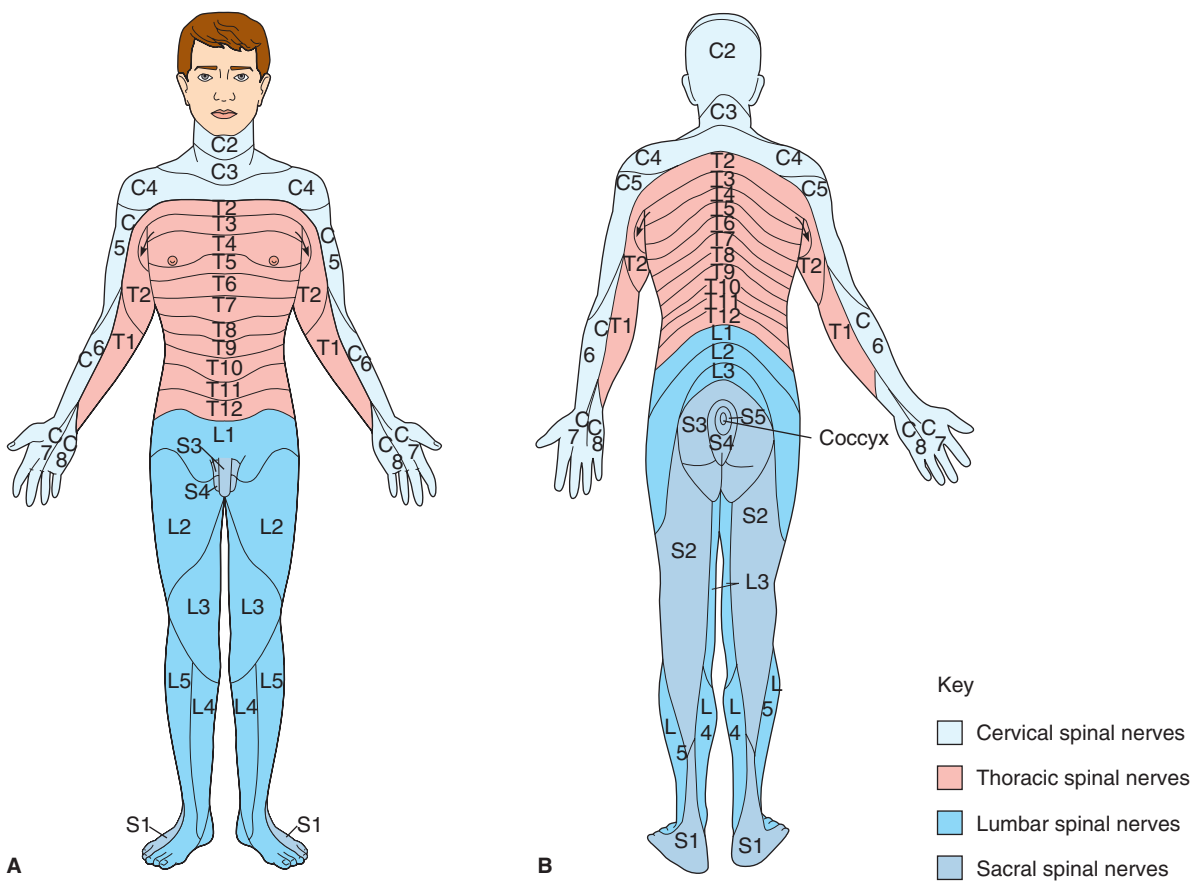

FIGURE 40.9 ■ *A*, Anterior and *B*, posterior dermatomes of the body

Cranial nerves

Twelve pairs of cranial nerves originate in the forebrain and brainstem (see Figure 40.10). The vagus nerve extends into the ventral body cavity, but the 11 other pairs innervate only head and neck regions. Although most are mixed nerves, three pairs (olfactory, optic and acoustic) are solely sensory. The cranial nerves and their related functions are listed in Table 40.4.

Reflexes

A reflex is a rapid, involuntary, predictable motor response to a stimulus. Reflexes are categorised as either somatic or autonomic. Somatic reflexes result in skeletal muscle contraction. Autonomic reflexes activate cardiac muscle, smooth muscle and glands. A reflex occurs over a pathway called a reflex arc.

The essential components of a reflex arc are a receptor, a sensory neuron to carry afferent impulses to the CNS, an integration centre in the spinal cord or brain, a motor neuron to carry efferent impulses and an effector (the tissue that responds by contracting or secreting) (see Figure 40.11).

Somatic reflexes mediated by the spinal cord are called *spinal reflexes*. Many spinal reflexes occur without impulses travelling to and from the brain, with the cord serving as the integration centre, whereas others require brain activity and modulation. *Deep tendon reflexes (DTRs)* occur in response to muscle contraction and cause muscle relaxation and lengthening. DTRs depend on intact sensory and motor nerve roots, functional synapses in the spinal cord, a functional neuromuscular junction and a competent muscle. Thus, an abnormal DTR could indicate a variety of health problems, including a lesion of a spinal nerve. Flexor, or withdrawal, reflexes are caused by actual or perceived painful stimuli and result in withdrawal of the part of the body that is threatened. Superficial responses result from gentle cutaneous stimulation. These responses depend on functional upper motor pathways and on an intact reflex arc.

The autonomic nervous system

The autonomic nervous system (ANS) is a division of the PNS that regulates the internal environment of the body. It is also called the general visceral motor system because it consists of motor neurons that innervate the body's viscera. The skeletal muscle activity and reflexes are regulated by a division of the PNS called the somatic nervous system; the ANS regulates the activity of cardiac muscle, smooth muscle and glands.

The ANS is primarily controlled by the reticular formation in the brainstem. Stimulation of centres in the medulla initiates reflexes that regulate cardiac rate, blood vessel diameter and gastrointestinal function.

The ANS has sympathetic and parasympathetic divisions. Although fibres from both divisions affect the same structures, the actions of the two divisions are opposite in effect and they serve to counterbalance each other. The main neurotransmitters

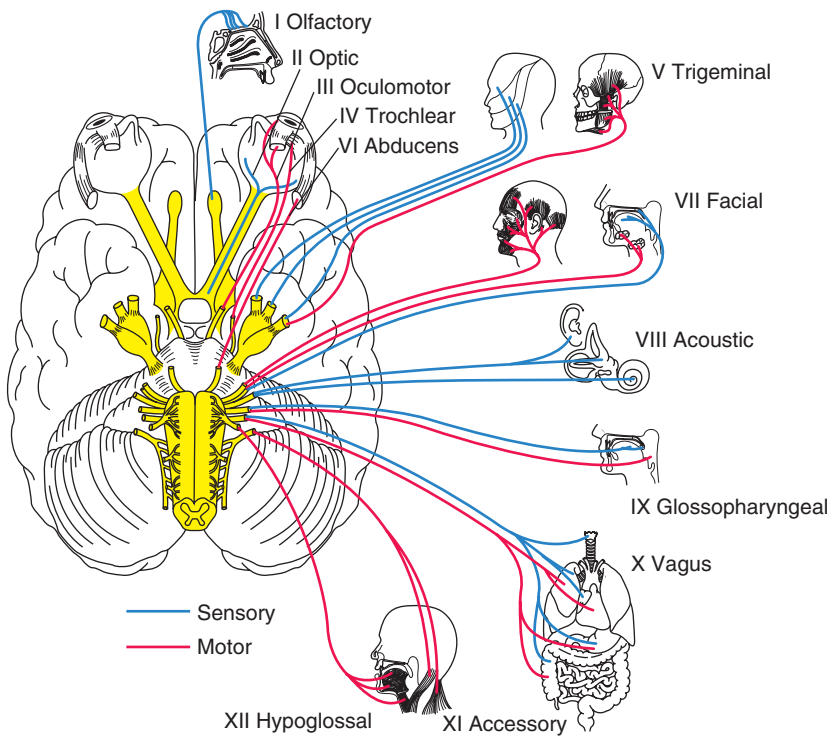

FIGURE 40.10 ■ Cranial nerves

TABLE 40.4 Cranial nerves

NAME	FUNCTION
I Olfactory	Sense of smell
II Optic	Vision
III Oculomotor	Eyeball movement Raising of upper eyelid Constriction of pupil Proprioception
IV Trochlear	Eyeball movement
V Trigeminal	Sensation of the upper scalp, upper eyelid, nose, nasal cavity, cornea and lacrimal gland Sensation of the palate, upper teeth, cheek, top lip, lower eyelid and scalp Sensation of the tongue, lower teeth, chin and temporal scalp Chewing
VI Abducens	Lateral movement of the eyeball
VII Facial	Movement of facial muscles Secretions of lacrimal, nasal, submandibular and sublingual glands Sensation of taste
VIII Acoustic	Sense of equilibrium Sense of hearing
IX Glossopharyngeal	Swallowing Gag reflex Secretions of parotid salivary gland Sense of taste Touch, pressure and pain from pharynx and posterior tongue Pressure from carotid arteries Receptors to regulate blood pressure
X Vagus	Swallowing Regulation of cardiac rate Regulation of respirations Digestion Sensation from thoracic and abdominal organs Proprioception Sense of taste
XI Accessory	Movement of head and neck Proprioception
XII Hypoglossal	Movement of tongue for speech and swallowing

for impulse transmission in the ANS are acetylcholine and noradrenaline. Acetylcholine is the primary neurotransmitter of the parasympathetic division. Noradrenaline is the primary neurotransmitter of the sympathetic division.

Sympathetic division

The sympathetic division of the ANS prepares the body to handle situations that are perceived as harmful or stressful and to participate in strenuous activity. Cell bodies for this division arise in the lateral horns of the spinal cord in the area from

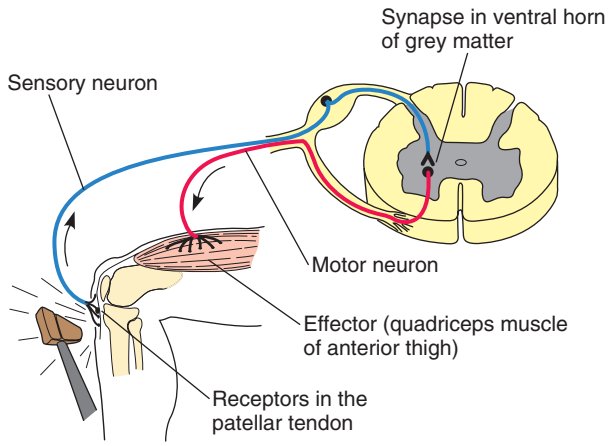

FIGURE 40.11 ■ A typical reflex arc of a spinal nerve. In the two-neuron reflex arc, the stimulus is transferred from the sensory neuron directly to the motor neuron at the point of synapse in the spinal cord

T1 to L2. The fibres separate after leaving the cord and form a chain of ganglia that extends from the neck to the pelvis. Long fibres then extend to the organs that are supplied by the sympathetic division. Stimulation of the sympathetic division can exert the following effects on target organs or tissues:

- dilated pupils
- inhibited secretions
- copious production of sweat (**diaphoresis**)
- increased rate and force of heartbeat
- vasodilation of the coronary arteries
- dilation of the bronchioles
- decreased digestion
- increased release of glucose by the liver
- decreased urine output
- vasoconstriction of arteries
- vasoconstriction of abdominal and skin blood vessels
- increased blood clotting
- increased metabolic rate
- increased mental alertness.

Parasympathetic division

The parasympathetic division of the ANS operates during non-stressful situations. Cell bodies for this division are located in the brainstem (for the cranial nerves) and in the lateral grey matter of S2 to S4. Other than the fibres supplying the cranial nerves III, VII, IX and X, the fibres are carried by the vagus nerve to body tissues, thoracic organs and visceral organs. Stimulation of the parasympathetic division of the ANS produces the following effects:

- constriction of pupils
- stimulation of glandular secretions
- decreased heart rate
- vasoconstriction of coronary arteries
- constriction of the bronchioles
- increased peristalsis and secretion of gastrointestinal fluid.

ASSESSING NEUROLOGICAL FUNCTION

Structures and functions of the neurological system are assessed by findings from a health assessment interview to collect subjective data, a physical assessment to collect objective data and diagnostic tests. Sample documentation of an assessment of the neurological system is included in the box below.

Health assessment interview

A health assessment to determine problems with neurological structure and/or function may be conducted during a health screening, may focus on a chief complaint (such as headaches) or may be part of a total health assessment. Health problems affecting the neurological system may manifest as problems with musculoskeletal function and an assessment of both systems may be necessary. If the person's level of consciousness is altered, the nurse may need to rely on family members for information. The person's level of consciousness may be assessed by using the Glasgow Coma Scale (see Table 40.5).

If the person has problems with neurological structure or function, analyse its onset, characteristics, course, severity, precipitating and relieving factors, and any associated symptoms, noting the time and circumstances. For example, ask the person the following:

- Describe the location and intensity of the pain you have experienced in your left leg. Is it made worse by coughing, sneezing or walking?
- When did you first notice that you were having numbness in your fingers?
- Describe the difficulty you have when you try to walk.

Questions about present health status include information about numbness, tingling sensations, tremors, problems with coordination or balance, or loss of movement in any part of the body. Ask the person about difficulty with speaking, seeing, hearing, tasting or detecting odours. In addition, elicit information about memory, feeling state (such as anxiety or depression), recent changes in sleep patterns, ability to perform self-care and activities of daily living, sexual activity and weight. If the person is taking prescribed medications, over-the-counter medications or herbal supplements, ask about the type and purpose, as well as the frequency and duration of use.

Ask about any past history of seizures, fainting, dizziness, headaches and any trauma, tumours or surgery of the brain, spinal cord or nerves. Discuss illnesses that may cause neurological manifestations, including cardiac disease, strokes, pernicious anaemia, sinus infections, liver disease and/or kidney failure. Also ask the person about family history of neurological health problems, diabetes mellitus, hypertension, seizures or mental health problems.

SAMPLE DOCUMENTATION

Assessment of the neurological system

11/5/2016
NURS
1000

45-year-old male having annual physical examination. No history of injury or infection involving the head or spine. No history of seizures, dizziness, headaches, memory loss or problems with speaking or swallowing. Alert, oriented to person, place and time. Able to follow directions, explain simple proverbs and compare unlike objects. Cranial nerve testing results:

I = Identifies scents correctly.
II = Vision 40/20 in both eyes. Has full visual fields bilaterally.
III, IV, VI = Bilateral full extraocular movements, pupils are equally round, react to light and accommodation. No ptosis present in either eye.
V = Able to identify sharp, dull and light touch to forehead, cheek and chin. Corneal reflex present bilaterally, but decreased (wears contact lenses).
VII = Able to smile, frown, wrinkle forehead, show teeth, puff out cheek, purse lips, raise eyebrows and close eyes against resistance.
VIII = Heard whispered words with both ears.
IX, X = Gag reflex present. Swallows without difficulty.
XI = Equal strength when shrugging both shoulders.
XII = Able to protrude tongue midline without tremors.

All extremities have full range of motion without tremors, tics or weakness. No atrophy of muscles noted. Can perform repetitive alternating movements without difficulty. Gait is steady. Negative Romberg test. All reflexes are 2+ bilaterally. Abdominal reflex present. No Babinski's present.

D. Sassir
(D SASSIR) RN

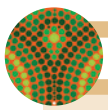
TABLE 40.5 Glasgow Coma Scale

ASSESSMENT	RESPONSE	SCORE*
Eyes open (Record C if eyes are closed by swelling.)	Spontaneously	4
	To speech	3
	To pain	2
	No response	1
Best motor response (Record best upper arm response.)	Obeys commands	6
	Localises pain	5
	Flexion withdrawal	4
	Abnormal flexion	3
	Abnormal extension	2
	No response	1
Best verbal response (Record T if an endotracheal or tracheostomy tube is in place.)	Oriented	5
	Confused	4
	Inappropriate words	3
	Incomprehensible sounds	2
	No response	1
Total score:		____

*A higher score indicates a higher level of functioning.

Question the person about occupational hazards, such as exposure to toxic chemicals or materials, use of protective headgear and the amount of time spent performing repetitive motions (e.g. data entry and assembly). Ask questions about self-care to assess the person's diet and use of tobacco, drugs or alcohol, and ask whether they wear a helmet when riding a bike or motorcycle or participating in contact sports, or use a seat belt when driving a vehicle.

Interview questions categorised by functional health patterns are listed in the 'Functional health pattern interview' table below.



FUNCTIONAL HEALTH PATTERN INTERVIEW Neurological system

FUNCTIONAL HEALTH PATTERN	INTERVIEW QUESTIONS AND LEADING STATEMENTS
Health perception–Health management	■ Have you ever had surgery, injury or illness of the neurological system, such as seizures, stroke, tumour, meningitis? If so, describe the problem and how it was treated. ■ Do you have high blood pressure? If so, how is it treated? ■ Have you ever had problems with the ability to move body parts? Describe. ■ Would you say you think clearly? If not, how and when did the change occur? ■ Are you having any problems with the ability to see, hear, taste or smell? Explain. ■ Have you ever had any diagnostic tests for a neurological problem, such as an MRI or spinal tap? If so, what were the results? ■ Do you take medications for seizures, headaches or other neurological problems? If so, what are they and how often do you take them? ■ Do you now or have you ever smoked, used street drugs or drunk alcohol? If so, what type, how much and for how long? ■ Where were you born and raised as a child?
Nutritional–Metabolic	■ Describe your usual food and fluid intake for a 24-hour period. ■ Have you noticed any problems with chewing or swallowing your food? ■ Do you have trouble with coughing when you eat or drink?
Elimination	■ Has there been any change in your urinary or bowel elimination? If so, describe the change. ■ Do you use laxatives, suppositories or enemas to assist with bowel elimination? If so, what type and how often? ■ Are you able to go to the bathroom without assistance? If not, describe your usual routine.
Activity–Exercise	■ Describe your usual activities in a 24-hour period. ■ Do you have any problems with balance, coordination or walking? Do you use any assistive device when you walk, such as a cane or walker? ■ Have you noticed any weakness in your arms or legs? If so, describe. ■ Are you able to move all of your body parts? If not, explain. ■ Do you trip or fall easily? ■ Have you experienced any shakiness or tremors? Where? ■ If you have seizures, what type do you have? Can you tell when they are going to happen? Does anything specific make you have a seizure? How do you feel after the seizure is over?
Sleep–Rest	■ Does this health problem interfere with your ability to sleep and rest? If so, how? ■ Do you take any medication to help you sleep? If so, what? ■ Describe your energy level. Do rest and sleep restore your energy?
Cognitive–Perceptual	■ Describe any headaches you experience, including frequency, type, location and precipitating/relieving factors. ■ Do you ever feel dizzy or have you fainted? Do you ever feel the room is spinning? Explain. ■ Do you ever experience any numbness, burning or tingling sensations? If so, where and when? ■ Do you have any visual problems, such as double vision, blurring or blind spots? ■ Do you have any problems with hearing? Explain. ■ Has there been any change in your ability to taste or smell? If so, explain. ■ Do you have any difficulty remembering things? If so, describe what you do.
Self-perception–Self-concept	■ How does having this condition make you feel about yourself?
Role–Relationships	■ How has having this condition affected your relationships with others? ■ Has having this condition interfered with your ability to work? Explain. ■ Has anyone in your family had problems with neurological disease? Explain.

(continued)

FUNCTIONAL HEALTH PATTERN INTERVIEW Neurological system (continued)

Sexuality–Reproductive	■ Has this condition interfered with your usual sexual activity?
Coping–Stress–Tolerance	■ Has having this condition created stress for you? If so, does your health problem seem to be more difficult when you are stressed? ■ Have you experienced any kind of stress that makes the condition worse? Explain. ■ Describe what you do when you feel stressed.
Value–Belief	■ Describe how specific relationships or activities help you cope with this problem. ■ Describe specific cultural beliefs or practices that affect how you care for and feel about this problem. ■ Are there any specific treatments that you would not use to treat this problem?

Physical assessment

Physical assessment begins when the nurse first meets the person and makes an overall evaluation of their mental and physical status. The mental status examination is conducted with both the nurse and the person seated. The rest of the neurological examination may be performed with the person either sitting or standing. A thorough neurological examination is discussed here, but in most instances the nurse will conduct a focused assessment specific to the person's health status.

The neurological system is assessed through inspection, palpation and percussion (with a reflex hammer). When conducting the mental status and cognitive portions of the examination, be aware that fatigue or illness may alter findings. Provide rest periods for the person as needed. When interpreting findings, consider the person's age, educational background and cultural orientation. Normal age-related findings for the older adult are summarised in Table 40.6.

The assessment should take place in a private, comfortable setting. Ask the person to remove outer clothing, shoes and stockings. Provide a gown for the person to wear. It is important to explain that the neurological examination is lengthy and may consist of questions and requests that seem strange to the person. Explain the rationale for each part of the examination.

A brief version of this physical assessment, often referred to as a *neuro check*, may be performed in a shorter time period when a person requires frequent ongoing assessments of neurological status (see Box 40.1).

BOX 40.1 Abbreviated neurological assessment (neuro check)

1. Assess level of consciousness (response to auditory and/or tactile stimulus).
2. Obtain vital signs (BP, P, R).
3. Check pupillary response to light.
4. Assess strength of hand grip and movement of extremities bilaterally.
5. Determine ability to sense touch/pain in extremities.

Diagnostic tests

The results of diagnostic tests of neurological structure and function are used to support the diagnosis of a specific injury or disease, to provide information to identify or modify the appropriate medications or therapy used to treat the disease, and to help nurses monitor the person's responses to treatment and nursing care interventions. Diagnostic tests to assess the structures and functions of the neurological system are described below and summarised in the following bulleted list. More information is included in the discussion of specific injuries or diseases in Chapters 41, 42 and 43.

- Radiological examinations of the skull and spine include standard x-rays, computed tomography (CT) scans, magnetic resonance imaging (MRI), magnetic resonance angiography (MRA) and magnetic resonance spectroscopy (MRS).

TABLE 40.6 Age-related changes in the neurological system

AGE-RELATED CHANGE	SIGNIFICANCE
• ↓ number of brain cells, cerebral blood flow and metabolism • Slower nerve conduction velocity	Delayed response to multiple stimuli and slower reflexes; may need additional time to process and respond to verbal stimuli
• Slower retrieval of information from long-term memory	There is some age-related forgetfulness, which can be improved by using memory aids such as making lists
• Slower response to changes in balance	May contribute to increased risk of falls
• May exhibit less readiness to learn and depend on prior experiences to solve problems • Is more easily distracted and has a decrease in the ability to maintain attention	Learning new skills or knowledge is improved when they are related to previously learned information and when limits are set on times for learning (e.g. no more than 30 minutes at one time).

Findings from these examinations are used to diagnose and evaluate fractures, vertebral displacements, tumours, haemorrhage, aneurysms, cysts, oedema, ischaemia, atrophy, necrosis, seizures, multiple sclerosis, Alzheimer's disease, coma and vascular lesions.

- Both positron emission tomography (PET) and single-photon emission computed tomography (SPECT) are used to assess brain function and blood flow, to differentiate types of dementia, to evaluate the stage of a brain tumour and to identify brain tumours, strokes and seizure disorders.
- Occlusion of the carotid arteries is evaluated by measuring velocity of blood flow with a carotid duplex study; and extracranial blood vessels are evaluated with a transcranial Doppler study.
- Electrical activity of the brain is measured with an electroencephalogram (EEG) to diagnose brain disease and brain death. A magnetoencephalogram (MEG) measures electrical activity of neurons to pinpoint the area of the brain affected by a stroke, brain trauma, brain disorders or seizures.
- Cerebrospinal fluid, removed through a lumbar puncture (LP), is examined in the laboratory to diagnose a variety of brain diseases and infections.
- A myelogram is used to identify lesions of the spinal cord, such as tumours or herniated intervertebral discs.

Regardless of the type of diagnostic test, the nurse is responsible for explaining the procedure and any special preparation needed, assessing for medication use that may affect the outcome of the tests, supporting the person during the examination as necessary, documenting the procedures as appropriate and monitoring the results of the tests.

Genetic considerations

When conducting a health assessment interview and a physical assessment, it is important for the nurse to consider genetic influences on the health of the adult. Several neurological diseases that directly affect the nervous system have a genetic component; some are due to mutation of a single gene while others have a more complex method of inheritance (Sobrido et al., 2012). During the health assessment interview, ask about family members with health problems affecting neurological structure or function. In addition, ask about a family history of problems with muscular coordination, Parkinson's disease, narcolepsy, tremor, seizures, Alzheimer's disease or motor neurone disease. During the physical assessment, assess for any manifestations that might indicate a genetic disorder (see the box below). If data are found to indicate genetic risk factors or alterations, ask about genetic testing and refer for appropriate genetic counselling and evaluation. Chapter 7 provides further information about genetics in medical–surgical nursing.

DIAGNOSTIC TESTS The neurological system

NAME OF TEST X-rays of skull and spine

PURPOSE AND DESCRIPTION Standard x-rays of the skull and spine are done to identify fractures, displacement of vertebrae, spinal curves and tissue displacement (as by tumours).

RELATED NURSING CARE No special preparation is needed.

NAME OF TEST Computed tomography (CT) scan

PURPOSE AND DESCRIPTION Used to identify intracerebral haemorrhage, tumours, cysts, aneurysms, oedema, ischaemia, atrophy and tissue necrosis. May also be used to evaluate a shift in intracranial contents and differentiate type of stroke. Involves computer-assisted x-rays of several levels of cross-sections of the body part being examined; may be done with or without contrast.

PREPARATION

- Ensure a signed consent form. Check hospital policy on withholding food and fluids. The person is usually on NBM status (except for the medications ordered as part of the test) for 8 hours before the test if it is done in the morning. If the test is done in the afternoon, the person may have a liquid breakfast. Give medications up to 2 hours before test.
- Assess for possible reaction to iodine dye (by asking about allergy to seafood). Document any allergy and inform the physician and radiology department.
- Remove metal hairpins, clips and earrings.

HEALTH EDUCATION FOR THE PERSON AND FAMILY

- If applicable, instruct the person not to drink or eat anything before the test except for the ordered medications.
- Inform them that they may be given an intravenous infusion. When the contrast dye is injected, they may feel warm and have a metallic taste in the mouth. The test will last from 30 to 90 minutes and their head will be positioned in a cradle.
- The CT scanner is circular with a round opening. Inform the person that they will be strapped to a special table and the scanner will revolve around the body part to be examined. The scanner will make a clicking noise. The test is painless and someone will always be immediately available during it.

(continued)

DIAGNOSTIC TESTS The neurological system (continued)

NAME OF TEST Magnetic resonance imaging (MRI), Functional MRI

PURPOSE AND DESCRIPTION An MRI is done to identify and monitor conditions of the brain and spinal cord, including stroke, tumours, trauma, seizures and multiple sclerosis. It uses magnetic energy to provide images. Gadolinium contrast media may be used to enhance visualisation. A functional MRI is done to evaluate metabolic or blood flow responses of the brain to specific tasks, such as activity and rest.

RELATED NURSING CARE Assess for metal implants (such as a pacemaker or defibrillator), body piercings and shrapnel, which would contraindicate tests.

NAME OF TEST Magnetic resonance angiography (MRA)

PURPOSE AND DESCRIPTION Can provide information about the blood vessels of the brain and identify vascular lesions. The MRA uses the signals from blood vessels to reconstruct only those vessels with blood flow. It can also be done using contrast media.

RELATED NURSING CARE Assess for metal implants (such as a pacemaker) and shrapnel, which would contraindicate tests.

NAME OF TEST Magnetic resonance spectroscopy (MRS)

PURPOSE AND DESCRIPTION Uses a scanner to confirm the presence of Alzheimer's disease, determine the extent of head injury from trauma or stroke, and identify the causes of coma.

RELATED NURSING CARE Assess for metal implants, as for an MRI, which would contraindicate tests.

NAME OF TEST Positron emission tomography (PET), Single-photon emission computed tomography (SPECT)

PURPOSE AND DESCRIPTION When used to study the brain, a PET can assess normal brain function and cerebral blood flow and volume; can differentiate different types of dementia; and can identify stages of brain tumours. A substance containing a radionuclide is given by gas or by injection, and cross-sections of tissue are detected and displayed by computer. A SPECT is similar to a PET, but uses different substances. It can be used to diagnose strokes, brain tumours and seizure disorders.

RELATED NURSING CARE Tell the person not to drink coffee or alcohol or to smoke for 24 hours before the test. Assess glucose levels pre test. Post test, encourage oral fluids to facilitate excretion of the radioactive substance.

NAME OF TEST Cerebral angiogram

PURPOSE AND DESCRIPTION The cerebral angiogram is the definitive diagnostic procedure for aneurysms, arteriovenous malformations, blood vessel patency and stenosis, thrombosis, vasospasm and space-occupying lesions (such as tumours or haematomas). May be performed either as part of a surgical procedure or with local anaesthesia. In radiology, a contrast medium is injected and films are taken at various time intervals.

RELATED NURSING CARE Obtain informed consent, inform about need to remain NBM for 8 hours prior to the procedure and explain that a burning sensation may be felt for a few (4 to 6) seconds behind the eyes or in the jaw, teeth, tongue or lips. Bed rest is maintained for 8 hours after the procedure, vital signs are monitored and fluids are forced to clear the contrast medium.

NAME OF TEST Carotid duplex study, Transcranial Doppler study

PURPOSE AND DESCRIPTION A carotid duplex study evaluates the velocity of blood flow through the carotid arteries and identifies occlusive disease. Uses sound waves produced by the blood flow to produce an image. A transcranial Doppler study follows the same procedure, but is used to evaluate intracranial blood vessels.

RELATED NURSING CARE No special preparation is needed.

DIAGNOSTICTESTS The neurological system (continued)

NAME OF TEST Electroencephalogram (EEG), Magnetoencephalogram (MEG)

PURPOSE AND DESCRIPTION An EEG is used to measure the electrical activity of the brain to diagnose brain disease and brain death. Electrodes are applied to the scalp with skin clips and a graphic picture is obtained (similar to an ECG of the heart). An MEG can identify the area of the brain affected by a stroke, brain disorders or trauma, or seizures. MEG detects magnetic fields generated by activity of neurons.

PREPARATION

- Explain the procedure, emphasising the importance of cooperation. Withhold fluids, foods and medications (as prescribed) that may stimulate or depress brain waves. These include anticonvulsants, tranquillisers, depressants and caffeine-containing foods (e.g. coffee, tea, colas and chocolate). Medications are usually withheld for 24 to 48 hours before the test. Help the person to wash their hair before the test.

HEALTH EDUCATION FOR THE PERSON AND FAMILY

- Inform the person that the test takes about 1 hour. It is painless and will be performed while sitting in a comfortable chair or lying on a stretcher. The electrodes are applied to the scalp with a thick paste.
- During the test, the person will first be asked to breathe in and out deeply for a few minutes. Then, they will close their eyes while a light is flashed on them and, finally, they will lie quietly with the eyes closed. After the test, the nurse will help the person wash the paste out of their hair.

NAME OF TEST Evoked potentials

PURPOSE AND DESCRIPTION Measures nerve conduction along pathways to evaluate evoked potential of muscle contractions. Used to diagnose and evaluate neuromuscular diseases and identify nerve damage. Transcutaneous or percutaneous electrodes are applied to the skin and provide recordings.

RELATED NURSING CARE No special preparation is needed.

NAME OF TEST Electromyogram (EMG)

PURPOSE AND DESCRIPTION Measures the electrical activity of skeletal muscles at rest and during contraction; useful in diagnosing neuromuscular diseases. Needle electrodes are inserted into skeletal muscle (as on the legs) and electrical activity can be heard, viewed on an oscilloscope and recorded on graph paper. Normally, there is no electrical activity at rest.

RELATED NURSING CARE Tell the person not to drink fluids containing caffeine or to smoke for 3 hours before the test and not to take medications such as muscle relaxants, anticholinergics and cholinergics.

NAME OF TEST Lumbar puncture (LP)

PURPOSE AND DESCRIPTION The lumbar puncture is used to measure CSF pressure and to obtain a sample of CSF to use in diagnosis of multiple sclerosis or increased intracranial pressure from meningitis, subarachnoid haemorrhage, brain tumour, brain abscess, encephalitis and viral infections. A needle is inserted in L3–L4 or L4–L5 and fluid is aspirated.

PREPARATION

- Ensure a signed consent form is provided. (This consent may be obtained as part of the general consent given on admission to the hospital or agency.)
- Ask the person to empty their bladder before the procedure begins. Help the person to assume a lateral recumbent position near the side of the bed. The person should assume the foetal position (knees flexed towards the head, head bent towards the chest), with their hands clasped around their knees.

HEALTH EDUCATION FOR THE PERSON AND FAMILY

- Inform the person that a local anaesthetic will be injected into the skin over the area of the needle insertion. This medication may cause a burning sensation. A long, thin needle will then be inserted into the lower back below the level of the spinal cord. Cerebrospinal fluid will be withdrawn. The cerebrospinal fluid pressure is measured with a calibrated tube called a manometer.
- Inform the person that there may be slight pain down one leg during the procedure and that it is important to remain still during the procedure.
- A small dressing will be used to cover the place where the needle was inserted. After the procedure, the person must remain flat in bed for the number of hours prescribed by the doctor. (This ranges from 4 to 24 hours.) The nurses will take their vital signs and look under the small dressing at regular intervals.

(continued)

DIAGNOSTIC TESTS The neurological system (continued)

- The person should drink fluids so that their body can replace the fluid that was withdrawn. If they have a headache or backache, they can take medications for pain. The person should notify their healthcare provider if they notice increased pain or drainage from the area where the procedure was done.

POST-PROCEDURE NURSING CARE

- Take and record vital signs as indicated by organisational standards. Monitor neurological status at least every 4 hours for 24 hours. Monitor the puncture site for leakage of cerebrospinal fluid or haematoma formation.
- Ensure that the person voids within 8 hours of the procedure. Encourage increased intake of fluids (up to 3000 mL in 24 hours).
- Administer analgesics as prescribed for pain.

RELATED NURSING CARE Related nursing care for the person having a lumbar puncture is described below.

NAME OF TEST Myelogram

PURPOSE AND DESCRIPTION Used to identify lesions of the spinal cord, such as tumours or herniated intervertebral disc. A lumbar puncture is done, a contrast medium is injected into the subarachnoid space and x-rays are taken.

PREPARATION

- Ensure a signed informed consent is provided.
- The meal prior to the procedure is usually omitted. The person should be well hydrated.
- Administer enemas or laxatives as ordered to ensure visualisation of lumbar spine. Administer prescribed pre-test medications, such as a sedative or diazepam (Valium).

HEALTH EDUCATION FOR THE PERSON AND FAMILY

- Inform the person that they will remain NBM several hours before the test.
- The examination will last about 1 hour. The position used to perform the examination will depend on the doctor. The person may have to lie on their stomach, sit and lean forward, or sit with the knees to the chest. A strap may be used to prevent falls and the table will be tilted during the examination.
- A lumbar puncture ('spinal tap') will be performed to inject the dye. A local anaesthetic will be used where the needle will be inserted. There may be a feeling of pressure during needle insertion. The needle will be inserted below the level of the spinal cord. Tell the physician if you experience pain.
- Inform the person that they must stay in bed with the head of the bed elevated for at least 6 to 12 hours. (The length of time will depend on physician preference and hospital policy.) The nurse will check their blood pressure, pulse and respirations. The nurse will also check their ability to feel and move at least every 4 hours (or more often) after the examination.

POST-PROCEDURE NURSING CARE

- Take and record vital signs and assess neurological status as prescribed (and at least every 4 hours) for 24 hours post examination. Record and report any changes. Assess the site of the lumbar puncture for leakage of cerebrospinal fluid or bleeding every 4 hours. Notify the physician of leakage or bleeding.
- Encourage increased intake of oral fluids to replace that withdrawn during the examination. (This may also help decrease a post-myelogram headache.) Make sure that the person voids within 8 hours after the examination. If policy permits, allow males to stand at the bedside or people of either gender to use the bathroom. Notify the physician if the person has not voided within 8 hours.
- Administer analgesics as prescribed for post examination pain, headache or muscle spasms. Keep the person's head elevated at least 30 degrees (in bed or in a chair) for 12 hours or as ordered.
- Resume diet if there is no nausea or vomiting. Force oral fluids to 2400 to 3000 mL in 24 hours, beginning immediately after the procedure.
- Administer prescribed medications for nausea. Do not give any phenothiazine derivatives for 48 hours (to reduce the possibility of seizures).

GENETIC CONSIDERATIONS Neurological disorders

- In all types of spinocerebellar ataxia, there is degeneration of the spinal cord and cerebellum, resulting in loss of muscular coordination and spasticity.
- One recently confirmed risk factor for Parkinson's disease is a positive family history of the disease. This neurodegenerative disease affects about 40 000 people in Australia, and is manifested by tremor, muscular stiffness, and difficulty with balance and walking (Brain Foundation, 2013).
- Although multiple sclerosis (MS) is not directly inherited, genetic factors may influence a predisposition to MS within families as well as the severity and course of the disease.
- Narcolepsy, a sleep disorder, does have a familial connection.
- Huntington's disease is an inherited degenerative disorder that leads to dementia. In Australia it currently affects 6 or 7 people in every 100 000.
- Friedreich's ataxia is a rare inherited disease that causes a progressive loss of voluntary muscle coordination and enlargement of the heart.
- Essential tremor, as a primary disorder, affects as many as 14 000 people across Australia and New Zealand (Medtronic, 2010). In more than half of cases, essential tremor is inherited as an autosomal dominant trait, meaning that children of an individual with the disease have a 50% chance of also developing the disorder.
- Epilepsy is one of the most common neurological diseases, characterised by abnormal cell firing in the brain that causes recurring seizures. Recent evidence suggests that there may be a genetic predisposition in up to 70% of cases (American Society of Neurological Surgeons, 2015).
- Charcot–Marie–Tooth syndrome is the most common inherited peripheral neuropathy in the world, characterised by a slowly progressive degeneration of the muscles of the foot, lower leg, hand and forearm.
- Alzheimer's disease (AD) is a leading cause of death in adults, increasing in incidence with age and more common in women. AD tends to run in families, with mutations in four genes believed to be responsible for the disease.
- Motor neurone disease (MND) is a neurological disease that causes progressive degeneration of motor neurons in the brain and spinal cord, resulting in paralysis and death. Chromosome abnormalities have been linked to familial MND.
- Although Tay–Sachs disease is most often considered a disease of children, there is a chronic adult form that causes neuron dysfunction and psychosis.

NEUROLOGICAL ASSESSMENTS

Technique/normal findings	Abnormal findings
Mental status	
Assess appearance, including dress, hygiene, grooming, gait and posture. *The person should be appropriately dressed and clean, with normal gait and posture.*	■ Unilateral neglect (inattention to one side of the body) may occur with some strokes. Poor hygiene and grooming may be seen in people with dementing disorders. ■ Abnormal gait and posture may be seen in transient ischaemic attacks (TIAs), strokes and Parkinson's disease.
Assess behaviour, including actions and affect, content and quality of speech and level of consciousness (LOC). Use the Glasgow Coma Scale (see Table 40.5) to document findings. *A score of 15 on the Glasgow Coma Scale indicates the person is alert and oriented.*	■ Emotional swings or changes in personality may be observed in people who have had a stroke. ■ The face appears mask like (very little expressive movement of facial muscles) in people with Parkinson's disease. ■ Apathy is seen in people with dementing disorders. ■ **Aphasia** (defective or absent language function) may occur in TIAs and strokes. Aphasias are seen with damage to the left cerebral cortex. Aphasias are more often seen with strokes of the left hemisphere than the right hemisphere. ■ **Dysphonia** (change in the tone of the voice) is common in strokes. Dysphonia is seen with paralysis of the vocal cords (cranial nerve X). ■ **Dysarthria** (difficulty speaking) is seen with lesions of upper and lower motor neurons, the cerebellum and the extrapyramidal tract. ■ Damage to the brainstem and/or cerebral cortex may alter LOC. ■ Drowsiness and decreased LOC may be associated with brain trauma, infections, TIAs, stroke and brain tumours. ■ Level of consciousness, ranging from confusion to coma, is usually altered with a stroke.

Technique/normal findings	Abnormal findings
Assess cognitive function. Note orientation to time, place and person. Note attention span and recent and remote memory. Ask the person to: ■ repeat five to seven numbers ■ recall three items after 5 minutes ■ recall their address, breakfast or birthday. Assess thought processes (both content and perceptions) by noting responses to questions. Note ability to understand what is said and to express thoughts. Note ability to make logical and safe judgments. *The person should be oriented to time, place and person; demonstrate attention and ability to remember recent and past events; respond appropriately to questions; and be able to make judgments.*	■ Disorientation to time and place may occur in people with stroke of the right cerebral hemisphere. ■ Memory deficits are often seen in people with a stroke. ■ Perceptual deficits may be seen in strokes. These same deficits may occur following brain trauma and in dementing disorders. ■ Impaired cognition is often noted with strokes, cerebral trauma and brain tumours.
Cranial nerves	
Test CN I (olfactory). Note the person's ability to smell scents (e.g. soap, coffee) with each nostril. This test is usually done only if a problem with the ability to smell is reported. *Sense of smell should be equal in both nostrils.*	■ **Anosmia** (an inability to smell) may be seen with lesions of the frontal lobe and may also occur with impaired blood flow to the middle cerebral artery.
Test CN II (optic). Assess vision in each eye with Snellen chart (see Chapter 44 for guidelines). *Based on previous ability to see and use of visual aids, the person should be able to see with both eyes.*	■ Blindness in one eye may be seen with strokes or with TIAs. Impaired vision or blindness in one side of both eyes (homonymous hemianopia) is associated with stroke. ■ Impaired vision may be seen with strokes and brain tumours. ■ Blindness or double vision may be noted with stroke and TIAs.
Test CN III, IV and VI (oculomotor, trochlear and abducens). Assess extraocular movements by asking the person to follow your finger as you write an H in the air (see Chapter 44). Assess PERRL ('pupils equally round and reactive to light') by covering one eye at a time and shining a bright light directly into the uncovered eye (use a penlight or the ophthalmoscope). See Chapter 44 for more detailed assessment guidelines. *Extraocular movements should be present bilaterally and pupils should be equally round and reactive to light.*	■ Nystagmus (involuntary eye movement) may be seen with strokes. ■ Constricted pupils are associated with impaired blood flow from a stroke.
Assess for ptosis (drooping eyelids). *Eyelids should not droop.*	■ Ptosis (also called Horner syndrome) occurs with strokes, myasthenia gravis and palsy of CN III.

Technique/normal findings	Abnormal findings
Test CN V (trigeminal). Assess ability to feel light, dull and sharp sensations on the face. With the person's eyes closed, check whether sensation is the same on both sides of the face. Stroke the cheek with a wisp of cotton for light touch, with a closed safety pin for dull touch and with a tongue depressor for sharp touch. If the sharp point of a safety pin is used to assess sharp touch, be sure to avoid scratching the surface of the skin and discard the pin after it is used. *Ability to feel light, dull and sharp sensations should be intact.*	■ Changes in facial sensations are noted with impaired blood flow to the carotid artery. ■ Decreased sensations to the face and cornea on the same side of the body, as well as numbness of the lip and mouth, occur with strokes. ■ Loss of facial sensation or contraction of the masseter and temporal muscles is seen with lesions of CN V. ■ Severe facial pain is seen with trigeminal neuralgia (tic douloureux).
Assess the corneal reflex by touching the corneal surface with a wisp of cotton. The reflex may be absent or decreased in people who wear contact lenses. *Normally the person blinks.*	■ The corneal reflex may be impaired with lesions of CN V or VII.
Test CN VII (facial). Assess ability to taste sweet, sour and salt on the anterior two-thirds of the tongue by asking the person to stick out their tongue and applying a sweet, sour or salty substance. Assess ability to frown, show teeth, blow out cheeks, raise eyebrows, smile and close eyes tightly. *Ability to taste sweet, sour and salt is intact. Should be able to frown, show teeth, blow out cheeks, raise eyebrows, smile and close eyes tightly. Muscle movement should be equal bilaterally.*	■ Loss of ability to taste may occur with brain tumours or with nerve impairment. ■ Asymmetry or decreased movement of facial muscles is noted with lesions of the upper and lower motor neurons. ■ Paralysis of the lower motor neurons from injury to CN VII results in the inability to close eyes, a flat nasolabial fold, paralysis of lower face and inability to wrinkle forehead. ■ Paralysis of the upper motor neurons from a stroke results in weakness of eyelids and paralysis of lower face. ■ Pain, paralysis and sagging of facial muscles is seen on the affected side in Bell's palsy.
Test CN VIII (acoustic). Assess ability to hear the ticking of a watch and whispered and spoken words (see Chapter 44). *The person should be able to hear with both ears.*	■ Decreased hearing or deafness may occur with strokes and/or tumours of CN VIII.
Test CN IX and X (glossopharyngeal and vagus). If gag reflex is intact, observe the person swallowing a small drink of water. Observe for a symmetrical rise of the soft palate and uvula as the person says 'ah'. Assess gag reflex by touching back of the person's throat with a tongue depressor. Assess ability to taste sweet, sour or salty substances on the posterior third of the tongue (see previous description). *The person should be able to swallow without difficulty, have symmetrical rise of the soft palate, have intact gag reflex and taste appropriately.*	■ Dysphagia (difficulty swallowing) is common with impaired blood flow to the brain. ■ Unilateral loss of the gag reflex occurs with lesions of CN IX and X.

Technique/normal findings	Abnormal findings
Test CN XI (spinal accessory). Assess the person's ability to turn their head and shrug their shoulders against resistance: ask the person to turn their head to one side against the resistance of your hand; ask them to shrug their shoulders while you exert downward pressure. Observe symmetry, strength and size of muscles. *The person should be able to turn their head and shrug their shoulders against resistance.*	■ Muscle weakness is noted with lower motor neuron disease. Contralateral hemiparesis is seen with strokes.
Test CN XII (hypoglossal). Assess the person's ability to stick out their tongue and move it from side to side against resistance of a tongue depressor. *The person should be able to stick out tongue and move it from side to side against resistance.*	■ Atrophy and **fasciculations** (twitches) of the tongue are seen in lower motor neuron disease. The tongue may deviate towards the involved side of the body.
Sensory function	
Assess ability to perceive various sensations. Touch both sides of various parts of the body (the chest, abdomen, arms and legs) with one or more of the following: ■ cotton wisp ■ sharp object ■ dull object ■ vibrating tuning fork placed on bony prominences. *The person can differentiate between soft and sharp and can feel vibrations appropriately.*	■ Decreased sensation of pain occurs with injury to the spinothalamic tract. ■ Decreased vibratory sensations are seen with injuries to the posterior column tract. ■ Transient numbness of face, arm or hand is seen with TIAs. ■ Sensory loss on one side of the body is seen with lesions of higher pathways to the spinal cord. ■ Bilateral sensory loss is seen in polyneuropathy (a disease in which multiple peripheral nerves are affected, such as Guillain–Barré syndrome or diabetes mellitus). Sensations are impaired with strokes, brain tumours and spinal cord trauma or compression.
Assess sense of position (**kinaesthesia**). Move the person's finger or big toe up or down. Ask the person to describe the movement. *The person can accurately describe position of their finger or toe when moved up or down.*	■ Lesions of the posterior column of the spinal cord may affect sense of position.
Assess ability to discriminate fine touch. Ask the person to identify: ■ object in hand, such as a coin or key (tests stereognosis) ■ number written on hand (tests graphaesthesia) (see Figure 40.12) ■ two points of simultaneous pinpricks on the hand (tests two-point discrimination) (see Figure 40.13) ■ where they are being touched (tests localisation) ■ how many sensations are felt when touched simultaneously on both sides of the body (tests extinction). *The person can identify and discriminate fine touch.*	■ Inability to discriminate fine touch (stereognosis, graphaesthesia, two points, point localisation and extinction) may occur with injury to the posterior columns or sensory cortex.

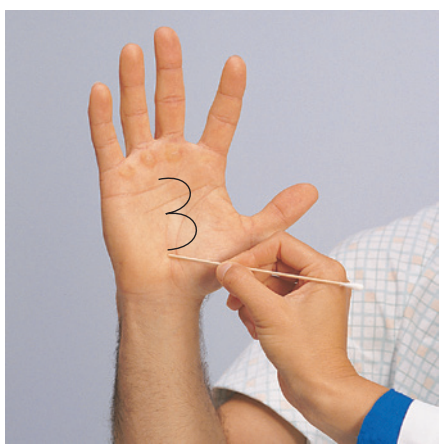


FIGURE 40.12 ■ Testing graphaesthesia

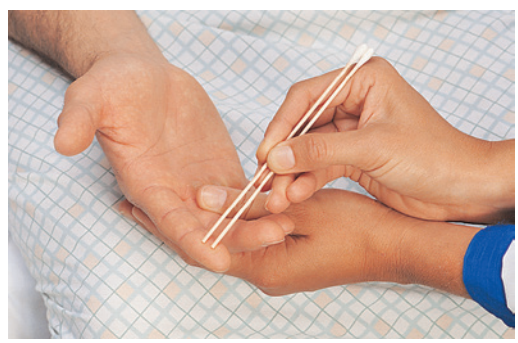

FIGURE 40.13 ■ Testing two-point discrimination

Technique/normal findings	Abnormal findings
Motor function	
Assess bilateral symmetry and size of muscles. Assess for **tremors** (rhythmic movements) and fasciculations (irregular movements). Observe movements as the person is at rest (not making a purposeful movement) and with activity (making a purposeful movement, such as reaching for a glass of water). *Muscles are bilaterally symmetrical and of equal size. Tremors or fasciculations are not present.*	■ Atrophy of muscles is seen with disease of the lower motor neurons. ■ Tremors that occur with activity are seen in multiple sclerosis and diseases of the cerebellar system. ■ Tremors that occur at rest and disappear with movement are common in Parkinson's disease. ■ Fasciculations occur in disease or trauma to the lower motor neurons, as a side effect of medications, in fever, in sodium deficiency and in uraemia.
Assess muscle tone. *Muscle tone is appropriate.*	■ Muscle tone is decreased (**flaccidity**) in disease or trauma of the lower motor neurons and early stroke. ■ Muscle tone is increased (**spasticity**) in disease of the corticospinal motor tract. ■ Muscles are rigid in disease of the extrapyramidal motor tract. ■ Muscles move in small, regular jerky movements (cogwheel rigidity) in Parkinson's disease.
Assess bilateral muscle strength and movement. Ask the person to: ■ squeeze your hands ■ push their feet against the resistance of your hands ■ raise both legs off the bed. See Chapter 37 for a scale to grade muscle strength. *Muscle strength and movement are bilaterally equal and strong.*	■ Weakness of the arms, legs or hands is often seen with TIAs. ■ Hemiplegia (paralysis of one-half of the body vertically) is noted with strokes. ■ Flaccid paralysis is noted with strokes. ■ Paralysis or decreased movement is seen in multiple sclerosis and myasthenia gravis. ■ There is total loss of motor function below the level of injury in complete spinal cord transection and in injuries to the anterior portion of the spinal cord. ■ Spasticity of muscles may occur as a result of incomplete spinal cord injuries.
Cerebellar function	
Assess the gait. Ask the person to walk normally, then in a heel-to-toe fashion, then on toes and finally on heels. *The person has appropriate gait and can walk heel-to-toe, on toes and on heels.* Perform Romberg's test. Ask the person to stand with their feet together and eyes closed. (Stand close to the person to prevent falling.) *There should be minimal swaying for up to 20 seconds.* Assess coordination. Observe ability to pat knees, alternating front and back of hands and increasing speed. Observe ability to touch each finger ofone hand to the thumb. Observe ability to touch the nose, then one of your fingers, then the nose again. Observe ability to run each heel down each shin, while in a supine position (see Figure 40.14). *The person demonstrates coordinated movements.*	■ **Ataxia** is a lack of coordination and a clumsiness of movements, with staggering, wide-based and unbalanced gait. Ataxia is often seen with strokes and cerebellar tumours. Swaying and falling are seen in cerebellar ataxia. Inability to walk on toes, then heels, may indicate disease of the upper motor neurons. ■ Spastic hemiparesis is often associated with strokes or upper motor neuron disease. The person walks with one leg stiffly dragging while the other leg circles out and forwards. One arm is held flexed and close to the side. ■ Steppage gait is noted with disease of the lower motor neurons. The person drags or lifts their foot high, then slaps the foot on to the floor. The person cannot walk on their heels. ■ Sensory ataxia may be associated with polyneuropathy or damage to the posterior columns. The person walks on their heels before bringing down their toes and the feet are held wide apart. Gait worsens with the eyes closed. ■ Parkinsonian gait is often seen in Parkinson's disease. The person stoops over while walking and shuffles their feet. Their arms are held close to the side. ■ A positive Romberg's test may be seen in cerebellar ataxia. ■ Ataxic movements are apparent in cerebellar disease.

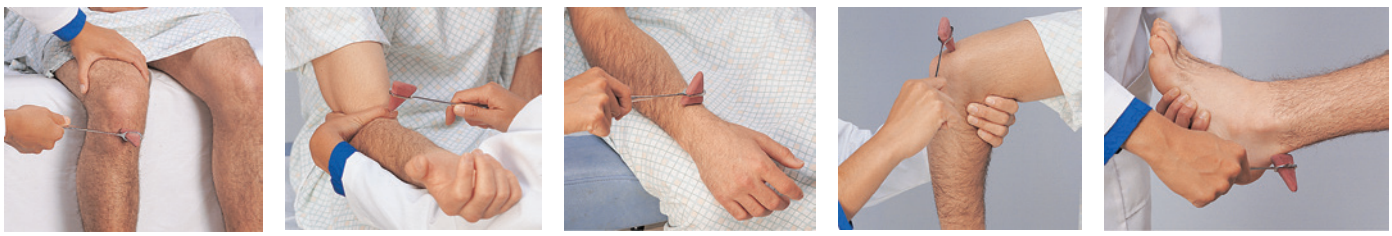
FIGURE 40.14 ■ Heel-to-shin test

REFLEX ASSESSMENTS

A reflex hammer is used to strike the tendon of various reflex sites. To test deep tendon reflexes, ask the person to lock the fingers of both hands together and then pull; this encourages relaxation and promotes reflexes of lower extremities. Superficial reflexes are assessed by lightly stroking the area with the end of a tongue depressor. The following criteria for recording reflexes are often used:

0 = absent or no response
1 = hypoactive; weaker than normal (+)
2 = normal (++)
3 = stronger than normal (+++)
4 = hyperactive, sustained clonus (++++)
A score of 2 is considered normal.

Technique/normal findings	Abnormal findings
Assess the patellar, biceps, brachioradialis, triceps and Achilles deep tendon reflexes (see Figure 40.15).	■ Hyperactive reflexes are present with lesions of upper motor neurons. ■ Decreased reflexes are present with lower motor neuron involvement.



A B C D E

FIGURE 40.15 ■ Deep tendon reflexes *A*, Using reinforcement technique to test the patellar reflex. *B*, Biceps reflex. *C*, Brachioradialis reflex. *D*, Triceps reflex. *E*, Achilles reflex

Assess for clonus by dorsiflexing the person's foot.	■ Clonus, a hyperactive, rhythmic dorsiflexion and plantar flexion, is noted with upper motor neuron disease.
Assess the superficial abdominal and cremasteric reflexes. Abdominal reflex: Lightly stroke the abdomen with a tongue depressor from the side to the midline. Normally the side of the abdomen being stroked will contract towards the umbilicus (see Figure 40.16). Cremasteric reflex: Lightly stroke the inner thigh of the male with a tongue depressor. *Normally, the testicle on the side being stroked will rise.*	■ Superficial reflexes may be absent with disease of the lower and upper motor neurons.

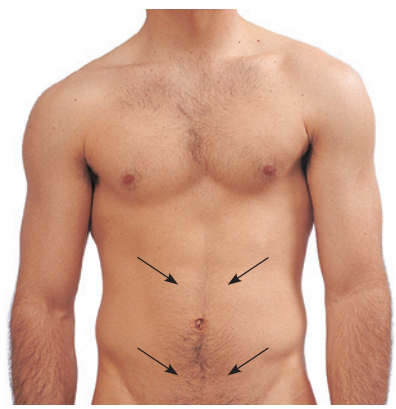


FIGURE 40.16 ■ Location of superficial abdominal reflexes

Assess the Babinski reflex (see Figure 40.17).	■ Dorsiflexion of the big toe and fanning of the other toes is seen with upper motor neuron disease of the pyramidal tract.

FIGURE 40.17 ■ Assessing the Babinski reflex

Technique/normal findings	Abnormal findings
Special neurological assessments	
Assess for Brudzinski's sign. With the person in the supine position, flex their head to their chest (see Figure 40.18). *There should be no pain, resistance or flexion of the hips or knees.*	■ Pain, resistance and flexion of hips and knees occur with meningeal irritation.
Assess for Kernig's sign. With the person supine, flex their knees and hips, then straighten their knee (see Figure 40.19). *There should be no pain or resistance.*	■ Excessive pain and/or resistance occurs with meningeal irritation.

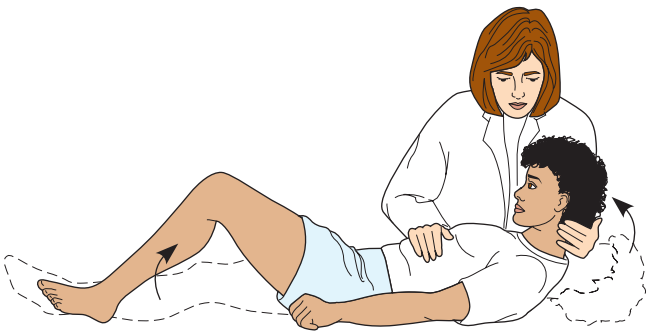

FIGURE 40.18 ■ Assessing for Brudzinski's sign

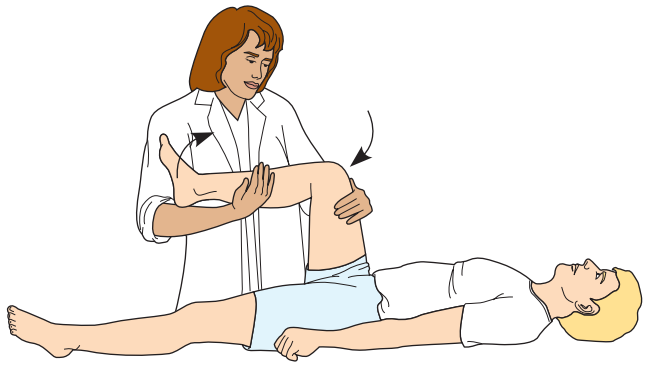

FIGURE 40.19 ■ Assessing for Kernig's sign

Assess for abnormal postures in people who are unconscious. *There should be no abnormal posturing.*

Observe for **decorticate posturing**, in which the upper arms are close to the sides; the elbows, wrists and fingers are flexed; the legs are extended with internal rotation; and the feet are plantar flexed (see Figure 40.20). Decorticate posturing occurs with lesions of the corticospinal tracts.

Observe for **decerebrate posturing**, in which the neck is extended, with the jaw clenched; the arms are pronated, extended and close to the sides; the legs are extended straight out; and the feet are plantar flexed (see Figure 40.21). Decerebrate posturing occurs with lesions of the midbrain, pons or diencephalon.

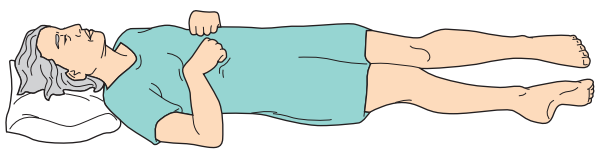

FIGURE 40.20 ■ Decorticate posturing

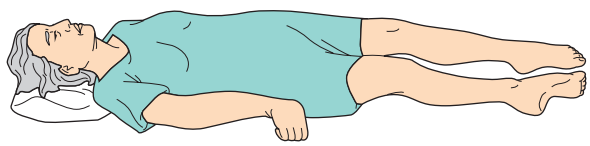

FIGURE 40.21 ■ Decerebrate posturing

CONCEPT CHECK

1 Which component of the brain protects it from harmful substances?
   1 the circulation of cerebrospinal fluid
   2 the large oxygen demand
   3 the structure of neurons
   4 the blood–brain barrier

2 Which pathophysiology results from damage to the lower motor neurons?
   1 loss of cognitive ability
   2 inability to communicate verbally
   3 loss of reflexes
   4 decreasing levels of consciousness

3 Which of the following statements about cerebrospinal fluid (CSF) is true?
   1 If CSF contains glucose, the person has a metabolic disorder.
   2 CSF circulates through the brain via the meninges.
   3 CSF protects the brain and spinal cord from trauma.
   4 A lumbar puncture is done to withdraw CSF from the brain.

4 Following a motorcycle crash, a person has damage to the posterior spinal roots. Which assessment would you expect to find?
1 loss of sensation to dull and sharp
2 flaccid paralysis of the legs
3 changes in peripheral vision in both eyes
4 decreased sense of smell and taste

5 You narrowly miss having a car crash while merging on to the freeway. Your body's responses to this stress are caused by which division of the autonomic nervous system?
1 sympathetic
2 parasympathetic
3 cholinergic
4 adrenergic

6 Which of the physical assessment techniques is not used in the neurological examination?
1 inspection
2 auscultation
3 percussion
4 palpation

7 What would you need to assess function of cranial nerve V (trigeminal)?
1 cotton ball and safety pin
2 stethoscope with bell and diaphragm
3 measuring tape and pencil
4 various scents, such as coffee and vanilla

8 In which of the following cases would assessing the corneal reflex be appropriate?
1 anyone over the age of 50
2 people who wear contact lenses
3 a person with spinal cord trauma
4 an unconscious person

9 You have been asked to assess a person's gag reflex. What equipment would you need to do this?
1 safety pin
2 cotton ball
3 tongue depressor
4 stethoscope

10 Which position best describes decorticate posturing?
1 neck extended, arms extended and pronated, feet plantar flexed
2 arms close to sides, elbows and wrists flexed, legs extended
3 in prone position with arms and knees sharply flexed
4 in supine position, spine extended, legs extended

CHAPTER 41

NURSING CARE OF PEOPLE WITH INTRACRANIAL DISORDERS

LAURA MELLISH

LEARNING OUTCOMES

- Compare and contrast the pathophysiology, manifestations, interprofessional care and nursing care of people with alterations in level of consciousness and increased intracranial pressure.
- Explain the pathophysiology, manifestations, complications, interprofessional care and nursing care of intracranial disorders, including headaches, epilepsy, traumatic brain injury, central nervous system infections and brain tumours.
- Describe criteria for diagnosing persistent vegetative state and brain death.
- Discuss the purposes, nursing implications and health education for the person and their family in relation to medications used to treat altered cerebral function, headaches, epilepsy, traumatic brain injury, central nervous system infections and brain tumours.
- Discuss surgical options for the treatment of increased intracranial pressure, epilepsy, traumatic brain injury and brain tumours.

CLINICAL COMPETENCIES

- Assess functional status of people with intracranial disorders and monitor, document and report abnormal manifestations.
- Determine priority nursing diagnoses, based on assessed data, to select and implement individualised nursing interventions for people with intracranial disorders.
- Administer oral and injectable medications used to treat intracranial disorders knowledgeably and safely.
- Provide skilled care to people having intracranial pressure monitoring, tonic–clonic seizures and intracranial surgery.
- Integrate interprofessional care into the care of people with intracranial disorders.
- Provide appropriate teaching and evidence-based practice to facilitate community-based care to promote safety and prevent injury, and to provide information and support necessary for long-term care of people with intracranial disorders.
- Revise the plan of care as needed to provide effective interventions to promote, maintain or restore functional health status to people with intracranial disorders.

KEY TERMS

The person with an intracranial disorder presents a unique nursing challenge. Problems the person experiences in the acute stage of the disorder are often a prelude to long-term problems requiring ongoing management. These long-term problems range from alterations in the body's basic functioning to dysfunctions in the complex processes of the human mind. Systemic problems may accompany or develop secondary to an intracranial disorder. Intracranial disorders may affect both the person's quality of life and that of the person's family. This chapter discusses altered level of consciousness and increased intracranial pressure, followed by discussion of intracranial disorders that may manifest these and other health problems. Information specific to the person with a stroke is provided in Chapter 42.

ALTERED CEREBRAL FUNCTION

The manifestations of altered cerebral function occur as a result of illness or injury. Assessment of the patterns of those manifestations helps determine the extent of the cerebral dysfunction and improvement or deterioration of cerebral function. Except in the case of direct damage to the brainstem and reticular activating system (RAS), brain function deterioration usually follows a predictable progression; that is, a pattern in which higher levels of function are impaired initially, progressing to impairment of more primitive functions. Altered level of consciousness (LOC) and behaviour changes are early manifestations of the deterioration of the function of the cerebral hemispheres. Structures in the midbrain and brainstem are affected sequentially, with characteristic changes in LOC; patterns of respiration, pupillary and oculomotor responses; and motor function. Manifestations of progressive deterioration of cerebral function are outlined in Table 41.1.

THE PERSON WITH ALTERED LEVEL OF CONSCIOUSNESS

Consciousness is a condition in which the person is aware of self and environment and is able to respond appropriately to stimuli. Full consciousness requires both normal rousal and full cognition.

- Rousal, or alertness, depends on the RAS, a diffuse system of neurons in the thalamus and upper brainstem.
- Cognition is a complex process involving all mental activities controlled by the cerebral hemispheres, including thought processes, memory, perception, problem solving and emotion.

These two components of consciousness depend on the normal physiological functions of and connections between the

TABLE 41.1 Progression of deteriorating brain function

LEVEL OF CONSCIOUSNESS	PUPILLARY RESPONSE	OCULOMOTOR RESPONSES	MOTOR RESPONSES	BREATHING
Alert; oriented to time, place and person	Brisk and equal; pupils regular	Eyes move as head turns; caloric testing (ear irrigation) produces nystagmus	Purposeful movement; responds to commands	Regular pattern with normal rate and depth
Responds to verbal stimuli; decreased concentration; agitation, confusion, lethargy; disoriented	Small and reactive	Roving eye movements; doll's eyes positive, with gaze fixed straight ahead; eye deviation away from cold caloric stimulus and towards warm stimulus	Purposeful movement in response to pain stimulus	Yawning, sighing respirations
Requires continuous stimulation to rouse			Decorticate posturing with upper extremity flexion	Cheyne–Stokes respirations with crescendo–decrescendo pattern in rate and depth followed by period of apnoea
Reflexive positioning to pain stimulus	Pupils fixed (non-reactive) in midposition	Caloric testing produces nystagmus	Decerebrate posturing with adduction and rigid extension of upper and lower extremities	Central neurogenic hyperventilation with rapid, regular and deep respirations; apneustic breathing with prolonged inspiration and pauses at full inspiration and following expiration
No response to stimuli	Pupils fixed in midposition	No spontaneous eye movement or nystagmus	Extension of upper extremities with flexion of lower extremities; flaccidity	Cluster or ataxic breathing with irregular pattern and depth of respirations; gasping respirations or apnoea

rousal mechanisms of the reticular formation and the cognitive functions of the cerebral hemispheres. Because rousal and cognition are independent components of consciousness, each can act separately on stimuli. For example, the RAS reacts to the discomfort caused by a full bladder by waking the person in the middle of the night. Once awake, however, the frontal cortex alerts the person that the bladder is full and prompts the person to go to the toilet and empty it.

Conditions that affect either the RAS or the function of the cerebral hemispheres can interfere with the normal level of consciousness. Terms describing LOC are listed and defined in Table 41.2. Nurses should remember that consciousness is a dynamic state: a person may pass from full consciousness to coma within hours or experience a slow diminishment of consciousness that does not become evident for weeks or months. The nurse can help provide effective care for a person with an altered LOC by looking beyond the diagnostic labels of consciousness and accurately assessing the person's behaviour and response to stimuli.

Pathophysiology

Level of consciousness may be altered by processes that affect the rousal functions of the brainstem, the cognitive functions of the cerebral hemispheres, or both. The main causes are: (1) lesions or injuries that affect the cerebral hemispheres directly and widely, or that compress or destroy the neurons of the RAS; and (2) metabolic disorders.

Rousal and cognition

The physiological seat of consciousness, the reticular formation, is a mass of nerve cells and fibres that make up the core of the brainstem, extending from the medulla to the midbrain. The axons of reticular neurons are exceptionally long and branch outwards to cells in the hypothalamus, thalamus, cerebellum and spinal cord. A system of reticular neurons within the RAS passes steady streams of impulses through thalamic relays in order to stimulate the cerebral cortex into wakefulness. The body's sensory tracts interact with RAS neurons; this interrelationship helps control the strength of the RAS's rousing effect on the cerebrum.

Damage to the RAS impairs the person's ability to maintain wakefulness and rousal. Stroke is the most common cause of RAS destruction. Other causes include demyelinating diseases, such as multiple sclerosis, tumours, abscesses and head injury. Function of the RAS may be suppressed by compression of the brainstem, which produces oedema and ischaemia. Pressure and compression of the brainstem may be due to tumours, increased intracranial pressure, haematomas, haemorrhage or aneurysm. Although it is possible to assess LOC or rousal in the person with RAS damage, the impairment in rousal may make it impossible to assess cognitive function.

The function of the brain, especially the cerebral hemispheres, depends on continuous blood flow with unimpeded supplies of oxygen and glucose. Processes that disrupt this flow of blood and nutrients may cause widespread damage to the cerebral hemispheres, impairing rousal and cognition. Bilateral hemispheric lesions (such as global ischaemia) or metabolic disorders (such as hypoglycaemia) are the most common causes of altered LOC related to cerebral dysfunction of the hemispheres. Localised masses, such as a haematoma or cerebral oedema, which displace normal structures and cause direct or indirect pressure on the opposite hemisphere or brainstem, can also affect LOC. The person who has widespread damage to the cerebral hemispheres but an intact RAS has sleep–wake cycles and may rouse in response to stimuli; the person cannot be said to be alert, however, because cognition is impaired.

Both localised neurological processes and systemic disorders can alter LOC. Processes occurring within the brain, which may directly destroy or compress neurological structures, include the following:

- increased intracranial pressure
- stroke
- haematoma
- intracranial haemorrhage
- tumours
- infections
- injury from excitatory amino acids
- demyelinating disorders.

TABLE 41.2 Terms used to describe level of consciousness

TERM	CHARACTERISTICS OF PERSON
Full consciousness	Alert; oriented to time, place and person; comprehends spoken and written words
Confusion	Unable to think rapidly and clearly; easily bewildered, with poor memory and short attention span; misinterprets stimuli; judgment is impaired
Disorientation	Not aware of or not oriented to time, place or person
Drowsy	Lethargic, somnolent; responsive to verbal or tactile stimuli but quickly drifts back to sleep
Stupor	Generally unresponsive; may be briefly roused by vigorous, repeated or painful stimuli; may shrink away from or grab at the source of stimuli
Semicomatose	Does not move spontaneously; unresponsive to stimuli, although vigorous or painful stimuli may result in stirring, moaning or withdrawal from the stimuli, without actual rousal
Coma	Unrousable; will not stir or moan in response to any stimulus; may exhibit non-purposeful response (slight movement) of area stimulated but makes no attempt to withdraw
Deep coma	Completely unrousable and unresponsive to any kind of stimulus, including pain; absence of brainstem reflexes, corneal, papillary and pharyngeal reflexes, and tendon and plantar reflexes

Any systemic condition that affects the delivery of blood, oxygen and glucose to the brain or alters cell membranes may also alter LOC. If cerebral blood flow is impaired or the person becomes hypoxic or hypoglycaemic, cerebral metabolism is impaired and level of consciousness declines rapidly. Severe hypoxia quickly leads to ischaemia. Ischaemia may be focal (e.g. following a stroke) or global (as from cardiac arrest or hypovolaemic shock). Widespread global ischaemia causes almost immediate unconsciousness (Grossman & Porth, 2013). People at particular risk include those with poorly controlled diabetes and those with cardiac or respiratory failure.

Other metabolic alterations that can affect LOC include fluid and electrolyte imbalances, such as hyponatraemia or hyperosmolality and acid–base alterations, such as hypercapnoea (an elevated arterial carbon dioxide level). Accumulated waste products and toxins from liver or kidney failure can affect neuronal and neurotransmitter function, altering LOC. Drugs that depress the central nervous system (e.g. alcohol, analgesics, anaesthetics) suppress metabolic and membrane activities in the RAS and cerebral hemispheres, thereby affecting LOC. Glutamate, the main excitatory neurotransmitter in the brain, may accumulate during prolonged ischaemia, resulting in acute glutamate toxicity and cell death.

Seizure activity, with abnormal electrical discharges from a local area of the brain or from the entire brain, commonly affects LOC. It appears that the spontaneous, disordered discharge of activity that occurs during a seizure exhausts energy metabolites or produces locally toxic molecules, altering LOC for a time after the seizure. Consciousness returns when the metabolic balance of the neurons is restored.

As the impairment of brain function progresses, more stimuli are required to elicit a response from the person. Initially, the person may rouse to verbal stimuli and respond appropriately to questions, remaining oriented to time, place and person. With deterioration of neurological function, the person becomes more difficult to rouse and may become agitated and confused when awakened. Orientation to time is lost initially, followed by orientation to place and then to person. Continuous stimulation or vigorous shaking is required to maintain wakefulness as LOC decreases. Eventually, the person does not respond, even with deep painful stimuli.

Patterns of respirations

Progressive impairment of neural function also causes predictable changes in respiratory patterns as respiratory centres are affected. In normal respirations, a rhythmic pattern is maintained by neural centres in the pons and medulla that respond to changes in arterial levels of oxygen (PaO_2) and carbon dioxide ($PaCO_2$). When there is damage to the RAS or cerebral hemispheres, neural control of these centres is lost and lower brainstem centres regulate breathing patterns by responding only to changes in $PaCO_2$, resulting in irregular respiratory patterns. The initial manifestations of deteriorating brain function are yawning and sighing. As outlined in Table 41.1, and illustrated in Table 41.3, progressive deterioration in brain function is accompanied by decreasing LOC and changes in breathing patterns. The types of respirations, by area of cerebral damage, are as follows:

- diencephalon: *Cheyne–Stokes respirations* (alternating regular periods of deep, rapid breathing followed by periods of apnoea)
- midbrain: *neurogenic hyperventilation* (may exceed 40 per minute), the result of uninhibited stimulation of the respiratory centres
- pons: *apneustic respirations*, characterised by sighing on mid-inspiration or prolonged inhalation and exhalation; results from excessive stimulation of the respiratory centres
- medulla: *ataxic/apnoeic respirations* (totally uncoordinated and irregular), probably as a result of the loss of responsiveness to CO_2.

Pupillary and oculomotor responses

The brainstem areas that control rousal are adjacent to areas that control the pupils. A predictable progression of pupillary and oculomotor responses occurs as the level of consciousness deteriorates towards coma (see Table 41.1). If the lesion or process affecting neurological function is localised, effects may initially be seen in the ipsilateral pupil (the pupil on the same side as the lesion). With generalised or systemic processes, pupils are affected equally. If the pupils are small and equally reactive, metabolic processes affecting LOC may be present. With compression of cranial nerve III at the midbrain, the

TABLE 41.3 Breathing patterns characteristic of altered level of consciousness

PATTERN		DESCRIPTION
Cheyne–Stokes respirations		A regular crescendo–decrescendo pattern with increasing, then decreasing, rate and depth of respirations followed by a period of apnoea
Central neurogenic hyperventilation		A sustained pattern of rapid, regular, deep respirations (hyperapnoea)
Apneustic breathing		Prolonged inspiration with a pause at full inspiration followed by expiration and a possible pause following expiration
Cluster breathing		Clusters of several breaths with irregular periods of apnoea between clusters
Ataxic respirations		Respirations that are completely irregular in pattern and depth with irregular periods of apnoea

pupils may become oval or eccentric (off centre). As the level of functional impairment progresses, the pupils become fixed (unresponsive to light) and, eventually, dilated.

In deteriorating LOC and coma, spontaneous eye movement is lost and reflexive ocular movements are altered. Normally, both eyes move simultaneously in the same direction; injury to the cranial nerve nuclei in the midbrain and pons can impair normal movement. Doll's eye movements are reflexive movements of the eyes in the opposite direction of head rotation; they are an indicator of brainstem function (see Figure 41.1). As a result of the oculocephalic reflex, the eyes move upwards with passive flexion of the neck and downwards with passive neck extension. As brainstem function deteriorates, this reflex is lost. The eyes fail to turn together and, eventually, remain fixed in the midposition as the head is turned.

Motor responses

The level of brain dysfunction and the side of the brain affected may be assessed by motor responses. These responses are the most accurate identifier of changes in mental status. In altered LOC, motor responses to stimuli range from an appropriate response to a command (e.g. 'squeeze my hand' or 'push my hands away with your feet') to flaccidity (see Table 41.1). Initially, the person may be able to move purposefully away from a noxious stimulus; for example, to brush the examiner's hand away from the face. As function declines, movements become more generalised (withdrawal, grimacing) and less purposeful. Reflexive motor responses may occur, including decorticate posturing with flexion of the upper extremities accompanied by extension of the lower extremities. With further decline, decerebrate posturing is seen, with adduction and rigid extension of the upper and lower extremities. Without intervention, the person eventually becomes flaccid, with little or no motor response to stimuli.

Coma states and brain death

Possible outcomes of altered LOC and coma include full recovery with no long-term residual effects, recovery with residual damage (such as learning deficits, emotional difficulties or impaired judgment) or more severe consequences, such as persistent vegetative state (cerebral death) or brain death. Resources for families are listed in Box 41.1.

PERSISTENT VEGETATIVE STATE **Persistent vegetative state** (also called irreversible coma) is a permanent condition of complete unawareness of self and the environment and loss of all cognitive functions. Usually the result of severe brain trauma or global ischaemia, this condition results from death of the cerebral hemispheres with continued function of the brainstem and cerebellum. While the homeostatic regulatory functions of the brain continue, the ability to respond meaningfully to the environment is lost. The diagnosis of persistent vegetative state requires that the condition has continued for at least 1 month (Grossman & Porth, 2013).

The person has sleep–wake cycles and retains the ability to chew, swallow and cough, but cannot interact with the environment. When awake, the eyes may wander back and forth across the room, but they cannot track an object or person. In a minimally conscious state, the person is aware of the environment and can follow simple commands, manipulate objects, gesture or verbalise to indicate 'yes/no' responses and make meaningful movements (such as blinking or smiling) in response to a stimulus. With appropriate supportive care, the person may remain in this state for years.

LOCKED-IN SYNDROME **Locked-in syndrome** is distinctly different from persistent vegetative state in that the person is alert and fully aware of the environment and has intact cognitive abilities, but is unable to communicate through speech or movement because of blocked efferent pathways from the brain. Motor paralysis affects all voluntary muscles, although the upper cranial nerves (I to IV) may remain intact, allowing the person to communicate through eye movements and blinking. In essence, the person is 'locked' inside a paralysed body while remaining fully conscious of self and environment. Infarction or haemorrhage of the pons that disrupts outgoing nerve tracts but spares the RAS is the usual cause of locked-in syndrome. This condition may also result when the corticospinal tracts between

the midbrain and pons are interrupted. Disorders of the lower motor neurons or muscles, such as acute polyneuritis, myasthenia gravis or motor neurone disease may also paralyse motor responses, leading to locked-in syndrome.

BRAIN DEATH **Brain death** is the cessation and irreversibility of all brain functions, including the brainstem. Although the exact criteria for establishing brain death may vary somewhat from state to state, it is generally agreed that brain death has occurred when there is no evidence of cerebral or brainstem function for an extended period (usually 6 to 24 hours) in a person who has a normal body temperature and is not affected by a depressant drug or alcohol poisoning. Generally recognised criteria are:

- unresponsive coma with absent motor and reflex movements
- no spontaneous respiration (apnoea)
- pupils fixed (unresponsive to light) and dilated
- absent ocular responses to head turning and caloric stimulation (caloric stimulation is performed by irrigating the ear with ice-cold water to test the oculovestibular reflex, a reflex controlled by the brainstem. Normally, the cold causes the eyes to move first towards the irrigated side, followed by a return to midline)
- flat electroencephalogram (EEG) and no cerebral blood circulation present on angiography (if performed)
- persistence of these manifestations for 30 minutes to 1 hour and for 6 hours after onset of coma and apnoea.

Apnoea in the comatose person is determined by the apnoea test. The ventilator is removed while maintaining oxygenation by tracheal cannula and allowing the PCO_2 to increase to 60 mmHg or higher. This level of carbon dioxide is high enough to stimulate respiration if the brainstem is functional. The EEG may be used to establish the absence of brain activity when brain death is suspected. A flat (isoelectric) EEG over a period of 6 to 12 hours in a person who is not hypothermic or under the influence of drugs that depress the central nervous system (CNS) is generally accepted as an indicator of brain death.

Prognosis

The prognosis for people with altered levels of consciousness and coma varies according to the underlying cause and pathological process. Age and general medical condition also play a role in determining outcome. Young adults may fully recover following deep coma from head injury, drug overdose or other cause. Recovery of consciousness within 2 weeks is associated with a favourable outcome. In general, the prognosis is poor for people who lack pupillary reaction or reflex eye movements 6 hours after the onset of coma.

INTERPROFESSIONAL CARE

Management of the person with an altered LOC or coma must begin immediately. The focus of management is to identify the underlying cause, preserve function and prevent deterioration if possible. Airway and breathing must be maintained during the initial acute stage until the diagnosis and prognosis can be established. Intravenous fluids are used to support circulation and to correct fluid, electrolyte and acid–base imbalances. Treatment protocols to reduce increased intracranial pressure or control seizure activity (discussed later in this chapter) may be initiated. Changes in LOC associated with craniocerebral trauma, such as haematomas, often require immediate surgical intervention.

Diagnosis

Although the person's history and physical examination findings often indicate the cause of alterations in LOC, several diagnostic tests may be useful in establishing the diagnosis. The tests used to evaluate for possible metabolic, toxic or drug-induced disorders include both radiological and laboratory tests.

CT and MRI scanning are done to detect neurological damage due to haemorrhage, tumour, cyst, oedema, myocardial infarction or brain atrophy. These tests may also identify displacement of brain structures by large or expanding lesions. Radioisotope brain scan is performed to identify abnormal lesions in the brain and evaluate cerebral blood flow. Cerebral angiography allows radiographic visualisation of the cerebral vascular system. This exam can identify lesions such as aneurysms, occluded vessels or tumours, and may also be used to determine cessation of cerebral blood flow and brain death. Transcranial Doppler studies use an ultrasound velocity detector that records sound waves reflected from RBCs in blood vessels to assess cerebral blood flow. Lumbar puncture with cerebrospinal fluid (CSF) analysis is performed when infection and possible meningitis are suspected as a cause of altered LOC. EEG is used to evaluate the electrical activity of the brain. (See Chapter 40 for further information and nursing implications of neurological tests.)

Laboratory tests are used to identify and monitor altered LOC. These may include any or all of the following:

- *Blood glucose* is measured immediately when coma is of unknown origin and hypoglycaemia is suspected or possible. When the blood glucose falls to less than 2.2 to 2.7 mmol/L, cerebral function declines rapidly. The person with type 1 diabetes is at particular risk of hypoglycaemia-induced coma.
- *Serum electrolytes*—sodium, potassium, bicarbonate, chloride and calcium, in particular—are measured to assess for metabolic disturbances and to guide intravenous therapy. Hyponatraemia, in which serum sodium levels are below

115 mmol/L (normal level: 135 to 145 mmol/L), is associated with coma and convulsions, especially if it develops rapidly.

- *Serum osmolality* is evaluated. Both hyperosmolar and hypo-osmolar states may be associated with coma. Hyperosmolality (above 320 mOsm/kg H_2O) causes cellular dehydration of brain tissue as fluid is drawn into the vascular system by osmosis. Hypo-osmolality (less than 250 mOsm/kg H_2O), by contrast, leads to cerebral oedema and swelling, impairing consciousness.
- *Arterial blood gases* (ABGs) are drawn to evaluate arterial oxygen and carbon dioxide levels, as well as acid–base balance. Hypoxaemia is a frequent cause of altered LOC; increased levels of carbon dioxide are also toxic to the brain and can induce coma, particularly when the onset of hypercapnoea is acute.
- *Liver function tests*, including bilirubin, aspartate transaminase (AST), alanine transaminase (ALT), lactate dehydrogenase (LDH), serum albumin and serum ammonia levels, are determined to evaluate hepatic function. High ammonia levels seen in hepatic failure interfere with cerebral metabolism and neurotransmitters, affecting LOC.
- Toxicology screening of blood and urine is done to determine if altered LOC is the result of acute drug or alcohol toxicity. Serum alcohol levels are measured and the blood is assessed for the presence of substances such as barbiturates, carbon monoxide or lead.

Medications

Medications are used to support homeostasis and normal function for the person with altered LOC, as well as to treat specific underlying disorders. An intravenous catheter is inserted and fluid balance is maintained using isotonic or slightly hypertonic solutions, such as normal saline or Hartmann's solution. The person's response to fluid administration is monitored carefully for evidence of increased cerebral oedema.

If hypoglycaemia is present, 50% glucose is administered intravenously to restore cerebral metabolism rapidly. Conversely, insulin is administered to the person with hyperglycaemia to reduce the blood glucose level and thus the serum osmolality. With narcotic overdose, naloxone is administered. Naloxone is a narcotic antagonist that competes for narcotic receptor sites, effectively blocking the depressant effect of the narcotic. Thiamine may be administered with glucose, particularly if the person is malnourished or known to abuse alcohol, to prevent exacerbation of Wernicke's encephalopathy, a haemorrhagic encephalopathy due to thiamine deficiency that is associated with chronic alcoholism (Papadakis, McPhee & Rabow, 2015).

Any underlying fluid and electrolyte imbalance is corrected by administering medications or appropriate electrolytes. For the person who is hyponatraemic and has a low serum osmolality, frusemide (Lasix) or an osmotic diuretic such as mannitol may be administered to promote water excretion. Appropriate antibiotics are administered intravenously to the person with suspected or confirmed meningitis.

Surgery

Although surgery is not indicated for most people with altered LOC, it may be necessary if the cause of coma is an intracerebral tumour, haemorrhage or haematoma. Surgical intervention is discussed later in this chapter, in the section on brain tumours. When there is a risk of increased intracranial pressure, the person is monitored continuously. These measures are discussed in the section on increased intracranial pressure that follows.

Other treatments

Support of the airway and respirations is vital in the person with an altered LOC. The person who is drowsy but rousable may need little more than an oral pharyngeal airway. With more severe alterations in consciousness, the person may need endotracheal intubation to maintain airway patency, particularly if the cough and gag reflexes are absent. Mechanical ventilation is indicated when hypoventilation or apnoea is present. Unless a not-for-resuscitation (NFR) order is in effect, mechanical ventilation should be initiated even if it has not been established that the disorder is reversible; without ventilatory support, cerebral anoxia develops rapidly and brain death may ensue. ABGs are monitored frequently to determine the adequacy of ventilation. Cautious hyperventilation may be used to reduce $PaCO_2$ and promote cerebral vasoconstriction to reduce cerebral oedema.

Nutrition

In people with long-term alterations in consciousness, such as vegetative state or locked-in syndrome, measures to maintain nutritional status are initiated. Enteral feedings with a gastrostomy tube are preferred if the person is unable to take enough food by mouth without aspirating. In some cases, total parenteral nutrition (TPN) may be used.

Nursing care

Nursing care of the person with an altered LOC is planned and implemented for a variety of responses of both the person and their family.

Support of the family

Family members of a person with an altered level of consciousness are often very anxious. It is difficult for the family to deal with the person's uncertain prognosis. They may experience various conflicting emotions, such as guilt and anger. Reinforce information provided by the doctor and encourage the family to talk to the person as though they are able to understand. Explain that this communication may initially seem awkward, but in time it will feel appropriate. Evaluate the family's readiness to receive explanations regarding the person's treatment and care. The presence of many tubes (e.g. intravenous line, catheter, ventilator) may be overwhelming to the family. They may not perceive the seriousness of the situation if a thorough explanation is not given. Include family members in the person's care as much as they wish to be involved.

Allow significant others to stay with the person when possible. Reinforce the need for family members to care for themselves by encouraging adequate meals and rest. Offer to contact support services such as friends, neighbours and social services that the hospital may provide. Ask family members to leave a telephone number where they can be reached and assure them that they will be called if any significant changes occur. Encourage family members to call if they have questions or concerns.

Nursing diagnoses and interventions

Nursing diagnoses and interventions discussed in this section are directed towards the unconscious person and focus on problems with airway maintenance, skin integrity, contractures and nutrition.

Ineffective airway clearance

Ineffective airway clearance related to loss of the cough reflex and the inability to expectorate is a major problem for the unconscious person. The cough reflex may be absent or impaired when conditions that produce coma depress the function of the medullary centres.

- Assess ability to clear secretions. Monitor breath sounds, rate and depth of respirations, dyspnoea, pulse oximeter and the presence of cyanosis. *The person's ability to clear secretions serves as the initial assessment base for developing further interventions.*
- In unconscious people or those without an intact cough reflex, maintain an open airway by periodic suctioning, limiting the time of suctioning to 10 to 15 seconds or less. Periodic suctioning may be necessary to clear the airway of mucus, blood or other drainage. *Suctioning for more than 15 seconds in the person with increased intracranial pressure may cause hypercapnia, which in turn vasodilates cerebral vessels, increases cerebral blood volume and increases intracranial pressure.*

CONSIDERATION FOR PRACTICE

If the person has a base-of-skull fracture or CSF draining from the ears or nose, never suction nasally.

- Turn from side to side every 2 hours and maintain a side-lying position with the head of the bed elevated approximately 30 degrees. Do not position the unconscious person on the back. *Turning the person from side to side facilitates respirations, prevents the tongue from obstructing the airway and helps prevent pooling of secretions in one area of the lungs (thus decreasing the risk of pneumonia).*
- If the person has a tracheostomy, provide tracheostomy care every 4 hours and suction when secretions are present (see Chapter 34) *to maintain an open airway.*
- Monitor the results of arterial blood gas analysis and pulse oximetry. Maintain records of trends. *ABGs and pulse oximetry directly measure the oxygen content of blood and are good indicators of the lungs' ability to oxygenate the blood.*

Risk of aspiration

The unconscious person with a depressed or absent gag and swallowing reflex is at high risk of aspiration. Drainage, mucus or blood may obstruct the airway and interfere with oxygenation. Pooling of aspiration secretions in the lungs also increases the risk of pneumonia.

- Assess swallowing and gag reflexes every shift as appropriate to the person's level of consciousness. *Deepening levels of unconsciousness may cause a loss in swallow and gag reflexes.*
- Monitor for and report manifestations of aspiration: crackles and wheezes, dullness to percussion over an area of the lungs, dyspnoea, tachypnoea and cyanosis. *Early recognition facilitates prompt intervention.*
- Provide interventions to prevent aspiration:
  - Maintain NBM status.
  - Place in the side-lying position.
  - Provide oral hygiene and suctioning as needed.

  The side-lying position allows secretions to drain from the mouth rather than into the pharynx. Oral hygiene and suctioning remove secretions that might otherwise be aspirated.

CONSIDERATION FOR PRACTICE

Never give oral food and fluids to people with a decreased LOC because of the risk of aspiration.

Risk of impaired skin integrity

The unconscious person is at risk of impaired skin integrity as a result of immobility and the inability to provide self-care. On average, healthy people change positions during sleep every 11 minutes; the unconscious person often cannot maintain the movement needed to prevent pressure on the skin, especially over bony prominences. As a result, the skin and subcutaneous tissues may become ischaemic and prone to develop pressure injury. Perspiration and incontinence of urine and stool may exacerbate the problem. Nursing interventions are directed at maintaining the integrity not only of the skin but also of the lips and mucous membranes.

- Assess skin every shift, especially over bony prominences, the back of the scalp and around genitals and buttocks. *The large surface area of the skin bears weight and is in constant contact with the surface of the bed. The skin, subcutaneous tissue and muscles, especially those tissues over bony prominences, undergo constant pressure. This impairs normal capillary blood flow, which interferes with the exchange of nutrients and waste products. Tissue ischaemia and necrosis may result and lead to the development of pressure injury.*
- Provide proper positioning. Reposition bed-bound people at least every 2 hours if this is consistent with the overall treatment goals. Keep the head of the bed elevated no higher than 30 degrees unless prescribed differently. Provide special pads and mattresses that distribute weight more evenly (e.g. alternating pressure air mattresses, egg-crate foam cushions, turning frames). Consider requesting/using a special therapeutic bed that automatically turns the person at regular intervals. Lift the person instead of dragging the person across the sheet. *When the head of the bed is elevated above 30 degrees,*

LINKS TO NATIONAL PATIENT SAFETY STANDARDS

NSQHS Standard 8: Preventing and Managing Pressure Injuries.

'The intention of this standard is to prevent patients from developing pressure injuries and effectively managing pressure injuries when they do occur.' (Australian Commission on Safety and Quality in Health Care (ACSQHC), 2012, p. 54).

Implementing this standard is achieved by the establishment of systems that ensure thorough screening for patients at risk and the utilisation of clinically appropriate prevention and management strategies.

Caring for individuals with decreased LOC will result in the need for vigilant pressure area care due to the person's inability to move voluntarily, which increases their risk of developing pressure injuries. Pressure area care of the person with decreased LOC involves regular repositioning as permitted by their clinical condition; the use of pressure-relieving devices such as alternating pressure air mattresses; the correct use of lifting aids such as slide sheets; keeping the person's skin clean and dry; regular inspection of pressure areas to detect deterioration; and the management of pressure injuries according to best practice guidelines.

Source: © Australian Commission on Safety and Quality in Health Care.

the person's torso tends to slide down towards the foot of the bed. Friction and perspiration cause the skin and superficial fascia to remain fixed against the bed linen while the deep fascia and skeleton slide downwards. When a person is pulled rather than lifted, the skin remains fixed to the sheet while the fascia and muscles are pulled upwards. These shearing forces promote tissue breakdown.

- Provide interventions to prevent breakdown of the skin and mucous membranes:
  - Keep bed linen clean, dry and wrinkle free.
  - Provide daily bath with mild soap.
  - Cleanse the skin after urine and faecal soiling with a mild cleansing agent.
  - Provide oral care and lubricate the lips every 2 to 4 hours.
  - Maintain accurate intake and output records.
  - Keep the cornea moist by instilling methyl cellulose solution (0.5–1%) and apply protective eye shields or close the eyelids with adhesive strips if the corneal reflex is absent.

  Keeping linen clean, dry and wrinkle free decreases the risk of injury from the shearing force of bed rest and protects against environmental factors that cause drying. Adequate hydration of the stratum corneum appears to protect the skin against mechanical insult. Preventing dehydration maintains circulation and decreases the concentration of urine, thereby minimising skin irritation in people who are incontinent. Proper eye care prevents corneal abrasion and irritation.

Impaired physical mobility

People who are unconscious are unable to maintain normal musculoskeletal movement and are at high risk of contractures related to decreased movement. Flexor and adductor muscles are stronger than the extensors and abductors, resulting in the rapid development of flexor and adductor contractures without preventive measures. Passive ROM exercises must be performed routinely to maintain muscle tone and function, to prevent additional disability and to help restore impaired motor function.

- Maintain extremities in functional positions by providing proper support devices. Remove support devices every 4 hours for skin care and passive ROM exercises. Provide pillows for the axillary region; rolled washcloths may be placed in elevated hands; use splints to prevent plantar flexion (foot drop). *Pillows in the axillary region help prevent adduction of the shoulder. Rolled washcloths help decrease oedema and flexion contracture of the fingers. Splints are useful in preventing plantar flexion.*
- Collaborate with a physiotherapist to develop and implement passive range-of-motion (ROM) exercises (unless contraindicated, as for the person with increased intracranial pressure) at least four times a day, keeping the following principles in mind:
  - Place one hand above the joint being exercised. The other hand gently moves the joint through its normal range of motion.
  - Move the body part to the point of resistance and stop.

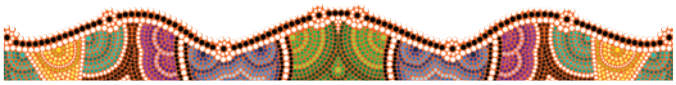
  Placing one hand above the joint provides support against gravity and prevents unwanted movement. ROM exercises help prevent contractures by stretching muscles and tendons and maintaining joint mobility.

Risk of imbalanced nutrition: less than body requirements

The unconscious person is at risk of an alteration in nutrition related to a reduced or complete inability to eat. This is especially true for the person who is unconscious as the result of an infection or trauma, both of which increase metabolic requirements.

- Monitor nutritional status through daily weights (on bed scales) and laboratory data. For accuracy, weigh the person at the same time each day, using the same scales. Ensure that the person wears the same clothing. *Changes in laboratory data with decreased nutrition include a decrease in the levels of serum prealbumin and serum transferrin.*
- Assess the need for alternative methods of nutritional support (tube feeding or total parenteral nutrition) through

collaboration with a dietitian. People unable to take oral food require parenteral nutrition or liquid feedings through a nasogastric, gastrostomy or jejunostomy tube. *Needs for protein, kilojoules, zinc and vitamin C increase during wound healing.*



THE PERSON WITH INCREASED INTRACRANIAL PRESSURE

Increased intracranial pressure (IICP) (also called *intracranial hypertension*) is sustained elevated pressure (10 mmHg or higher) within the cranial cavity (Dorman Wagner, Johnson & Hardin-Pierce, 2013). Transient increases in ICP occur with normal activities such as coughing, sneezing, straining or bending forward. These transient increases are not harmful; however, sustained IICP can result in significant tissue ischaemia and damage to delicate neural tissue. Cerebral oedema is the most frequent cause of sustained increases in ICP. Other causes include head trauma, tumours, abscesses, stroke, inflammation and haemorrhage.

Pathophysiology

In the adult, the rigid cranial cavity created by the skull is normally filled to capacity with three essentially non-compressible elements: the brain (80%), cerebrospinal fluid (8%) and blood (12%). A state of dynamic equilibrium exists; if the volume of any of the three components increases, the volume of the others must decrease to maintain normal pressures within the cranial cavity. This is known as the *Monro–Kellie hypothesis*. The normal intracranial pressure is 5 to 10 mmHg (measured intracranially with a pressure transducer while the person is lying with the head elevated 30 degrees) or 60 to 180 cm H_2O (measured with a water manometer while the person is lying in a lateral recumbent position).

Cerebral blood flow and perfusion are important concepts for understanding the development and effects of IICP. Whereas blood and CSF contribute roughly an equal percentage to normal intracranial volume, vascular factors account for twice the amount of increase in ICP that CSF does. The brain requires a constant supply of oxygen and glucose to meet its metabolic demands; 15–20% of the resting cardiac output goes to the brain to meet its metabolic needs. Interruption of the cerebral blood flow leads to ischaemia and disruption of the cerebral metabolism.

Pressure and chemical autoregulation are compensatory mechanisms in which cerebral arterioles change diameter to maintain cerebral blood flow when ICP increases. In pressure autoregulation, stretch receptors within small blood vessels of the brain cause smooth muscle of the arterioles to contract. Increased arterial pressure stimulates these receptors, leading to vasoconstriction; when arterial pressure is low, stimulation of these receptors decreases, causing relaxation and vasodilation. Chemical, or metabolic, autoregulation works in much the same way as pressure autoregulation. In this case, the stimulus is a build up of metabolic by-products of cell metabolism, including lactic acid, pyruvic acid, carbonic acid and carbon dioxide. Carbon dioxide and increased hydrogen ion concentration are potent cerebral vasodilators that may act locally or systemically to increase cerebral blood flow. Conversely, a fall in $PaCO_2$ causes cerebral vasoconstriction. Arterial oxygen tension (PaO_2) also affects cerebral blood flow, although it is a less powerful mechanism than that exerted by carbon dioxide and hydrogen ions.

IICP may result from an increase in intracranial contents from a space-occupying lesion, hydrocephalus, cerebral oedema (swelling), excess CSF or intracranial haemorrhage. Displacement of some CSF to the spinal subarachnoid space and increased CSF absorption are early compensatory mechanisms. The low-pressure venous system is also compressed and cerebral arteries constrict to reduce blood flow. Brain tissue's ability to accommodate change is relatively restricted. The relationship between the volume of the intracranial components and intracranial pressure is known as *compliance*. When the capacity to compensate for pressure in the cranium is exceeded, increased intracranial pressure (hypertension) develops. Intracranial hypertension is a sustained state of IICP and is potentially life threatening.

Autoregulatory mechanisms have a limited ability to maintain cerebral blood flow. When autoregulation fails, cerebrovascular tone is reduced and cerebral blood flow becomes dependent on changes in blood pressure. Autoregulation may be lost either locally or globally because of several factors, including increasing intracranial pressure, local or diffuse cerebral tissue ischaemia or inflammation, prolonged hypotension and hypercapnoea or hypoxia.

Manifestations

With loss of autoregulation, intracranial pressure continues to rise and cerebral perfusion falls. Cerebral tissue becomes ischaemic and manifestations of cellular hypoxia appear. The manifestations of IICP are listed in the following box.

Level of consciousness

Because the neurons of the cerebral cortex are most sensitive to oxygen deficit, changes in cortical function are the earliest manifestations of increasing ICP (Grossman & Porth, 2013). Behaviour and personality changes occur; the person may become irritable and agitated. Memory and judgment are impaired and speech pattern changes may be noted. The person's LOC decreases. As cerebral hypertension and hypoxia progress, the LOC continues to decrease in a predictable pattern to coma and unresponsiveness.

Motor responses

Pressure on the pyramidal tract often causes weakness (hemiparesis) on the contralateral side early in IICP. As ICP continues to increase, hemiplegia and abnormal motor responses, such as decorticate or decerebrate posturing, develop. (See Chapter 40 for an illustration of these postures.)

Vision and pupils

Altered vision is an early manifestation of IICP; it is caused by pressure on the visual pathways and cranial nerves. Blurred vision, decreased visual acuity and diplopia are common.

MANIFESTATIONS Increased intracranial pressure

- Decreased level of consciousness: early—confusion; restlessness, lethargy; disorientation, first to time, then to place and person; late—comatose with no response to painful stimuli.
- Pupillary dysfunction: sluggish response to light progressing to fixed pupils; with a localised process, pupillary dysfunction is first noted on the ipsilateral side.
- Oculomotor dysfunction: inability to move eye(s) upwards; ptosis (drooping) of the eyelid.
- Visual abnormalities: decreased visual acuity, blurred vision, diplopia.
- Papilloedema: may be a late sign.
- Motor impairment: early—hemiparesis or hemiplegia of the contralateral side; late—abnormal responses such as decorticate or decerebrate positioning; flaccidity.
- Headache: uncommon but may occur with processes that slowly increase ICP; worse on rising in the morning and with position changes.
- Projectile vomiting without nausea.
- Cushing's response: increased systolic blood pressure, widening pulse pressure, bradycardia.
- Respirations: altered respiratory pattern related to level of brain dysfunction.
- Temperature: may be significantly elevated as compensatory mechanisms fail.

Pupillary and oculomotor responses are affected as well. Because the cause of IICP is often localised at first, pupillary changes, including gradual dilation and sluggish response to light, may initially be limited to the ipsilateral side.

Vital signs

Ischaemia of the vasomotor centre in the brainstem triggers the CNS ischaemic response, a late sign of IICP. Neuronal ischaemia in the vasomotor centre causes a marked increase in the mean arterial pressure (MAP), with a significant increase in systolic blood pressure and increased pulse pressure. The increased MAP causes reflexive slowing of the cardiac rate. This trio of manifestations (increased MAP, increased pulse pressure and bradycardia) is known as *Cushing's response* (or triad) and represents the brainstem's final effort to maintain cerebral perfusion (Grossman & Porth, 2013). The respiratory pattern also changes, often in the predictable progression outlined earlier in Table 41.1. Although the temperature is usually normal in early stages, as ICP continues to increase, hypothalamic function is impaired and the temperature may rise dramatically.

Other manifestations

Additional manifestations of IICP include headache, particularly on rising, that worsens with position changes. Headache is more common with slowly developing IICP and occurs because of pressure on pain-sensitive structures, such as the middle meningeal arteries, the venous sinuses and the dura at the base of the skull. Papilloedema (oedema and swelling of the optic disc) may be noted on funduscopic examination. Vomiting, often projectile and occurring without warning, may develop.

Cerebral oedema

Cerebral oedema is an increase in the volume of brain tissue due to abnormal accumulation of fluid. Cerebral oedema is often associated with increased IICP; it may occur as a local process in the area of a tumour or injury, or it may affect the entire brain. Two types of cerebral oedema have been identified and are described as follows (Grossman & Porth, 2013):

1. *Vasogenic oedema*, an increase in the capillary permeability of cerebral vessels, occurs with impairment of the blood–brain barrier, allowing diffusion of water and protein into the interstitial spaces of the brain. A variety of pathologies, such as ischaemia, haemorrhage, brain tumours and injuries and infections (such as meningitis), may cause the increase in capillary permeability. The site of the brain injury, the level of increase in capillary permeability and the person's systemic blood pressure influence the rate and extent of the oedema's spread. Vasogenic oedema is manifested by focal (localised) neurological deficits, altered levels of consciousness and severe intracranial hypertension.
2. *Cytotoxic oedema*, actual swelling of the brain cells from an increase in intracellular fluid, involves changes in the functional or structural integrity of cell membranes due to pathologies such as water intoxication (such as from the syndrome of inappropriate secretion of antidiuretic hormone (SIADH)) or severe ischaemia, intracranial hypoxia, acidosis and brain trauma. With abnormally low cerebral perfusion, oxygen and nutrients are depleted, intracranial cells switch to anaerobic metabolism and the sodium–potassium pump in the cell walls is impaired. Sodium diffuses into the cells, pulling fluid with it. The cells swell and intracranial pressure rises. Accumulated metabolic waste products, such as lactic acid, contribute to a rapid deterioration of cell function. Cytotoxic oedema is a slowly progressive process that results in altered consciousness. The oedema may be so severe that it causes cerebral infarction with brain tissue necrosis.

Cerebral oedema tends to be proportional to the extent of the pathology precipitating it. Brain function is not disrupted by cerebral oedema unless the oedema causes an increase in ICP. When it does, a vicious cycle can ensue: cerebral oedema increases ICP, which in turn decreases cerebral blood flow. Brain tissue becomes hypoxic and ischaemic, increasing toxic metabolic by-products, hydrogen ion concentration and carbon dioxide levels in the tissue. Autoregulatory mechanisms cause vasodilation and increase cerebral blood flow, further increasing cerebral oedema and intracranial pressure. Without effective intervention, the person's condition can deteriorate rapidly; ICP increases to the point where brain structures herniate.

Hydrocephalus

Hydrocephalus refers to a progressive dilation of the ventricular system, which becomes dilated as the production of CSF exceeds its absorption (Hickey, 2013). Hydrocephalus may increase ICP when it develops acutely. It is generally classified as either non-communicating or communicating hydrocephalus. Non-communicating hydrocephalus occurs when CSF

drainage from the ventricular system is obstructed. It may develop when a mass or tumour, inflammation or haemorrhage, or congenital malformation obstructs the ventricular system. Communicating hydrocephalus is a condition in which CSF is not effectively reabsorbed through the arachnoid villi. It may occur secondarily to subarachnoid haemorrhage or scarring from infection. In *normal pressure hydrocephalus*, seen most often in adults aged 60 or older, ventricular enlargement causes cerebral tissue compression but the CSF pressure on lumbar puncture is normal. This condition may follow cerebral trauma or surgery, or the cause may not be known.

Manifestations of hydrocephalus depend on the rate of its development. They may be mild and insidious in onset, presenting as progressive cognitive dysfunctions, gait disruptions and urinary incontinence. If the process causing hydrocephalus is an acute one, the manifestations are those of IICP.

Brain herniation

If IICP is not treated, cerebral tissue is displaced towards a more compliant area. This can result in brain herniation, the displacement of brain tissue from its normal compartment under dural folds of the falx cerebri or through the tentorial notch or incisura of the tentorium cerebelli (Grossman & Porth, 2013). Herniation of the cerebellum through the tentorium exerts pressure on the brainstem, with subsequent herniation through the foramen magnum. This is a lethal complication of IICP because it puts pressure on the vital centres of the medulla.

Brain herniation syndromes are generally categorised as supratentorial or infratentorial, depending on their location above or below the tentorium cerebelli (see Figure 41.2).

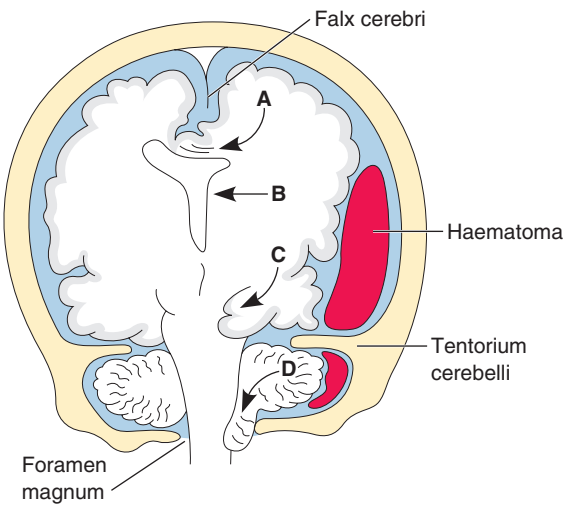


FIGURE 41.2 ■ Forms of brain herniation due to intracranial hypertension. *A*, Cingulate herniation occurs when the cingulate gyrus is compressed under the falx cerebri. *B*, Central herniation occurs when a centrally located lesion compresses central and midbrain structures. *C*, Lateral herniation occurs when a lesion at the side of the brain compresses the uncus or hippocampal gyrus. *D*, Infratentorial herniation occurs when the cerebellar tonsils are forced downwards, compressing the medulla and top of the spinal cord

Supratentorial herniation syndromes include cingulate herniation, central or transtentorial herniation, uncal or lateral transtentorial herniation, and infratentorial herniation.

- *Cingulate herniation* (see Figure 41.2A) occurs when the cingulate gyrus is displaced under the falx cerebri. Local blood supply and cerebral tissue are compressed, resulting in ischaemia and further increases in intracranial pressure.
- *Central or transtentorial herniation* is the downward displacement of brain structures, including the cerebral hemispheres, basal ganglia, diencephalon and midbrain through the tentorial incisura (see Figure 41.2B). The person's neurological signs may deteriorate rapidly, with decreased LOC progressing to coma, Cheyne–Stokes respirations progressing to central neurogenic hyperventilation and pupils progressing from small and reactive to midsized and fixed. The person may demonstrate abnormal motor responses with unilateral decorticate posturing.
- *Uncal or lateral transtentorial herniation* occurs when a lateral mass displaces cerebral tissue centrally, forcing the medial aspect of the temporal lobe under the edge of the tentorial incisura (see Figure 41.2C). The oculomotor nerve (cranial nerve III) often becomes trapped between the uncus and the tentorium, causing ipsilateral pupillary dilation. Other manifestations include alterations in LOC, motor deficits (which may occur on the same side as the herniation because of compression of the cerebral peduncle on the opposite side), decreased sensation, respiratory changes, abnormal positioning and eventual respiratory arrest.
- *Infratentorial herniation* results from increased pressure within the infratentorial compartment. Herniation may occur either upwards, with structures displaced through the tentorial incisura, or downwards, with displacement through the foramen magnum (see Figure 41.2D). Downward displacement compresses the medulla, including its centres for controlling vital functions. Manifestations associated with medullary compression include coma, altered respiratory patterns, fixed pupils and decorticate or decerebrate posturing. Respiratory or cardiac arrest may occur.

INTERPROFESSIONAL CARE

Management of the person with IICP is directed towards identifying and treating the underlying cause of the disorder and controlling ICP to prevent herniation syndrome. IICP is a medical emergency and there is little time to complete lengthy diagnostic tests. The diagnosis must be made on the basis of observation and neurological assessment; even subtle changes may be clinically significant.

Diagnosis

Diagnostic tests focus on identifying the presence of IICP and its underlying cause. A CT scan or MRI is generally the initial test used to identify the possible causes of IICP (such as space-occupying lesions or hydrocephalus) and to evaluate therapeutic options. In general, a lumbar puncture is not performed when IICP is suspected because the sudden release of the pressure in the skull may cause cerebral herniation.

In addition to the diagnostic tests listed in the previous section for altered LOC, the following specific tests are usually ordered and their results closely monitored:

- Serum osmolality is an indicator of hydration status in the person with IICP. The test measures the number of dissolved particles (electrolytes, urea, glucose) in the serum. The normal range for the adult is 280 to 300 mOsm/kg H_2O. In addition to the restriction of fluids in the person with IICP, serum osmolality is maintained at a slightly elevated level (325 mOsm/kg H_2O) to draw excess intracellular fluid into the vascular system.
- ABGs are monitored frequently to assess pH and levels of oxygen and carbon dioxide. Hydrogen ions and carbon dioxide are both potent vasodilators; hypoxaemia also causes vasodilation, although to a lesser degree.

Medications

Medications play an important role in the management of IICP. Diuretics, particularly osmotic diuretics, are commonly used to reduce ICP and are the mainstays of pharmacological treatment. Nursing implications for these medications are described in the 'Medication administration' box below.

MEDICATION ADMINISTRATION — Increased intracranial pressure

Note: Because the person with IICP often has an altered level of consciousness, education of the person and their family is not discussed here.

OSMOTIC DIURETICS

Mannitol (osmitrol)
Urea
Glucose

Osmotic diuretics (hyperosmotic agents) draw fluid out of brain cells by increasing the osmolality of the blood. The effects of these drugs vary with the type of injury. Mannitol therapy is often initiated if the person's ICP exceeds 15 to 20 mmHg for at least 10 minutes. Both intravenous bolus and continuous infusion techniques are used. Repeated use of mannitol can lead to continual elevations in serum osmolality, with attendant risk of seizures and serious fluid and electrolyte imbalance. Urea is seldom administered intravenously because a severe local reaction may result if leakage occurs at the injection site. Mannitol and urea are used cautiously if renal disease is present.

Nursing responsibilities

- Monitor vital signs, urinary output, central venous pressure (CVP) and pulmonary artery pressures (PAP) before and every hour throughout administration.
- Assess person for manifestations of dehydration.
- Assess person for muscle weakness, numbness, tingling, paraesthesia, confusion and excessive thirst.
- Assess person for pulmonary oedema while administering the medication.
- Monitor neurological status and intracranial pressure readings.
- Monitor renal function and serum electrolytes throughout therapy.
- Do not administer the medication if crystals are present in the solution. Administer with an in-line filter. Observe infusion site frequently for infiltration.
- Do not administer mannitol solution with blood.
- Do not discontinue medication abruptly. Rebound migraine headaches may occur.

LOOP DIURETICS

Frusemide (Lasix)
Ethacrynic acid (Edecrin)

Loop diuretics such as frusemide and ethacrynic acid inhibit sodium and chloride reabsorption at the ascending loop of Henle. They cause a reduction in the rate of CSF production, thus reducing the ICP.

Nursing responsibilities

- Monitor vital signs and electrolytes closely.
- Assess fluid status throughout therapy.
- Monitor blood pressure and pulse before and during administration.
- Monitor renal laboratory studies closely.
- Use an infusion pump to ensure accurate dosage.

INTRAVENOUS FLUIDS

Keeping the person moderately dehydrated to maintain serum osmolality can be effective in reducing cerebral oedema. When giving intravenous fluids, closely monitor the osmolality of the solutions; if people with increased ICP are given hypo-osmolar solutions, increased cerebral oedema can occur. Preferred solutions include 0.45–0.9% sodium chloride solutions.

Nursing responsibilities

- Monitor fluid status closely.
- Monitor neurological status closely.
- Avoid administering hypo-osmolar solutions, such as 5% dextrose in water.
- Half-strength normal saline (0.45% sodium chloride) is considered a suitable fluid for a person who has IICP.
- Take care not to restrict fluids excessively in people receiving dehydrating agents (such as osmotic or loop diuretics).

OTHER PHARMACOLOGICAL INTERVENTIONS FOR IICP

- Antipyretics, such as paracetamol, are used to reduce hyperthermia, thereby decreasing the high cerebral metabolism that contributes to IICP.
- Anti-ulcer drugs, such as histamine H_2 antagonists (e.g. ranitidine (Zantac) or sucralfate (Carafate), are used in people with IICP to decrease the development of stress ulcers.
- Antihypertensive agents, such as beta-adrenergic blocking agents, may be used if the mean arterial pressure (MAP) is high.
- Vasopressors may be used if the MAP is low.
- Anticonvulsants may be given to prevent or treat seizures.

Osmotic diuretics work by increasing the osmolarity of the blood, thereby drawing water out of oedematous brain tissue and into the vascular system for elimination via the kidneys. The effects of these drugs vary with the type of injury. Regardless of the agent used, the optimal dose is the lowest that reduces ICP. Mannitol is the most commonly employed osmotic diuretic. Glucose, urea and glycerol are other osmotic diuretics that may be used. Urine output by indwelling catheter is monitored. Electrolyte levels are carefully assessed and potassium is replaced as indicated.

Loop diuretics, such as frusemide (Lasix) (the drug of choice) and ethacrynic acid (Edecrin), may be prescribed for some people with IICP. These diuretics act on the renal tubule and are extremely effective in promoting diuresis. Additionally, loop diuretics may be used to manage the rebound effect that may occur with mannitol administration.

Sedation and paralysis are used as chemical restraints to control restlessness and agitation because these movements increase blood pressure, ICP and cerebral metabolism. Paralysis with neuromuscular blockage is most often accomplished with pancuronium. Close monitoring during treatment for residual muscle weakness and signs of respiratory distress are essential. A peripheral nerve stimulator may be used for this purpose.

Antipyretics, such as paracetamol, are used alone or in combination with a hypothermia blanket to treat hyperthermia. Hyperthermia increases the cerebral metabolic rate and exacerbates an existing increase in ICP. Anticonvulsants are often required to manage seizure activity associated with brain injury and IICP. Gastrointestinal prophylaxis with intravenous histamine H_2 antagonists or proton pump inhibitors are often used, because people with IICP are at increased risk of developing stress gastritis and ulcers (Papadakis et al., 2015).

Intravenous fluids are usually necessary to maintain the person's fluid and electrolyte balance as well as vascular volume. If the person's blood pressure is unstable, vasoactive medications may be administered to maintain the MAP in a range that supports cerebral perfusion while minimising increases in ICP. When enteral feeding is not possible, total parenteral nutrition (TPN) may be administered.

Surgery

People with IICP may undergo various intracranial surgical techniques to treat the underlying cause (see the discussion in the later section on brain tumours). In addition, infarcted or necrotic tissue may be resected to reduce brain mass. A drainage catheter or shunt may be inserted laterally via a burr hole into a ventricle to drain excess CSF and reduce hydrocephalus. The removal of even a small amount of CSF may dramatically reduce IICP and restore cerebral perfusion pressure.

ICP monitoring

Critical to preserving brain function and preventing secondary brain damage from IICP are careful assessments and monitoring with ICP monitors, measuring cerebral blood flow and cerebral perfusion pressure, and measuring oxygen levels of brain tissue. Intracranial pressure monitors facilitate continual assessment of ICP and the effects of medical therapy and nursing interventions on ICP. In addition, cerebral perfusion pressure (the difference between MAP and ICP) can be readily calculated, allowing more precise manipulation of therapeutic measures to maintain cerebral perfusion and thereby prevent ischaemia. The criteria for ICP monitoring depends on the person, but in general, people who are comatose and have a Glasgow Coma Score (described in Chapter 40) of 8 or less should be monitored.

Basic monitoring systems include an intraventricular catheter, subarachnoid bolt or screw, and epidural probe (see Figure 41.3). Intraventricular fluid-filled catheters are placed in the anterior horn of the lateral ventricle (most often in the right side). Ventricular catheters can both drain CSF and measure ICP. The ICP value is measured deep in the brain and is considered the most reflective of the whole brain pressure. Subarachnoid devices are placed in the subarachnoid space. A fibre-optic transducer-tipped catheter can be placed in the epidural, subdural or parenchymal space, with ICP values considered very accurate. Once the intracranial sensor is implanted, it is connected to a transducer that converts the impulses to a signal that the recording device can translate into an oscilloscope tracing, digital value or graphic recording. Factors that increase the risk of infection during ICP monitoring are listed in Table 41.4.

Transcranial blood flow is monitored with transcranial Doppler studies (TCD) to measure the velocity of blood flow

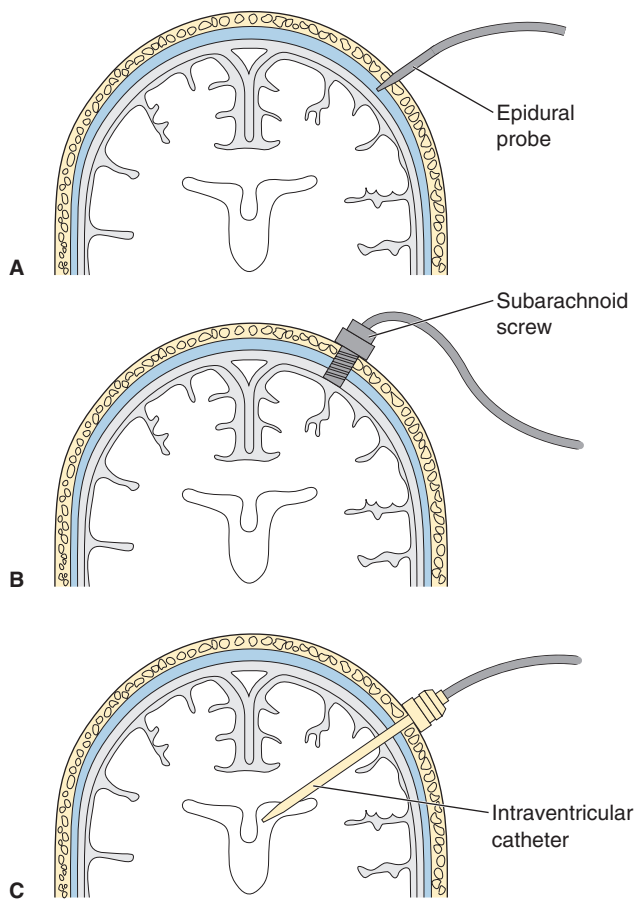

FIGURE 41.3 ■ Types of intracranial pressure monitoring. *A*, Epidural probe. *B*, Subarachnoid screw. *C*, Intraventricular catheter

TABLE 41.4 Risk factors for infection with intracranial pressure monitoring

FACTOR	RATIONALE
Intraventricular catheter	Is more invasive than other monitoring devices
Open head trauma or neurosurgery	Disrupts protective skin and skeletal barriers
Intracranial haemorrhage	Necessitates frequent flushing of catheter to maintain patency
Older adult	Tends to have impaired immune defences
Monitoring for more than 3 to 5 days; or open system or frequent irrigation	Offers increased opportunity for pathogens to enter and grow

in the cerebral vessels. Cerebral perfusion pressure (CPP) is the pressure required for the heart to provide the brain with blood, calculated by subtracting ICP from MAP. (Normal CPP is 70 to 95 mmHg.) Brain oxygenation monitoring may be conducted by using a jugular bulb oxygen saturation (SjO_2) monitor connected to a small fibre-optic catheter inserted into the jugular vein. (Normal SjO_2 is 50–75%.) Another device used to monitor brain tissue oxygenation is the LICOX system, which includes information about ICP, oxygen status and temperature status within the brain tissue itself (Keddie & Rohman, 2012). In addition, cerebral microdialysis catheters can provide information about the nature of the cerebral interstitial fluid.

Mechanical ventilation

People with IICP often require intubation and are placed on a ventilator for respiratory management. Mechanical ventilation may be used to maintain partial pressure of oxygen and carbon dioxide, thus preventing hypoxaemia and hypercapnoea, both of which can increase intracranial pressure. It is important to maintain adequate oxygenation with a partial pressure of arterial oxygen at about 100 mmHg and a partial pressure of arterial carbon dioxide of about 35 mmHg. The person with IICP and signs of impending herniation may be judiciously hyperventilated to cause cerebral vasoconstriction; however, this also increases cerebral ischaemia.

Nursing care

The nursing care of people with IICP involves identifying those at risk and managing factors known to increase intracranial pressure. A major focus is protecting the person from sudden increases in ICP or a decrease in cerebral blood flow.

Nursing diagnoses and interventions

Nursing interventions include performing neurological assessments, maintaining the patency of the airway, ensuring adequate ventilation, positioning and moving, instituting seizure precautions and monitoring fluids and electrolytes. Additionally, both the person and their family need emotional support during this period. The person with IICP has varied responses to actual or potential changes in physiological processes.

Ineffective tissue perfusion: cerebral

A number of disorders may lead to IICP, including cerebral oedema, hydrocephalus, space-occupying lesions and haemorrhage, herniation syndromes and changes in carbon dioxide concentrations. Increasing intracranial pressure alters cerebral perfusion and oxygenation of brain cells. The person with IICP requires intensive care and often needs ventilator assistance.

- Assess for and report manifestations of IICP every 15 minutes to 1 hour and as necessary. Assessment areas include LOC, behaviour, motor/sensory functions, pupillary size and reaction to light, and vital signs, including temperature. Look for trends, because vital signs alone do not correlate well with early deterioration. *Assessment of neurological status establishes the person's clinical condition and provides a baseline for measuring changes. Sudden changes in neurological signs often indicate deterioration. An elevated temperature with increased oxygen consumption further increases intracranial pressure. Pupillary responses mirror the status of the midbrain and pons. Pressure on the brainstem may compromise the function of cranial nerves IX and X and protective mechanisms, such as the gag and cough reflexes.*

CONSIDERATION FOR PRACTICE

Often, the earliest manifestations of a change in intracranial pressure are alterations in the level of consciousness and respirations.

- For the person on a ventilator: maintain patency of the airway; pre-oxygenate with 100% oxygen before suctioning; limit suctioning to 10 seconds; suction gently. *Pre-oxygenation helps maintain oxygen levels during suctioning. Suctioning stimulates the cough reflex and Valsalva manoeuvre. Correct suctioning minimises the risk of hypoxaemia.*
- Monitor ABGs. *ABGs provide a reliable indicator of oxygen and carbon dioxide levels. If oxygen concentration is low, oxygen may be given or increased.*
- Elevate head of the bed to 30 degrees or keep flat, as prescribed; maintain the alignment of the head and neck to avoid hyperextension or exaggerated neck flexion; avoid prone position. *Keeping the head of the bed elevated facilitates venous drainage from the cerebrum. Obstruction of jugular veins can impede venous drainage from the brain.*
- Monitor bladder distension and bowel constipation. Administer stool softeners and use the Credé technique (applying pressure to the suprapubic region with the fingers of one or both hands) to empty the bladder. If the Credé technique is not effective, evaluate the pros and cons of urinary catheterisation if the bladder remains distended.

Constipation and bladder distension increase intrathoracic or intra-abdominal pressure and place the person at risk of impaired venous drainage from the brain.

- If alert, assist the person in moving up in bed. Do not ask to push with heels or arms or push against a footboard. Avoid a footboard and restraints. *Moving up in bed requires pushing. Helping the person move prevents initiation of the Valsalva manoeuvre, which increases intracranial pressure.*
- Plan nursing care so that activities are not clustered together; avoid turning the person, getting the person on the bedpan or suctioning within the same time period. Schedule nursing care to provide rest periods between procedures. *Multiple procedures, including certain nursing care activities, can increase ICP. Constant stimulation tends to increase ICP. Individualised nursing care ensures optimal spacing of activities and rest.*
- Provide a quiet environment, limiting noxious stimuli. Avoid jarring the bed. Try to limit situations that cause emotional upset; maintain a calm, reassuring manner; caution family members to refrain from unpleasant conversations or conversations that may be emotionally stimulating to the person. *Noxious stimuli and emotional upsets cause an elevation in ICP.*
- Maintain fluid limitations, if prescribed. *Restricting fluids helps decrease cerebral oedema by reducing total body water.*

Risk of infection

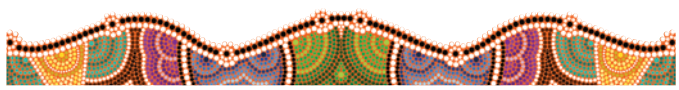
Although any person with an open head wound is at risk of infection, the interventions discussed here are for the person with an intracranial monitoring device. Most clinical units have written protocols for managing these systems. The following nursing actions serve only as a general guide.

- Keep dressings over the catheter dry and change dressings on a prescribed basis (usually every 24 to 48 hours). *Wet dressings are conducive to bacterial growth.*
- Monitor the insertion site for leaking CSF, drainage or infection. Monitor for manifestations of infection, including changes in vital signs, chills, increased WBC counts and positive cultures of drainage. *Close monitoring helps detect the earliest signs of infection and helps prevent major complications. Fever is usually considered the key assessment. However, fever in a person with a neurological disorder may be due to damage to the hypothalamus. Headache, generalised muscle aches, shivering and chills may also be seen in the person with infection.*
- Use strict aseptic technique when in contact with the device. Check drainage system for loose connections. *The use of aseptic technique and monitoring drainage systems for loose connections help prevent hospital-acquired infections. Most such infections are transmitted by healthcare workers who fail to wash their hands properly, to change gloves between people or to follow aseptic technique protocols. Invasive procedures provide an excellent opportunity for microbes to enter the body.*

Health education for the person and family

Teach the person at risk of or having IICP (and able to follow instructions) to avoid coughing, blowing the nose, straining to have a bowel movement, pushing against the bed rails or performing isometric (muscle-contracting) exercises. Advise the person to maintain head and neck alignment when turning in bed and to take rest periods.

Encourage the family to talk to the person, but maintain a quiet environment with a minimum of stimuli. Inform family members that upsetting the person may increase intracranial pressure and that they should avoid discussions that may distress the person. For people unable to make decisions about treatment and to sign informed consent, the family must carry out these functions.



LINKS TO NATIONAL PATIENT SAFETY STANDARDS

NSQHS Standard 3:

Preventing and Controlling Health Care Associated Infections.

'The intention of this standard is to prevent patients from acquiring preventable healthcare associated infections and effectively manage infections when they occur by using evidence-based strategies.' (ACSQHC, 2012, p. 26)

Implementing this standard is achieved by ensuring adequate strategies that address both prevention and control of healthcare-associated infections are developed and applied to clinical practice. These strategies include the development of appropriate infection-control policies and procedures; adhering to infection-control policies and procedures; surveillance of healthcare-associated infection rates; monitoring of staff compliance with infection-control procedures; training and education for all staff; and education for individuals and their families and caregivers.

Caring for individuals with head injuries requires strict adherence to infection-control policies and procedures, particularly for those individuals with open skull fractures or ICP monitors in place. People with head injuries are also at risk of developing pneumonia and urinary tract infections.

THE PERSON WITH A HEADACHE

Headache, one of the most frequent manifestations of a health problem people experience, is pain within the cranial vault. Headaches may occur as a result of benign or pathological conditions, intracranial or extracranial conditions, diseases of other body systems, stress, musculoskeletal tension or a combination of these factors.

Most headaches are mild, transient and relieved by a mild analgesic. However, some headaches are chronic, intense and recurrent. Manifestations of headache vary according to the cause, type and precipitating symptoms.

Pathophysiology

The bones and brain tissue itself lack pain-sensitive nerve fibres, but selected structures within the cranial vault are sensitive to pain. Headache is experienced when there is traction, pressure, displacement, inflammation or dilation of nociceptors (nerve endings that are receptors of noxious stimuli) in areas sensitive to pain (Hickey, 2013). Pain-sensitive structures include supporting structures, such as the skin, muscles and periosteum; the nasal cavities and sinuses; portions of the meninges, cranial nerves II, III, IV, V, VI, IX and X; and cerebral vessels, including extracranial arteries and the venous sinuses. Most facial and scalp structures are sensitive to pain. The most common types of headaches are migraine, cluster and tension headaches (see Table 41.5).

Migraine headache

Migraine headache is a recurring vascular headache lasting from 4 to 72 hours, often initiated by a triggering event and usually accompanied by a neurological dysfunction. It affects about 3 million people worldwide, with three times as many women as men having migraines (Headache Australia, 2015). It is more common between the ages of 12 and 40 years with prevalence declining thereafter. Migraine headaches may occur daily or as infrequently as once a year.

There are two types of migraine headaches: common migraine (without an aura) and classic migraine (with an aura; most often experienced as a visual disturbance prior to the pain). Common migraines occur in 80% of the people who are affected by this disorder. Headaches classified as migraines may differ in intensity, duration and frequency. The exact causes of migraine are not fully understood, but they are believed to be the result of abnormalities in cerebrovascular blood flow, a reduction in brain and electrical activity, or increased release of sensory substances such as serotonin, noradrenaline substance P, nitric oxide or glutamate.

A variety of factors are believed to trigger the onset of a migraine headache. Rapid changes in blood glucose levels, stress, emotional excitement, fatigue, hormonal changes due to menstruation, stimuli such as bright lights, and food high in tyramine or other vasoactive substances (e.g. aged cheese, nuts, chocolate and alcoholic beverages) have been associated with migraine attacks. Hypertension and fever may make the disorder worse.

COMMON MIGRAINE This type is the most common and is associated with hereditary factors. The aura stage is absent; people are aware only that a headache is imminent. The headache develops gradually, lasting hours to days, and may occur in women during periods of premenstrual tension and fluid retention. Chills, nausea and vomiting, fatigue and nasal congestion are often present.

TABLE 41.5 Comparison of migraine, cluster and tension headaches

TYPE	RISK FACTORS	FREQUENCY AND DURATION	DESCRIPTION	PRODROMAL AND ASSOCIATED MANIFESTATIONS
Migraine	Female Family history of migraine headache	Episodic: • Tends to occur with stress and crisis • Often correlates with menstrual cycle • Can last hours to days	Slow onset; pain becomes more severe, involving one side of head more than other	Prodromal manifestations: visual defects, confusion, paraesthesias Associated manifestations: nausea, vomiting, chills, fatigue, irritability, sweating
Cluster	Male Use of alcohol or nitrates May begin in early childhood	Episodes are clustered together in rapid succession for a few days or weeks with remissions that last for months Can last a few minutes to a few hours	May begin in infraorbital region and spread to head and neck; throbbing, deep pain, often unilateral	Prodromal manifestations: uncommon Associated manifestations: flushing, tearing of eyes, nasal congestion, sweating and swelling of temporal vessels
Tension	Related to tension and anxiety No family history Often begins in adolescence	Episodic: • Varies with amount of stress • Duration also varies; can be constant	Tight, pressing, vice-like; may involve neck and shoulders	Prodromal manifestations: uncommon Associated manifestations: sustained contraction of neck muscles

CLASSIC MIGRAINE The classic migraine headache has several stages, as follows:

- The aura stage is characterised by sensory manifestations, usually visual disturbances such as bright spots or flashing lights zigzagging across the visual fields. This stage lasts from 5 to 60 minutes. Less common sensory symptoms include numbness or tingling of the face or hand, weakness of an arm or leg, mild aphasia, confusion, drowsiness and lack of coordination. Additionally, some people experience a premonition the day prior to an attack. They may feel nervous or have other mood changes. The aura period corresponds with the initial physiological change of vasoconstriction.
- The headache stage is characterised by vasodilation, a decline in serotonin levels and the onset of throbbing headache. It appears that the pain is related to increased vessel permeability and polypeptide exudation by perivascular nerve endings rather than the vasodilation itself. Cerebral arteries are dilated and distended, with walls that are oedematous and rigid. Beginning unilaterally, the headache eventually may involve both sides as it increases in intensity during the next several hours. Nausea and vomiting often occur. The person may be acutely ill and is often extremely irritable. The sensory organs often become hypersensitive and the person withdraws from sound and light. The scalp is tender. The headache may last from several hours to a day or two.
- During the post-headache phase, the headache area is sensitive to touch and a deep aching is present. The person is exhausted. Vessel size and serotonin levels return to normal.

Cluster headache

A *cluster headache* is an extremely severe, unilateral, burning pain located behind or around the eyes. The cluster headache is predominantly experienced by men between the ages of 20 and 40 years. The headaches occur in groups or 'clusters' of one to eight each day for several weeks or months, followed by remission lasting months to years (Hickey, 2013). The physiological mechanism underlying cluster headaches is not well understood, but involves a vascular disorder, a disturbance of serotonergic mechanisms, a sympathetic defect or deregulation of the hypothalamus.

Although the headache may occur at any time, it typically begins 2 to 3 hours after falling asleep, awakens the person and then lasts from 15 to 180 minutes. Prodromal signs are absent. Intense unilateral pain around or behind one eye is accompanied by rhinorrhoea, lacrimation, flushing, sweating, facial oedema and possible miosis or ptosis on the affected side. The same side of the head is involved in each cluster of attacks.

The headaches often occur in spring and autumn and then disappear for an extended period. Attacks may be triggered by drinking alcohol, eating specific foods, medications such as glyceryl trinitrate (nitroglycerine), or there may be no known precipitating event.

Tension headache

Tension headache is characterised by bilateral pain, with a sensation of a band of tightness or pressure around the head. Sharply localised painful spots (trigger points) may be present. The onset is gradual and the intensity, frequency and duration of the attack vary greatly. This type of headache is caused by sustained contraction of the muscles of the head and neck. It is often precipitated by stressful situations and anxiety. Secondary causes include prolonged computer use and disorders of the eyes, ears, sinuses or cervical vertebrae. Abnormal posture associated with occupations that require bending over a desk (e.g. office workers, students) often precipitates tension-type headache. Additionally, slouching while reading or watching television can lead to muscle contraction. Most headaches are tension-type headaches.

INTERPROFESSIONAL CARE

Identifying the underlying cause(s) of the headache is the initial focus of interprofessional care. If the underlying cause is treatable, the headache will often decrease or disappear. An accurate diagnosis of the type of headache is key to the treatment.

Therapeutic management for migraine headache includes a combination of education, medications and measures to control contributing factors. Dietary changes such as eliminating caffeine, cured meats, monosodium glutamate (MSG) and foods containing tyramine (red wine, aged cheese and others) may be necessary. Stress management or biofeedback is also part of the overall strategy. Treatment protocols for cluster headache include eliminating aggravating factors (e.g. consumption of alcohol) and using medications and oxygen inhalation. The management of tension headaches is directed towards reducing the person's level of stress and relieving pain with ice and aspirin or non-steroidal anti-inflammatory drugs (NSAIDs).

Diagnosis

Diagnosis and treatment are based on history, identifying triggering or precipitating events, and the type of headache. A thorough history and physical examination are integral parts of the assessment. Neurodiagnostic testing may be done to rule out a structural disease process. Testing may include a brain scan, MRI, x-ray studies of the skull and cervical spine, EEG or lumbar puncture for CSF if inflammation is suspected. Serum metabolic screens and hypersensitivity testing also may be performed if systemic problems are suspected.

Medications

Pharmacological management depends on the type of headache. The goals of treatment are to reduce the frequency and severity of headaches and to limit or relieve a headache that is beginning or in progress.

The management of migraine headache includes administering medications to prevent pain (prophylactic therapy) as well as drugs to stop (or abort) a headache in progress. The person with frequent migraine headaches is a candidate for prophylactic therapy. Drugs used to reduce the frequency and severity of migraine include:

- Methysergide maleate (Deseril) is a serotonin antagonist that competitively blocks serotonin receptors in the CNS and is also a potent vasoconstrictor.
- Propranolol hydrochloride (Inderal) is a beta-blocker that prevents dilation of vessels in the pia mater and inhibits serotonin uptake.
- Topiramate (Topamax) and sodium valproate (Epilim) are CNS agents and anticonvulsants.

When the manifestations of migraine are recognised early, several medications may be used to abort or limit the severity and duration of the headache. Ergotamine tartrate (Cafergot) is a complex drug that reduces extracranial blood flow, decreases the amplitude of cranial artery pulsation and decreases basal artery hyperperfusion. Administered at the onset of an attack, ergotamine controls up to 70% of acute attacks. Sumatriptan (Imigran) is available in oral, nasal spray or subcutaneous injection forms. It binds with serotonin receptors and is rapidly effective. Zolmitriptan (Zomig), a selective serotonin receptor agonist, is administered orally and is effective in the treatment of acute headache. Once a migraine is in progress, a narcotic analgesic such as codeine or pethidine may be required. Anti-emetics may be prescribed to control nausea and vomiting.

Many of the same medications used for migraine also prevent or treat cluster headache. Because the onset of cluster headaches is abrupt, abortive therapy is not possible. Medications such as ergotamine tartrate may be given in suppository form at bedtime to prevent headache during the episodic attacks. Inhaling 100% oxygen at 7 L/min for 15 minutes at the onset of an attack may relieve a person's headache (Papadakis et al., 2015).

Non-narcotic analgesics such as aspirin or paracetamol may relieve tension headaches. Additionally, tranquillisers such as diazepam may reduce muscle tension.

Nursing implications for drugs commonly prescribed for headaches are described in the 'Medication administration' box below.

Alternative and complementary therapies

The following alternative and complementary therapies are used to relieve the pain of headaches:

- vitamin D, elemental calcium, riboflavin (vitamin B) and magnesium
- acupuncture
- relaxation, guided imagery, massage
- melatonin, 5-HTP, CoQ10
- magnetic field therapy
- herbal therapy
- osteopathic manipulation.

Nursing care

In addition to the nursing care discussed in this section, a nursing care plan for a person with a migraine headache follows.

Health promotion

Teach people with tension headaches relaxation techniques, such as massage and biofeedback. Counselling for chronic anxiety may also be helpful. Triggers for migraine or cluster headache should be identified and, if possible, eliminated. For example, avoiding physical and emotional stress, having regular and consistent sleep patterns, eating meals regularly, and avoiding specific foods or alcohol can be incorporated into daily life and are helpful. Specific suggestions are outlined in Box 41.2.

BOX 41.2 Suggestions to decrease incidence of migraine headaches

- Wake up at the same time each morning.
- Exercise at least three times a week.
- No smoking or caffeine after 3 pm.
- No artificial sweeteners.
- No MSG.
- Reduce or eliminate red wine, cheese, alcohol, chocolate and caffeine.
- Try a gluten-free diet.

Assessment

Collect the following data through the health history and physical examination.

- *Health history:* history of intracerebral trauma, tumour or infection; detailed history and description of headache characteristics; family history; triggering factors; usual diet; effects of recurring headaches on lifestyle, activities of daily living (ADLs) and role performance.
- *Physical assessment:* skin (diaphoresis, pallor, flushing), eyes (sensitivity to light, tearing), muscle strength and movement.

Nursing diagnoses and interventions

The primary response of the person requiring nursing interventions is acute pain. Develop nursing interventions to help the person identify strategies for controlling the pain and discomfort of the headache.

Acute pain

Headaches originate from both intracranial and extracranial sources and range in severity from benign, transient discomfort to severe, incapacitating pain. Interventions focus on teaching the person self-care measures to control or relieve the pain and reducing any associated problems, such as nausea and vomiting or anxiety.

- Advise to maintain a diary of headaches, including duration, onset, location, relation to menstruation or food intake and related manifestations such as factors that relieve or intensify the pain. A thorough assessment of the headache is essential for both the person and the healthcare provider to identify the circumstances and patterns of headache occurrence.
- Ask the person to rate the pain or discomfort on a scale of 0 to 10 (with 10 being the worst pain). Using a scale to rate the pain provides an objective measure of the person's subjective experience of the pain or discomfort. The scale can also be used to evaluate the effectiveness of pain relief measures.
- Advise to minimise light, noise and activity, and to rest in a quiet, non-stimulating environment when experiencing a headache. Manipulating the environment helps reduce noxious stimuli that may increase pain.
- Advise to use non-invasive and non-pharmacological pain relief measures such as deep breathing or relaxation to facilitate self-management of pain (see Chapter 8). Alternative strategies to control pain can help to reduce tension and increase the person's sense of control over the pain.

MEDICATION ADMINISTRATION Headaches

BETA-BLOCKERS

Propanolol hydrochloride (Inderal)
Pindolol (Barbloc)
Atenolol (Tenormin)
Timolol (Blocadren)

Beta-blockers are effective in the prophylactic treatment of headache. They act by combining with beta-adrenergic receptors to block the response to sympathetic nerve impulses, circulating catecholamines or adrenergic drugs.

Nursing responsibilities

- Before beginning therapy, determine pulse and blood pressure in both arms with the person lying, sitting and standing.
- Assess baseline and monitor serum glucose level, FBC, electrolytes and liver and renal function studies.
- Note any history of diabetes or impaired renal function.
- Note the rate and quality of respirations; drugs in this category may cause dyspnoea and bronchospasm.
- Administer the drug with meals to prevent gastrointestinal disturbances.
- Be alert that beta-blockers cause bradycardia and the heart rate may not rise in response to stress, such as exercise or fever. Notify the primary healthcare provider if pulse falls below 50 or if blood pressure changes significantly.
- Teach the person or family member how to take a pulse and blood pressure reading.

Health education for the person and family

- Take the medication with meals to provide a coating for the gastrointestinal tract and prevent gastrointestinal disturbances.
- Return for blood work as prescribed.
- Take the last dose of the day at bedtime.
- Rise from a sitting or lying position to a standing position slowly to avoid dizziness and falls.
- Take pulse and blood pressure each day and maintain a record of readings.
- Avoid excessive intake of alcohol, coffee, tea or cola. Consult with the healthcare provider before taking any over-the-counter medications.
- Report any cough, nasal stuffiness or feelings of depression to the healthcare provider.

TRICYCLIC ANTIDEPRESSANTS

Imipramine hydrochloride (Tofranil)
Amitriptyline hydrochloride (Endep)

The tricyclic antidepressants have been successful in the prophylaxis of cluster and migraine headaches. Although the exact mechanism is not known, they do prevent the re-uptake of noradrenaline or serotonin or both. They are chemically related to the phenothiazines and as such they exhibit many of the same pharmacological effects (e.g. anticholinergic, antiserotonin, sedative, antihistaminic and hypotensive effects).

Nursing responsibilities

- Assess baseline FBC and liver function studies, heart sounds and neurological status before initiating prescribed therapy.

Health education for the person and family

- Make position changes slowly.
- Chew sugarless gum to relieve dry mouth.
- Do not abruptly quit taking the medication.

ERGOT ALKALOID DERIVATIVES

Methysergide maleate (Deseril)

Methysergide is an ergot alkaloid derivative structurally related to LSD. It acts by stimulating smooth muscle, leading to vasoconstriction. It is thought that methysergide prevents headaches by blocking the effects of serotonin, a powerful vasodilator believed to play a role in vascular headaches. It also inhibits the release of histamine from mast cells and prevents the release of serotonin from platelets.

Nursing responsibilities

- Note any history of kidney or hepatic disease.
- Assess baseline eosinophil and neutrophil counts before beginning therapy.
- Administer the drug with meals or milk to minimise gastrointestinal irritation due to increased hydrochloric acid production.
- Assess for kidney, CNS and cardiovascular complications.
- Drug dosage should be gradually reduced over 2 to 3 weeks to prevent rebound headaches. A drug-free interval of 3 to 4 weeks is required with each 6-month course of therapy to prevent complications.
- Monitor for signs of ergotism, such as coldness or numbness of the fingers and toes, nausea, vomiting, headache, muscle pain and weakness. Vasoconstriction may further impair peripheral circulation and increase blood pressure.

Health education for the person and family

- Take the medication with meals or milk to minimise gastrointestinal upset.
- Report to the healthcare provider nervousness, weakness, rashes, hair loss or swelling of the extremities.
- Weigh daily and report any unusual weight gain to the healthcare provider.
- Return to the healthcare provider for a check-up at least every 6 months or as instructed. Do not take the drug on a regular basis for longer than 6 months, but do not abruptly stop taking it.
- Return for follow-up blood work as ordered.

SEROTONIN SELECTIVE AGONISTS

Sumatriptan succinate (Imigran)
Zolmitriptan (Zomig)

These agents bind to vascular receptors to vasoconstrict cranial blood vessels and relieve migraine headache.

Nursing responsibilities

- Assess for history of peripheral vascular disease, kidney or hepatic problems, and pregnancy.
- Evaluate relief of migraine headache and assess for side effects of photophobia, sound sensitivity, and nausea and vomiting.

Health education for the person and family

- Do not use more than two injections in a 24-hour period and allow at least 1 hour between injections.

MEDICATION ADMINISTRATION Headaches (continued)

- Use the autoinjector to administer the medication and follow instructions for the proper method of giving the injection and disposing of the syringe.
- Report wheezing, heart palpitations, skin rash, swelling of the eyelids or face, or chest pain to the healthcare provider immediately.

CALCIUM CHANNEL BLOCKERS

Verapamil (Isoptin)
Nifedipine (Adalat)

The calcium channel blockers may have value in controlling cerebral vasospasms by two mechanisms: inhibiting the influx of calcium into the cerebral artery; and interfering with the destruction of erythrocytes and aggregation of platelets.

Nursing responsibilities

- These drugs cause peripheral vasodilation. Therefore, monitor blood pressure and pulse during the initial administration of the drug. Any excessive hypotensive response and tachycardia may precipitate angina. Request written parameters for safe drug administration.
- Monitor intake and output and daily weights. Assess for manifestations of congestive heart failure: weight gain, peripheral oedema, dyspnoea, rales and jugular vein distension.
- Teach the person and family members how to take pulse and blood pressure readings.

Health education for the person and family

- Take the medication with meals to reduce gastrointestinal irritation.
- Take pulse and blood pressure before taking medications each day at the same time and follow instructions regarding when to withhold medication and when to contact the healthcare provider. Keep a record of pulse and blood pressure readings.
- Report any side effects, such as dizziness, vertigo, unusual flushing, facial warmth or headaches, to the healthcare provider.
- Report immediately any swelling of the hands or feet, pronounced dizziness or chest pain accompanied by sweating, shortness of breath or severe headaches.

NON-STEROIDAL ANTI-INFLAMMATORY DRUG (NSAID): SALICYLATE

Acetylsalicylic acid, or aspirin, is a non-narcotic analgesic, antipyretic, anti-inflammatory agent used to relieve headache pain.

Nursing responsibilities

- Determine the type and pattern of pain. If aspirin was used in the past for pain control, note its effectiveness.
- Note any history of peptic ulcers or other conditions that may suggest potential problems with the use of salicylates.
- Assess people receiving anticoagulant therapy for bruises, bleeding of the mucous membranes or blood in the urine or stool.

Health education for the person and family

- Take aspirin after meals or before meals with an antacid and a full glass of water to minimise gastric irritation.
- Report ringing in the ears, unusual bleeding of gums, bruising or black tarry stools to the primary healthcare provider.
- Monitor blood glucose levels carefully (if you have diabetes) and report hypoglycaemia if it occurs.

ERGOTAMINE

Caffeine-ergotamine tartrate combination (Cafergot)
Ergotamine tartrate (Gynergen)

Ergot alkaloids vasoconstrict the cerebral blood vessels, decreasing the amplitude of the pulsations of the cranial arteries. The major use of ergot alkaloids is for the treatment of migraine headaches. Cafergot has the same actions as Gynergen; in addition, the caffeine it contains provides a vasoconstrictive action, enhancing the effects of ergotamine.

Nursing responsibilities

- Because the drug accumulates in the body and is eliminated slowly, ergotamine poisoning may occur. Sepsis, renal and vascular disease, heavy smoking, malnutrition, pregnancy, contraceptive hormones and fever can increase the risk of ergotamine poisoning.
- These drugs are contraindicated in people with diabetes mellitus, sepsis, hepatic or kidney disease, peripheral and coronary artery disease, hypertension and pregnancy.

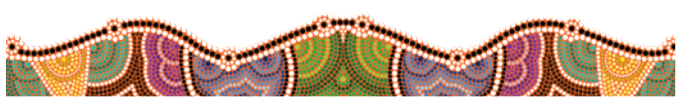
Health education for the person and family

- Take the drug immediately at onset of headache.
- Report the following to your healthcare provider: pain in the leg muscles, weakness and coldness or numbness of fingers or toes.
- A dose of Cafergot taken late in the day may prevent sleep because of the effects of caffeine.

- Suggest application of cold compresses or dry heat to the head and neck. The application of cold causes vasoconstriction, which helps reduce pain in vascular headaches. Application of heat can reduce muscle tension and improve circulation.
- Advise to follow good nutrition guidelines, get regular exercise and sleep, and minimise stress. Headaches are more likely to occur when ill, tired or under stress.

Community-based care

In addition to implementing comfort measures, personal education has a high priority. Develop a teaching plan to help the person learn how to limit attacks (e.g. by avoiding precipitating factors) and reduce the effects of the headache. Provide specific information about prescribed medications. Referrals for methods of stress reduction may be necessary for people with long-term or migraine headaches.



NURSING CARE PLAN A person with a migraine headache

Becky Friedman is a 30-year-old primary school teacher. Her friends and the other teachers regard Ms Friedman as an enthusiastic person who sets high standards for herself and strives for perfection. During the third term (the start of spring), Ms Friedman begins to miss work and sometimes appears very nervous. One day, another teacher notices Ms Friedman running down the hall and into the bathroom; the teacher finds Ms Friedman vomiting. As she washes up, Ms Friedman tells the other teacher that she has been having headaches since she began menstruating, but that they have never been as intense and frequent as during this past year. Ms Friedman agrees to see the nurse practitioner, Jane Schickadanz, at the school clinic for evaluation.

ASSESSMENT

During her health history, Ms Friedman relates that each month before her menstrual cycle she becomes nervous and sees flashing lights. She also has difficulty expressing herself and thinking clearly. The next day she develops a 'sick headache'. She states that the headache can last 1 to 2 days and that afterwards she cannot brush her hair because her scalp hurts. Ms Friedman attributes these symptoms to PMS and adds that she thinks she is allergic to cheese and nuts because she gets sick after eating them. After assessment and in consultation with the doctor, Ms Schickadanz diagnoses Ms Friedman's problem as a migraine with aura headache. Sumatriptan succinate (Imitrex) is prescribed.

DIAGNOSES

- *Acute pain* related to vasodilation of cerebral vessels and a decreased serotonin level manifested by the presence of headaches.
- *Knowledge deficit* related to pain management, evidenced by inadequate use of analgesia.
- *Altered role performance* related to pain, evidenced by an inability to perform occupational tasks.

PLANNING

- Provide education about migraine and methods of treatment.

Expected outcomes

- Experience reduced frequency and duration of pain.
- Identify available resources for helping with self-management of pain.

IMPLEMENTATION

- Ask Ms Friedman to keep a diary of her headaches for the next month, noting times of their occurrence, location and duration of pain, and factors that trigger the onset, such as her menstrual period or certain foods.
- Advise Ms Friedman to take medication at the first awareness of an impending attack.
- Suggest an appointment with a counsellor to learn methods of relaxation and stress relief.
- Request a dietary referral for elimination of foods that might precipitate headaches.

EVALUATION

Four weeks after beginning medication therapy with Imitrex and relaxation techniques, Ms Friedman has noted a decrease in the intensity of the headaches. She reports that the medication has stopped the headaches, which, she has noted, tend to occur more frequently immediately before her menstrual period. She is walking for 30 minutes each day and has made changes in her usual diet. Ms Friedman states, 'I feel good about going to work with my kids at school and knowing I can control my pain.'

CRITICAL THINKING IN THE NURSING PROCESS

1. List the questions you would include in a health history that would identify stressors consistent with migraine headaches.
2. Develop a teaching plan for Ms Friedman that includes methods of reducing fluid retention before her menstrual period, as well as a suggested diet based on the food guide pyramid.

REFLECTION ON THE NURSING PROCESS

1. Outline what you have learned from this case study that you will apply to your future nursing practice.
2. Which education strategies could you use to develop a plan of care for Ms Friedman for the nursing diagnosis of *Disturbed sleep pattern* related to pain, evidenced by fatigue?

THE PERSON WITH EPILEPSY

Epilepsy (also called *seizure disorder*) is a chronic disorder of abnormal, recurring, excessive and self-terminating electrical discharge from neurons. Epilepsy is characterised by recurring seizures accompanied by some type of change in behaviour. A **seizure** (sometimes called a convulsion) is a single event of abnormal electrical discharge in the brain resulting in an abrupt and temporary altered state of cerebral function (Hickey, 2013). This abnormal neuronal activity, which may involve all or part of the brain, disturbs skeletal motor function, sensation, autonomic function of the viscera, behaviour and/or consciousness. Epilepsy is categorised as a paroxysmal disorder because its manifestations are discontinuous; that is, minutes, days, weeks or even years may elapse between seizures.

Incidence and prevalence

Epilepsy is one of the most common neurological conditions, affecting an estimated 275 000 people in Australia (Epilepsy Centre, 2015). There is a strong genetic component. Although people of any age may be affected, the prevalence and incidence of epilepsy increases dramatically in older adults (see the following 'Meeting individualised needs' box).

The incidence of epilepsy is increasing. Researchers have suggested that the increase may be due to technological advances in obstetric and paediatric care that allow extremely high-risk neonates to survive, and to other technological advances that have improved survival rates after craniocerebral trauma.

Isolated seizure episodes may occur in otherwise healthy people for a variety of reasons, including an acute febrile state,

FAST FACTS

- Epilepsy affects people of all ages and cultural backgrounds.
- Approximately 275 000 Australians have epilepsy (Epilepsy Centre, 2015).
- Epilepsy is not a mental disorder.

infection, metabolic or endocrine disorder (such as hypoglycaemia) or exposure to toxins. Epilepsy may be idiopathic (i.e. it may have no identifiable cause) or it may be secondary to birth injury, infection, vascular abnormalities, trauma or tumours.

Pathophysiology

Normally, when the mind is actively working, electrical activity in the brain is unsynchronised; when the mind is at rest, electrical activity is mildly synchronised. It is believed that most seizures arise from a few unstable, hypersensitive and hyper-reactive neurons in the brain. During a seizure, these neurons produce a rhythmic and repetitive hypersynchronous discharge. Although the exact initiating factor for seizure activity has not been identified, several theories have been proposed (Grossman & Porth, 2013):

- alterations in the permeability of, or ion distribution across, cell membranes
- alterations in the excitability of neurons resulting from neuroglia (neuroglia are CNS connective or supporting cells; they include astrocytes, oligodendroglia and microglia)
- scarring or decreased inhibition of activity in the cerebral cortex or thalamic region
- imbalances of excitatory and inhibitory neurotransmitters such as acetylcholine (ACh) or gamma aminobutyric acid (GABA).

All people have a seizure threshold; when this threshold is exceeded, a seizure may result. In some people, the seizure threshold may be abnormally low, increasing their risk of seizure activity; in other people, pathological processes may alter the seizure threshold (Grossman & Porth, 2013). The neurons that initiate seizure activity are called the *epileptogenic focus*. Abnormal neuronal activity may remain localised, causing a partial or focal seizure, or it may spread to involve the entire brain, causing generalised seizure activity.

Seizures may also be provoked or unprovoked. Unprovoked (primary or idiopathic) seizures have no identifiable cause, with multiple episodes diagnosed as a seizure disorder. Provoked (secondary) seizure aetiologies include febrile seizures in children, toxaemia of pregnancy, rapid withdrawal from alcohol or barbiturates, systemic metabolic conditions (such as hypoglycaemia, hypoxia, uraemia and electrolyte imbalances) and pathologies of the brain (such as meningitis, cerebral bleeding or cerebral oedema).

Metabolic needs of the brain increase dramatically during seizure activity. The demand for adenosine triphosphate (ATP), the energy source of the brain, increases by approximately 250%. Consequently, the demand for glucose and oxygen (which are needed to produce ATP) increases and oxygen consumption increases by about 60%. To supply this increased oxygen need and remove carbon dioxide and other metabolic by-products, cerebral blood flow increases to about 2.5 times that of the normal rate. As long as oxygenation, blood glucose levels and cardiac function remain normal, cerebral blood flow can respond to this increased metabolic demand of the brain. If cerebral blood flow cannot meet these needs, however, cellular exhaustion and cellular destruction may result.

Manifestations

Although seizures may be categorised in several different ways, the classification developed by the International League Against Epilepsy is the most useful clinically (cited in Papadakis et al., 2015). In this classification, seizures are divided into those that affect only part of the brain (partial seizures) and those that are generalised (affect all of the brain). An individual may have more than one type in what are called mixed seizures.

Partial seizures

Partial (or focal) seizures involve the activation of only a restricted part of one cerebral hemisphere. A partial seizure

MEETING INDIVIDUALISED NEEDS Epilepsy in older adults

For years, epilepsy was believed to be a disease that only affected children. However, the incidence of epilepsy is higher in older adults than in children. In people aged 65 years and over there has been a significant increase in the development of new seizure activity (Epilepsy Action Australia, 2015). These data have important implications for nursing assessments and care.

- The most common cause of epilepsy in older adults is arteriosclerosis of the cerebrovascular system (with up to 80% of the older population having arteriosclerosis).
- The manifestations of epilepsy in older adults are different from those in younger adults and children. Although 60% of younger people have generalised tonic–clonic seizures, only 30% of older adults have generalised tonic–clonic seizures. The most common type of seizure in older adults is a complex partial seizure.
- Older adults tend to have longer post-seizure manifestations than younger adults.
- Epilepsy that begins in older adults is often easier to control with anti-epileptic drugs (AEDs) than that in younger people. However, some AEDs decrease the effect of statins used to treat arteriosclerosis (the most common cause of epilepsy in older adults).

accompanied by no alteration in consciousness is called a simple partial seizure; one in which consciousness is impaired is called a complex partial seizure.

SIMPLE PARTIAL SEIZURES The manifestations of *simple partial seizures* depend on the involved area of the brain. Manifestations may include alterations in motor function, sensory signs or autonomic or psychic symptoms. Typically, the motor portion of the cortex is affected, causing recurrent muscle contractions of the face or a contralateral part of the body, such as a finger or hand. This motor activity may stay confined to one area or spread sequentially to adjacent parts, a phenomenon known as a *Jacksonian march* or *Jacksonian seizure*. Manifestations of a simple partial seizure involving the sensory portion of the brain may include abnormal sensations or hallucinations. Disruptions in the function of the autonomic nervous system, with resulting tachycardia, flushing, hypotension and hypertension, or psychic manifestations, such as a sense of déjà vu (a feeling that 'this has happened before') or inappropriate fear or anger, may also be experienced during a simple partial seizure.

COMPLEX PARTIAL SEIZURES During a *complex partial seizure*, consciousness is impaired and the person may engage in repetitive, non-purposeful activity, such as lip smacking, aimless walking or picking at clothing. These behaviours are known as automatisms. During the seizure, the person loses conscious contact with the environment; amnesia is common after the seizure and several hours may elapse before the person regains full consciousness. Complex partial seizures usually originate in the temporal lobe and may be preceded by an aura, such as an unusual smell, a sense of déjà vu or a sudden intense emotion.

Generalised seizures

Generalised seizures involve both hemispheres of the brain as well as deeper brain structures, such as the thalamus, basal ganglia and upper brainstem. Consciousness is always impaired with generalised seizures. Absence and tonic–clonic seizures are the common forms of generalised seizure activity; they occur more frequently (especially in children) than partial seizures.

ABSENCE SEIZURES *Absence (petit mal) seizures* are characterised by a sudden brief cessation of all motor activity accompanied by a blank stare and unresponsiveness. Absence seizures are more common in children than in adults. The seizure typically lasts only 5 to 10 seconds, although some may last for 30 seconds or more. Movements such as eyelid fluttering, or automatisms such as lip smacking, may occur during an absence seizure. Seizure activity may vary from occasional episodes to several hundred per day.

TONIC–CLONIC SEIZURES *Tonic–clonic seizures* (grand mal) are the most common type of seizure activity in adults. This type of seizure activity follows a typical pattern. A warning *aura* may precede generalised seizure activity. The aura may be a vague sense of uneasiness or an abnormal gustatory, visual, auditory or visceral sensation (such as a metallic taste in the mouth, a smell of burning rubber or seeing a bright light). Often, however, the seizure occurs without warning.

The seizure begins with a sudden loss of consciousness and sharp tonic muscle contractions (the tonic phase of the seizure). With the muscle contraction, air is forced out of the lungs and the person may cry out. Postural control is lost and the person falls to the floor in the opisthotonic posture (see Figure 41.4A). Muscles are rigid, with the arms and legs extended and the jaw clenched. Urinary incontinence is common; bowel incontinence may also occur. Breathing ceases and cyanosis develops during the tonic phase of a seizure. The pupils are fixed and dilated. The tonic phase lasts an average of 15 seconds, although it may persist for up to a minute.

The clonic phase, which follows the tonic phase, is characterised by alternating contraction and relaxation of the muscles in all the extremities along with hyperventilation (see Figure 41.4B). The eyes roll back and the person froths at the mouth. The clonic phase varies in duration and subsides gradually. The entire tonic–clonic portion of the seizure generally lasts no more than 60 to 90 seconds.

Following the clonic phase of seizure activity, the person remains unconscious and unresponsive to stimuli. This period is known as the postictal period or phase. The person is relaxed and breathes quietly. The person regains consciousness gradually and may be confused and disoriented on waking. Headache, muscle aches and fatigue often follow the seizure and the person may sleep for several hours. Amnesia of the seizure is usual; the person also may not recall events just prior to the seizure activity.

Because of the lack of warning with tonic–clonic seizures, the person may experience injury. Head injury, fractures, burns or motor vehicle crashes may occur secondarily to seizure activity.

Status epilepticus

Status epilepticus can develop during seizure activity. In this case, the seizure activity becomes continuous, with only very

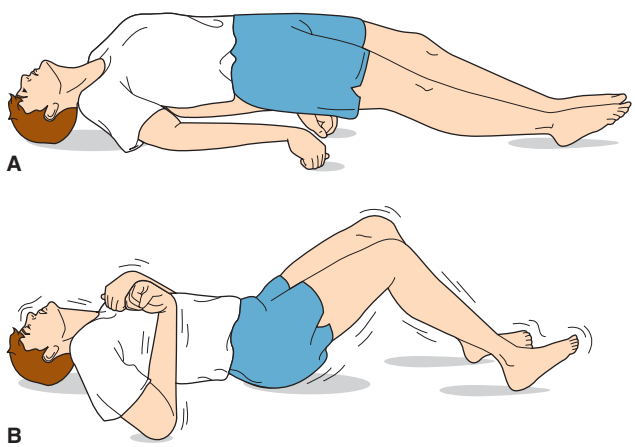


FIGURE 41.4 ■ Tonic–clonic seizures in grand mal seizures. *A*, Tonic phase. *B*, Clonic phase

short periods of calm between intense and persistent seizures. The repetitive seizures may be of any type, although they are usually generalised tonic–clonic (Grossman & Porth, 2013). Repeated seizures have a cumulative effect, producing muscular contractions that can interfere with respirations. The person is in great danger of developing hypoxia, acidosis, hypoglycaemia, hyperthermia and exhaustion if the convulsive activity is not halted. Status epilepticus is considered a life-threatening medical emergency that requires immediate treatment.

INTERPROFESSIONAL CARE

Initial treatment focuses on controlling the seizure; the long-term goal is to determine the cause and prevent future seizures. Interprofessional care includes diagnostic testing, medications and, in some cases, surgery.

Diagnosis

Diagnostic testing is performed to confirm the seizure diagnosis and to determine any treatable causes and precipitating factors. (See Chapter 40 for a description of neurological tests and related nursing care.) Radiological examinations include an MRI or CT scan to determine abnormalities in the brain and a skull x-ray to identify any bony abnormalities. An electroencephalogram (EEG) helps localise any brain lesions and confirm the diagnosis. A lumbar puncture may be performed to assess spinal fluid for CNS infections (increased WBCs) or tumours (increased protein levels). Blood studies are used to assess blood count, electrolytes, blood urea and blood glucose.

Medications

Anti-epileptic drugs (AEDs) (also called anticonvulsant drugs) can reduce or control most seizure activity. More than 20 drugs are used in the treatment of epilepsy. These medications do not cure the disorder; they only manage its manifestations. AEDs generally act in one of two ways: by raising the seizure threshold or by limiting the spread of abnormal activity within the brain.

The goals of medications for epilepsy are to protect the person from harm and to reduce or prevent seizure activity without impairing cognitive function or producing undesirable side effects. Ideally, the lowest possible dose of a single medication that will control the person's seizures is prescribed; often, however, several medications must be tried before the most effective is identified and a combination of drugs may be needed to manage the person's seizures. Therapy is individualised, based on the type of seizure activity and the person's response to the medication. Some drugs recommended for newly diagnosed adults with either partial or mixed seizures, and commonly used in Australia, are phenytoin (Dilantin), sodium valproate (Epilim), gabapentin (Neurontin), lamotrigine (Lamictal), oxcarbazepine (Trileptal) and topiramate (Topamax). Examples of and nursing implications for AEDs are described in the 'Medication administration' box below; drug interactions are listed in Box 41.3.

BOX 41.3 Drug interactions with AEDs

- *Sodium valproate (Epilim) and phenobarbital*. Blood levels of phenobarbital may rise significantly when sodium valproate is added to the person's medication regimen.
- *Phenobarbital and digoxin*. This combination may increase the metabolism of digoxin, resulting in decreased digoxin levels.
- *Phenobarbital and warfarin (Coumadin).* Phenobarbital may decrease the absorption of warfarin from the gastrointestinal tract and decrease the drug's anticoagulant response.
- *Disulfiram (Antabuse) and phenobarbital.* This combination may inhibit the metabolism of the anticonvulsant drug and increase the incidence of side effects associated with the anticonvulsant drug.
- *Carbamazepine and oral contraceptives.* Carbamazepine decreases the effectiveness of oral contraceptives.
- *Other drugs.* Other drugs reported to interact with anticonvulsant drugs include aspirin, certain antibiotics, isoniazid, acetazolamide (Diamox), antacids, folic acid and narcotics.

If the person has been seizure free for at least 3 years, withdrawal of medications may be considered, with the dose of one drug at a time reduced over weeks or months. There is no way to predict which people can remain seizure free without medication, but if seizures reoccur, the same medications usually provide good control.

Status epilepticus requires immediate intervention to preserve life. Establishing and maintaining the airway is a priority. A solution of 50% dextrose is administered intravenously to prevent hypoglycaemia. Diazepam (Valium) or lorazepam (Ativan) is given intravenously and the dose repeated in 10 minutes if necessary to stop seizure activity. Phenytoin (Dilantin) is administered intravenously for longer-term control of seizures. Phenobarbital may also be administered to people in status epilepticus.

Surgery

Resective surgery, with removal of the epileptogenic focus, is an option that is still in its early stages. Candidates for this type of surgery include those who are unresponsive to medical management, who have a unilateral focus and who have impaired quality of life from seizures. Resections of the temporal lobe are most commonly performed and are most effective for partial complex seizures. An estimated 5% of people with epilepsy may be candidates for surgery. The goal of surgery is to reduce the person's uncontrollable seizures.

To be selected as a candidate for surgery, the person must be highly motivated and psychologically prepared. A psychological screening is required because the preoperative preparation is extensive and time consuming and the

surgery is long and requires that the person remain awake during surgery so that they can cooperate and respond to commands. The EEG is monitored during surgery to identify the epileptogenic focus and evaluate the effect of surgical intervention.

General postoperative care for the person with intracranial surgery follows the nursing management guidelines outlined later in the chapter. Specific preoperative and postoperative care for a person with a seizure disorder is described in the box below.

Vagal nerve stimulation therapy

Vagal nerve stimulation (VNS) therapy is approved as a treatment for people with partial-onset seizures who do not respond to AEDs. The therapy does not stop the seizures, but rather reduces their number and improves the person's quality of life. It is almost always necessary to continue taking AEDs. The therapy is designed to prevent seizures by sending regular small pulses of electrical energy to the brain via the vagus nerve. A flat, round battery (about the size of a dollar coin) is implanted in the chest wall, and electrodes are threaded under the skin and wound around the vagus nerve in the neck. The battery is programmed to deliver a few seconds of electrical energy every few seconds. If the person feels that a seizure is about to happen, a discharge can be activated by passing a small magnet over the battery. In some people this stops the seizures. Side effects are hoarseness and throat discomfort.

Nursing care

See below for a nursing care plan for a person with seizures.

Health promotion

Health promotion activities for the person with seizures focus on teaching to reduce the incidence of seizure activity and to promote safety. Stress the following:

- Know the importance of follow-up care, of keeping medical appointments and of continuing to take AEDs as prescribed even when no seizures are experienced.

MEDICATION ADMINISTRATION Seizures

ANTI-EPILEPTIC DRUGS (AEDS)

Examples of AEDs are:
Phenytoin (Dilantin)
Phenobarbital
Primidone (Mysoline)
Carbamazepine (Tegretol)
Sodium valproate (Epilim)
Ethosuximide (Zarontin)
Clonazepam (Rivotril)
Gabapentin (Neurontin)
Lamotrigine (Lamictal)
Tiagabine hydrochloride (Gabitril)
Levetiracetam (Keppra)

AEDs are used to control chronic seizures and involuntary muscle spasms or movements characteristic of certain neurological diseases. These drugs act in the motor cortex of the brain to reduce the spread of electrical discharges from the rapidly firing epileptic foci in this area. These agents control seizures without impairing the normal functions of the CNS. Drugs effective against one type of seizure may not be effective against another; anticonvulsant therapy must be individualised.

Nursing responsibilities

- Monitor blood pressure, pulse and respirations.
- Note evidence of CNS side effects, such as blurred vision, dimmed vision, slurred speech, nystagmus or confusion. Gingival hyperplasia may be noted in people taking phenytoin.
- Recognise that if people are to be on prolonged therapy, they may need a diet rich in vitamin D.
- Monitor the serum calcium level as ordered; phenytoin can contribute to demineralisation of bone.
- When administering anticonvulsants intravenously, monitor closely for respiratory depression and cardiovascular collapse.
- Administer gabapentin 2 hours after antacids.
- Administer tiagabine hydrochloride with food.

Health education for the person and family

- Take the exact dosage prescribed. Do not increase, decrease or discontinue the dosage without obtaining the healthcare provider's approval; doing so may lead to convulsions.
- Avoid hazardous tasks until the drug has been regulated. AEDs may at first decrease mental alertness and cause drowsiness, headache, dizziness and incoordination of muscles. These effects are usually dose related and may disappear with a change of dosage or continued therapy.
- If you are taking phenytoin (Dilantin), maintain good oral hygiene: use a soft toothbrush, massage the gums and floss daily.
- It is very important to obtain liver function studies regularly as ordered by the healthcare provider. This will help detect early signs of hepatitis and other liver problems. Report for all scheduled laboratory studies, including complete blood count, kidney and liver function studies, and drug levels.
- Carry identification indicating the type of seizures for which you are being treated.
- Do not take gabapentin 1 hour before or less than 2 hours after an antacid.
- If you are taking lamotrigine and develop a rash, tell your healthcare provider.
- Take tiagabine hydrochloride (Gabitril) with food.

- Review any state and local laws that apply to people with seizure disorders. Driving a motor vehicle is usually prohibited for 6 months to 2 years after a seizure episode. Usually, a driver's licence can be reinstated or obtained after a seizure-free period and a letter from the nurse practitioner or doctor.
- Know drug interactions with other prescribed drugs, over-the-counter (OTC) drugs, street drugs and alcohol.
- Teach family members first aid for a seizure:
  - Cushion the head.
  - Loosen anything tight around the neck.
  - Turn on the side.
  - Nothing in the mouth.
  - Don't hold down.
- Teach family members to call for medical assistance:
  - if the seizure lasts for more than 5 minutes
  - if there is slow recovery, a second seizure or difficulty breathing after the seizure
  - if there are signs of injury (such as bleeding from the mouth).

Assessment

Collect the following data through the health history and physical examination:

- *Health history:* past seizures; age when the first seizure occurred, most recent seizure; factors precipitating a seizure, any warning signs (aura); prophylactic anticonvulsant therapy; and specific concerns the person may have about the seizures.
- *Physical assessment:* important data used in determining an accurate diagnosis describes manifestations obtained from nursing assessments before, during and after a seizure. (Table 41.6 lists nursing assessments with rationale.)

Nursing diagnoses and interventions

Nursing care of people with a seizure disorder focuses on providing care during and immediately after the seizure and on personal/family teaching. The person with seizures has a wide variety of responses to actual or potential changes in health status; interventions discussed in this section focus on facilitating physical and psychological comfort and safety.

Risk of ineffective airway clearance

During a seizure, the tongue may fall back and obstruct the airway, the gag reflex may be depressed, and secretions may pool at the back of the throat. These may put the person at risk of an obstructed airway. Most seizures occur in the home or community; therefore, teach these interventions to the person's family:

- Provide interventions to maintain a patent airway:
  - Loosen clothing around the neck.
  - Turn on the side.
  - Do not force anything into the mouth.
  - If prescribed and available, administer oxygen by mask.
  - Although it was at one time believed that it was necessary to place a padded tongue blade in the person's

TABLE 41.6 Nursing assessments before, during and after a seizure

ASSESSMENT	RATIONALE
What was the person's level of consciousness? If consciousness was lost, at what point?	Indicates area of brain involved and type of seizure
What was the person doing just before the attack?	May suggest precipitating factors
In which part of the body did the seizure start?	May indicate the site of seizure activity in the brain tissue; for example, if jerking movements were first observed in right hand, the seizure focus may be in left motor cortex
Was there an epileptic cry?	Usually indicates the tonic stage of a generalised tonic–clonic seizure
Were any automatisms such as eyelid fluttering, chewing, lip smacking or swallowing observed?	Often seen in complex, partial and absence seizures
How long did movements last? Did the location or character change (tonic to clonic)? Did movements involve both sides of the body or just one?	Indicates areas in which focal activity originated
Did the head and/or eyes turn to one side and, if so, which side?	Helps localise the focus of the seizure. During the seizure, the head and eyes typically will turn away from the side of the epileptogenic focus
Were there changes in pupillary reactions?	Indicates involvement of the autonomic nervous system
If the person fell, was the head hit?	Skull x-ray studies may be needed to rule out subdural haematoma or fracture
Was there foaming or frothing from the mouth?	Usually indicates a tonic–clonic seizure

NURSING CARE OF THE PERSON with seizures who is having surgery

PREOPERATIVE CARE

- For most people, AEDs are withheld the morning or evening of the day before surgery. *AEDs may interfere with intraoperative EEG monitoring.*
- For people with frequent and/or severe seizures, however, a partial dose of medication may be administered. *This prevents seizures or status epilepticus during surgery.*
- A low dose of analgesics is administered before surgery. *The person must remain awake throughout the lengthy procedure to respond to commands during EEG recording.*

POSTOPERATIVE CARE

- AEDs are administered parenterally until the person can tolerate oral fluids; medications are then continued orally. *It is common for the person to have seizures in the early postoperative period.*
- Steroids are administered for the first 3 days after surgery and are tapered and then discontinued during the following week. *Steroids are given to decrease cerebral oedema.*

NURSING CARE PLAN A person with a seizure disorder

Janet Carlson is a 19-year-old university student who lives with her parents and one younger sister. Although Janet had seizures while she was at high school, they have been controlled with medication. However, she had a tonic–clonic seizure yesterday and immediately made an appointment with her family GP. She is currently taking phenytoin (Dilantin) 300 mg/day as a maintenance medication to prevent seizures.

ASSESSMENT

Evita Farias, RN, completes a health history for Ms Carlson. During the history, she tells Ms Carlson that she has been under stress because of difficulties in completing her course requirements this semester. She has not been sleeping as many hours per night and sometimes she forgets to take her medication. Ms Carlson's serum phenytoin level is 8 mg/mL. Therapeutic level is 10 to 20 mg/mL.

DIAGNOSES

- *Risk of injury* related to recurrence of generalised tonic–clonic seizure activity and low serum phenytoin levels, evidenced by increased seizure activity.
- *Deficient knowledge* related to activities that may trigger seizure occurrence, the effect of stress on seizures and medication information manifested by increased seizure activity.

PLANNING

- Improved management of epilepsy through compliance with management regimens and increased knowledge of epilepsy.

Expected outcomes

- Awareness of precipitating and triggering factors related to the onset of seizures.
- Awareness of the relationship between emotional and physical stress and seizures.
- Awareness of the importance of taking AEDs.

IMPLEMENTATION

- Teach Ms Carlson and her family the following:
  - current information about seizures
  - care during and after a seizure
  - medication protocols
  - factors and activities that can trigger seizures
  - the importance of follow-up care.
- Refer Ms Carlson and her family to a local epilepsy support group.
- Recommend that she purchase and wear a MedicAlert® bracelet.

EVALUATION

Ms Carlson is instructed to continue taking Dilantin 300 mg/day. She states the importance of nutrition, rest and measures to reduce stress. She also discusses the importance of maintaining the proper blood levels of her medication, stating that too little or too much of the medication could cause problems. Ms Carlson recognises that the seizures had recurred during a busy time in high school during which she had forgotten to take her medication. She is now wearing a MedicAlert® bracelet. Ms Carlson is provided with the telephone number of Epilepsy Action Australia.

CRITICAL THINKING IN THE NURSING PROCESS

1. If you were Ms Carlson's nurse, would your teaching differ if she were living alone? If so, how?
2. Ms Carlson tells you that although she knows she should not drive a car, she often drives her friend to work. How would you approach this problem?

REFLECTION ON THE NURSING PROCESS

1. Which safety strategies could family members implement in the event of a person having a seizure?
2. Outline what you have learned from this case study that you will apply to your future nursing practice.

mouth during a seizure, this is no longer recommended; an improperly placed tongue blade can obstruct the airway. *Turning the person on the side allows secretions to drain from the mouth.*

- Teach family members or significant others how to care for the person during a seizure to prevent airway obstruction. *Family members are often the only people present to provide this emergency intervention.*

Anxiety

The person with a seizure disorder is understandably anxious about the future, with questions about ability to go to school or university, work, have a family and drive a car. Feelings of embarrassment about having a seizure in public and rejection by others are common and also increase the person's anxiety.

- Provide support by explaining that concerns are normal. It is important to be sensitive to the effect of seizures on the person's self-concept and body image; alterations in these areas not only increase anxiety but also cause withdrawal from socialisation with others. *Demonstrating acceptance of the person's concerns allows further discussion.*
- Help identify safe leisure activities. *Worrying about being hurt if a seizure occurs may cause withdrawal from social activities that are pleasurable.*
- Provide information about sources and support groups. *Sharing information with other people with similar health problems allows for a more realistic viewpoint; accurate information can clear up misconceptions that cause anxiety.*
- Provide accurate information about hiring practices and legal limitations on driving or operating heavy or dangerous machinery. *Accurate information decreases anxiety about the unknown. The federal* Disability Discrimination Act *in Australia prohibits discrimination; however, there are legal limitations on driving until the person is proved free of seizures.*

Community-based care

Teaching follows a systematic assessment of the needs of both the person and their family. Include family members so that they can learn seizure management, including the care and observations necessary before and during a seizure. Stress the importance of safety and keeping the airway patent.

Help both the person and their family adjust to a diagnosis of epilepsy. Address the following topics:

- the importance of wearing a MedicAlert® bracelet or carrying a medical alert card at all times
- avoiding alcoholic beverages and limiting coffee intake
- taking showers versus baths because of safety issues during a generalised seizure
- factors that may trigger a seizure, such as abrupt withdrawal from medication, constipation, fatigue, excessive stress, fever, menstruation, sights and sounds such as television, flashing video and computer screens
  - helpful resources, including:
  - Epilepsy Action Australia: www.epilepsy.org.au
  - Epilepsy Australia: www.epilepsyaustralia.net
  - Epilepsy Foundation: www.epinet.org.au.

TRAUMATIC BRAIN INJURY

Traumatic brain injury (TBI) (also called *craniocerebral trauma*) refers to any injury of the scalp, skull (cranium or facial bones) or brain. TBI is the second-largest cause of death and disability in Australia and worldwide, with occurrence three times greater in the Indigenous Australian population, particularly females. TBI may be defined as a traumatic insult to the brain capable of causing physical, intellectual, emotional, social and vocational changes. A TBI may be classified as a penetrating (open) head injury (e.g. resulting from a knife, bullet or baseball bat) or a closed head injury (a blunt injury to the brain that does not result in an open skull fracture). TBI may cause problems with cognition, movement, sensation and emotions. Even mild brain injuries, if repeated over an extended period of time, can result in cumulative neurological and cognitive deficits.

FAST FACTS

- Each year, 1000 Australians sustain a TBI (Australian Trauma Quality Improvement Program, 2012).
- In 2004–2005, 22 710 Australians were hospitalised with TBI as the primary or associated diagnosis. Of these, 980 died (Australian Institute of Health and Welfare (AIHW), 2007).
- Approximately 438 300 Australians live with a disability as the result of a TBI (AIHW, 2007).

In Australia, the leading causes of TBI are falls (40%), followed by transportation accidents (31%) and assaults (14%). Elevated blood alcohol levels, not wearing motorcycle helmets and not wearing seat belts contribute significantly to the risk of crashes and subsequent injury. Other causes of head injury include sports injuries and occupational and recreational injuries (Brain Injury Australia, 2015). Adults aged 15 to 44 are at the greatest risk, with a male-to-female ratio in the Anglo-Saxon population of 3:1 (Hickey, 2013). Other risk factors include being over the age of 75 and living in a high-crime area.

Specific damage following craniocerebral injuries is related to the mechanism of the injury (how it occurs), the nature of the injury (type) and the location of the injury (where it occurs).

Head injuries may be classified as blunt or penetrating and can occur through several mechanisms:

- Acceleration injury is sustained when the head is struck by a moving object, such as a swinging bat.
- Deceleration injury occurs when the head hits a stationary object, such as a concrete wall.
- Acceleration–deceleration injury (also called a *coup–contrecoup* phenomenon) occurs when the head hits an object and the brain 'rebounds' within the skull (see Figure 41.5). The brain is injured at the point of impact (the coup) and on the opposite side of the impact (the contrecoup).

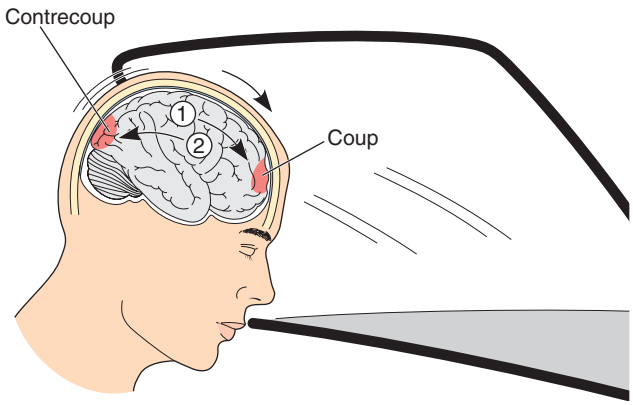

FIGURE 41.5 ■ Coup–contrecoup head injury. Following the initial injury (coup), the brain rebounds within the skull and sustains additional injury (contrecoup) in the opposite part of the brain

TABLE 41.7 Types of skull fractures

TYPE	DESCRIPTION
Linear	Simple, clean break in skull
(simple)	Occurs with low-velocity injuries
Comminuted	Bone is crushed into small, fragmented pieces
	Usually seen with high-impact injuries
Depressed	Inward depression of bone fragments
	Usually due to a powerful blow to the skull
	The dura may or may not be intact
	Bone fragments may penetrate into the brain tissue
Basilar	Occurs at the base of the skull
	May be linear, comminuted or depressed

Two or more areas of the brain can be injured as a result of this phenomenon.

- Deformation injuries are those in which the force deforms and disrupts the integrity of the impacted body part (e.g. skull fracture).

Types of craniocerebral trauma include injuries to the skull (including fractures), injuries to the brain (including concussion and contusion) and intracranial haemorrhage (including haematomas). Brain injury can result either from the direct effects of the trauma on brain tissue or from secondary responses to trauma, such as cerebral oedema, haematoma (blood clot), swelling or increased intracranial pressure.

THE PERSON WITH A SKULL FRACTURE

A *skull fracture* is a break in the continuity of the skull. It may occur with or without damage to the brain; however, intracranial trauma often results from skull fractures. The considerable force of impact significantly increases the risk of underlying haematoma formation. Disruption of the skull can also cause cranial nerve injury, allow bacteria to enter the cranial vault, and/or allow CSF to leak out.

Pathophysiology

Skull fractures are classified as open or closed. In an open fracture, the dura is torn; and in a closed fracture, the dura is not torn. Skull fractures are further classified into one of four categories: linear, comminuted, depressed or basilar (see Table 41.7).

Linear fractures

Linear fractures are the most common, accounting for 80% of all skull fractures. They typically extend from the point of impact towards the base of the skull. Although the risk of infection or CSF leakage is minimal with this type of fracture because the dura usually remains intact, subdural or epidural haematomas (a collection of blood) frequently underlie the fracture. A haematoma (discussed later in this chapter) places pressure on underlying brain tissue, increasing both intracranial pressure and the risk of brain damage.

Comminuted and depressed fractures

Comminuted and depressed skull fractures increase the risk of direct damage to brain tissue from bruising (contusion) and bone fragments. However, the risk of secondary brain injury may be reduced in these fractures, because in breaking the bone, the traumatic impact energy is distributed and dissipated. If the skin overlying the fracture is lacerated or the dura is torn, the risk of infection is increased.

Basilar fractures

Basilar skull fractures involve the base of the skull and usually are extensions of adjacent fractures, although they may occur independently. Although most basilar skull fractures are uncomplicated, they may involve the sinuses of the frontal bone or the petrous portion of the temporal bone (middle ear). If the dura is disrupted, CSF may leak through the tear. CSF leakage may include *rhinorrhoea* (CSF leakage through the nose) or *otorrhoea* (CSF leakage from the ear). Blood may be visible behind the tympanic membrane (haemotympanum) or ecchymosis may be noted over the mastoid process (Battle's sign). Bilateral periorbital ecchymosis ('raccoon eyes') is another possible manifestation. If CSF leakage is present, the risk of infection is high. Other complications of basilar skull fractures include injury to the internal carotid artery and compression of cranial nerve I, II, III, IV, V, VII or VIII.

INTERPROFESSIONAL CARE

Treatment of the person with a skull fracture depends on the type and location of the fracture. Skull fracture may be only one of several head injuries.

A simple linear fracture generally requires bed rest and observation for underlying injury to brain tissue or haematoma formation. No specific treatment is required. Depressed skull fractures require surgical intervention, usually within 24 hours of the injury, to debride the wound completely and remove bone fragments, which may become embedded in brain tissue or cerebral blood vessels. If depressed deeply, the bone may be elevated. If cerebral oedema is not present, a cranioplasty with insertion of acrylic bone may be performed. Basal skull fractures do not require surgery unless CSF leakage persists. Regular neurological assessments and observation for manifestations of meningitis are required for the hospitalised person. Antibiotics may be administered prophylactically.

Nursing care

The person with a craniocerebral trauma may have a variety of responses and healthcare needs, depending on the location and extent of the trauma. Many of those problems, with related nursing interventions, are discussed in other sections of this chapter, including seizures, increased intracranial pressure and bleeding within the brain.

Nursing diagnoses and interventions

Risk of infection

The person with a skull fracture is at increased risk of infection related to access to the cranial contents through a tear in the dura. In an open, depressed fracture, the wound may be contaminated by dirt, hair or other debris.

- Monitor for otorrhoea or rhinorrhoea. *Open fractures of the skull increase the possibility of leakage of CSF from the ears or nose.*
- Test drainage of clear fluid from ear and nose for glucose by using a glucose reagent strip, such as Dextrostix. *Clear drainage that tests positive for glucose indicates leakage of CSF; however, be aware that false positives may occur.*
- *Observe blood-tinged fluid for 'halo' sign. CSF dries in concentric rings on gauze or tissues. This sign is suggestive of CSF leakage.*
- Keep the nasopharynx and the external ear clean. Place a piece of sterile gauze in the ear or tape a sterile cotton pad loosely under the nose; change dressings when they become wet. *Wet dressings facilitate movement of organisms.*
- Instruct person not to blow nose, cough or inhibit sneeze; sneeze through open mouth. *Blowing the nose and coughing increase ICP. Withholding a sneeze forces bacteria backwards.*
- Use aseptic technique at all times when changing head dressings or ICP monitor dressings and insertion sites. *Using aseptic technique reduces the possibility of introducing infection.*

Knowledge deficit: skull fracture

The person and their family need to be informed about the degree of injury that has occurred with the skull fracture. The person with a linear fracture, who may not be hospitalised, will need teaching that focuses on the need to monitor progress closely. To prevent complications, advise the person and their family to go to the emergency room if the person experiences any of the following:

- growing drowsiness or confusion
- difficulty waking (instruct a family member to wake the person every 2 hours during the first night home)
- vomiting (especially if projectile)
- blurred vision
- slurred speech
- prolonged headache
- blood or clear fluid leaking from the ears or nose
- weakness in an arm or leg
- stiff neck
- seizure.

THE PERSON WITH A FOCAL OR DIFFUSE TRAUMATIC BRAIN INJURY

Even when the skull and other structures overlying the brain remain intact, a blow to the head can cause significant brain injury. Closed head injuries may result in either focal or diffuse damage to the brain. They range in severity from mild to severe.

Pathophysiology

Brain injury results from both primary and secondary mechanisms. Primary injury results from the impact. A blow to the head, even with no break in the skull, can cause serious and diffuse brain injury. Injury to axons disrupts oligodendroglia and direct mechanical disruption is caused by debris and leakage. The immediate vascular response to the injury results in increased capillary permeability to solutes.

Secondary injury is the progression of the initial injury resulting from events that affect perfusion and oxygenation of brain cells. These events include intracranial oedema, haematoma, infection, hypoxia or ischaemia. Cerebral ischaemia is the most common cause of secondary brain injury (Grossman & Porth, 2013). Ischaemia leads to cerebral hypoxia, with consequences of increased glial permeability to sodium (cytotoxic oedema), an influx of calcium with changes in electrophysiology and release of free fatty acids and lactic acidosis.

TABLE 41.8 Systemic effects of acute brain injury

CAUSE	EFFECT
• Stimulation of the sympathetic nervous system, which stimulates the adrenal cortex and medulla to increase glucocorticoid and mineralocorticoid levels	• Increased metabolism of carbohydrates, fats and proteins • Retention of sodium and water
• Stimulation of the sympathetic nervous system, increasing the serum catecholamine levels	• Hypertension • EEG changes • Arrhythmias (bradycardia, sinus tachycardia)
• Altered release of ADH from the posterior pituitary	• Retention of water or diuresis and diabetes insipidus
• Neurogenic pulmonary dysfunction	• Abnormal respiratory patterns • Reduced residual capacity with retention of CO_2, vasodilation and increased ICP • Pulmonary oedema
• Stress response to trauma	• Hyperglycaemia
• Increased platelet, plasma fibrinogen and thromboplastin levels	• Decreased clotting and prothrombin times • Vascular occlusion • Disseminated intravascular coagulation • Anaemia
• Immunosuppression	• Infection
• Decreased gastric motility and increased gastric acidity	• Gastritis • Gastric ulcers

Acute brain injury affects all body systems as well as the central nervous system. Systemic effects of acute brain injury are listed in Table 41.8.

Focal brain injuries

Focal brain injuries are specific, grossly observable brain lesions confined to one area of the brain. They include contusions, lacerations and intracranial haemorrhage. The force of an impact produces contusions from direct contact with the inside of the skull that in turn may cause epidural haemorrhage and subdural and intracerebral haematomas. The mechanisms of injury are coup and/or contrecoup damage to the brain at the point of the impact and the rebound effect. The damaged brain area is surrounded by oedema, contributing to IICP. Infarction and necrosis, multiple haemorrhages and oedema are found within the contused areas. The maximum effects of the injury peak in 18 to 36 hours.

Intracranial haemorrhage can result directly from the trauma (e.g. beneath a fracture) or from shearing forces on cerebral arteries and veins that occur with acceleration–deceleration. Depending on the site and rate of bleeding, manifestations may appear immediately or may not become evident for hours or even weeks. Intracranial haemorrhages and the haematomas they cause place pressure on surrounding structures, causing manifestations of an expanding focal lesion. They also cause IICP, leading to altered levels of consciousness and potential herniation syndromes. Intracranial haematomas are classified by their location as epidural, subdural or intracerebral. Table 41.9 compares the frequency, locations/common sites, precipitating factors and manifestations of intracranial haematomas; Figure 41.6 illustrates their locations.

CONTUSION A *contusion* is a bruise of the surface of the brain, typically accompanied by small, diffuse venous haemorrhages. Both white and grey matter may have a bruised, discoloured appearance. A decrease in pH, with accumulation of lactic acid and decreased oxygen consumption, may hinder cell function. Contusions (and other focal brain injuries) occur when the brain strikes the inner skull, often with a coup (point of impact) lesion and a contrecoup lesion on the opposite side of the brain. Contusions occur most frequently near bony prominences of the skull. Cerebral oedema can follow contusion, resulting in IICP. Contusions—small, diffuse venous

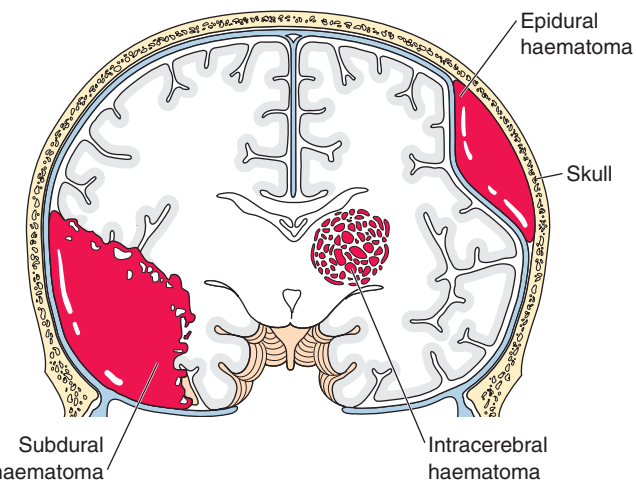

FIGURE 41.6 ■ Three types of haematoma: epidural haematoma, subdural haematoma and intracerebral haematoma

TABLE 41.9 Comparison of intracranial haematomas

TYPE/FREQUENCY	LOCATION/COMMON SITE	PRECIPITATING FACTORS	MANIFESTATIONS
Epidural haematoma 2–6% of all types of head injuries	Located in the space between the skull and the dura mater Common site: the temporal bone (over the middle meningeal artery)	Skull fractures Contusion	Momentary loss of consciousness followed by a lucid period lasting from a few hours to 1 to 2 days Rapid deterioration in LOC (drowsiness to confusion to coma) Seizures Headache Hemiparesis (may be ipsilateral or contralateral) Fixed dilated ipsilateral pupil Rise in blood pressure, with decreases in pulse and respirations, indicates a rapidly increasing haematoma
Subdural haematoma Approximately 29% of all types of head injuries	Located in the space below the dural surface (between the dura and arachnoid and pia mater layers of meninges) Common site: may occur any place in cranium	Closed head injury Acceleration–deceleration injury Cerebral atrophy (seen in older adults) Chronic alcoholism Use of anticoagulants Contusion	Acute: • headache • drowsiness • agitation • slowed thinking • confusion Subacute: • same as those of acute subdural haematoma but develop more slowly Chronic: • manifestations may not appear until weeks to months after injury • confusion, slowed thinking, drowsiness
Intracerebral haematoma 14–15% of all types of head injuries	Located directly in the brain tissue Common sites: frontal or temporal region	Gunshot wounds Depressed bone fractures Stab injury Long history of systemic hypertension Contusions	Headache Deteriorating consciousness to deep coma Hemiplegia on contralateral side Dilated pupil on the side of the clot

haemorrhages—and brain swelling are at their peak 12 to 24 hours after injury.

Manifestations of the contusion depend on the size and location of the brain injury. An initial loss of consciousness occurs; LOC may remain altered and behaviour changes such as combativeness may persist for an extended period. Full consciousness may be regained extremely slowly and residual deficits may persist; in some people, full LOC never really returns. Focal effects of the contusion may cause loss of reflexes, hemiparesis (muscular weakness of one-half of the body) or abnormal posturing. Manifestations of IICP may occur if cerebral oedema develops. Regaining full LOC may take an extended period of time and residual deficits may persist.

EPIDURAL HAEMATOMA An **epidural haematoma** (also called an *extradural haematoma*) develops in the potential space between the dura and the skull, which normally adhere to one another. As the blood collects, the expanding haematoma strips the dura away from the skull. Epidural haematomas affect young to middle-aged adults more frequently than older adults, because the dura becomes more tightly attached to the skull with ageing.

Epidural haematomas usually result from a skull fracture that tears an artery, often the middle meningeal artery. Because epidural haematomas are arterial in origin, they tend to develop rapidly. The person may lose consciousness with the initial injury and then have a brief lucid period before the LOC rapidly declines from drowsiness to coma as the haematoma expands, stripping the dura away from the skull and placing pressure on brain tissue. Other manifestations include headache, vomiting, a fixed, dilated pupil on the same side (ipsilateral) as the haematoma, contralateral (opposite side) hemiparesis or

hemiplegia and possible seizures. Because epidural haematomas usually develop rapidly, timely intervention is vital to prevent significant increases in ICP and herniation.

SUBDURAL HAEMATOMA **Subdural haematomas**, in which a localised mass of blood collects between the dura mater and the arachnoid mater, are more common than epidural haematomas. Acute subdural haematomas are usually located at the top of the head and develop within 48 hours of the initial head injury. Chronic subdural haematomas develop over weeks or months. The chronic type is seen most often in the older adult and people who have some brain atrophy with subsequent enlarged epidural space. These haematomas are often venous in origin, although they may involve bleeding from small arteries as well. Subdural haematomas may form without direct trauma or contusion; acceleration–deceleration forces may tear the bridging veins that connect veins on the surface of the cerebral cortex to the dural sinuses. As blood collects, it places direct pressure on underlying brain tissue.

Acute subdural haematomas develop rapidly following head injury. Although a lucid period may occur, the person commonly develops drowsiness, confusion and enlargement of the ipsilateral pupil within minutes or hours of the injury. If responsive, the person may complain of a unilateral headache. Hemiparesis and respiratory pattern changes may occur.

Chronic subdural haematomas are often associated with relatively minor trauma such as a fall. Weeks to months may elapse before manifestations of the haematoma occur; the initial trauma may have been forgotten. Chronic subdural haematomas may also occur spontaneously in the older adult or in people with bleeding disorders. Manifestations of the haematoma develop slowly and may be mistaken for the onset of dementia in the older adult. Slowed thinking, confusion, drowsiness or lethargy are common early manifestations. Other manifestations include headache, dilation and sluggishness of the ipsilateral pupil, and possible seizures.

INTRACEREBRAL HAEMATOMA **Intracerebral haematomas** may be single or multiple and are associated with contusions. They may occur in any location but usually are found in the frontal or temporal lobes. They may result from closed head trauma, particularly contusion or shearing of small blood vessels deep within the hemispheres. Intracerebral haematomas can also accompany other types of head trauma such as lacerations. Older adults are particularly vulnerable to intracerebral haemorrhage because cerebral blood vessels are more fragile and easily torn.

The manifestations of intracerebral haematoma vary according to the location of the haematoma. Headache may develop, along with decreasing LOC, hemiplegia and dilation of the ipsilateral pupil. The expanding clot increases intracranial pressure and herniation may occur.

Diffuse brain injuries

A diffuse brain injury (DBI) affects the entire brain and is caused by a shaking motion, with twisting movement (rotational acceleration) as the primary mechanism of injury. DBIs include concussions and diffuse axonal injuries. Shearing stresses on brain tissue cause axonal damage from shearing, tearing or stretching of nerve fibres. The most serious axonal injuries are located furthest from the brainstem, with the frontal and temporal axonal tracts being most vulnerable to injury. Physical deficits resulting from DBIs include spastic paralysis, peripheral nerve injury, swallowing disorders, visual and hearing impairments, and taste and smell disorders. Damage decreases the speed of information processing and responding and disrupts attention, resulting in serious cognitive and affective impairments. Cognitive deficits that may result include disorientation and confusion, short attention span, problems with memory and learning, perceptual problems and poor judgment. Possible behavioural deficits include agitation, impulsivity, depression and social withdrawal.

Initially, the damage involves tearing of axons, blood vessels and brain tissue (visible only by electron microscope). The number of damaged axons progressively increases, with pathology involving the nuclei and axons. The damaged axons, which resemble sausage links, regress into round balls called retraction balls (visible with light microscopy). After several weeks, the retraction balls are replaced by clusters of microglia. In the final phase, astrocytosis (equivalent to scarring) occurs at the site of axonal damage, accompanied by demyelination of long axon tracts.

The categories of DBI include mild concussion, classic cerebral concussion and diffuse axonal injury. Manifestations of a concussion are listed in the box below.

MILD CONCUSSION The word **concussion** means violent shaking. A concussion involves temporary axonal disturbances. It is defined as a momentary interruption of brain function. A concussion is associated with an immediate, brief loss of consciousness on impact. Altered consciousness may last only seconds or may persist for several hours. Amnesia for events immediately preceding (antegrade amnesia) and following (retrograde amnesia) the injury is common. Other manifestations of concussion include headache, drowsiness, confusion, dizziness and visual disturbances such as diplopia or blurred vision.

MANIFESTATIONS Concussion

- Immediate loss of consciousness (lasting usually no longer than 5 minutes)
- Amnesia regarding events surrounding injury
- Headache
- Drowsiness, confusion, dizziness
- Visual disturbances
- Possible brief seizure activity with transient apnoea, bradycardia, pallor and hypotension

POST-CONCUSSION SYNDROME

- Persistent headache
- Dizziness
- Irritability and insomnia
- Impaired memory and concentration, learning problems

CLASSIC CEREBRAL CONCUSSION A classic cerebral concussion involves diffuse cerebral disconnection from the brainstem RAS. An immediate loss of consciousness occurs, lasting less than 6 hours. Both retrograde and anterograde amnesia occur. Cerebral contusions may be present. In a severe concussion, a brief seizure and respiratory arrest may occur; transient pallor, bradycardia and hypotension may accompany loss of consciousness.

Following concussion, people may develop post-concussion syndrome with persistent headache, dizziness, irritability, insomnia, impaired memory and concentration, and learning problems. Post-concussion syndrome may last for several weeks or, rarely, up to a year.

DIFFUSE AXONAL INJURY Diffuse axonal injury (DAI) is a brain injury in which a high-speed acceleration–deceleration injury, typically associated with motor vehicle crashes, causes widespread disruption of axons in the white matter. Focal lesions may be found in the corpus callosum, midbrain and brainstem. An immediate loss of consciousness occurs. The prognosis is poor; most people with severe DAI either die or remain in a persistent vegetative state.

DAIs may range from mild to severe. In mild DAI, coma lasts 6 to 24 hours, and cognitive, psychological and sensorimotor deficits may persist. In moderate DAI, injury and impairment is spread throughout the cerebral cortex and diencephalon. There is axonal tearing, coma lasting more than 24 hours and often incomplete recovery. In severe DAI, axonal injury occurs in both cerebral hemispheres, the diencephalon and the brainstem. Immediate autonomic dysfunction occurs and IICP is manifested. Profound cognitive and sensorimotor deficits occur, involving movement, verbal and written communication, ability to learn and reason, and ability to modulate behaviour.

INTERPROFESSIONAL CARE

The person with a brain injury may receive medical and/or surgical treatment. Specific guidelines for the medical management of head injury have been developed for concussion and acute TBI by each state and territory Department of Health. These guidelines include the following:

- *Concussion*. Following a concussion, the person may be observed for 4 hours in the emergency department (ED) and then discharged home with instructions for further observation to detect manifestations of secondary injury. If the loss of consciousness lasted for more than 2 minutes, the person may be admitted to the hospital for observation.
- *Acute TBI*. Recognition and management of acute TBI with transport to an ED is essential to personal outcomes. Morbidity and mortality increase with hypotension (systolic pressure less than 90 mmHg) and hypoxia (PaO_2 less than 60 mmHg), so fluids are given to support a mean systolic arterial blood pressure at more than 90 mmHg (Hickey, 2013). Assessment of the person's airway, breathing and circulation (ABCs), with management of dysfunction, is necessary to decrease the secondary effects of the brain injury. The fluid of choice for intravenous fluids is hypertonic saline, because it reduces intracranial hypertension. An intracranial pressure monitor probe may be inserted to assess ICP and monitor therapy to reduce cerebral oedema and maintain cerebral perfusion. Osmotic diuretics such as mannitol also may be administered to reduce cerebral oedema. Adequate oxygenation is vital to maintain cerebral metabolism; carbon dioxide is a potent vasodilator, and increased levels may contribute to cerebral oedema and IICP.

On admission to the ICU from the ED, the person may be placed on a special bed and connected to various monitoring devices. Invasive lines are inserted, including a central venous pressure (CVP) catheter, arterial line, pulmonary catheter, ventriculostomy, ICP monitor and, perhaps, a retrograde jugular catheter. In most instances, an endotracheal tube is inserted and connected to a mechanical ventilator, cardiac monitoring is initiated, bilateral sequential calf compressors are applied, pulse oximetry is started and a rectal temperature probe is inserted. All values are monitored for changes to ensure early detection of cerebral hypoxia and impending ischaemia to prevent secondary brain injury.

Diagnosis

Diagnostic testing may be done to monitor haemodynamic status and detect conditions that may contribute to cerebral oedema. Radiological examinations include skull x-rays (to identify skull fractures and assess penetrating objects) and CT scan or MRI to detect contusions and lacerations associated with diffuse axonal injury. ABGs are analysed, with particular attention to oxygen and carbon dioxide levels.

Managing ICP

ICP is managed (as described in a previous section) to re-establish equilibrium of the intracranial contents and prevent secondary brain damage. Treatments include airway management, hyperventilation (used if signs of herniation appear), fluid resuscitation, positioning, temperature regulation and medications. Medications other than those previously discussed include a category of drugs called neuroprotectants. These drugs are used to treat or alter some of the pathological pathways that occur in ischaemia and must be administered within a short time of the injury to be effective. Classifications of the drugs include lipid peroxidase inhibitors, free radical scavengers, receptor antagonists, calcium channel blockers and gangliosides.

Surgery

Small subdural haematomas can frequently be reabsorbed and may be treated conservatively, with close observation and supportive care. However, the treatment of choice for epidural haematomas and large acute subdural haematomas is surgical evacuation of the clot. This can often be

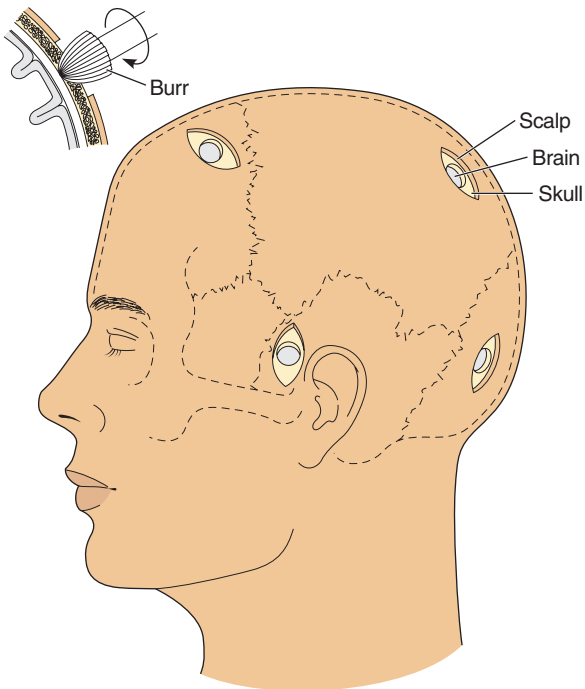

FIGURE 41.7 ■ Possible locations of burr holes

performed through burr holes made into the skull (see Figure 41.7). In an epidural haematoma, the bleeding vessel can also be ligated during this procedure, preventing further bleeding. Rebleeding may occur following evacuation of an acute subdural haematoma in older adults and in people with chronic alcoholism. A craniotomy is necessary to evacuate chronic subdural haematomas because the haematoma tends to solidify, making it difficult or impossible to remove through burr holes. Surgery is less successful in treating intracerebral haematomas because of widespread tissue damage. Supportive care to manage intracranial pressure and prevent complications is provided.

Nursing care

In addition to the nursing care discussed in this section, a nursing care plan for a person with a subdural haematoma follows.

Health promotion

The best way to treat any injury is to prevent it from happening. Public education must continue to stress the importance of safe driving, the dangers of driving under the influence of alcohol or drugs, and the necessity of wearing seat belts and cycle helmets. Legislation changes mandating the use of seat belts, child safety restraints and installation of airbags are all examples of health promotion. Other behaviours that can reduce the morbidity and mortality associated with TBI are following gun safety rules, promoting farm safety and teaching older adults about safety (such as preventing falls) in the home.

Assessment

Collect the following data through the health history and physical examination (see Chapter 40):

- *Health history:* a history of the injury is helpful in understanding the nature of the craniocerebral trauma; knowledge about loss of consciousness assists the nurse in planning care.
- *Physical examination:* neurological assessment, including pupils, LOC, Glasgow Coma Scale, brainstem reflexes (cornea, cough, gag, extraocular movements), vital signs; skull and face (deformity, lacerations, bruising, bleeding); movement of extremities.

Nursing diagnoses and interventions

Nursing care of the person in the acute care phase initially focuses on maintaining an effective airway and breathing pattern. Nursing care is also directed towards continuous assessment and monitoring of neurological function as well as other body systems. This close monitoring provides early recognition and treatment of problems and complications and initiation of aggressive forms of therapy that may be needed.

Many nursing diagnoses associated with traumatic brain injury correspond with those outlined previously in the sections on the person with altered LOC and IICP. Specific nursing diagnoses discussed in this section focus on problems with intracranial adaptive capacity, airway clearance and breathing patterns.

Decreased intracranial adaptive capacity

The person with a traumatic brain injury has or is at high risk of IICP. As the mechanisms that normally compensate for changes in intracranial pressure are compromised, intracranial pressure increases in disproportional response to a variety of stimuli. (See the discussion earlier in the chapter for other nursing diagnoses and interventions for the person with IICP.)

- Monitor for manifestations of IICP, including eye opening response, motor response and verbal response. *These responses evaluate the ability to integrate commands with conscious and involuntary movement.*
- Monitor for changes in vital signs: bradycardia or tachycardia, varying breathing patterns, hypertension, and/or widening pulse pressure. *Vital signs vary depending on the site of impairment. Cushing's triad (bradycardia, increased systolic blood pressure and increased pulse pressure) indicates brainstem ischaemia leading to cerebral herniation.*

NURSING CARE PLAN A person with a subdural haematoma

Wong Lee is a 50-year-old boat mechanic who is married and has three sons. Although Mr Lee has been through rehabilitation twice for alcoholism, he has not been able to quit drinking. His doctor has explained the physical consequences and the possible interaction between alcohol and the anticoagulant Mr Lee is taking for chronic atrial fibrillation. While attending a family reunion, during which he eats a large meal and drinks several beers, Mr Lee joins a game of cricket. Mrs Lee is concerned that Mr Lee has consumed too much alcohol to play cricket in the heat, but Mr Lee is adamant and states that he wants to bowl. During Mr Lee's first over the batter hits a ball that strikes Mr Lee in the head. Mr Lee stumbles and drops to the ground, holding his head. He does not lose consciousness and gets up on his own. His sons and wife try to persuade him to go to the hospital, but Mr Lee insists he feels fine.

Two weeks later, after an evening of consuming several mixed drinks, Mr Lee develops a headache. He attributes the headache to a hangover, but instead of improving the next day, the headache becomes steadily worse. He becomes confused and disoriented. His wife, concerned that his drinking is increasing again, calls the doctor, who admits Mr Lee to the detoxification centre at the local hospital. A CT scan is performed. The diagnosis of a subdural haematoma is made and Mr Lee is transferred to the neurosurgical ward.

ASSESSMENT

When Saundra Knight, the nurse on the neurosurgical ward, enters the room, she notices that Mr Lee is sitting in bed, laughing softly and unable to hold himself upright while sitting in the bed, and is giddy. As she begins to talk to Mr Lee, he states, 'Don't ask me anything—I can't think. My headache is getting worse.' Over the next few hours, the giddiness subsides and Mr Lee becomes drowsy. Ms Knight reports a Glasgow Coma Scale score of 11. An ICP monitor is inserted and reveals increased intracranial pressure. Mr Lee is scheduled to have burr holes and haematoma evacuation that afternoon.

DIAGNOSES

- *Risk of ineffective breathing pattern related to pressure on* the respiratory centre by an intracranial haematoma, evidenced by either an increase or decrease in respiratory rate.
- *Ineffective cerebral tissue perfusion* related to increased intracranial pressure secondary to cerebral oedema, evidenced by a decreased LOC.

PLANNING

Maintain ICP within normal limits through close observation and assessment.

Expected outcomes

- Maintain a respiratory rate and rhythm within normal limits.
- Maintain adequate cerebral perfusion, as evidenced by stable vital signs, stable neurological status and no decrease in level of consciousness.

IMPLEMENTATION

- Perform neurological assessment every 2 hours or as needed.
- Monitor vital signs every 2 hours or as needed.
- Explain to the family the procedure for intracranial surgery.

EVALUATION

The first day postoperatively, Mr Lee begins breathing on his own without ventilatory support. His respiratory rate and rhythm are within normal limits, with no signs of abnormal breath sounds. The ICP monitor readings are appropriate and Mr Lee shows significant improvement in level of consciousness, with a Glasgow Coma Scale score of 15. Mr Lee continues to improve and is discharged home 5 days after surgery.

CRITICAL THINKING IN THE NURSING PROCESS

1. Describe the similarities and differences between Mr Lee's disorder and the manifestations of other types of intracranial haematomas.
2. Mr Lee keeps trying to pull out his ICP line. You know he should not be restrained because pulling against restraints increases restlessness and increases intracranial pressure. What would you do?

REFLECTION ON THE NURSING PROCESS

1. Develop a care plan for the nursing diagnosis of *Acute confusion* related to increased intracranial pressure, evidenced by an altered LOC.
2. Outline what you have learned from this case study that you will apply to your future nursing practice.

- Monitor for vomiting, headache, lethargy, restlessness, purposeless movements and changes in mentation. *These manifestations may be early indicators of intracranial pressure changes.*
- Monitor temperature and initiate hypothermia treatment as prescribed. *Impaired hypothalamic function can interfere with temperature regulation. Hyperthermia may increase ICP.*
- Monitor fluid status: regularly compare intake and output, review serum osmolality and use an infusion pump to administer IV fluids (if prescribed). *Osmotic diuretics, if used to treat cerebral oedema, may cause hypotension and decreased cardiac output.*

CONSIDERATION FOR PRACTICE

Overhydration from rapid infusion of IV fluids may cause or further increase IICP.

Ineffective airway clearance

The primary objective in the care of any trauma person is maintaining a patent airway to prevent hypoxia. However, in the initial acute care phase, the risk of cervical vertebral fractures and spinal cord injury may complicate the process of establishing a patent airway. In addition, other

multisystem injuries may complicate the interpretation of vital signs. In general, all unconscious people with a head injury should be intubated with an endotracheal tube to prevent aspiration. Peoples with head trauma may also require a tracheostomy to provide an airway and may be placed on a ventilator.

- Monitor neurological manifestations on a regular schedule. *Changes in neurological manifestations may indicate IICP, with the risk of further depression of the respiratory system and respiratory arrest.*
- Maintain head and neck in neutral alignment, immobilised until injury is determined. *Head rotation and neck flexion are associated with IICP, decreased jugular venous outflow and localised changes in cerebral blood flow. Immobilisation prevents spinal cord injury in suspected or actual fractures of the cervical spine; spinal cord injury at this level would further impair respiratory function.*
- Clear the nose and mouth of mucus and blood. *This helps maintain patency of the upper airway.*
- Suction the airway as needed, limiting suctioning time to no more than 10 seconds at one time. Do not suction the nasal passages until a dural tear has been ruled out. *Suctioning is usually necessary to maintain a patent airway.*

Ineffective breathing pattern

The person with a traumatic brain injury and haematoma is at high risk *of Ineffective breathing pattern* related to IICP. If ICP increases dramatically, tentorial herniation may occur, leading to sudden respiratory arrest.

- Monitor the respiratory pattern for rate, depth and rhythm every 2 hours or as needed if the person is not on a ventilator. Assess breath sounds, presence of cyanosis, restlessness and use of accessory respiratory muscles. Monitor pulse oximetry and blood gas levels. *Head injuries may cause alterations in respirations. An increased respiratory rate may indicate hypoxia. A decrease in respiratory rate may be the result of depression of the medullary respiratory centre.*
- Monitor ICP readings. *Continuous measurement of ICP is used to diagnose and monitor increased intracranial pressure. As ICP increases, herniation may occur, leading to respiratory arrest and death.*

CONSIDERATION FOR PRACTICE

In general, an initial increase in intracranial pressure causes respirations to slow; as the pressure continues to increase, respirations become rapid.

- If the person is not intubated, prepare for oxygen administration and/or tracheal intubation if respiratory distress occurs. *Supplying oxygen prevents hypoxia until a haematoma can be evacuated, relieving pressure on the respiratory centre.*
- Prepare for cranial surgery if deteriorating respiratory pattern and neurological changes are noted. *Surgical intervention usually consists of placing several burr holes in the skull or performing a craniotomy to remove the haematoma. (Intracranial surgery is discussed later in the chapter.) However, the cerebral oedema and increased intracranial pressure may cause death even if surgery is performed.*

Community-based care

Concussion

Advise the person and their family that a post-concussion syndrome sometimes occurs. If the person experiences persistent headaches and dizziness, is uncharacteristically emotional, seems overly tired or has difficulty paying attention or remembering, the healthcare provider should be notified. Explain that these manifestations may persist for some time. Rehabilitation may help the person compensate for memory impairment and attention deficits.

Acute brain injury

People who survive an acute brain injury will require long-term physical care and rehabilitation. Although recovery is highly individualised, many people who regain consciousness require lifelong care; others remain in a coma or vegetative state. The family often expects the person to recover fully after the coma subsides and they need information about the real possibility of residual deficits in self-care, emotional responses, cognition, communication and movement (see the 'Translation to practice' box below). Topics that should be addressed for home care include:

- The need to encourage self-care and independence as much as possible.
- Information to enhance recovery (Synapse, 2013):
  - Get lots of rest. Don't rush back to work or university.
  - Avoid anything that could cause another blow or jolt to the head.
  - Consult with doctor about when it will be safe to drive a car, ride a bike or use heavy equipment. (Reaction time is often slower after a TBI.)
  - Take only prescribed drugs and don't drink alcohol.
  - Write things down if you are having problems remembering.
  - If the injury was severe, therapy may be needed to learn lost skills, such as speaking, walking or reading.
  - Safety issues.
  - Equipment needs, such as a mobility aids and hospital bed.
  - Vocational counselling and services.
  - Referral to community resources and support groups.

TRANSLATION TO PRACTICE Evidence-based practice: caregivers of young adults with TBI

Traumatic brain injury (TBI) is a leading cause of death and disability across all age groups, but the age group most affected is young adults, especially young men. This is the result of increased risk-taking behaviour in this age group, including drinking alcohol and using drugs while operating a motor vehicle. This population of TBI survivors is large and caring for them is expensive. Most research of TBI survivors has focused on problems of the survivor, but few have examined the burden placed on the family. This is especially true for the experience of the survivors' mothers, who are in almost all cases the primary caregiver. A study was conducted by Kao and Stuifbergen (2004) to describe the meaning of the experience of the relationship between young adult TBI survivors and their mothers. Both the survivors and the mothers were interviewed and the data were analysed to describe the experience. The survivors described having a sense of being abnormal; the mothers struggled with a balance of protecting their children and letting them become independent. The mothers also struggled to maintain relationships inside and outside of the family. All these experiences resulted in ongoing stress for the mothers.

IMPLICATIONS FOR NURSING

The findings of this study have implications for community-based teaching and interventions for TBI survivors and their caregivers. Each year a significant number of TBI survivors leave the acute care setting and return to their homes, where caregivers are often unprepared for the lifelong multiple disabilities and problems they will face.

Developing an appropriate tool to measure family caregiver burden for those with disabilities from TBI is recommended, so as to be able to design and implement individualised interventions and teaching. The teaching and interventions should be developed as part of a systematic and integrated discharge plan, a community-based program and a follow-up approach to assist TBI survivors and their families to effectively decrease the stressors that are a part of caregiver load.

CRITICAL THINKING IN PERSON-CENTRED CARE

1. You are making a home visit to a 22-year-old woman who has recently been discharged from acute care following a serious car crash resulting in mild diffuse axonal injury. She says to you, 'This is my third year of nursing at university. Will I be able to be a nurse?' How would you respond?
2. On discharge from the hospital, a nursing diagnosis for a young adult TBI survivor who would be cared for at home by his single mother was *Risk of parental role conflict related to caring for a child with TBI manifested by lack of independence*. Do you think this is an appropriate diagnosis? Why or why not?
3. If you were to outline topics for a program to reduce the incidence of TBI in a rural community, how would it differ from one for residents of a large urban city?

CENTRAL NERVOUS SYSTEM INFECTIONS

THE PERSON WITH A CENTRAL NERVOUS SYSTEM INFECTION

The central nervous system, including the meninges, neural tissues and blood vessels, may be directly affected by bacteria, viruses, fungi, protozoans and rickettsiae. The CNS may also be affected by toxins from bacterial infections. In general, organisms enter the brain in two ways: through the bloodstream by crossing the blood–brain barrier, or by direct invasion through a skull fracture or bullet hole. Very rarely, a CNS infection occurs as a result of contamination of a surgical field or lumbar puncture. The main CNS infections include meningitis, encephalitis and brain abscesses.

The incidence of pathogenic infections of the CNS increases with the onset of AIDS. People who are HIV positive may have CNS infections caused by toxoplasmosis, cryptococcus, tuberculosis, herpes simplex, cytomegalovirus (CMV) or a polyoma virus (resulting in progressive multifocal leucoencephalopathy).

Pathophysiology

When pathogens enter the CNS and the meninges, an inflammatory process results. The pathology of CNS infections includes the invading pathogens, the subsequent inflammation and the increase in intracranial pressure that may result from the inflammatory processes. Both the pathogenic damage and the IICP may result in brain damage and life-threatening complications.

Meningitis

Meningitis is an inflammation of the pia mater, the arachnoid and the subarachnoid space. Inflammation spreads rapidly throughout the CNS because of the circulation of CSF around the brain and spinal cord. Meningitis may be acute or chronic, and it may be bacterial, viral, fungal or parasitic in origin. Meningococcal meningitis may occur in epidemics among people who are in close contact with one another, such as members of the armed forces and students living in

residential colleges. Pneumococcal meningitis, in contrast, primarily affects the very young and very old.

The organism responsible for meningitis must overcome non-specific and specific host defence mechanisms to invade and replicate in the CSF. These defences include the skin barrier, the blood–brain barrier, the non-specific inflammatory response and the immune response. Host response to the particular pathogen is responsible for the manifestations of clinical meningitis. The organisms that initiate the host response in meningitis demonstrate an affinity for the nervous system. They colonise and invade the nasopharyngeal mucosa, survive intravascularly and penetrate the CNS if the blood–brain barrier is damaged, as can happen during surgery.

Infection of the CSF and meninges causes an inflammatory response in the pia, arachnoid and CSF. Because the meninges and subarachnoid space are continuous around the brain, spinal cord and optic nerves, the infection and inflammatory response are always cerebrospinal, involving both the brain and the spinal cord. Inflamed blood vessels in the area leak fluids as cell permeability increases. Purulent exudate infiltrates cranial nerve sheaths and blocks the choroid plexus and subarachnoid villi. IICP occurs as brain tissue responds to the pathogen. With an increase in ICP, cerebral perfusion decreases and cerebral autoregulation is lost.

BACTERIAL MENINGITIS The causative organisms of bacterial meningitis include *Neisseria meningitis*, meningococcus, *Streptococcus pneumoniae*, *Haemophilus influenzae* and *Escherichia coli*. Risk factors include head trauma with a basal skull fracture, otitis media, mastoiditis, sinusitis, neurosurgery, systemic sepsis or immunocompromise (Grossman & Porth, 2013). Even when appropriate antibiotics are used, the mortality rate for adults remains at approximately 25%.

Once the pathogen enters the central nervous system, it or its toxic products (free radicals) initiate an inflammatory response in the meninges, CSF and ventricles. Meningeal vessels become engorged and their permeability increases. Phagocytic white blood cells migrate into the subarachnoid space, forming a purulent exudate that thickens and clouds the CSF and interferes with its flow. Rapid exudate formation causes further inflammation and oedema of meningeal cells. Blood vessel engorgement, exudate formation, impaired CSF flow and cellular oedema cause the intracranial pressure to increase.

Manifestations The person with bacterial meningitis typically presents with fever and chills, headache, back and abdominal pain, and nausea and vomiting. (The older adult may not have a high fever, but may instead exhibit confusion.) Meningeal irritation causes nuchal rigidity (stiff neck) and positive Brudzinski's sign (flexion of the neck that causes the hip and knee to flex) and positive Kernig's sign (inability to extend the knee while the hip is flexed at a 90-degree angle). Photophobia is present; the person may also experience diplopia. With meningococcal meningitis, a rapidly spreading petechial rash involving the skin and mucous membranes may be noted. The person may also have IICP, manifested by decreased LOC, seizures, changes in vital signs and respiratory pattern, and papilloedema. The manifestations of bacterial meningitis are listed in the box below.

MANIFESTATIONS Bacterial meningitis

- Restlessness, agitation and irritability
- Severe headache
- Signs of meningeal irritation:
  - Nuchal rigidity
  - Positive Brudzinski's sign
  - Positive Kernig's sign
- Chills and high fever
- Confusion, altered LOC
- Photophobia (aversion to light), diplopia
- Seizures
- Signs of increased ICP (widened pulse pressure and bradycardia, respiratory irregularity, decreased LOC, headache and vomiting)
- Petechial rash (in meningococcal meningitis)

Complications Complications of bacterial meningitis include arthritis, cranial nerve damage and hydrocephalus. Cranial nerve VIII, the auditory nerve, is frequently affected, with resulting nerve deafness. Thrombophlebitis may develop in cerebral vessels, with infarction of surrounding tissues (Grossman & Porth, 2013).

VIRAL MENINGITIS Acute viral meningitis, also called *aseptic meningitis*, is a less severe disease than bacterial meningitis. It can be caused by numerous viruses, such as herpes simplex, herpes zoster, Epstein–Barr virus or cytomegalovirus (CMV). Viral meningitis most often appears after a case of mumps. Although viral infection also triggers the inflammatory response, the course of the disease is benign and of short duration. Recovery is uneventful.

Manifestations The manifestations of viral meningitis are similar to those of bacterial meningitis, although usually milder. The person may have a mild flu-like illness prior to the onset of meningitis. Headache is intense and is accompanied by malaise, nausea, vomiting and lethargy. Photophobia may be present. The person generally remains oriented, although possibly drowsy. Temperature is mildly elevated. Neck stiffness, positive Brudzinski's sign and positive Kernig's sign are usually present.

Encephalitis

Encephalitis is an acute inflammation of the parenchyma of the brain or spinal cord. It is almost always caused by a virus, but it may also be caused by bacteria, fungi and other organisms. Other less common causes include ingested lead; post-vaccination encephalitis (from vaccines for measles, mumps and rabies) and HIV (Grossman & Porth, 2013). See Table 41.10 for a list of the most common causes of encephalitis.

VIRAL ENCEPHALITIS Viruses depend on living tissue for reproduction and become highly destructive when they invade brain tissue. The inflammatory response extends over the cerebral cortex, the white matter and the meninges, with

TABLE 41.10 Causes of encephalitis

CAUSE	COMMENTS
Arboviruses	Transmitted by bites from ticks and mosquitoes. Bites from ticks occur more frequently in spring. Bites from mosquitoes occur in middle to late summer. Most common type is the Ross River virus. May destroy major parts of the lobe or hemisphere. 20% of people who develop Murray Valley encephalitis die and 40% develop permanent neurological damage (e.g. seizures, blindness, deafness, speech disorders or mental retardation). Young Indigenous children in Western Australia have significantly poor outcomes. The incubation is 5 to 15 days. Mortality rates associated with arboviruses are higher than those associated with enteroviruses.
Enteroviruses, such as echovirus, coxsackievirus, poliovirus, paramyxovirus (the virus that causes mumps), and varicella zoster (the virus that causes chickenpox)	Infection occurs more frequently in summer (except infection by the mumps virus, which occurs more frequently in early winter). Some degree of protection can be afforded by immunisation against measles, mumps and poliomyelitis. Mortality rates are lower than those associated with herpes simplex type 1 virus.
Herpes simplex type 1 virus	Most common non-epidemic encephalitis in Australia. Can occur any time of year and throughout the world. Has an affinity for the frontal and temporal lobes. Prognosis is grave but not hopeless: mortality rate can be as high as 40% and the person may die within 2 weeks.
Amoebic meningoencephalitis due to infection by *Naegleria* and *Acanthamoeba* protozoa	Both protozoa are found in warm freshwater. Enter the nasal mucosa of people swimming in dams or lakes. May also be found in soil and decaying vegetation. Incidence of infection is increasing.
Exogenous poisoning	May occur after ingestion of lead or arsenic or inhalation of carbon monoxide.

degeneration of the neurons. The pathology of encephalitis includes local necrotising haemorrhage, which ultimately becomes generalised, with prominent oedema. There is progressive degeneration of nerve cell bodies. The inflammatory response in encephalitis does not cause exudate formation as it does in meningitis. Certain viruses show a propensity for specific areas of the brain (e.g. herpes simplex virus involves frontal and temporal lobes). The virus gains access to the CNS via the bloodstream or along peripheral or cranial nerves, or it may already be present in the meninges in the person with meningitis.

The manifestations of viral encephalitis vary, depending on the organism and area of the brain affected. Usual manifestations are similar to those of meningitis, including fever, headache, seizures, stiff neck and altered LOC. The person may be disoriented, agitated and restless, or lethargic and drowsy. As the disease progresses, the LOC deteriorates and the person may become comatose.

ARBOVIRUS ENCEPHALITIS The arboviruses are arthropod (mosquito or tick)-borne agents that infect humans. They include many different types, including dengue, Ross River virus, Barmah Forest virus, Japanese encephalitis, Murray Valley encephalitis and Kunjun. In Australia, adults are most often infected with Ross River virus, with older adults affected more often. The arthropods may live in small mammals and birds or may be carried by horses and deer.

The arthropod-borne agents cause widespread degeneration of nerve cells, and oedema and necrosis—with or without haemorrhage—occur. IICP may develop. Manifestations include fever, malaise, sore throat, nausea and vomiting, stiff neck, tremors, paralysis of extremities, exaggerated deep tendon reflexes, seizures and altered LOC.

Brain abscess

A brain abscess is an infection with a collection of purulent material within the brain tissue. Approximately 80% are found in the cerebrum and 20% are cerebellar.

The causes of a brain abscess include open trauma and neurosurgery; infections of the mastoid, middle ear, nasal cavity or nasal sinuses; metastatic spread from distant foci (such as heart, lungs, skin, abscessed teeth and dirty needles); and arising from other associated areas of infection. The immunocompromised are at increased risk of abscesses. The most common pathogens causing the abscess are streptococci, staphylococci and bacteroids. Yeast and fungi may also cause brain abscess.

A brain abscess results from the presence of microorganisms in the brain tissue. If the abscess is encapsulated, it has the ability to enlarge and, therefore, behave as a space-occupying lesion within the cranium. This predisposes the person not only to the systemic effects of the inflammatory process but also to the serious consequences of increased intracranial pressure. Occasionally, the abscess does not become encapsulated;

instead, it spreads through the brain tissue to the subarachnoid space and ventricular system.

Initially, the person exhibits the general symptoms associated with an acute infectious process, such as chills, fever, malaise and anorexia. Because brain abscess generally forms after infection, the person may consider these signs to be an exacerbation of that illness. The person may experience seizures, altered LOC and manifestations of IICP. As the abscess enlarges, specific symptoms are related to location; for example, the person with a frontal lobe abscess may have contralateral hemiparesis, expressive aphasia, focal seizures and frontal headache.

INTERPROFESSIONAL CARE

Bacterial meningitis is a medical emergency that, if not treated immediately, can be fatal within days. Successful management depends on rapid diagnosis and aggressive treatment with antibiotics and corticosteroids to eradicate the infecting organism and support vital functions. The person may be placed in strict or respiratory isolation until the organism has been identified, depending on hospital policy. Universal precautions apply to CSF as well as blood.

Treatment for viral meningitis focuses on managing symptoms and is supportive. Antipyretics and analgesics may provide relief. Antibiotic therapy is not indicated and isolation precautions are not required.

Treatment of the person with a brain abscess focuses on prompt initiation of antibiotic therapy. Other manifestations are treated symptomatically, as with the person diagnosed with meningitis or encephalitis. If pharmacological management is not effective, the abscess may be drained or, if it is encapsulated, removed.

Diagnosis

The diagnosis of meningitis is based on manifestations and diagnostic test results. Gram stain and culture of the CSF are used to determine if a bacterial infection is present and to determine the specific infectious agent. Counterimmunoelectrophoresis (CIE) is a laboratory test that may be ordered to determine the presence of viruses or protozoa. Polymerase chain reaction techniques may be used to detect viral DNA or RNA in spinal fluid. CT scan will show an area of increased contrast surrounding a low-density core with brain abscess.

Lumbar puncture with examination of the CSF is the definitive diagnostic measure for bacterial meningitis. Data that indicate bacterial meningitis include turbid, cloudy fluid; a markedly increased white blood cell (WBC) count and protein content; and a decreased glucose content. The opening pressure on the lumbar puncture is elevated. In contrast, the person with encephalitis may have a normal CSF analysis and pressure or may have some lymphocytes. The person with a brain abscess will have a markedly elevated pressure with elevated protein content and elevated WBC count. Glucose content is normal. (Because a lumbar puncture in the presence of a space-occupying lesion can result in brain herniation and death, a CT scan is performed first if neurological findings support such a lesion.)

Medications

Immediate intravenous administration of a broad-spectrum antibiotic that crosses the blood–brain barrier into the subarachnoid space is instituted in cases of bacterial meningitis. Once culture reports identify the causative organism, drug therapy is continued from 7 to 21 days, using the most effective drug or drugs specific to that bacterium. The cephalosporin antibiotics are preferred. A major concern in the treatment of CNS infections is penicillin-resistant streptococci. Recommendations for treatment are for a broad-spectrum cephalosporin, such as rifampicin (Rifadin), cefotaxime (Cefotaxime Sandoz) or vancomycin (Vancomycin Sandoz). However, as the bacteria are killed, the toxins they release increase production of inflammatory cytokines, which are potentially lethal. Steroids such as dexamethasone (Decadron) are often given with the antibiotics to suppress inflammation. The CDC recommends that the person remain on isolation for 24 hours after the start of antibiotic therapy.

Treatment for encephalitis consists of administering specific medications and preventing complications. Fungal meningitis is treated with antifungal agents, such as amphotericin-B (Amphotec), flucytosine (Ancontil) and fluconazole (Diflucan). Viral encephalitis is treated with intravenous aciclovir (aciclovir intravenous infusion).

Antibiotic therapy is the primary treatment for brain abscess. A combination of broad-spectrum antibiotics is used if the infecting organism is unknown.

Anticonvulsant medications such as phenytoin (Dilantin) are often prescribed to prevent or control seizure activity. Antipyretic and analgesic medications may provide symptomatic relief; however, analgesics that have a depressant effect on the CNS (such as opiates) are avoided to prevent masking of early manifestations of deteriorating LOC. The person initially may require anti-emetics to control nausea and vomiting. Fluid and electrolyte status is maintained through intravenous fluid replacement until the person is able to resume oral intake.

Surgery

Surgical drainage of an encapsulated abscess may be necessary. The decision to perform surgery is based on the person's general condition, the stage of abscess development and the site of the abscess.

Nursing care

Central nervous system infections are serious illnesses, with potentially life-threatening effects and complications. Nursing assessments and interventions are critical in identifying changes in the person's neurological status and preventing complications from IICP. In addition to the nursing care described in this section, a nursing care plan for a person with bacterial meningitis follows.

Health promotion

As with many other intracranial injuries and disorders, educational activities to promote health by preventing CNS infections are important nursing interventions. The following information should be provided:

- Vaccinations for meningococcal meningitis are recommended or required for members of the armed forces and tertiary students (groups at increased risk of invasive meningococcal meningitis).
- Administration of prophylactic rifampicin (Rifadin) is recommended for people exposed to meningococcal meningitis.
- Mosquito control with repellents, insecticides and protective clothing.
- Destruction of the insect larvae and elimination of breeding places, such as pools of stagnant water.
- Vaccination against Japanese B encephalitis (recommended for summer travellers to rural East Asia).
- Prompt diagnosis and treatment of infections of the head, neck and respiratory system.

Assessment

Collect the following data through the health history and physical examination (see Chapter 40). Further focused assessments are described with nursing interventions below.

NURSING CARE PLAN A person with bacterial meningitis

Monty Cook is a 22-year-old musician who plays in a local rock band. He is unmarried and lives with his parents. He is known by everyone in the community as a quiet, low-key, easygoing person and an excellent guitar player. During a performance 2 days ago at the local pub, he had difficulty playing his guitar, complaining of bright stage lights blazing in his eyes. When he tried to keep his head down to prevent the lights from hurting his eyes, he noticed his neck was very stiff. After the performance, one of the newest members of the band remarked that it certainly was not their best performance. Monty responded angrily that maybe the new members of the group needed more practice. Then he stomped out and went home to bed.

He wakes at 4 am with a severe headache, sweating and chills; his temperature is 38.9°C and he cannot bend his neck without severe pain. His mother recognises that he is agitated and irritable, which is uncharacteristic. Frightened, she rushes him to the hospital emergency room. A lumbar puncture performed in the emergency room reveals turbid, cloudy fluid; a markedly increased WBC count; and protein with a decreased glucose content. Bacterial meningitis is the medical diagnosis. Mr Cook is admitted to the hospital for treatment and care.

ASSESSMENT

When the nurse, Aisha Aldi, enters Mr Cook's isolation room, she sees him thrashing about in the bed, talking incoherently and becoming more agitated. On assessment, Ms Aldi notes dry mucous membranes, cracked lips and small petechiae over the upper torso and abdomen. Mr Cook's temperature is 40°C. Kernig's sign is positive. Intravenous broad-spectrum antibiotics are prescribed and initiated. After the first 2 hours of care, Ms Aldi notes a decrease in Mr Cook's level of consciousness.

DIAGNOSES

- *Hyperthermia* related to infection and abnormal temperature regulation by hypothalamus, evidenced by an increased body temperature.
- *Disturbed thought processes* related to intracranial infection, evidenced by confusion, agitation and uncharacteristic behaviours.
- *Risk of injury* related to progression of illness manifested by increased confusion and agitation.

PLANNING

Monitor the person's condition, provide appropriate nursing care and maintain the person's safety.

Expected outcomes

- Have a decrease in body temperature.
- Become less restless and agitated.
- Remain free of injury.

IMPLEMENTATION

- Monitor vital signs every 2 hours.
- Provide sponge baths if temperature continues to rise.
- Provide a quiet, non-stimulating environment with the shades drawn.
- Provide oral care every 4 hours.
- Measure and compare intake and output every 2 hours.
- Perform neurological assessments every 2 to 4 hours.
- Monitor for and report seizure activity and decreasing level of consciousness.
- Keep bed in low position with side rails elevated.
- Administer prescribed intravenous antibiotics.

EVALUATION

After 4 days of antibiotic therapy, Mr Cook's temperature has returned to near normal. Ms Aldi notes that he has begun opening his eyes and visually tracking her as she moves about the room. Mr Cook responds to a request to squeeze Ms Aldi's fingers and after several hours asks her what had happened. On day 5, Mr Cook states that he feels better and his headache is gone. He asks for sips of juice and begins urinating regularly. Seven days after admission, Mr Cook is discharged and is able to go home with his mother. He has some weakness in his legs, but otherwise has no evidence of neurological deficits.

CRITICAL THINKING IN THE NURSING PROCESS

1. Which strategies should the nurse use to decrease the environmental stimuli for Mr Cook and what is the rationale for doing these?
2. If you were caring for Mr Cook in the initial phase of the illness and he became combative, what would you do?

REFLECTION ON THE NURSING PROCESS

1. Develop a plan of care for the nursing diagnosis of *Acute pain* related to meningitis manifested by headaches. Consider the effect of narcotics on respiratory function in designing the plan.
2. Outline what you have learned from this case study that you will apply to your future nursing practice.

- *Health history:* risk factors (concurrent infections, other illnesses, travel), when manifestations began, severity of manifestations, current nausea and headache, seizures.
- *Physical examination:* Glasgow Coma Scale, level of consciousness, vital signs, motor function, pupillary check, cranial nerves, neck ROM, Brudzinski's sign, Kernig's sign, skin (rash, petechiae, purpura), muscle movement and strength, speech.

Nursing diagnoses and interventions

In planning and implementing nursing care for the person with a CNS infection, the prognosis may depend on the supportive care given. The person is often very ill and the combination of fever, dehydration and cerebral oedema may predispose the person to seizures. Airway obstruction, respiratory arrest or cardiac arrhythmias may occur. Nursing diagnoses and interventions previously discussed for the person with an altered LOC, IICP and seizures are also appropriate for the person with a CNS infection. Nursing interventions in this section focus on *Ineffective protection* and *Risk of fluid volume deficit*.

Ineffective protection

People with CNS infections are less able to protect themselves against insults from both internal and external sources. The effects of the inflammation and resulting pathophysiological processes may include pain, fever, altered LOC, seizures, IICP and cranial nerve dysfunction. In addition, pathophysiological effects on the brain from toxins or thrombosis of a cerebral vessel may lead to permanent neurological deficits, such as loss of motor function or dementia.

- Monitor neurological status on a regular basis. *Many complications are evidenced by changes in neurological manifestations.*
- Monitor vital signs, including temperature, on a regular basis. *The person often has a high temperature throughout the illness, ranging from 38°C to 40.5°C.*
- Monitor levels of consciousness. Assess levels of orientation, memory, attention span and response to stimuli. *Early in the infection, the person often has problems with memory and orientation. There may be problems with following commands, restlessness, irritability and combativeness. As the illness progresses, the LOC decreases to lethargy and finally into deep coma.*

CONSIDERATION FOR PRACTICE

Hyperthermia may result from increased intracranial pressure, while an increased temperature can also increase ICP.

- Monitor for manifestations of seizure activity and institute seizure precautions:
  - Monitor twitching of hands or face and tonic–clonic movements.
  - Have an oral airway and suction equipment readily available.
  - Pad side rails, maintain bed in low position and keep side rails up.

  Irritation of the cerebral cortex secondary to meningeal inflammation may cause seizures. Careful monitoring and seizure precautions are necessary to prevent injury.
- Monitor for manifestations of cranial nerve damage; monitor extraocular movements, facial movement, dizziness, ability to hear, double vision, drooping upper eyelids (ptosis) and pupillary changes. *Cranial nerve dysfunction may result from inflammation or vascular changes in the brain.*
- Monitor for manifestations of increased intracranial pressure: decreased pulse, increased blood pressure, widening pulse pressure, respiratory changes and vomiting. *IICP from infectious or inflammatory exudate, cerebral oedema and hydrocephalus.*
- Administer prescribed medications and maintain prescribed fluid restrictions. *Diuretics are often prescribed to prevent increases in ICP, anticonvulsants are prescribed to prevent or control seizures, and antibiotics are prescribed to eradicate the bacteria. Fluids may be restricted to help prevent IICP.*

Risk of fluid volume deficit

The person is at risk of fluid volume deficit related to increased metabolic rate, diaphoresis and fluid restrictions.

- Monitor for presence or worsening of fluid volume deficit.
- Measure and compare intake and output every 2 to 4 hours.
- Monitor daily body weights.
- Monitor skin turgor.
- Monitor condition of mucous membranes.
- Monitor urine amount, colour and odour.
- Monitor BUN:creatinine ratio.

The elastic property of the skin depends partially on interstitial fluid volume. If there is a fluid volume deficit, skin flattens more slowly after a pinch is released. Mucous membranes are dry. In fluid volume deficit, urine output is decreased, urine is dark in colour and concentrated with a strong odour, and urine specific gravity is greater than 1.020 and BUN will rise out of proportion to serum creatinine.

CONSIDERATION FOR PRACTICE

A weight loss of 0.5 kg represents a fluid loss of approximately 500 mL.

- When administering fluids, either orally or parenterally, consider concurrent illnesses. *People with IICP or kidney failure require complex management.* See Chapter 9 for a further discussion of fluid volume deficit.

Community-based care

The importance of preventive measures, such as recognising predisposing conditions, is a major focus for education. People who have had close contact with the person with meningitis should be monitored for fever, headache or neck stiffness. Some doctors believe that those closest to the person are

candidates for antimicrobial prophylaxis. Also address the following topics:

- the need to report any manifestations of ear infection, sore throat or upper respiratory infection
- the names and purposes of all medications that may be prescribed
- the importance of taking all medication until completely gone, because some people may think it is acceptable to stop the medication as soon as they feel better.

TUMOURS OF THE BRAIN

THE PERSON WITH A BRAIN TUMOUR

Brain tumours are growths within the cranium, including tumours in brain tissue, meninges, the pituitary gland or blood vessels. Brain tumours may be benign or malignant, primary or metastatic, and intracerebral or extracerebral. Regardless of type or location, brain tumours are potentially lethal as they grow within a closed cranial vault and displace or impinge on CNS structures.

Incidence and prevalence

An estimated 1400 new cases of malignant brain tumours are diagnosed annually in Australia and approximately 1200 people die each year (Brain Foundation, 2015). Although brain tumours can occur in any age group, the highest incidence in adults is in those aged 50 to 70. In the adult population, the most common tumour is glioblastoma multiforme, followed by meningioma and cytoma. Glioblastomas represent more than 50% of all primary intracranial lesions.

The cause of many brain tumours is unknown. Although a number of chemical and viral agents can cause brain tumours in laboratory animals, there is no evidence that these agents cause tumours in humans. Other factors associated with brain tumours include heredity, cranial irradiation and exposure to some chemicals (Grossman & Porth, 2013).

Pathophysiology

Brain tumours may be classified as benign or malignant, based on the tissue type and characteristics of the cells. The use of the term *benign* may be misleading. A tumour that is benign by histological examination but is surgically inaccessible may continue to grow and expand, increasing intracranial pressure and causing neurological deficits, herniation and finally death. In discussions of brain tumours, the term *malignant* is used to describe the lack of cell differentiation, the invasive nature of the tumour and its ability to metastasise.

Brain tumours also may be classified as primary or metastatic, depending on their origin (see Table 41.11). Primary tumours of CNS tissue arise from the cells and structures that are found within the brain; for example, neurons and neuroglia. The primary intracranial tumours that originate in the skull cavity but not from brain tissue itself arise from the supporting structures, including the meninges, pituitary gland and pineal gland. Primary brain tumours rarely metastasise outside the CNS. Metastatic brain tumours originate from structures outside the brain, such as the breasts, lungs and prostate gland.

Focal disturbances take place when there is compression of brain tissue and infiltration or direct invasion of brain parenchyma with destruction of neural tissue. As the tumour grows, oedema develops in adjacent tissues. The mechanism is not completely understood, but it is thought that an osmotic gradient causes the tumour to absorb fluid. Some tumours may cause haemorrhage. Venous obstruction and oedema due to breakdown of the blood–brain barrier increase intracranial volume and intracranial pressure. Obstruction of the circulation of CSF from the lateral ventricles to the subarachnoid space causes hydrocephalus.

An estimated 25% of people with cancer develop brain metastasis. Metastatic brain tumours present in the same way as primary brain tumours, with IICP and focal and/or diffuse cerebral dysfunction. The most common source of intracranial metastasis is cancer of the lung. Other common primary sites are the breast, kidney and gastrointestinal tract. The metastasis reaches the brain through the circulation. In most cases, the tumours are multiple and are scattered through the cerebellum and cerebrum.

Manifestations

Multiple manifestations can develop as a result of the growth of the tumour, while others are related to the location of the lesion. Some of the more common manifestations include changes in cognition or consciousness, a headache that is usually worse in the morning, seizures and vomiting. Compression of brain tissue and the invasion of the brain tumour into the cerebral tissue may lead to changes typically seen with cerebral oedema and IICP. Cerebral blood supply may diminish as the tumour compresses blood vessels. Shifts in brain tissue can occur, leading to brain herniation syndromes and, if untreated, death. See the ‘Manifestations’ box below.

INTERPROFESSIONAL CARE

Treatment for a brain tumour may involve chemotherapy, radiation therapy, surgery or any combination of these. Several variables are considered when selecting the appropriate treatment modality: the size and location of the tumour, the type of tumour, related symptoms (such as neurological deficits) and the person’s overall condition.

TABLE 41.11 Classification of brain tumours

TUMOUR TYPE	TUMOUR NAME	CHARACTERISTICS
Primary tumours:		
Intracerebral tumours: Account for 40–50% of all brain tumours Originate from neuroglia and invade brain tissue Most common type of brain tumour	Glioma • Astrocytoma • Glioblastoma multiforme • Ependymoma • Oligodendroglioma • Astroblastoma	 Most common glioma Graded I to IV according to degree of cell differentiation Most malignant form Fast-growing tumour that develops from lining of ventricles Graded I to IV according to degree of cell differentiation Slow growing Rare, slow growing May be encapsulated Benign
Extracerebral tumours: Tumours arising from the supporting structures of the nervous system Account for 10–15% of all brain tumours	Medulloblastoma Meningioma Acoustic neuroma	Fast growing and malignant Occurs primarily in children; can occur in adults Found in cerebellum Slow growing Develops in meninges (especially dura) Firm and encapsulated Slow growing Benign Originates from Schwann cells of the cranial nerve XIII May also affect cranial nerves V, VII, IX and X Also called neurofibromatosis Genetic origin due to autosomal dominant Mendelian trait Firm, encapsulated lesions attached to nerve
Congenital (developmental) tumours: Account for 4–8% of all brain tumours	Haemangioblastoma Craniopharyngioma	Vascular tumour Slow growing Originates from Rathke's pouch Solid or cystic tumour Compresses pituitary gland Presses on the third ventricle and may cause blockage of cerebrospinal fluid (CSF)
Pituitary adenomas: Account for 8–12% of all brain tumours	Chromophobic Eosinophilic Basophilic	Account for 90% of pituitary tumours Non-secreting tumour Slow growing Secreting tumours that produce growth hormone Secreting tumours that produce adrenocorticotropic hormone Fast growing
Secondary tumours		
Metastatic brain tumours: Account for 10% of all brain tumours		Slow-growing tumours that arise from other parts of the body Usually well differentiated from the brain Spread from tumours of the lung, breast, lower gastrointestinal tract, pancreas, kidney, skin

MANIFESTATIONS Brain tumours

FRONTAL LOBE TUMOURS
- Inappropriate behaviour
- Personality changes
- Inability to concentrate
- Impaired judgment
- Recent memory loss
- Headache
- Expressive aphasia
- Motor dysfunctions

PARIETAL LOBE TUMOURS
- Sensory deficits: paraesthesia, loss of two-point discrimination, visual field deficits

TEMPORAL LOBE TUMOURS
- Psychomotor seizures

OCCIPITAL LOBE TUMOURS
- Visual disturbances

CEREBELLUM TUMOURS
- Disturbances in coordination and equilibrium

PITUITARY TUMOURS
- Endocrine dysfunction
- Visual deficits
- Headache

Diagnosis

The following diagnostic tests may be ordered.

- A CT scan or an MRI with gadolinium enhancement can locate the tumour and define its size, shape, extent to which normal anatomy is distorted and the degree of any associated cerebral oedema.
- Arteriography may show stretching or displacement of cerebral vessels by the tumour, as well as the presence of tumour vascularity.
- EEG provides information about cerebral function, may demonstrate focal or diffuse changes, and is useful if seizures are present.
- Endocrine studies are conducted if a pituitary tumour is suspected.

Medications

The choice of drug for treatment is based on the type of tumour, its location and the person's response to therapy. The use of chemotherapy to treat brain tumours is still emerging. An intraventricular method of medication administration uses an Ommaya reservoir that has been surgically implanted into a lateral ventricle of the brain (see Figure 41.8). Other medications that may be prescribed include corticosteroids and anticonvulsants.

Surgery

Surgery is used to remove tumours, to reduce the size of the tumour or for symptom relief (palliation). The type of procedure, the surgical approach and the timing of surgery (emergency versus planned procedure) influence the overall nursing management of the person having intracranial surgery.

Some of the more common intracranial neurosurgical procedures follow:

- *Burr hole:* a hole made in the skull with a special drill. The hole may facilitate the evacuation of an extracerebral clot or a series of holes may be made in preparation for craniotomy (see Figure 41.7).
- *Craniotomy:* a surgical opening into the cranial cavity (see Figure 41.9). For a craniotomy, a series of burr holes are made. The bone between the holes is then cut with a special saw called a craniotome. The tumour is excised and the bone flap is returned to the opening. A craniotomy may also be performed to repair defects associated with traumatic head injuries or to repair a cerebral aneurysm.
- A supratentorial craniotomy refers to surgery above the tentorium. It provides access to the frontal, temporal, parietal and occipital lobes. The incision for this procedure is usually within the hairline over the area involved.
- An infratentorial craniotomy refers to surgery below the tentorium. Access is provided to lesions in the cerebellum and the brainstem. The incision is made at the nape of the neck, around the occipital lobe.
- *Craniectomy:* an excision of a portion of the skull and complete removal of the bone flap. This procedure may be done to provide decompression after cerebral oedema. Pressure on the brain structures is lessened by providing space for expansion.
- *Cranioplasty:* plastic repair to the skull in which synthetic material is inserted to replace the cranial bone that was removed. This procedure may be performed after a large craniectomy. The plastic repair restores the contour and integrity of the cranium.

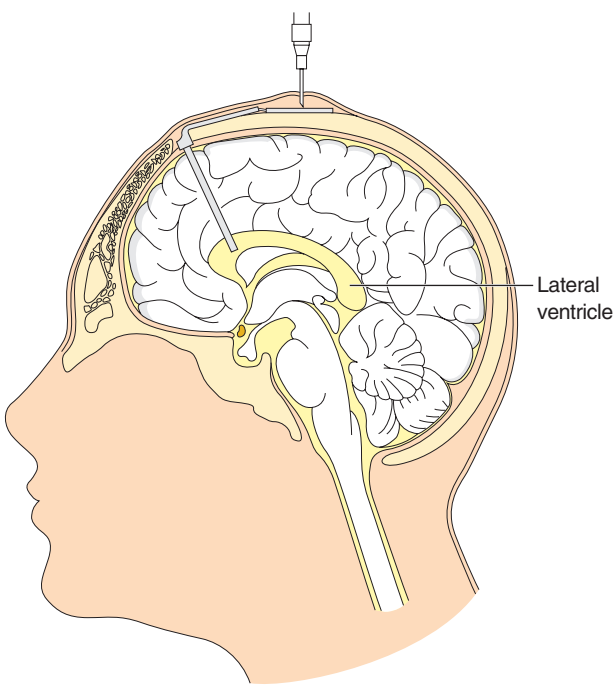

FIGURE 41.8 ■ Ommaya reservoir for medication administration

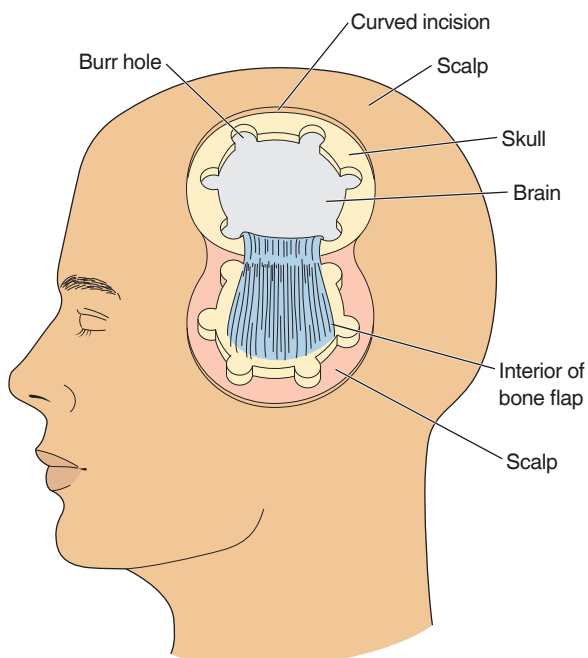

FIGURE 41.9 ■ In a craniotomy, a portion of the skull and overlying scalp is removed to allow access to the brain

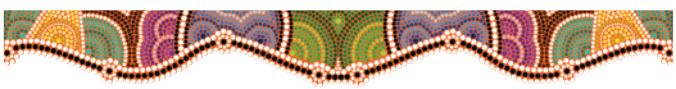
Radiation therapy

Radiation therapy may be administered alone or as adjunctive therapy with surgery. Radiation is often the treatment of choice for surgically inaccessible tumours; it may also be used to decrease the size of a tumour prior to surgery. Tumours that were not completely excised by surgery may also be treated with radiation.

Specialty procedures

Technological advances—including the development of special instruments, the use of stereotaxic techniques for localising a specific target and the use of the laser beam—have greatly advanced neurosurgical practice. Microsurgery involves an operating microscope with microinstruments and supportive illumination equipment. Using stereotaxic techniques to precisely locate a specific target point allows for location of discrete areas of the brain that control specific functions and exact locations of deep brain lesions. The use of a laser beam for excision of a tumour results in less damage to surrounding tissue and less postoperative swelling. The gamma knife, which is not actually a knife but a gamma unit, consists of a heavily shielded helmet containing 201 sources of cobalt-60, which is capable of destroying deep and otherwise inaccessible lesions in a single treatment session. A new area of chemotherapy is that of biodegradable anhydrous wafers, which are impregnated with the chemotherapy drug and implanted into the tumour at the time of surgery. The wafers are made so that they slowly release the drug over a period of many months (Grossman & Porth, 2013).



Nursing care

The nursing care of the person with a brain tumour includes support during the diagnostic period and specific management as directed by the selected treatment. The foundation for care is data from the health history and physical assessment, which includes identifying neurological deficits. This information directs planning and implementing care. Many of the alterations in health commonly experienced by the person with a brain tumour have been discussed throughout this chapter, including altered level of consciousness, increased intracranial pressure and seizures. The person will require intensive care in the immediate postoperative period. In addition to the nursing care described in this section, a nursing care plan for a person with a brain tumour follows.

Nursing diagnoses and interventions

This section of the chapter focuses on nursing interventions for the person who has intracranial surgery. The nursing diagnoses discussed are *Anxiety*, *Risk of infection*, *Ineffective protection*, *Acute pain* and *Low self-esteem*.

Anxiety

The diagnosis of a brain tumour brings anxiety and feelings of uncertainty about the future. Both the person and family members are likely to be apprehensive and require education and emotional support.

- Explain routine medical procedures, including blood work and radiological studies. *Baseline laboratory and radiological studies are needed to ensure that the person has no other pre-existing medical condition. Explaining the procedures and assisting the person through this process help decrease anxiety.*
- Reinforce, clarify and repeat information. *Both the person and their family may have limited understanding of the scheduled diagnostic tests, procedures and treatment modalities. The person may be confused or have altered thought processes as a result of the tumour. Information may need to be repeated or re-explained.*
- Encourage the person and their family to verbalise feelings, questions and fears; provide realistic information appropriate to their level of understanding. *Verbalisation helps reduce anxiety and fear.*
- Review the person and their family's strengths and effective coping skills. *Personal strengths, support systems and coping skills can aid in the development of appropriate strategies to reduce anxiety.*
- Arrange for a member of the clergy to visit if desired. *Faith in a higher being is often a strong source of strength and support.*
- Provide preoperative teaching, including the following information:
  - type of anaesthesia and surgery
  - time surgery will begin and expected length of procedure and recovery room stay
  - where the person will be taken after surgery (ICU) (if possible, show the person and their family the ICU and introduce them to the nurse who will be in charge of care after the surgery)
  - where the family can wait during and following surgery
  - appearance of the person after surgery, which may include swollen, bruised eyelids and other facial features; a large dressing covering the head; a partially or fully shaved head; and a tracheostomy or endotracheal tube
  - behaviour of the person after surgery, which will differ depending on the site of surgery, although cognitive and behavioural changes are common.

  Information about what to expect reduces anxiety.
- Allow time for the person and their family to be together. *People need quiet time together with their families to support each other and prepare emotionally for surgery.*

Risk of infection

The person who has had intracranial surgery is at risk of infection from multiple invasive lines, the scalp wound and the risk of introduction of bacteria into the operative area. The nurse provides interventions to monitor for and prevent infection.

- Monitor for leakage of CSF:
  - presence of glucose in clear drainage from ears, nose or wound
  - complaints of 'something dripping down the back of the throat'
  - constant swallowing.

  These manifestations indicate an opening in the dura, which provides an avenue for an ascending infection.

- Provide interventions to prevent contamination of area leaking CSF:
  - If leaking from the nose: keep head of bed elevated 20 degrees unless contraindicated; do not suction nasally; do not clean nose; tell person not to put finger in nose; do not insert packing.
  - If leaking from the ear: position person on side of leakage unless contraindicated; do not clean ear; tell person not to put finger in ear; do not insert packing.
  - Place a sterile dressing over the area of drainage and change as soon as it becomes damp.

  Leakage of CSF indicates a break in the dura and increases the risk of an ascending infection. Surgery may be necessary to repair the break; however, the leak usually heals spontaneously in about 1 week.
- Monitor for and report manifestations of infection:
  - Take and record temperature on a regular basis.
  - Assess IV insertion sites for redness, swelling, drainage and pain.
  - Assess scalp wound for redness, swelling, bulging, drainage and pain.
  - Assess for manifestations of meningitis: fever and chills, increasing headache, neck stiffness, positive Kernig's or Brudzinski's sign, photophobia.
  - Monitor laboratory reports for increased WBC count.

  Intact skin is the first line of defence against infection. Any break in the skin increases the risk of infection. Intracranial surgery increases the risk of meningitis, with infectious agents ascending into the brain.
- Implement interventions to prevent infection:
  - Use strict aseptic technique when changing dressings and when caring for wound drains and ICP monitor lines.
  - Keep the person's hands away from drains and dressings; use mitten restraints if necessary.
  - Administer prescribed antibiotics.

  Sterile technique decreases the risk of introducing infection into a wound. Antibiotics are usually prescribed prophylactically to prevent infection.

Ineffective protection

The person who has intracranial surgery does not have normal human defences against changes in intracranial pressure and is also at risk from cerebral oedema and a shift of intracerebral contents. In addition, the surgery may cause cerebral bleeding or haematoma formation.

- Monitor for manifestations of increased intracranial pressure:
  - restlessness, agitation and decreasing LOC
  - headache
  - vomiting
  - seizures
  - decreasing sensory and motor function
  - changes in pupil size and reaction
  - changes in vital signs: altered respiratory rate or depth, increasing pulse pressure, decreasing pulse rate, increasing blood pressure
  - abnormal posturing.

  Increasing intracranial pressure is manifested by alterations in the functions and centres controlled by the brain.
- Implement interventions to decrease the risk of IICP:
  - Elevate the head of the bed 15 to 30 degrees as prescribed (unless contraindicated).
  - Avoid neck flexion or rotation; keep head in midline position unless a large bone flap or mass was removed; then position the person on unoperated side to decrease venous congestion in the operative area.
  - Do not take rectal temperatures.
  - Avoid clustering activities that increase intracranial pressure: suctioning, turning and bathing.
  - Administer medications to prevent vomiting.
  - Do not suction for more than 10 seconds at one time.
  - Teach the person (if possible) to avoid coughing, sneezing and straining to have a bowel movement.
  - Maintain fluid restrictions as prescribed.
  - For internal shunts: avoid pressure on the shunt, reservoir or tubing. Pump the shunt only if prescribed.
  - For external shunts: avoid kinks in tubing and maintain the drainage collecting device and the person's head at the prescribed levels.

  Keeping the head of the bed slightly elevated facilitates venous drainage from the brain. Neck flexion or rotation disrupts circulation to and from the brain. Rectal stimulation, suctioning, turning, bathing, coughing, sneezing and straining to have a bowel movement all initiate the Valsalva manoeuvre, which constricts the jugular veins and impairs venous return from the brain. Fluid restriction may be prescribed to dehydrate the person slightly and lessen ICP.
- Maintain (as much as possible) a quiet, calm, softly lighted environment. *Avoid excessive sensory stimulation. These interventions promote rest and decrease stimulation, thereby reducing ICP.*
- Implement interventions to prevent seizures or, if they occur, to prevent injury to the person:
  - Pad side rails of the bed.
  - Place bed in lowest position and keep side rails up.
  - Carry out interventions to prevent and treat IICP.
  - Have an oral airway (Guedel's) and suction equipment immediately available.
  - Administer prescribed anticonvulsants.
  - If a seizure occurs: maintain a patent airway; do not restrain the person; do not force anything into the person's mouth; provide physical and emotional support.

  These interventions promote safety and help prevent injury. Anticonvulsants are often prescribed prophylactically to prevent seizures after intracranial surgery.
- Carefully monitor hydration status. Compare trends in intake and output, laboratory results of serum osmolality and urine specific gravity and osmolality. *Changes in*

NURSING CARE PLAN A person with a brain tumour

Claire Lange is a 44-year-old morning television presenter. During a midweek program, she confuses several major news items so badly that her co-anchor tries to correct her. Ms Lange responds angrily that she does not need any help and then rises and storms off the set. As she leaves the camera area, she limps noticeably and appears to drag her left leg. The show's producer asks her what is wrong; she screams that nothing is wrong—she simply has another headache. He follows her to her dressing room and enquires about her headaches. She tells him that they come and go but have been getting worse lately. He then asks her if she has injured her left leg; she responds that the leg was weak because she was tired. As the producer leaves the dressing room, Ms Lange begins to shake and collapses on the floor. The producer recognises that she is having a seizure and calls for an ambulance.

Ms Lange is admitted to the neurology ward of the local hospital for evaluation. A CT scan, MRI and EEG are completed and identify an intracranial mass. A biopsy of the mass is positive for malignant cells. A glioma in the frontal lobe is identified and surgery is scheduled for that week.

ASSESSMENT

When Clara Rosetti, RN, enters Ms Lange's room, she sees Ms Lange looking at her shoulder-length hair in the mirror. Ms Lange tells Ms Rosetti that she has never in her life worn her hair any shorter and 'Now you're going to cut it all off!' She paces the room and makes the statement, 'I guess the hair isn't really important if I survive this situation.' She also says that she has a headache.

DIAGNOSES

- *Acute pain* related to tumour and increase in intracranial pressure manifested by the onset of headaches.
- *Disturbed body image* related to surgery manifested by anxiety surrounding potential hair loss and appearance postoperatively.
- *Anxiety* related to unknown future following surgery, evidenced by emotional distress.

PLANNING

- Reduce anxiety and fear and manage pain effectively.

Expected outcomes

- Verbalise the causes of pain.
- Verbalise an understanding of the changes in body appearance that are associated with the scheduled intracranial surgery (e.g. shaving of the head prior to surgery, cranial incision and facial swelling postoperatively).
- Identify measures that will help minimise the effect of the hair loss.
- Verbalise a reduction in anxiety.

IMPLEMENTATION

- Assess level of discomfort using a rating scale of 0 to 10.
- Provide a quiet, non-stimulating environment.
- Position the person for comfort, keeping the head of the bed elevated to promote venous drainage.
- Assess level of consciousness for potential increases in ICP.
- Encourage to verbalise feelings about the surgery.
- Suggest measures that may help minimise the hair loss, such as the use of turbans, scarves, hats and wigs.
- Suggest relaxation techniques to decrease anxiety.

EVALUATION

By the time of surgery, Ms Lange has recognised the relationship between the brain tumour and the headache. She states that lying in a flat position and coughing increase the headache. The head of the bed is kept at a 30- to 45-degree angle. Daily activities are spaced to provide periods of rest. Ms Lange demonstrates no significant changes in level of consciousness. She has talked about the effect of the hair loss and her television responsibilities. Ms Lange has learned that the hair preparation would be done in surgery and that the hair would be saved for her. She states she has already consulted her hairdresser and that 'scarves and turbans are on the way'.

CRITICAL THINKING IN THE NURSING PROCESS

1. Outline interventions to decrease intracranial pressure both before and after surgery.
2. When making your initial assessments on the morning of surgery, you find that Ms Lange has a decreased pulse and increased blood pressure. She tells you her headache is worse and suddenly vomits. What do you do now?
3. Ms Lange asks you to be sure that she has absolutely no visitors after surgery because she knows how ugly she will look. How would you respond?

REFLECTION ON THE NURSING PROCESS

1. Which communication and education strategies could you use when caring for people undergoing neurosurgery?
2. Outline what you have learned from this case study that you will apply to your future nursing practice.

fluid balance and osmolality may result from excess intravenous fluids, osmotic diuretics, surgically induced diabetes insipidus or syndrome of inappropriate antidiuretic hormone secretion, fever, diarrhoea, tube feedings or hyperglycaemia.

Acute pain

The person who has intracranial surgery has pain, manifested as a headache, as a result of either compression or displacement of brain tissue or from increased intracranial pressure. A headache may also be a manifestation of meningitis.

- Assess the location, duration and intensity of the pain, using a scale from 0 (no pain) to 10 (worst pain) in the person who can verbally communicate. *The person is the best source of information about pain.*
- Implement interventions to reduce the pain:
  - Raise the head of the bed slightly.
  - Reduce noise and bright lights in the room.

- If allowed, loosen head dressing.
- Administer narcotic analgesics with caution.

Non-pharmacological measures may be used to reduce IICP and headache.

CONSIDERATION FOR PRACTICE

Narcotic analgesics mask changes in eye signs and depress respirations.

Situational low self-esteem

The person who has intracranial surgery has many alterations that affect self-esteem and body image. Physical changes include a loss of hair on the scalp, swelling and bruising in the eyelids and face, and perhaps an indentation in the skull. The person is no longer independent in self-care, but must depend on others to meet basic needs. There are often long-term neurological deficits, affecting areas such as speech, vision and motor abilities, which require changes in roles and relationships.

- Assess for verbal and non-verbal manifestations of negative self-esteem:
  - denial of changes
  - preoccupation with changes
  - refusal to look in the mirror
  - withdrawal from family and friends
  - expressions of grief and loss (see Chapter 4).

  Low self-esteem can be initiated by stressful situations and changes in body image.
- Provide interventions to improve self-concept:
  - Limit negative self-assessment.
  - Help focus on positive areas of life.
  - Help identify sources of support and strength.
  - Help identify and use helpful coping methods.
  - Encourage significant others to visit.
  - Encourage independence in self-care.

  Self-esteem is derived from one's own perceptions of competence and from the responses of others. When one's self-concept and self-ideal are congruent, self-esteem is enhanced.

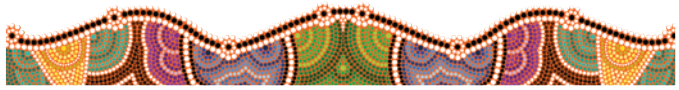
Community-based care

The effect of the possible outcomes following the surgery produces fear in both the person and their family, interfering with their ability to retain information. The person may have cognitive or neurological deficits that interfere with learning. Family members also must be assessed for their ability to cope with the stress of the surgery. Information may have to be repeated several times.

People and their families who have experienced intracranial surgery require emotional support. The process of recovery is often extended and may involve adaptation to changes in body image and management of any motor or sensory deficits. The family should be involved in the care of the person. If family members are willing, they may begin to assist with ADLs while the person is in the hospital, such as assisting with personal hygiene and meals. People should also be encouraged to take an active role in their own care. Discharge planning includes a discussion of the following topics: medication information; wound care; the use of wigs, turbans, hats or colourful scarves; and the importance of follow-up visits. In addition, emphasise the importance of reporting manifestations such as stiff neck, increasing headache, elevated temperature, new motor or sensory deficits, vision changes or seizures.

Provide information about the overall treatment plan, management of deficits and/or disabilities, and future needs. Specific teaching topics are as follows:

- safety measures for motor deficits, sensory deficits, lack of coordination, seizures and cognitive deficits
- comfort measures for nausea, vomiting and pain
- measures for communication if aphasia is present
- measures to improve vision if visual deficits are present
- how to buy wigs and hairpieces
- referrals to support groups and community resources
- helpful resources:
  - Brain Foundation: brainfoundation.org.au
  - Brain Tumour Alliance Australia: www.btaa.org.au
  - Cancer Council Australia: www.cancer.org.au
  - Sydney Neuro-Oncology Group (SNOG): www.snog.org.au.



CHAPTER HIGHLIGHTS

- Altered level of consciousness (LOC) is a common response to intracranial disorders and is an early manifestation of deterioration of the function of the cerebral hemispheres. The alteration in cerebral function occurs in a sequential pattern, with characteristic changes in LOC, respiratory patterns, pupillary and oculomotor responses, and motor function. Coma states include persistent vegetative state and locked-in syndrome.
- Increased intracranial pressure (IICP) is a sustained elevated pressure (≥ 10 mmHg) within the cranial cavity. IICP may result from cerebral oedema, hydrocephalus, head trauma, tumours, abscesses, inflammation, haemorrhage or stroke.
- The manifestations of IICP include a decreasing LOC, abnormal motor weakness and responses, altered vision, altered vital signs, headache, papilloedema and projectile vomiting. If untreated, IICP causes a displacement (herniation) of cerebral tissue, herniation of the cerebellum through the tentorium, followed by herniation of the brainstem through the foramen magnum. This is a lethal complication of IICP because it puts pressure on the vital centres in the medulla. IICP is primarily managed with osmotic diuretics and monitored with continuous intracranial pressure monitors.
- Headaches, a common type of intracranial pain, are categorised as tension, migraine and cluster. A classic migraine is characterised by an aura; a common migraine does not have an aura.
- Epilepsy is a chronic disorder of abnormal, recurring, excessive and self-terminating electrical discharges from neurones. A seizure is a single event of abnormal electrical discharge.

Seizures are categorised into those that affect only a part of the brain (partial seizures) and those that affect all of the brain (generalised). The most common type of seizure in adults is a tonic–clonic generalised seizure. Seizures are treated medically with anti-epileptic drugs (AEDs), surgery, and/or vagal nerve stimulation therapy.

- Traumatic brain injury (TBI) refers to any injury of the scalp, skull or brain and is a leading cause of death and disability. TBIs include skull fractures and focal or diffuse brain injury. An acute brain injury affects all body systems and carries the risk of secondary injury to the brain from hypoxia and ischaemia.
- An epidural haematoma develops in the potential space between the dura and the skull. A subdural haematoma collects between the dura mater and the arachnoid mater. Diffuse brain injuries include contusions, concussions and diffuse axonal injury. People with an acute TBI must have immediate transport and treatment in an ED, followed by care in a critical care unit. They will require long-term physical care and rehabilitation.
- Central nervous system infections may be caused by bacteria, bacterial toxins, viruses, fungi, protozoans and rickettsiae. Organisms may enter the brain through the bloodstream or by direct invasion. The main CNS infections are meningitis, encephalitis and brain abscess. CNS infections are treated with broad-spectrum antibiotics and antifungal agents.
- Brain tumours are growths within the cranium, including on or in brain tissue, the meninges, the pituitary gland or blood vessels. Brain tumours may be benign or malignant, primary or metastatic, and intracerebral or extracerebral. Regardless of the type or location, brain tumours are potentially lethal because they displace or impinge on CNS structures within a closed bony system.

CONCEPT CHECK

1 Which of the following pathophysiological events results in irregular respiratory patterns as LOC decreases?
1. pressure on the meninges
2. reflexive motor responses
3. loss of the oculocephalic reflex
4. brainstem responses to changes in $PaCO_2$

2 The unconscious person has depressed or absent gag and swallowing reflexes. Which nursing diagnosis would be appropriate?
1. *Decreased intracranial adaptive capacity*
2. *Risk of aspiration*
3. *Imbalanced nutrition: less than body requirements*
4. *Ineffective breathing pattern*

3 What is the rationale for the use of osmotic diuretics to treat IICP?
1. Hyperthermia increases the cerebral metabolic rate and exacerbates IICP.
2. Increased blood osmolality draws oedematous fluid into the vascular system.
3. People with IICP are at increased risk of gastrointestinal haemorrhage.
4. Brain injury and IICP often cause seizures.

4 You are monitoring the neurological status of a person in a coma. Which of the following commands would be most accurate in identifying changes in mental status?
1. 'Tell me your name.'
2. 'Look at this light when I shine it in your eyes.'
3. 'Squeeze my hand.'
4. 'Are you having trouble breathing?'

5 On admission to the ED, a person who has altered LOC has a variety of laboratory tests to facilitate the diagnosis of the aetiology of the condition. Which tests would likely be performed? (Select all that apply.)
1. blood glucose
2. serum electrolytes
3. blood and urine toxicology
4. urine for WBCs
5. spinal fluid osmolarity

6 Of the following diagnostic tests, which one is the most accurate indicator of hydration status in the person with altered LOC?
1. FBC
2. urinalysis
3. serum osmolality
4. blood culture

7 Which manifestation is consistently assessed in people with generalised seizures?
1. loss of consciousness
2. repetitive non-purposeful activity
3. tonic movements
4. clonic movements

8 When assessing a person with a head injury, you test fluid dripping from one ear for glucose. What are you assessing for?
1. infection
2. blood
3. CSF
4. serum

9 You are administering an anti-epileptic drug to a person newly diagnosed with seizures. The person says, 'Will this cure my convulsions?' What would you say?
1. 'No, but it will relieve your headache.'
2. 'No, but it will help decrease the aura you experience.'
3. 'No, not for the first year.'
4. 'No, but it may reduce or control them.'

10 Which of the following statements is true of brain tumours?
1. All brain tumours are potentially lethal.
2. Only malignant tumours are lethal.
3. Metastatic brain tumours are benign tumours.
4. Benign brain tumours rarely require treatment.

CHAPTER 42

NURSING CARE OF PEOPLE WITH CEREBROVASCULAR AND SPINAL CORD DISORDERS

DEBRA RAYMOND

KEY TERMS

LEARNING OUTCOMES

- Identify prevalence, incidence and risk factors responsible for disorders of cerebral blood flow and spinal cord structure and function.
- Explain the pathophysiology, manifestations, complications, interprofessional care and nursing care of people with stroke, ruptured intracranial aneurysm, arteriovenous malformation, spinal cord injury, herniated intervertebral disc and spinal cord tumour.
- Compare and contrast the acute treatment and care of the person with a stroke or ruptured intracranial aneurysm and a spinal cord injury.
- Discuss the pathophysiological effects of injuries and tumours of the spinal cord by level of injury.
- Discuss the purposes, nursing implications and health education of the person and family for medications used to treat stroke, ruptured intracranial aneurysm and spinal cord injury.
- Describe the methods used to stabilise and immobilise spinal cord injuries.
- Describe the surgical procedures used to treat cerebrovascular and spinal cord disorders.

CLINICAL COMPETENCIES

- Assess functional status of people with cerebrovascular and spinal cord disorders and monitor, document and report abnormal manifestations.
- Use evidence-based research to promote early recognition and treatment of the warning signs of a stroke.
- Determine priority nursing diagnoses, based on assessed data, to select and implement individualised nursing interventions for people with cerebrovascular and spinal cord disorders.
- Administer oral and injectable medications used to treat cerebrovascular and spinal cord disorders knowledgeably and safely.
- Provide skilled care to people having a carotid endarterectomy, halo fixation and a posterior laminectomy.
- Integrate interprofessional care into the care of people with cerebrovascular and spinal cord disorders.
- Provide appropriate teaching to facilitate self-catheterisation, self-care of a ruptured intervertebral disc and community-based self-care of disabilities resulting from cerebrovascular and spinal cord disorders.
- Revise the plan of care as needed to provide effective interventions to promote, maintain or restore functional health status to people with cerebrovascular and spinal cord disorders.

The health problems discussed in this chapter result from alterations in cerebral blood flow and disorders of the spinal cord. People with disorders of cerebral blood flow and the spinal cord experience a wide variety of neurological deficits that affect cognitive and perceptual functional health patterns. They also require treatment and care for both acute and long-term health problems.

Nursing care for people with these disorders is tailored to meet the needs of the person and is individualised according to the person's responses to alterations in intracranial and spinal cord structure and function. This chapter's discussion of nursing care includes consideration of both acute and long-term healthcare needs. The disabilities and long-term effects resulting from cerebrovascular disorders and spinal cord injuries almost always cause loss and grief, not only in the person but also in the family of the person. Chapter 4 provides information about person responses to loss and nursing interventions to help reduce grieving.

CEREBROVASCULAR DISORDERS

THE PERSON WITH A STROKE

A **stroke** (*cerebral vascular accident* (*CVA*)) is a condition in which neurological deficits result from a sudden decrease in blood flow to a localised area of the brain. Strokes may be *ischaemic* (when blood supply to a part of the brain is suddenly interrupted by a thrombus (blood clot), embolus (foreign matter travelling through the circulation) or stenosis (narrowing)) or *haemorrhagic* (when a blood vessel breaks open, spilling blood into spaces surrounding neurons). The neurological deficits caused by ischaemia and the resultant necrosis of cells in the brain vary according to the area of the brain involved, the size of the affected area and the length of time blood flow is decreased or stopped. A major loss of blood supply to the brain can cause severe disability or death. When the duration of decreased blood flow is short and the anatomical area involved is small, the person may not be aware that damage has been done.

Incidence and prevalence

On average, someone in Australia has a stroke every 10–13 minutes. Stroke is the second leading cause of death in Australia and a major cause of disability: approximately 60 000 people suffer a stroke each year. Of these, many people who survive are left with some type of functional impairment. Although strokes occur in every age group, the highest incidence occurs in people over 75 years of age. Strokes occur more frequently in men than women and Australian men are also more likely to suffer a stroke at a younger age than women (National Stroke Foundation, 2012). Indigenous Australians are almost twice as likely to experience cerebrovascular disease and twice as likely to die as a result than non-Indigenous Australians (Gray, Brown & Thomson, 2012).

Risk factors

Certain diseases and lifestyle habits increase the risk of a stroke, including the following (Australian Institute of Health and Welfare (AIHW), 2006; National Stroke Foundation, 2012):

- *Hypertension*. Hypertension is the greatest risk factor for a stroke. Increased systolic and diastolic blood pressure is associated with damage to all blood vessels, including the cerebral vessels. People with hypertension have a four to six times greater risk of stroke than those without hypertension. Thirty per cent of Australian adults over 25 years of age have hypertension.
- *Heart disease*. Atrial fibrillation increases the risk of stroke five-fold (American Heart Association (AHA), 2009). Other cardiovascular problems that increase the risk of a stroke are mitral valve stenosis, patent foramen ovale and cardiac surgery.
- *Diabetes mellitus*. Diabetes leads to vascular changes in both the systemic and cerebral circulation and increases the risk of hypertension. (The prevalence of hypertension is 40% higher in people with diabetes.) The person with diabetes is three times more likely to have a stroke than those without diabetes. Some 7.6% of Australian adults over the age of 25 years have diabetes.
- *Blood cholesterol levels*. Increased blood cholesterol levels contribute to the risk of atherosclerosis, including arteries in the cerebral circulation. Fifty-one per cent of the Australian population over 25 years have an elevated cholesterol level.
- *Smoking*. Cigarette smoking doubles a person's risk of ischaemic stroke and increases the risk of cerebral haemorrhage by up to 3.5%. Smoking is directly responsible for more strokes in young adults. Seventeen per cent of Australians over the age of 14 years smoke daily.
- *Substance abuse*. The injection of unpurified substances increases the risk of a stroke and abuse of certain drugs can decrease cerebral blood flow and increase the risk of intracranial haemorrhage. Substances associated with strokes include marijuana, anabolic steroids, heroin, amphetamines and cocaine.

FAST FACTS

Estimated cost of stroke in Australia

- Total healthcare cost of stroke was $606 million in 2008–2009.
- The largest portion of the cost is spent on hospital care.
- The total financial cost in 2012 for stroke was estimated to be $5 billion a year.

Sources: AIHW (2008); National Stroke Foundation (2016).

Other risk factors include a family history of stroke, obesity, a sedentary lifestyle, recent viral and bacterial infections, and previous transient ischaemic attacks. Risk factors specific to women are oral contraceptive use, pregnancy, childbirth, menopause, migraine headaches with aura, autoimmune disorders (such as diabetes and lupus) and clotting disorders.

In addition, having a stroke is a major risk factor for having another stroke (called recurrent stroke); about 25% of people who have a stroke and recover have another stroke within 5 years. The risk is highest immediately after a stroke, then decreases with time (American Heart Association (AHA), 2009; National Institute of Neurological Disorders and Stroke (NINDS), 2012a).

Pathophysiology

The brain, which makes up only 2% of total body weight, receives approximately 20% of the cardiac output each minute (about 750 mL) and accounts for 20% of the body's oxygen consumption. Cerebral blood flow, especially in the deep cerebral vessels, is largely self-regulated by the brain to meet metabolic needs. This self-regulation (also called autoregulation) allows the brain to maintain a constant blood flow despite changes in systemic blood pressure. However, autoregulation is not effective when systemic blood pressure falls below 50 mmHg or rises above 160 mmHg. In the latter case, the increased systemic pressure (as in hypertension) causes an increase in cerebral blood flow with resultant over-distension of cerebral vessels. Cerebral blood flow also increases in response to increased carbon dioxide concentrations, increased hydrogen ion concentrations and decreased oxygen concentrations.

When blood flow to and oxygenation of cerebral neurons are decreased or interrupted, pathophysiological changes at the cellular level take place in 4 to 5 minutes. Cellular metabolism ceases as glucose, glycogen and adenosine triphosphate (ATP) are depleted and the sodium–potassium pump fails. Cells swell as sodium draws water into the cell. Cerebral blood vessel walls also swell, further decreasing blood flow. Even if circulation is restored, vasospasm and increased blood viscosity can continue to impede blood flow. Severe or prolonged ischaemia leads to cellular death. A central core of dead or dying cells is surrounded by a band of minimally perfused cells, called the penumbra. Although cells in the penumbra have impaired metabolic activities, their structural integrity is maintained. The survival of these cells depends on a timely return of adequate circulation, the volume of toxic products released by adjacent dying cells, the degree of cerebral oedema and alterations in local blood flow. The potential survival of cells in the penumbra has led to the use of fibrinolytic agents in the early treatment of ischaemic stroke (Porth, 2010).

The neurological deficits that occur as a result of a stroke can often be used to identify its location. Because the motor pathways cross at the junction of the medulla and spinal cord (decussation), strokes lead to loss or impairment of sensorimotor functions on the side of the body opposite the side of the brain that is damaged. This effect, known as a **contralateral deficit**, causes a stroke in the right hemisphere of the brain to be manifested by deficits in the left side of the body (and vice versa).

A stroke is characterised by a gradual or rapid onset of neurological deficits due to compromised cerebral blood flow. Strokes may result from a variety of problems, including cerebral thrombosis, cerebral embolism and cerebral haemorrhage.

Ischaemic stroke

Ischaemic strokes result from blockage and/or stenosis of a cerebral artery decreasing or stopping blood flow and ultimately causing a brain infarction. This type of stroke accounts for about 80% of all strokes (NINDS, 2012a). The blockage may result from a blood clot (either as a thrombus or an embolus) or from stenosis of a vessel resulting from a build up of plaque. Plaque may cause stenosis in large blood vessels (called large vessel disease) or small blood vessels (called small vessel disease). Large vessel disease usually is the result of thrombi. Small vessel strokes, called lacunar infarcts, are small to very small infarcts in the deep, non-cortical areas of the brain or the brainstem. Ischaemic strokes are classified as transient, thrombotic or embolic.

TRANSIENT ISCHAEMIC ATTACK A **transient ischaemic attack (TIA)**, sometimes called a mini-stroke, is a brief period of localised cerebral ischaemia that causes neurological deficits lasting for less than 24 hours (usually less than 1 to 2 hours) (Porth, 2010). The deficits may be present for only minutes or may last for hours. TIAs are often warning signals of an ischaemic thrombotic stroke. One or many TIAs may precede a stroke, with the time between the TIA and a stroke ranging from hours to months. One in five people who have a TIA will have an acute stroke within 3 months (National Stroke Foundation, 2012). The aetiology of TIA includes inflammatory artery disorders, sickle cell anaemia, atherosclerotic changes in cerebral blood vessels, thrombosis and emboli. Neurological manifestations of a TIA vary according to the location and size of the cerebral vessel involved. Manifestations have a sudden onset and often disappear within minutes or hours. Commonly occurring deficits include contralateral numbness or weakness of the leg, hand, forearm and corner of the mouth (due to middle cerebral artery involvement); aphasia (due to ischaemia of the left hemisphere); and visual disturbances such as blurring (due to involvement of the posterior cerebral artery) (Porth, 2010). The person may also experience a visual disturbance called *amaurosis fugax* (a fleeting blindness of one eye, described as a shade coming down over vision in the affected eye).

THROMBOTIC STROKE A thrombotic stroke is caused by occlusion of a large cerebral vessel by a thrombus (blood clot). Thrombotic CVAs most often occur in older people who are resting or sleeping. The blood pressure is lower during sleep, so there is less pressure to push the blood through an already narrowed arterial lumen and ischaemia may result.

Thrombi tend to form in large arteries that bifurcate and have narrowed lumens as a result of deposits of atherosclerotic plaque. The plaque involves the intima of the arteries, causing the internal elastic lamina to become thin and frayed with exposure of underlying connective tissue. This structural change causes platelets to adhere to the rough surface and release the enzyme adenosine

diphosphate. This enzyme initiates the clotting sequence and the thrombus forms. A thrombus may remain in place and continue to enlarge, completely occluding the lumen of the vessel, or a part of it may break off and become an embolus.

The most common locations of thrombi are the internal carotid artery, the vertebral arteries and the junction of the vertebral and basilar arteries. Thrombotic strokes affecting the smaller cerebral vessels are called lacunar strokes, because the infarcted areas slough off, leaving a small cavity or 'lake' in the brain tissue. A thrombotic stroke usually affects only one region of the brain that is supplied by a single cerebral artery.

A thrombotic stroke occurs rapidly but progresses slowly. It often begins with a TIA and continues to worsen over 1 to 2 days; the condition is called a *stroke in evolution*. When maximum neurological deficit has been reached, usually in 3 days, the condition is called a *completed stroke*. At that time, the damaged area of brain tissue is oedematous and necrotic.

EMBOLIC STROKE An embolic stroke occurs when a blood clot or clump of matter travelling through the cerebral blood vessels becomes lodged in a vessel too narrow to permit further movement. The area of the brain supplied by the blocked vessel becomes ischaemic. The most frequent sites of cerebral emboli are at bifurcations of vessels, particularly those of the carotid and middle cerebral arteries. This type of stroke is typically seen in people who are younger than those experiencing thrombotic strokes and occurs when the person is awake and active.

Many embolic strokes originate from a thrombus in the left chambers of the heart, formed during atrial fibrillation. These are referred to as cardiogenic *embolic strokes*. Emboli result when parts of the thrombus break off and are carried through the arterial system to the brain. Cerebral emboli may also be caused by carotid artery atherosclerotic plaque, bacterial endocarditis, recent myocardial infarction, rheumatic heart disease and ventricular aneurysm.

An embolic stroke has a sudden onset and causes immediate deficits. If the embolus breaks down and is absorbed by the body, manifestations will disappear in a few hours to a few days. If the embolus is not absorbed, manifestations will persist. Even if the embolus is absorbed, the vessel wall where the embolus lodges may be weakened, increasing the potential for cerebral haemorrhage.

Haemorrhagic stroke

A **haemorrhagic stroke**, or intracranial haemorrhage, occurs when a cerebral blood vessel ruptures. It occurs most often in people with sustained increase in systolic–diastolic blood pressure. Intracranial haemorrhage usually occurs suddenly, often when the affected person is engaged in some activity. Although hypertension is the most common cause, a variety of factors may contribute to a haemorrhagic stroke, including rupture of a brittle plaque-encrusted artery wall, ruptured intracranial aneurysms, trauma, erosion of blood vessels by tumours, arteriovenous malformations, anticoagulant therapy and blood disorders. Of all forms of stroke, this form is most often fatal and occurs in about 20% of all strokes (NINDS, 2012a). There are two types of haemorrhagic strokes: intracerebral haemorrhage and subarachnoid haemorrhage. Haemorrhagic strokes that result from ruptured cerebral aneurysm or an arteriovenous malformation are discussed in the following sections of the chapter.

As a result of the blood vessel rupture, blood enters the brain tissue, the cerebral ventricles or the subarachnoid space, compressing adjacent tissues and causing blood vessel spasm and cerebral oedema. Blood in the ventricles or subarachnoid space irritates the meninges and brain tissue, causing an inflammatory reaction and impairing absorption and circulation of cerebrospinal fluid (CSF).

The onset of manifestations from a haemorrhagic stroke is rapid. Manifestations depend on the location of the haemorrhage, but may include vomiting, headache, seizures, hemiplegia and loss of consciousness. Pressure on the brain tissue from increased intracranial pressure (discussed in Chapter 41) may cause coma and death.

Manifestations

Manifestations of a stroke vary according to the cerebral artery involved and the area of the brain affected. Manifestations are always sudden in onset, focal and usually one sided. The most common manifestation is weakness involving the face and arm, and sometimes the leg. Other common manifestations are numbness on one side, loss of vision, speech difficulties, a sudden severe headache and difficulties with balance. The various deficits associated with involvement of a specific cerebral artery are collectively referred to as stroke syndromes, although the deficits often overlap, as shown in the box below.

Early warning signs of strokes are shown in Box 42.1.

MANIFESTATIONS Stroke by involved cerebral vessel

INTERNAL CAROTID ARTERY
- Contralateral paralysis of the arm, leg and face
- Contralateral sensory deficits of the arm, leg and face
- If the dominant hemisphere is involved: aphasia
- If the non-dominant hemisphere is involved: apraxia, agnosia, unilateral neglect
- Homonymous hemianopia

MIDDLE CEREBRAL ARTERY
- Drowsiness, stupor, coma
- Contralateral hemiplegia of the arm and face
- Contralateral sensory deficits of the arm and face
- Global aphasia (if dominant hemisphere involved)
- Homonymous hemianopia

ANTERIOR CEREBRAL ARTERY
- Contralateral weakness or paralysis of the foot and leg
- Contralateral sensory loss of the toes, foot and leg
- Loss of ability to make decisions or act voluntarily
- Urinary incontinence

VERTEBRAL ARTERY
- Pain in face, nose or eye
- Numbness and weakness of the face on involved side
- Problems with gait
- Dysphagia

BOX 42.1 Early warning signs of strokes

Making sure the public has a good understanding of early warning signs using the FAST acronym is vital to ensuring rapid treatment of a person suffering a stroke.

- **F**ACE—check their face. Has their mouth drooped?
- **A**RMS—can they lift both arms?
- **S**PEECH—is their speech slurred? Do they understand you?
- **T**IME—time is critical. If you see any of these signs, call 000 or mobile 112 immediately!

Source: National Stroke Foundation (2012).

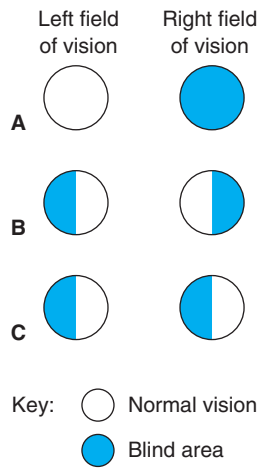

FIGURE 42.1 ■ Abnormal visual fields. *A*, Normal left field of vision with loss of vision in right field. *B*, Loss of vision in temporal half of both fields (bitemporal hemianopia). *C*, Loss of vision in nasal field of right eye and temporal field of left eye (homonymous hemianopia)

Complications

Typical complications include sensoriperceptual deficits, cognitive and behavioural changes, communication disorders, motor deficits and elimination disorders. These may be transient or permanent, depending on the degree of ischaemia and necrosis as well as time of treatment. As a result of the neurological deficits, the person with a stroke has complications that involve many different body systems (see the box below). The disabilities resulting from a stroke often cause serious alterations in functional health status.

Sensoriperceptual deficits

A stroke may involve pathological changes in neurological pathways that alter the ability to integrate, interpret and attend to sensory data. The person may experience deficits in vision, hearing, equilibrium, taste and sense of smell. The ability to perceive vibration, pain, warmth, cold and pressure may be impaired, as may proprioception (the body's sense of its position). The loss of these sensory abilities increases the risk of injury. Deficits may include:

- **hemianopia**—the loss of half of the visual field of one or both eyes; when the same half is missing in each eye, the condition is called *homonymous hemianopia* (see Figure 42.1)
- **agnosia**—the inability to recognise one or more subjects that were previously familiar; agnosia may be visual, tactile or auditory
- **apraxia**—the inability to carry out some motor pattern (e.g. drawing a figure, getting dressed) even when strength and coordination are adequate.

Another form of sensory–perceptual deficit is the **neglect syndrome** (or *unilateral neglect*), in which the person has a disorder of attention. In this syndrome, the person cannot integrate and use perceptions from the affected side of the body or from the environment on the affected side and ignores that part. In severe cases, the person may even deny the paralysis. This deficit is more common following a stroke of the right hemisphere where damage to the parietal lobe (a centre for mediation of directed attention) results in perceptual deficits.

Pain and discomfort may accompany a stroke, with the person experiencing acute pain, numbness or strange sensations. Although not common, damage to the thalamus may cause *central stroke pain* or *central pain syndrome*. The pain in this syndrome includes hot and cold, burning, tingling and sharp stabbing pain, most often in the extremities. It is worsened by movement and temperature changes. The painful sensations are not relieved by pain medications, nor are there any specific treatments.

Cognitive and behavioural changes

A change in consciousness, ranging from mild confusion to coma, is a common manifestation of a stroke. It may result from tissue damage following ischaemia or haemorrhage involving either the carotid or the vertebral arteries. Altered consciousness may also be the result of cerebral oedema or increased intracranial pressure.

Behavioural changes include emotional lability (in which the person may laugh or cry inappropriately), loss of self-control (manifested by behaviour such as swearing or refusing to wear clothing) and decreased tolerance for stress (resulting in anger or depression). Intellectual changes may include memory loss, decreased attention span, poor judgment and an inability to think abstractly.

Communication disorders

Communication is a complex process, involving motor functions, speech, language, memory, reasoning and emotions. Communication disorders are usually the result of a stroke affecting the dominant hemisphere. The left hemisphere is dominant in about 95% of right-handed people and 70% of left-handed people (Porth, 2010).

Many different impairments may occur and most are partial. Disorders of communication affect both speech (the mechanical act of articulating language through the spoken word) and language (the vocal or written formulation of ideas to communicate thoughts and feelings). Language involves oral and

MANIFESTATIONS AND COMPLICATIONS Stroke by body system

INTEGUMENT
- Decubitus (pressure) ulcers

NEUROLOGICAL
- Hyperthermia
- Neglect syndrome
- Seizures
- Agnosias
- Communication deficits
  - a Expressive aphasia
  - b Receptive aphasia
  - c Global aphasia
  - d Agraphia
- Visual deficits
  - a Homonymous hemianopia
  - b Diplopia
  - c Decreased acuity
- Cognitive changes
  - a Memory loss
  - b Short attention span
  - c Distractibility
  - d Poor judgment
  - e Poor problem-solving ability
  - f Disorientation
- Behavioural changes
  - a Emotional lability
  - b Loss of social inhibitions
  - c Fear
  - d Hostility
  - e Anger
  - f Depression
- Increased intracranial pressure
- Alterations in consciousness
- Sensory loss (touch, pain, heat, cold, pressure)

RESPIRATORY
- Respiratory centre damage
- Airway obstruction
- Decreased ability to cough

GASTROINTESTINAL
- Dysphagia
- Constipation
- Stool impaction

GENITOURINARY
- Incontinence
- Frequency
- Urgency
- Urinary retention
- Renal calculi

MUSCULOSKELETAL
- Hemiplegia
- Contractures
- Bony ankylosis
- Disuse atrophy
- Dysarthria

written expression and auditory and reading comprehension. These disorders include:

- aphasia—the inability to use or understand language; aphasia may be expressive, receptive or mixed (global)
- expressive aphasia—a motor speech problem in which one can understand what is being said but can respond verbally only in short phrases; also called *Broca's aphasia*
- receptive aphasia—a sensory speech problem in which one cannot understand the spoken (and often written) word. Speech may be fluent but with inappropriate content; also called *Wernicke's aphasia*
- mixed or global aphasia—language dysfunction in both understanding and expression
- dysarthria—any disturbance in muscular control of speech.

Motor deficits

Body movement results from a complex interaction between the brain, spinal cord and peripheral nerves. The motor areas of the cerebral cortex, the basal ganglia and the cerebellum initiate voluntary movement by sending messages to the spinal cord, which then transmits the messages to the peripheral nerves. A stroke may interrupt the central nervous system (CNS) component of this relay system and produce effects in the contralateral side ranging from mild weakness to severe limitation of any kind of movement.

Depending on the area of the brain involved, strokes may cause weakness, paralysis and/or spasticity. The deficits include:

- **hemiplegia**—paralysis of the left or right half of the body (see Figure 42.2)
- **hemiparesis**—weakness of the left or right half of the body
- flaccidity—absence of muscle tone (hypotonia)
- spasticity—increased muscle tone (hypertonia), usually with some degree of weakness. The flexor muscles are usually more strongly affected in the upper extremities and the extensor muscles are more strongly affected in the lower extremities.

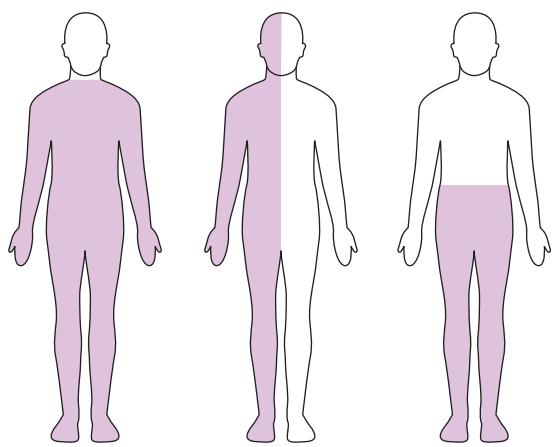

FIGURE 42.2 ■ Types of paralysis. *A*, Quadriplegia is complete or partial paralysis of the upper extremities and complete paralysis of the lower part of the body. *B*, Hemiplegia is paralysis of one half of the body when it is divided along the median sagittal plane. *C*, Paraplegia is paralysis of the lower part of the body

When the corticospinal tract is involved, the affected arm and leg almost always are initially flaccid and then become spastic within 6 to 8 weeks. Spasticity often causes characteristic body positioning: adduction of the shoulder, pronation of the forearm, flexion of the fingers and extension of the hip and knee. There is often foot drop, outward rotation of the leg and dependent oedema in the involved extremities.

The motor deficits may result in altered mobility, further impairing body function. The complications of immobility

involve multiple body systems and include orthostatic hypotension, increased thrombus formation, decreased cardiac output, impaired respiratory function, osteoporosis, formation of renal calculi, contractures and decubitus ulcer formation.

Elimination disorders

Disorders of bladder and bowel elimination are common. A stroke may cause partial loss of the sensations that trigger bladder elimination, resulting in urinary frequency, urgency or incontinence. Control of urination may be altered as a result of cognitive deficits. Changes in bowel elimination are common, resulting from changes in level of consciousness (LOC), immobility and dehydration (Hickey, 2013).

INTERPROFESSIONAL CARE

The type of treatment a person with a stroke receives depends on the stage of the disease. In general, there are three treatment stages: stroke prevention, acute care immediately after a stroke and rehabilitation after a stroke. The person with an acute stroke may receive medical and/or surgical treatment. The focus in the acute care phase is on diagnosing the type and cause of the stroke, supporting cerebral circulation and controlling or preventing further deficits. The goals of stroke care are to minimise brain injury and maximise recovery. In Australia, it is recommended that a person suffering from a stroke is cared for in a specialist stroke unit where possible; these units have been shown to decrease morbidity and mortality rates (AIHW, 2006).

Diagnosis

Diagnosis begins with a complete history and careful physical assessment, including a thorough neurological examination. The time of the onset of stroke manifestations is a critical part of assessment. The National Institute of Health (NIH) Stroke Scale is a clinical evaluation tool widely used to assess neurological outcome and degree of recovery. Part of the Scale is detailed in Table 42.1. The tool measures LOC, vision, facial paralysis, motor abilities, ataxia, sensation, language and attention.

Imaging tests are used to identify an increased risk of a stroke or to identify pathophysiological changes after a stroke has occurred.

Computed tomography (CT) is the first imaging technique used to demonstrate the presence of haemorrhage, tumours, aneurysm, ischaemia, oedema and tissue necrosis. A CT scan can also demonstrate a shift in intracranial contents and is useful in distinguishing the type of stroke (e.g. a haemorrhagic stroke results in an increase in density). Cerebral infarctions usually are visible with a CT scan 6 to 8 hours post stroke; haemorrhage is visible immediately. Other imaging tests that may be used for diagnosis include cerebral arteriogram,

TABLE 42.1 NIH Stroke Scale: assessment of level of consciousness

INSTRUCTIONS	SCALE DEFINITION	SCORE
1a. **Level of consciousness (LOC)**: The investigator must choose a response, even if a full evaluation is prevented by such obstacles as an endotracheal tube, language barrier, orotracheal trauma/bandages. A 3 is scored only if the person makes no movement (other than reflexive posturing) in response to noxious stimulation.	0 = Alert, keenly responsive. 1 = Not alert, but arousable by minor stimulation to obey, answer or respond. 2 = Not alert, requires repeated stimulation to attend or is obtunded and requires strong or painful stimulation to make movements (not stereotyped). 3 = Responds only with reflex motor or autonomic effects or totally unresponsive, flaccid and flexic.	_____
1b. **LOC questions**: The person is asked the month and their age. The answer must be correct. There is no partial credit for being close. Aphasic and stuporous people who do not comprehend the questions will score 2. People unable to speak because of endotracheal intubation, orotracheal trauma, severe dysarthria from any cause, language barrier or any other problem not secondary to aphasia are given a 1. It is important that only the initial answer be graded and that the examiner not 'help' the person with verbal or non-verbal cues.	0 = Answers both questions correctly. 1 = Answers one question correctly. 2 = Answers neither question correctly.	_____
1c. **LOC commands**: The person is asked to open and close the eyes and then to grip and release the non-paretic hand. Substitute another one-step command if the hands cannot be used. Credit is given if an unequivocal attempt is made but not completed due to weakness. If the person does not respond to command, the task should be demonstrated to them (pantomime) and the results scored (i.e. follows none, one or two commands). A person with trauma, amputation or other physical impediments should be given suitable one-step commands. Only the first attempt is scored.	0 = Performs both tasks correctly. 1 = Performs one task correctly. 2 = Performs neither task correctly.	_____

Note: This is a sample of only one part of the NIH Stroke Scale. The entire scale may be viewed as a PDF file at www.ninds.nih.gov/doctors/NIH_Stroke_Scale.pdf.

transcranial Doppler ultrasound, MRI, MRA, PET and SPECT (see the 'Diagnostic tests' box in Chapter 40).

A lumbar puncture may be performed to obtain CSF for examination if there is no danger of increased intracranial pressure (ICP). (Removal of CSF when intracranial pressure is increased can result in herniation of the brainstem.) A thrombotic stroke may elevate CSF pressure; after a haemorrhagic stroke, frank blood may be seen in the CSF.

In addition to imaging tests, a blood test has recently been approved to screen for recurrent stroke risk. The PLAC test scans the blood for high levels of lipoprotein-associated phospholipase A2 (Lp-Pla2), found to be more common in a person who has had a stroke.

Medications

Medications are administered to prevent a stroke in a person with a TIA or a previous stroke and to treat the person during the acute phase of a stroke.

PREVENTION Antiplatelet agents are often used to treat a person with a TIA or who has had a previous stroke. Platelets are concentrated in arteries with a high blood flow where they adhere to endothelial tissue damaged by atherosclerosis and occlude the vessel. The drugs used to prevent clot formation and blood vessel occlusion include aspirin, clopidogrel (Plavix), dipyridamole (Persantine) and ticlopidine hydrochloride (Ticlopidine Hexal).

Daily low-dose aspirin reduces TIA occurrence and stroke risk by interfering with platelet aggregation. Ticlopidine hydrochloride is a platelet-aggregation inhibitor that has shown reduction in thrombotic stroke risk.

ACUTE STROKE Medications are used to treat the person during the acute phase of an ischaemic stroke to prevent further thrombosis formation, increase cerebral blood flow and protect cerebral neurons. The type of medication used varies according to the type of stroke.

Anticoagulant drug therapy (discussed in Chapter 32) is often ordered for an ischaemic stroke. The most commonly used anticoagulants are warfarin (Coumadin), heparin and enoxaparin (Clexane). Anticoagulants are never administered to a person with a haemorrhagic stroke. Anticoagulants do not dissolve an existing clot but prevent further extension of the clot and formation of new clots. Sodium heparin may be given subcutaneously or by continuous IV infusion, or warfarin sodium (Coumadin) may be given orally.

Fibrinolytic therapy, using a tissue plasminogen activator such as recombinant tissue plasminogen activator alteplase (rt-PA, tPA), sometimes given concurrently with an anticoagulant, is used to treat thrombotic stroke. The drug converts plasminogen to plasmin, resulting in fibrinolysis of the clot. To be effective, it must be given intravenously as soon as possible after the onset of manifestations, after confirming (with a CT scan) that the person has had an ischaemic stroke. Within Australia current guidelines state the drug must be given within 4.5 hours of onset of symptoms (National Stroke Foundation, 2010). Antithrombotic drugs, which inhibit the platelet phase of clot formation, have been used as a preventive measure for the person at risk of embolic and thrombotic CVA. Both aspirin and dipyridamole have been used for this purpose. These drugs are sometimes also used in combination with other drugs during acute treatment. Antiplatelet agents are contraindicated in the person with a haemorrhagic stroke.

Management of hypertension is controversial but if the person is eligible for fibrinolytic therapy, blood pressure control is essential to decrease the risk of bleeding. If the blood pressure is sustained at levels 185 mmHg systolic or 110 diastolic, the person cannot be treated with IV tPA (AHA, 2005).

Corticosteroids, such as prednisone or dexamethasone, have been used to treat cerebral oedema, but the results are not always positive. If the person has an increased ICP, hyperosmolar solutions (such as mannitol) or diuretics (such as frusemide) may be administered. Anticonvulsants, such as phenytoin (Dilantin), and barbiturates may be prescribed if increased ICP causes seizures. Increased ICP is discussed in Chapter 41.

Treatments

The treatments used in the management of a stroke include surgery and rehabilitation.

SURGERY Surgery may be performed to prevent the occurrence of a stroke, to restore blood flow when a stroke has already occurred or to repair vascular damage or malformations. A carotid endarterectomy at the carotid artery bifurcation may be performed to remove atherosclerotic plaque in the person who has suffered a TIA (see Figure 42.3). Nursing care for the person in the initial postoperative period following a carotid endarterectomy is described in the following box.

When an occluded or stenotic vessel is not directly accessible, an extracranial–intracranial bypass may be performed. Bypass of the internal carotid, middle cerebral or vertebral arteries may be required. The indications for the bypass are manifestations of ischaemia caused by TIAs or a mild completed stroke. The procedure re-establishes blood flow to the affected area of the brain.

A carotid angioplasty with stenting is a newer option for treating cerebral stenosis. During the procedure an angioplasty balloon catheter is inserted through an artery in the person's arm or leg. Under fluoroscopy, the catheter is advanced to the area of carotid artery stenosis and a small filter is inserted to catch any

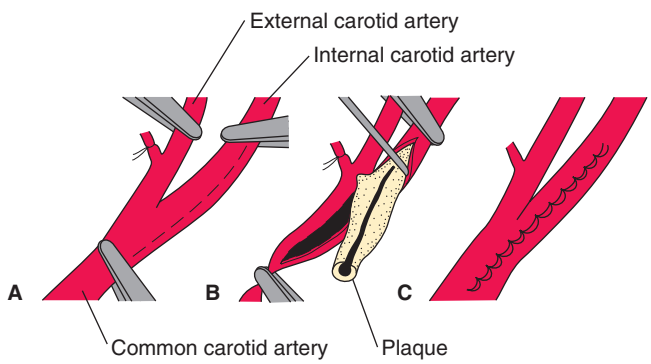

FIGURE 42.3 ■ Carotid endarterectomy. *A*, The occluded area is clamped off and an incision is made in the artery. *B*, Plaque is removed from the inner layer of the artery. *C*, To restore blood flow through the artery, the artery is sutured or a graft is completed

clots or pieces of debris that might break loose. The balloon is then inflated to widen the artery, followed by insertion of a permanent stent in the area of the angioplasty (Palmieri, 2006).

REHABILITATION Various types of therapy are necessary for post-stroke rehabilitation. Listed below are the types and goals of therapies used:

- Physiotherapy may help prevent contractures and improve muscle strength and coordination. Physiotherapists teach exercises to enable the person to relearn how to walk, sit, lie down and change from one type of movement to another.
- Occupational therapy provides assistive devices and a plan for regaining lost motor skills that greatly improve quality of life after a stroke. These skills include eating, drinking, bathing, cooking, reading, writing and toileting.
- Speech therapy is provided to help the person relearn language and communication skills, as well as improve swallowing.

Nursing care

Even though many people who have a stroke have full recovery, a substantial number are left with disabilities that affect their physical, emotional, interpersonal and family status. The required nursing care is often complex and multidimensional, requiring consideration of continuity of care for the person in acute care settings, long-term care settings, rehabilitation centres and the home.

Nurses caring for people who have had a stroke require knowledge and skill to meet their needs during both the acute and the rehabilitative phases of care. The person may have multiple losses: loss of mobility, ability to provide self-care, communications, concept of self and interpersonal or intimate relationships with others. Holistic, individualised nursing care is essential in all settings and focuses on promoting the achievement of maximum potential and quality of life.

The person's family is often faced with many changes. The young to middle-aged adult with a family member who has had a stroke may be faced with economic difficulties and social isolation. The middle-aged adult family member may become the caretaker for an older parent—in essence, switching roles with the parent. An older adult may not be able to care for a spouse and may have to accept residential care placement. In addition, the older adult who has no family may have to struggle alone to regain the ability to function independently. Although not all of these problems are amenable to nursing solutions, the nurse is most often the healthcare provider who assesses and identifies the needs of each individual and provides information and referrals to the person and families to help meet those needs.

Because a stroke has the potential to cause many different health problems, a wide variety of nursing diagnoses may be appropriate. It is important to remember that each person will be affected differently, depending on the degree of ischaemia and the area of the brain involved. Nursing diagnoses discussed in this section focus on problems with cerebral tissue perfusion (specific to nursing care during the acute phase), physical mobility, self-care, communication, sensory–perceptual deficits, bowel and urine elimination, and swallowing (specific to prevention of complications and rehabilitation). A nursing care plan for a person with a stroke is found overleaf.

NURSING CARE OF THE PERSON having a carotid endarterectomy

POSTOPERATIVE CARE

- Position on the unoperated side and either maintain a flat position or elevate the head of the bed 30 degrees as prescribed. Maintain head and neck alignment and avoid rotating, flexing or hyperextending the head. *Pressure on the wound is undesirable. Elevating the head decreases oedema in the operative site. Maintaining head and neck alignment prevents additional tension or pressure on the operative side.*
- Support the head when changing position. Teach to support the head with the hands when able to move about. *Supporting the head helps prevent stress on the operative site (which may cause bleeding and haematoma formation); it also helps reduce stress on the suture line.*
- Perform focused assessments to monitor for complications:
  a. *Haemorrhage*. Assess the dressing and the area under the neck and shoulders for drainage. Assess for increased pulse and decreased blood pressure. *The most common cause of respiratory problems is pressure on the trachea from a haematoma formation.*
  b. *Respiratory distress*. Assess respiratory rate, rhythm, depth and effort. Observe for restlessness. Keep a tracheostomy tray at the bedside. *Respiratory distress may result from oedema and haematoma formation, which may compress the trachea.*
  c. *Cranial nerve impairment*. Observe and record any facial drooping, tongue deviation, hoarseness, dysphagia or loss of facial sensation. *Cranial nerves may be stretched during surgery, leading to temporary deficits in cranial nerve function.*
  d. *Hypertension or hypotension*. Take and record blood pressure at least hourly. Report any changes immediately and implement orders for medications to treat hypertension or hypotension. *About one-half of all people having a carotid endarterectomy develop unstable blood pressure related to surgical denervation of the carotid sinus. Uncontrolled hypertension may precipitate a CVA. The most common problem is hypotension, possibly related to stimulation of the carotid body baroreceptors, which are exposed during surgery. Hypotension may result in myocardial ischaemia.*

Health promotion

Health promotion activities focus on stroke prevention, especially for the person with known risk factors. It is important to discuss, as appropriate, the importance of stopping smoking and drug use with people of all ages. Maintaining a normal weight through diet and exercise can help reduce obesity, which increases the risk of hypertension and type 2 diabetes mellitus. (Both, in turn, increase the risk of a stroke.) Cholesterol levels should be screened regularly to monitor for hyperlipidemia. Regular healthcare to monitor for and treat cardiovascular disorders and to detect and treat infections such as infective endocarditis is important. It is also important to increase public awareness of the signs of a TIA or stroke, and of the need to call 000 or mobile 112, or to seek immediate medical care if the following warning signs or symptoms suddenly occur:

- weakness or numbness of the face, arm or leg, especially on one side of the body
- confusion, difficulty speaking or understanding speech
- trouble walking, dizziness, loss of coordination
- difficulty with vision in one or both eyes
- severe headache without a cause.

Information about public awareness of stroke manifestations and the need for immediate treatment are discussed in the 'Translation to practice' box.

Assessment

The following data is collected through the health history and physical examination (see Chapter 40). Further focused assessments are described with nursing interventions. Gender-specific questions are required to assess risk factors for stroke; risk factors are different for men and women (see box below).

- *Health history:* risk factors, previous stroke, drug use (prescribed, over-the-counter, street drugs), smoking history, when manifestations began, severity of manifestations, presence of incontinence, LOC, family support system.
- *Physical assessment:* LOC, motor strength, coordination, communication, cranial nerves, sensory function.

MEETING INDIVIDUALISED NEEDS

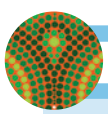
Risk factors for stroke in women

Some risk factors for stroke apply only to women—most specifically pregnancy, childbirth and menopause. These risks are the result of fluctuations in hormones that occur at different stages of life. However, other risks are also more common for women and information should be collected during a health history. For accurate assessment, ask the following questions, depending on the woman's age:

- How many pregnancies have you had?
- Have you had a miscarriage? If so, how many?
- How many births have you had? When was your last delivery?
- When was your last menstrual cycle?
- Do you take any type of hormone replacement therapy?
- Do you take birth control pills?
- Do you have migraine headaches? If so, do you have an aura?
- Have you ever been diagnosed with diabetes or lupus?
- Have you ever been diagnosed with a clotting disorder? Have you ever had a clot in your leg?

Nursing diagnoses and interventions

The acute phase of a stroke is most often the time from admission to the hospital until the person is stabilised, usually 24 to 72 hours after admission (Hickey, 2013). Depending on the severity of the stroke, the person may be admitted to the intensive care unit. Regardless of the hospital setting, the nurse provides interventions to maintain body functions and prevent complications.



TRANSLATIONTO PRACTICE Evidence-based practice: improved rapid treatment of a stroke

Stroke is the second leading cause of death in Australia and is also a leading cause of severe, long-term disability (National Stroke Foundation, 2012). The risk of disability and death can be reduced in people who experience a sudden ischaemic stroke by the administration of tissue plasminogen activator (tPA). To be effective, tPA must be administered within 4.5 hours of the warning signs of a stoke, but the public's awareness of stroke manifestations and of the need for immediate treatment remains poor. In Australia, 39% of people presenting to hospital with a stroke arrive within 3 hours; however, only 3% of all ischaemic stroke victims receive thrombolytic therapy (National Stroke Foundation, 2010). Further emphasis on achieving higher rates of thrombolytic treatment is required to improve morbidity and mortality rates.

IMPLICATIONS FOR NURSING

Nurses provide information to the public in a wide variety of health promotion activities, including stroke awareness and the need for immediate treatment to ensure the best outcomes of care. It is important that the programs be geared towards the specific population most at risk and target people from all socioeconomic and cultural backgrounds. Although not measured in this study, factors that affect behaviour, such as perceived risk, benefits and barriers of care, readiness to change and self-efficacy, are areas that may be effective in designing educational programs to increase stroke awareness.

CRITICAL THINKING IN PERSON CARE

1. If you were planning a stroke awareness education program, where would you implement it in order to reach the largest population? How would you advertise stroke warning signs to reach the most people?
2. Think of a slogan for the public that increases awareness of the 4.5-hour time limit for treatment with tPA.

Ineffective tissue perfusion: cerebral

The initial assessment and care of the person admitted for intensive care focuses on identifying changes that may indicate altered cerebral perfusion. The person's airway, breathing, circulation and neurological status are monitored, and interventions are provided to maintain cerebral perfusion.

- Monitor respiratory status and airway patency. Auscultate pulmonary sounds and monitor respiratory rate and results of arterial blood gas studies.
- Suction as necessary, using care to suction no longer than 10 seconds at any one time and using sterile technique.
- Place in a side-lying position.
- Administer oxygen as prescribed.
  The person is often unconscious and breathing may be impaired. Suctioning removes secretions that not only obstruct airflow but also pose a risk of aspiration and pneumonia. Suctioning for longer than 10 seconds at a time may increase intracranial pressure (Hickey, 2013). Respiratory complications develop rapidly, as manifested by crackles and wheezes, rapid respirations and respiratory acidosis. The administration of oxygen decreases the risk of hypoxia and hypercapnia, which can increase cerebral ischaemia and intracranial pressure.

CONSIDERATION FOR PRACTICE

Positioning the person on the side allows secretions to drain out of the mouth, helping to prevent aspiration.

- Monitor mental status and LOC (Glasgow Coma Scale): restlessness, drowsiness, lethargy, inability to follow commands, unresponsiveness.
- Monitor strength and reflexes and assess for pain, headache, decreased muscle strength, sluggish pupillary reflexes, absent gag or swallowing reflexes, hemiplegia, Babinski's sign and decerebrate or decorticate posturing.
  Frequent monitoring of neurological status is necessary to detect changes. Alterations in mental status, LOC, movement, strength and reflexes indicate increased intracranial pressure, the main cause of death in the acute phase of a stroke.
- Continuously monitor cardiac status, observing for arrhythmias. *A stroke may cause cardiac arrhythmias, including bradycardia, PVCs (premature ventricular contractions), tachycardia and AV block. Characteristic ECG changes include a shortened PR interval, peaked T waves and a depressed ST segment.*
- Monitor body temperature. *Hyperthermia may develop if the hypothalamus is affected.*
- Maintain accurate intake and output records; measure urinary output via a Foley catheter. *A stroke may damage the pituitary gland, resulting in diabetes insipidus and the possibility of dehydration from greatly increased urinary output.*

CONSIDERATION FOR PRACTICE

Diabetes insipidus is indicated by a large output of dilute urine; dehydration is indicated by scanty amounts of dark, concentrated urine.

- Monitor for seizures. Pad the side rails and administer prescribed anticonvulsants. *Seizures may be the result of cerebral tissue damage or increased intracranial pressure. Padded side rails prevent injury if a seizure occurs. Anticonvulsants prevent or treat seizures.*

Impaired physical mobility

The goals of care for the person with impaired mobility are to maintain and improve functional abilities (by maintaining normal function and alignment, preventing oedema of extremities and reducing spasticity) and to prevent complications.

- Encourage active range-of-motion (ROM) exercises for unaffected extremities and perform passive ROM exercises for affected extremities every 4 hours during day and evening shifts, and once during the night shift. Support the joint during passive ROM exercises. *Active ROM exercises maintain or improve muscle strength and endurance and help to maintain cardiopulmonary function. Passive ROM exercises do not strengthen muscles but do help maintain joint flexibility.*

CONSIDERATION FOR PRACTICE

Both active and passive exercises increase venous return, decreasing the risk of thrombophlebitis.

- Turn every 2 hours around the clock, following a posted schedule for side-to-side and supine-to-prone position changes. (Verify prone positioning with the doctor.) Maintain body alignment and support extremities in proper position with pillows. *Turning on a regular basis, accompanied by proper positioning, maintains joint function, alleviates pressure on bony prominences that can lead to skin breakdown, decreases dependent oedema in hands and feet, and lessens the risk of complications resulting from immobility (see Figure 42.4).*

CONSIDERATION FOR PRACTICE

When lying on the affected side, the person may be restless because they do not have normal sensation and feel as if they may fall.

- Monitor the lower extremities each shift for symptoms of thrombophlebitis. Assess for increased warmth and redness in calves; measure the circumference of the calves and thighs. *People on bed rest (especially those with loss of muscle strength and tone) are particularly prone to the development of deep venous thrombosis. Promptly report manifestations of thrombophlebitis.*
- Collaborate with the physiotherapist as the person gains mobility, using consistent techniques to move the person from the bed to the wheelchair and to help the person ambulate. *The use of consistent techniques facilitates rehabilitation.*

Self-care deficit

The person who has had a stroke may have a self-care deficit as a result of impaired mobility or mental confusion. It is important for the person to perform as many of their own

NURSING CARE PLAN A person with a stroke

Phillip Boren is a 63-year-old male who had a stroke due to right cerebral thrombosis 1 week ago. He is a history teacher at the local high school. His hobbies are wood carving and gardening. For the past 2 years, Mr Boren has been taking medication for hypertension, but his wife Emily reports that he often forgets to take it and that his blood pressure was high at his last physical examination. Mrs Boren tells the staff that she has never had to worry about her husband's health before and that she wants to learn everything she can to care for him at home. However, she says that her husband was always the one to make the decisions and pay the bills. Mrs Boren adds that all the children, grandchildren and neighbours want to see Mr Boren back at home as soon as possible.

ASSESSMENT

Carol Merck, RN, the nurse assigned to Mr Boren, completes a health history and physical assessment, with Mrs Boren providing information for the history. Mrs Boren reports that her husband did have several spells of dizziness and blurred vision the week before his stroke, but they lasted only a few minutes and he believed them to be due to 'old age and working out in the sun'. On the morning of admission, Mr Boren woke up and could not move his left arm or leg; he also could not speak sensibly. Mrs Boren called 000 and an ambulance took her husband to the hospital.

Physical assessment findings include the following: Mr Boren is drowsy but responds to verbal stimuli. Although he does not respond verbally, he can nod his head to indicate 'yes' when asked questions. Flaccid paralysis is present in his left arm and left leg, with no response noted to touch in those extremities. (He is left handed.) Visual fields are decreased in a pattern consistent with homonymous hemianopia. A CT scan, negative on admission, is repeated on the day after admission and confirms the medical diagnosis of a right-brain stroke due to a thrombus of the middle cerebral artery.

Mr Boren's medical treatment includes heparin sodium administered by continuous intravenous drip, with clotting studies to be performed every 4 hours and the dose adjusted accordingly.

DIAGNOSES

- *Risk of feeding self-care deficit* related to loss of the ability to use the left hand and arm and manifested by a failure to feed self.
- *Risk of impaired physical mobility* related to neurological deficits causing left hemiplegia and manifested by difficulty mobilising.
- *Risk of impaired skin integrity* related to inability to change position and manifested by the development of pressure area sores.
- *Risk of disturbed visual sensory perception* related to changes in visual fields and manifested by difficulty in performing activities of daily living (ADLs).
- *Risk of impaired verbal communication* related to cerebral injury and manifested by slurred or incoherent speech.

PLANNING

- Arrange mealtimes so that Mr Boren is sitting up by the window in a clean and private environment.
- Encourage Mrs Boren to visit at mealtimes, to assist with meals and periodically to bring a favourite food from home.
- Establish and maintain a regular schedule for turning when Mr Boren is in bed.
- Ensure marker and paper are available for alternative communication.

Expected outcomes

- Learn to use his right hand to feed himself.
- Participate in exercises necessary to maintain muscle strength and tone.
- Maintain skin integrity.
- Indicate understanding that visual fields may improve in a few weeks.
- Practise and implement speech therapy activities while at the same time using alternative methods of communication.

IMPLEMENTATION

- Provide adaptive devices (silverware with thick handles and non-slip plates).
- Provide passive ROM exercises for his left arm and leg; schedule active ROM exercises for his right extremities, as well as quadriceps and gluteal sets every 4 hours during waking hours.
- Keep his skin clean and dry at all times.
- Place objects (e.g. call bell, tissues) on unaffected side and approach him from that side.
- Support attempts to communicate verbally; when he is not understood, he may prefer to use a large marker and tablet.

EVALUATION

Mr Boren is discharged to his home after being in the hospital for 10 days. During the first 2 months after discharge, Martha Grimes, RN, the community health nurse, visits Mr and Mrs Boren at home. At the end of 2 months, Mr Boren is using his right hand to feed himself. He has regained partial use of his left arm and leg, and is using a walker to move around the house and yard; he is even able to work in his flower garden. His skin has remained intact and his vision is back to normal. He is slowly relearning speech; this has been the most difficult change for him to accept.

CRITICAL THINKING IN THE NURSING PROCESS

1. Hypertension is sometimes referred to as 'the silent killer'. Provide justifications for this statement.
2. What would be your reply if, after you had completed passive ROM on Mr Boren's left arm, he wrote: 'I just ignore that part of my body—it doesn't work anyway.'?
3. Which communication and education strategies would you implement to assist Mr Boren and his family?

REFLECTION ON THE NURSING PROCESS

1. Reflecting on your experience with people who have suffered a stroke, which allied team members should become involved in Mr Boren's care? Why?
2. What information could you provide to Mr Boren's wife to assist her when Mr Boren is discharged home?

FIGURE 42.4 ■ Positioning the person with hemiplegia is important in preventing deformity of the affected extremities. *A*, With the person in a supine position, place a pillow in the axilla (to prevent adduction) and under the hand and arm, with the hand higher than the elbow (to prevent flexion and oedema). *B*, When the person is lying supine, use a pillow from the iliac crest to the middle of the thigh to prevent external rotation of the hip. *C*, When the person is in the prone position, place a pillow under the pelvis to promote hip hyperextension

ADLs as possible to promote functional ability, increase independence, decrease feelings of powerlessness and improve self-esteem.

Before establishing a plan to increase self-care, determine which hand was dominant before the stroke. If the person's dominant side is affected, self-care will be more difficult.

- Encourage use of the unaffected arm to bathe, brush teeth, comb hair, dress and eat. *Use of the unaffected arm promotes functional ability and independence.*
- Teach the person to put on clothing by first dressing the affected extremities and then dressing the unaffected extremities. *This technique facilitates self-dressing with minimal assistance.*
- Collaborate with the occupational therapist in scheduling times for training for upper extremity functioning necessary for ADLs. Encourage the use of assistive devices (if required) for eating, physical hygiene and dressing. *Following a regular schedule in daily routines promotes learning. The use of assistive devices promotes independence and decreases feelings of powerlessness. Optimal grooming facilitates positive self-concept.*

Impaired verbal communication

The person who loses communication abilities requires intensive speech therapy and emotional support. It is important to determine the specific nature of the impairment when planning interventions and helping family members understand specific problems. Although the speech therapist is usually most involved with speech rehabilitation, nurses must plan interventions to meet communication needs during all phases of care.

Use the following guidelines:

- Approach and treat the person as an adult.
- Do not assume that the person who does not respond verbally cannot hear. Do not use a raised voice when addressing the person.
- Allow adequate time for the person to respond.
- Face the person and speak slowly.
- When you do not understand the person's speech, be honest and say so.
- Use short, simple statements and questions. *Accepting the person and providing dignity and respect enhances the nurse–person relationship. Allowing adequate response time and using short verbal statements or questions while facing the person motivates the person to communicate and decreases frustration.*
- Accept frustration and anger as a normal reaction to the loss of function. *Anger represents the person's frustration at the inability to control the loss of function.*
- Try alternative methods of communication, including writing tablets, flash cards and computerised talking boards. *The person who is unable to communicate verbally may use other methods effectively.*

Risk of impaired urinary elimination and constipation

Both urinary and bowel elimination may be altered because of neurological deficits, impaired mobility, cognitive impairment, communication deficits or pre-existing problems (especially if the person is an older adult). Other causes include changes in food and fluid intake and side effects of medications. Urinary incontinence or retention, and constipation and faecal impaction are the usual manifestations.

- Assess for urinary frequency, urgency, incontinence, nocturia and voiding in small amounts. In addition, assess the person's ability to respond to the need to void, to use the call light and to use toileting equipment.

CONSIDERATION FOR PRACTICE

Voiding small amounts of urine frequently may be a manifestation of a bladder dysfunction. Assess for a distended bladder.

- Encourage bladder training by having the person void on schedule, such as every 2 hours, rather than in response to the urge to void.
- Educate the person about Kegel exercises. To perform Kegel exercises, the person contracts the perineal muscles as though stopping urination, holds the contraction for 5 seconds and then releases.
- Use positive reinforcement (verbal praise) for successful management of urinary elimination.
  Voiding every 2 hours or on schedule promotes bladder tone and urine storage. Kegel exercises increase pubococcygeal muscle tone and bladder control, decreasing incontinence. Positive reinforcement can be a useful part of the teaching program.
- Discuss pre-stroke bowel habits, as well as the pattern of bowel elimination since the stroke.
- If the person is able to swallow without difficulty, encourage fluids (up to 2000 mL per day) and a high-fibre diet.
- Increase physical activity as tolerated.
- Assist in using the toilet facilities at the same time each day (based on usual patterns of bowel elimination), ensuring privacy and having the person sit in an upright position if at all possible.
- Administer prescribed stool softeners if the person is following a bowel elimination routine or is not drinking sufficient fluids.
  Increased fluids, fibre and activity stimulate intestinal motility. Establishing a regular daily time for bowel movements in the upright position and in privacy promotes normal bowel elimination. Stool softeners help prevent the formation of hard stool that is more difficult to expel.

Impaired swallowing

A stroke may impair the ability to swallow. Weakness or lack of coordination of the tongue, attention deficits and deficits involving the swallowing reflex all play a role. Dysphagia (difficulty swallowing) may result in choking, drooling, aspiration or regurgitation. Nursing care focuses on maintaining safety by preventing aspiration and on ensuring adequate nutrition.

- Monitor results of swallowing studies prior to providing oral food and fluids. The speech therapist should be consulted to access the person for the most appropriate diet.
- Ensure safety when eating:
  - Position in upright sitting position with neck slightly flexed.
  - Order puréed or soft food. Liquids should be of the same consistency as honey.
  - Feed or teach the person to eat by putting food behind the front teeth on the unaffected side of mouth and tilting the head slightly backwards. Teach to swallow one bite at a time.
  - Assess for coughing with eating or drinking. *Coughing may be indicative of dysphagia.*

CONSIDERATION FOR PRACTICE

After eating, check the mouth for 'pocketing' of food, especially in the affected cheek.

- Have suction equipment available at the bedside in case of choking or aspiration.
  Sitting upright with the head and neck first slightly flexed and then tilted back helps the person swallow. The person can usually swallow puréed or soft foods more easily than liquid or solid foods. Using the unaffected side of the mouth helps prevent food from collecting in the mouth and makes swallowing safer; in addition, food is less likely to fall out of the mouth.
- Monitor lung sounds. *Coarse lung sounds heard in the right upper and/or lower lobes may indicate aspiration as the right bronchus is the first division of the bronchi and where the majority of aspirations occur.*
- Minimise distractions and, if necessary, give step-by-step instructions for eating. *Distractions increase the risk of aspiration. Complex activities are easier to perform when broken down into small steps.*

Community-based care

Throughout the rehabilitation process, it is important to encourage self-care as much as possible but also to involve family members in the plan of care. Stress that ADLs may take twice as long as they did before the stroke. Emphasise that physical function may continue to improve for up to 3 months and speech may continue to improve for even longer. Address the following topics in preparing the person and family for community-based care:

- physical care, medications, physiotherapy, occupational therapy, speech therapy
- realistic expectations
- time off for the caregiver; respite care services
- distributors for equipment and supplies
- home environment conducive to using equipment (e.g. a wheelchair or walker)
- home and equipment modifications (e.g. a raised toilet seat, grab bars in the bathroom, a bath chair, a vise lid opener, a long-handled shoehorn)
- home health services
- community resources, such as Meals on Wheels, senior centres, elder care, large-print telephone buttons, stroke clubs, VitalCall (emergency alerting systems through a local hospital

or agency). Financial assistance may be available within the community for housekeeping and personal care assistance

THE PERSON WITH AN INTRACRANIAL ANEURYSM

An **intracranial aneurysm** is a saccular outpouching of a cerebral artery that occurs at the site of a weakness in the vessel wall. The weakness may be the result of atherosclerosis, a congenital defect, trauma to the head, ageing or hypertension. A ruptured cerebral aneurysm is the most common cause of a haemorrhagic stroke.

Incidence and prevalence

Studies suggest the average prevalence of intracranial aneurysms is around 2% of the population; most go through life without any manifestations of bleeding. However, it is estimated that 50–80% of these will never rupture (Brain Aneurysm Foundation, 2011). Intracranial aneurysms are most common in adults aged 30 to 60 (Hickey, 2013).

The exact aetiology is unknown, but theories of cause include: (1) a developmental defect in the vessel wall; and (2) degeneration or fragility of the vessel wall due to conditions such as hypertension, atherosclerosis, connective tissue disease or abnormal blood flow. Hypertension and cigarette smoking may be contributing factors.

Pathophysiology

Intracranial aneurysms tend to occur at the bifurcations and branches of the carotid arteries, and the vertebrobasilar arteries at the circle of Willis, with most aneurysms (85%) located anteriorly. They range in size from smaller than 15 mm to larger than 50 mm. Intracranial aneurysms tend to enlarge with time, making the vessel wall thin and increasing the probability of rupture.

There are several different types of intracranial aneurysms. A *berry aneurysm* is probably the result of a congenital abnormality of the tunica media of the artery. The aneurysm usually ruptures without warning. A *saccular aneurysm* is any aneurysm with a saccular outpouching which distends only a small portion of the vessel wall. This type of aneurysm is often caused by trauma. In a *fusiform aneurysm*, the entire circumference of a blood vessel swells to form an elongated tube. Most aneurysms of this type occur as a result of the changes of arteriosclerosis. Fusiform aneurysms act as space-occupying lesions. In a *dissecting aneurysm*, the tunica intima pulls away from the tunica media of the artery and blood is forced between the two layers. It may result from atherosclerosis, inflammation or trauma. *Mycotic aneurysms* are caused by emboli from infections such as bacterial endocarditis.

Intracranial aneurysms typically rupture from the dome rather than the base, forcing blood into the subarachnoid space at the base of the brain. The aneurysm may also rupture and force blood into brain tissue, the ventricles or the subdural space. This discussion focuses on intracranial haemorrhages due to rupture of a cerebral aneurysm. See Chapter 41 for further discussion of types of intracranial bleeding and haematomas.

Manifestations

An intracranial aneurysm is usually asymptomatic until it ruptures, although very large aneurysms may cause headache and/or neurological deficits due to pressure on adjacent intracranial structures. Small leakages of blood may occur periodically, causing headache, nausea, vomiting and pain in the neck and back. The person may also have prodromal manifestations before the rupture occurs, such as headache, eye pain, visual deficits and a dilated pupil.

The manifestations of a ruptured intracranial aneurysm (and subsequent subarachnoid haemorrhage) include a sudden, explosive headache; loss of consciousness; nausea and vomiting; a stiff neck and photophobia (due to meningeal irritation); cranial nerve deficits; stroke syndrome manifestations; and pituitary malfunctions (that result primarily from changes in ADH secretion).

The severity of the rupture is often inferred from the manifestations of the subarachnoid haemorrhage. The Hunt–Hess classification of subarachnoid manifestations is frequently used to classify non-traumatic subarachnoid haemorrhages. The grades of severity are:
- grade 1—asymptomatic or minimal headache and slight neck rigidity
- grade 2—moderate to severe headache, neck rigidity, cranial nerve deficits
- grade 3—drowsy, lethargic, mild neurological deficits
- grade 4—stuporous, moderate to severe hemiparesis, early decerebrate rigidity
- grade 5—deep coma, decerebrate rigidity, moribund appearance.

Fibrin and platelets seal off the bleeding point, but the escaped blood forms a clot that irritates the brain tissue. The resulting inflammatory response causes cerebral oedema and both the oedema and the haemorrhage increase intracranial pressure (Hickey, 2013). Bleeding into the subarachnoid space causes meningeal irritation. Hypothalamic dysfunction and seizures are also potential complications.

Complications

The main complications of a ruptured intracranial aneurysm are rebleeding, vasospasm and hydrocephalus.

Rebleeding

The greatest risk of rebleeding is within the first day after the initial rupture and again in 7 to 10 days (when the initial clot breaks down). Rebleeding is manifested by a sudden severe

headache, nausea and vomiting, decreasing levels of consciousness and new neurological deficits (Hickey, 2013). The mortality from rebleeding is as high as from the initial rupture.

Vasospasm

Cerebral vasospasm is a common but dangerous complication that occurs between 3 and 10 days after a subarachnoid haemorrhage. It is associated with a large number of deaths and disability. A cerebral vasospasm narrows the lumen of one or more cerebral vessels, causing ischaemia and infarction of tissue supplied by the affected vessels. The actual cause is unknown, but it occurs in blood vessels surrounded by thick blood clots, suggesting that some substance in the clot initiates the spasm. The manifestations vary according to the degree of spasm and the area of brain affected. Regional alterations may cause focal deficits (such as hemiplegia), whereas global alterations cause loss of consciousness.

Hydrocephalus

Hydrocephalus, an abnormal accumulation of CSF within the cranial vault and dilation of the ventricles, is a potential complication of a ruptured intracranial aneurysm. Hydrocephalus is thought to be the result of obstruction of reabsorption of CSF through the arachnoid villi. The obstruction is caused by an increased protein content of the CSF because of lysis of blood in the subarachnoid space (Porth, 2010). The accumulation of CSF increases intracranial pressure. Initial manifestations of hydrocephalus are typically non-specific but commonly include decreasing levels of consciousness.

INTERPROFESSIONAL CARE

The care of the person with a ruptured intracranial aneurysm includes determining the location of the aneurysm, treating the manifestations of the haemorrhage and preventing rebleeding and vasospasm. Interventions using radiology, angiography and a variety of procedures may prevent aneurysm rupture or stop the bleeding. Surgery is usually the treatment of choice to repair the bleeding artery.

Diagnosis

The diagnostic tests conducted to identify the site and extent of a ruptured intracranial aneurysm, as well as rebleeding, are a CT scan and bilateral carotid and vertebral cerebral angiograms. A cerebral angiogram is the gold standard for evaluating cerebral aneurysm; it can demonstrate the source of the aneurysm about 80–85% of the time (Hickey, 2013). A lumbar puncture will reveal blood-tinged spinal fluid. These tests are described in Chapter 40.

Medications

Calcium channel blockers, such as nimodipine (Nimotop), are used to improve neurological deficits due to vasospasm following subarachnoid haemorrhage from ruptured intracranial aneurysms. Administered for 21 consecutive days, they have been found to enhance collateral blood flow and reduce the incidence of ischaemic deficits from arterial spasm without side effects (Hickey, 2013).

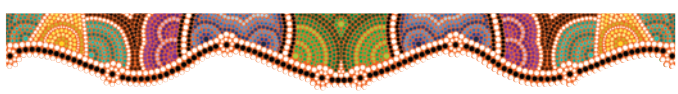
Other medications that may be prescribed include anticonvulsants, such as phenytoin (Dilantin), to prevent seizures if the person has increased intracranial pressure; analgesics for headache; and stool softeners to prevent constipation and straining with a bowel movement (which increases intracranial pressure and blood pressure, and may cause rebleeding).

Procedures used to treat aneurysm

Treatments for an intracranial aneurysm are performed either to prevent rupture or to isolate the vessel to prevent further bleeding. The person with good neurological status may have surgery soon after the rupture. In the person with significant neurological deficits, surgery may be delayed until they are more stable and less at risk of vasospasm; however, the trend is towards surgery as soon as possible.

Several different types of procedures are used to repair a ruptured intracranial aneurysm or to prevent the rupture of an existing large aneurysm. These include:

- The skull is opened (craniotomy) and the aneurysm is located. The neck of the aneurysm may be clipped with a metal clip (preventing the entry of blood into the aneurysm) or the involved artery may be clipped both proximally and distally to the aneurysm to isolate the affected area.
- Endovascular Guglielmi detachable coils (GDCs) are a method used to treat non-ruptured aneurysms. One or more small platinum coils are inserted through a microcatheter and threaded through the carotid or femoral artery to the site of the aneurysm, where they are released and fill the body of the aneurysm. The coils initiate the immune response and the body produces a blood clot inside the aneurysm, strengthening the artery walls and reducing the risk of rupture. After the aneurysm is stabilised, it can be clipped with less risk of haemorrhage and death (NINDS, 2012a). However, endovascular coil procedures are also effective without surgery, especially for smaller aneurysms.
- Stents, which are coil or mesh tubes introduced into the body through a catheter, are used to cover the neck of an aneurysm, while coils are deposited within the body of the aneurysm.
- Balloon remodelling is used for large, multiple or surgically inaccessible aneurysms. A balloon is placed across the neck of the aneurysm and coils are inserted into the body of the aneurysm. The balloon prevents the coils from moving out to the aneurysm.
- Parent vessel occlusion is performed to occlude the parent vessel that supplies blood to the aneurysm. Prior to permanent occlusion, the risk of neurological impairment is assessed by monitoring motor, sensory and cognitive functions in an awake person while temporary occlusion is conducted.



Nursing care

Nursing care is planned and implemented for the person with a ruptured intracranial aneurysm to prevent rebleeding, as well as to meet needs resulting from neurological deficits.

Nursing diagnoses and interventions

Appropriate nursing diagnoses and interventions are described earlier in the chapter in the discussion of nursing care for the person with a stroke. The priority interventions in the acute care stage of a ruptured intracranial aneurysm focus on ineffective cerebral tissue perfusion.

Ineffective tissue perfusion: cerebral

These interventions are for the care of the person immediately after the intracranial aneurysm ruptures. The expected outcome of care is preventing rebleeding and improving cerebral tissue perfusion.

- Institute aneurysm precautions to prevent rebleeding, as follows:
  - Keep the person in a private, quiet, darkened room. Disconnect or remove the telephone. Avoid using bright overhead lights. *A quiet environment helps prevent an increase in blood pressure, which could precipitate rebleeding. The person may experience photophobia (abnormal sensitivity to light) if haemorrhage has damaged the oculomotor nerve.*
  - Elevate the head of the bed 30 to 45 degrees; follow prescribed activity orders (usually complete bed rest, but in some cases bathroom privileges may be approved). *Elevating the head of the bed promotes venous return from the brain and thus decreases intracranial pressure. Decreasing activity reduces the likelihood of increases in blood pressure.*
  - Limit visitors to two family members at any one time and limit the duration of visits. Monitor the person's response to visitors and decrease interactions if the person becomes agitated or upset. *Psychological stress may increase blood pressure and the risk of rebleeding; however, social isolation may increase anxiety and stress. Each person (and family) must be individually evaluated.*
  - Allow reading, watching television or listening to the radio to promote relaxation. *Although these passive activities were previously contraindicated for the person on aneurysm precautions, current therapy is based on the belief that these activities promote relaxation and help control blood pressure.*
- Prevent constipation and straining to have a bowel movement. Administer stool softeners as prescribed. Collaborate with the person and doctor about use of a bedside commode or the bathroom. Do not administer enemas. *The person is at risk of constipation as a result of decreased mobility and the administration of narcotics (such as codeine) for headache. When straining to have a bowel movement, the person uses the Valsalva manoeuvre, which increases intracranial pressure and may precipitate rebleeding.*
- If the person is alert (and depending on doctor preference), allow them to feed self and provide own personal care. *In many instances, self-care causes less anxiety and stress than care provided by the nurse. The extent of care provided varies according to the person's condition and the doctor's preferences. The person who may have to go to theatre will be kept nil by mouth.*

CONSIDERATION FOR PRACTICE

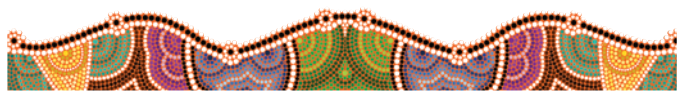
Maintaining a daily stool chart is an important assessment in preventing constipation.

- Monitor vital signs and neurological status as indicated by the person's condition. (Frequency of assessments may range from every 15 minutes to every 4 hours.) *Vital signs and neurological assessments provide ongoing data for evaluation of changes indicative of increasing intracranial pressure and decreasing neurological function. Report any change immediately to the doctor.*

CONSIDERATION FOR PRACTICE

Restlessness and changes in respirations are often early manifestations of increased intracranial pressure.

- Maintain seizure precautions: have suction equipment and an oropharyngeal tube at the bedside, maintain the bed in the low position and keep the side rails padded and raised. *Applying suction and inserting an oropharyngeal airway may be necessary to maintain an open airway in case of seizure. A lowered bed and padded, raised side rails prevent injury if a seizure occurs.*
- Avoid positioning and activities that increase intracranial pressure such as coughing, sneezing, vomiting, sharply flexing the neck, blowing the nose, enemas or moving self up in bed. *These measures help to prevent increasing intracranial pressure and rebleeding.*



THE PERSON WITH AN ARTERIOVENOUS MALFORMATION

An arteriovenous (AV) malformation is a congenital intracranial lesion, formed by a tangled collection of dilated arteries and veins that allows blood to flow directly from the arterial into the venous system, bypassing the normal capillary network. Most AV malformations (90%) are located in the cerebral hemispheres; the remainder are found in the cerebellum and brainstem.

Rupture of vessels in the malformations accounts for 2% of all strokes. People with this condition develop manifestations before 40 years of age; it affects men and women equally (Porth & Matfin, 2014). The manifestations are the result of spontaneous bleeding from the lesion into the subarachnoid space or brain tissue.

Pathophysiology

AV malformations displace, rather than encompass, normal brain tissue (Hickey, 2013). The pathophysiological effects of an AV malformation are the result of the shunting of blood from the arterial to the venous system and of altered perfusion of cerebral tissue near the malformation. The shunting of arterial blood directly into the venous system within the malformation transfers the higher arterial pressure directly into the lower-pressure venous

system. This increased pressure is likely to cause spontaneous bleeding or progressive expansion and rupture of a blood vessel.

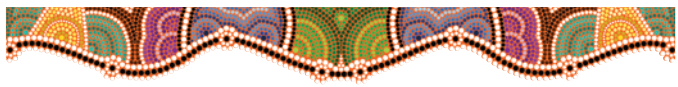
Altered cerebral perfusion results when blood flow through a large, high-flow malformation is diverted from the normal cerebral circulation, causing tissue ischaemia of the area surrounding the malformation. This is sometimes called a vascular 'steal' phenomenon.

AV malformations range in size from very small to very large. Large malformations are usually initially manifested by seizure activity. In contrast, the manifestations of a small malformation are more often due to a haemorrhage that causes neurological deficits. In both instances, the person may have recurrent headaches that do not respond to treatment.

INTERPROFESSIONAL CARE

AV malformations are diagnosed with the same diagnostic tests used to diagnose an intracranial aneurysm.

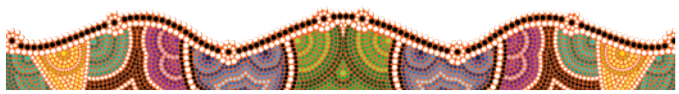
If the malformation is accessible, the ideal treatment is excision of the malformation and removal of any haematoma. Large malformations may be treated by embolisation. In this procedure, substances such as Gelfoam or metallic pellets are introduced into the involved area of the cerebral circulation, where they form emboli and gradually obstruct blood flow in the malformation. Inaccessible malformations are also treated with radiation therapy or laser therapy to coagulate blood in the malformation and thicken its vascular elements, eventually obstructing it. When the malformation is excised or obstructed, blood flow is no longer shunted and cerebral perfusion improves.



Nursing care

Nursing care depends on the condition of the malformation. If haemorrhage has not occurred, teach the person to avoid activities that raise blood pressure or could cause injury. The person is usually given medications to control blood pressure and prevent seizures.

If the malformation ruptures and causes an intracranial haemorrhage, nursing care is the same as for any person who has had a haemorrhagic stroke (discussed earlier in this chapter).



SPINAL CORD DISORDERS

THE PERSON WITH A SPINAL CORD INJURY

Nursing care of the person with a spinal cord injury takes place from the acute management phase through ongoing rehabilitation in a variety of settings. Although priorities of care may change depending on the person and the setting, care focuses on maximising functional health status to preserve quality of life. The nurse provides care and also collaborates with other healthcare professionals in meeting this goal.

Incidence and prevalence

A **spinal cord injury (SCI)** is usually due to trauma. The main causes of SCI are contusion, laceration, transection, haemorrhage and damage to blood vessels that supply the spinal cord. If vertebrae are fractured and ligaments are torn, bony fragments can damage the cord and make the spinal column unstable. Injury to blood vessels supplying the cord can cause permanent damage. The injury is identified by vertebral level. For example, a C6 spinal cord injury is at the sixth cervical vertebra.

Risk factors

The three main risk factors for SCIs are age, gender and alcohol or drug abuse. Young men are more prone than women to risk-taking behaviours. Older adults are more likely to have a cord injury from even minor trauma as a result of age-related vertebral degeneration. Motor vehicle crashes while under the influence of alcohol or drugs are a major source of trauma to people of all ages.

FAST FACTS

- Approximately 300–400 Australians have an SCI each year.
- An estimated 10 000 people in Australia are living with SCIs.
- The cost associated with care of people with SCIs is estimated at $500 million per year.
- The majority of SCIs (79%) are due to traumatic injuries such as motor vehicle crashes, acts of violence, falls and sports injuries.
- The highest prevalence of SCI occurs in the 15–24-year-old age group.

Source: AIHW (2010).

Pathophysiology

The spinal cord provides a two-way pathway for the conduction of impulses and information to and from the brain and the body, serves as a major reflex centre and (through its attached spinal nerves) is involved in the sensory and motor innervation of the entire body below the head. It consists of an outer region of white matter and an inner region of grey matter. The grey matter comprises the central canal of the cord, the posterior horns, the anterior horns and the lateral horns. It is divided into a sensory half (dorsally) and a motor half (ventrally) and innervates somatic and visceral regions of the body. The white matter consists of tracts or pathways that convey information. The ascending (sensory)

pathways carry information about proprioception, fine touch, discrimination, pain, temperature, deep pressure and touch. The descending (motor) pathways carry information about movement. The pyramidal tracts control skilled voluntary movements (such as writing). The extrapyramidal tracts (all tracts other than the pyramidal tracts) bring about all other body movements. See Chapter 40 for further information.

When the spinal cord is injured, the primary injury causes microscopic haemorrhages in the grey matter of the cord and oedema of the white matter of the cord. These initial pathological changes are followed by the secondary injury, with mechanisms that increase the area of injury. The haemorrhages extend, eventually involving the entire grey matter. Microcirculation to the cord is impaired by oedema and haemorrhage. The injured tissue releases noradrenaline, serotonin, dopamine and histamine; these vasoactive substances cause vasospasm and further decrease microcirculation. As a result, vascular perfusion and oxygen tension of the affected area are decreased, which leads to ischaemia.

When ischaemia is prolonged, necrosis of both grey and white matter begins within a few hours and within 24 hours the function of nerves passing through the injured area is lost. Although circulation returns to the white matter of the cord in about 24 hours, decreased circulation in the grey matter continues. Because oedema extends the level of injury for two cord segments above and below the affected level, the extent of injury cannot be determined for up to 1 week.

Tissue repair occurs over a period of 3 to 4 weeks. Phagocytes enter the area 36 to 48 hours after the initial injury. Neurons degenerate and are removed by microphages in the first 10 days after the injury. RBC disintegrate and the haemorrhages are reabsorbed. Eventually the area of injury is replaced by acellular collagenous tissue and the meninges thicken.

Forces resulting in SCI

SCIs are the result of the application of excessive force to the spinal column. The most common causes of abnormal spinal column movements are acceleration and deceleration (forces that are applied to the body; for example, in motor vehicle crashes and falls). Acceleration occurs when external force is applied in a rear-end collision; the upper torso and head are forced backwards and then forwards. Deceleration occurs in a head-on collision; the external force is applied from the front. The head and body move forwards until they meet a stationary object and then are forced backwards. The following forces and movements (see Figure 42.5) may cause a variety of SCIs, with the extent of injury depending on the amount and direction of motion and the rate of application of force:

- *Hyperflexion*, or forcible forward bending, may compress vertebral bodies and disrupt ligaments and intervertebral discs.
- *Hyperextension*, or forcible backward bending, often disrupts ligaments and causes vertebral fractures. A whiplash injury is a less severe form of hyperextension, with injury to soft tissues but no vertebral or spinal cord damage.
- *Axial loading*, a form of compression, is the application of vertical force to the spinal column (e.g. by falling and landing on the feet or buttocks, or by diving into shallow water).

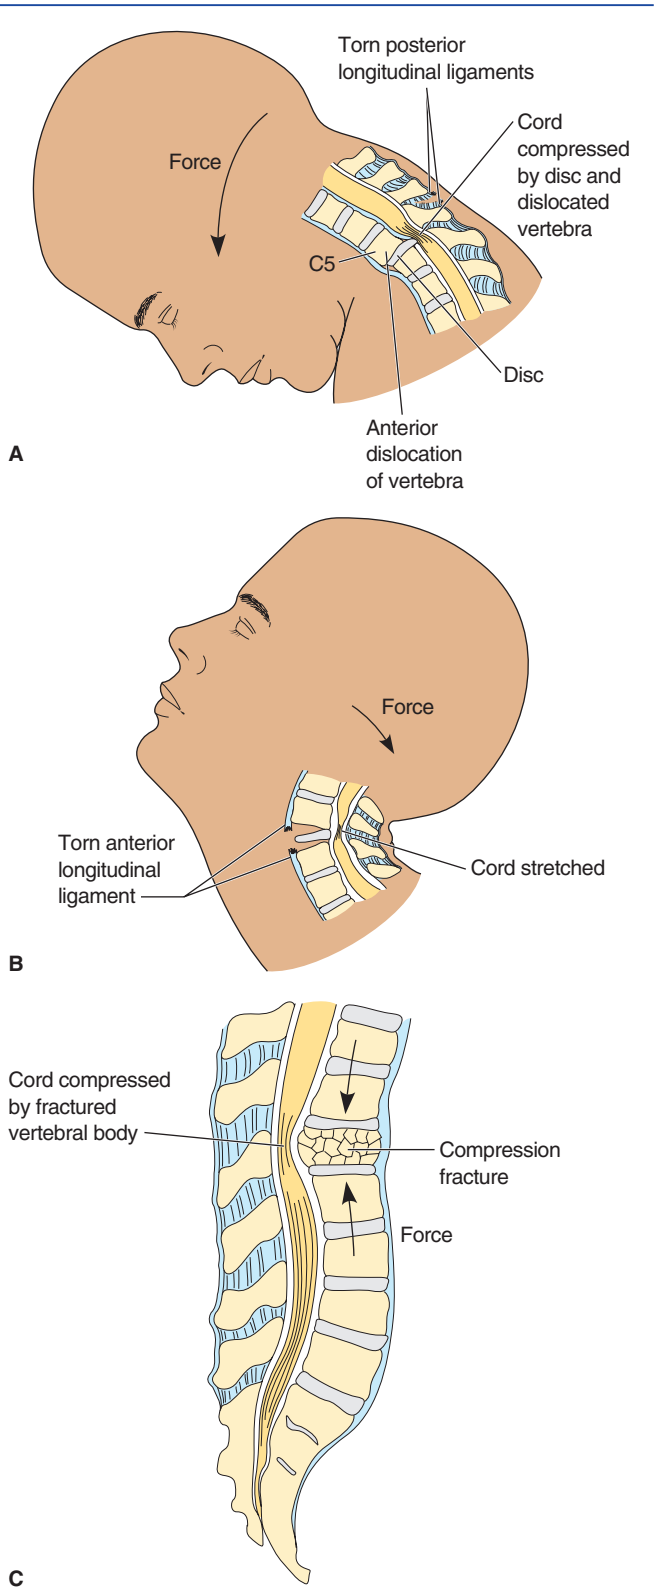


FIGURE 42.5 ■ Spinal cord injury mechanisms. *A*, Hyperflexion. *B*, Hyperextension. *C*, Axial loading, a form of compression

- *Excessive rotation*, in which the head is excessively turned, may tear ligaments, fracture articular surfaces and cause compression fractures.

The alteration of the spinal cord and soft tissues caused by these abnormal movements is called deformation.

The spinal cord may be penetrated by bullets and other foreign objects (e.g. sharp objects used as weapons, shrapnel from explosions). Penetrating injuries may cause vertebral fractures, tear ligaments and muscles, or cut through a part or all of the spinal cord. Complete severing of the cord is rare.

Sites of pathology

Injuries occur most often in the lumbar and cervical regions. The most frequent sites of injury of the cord are at the first, second and fourth to sixth cervical vertebrae (C1, C2, C4 to C6); and the eleventh thoracic to second lumbar vertebrae (T11 to L2). Because the cervical spine has a wider range of movement than the rest of the spine, the cervical portion is more likely to be affected by externally applied forces. In addition, the cord fills most of the vertebral canal in the cervical and lumbar regions and thus is more easily injured. Damage to the vertebrae and ligaments causes the spinal column to become unstable, increasing the possibility of compression or stretching of the spinal cord with any further movement.

Classification of SCIs

SCIs are classified according to systems—for instance: (1) as complete or incomplete cord injury, (2) by cause of injury, and (3) by level of injury. In clinical practice, these classifications often overlap. In a *complete SCI* (about 45% of all injuries), the motor and sensory neural pathways are completely interrupted (transected), resulting in total loss of motor and sensory function below the level of the injury. However, 'complete' does not necessarily mean the spinal cord has been severed. In an *incomplete SCI* (about 55% of all injuries), the motor and sensory pathways are only partially interrupted, with variable loss of function below the level of injury. Incomplete SCIs are further classified into syndromes, as outlined in Table 42.2. Both complete and incomplete injuries can occur in paraplegia and quadriplegia. The alterations in function that occur as the result of SCIs vary greatly depending on the amount of tissue damage and the level of injury.

Manifestations

The spinal cord, the vertebrae, the intervertebral discs, the spinal nerves, the ligaments and the surrounding soft tissue structures are in such close anatomical proximity that any condition or injury affecting one structure may well affect any one or all of the other structures. The conditions with the most critical effects are disorders affecting the spinal cord. Disorders and injuries of the spinal cord have the potential to affect movement, perception, sensation, sexual function and elimination. Manifestations and complications of SCI by body system are listed in the box below.

Spinal shock is the temporary loss of reflex function (called *areflexia*) below the level of injury. This response begins immediately after complete transection of the spinal cord, when connections between the brain and the spinal cord are interrupted and the cord does not function at all. The response also occurs (although in varying degrees) after partial transection, as well as after spinal cord contusions, compression and ischaemia.

Normal activity of the spinal cord is dependent on constant impulses from the higher centres of the brain. When damage from an injury stops these impulses, spinal shock follows. There is loss of motor function, tendon reflexes and autonomic function. Spinal shock may begin within 1 hour of the injury. The condition may last from a few minutes to several months

TABLE 42.2 Incomplete spinal cord injury syndromes

TYPE	CAUSE	LOCATION	DEFICITS
Central syndrome	Cord transection Hyperextension	Cervical	Spastic paralysis of the upper extremities Variable paralysis of the lower extremities Variable effects on the bowel, the bladder and sexual function
Anterior syndrome	Damage to the anterior spinal artery Infarction of the anterior spinal artery Hyperflexion	Anterior two-thirds of the cord	Paralysis below the level of injury Loss of temperature and pain sensation below the level of injury
Posterior syndrome	Vertebral dislocation Herniated disc Compression	Nerve roots	Weakness in isolated muscle groups Tingling, pain Decreased or absent reflexes in the involved area Bowel or bladder dysfunction
Brown–Séquard syndrome	Penetrating trauma	Hemisection of the anterior and posterior cord	Paralysis below the level of injury on the ipsilateral (same) side of the body Contralateral loss of temperature and pain sensation below the level of injury Ipsilateral loss of proprioception below the level of injury
Homer's syndrome	Incomplete cord transection	Cervical sympathetic nerves	Ipsilateral ptosis of the eyelid, constricted pupil and facial anhidrosis (inability to perspire)

MANIFESTATIONS AND COMPLICATIONS Spinal cord injury by body system

INTEGUMENT
- Decubitus (pressure) ulcers

NEUROLOGICAL
- Pain
- Areflexia
- Hypotonia
- Autonomic dysreflexia

CARDIOVASCULAR
- Spinal shock
- Paroxysmal hypertension
- Orthostatic hypotension
- Cardiac arrhythmias
- Decreased venous return
- Hypercalcaemia

RESPIRATORY
- Limited chest expansion
- Decreased cough reflex
- Decreased vital capacity

GASTROINTESTINAL
- Stress ulcers
- Paralytic ileus
- Stool impaction
- Stool incontinence

GENITOURINARY
- Urinary retention
- Urinary incontinence
- Neurogenic bladder
- Impotence
- Testicular atrophy
- Inability to ejaculate
- Decreased vaginal lubrication

MUSCULOSKELETAL
- Joint contractures
- Bone demineralisation
- Osteoporosis
- Muscle spasms
- Muscle atrophy
- Pathological fractures
- Paraplegia
- Quadriplegia

(although it usually lasts from 1 to 6 weeks) and then reflex activity returns. Spinal shock ends slowly, with the gradual reappearance of reflexes, hyperreflexia (increased reflex responses), muscle spasticity and reflex bladder emptying.

The manifestations of acute spinal shock (which vary in degree) include the following:

- flaccid paralysis of skeletal muscles below the level of injury
- loss of all spinal reflexes below the level of injury
- loss of sensations of pain, touch, temperature and pressure below the level of injury
- absence of visceral and somatic sensations below the level of injury
- bowel and bladder dysfunction
- loss of the ability to perspire below the level of injury.

A person with a cervical or upper thoracic SCI may also have neurogenic shock, resulting in cardiovascular changes. These changes are due to the inability of higher centres in the brainstem to modulate reflexes. As a result, vascular beds below the level of injury dilate and the cardiac accelerator reflex is suppressed. The person experiences hypotension and bradycardia. Other manifestations may include respiratory insufficiency due to loss of innervation of the diaphragm in C1 to C4 injuries, hypothermia, paralytic ileus, urinary retention and oliguria.

Both bradycardia and hypotension may persist even after the spinal shock resolves. In addition to losing sympathetic control of the heart rate, the person with a high-level SCI experiences decreased peripheral resistance and loss of muscle activity. These changes result in sluggish blood flow and decreased venous return, increasing the risk of thrombophlebitis.

Complications

The complications of an SCI involve many different body systems and result often in permanent disability and loss of functional health status. The complications include, but are not limited to, upper and lower motor neuron deficits, paraplegia and quadriplegia, and autonomic dysreflexia. Other complications, depending on the level and severity of the injury, are ineffective respirations, altered skin integrity, increased risk of thrombosis and alterations in bowel elimination, urinary elimination and sexual pattern.

Upper and lower motor neuron deficits

Injuries to the spinal cord are often classified as either *upper motor neuron lesions* or *lower motor neuron lesions*. Motor neurons are functional units that carry motor impulses. The upper motor neurons (located in the cerebral cortex, thalamus, brainstem and corticospinal and corticobulbar tracts) are responsible for voluntary movement. When these motor pathways are interrupted, the person experiences spastic paralysis and hyperreflexia and may be unable to carry out skilled movement.

Lower motor neurons (located in the anterior horn of the spinal cord, the motor nuclei of the brainstem and the axons that reach the motor end plate of skeletal muscles) are responsible for innervation and contraction of skeletal muscles. Interruption of lower motor neurons results in muscle flaccidity and extensive muscle atrophy, with loss of both voluntary and involuntary movement. If only some of the motor neurons supplying a muscle are affected, the person experiences partial paralysis (paresis); if all motor neurons to a muscle are affected, the person experiences complete paralysis. Hyporeflexia is also present.

Paraplegia and quadriplegia

Two common neurological deficits resulting from an SCI are paraplegia and quadriplegia (see Figure 42.2). **Paraplegia** is paralysis of the lower portion of the body, sometimes involving the lower trunk. Paraplegia occurs when the thoracic, lumbar and sacral portions of the spinal cord are injured, causing loss or impairment of sensory and/or motor function. **Quadriplegia**, also called *tetraplegia*, occurs when cervical segments of the cord are injured, impairing function of the arms, trunk, legs and pelvic organs.

Autonomic dysreflexia

Autonomic dysreflexia (also called *autonomic hyperreflexia*) is an exaggerated sympathetic response that occurs in the person with SCIs at or above the T6 level. This response, which is seen only after recovery from spinal shock, occurs as a result of a lack of control of the autonomic nervous system by higher

centres. When stimuli are unable to ascend the cord, mass reflex stimulation of the sympathetic nerves below the level of the injured cord area occurs, triggering massive vasoconstriction. In response, the vagus nerve causes bradycardia and vasodilation above the level of injury. If untreated, autonomic dysreflexia can cause seizures, a stroke or a myocardial infarction, and is potentially fatal (Hickey, 2013).

Autonomic dysreflexia is triggered by stimuli that would normally cause abdominal discomfort (a full bladder is the most common cause), by stimulation of pain receptors and by visceral contractions (Porth, 2010). Causes include faecal impaction, bladder infections or stones, intrauterine contractions, ejaculation, peritonitis and stimulation from pressure injuries or ingrown toenails. The most common precipitating event is a blocked urinary catheter.

The manifestations of this condition include: pounding headache; bradycardia; hypertension (with readings as high as 300/160); flushed, warm skin with profuse sweating above the lesion and pale, cold and dry skin below it; and anxiety (Porth, 2010). Dysreflexia is a neurological emergency and requires immediate treatment.

BOX 42.2 Assessment findings in acute SCI

Cervical injury
- Paralysis or weakness of extremities
- Respiratory distress manifested by changes in ABG studies, cyanosis, flaring of the nostrils, use of accessory muscles of respiration and restlessness
- Pulse rate below 60 and systolic BP below 80
- Decreased peristalsis

Thoracic and lumbar injury
- Paralysis or weakness of extremities

Spinal shock
- Loss of skin sensation
- Flaccid paralysis, areflexia
- Absent bowel sounds
- Bladder distension
- Decreasing blood pressure
- Absence of the cremasteric reflex in males (retraction of the left or right testicle in response to stimulation of the skin of, respectively, the inner left or right thigh)

INTERPROFESSIONAL CARE

The person with an acute SCI requires emergency assessment and care, and medications; sometimes the person also requires immobilisation and surgery. The person is first assessed and stabilised at the scene of the accident, initially treated in the emergency room and then admitted to the hospital's critical care unit.

Emergency care

The danger of death from SCI is greatest when there is damage to or transection of the upper cervical region. When the injury is at the C1 to C4 level, respiratory paralysis is common and the person who survives requires ventilator assistance to breathe. Injuries below C4 may increase the risk of respiratory failure if oedema ascends the cord. It is of critical importance not to complicate the initial injury by allowing the fractured vertebrae to damage the cord further during transport to the hospital. Although at one time injuries to the high cervical cord were almost always fatal, advances in trauma care have greatly improved the survival rate.

All people who have sustained trauma to the head or spine, or who are unconscious, should be treated as though they have a spinal cord injury. Pre-hospital management includes rapid assessment of the ABCs (airway, breathing, circulation), immobilising and stabilising the head and neck, removing the person from the site of injury, stabilising other life-threatening injuries and rapidly transporting the person to the appropriate facility. Guidelines for emergency care are as follows:

- Avoid flexing, extending or rotating the neck.
- Immobilise the neck, placing rolled towels or blankets on each side of the person's neck, or apply a cervical collar before moving the person onto a backboard.
- Secure the head by placing a belt or tape across the forehead and securing it to the stretcher.
- Maintain the person in the supine position.
- Transfer directly from the stretcher with backboard still in place to the type of bed that will be used in the hospital.

Assessment findings at the scene of the accident or in the emergency room vary according to the level of injury. The assessment findings common to the level of injury and spinal shock are outlined in Box 42.2.

The person in the emergency department with a suspected or identified SCI is also treated for respiratory problems, paralytic ileus, atonic bladder and cardiovascular alterations. Respiratory distress in the person with a cervical-level injury is treated by placing the person on a ventilator. Oxygen is administered to the person with a thoracic-level injury. Paralytic ileus (obstruction of the intestines due to lack of peristalsis) is common in the person with a spinal cord injury and is treated by the insertion of a nasogastric tube with connection to suction. To prevent over-distension of an atonic bladder, an indwelling catheter is inserted and connected to dependent drainage. Cardiovascular status is assessed on a continuous basis by inserting invasive monitoring devices, such as a Swan–Ganz catheter, or continuous cardiac output monitoring and attaching the person to a cardiac monitor, or by arterial monitoring to identify hypotension and to draw arterial blood gases (ABGs).

High-dose corticosteroid protocol using methylprednisolone must be implemented within 8 hours of the injury to improve neurological recovery. Clinical research indicates that the use of this adrenocorticosteroid is effective in preventing secondary spinal cord damage from oedema and ischaemia. Treatment with GM1 ganglioside for 3 to 4 weeks is an experimental approach that has been effective for some people (Papadakis & McPhee, 2015).

Diagnosis

Diagnostic tests are ordered to identify the level and extent of injury and to detect any complications. The tests include x-ray of the spine, CT or MRI of the spine and somatosensory evoked potential studies to locate the level of spinal cord injury by

stimulating peripheral nerves and measuring response times. ABGs are measured to establish a baseline or to identify problems due to respiratory insufficiency.

Medications

The pharmacological treatment of the person with an SCI is symptomatic. It is directed primarily towards decreasing oedema from the injury, treating hypotension and bradycardia, and treating spasticity.

- Corticosteroids, discussed earlier in this section, may be used to decrease or control oedema of the cord.
- Vasopressors are used in the immediate acute care phase to treat bradycardia or hypotension due to spinal and neurogenic shock. Examples of drugs are dopamine to treat hypotension in neurogenic shock and dobutamine to support cardiac function. Atropine should be available at the bedside to treat bradycardia.
- Antispasmodics are used to treat spasticity in the person with SCI. Both baclofen and diazepam may be used. A discussion of nursing implications of treatment with antispasmodics is found in the 'Medication administration' box below.
- Analgesics such as non-steroidal anti-inflammatory drugs (NSAIDs) and narcotics are administered to reduce pain.
- Proton pump inhibitors, such as omeprazole, esomeprazole, rabeprazole or pantoprazole, are often administered to prevent stress-related gastric ulcers, a common complication in SCI.
- Unless contraindicated, anticoagulants (heparin or warfarin) may be given to prevent thrombophlebitis.
- Stool softeners may be administered as part of a bowel retraining program.

Treatments

The treatments used in the management of an SCI include surgery, stabilisation and immobilisation.

SURGERY Early surgical treatment may be necessary if there is evidence of compression of the spinal cord by bone fragments or a haematoma. Surgery may also be done to stabilise and support the spine. However, many people are treated with stabilisation devices and do not require surgery. Surgeries that may be performed include a decompression laminectomy, a spinal fusion and insertion of metal rods. Surgeries of the spine are discussed later in the chapter.

STABILISATION AND IMMOBILISATION As a result of one or more dislocations or fractures of the cervical vertebrae, the person with an SCI may be immobilised in some type of traction or external fixation device to stabilise the vertebral column and prevent any further damage (see Figure 42.6).

FIGURE 42.6 ■ External fixation device

MEDICATION ADMINISTRATION Antispasmodics in spinal cord injury

ANTISPASMODICS

Baclofen
Diazepam
Orphenadrine citrate

These drugs depress the CNS and inhibit the transmission of impulses from the spinal cord to skeletal muscle. They are used to control muscle spasm and pain associated with acute or chronic musculoskeletal conditions. They are not always effective in controlling spasticity resulting from cerebral or spinal cord conditions.

Nursing responsibilities

- Assess the person's spasticity and involuntary movements to obtain baseline data for comparison with results of therapy.
- Do not expect therapy to have effects for 1 week.
- Administer oral medications with food to decrease gastrointestinal symptoms.

Health education for the person and family

- These drugs may cause drowsiness, diplopia and impotence.
- Take your medications with meals to decrease gastric irritation.
- Physical improvement may take several weeks.
- Report slurred speech, drooling or inability to carry out usual functions to the doctor.
- Do not stop taking the medication without consulting your healthcare provider.

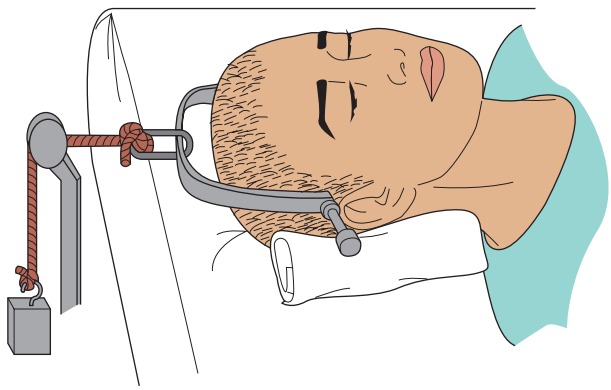

FIGURE 42.7 ■ Cervical traction may be applied by several methods, including Gardner–Wells tongs

Traction may also be used to stabilise the spinal column for the person who is not yet in a condition to have surgery or who has severe bleeding and oedema of the injured cord. The doctor applies the traction or fixation device; the nurse is responsible for assessments and interventions following the application.

Although used less frequently today, various devices provide cervical traction. For example, Gardner–Wells tongs may be used (see Figure 42.7). In this type of traction, the doctor applies pins to the skull, approximately 1 cm above each ear and weights are attached to the device.

The halo external fixation device is often used to provide stabilisation if there is no significant involvement of the ligaments (see Figure 42.8). It is most often used to provide stability for fractures of the cervical and high thoracic vertebrae without cord damage. This device allows greater mobility, self-care and participation in rehabilitation programs. The device is secured with four pins inserted into the skull: two in the frontal bone and two in the occipital bone. The halo ring is then attached to a rigid plastic vest lined with sheepskin. Nursing care of the person using a halo fixation device are described in the box below.

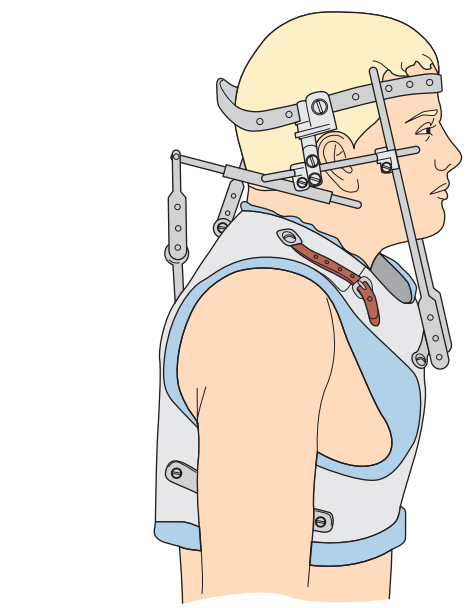

FIGURE 42.8 ■ The halo external fixation device

Nursing care

During both the acute phase and the rehabilitative phase, the person with an SCI has complex needs that involve all members of the healthcare team. Because these injuries are more common in younger people, consideration of lifelong effects on both the person and the family is essential. The nurse coordinates person care and develops and implements a care plan that is individualised to each person and family. The focus of the plan is to prevent the secondary complications of immobility and altered body functions, to promote self-care and to educate the person and family. A nursing care plan for a person with an SCI is found below.

Health promotion

Health promotion for SCIs primarily involves preventing injuries. Nurses can provide valuable information in the community and in the workplace to prevent SCIs. Programs that focus on wearing seat belts and using approved infant seats and child booster chairs in motor vehicles can do much to help decrease the number of SCIs each year. Education programs that promote workplace safety should include information on preventing falls and using heavy equipment safely.

Assessment

The following data are collected through the health history and physical examination (see Chapter 40). Further focused assessments are described with nursing interventions in the next section.

- *Health history:* time, location and type of event causing injury; location, duration, quality and intensity of pain; dyspnoea; sensation; paraesthesia.
- *Physical examination*: vital signs, motor strength, movement, spinal reflexes, bowel sounds, bladder distension.

Nursing diagnoses and interventions

Because an SCI has many possible effects, many nursing diagnoses may be appropriate. Nursing diagnoses discussed in this section focus on problems with physical mobility, respirations, dysreflexia, bowel and bladder elimination, sexual dysfunction and self-esteem.

Impaired physical mobility

After the initial period of spinal shock and areflexia, the person regains spinal reflex activity and muscle tone that is not

NURSING CARE OF THE PERSON in halo fixation

- Maintain integrity of the halo external fixation device.
  a. Inspect pins and traction bars for tightness; report loosened pins to the doctor.
  b. Tape the appropriate wrench to the head of the bed for emergency intervention.
  c. Never use the halo ring to lift or reposition the person.

  Loosening of the apparatus poses the risk of further damage to the cord. It is the responsibility of the nurse to maintain the integrity of the apparatus and the safety of the person.
- Assess muscle function and skin sensation every 2 hours in the acute phase and every 4 hours thereafter.
  a. Assess motor function on a scale of 0 to 5, with 0 being no evidence of muscle contraction and 5 being normal muscle strength with full range of motion.
  b. Assess sensation by comparing touch and pain, moving from impaired to normal areas and testing both the right and left sides of the body.

  Monitoring muscle function and skin sensation allows early identification of potential neurological deficits.
- Monitor pin sites each shift and follow hospital policy for pin care. Some general guidelines are:
  a. Assess pin sites for redness, oedema and drainage.
  b. Depending on policy, clean each pin site with a sterile applicator dipped in hydrogen peroxide, apply a topical antibiotic and cover with sterile 5 cm split gauze squares.

  Organisms can enter the body through the pin-insertion site; assessments and care are provided to detect signs of and prevent infection.
- Maintain skin integrity.
  a. Turn the immobile person every 2 hours.
  b. Inspect the skin around edges of the vest every 4 hours.
  c. Change the sheepskin liner when it is soiled and at least once each week.

  These interventions prevent skin injury and irritation.

under the control of higher centres. The person with injuries above the level of T12 experiences involuntary spastic movements of skeletal muscles. These movements reach a peak about 2 years after the injury and then gradually subside (Porth, 2010). Spasms impair the ability to carry out ADLs and work. In addition, the paraplegia or quadriplegia increases the potential for impaired skin integrity, thrombophlebitis and contractures.

The goals of care for the person with impaired mobility related to an SCI are to reduce the effects of spasticity and to prevent complications involving the skin, the cardiovascular system and joint function.

- Perform passive ROM exercises for all extremities at least twice a day. Identify stimuli that cause spastic movements and either avoid the stimuli (such as certain exercises) or teach the person to expect the movements. *ROM exercises help prevent contractures and stretch spastic muscles, promoting rehabilitation.*
- Maintain skin integrity by turning every 2 hours, assessing pressure points at least once each shift and using a pressure-relieving mattress if necessary. The person may be placed on a regular or special bed, such as a kinetic bed. *Immobility compresses soft tissues and promotes the development of decubitus ulcers. The lack of sensory warning mechanisms and of voluntary motor control of skin dermatomes further increases the risk of altered skin integrity. Special beds allow movement or turning while keeping the spinal column in alignment.*
- Assess the lower extremities each shift for manifestations of thrombophlebitis. Observe for redness and for increased heat every shift; measure thigh and calf circumference daily. If anti-embolic stockings (TEDs) are ordered, remove for 30 to 60 minutes each shift. Assess for skin impairment and provide skin care while TEDs are removed. *The person with neurological deficits is at high risk of deep venous thrombosis (DVT) as a result of immobility, vasomotor dysfunction and decreased venous return with venous stasis. Anti-embolic stockings help to prevent the pooling of blood in the lower extremities and increase venous return, lessening the risk of venous stasis and thrombus formation. Sequential compression devices or calf compressors reduce venous stasis by intermittently squeezing blood from the deep veins in the legs, thereby lessening the risk of DVT (Rolls, 2008).*

CONSIDERATION FOR PRACTICE

Removing TED stockings each shift not only promotes healthy skin but also lets the nurse assess skin integrity.

Impaired gas exchange

Injuries at the level of T1 to T7 leave the phrenic nerve intact, but the innervation of intercostal muscles is affected, compromising respiratory function. In addition, because the abdominal muscles are paralysed, the person cannot expel secretions by coughing. The person with cord injuries at C3 or above has paralysis of the respiratory muscles and cannot breathe without a ventilator.

- Monitor vital capacity and respiratory effectiveness, assessing for tachycardia, restlessness, PaO_2 less than 60 mmHg, $PaCO_2$ greater than 50 mmHg and vital capacity less than 1 L. *People with cervical cord injuries frequently require ventilatory support because of reduced vital capacity and inability to expel secretions by coughing.*

CONSIDERATION FOR PRACTICE

Changes in ABGs and vital capacity signal respiratory insufficiency.

- Monitor for signs of ascending oedema of the spinal cord, including difficulty in swallowing or coughing, respiratory stridor, use of accessory muscles of respiration, bradycardia and increased motor and sensory loss. *Haemorrhage and oedema can further impair respiratory function.*
- Help the person to cough, as follows: place the hand between the umbilicus and xiphoid process and push in and up as the person exhales and coughs. *The person who is unable to cough effectively and has decreased ventilatory capacity may develop atelectasis, pneumonia and respiratory failure.*

NURSING CARE PLAN A person with an SCI

Jim Colins, a 19-year-old university student, is admitted to the hospital by ambulance following a car crash. His family (father, mother and sister) live 200 km away and cannot visit often, although they are very concerned. On admission to the hospital, a CT scan of the spine shows a fracture and partial laceration of the cord at the C7 level. Mr Colins is in halo traction. One night, he tells the nurse, 'I wish I had just died when I got hurt. I don't think I can stand to live like this.'

ASSESSMENT

When Mr Colins is admitted to the critical care unit, he has flaccid paralysis involving all extremities. He has no sensation below the clavicle or in portions of his arms and legs. His bladder is distended and bowel sounds are absent. Other assessment findings include BP 90/56, P 50, T 36.1°C, arterial blood gases PH 7.4, PaO_2 96, $PaCO_2$ 37, SaO_2 96%. Oxygen per nasal prongs is given at 2 L/min and halo traction is applied. A Foley catheter is inserted into his bladder and a nasogastric tube is inserted and attached to low-pressure continuous suction.

After 7 days, Mr Colins is moved from the critical care unit to the neurosurgical unit for continuing care and planning for transfer to a rehabilitation hospital in his home town. His vital signs have stabilised and are normal for his age; respirations and oxygenation are normal. Other neurological assessments remain the same.

DIAGNOSES

- *Risk of impaired physical mobility* related to paralysis of lower and upper extremities and manifested by inability to mobilise independently.
- *Risk of bowel incontinence* related to lack of voluntary sphincter control and manifested by faecal incontinence.
- *Dysfunctional grieving* related to denial of loss and manifested by depression, anger or denial.

PLANNING

- Plan to begin mobilisation and ROM exercises in the morning when Mr Colins is not tired.
- His usual time for a bowel movement is after breakfast; schedule retraining program for that time.
- Discuss the grief process with Mr Colins and his family.

Expected outcomes

- Be actively involved in exercise programs.
- Have a soft, formed stool every second or third day.
- Verbally express his grief to parents and staff.

IMPLEMENTATION

- Conduct passive exercises on all extremities four times a day.
- Provide progressive mobilisation by initially raising the head of the bed 90 degrees (repeat two to three times during the first day of movement); if blood pressure remains normal, dangle the legs for 5 minutes before transferring him to a chair.
- Encourage a diet high in fibre and fluids. Likes wholemeal bread, orange juice and cola; does not like water.
- Promote grief work by providing time to express feelings. Explain to the family that his denial and anger are part of the grieving process.
- Determine food likes and dislikes, and order preferred foods from the menu. Encourage his friends to bring in his favourite foods periodically.
- Take and record weight every third day, using the bed scales.

EVALUATION

By the time Mr Colins is transferred to the rehabilitation hospital he is looking forward to learning how to use special equipment and getting his own motorised wheelchair. He is able to sit up in a chair without dizziness or hypotension. The use of ordered stool softeners combined with a high-fibre diet and fluid intake of 2000 to 3000 mL per day has maintained bowel elimination. Mr Colins and his parents have spent 3 hours talking about their feelings related to the accident and the future. Although the discussion is emotionally difficult, all three say they now feel much better. Mr Colins still has episodes of angry outbursts and tears, but he is more optimistic about what can be done and believes he can finish university. He selects foods from the menu each day and eats most of his meals, but he especially enjoys the times his friends bring in pizza or Thai takeaway.

CRITICAL THINKING IN THE NURSING PROCESS

1. Considering Mr Colins's age and developmental level, do you think his emotional responses to his injury were appropriate?
2. Issues of sexuality are obviously important to the person with a spinal cord injury. How would you approach Mr Colins about this topic?
3. Which issues in this case study will influence your future practice?

REFLECTION ON THE NURSING PROCESS

1. Design an education strategy to help educate Mr Colins about pressure areas and care needed to prevent them.
2. Outline a nursing discharge program for Mr Colins, incorporating useful information for Mr Colins's family about available resources.

Ineffective breathing patterns

Respiratory function is impaired in the person with an SCI in the cervical and thoracic levels if the diaphragm (innervated at C3 to C5), the intercostal muscles (innervated at T1 to T7) and the abdominal muscles are affected. In the person with injury at higher levels, assisted ventilation and a tracheostomy are necessary; when the injury is at lower levels, the person's ability to take a deep breath and cough is diminished. The goal of nursing interventions is to maintain normal respiratory rate (12 to 20 breaths per minute) and to prevent pulmonary complications such as atelectasis and pneumonia.

- Assess respiratory rate, rhythm and depth every 4 hours (or more frequently if needed). Auscultate breath sounds as a part of respiratory assessment. *Injury to the cord in the cervical or thoracic regions can decrease respiratory function and increase the risk of respiratory problems.*

CONSIDERATION FOR PRACTICE

Auscultate the lungs for crackles and wheezes.

- Monitor results of oxygen saturation with pulse oximetry and ABG studies. *ABG studies provide information about gas exchange; decreasing pH, oxygen and oxygen saturation levels, and increasing carbon dioxide levels, signal respiratory acidosis.*
- Administer supplemental oxygen as prescribed. *Oxygen saturation must be maintained at 100% with supplemental oxygen to prevent hypoxaemia and secondary SCI in all acute SCI.*
- Help the person turn, cough and deep breathe at least every 2 hours. Use assisted coughing as necessary. *Paralysis of intercostal or abdominal muscles decreases the ability to expel secretions by coughing; retained secretions increase the risk of pneumonia. The inability to breathe deeply may result in atelectasis.*
- Increase fluids given by mouth to 3000 mL per day (if oral intake is approved), according to the person's preference for type of liquids and predicated on the person's ability to swallow. *Increased fluid intake thins secretions, which can more easily be expelled and expectorated.*

Dysreflexia

Autonomic dysreflexia is an emergency that requires immediate assessment and intervention to prevent complications of extremely high blood pressure (loss of consciousness, seizure and even death).

- Elevate the head of the person's bed and remove TEDs or sequential compression boots. *These measures increase pooling of blood in the lower extremities and decrease venous return, thus decreasing blood pressure.*
- Assess blood pressure every 2 to 3 minutes while at the same time assessing for stimuli that initiated the response (such as a full bladder, impacted stool or skin pressure). *The most serious danger in dysreflexia is elevated blood pressure, which could precipitate a stroke, myocardial infarction, arrhythmias or seizures. If the person has a Foley catheter, ensure that there are no kinks in the tubing. If the person does not have a Foley catheter, drain the bladder with a straight catheter. If manifestations persist, assess for a faecal impaction. If an impaction is present, insert lignocaine into the anus, wait 10 minutes, and manually remove the impaction.*

CONSIDERATION FOR PRACTICE

Blood pressure readings may be as high as 300/160.

- If blood pressure remains dangerously elevated, the doctor may prescribe intravenous administration of an antihypertensive agent such as diazoxide. Other medications that may be used include nifedipine and hydralazine.

CONSIDERATION FOR PRACTICE

It is important to closely monitor for hypotension following administration of antihypertensive medications, especially if the stimulus for the dysreflexia has been removed.

Impaired urinary elimination and constipation

Depending on the level of the injury, the person with an SCI may have alterations in bowel and bladder function. The person with injuries to the cord at or above the S2 to S4 levels will have a neurogenic bladder, with deficits in control of micturition. Voluntary and involuntary bowel control is affected in the person with a lower motor neuron injury. Both bowel and bladder retraining are possible; if not, some form of assisted elimination is necessary. Although an indwelling catheter may be used in the acute phase of care, the goal is to re-establish a catheter-free state.

- Monitor for manifestations of a full bladder. *Over-distension stretches the bladder and can lead to backflow of urine into the ureters and kidney; stasis of urine in an incompletely emptied bladder increases the risk of infection.*

CONSIDERATION FOR PRACTICE

A distended bladder can be palpated over the lower abdomen above the pubic symphysis.

- Teach the person to use trigger voiding techniques prior to straight catheterisation. These techniques include stroking the inner thigh, pulling the pubic hair, tapping on the abdomen over the bladder and (in females) pouring warm water over the vulva. *These trigger voiding techniques stimulate parasympathetic nerve fibres to cause reflex activity and may facilitate voiding.*
- Teach self-catheterisation to the person who will be able to carry out the procedure alone or with minimal assistance (see Procedure 42.1). *Straight catheterisation at regular intervals is part of bladder training because periodic*

PROCEDURE 42.1 Self-catheterisation

Self-catheterisation on an intermittent basis (usually as part of self-care at home) is a clean, rather than sterile, procedure. The hands should be washed before and after the procedure and the urinary meatus should be cleaned by washing with soap and water.

Attempt to void. If urine is not of sufficient quantity (at least 100 mL), or if you cannot void at all, perform self-catheterisation. *A large amount of residual urine means that more frequent catheterisations (every 4 to 6 hours) are necessary.*

FEMALE SELF-CATHETERISATION

- While sitting on the wheelchair or the commode, locate the urethra. Visualise the urethra by looking in a mirror or palpate the urethra with a fingertip. *Visualisation or palpation of the meatus is necessary for proper catheter insertion.*
- Lubricate the meatus with a water-soluble lubricant. *Lubrication facilitates the insertion of the catheter and reduces trauma to tissues.*
- Take a deep breath and insert the catheter tip 5 to 7 cm or until urine flows. *The catheter enters the bladder more easily when the sphincter is relaxed. The deep breath relaxes the sphincter. The female urethra is 4 to 6.5 cm long.*
- Hold the catheter securely and allow urine to drain until the flow stops. *Withdrawing and reinserting the catheter increase the risk of infection.*

MALE SELF-CATHETERISATION

- Sit either on the commode or in the wheelchair. Hold the penis with slight upward tension and extend it to its full length. *Extending the penis straightens the urethra.*
- Lubricate the catheter from the tip to about 15 cm downwards. *Lubrication is especially important for male catheterisation because of the length of the urethra.*
- Take a deep breath and insert the catheter 15 to 17 cm or until urine flows. *The catheter enters the bladder more easily when the sphincter is relaxed. The deep breath relaxes the sphincter. The male urethra is about 15 cm long.*
- Hold the catheter securely and allow urine to drain until flow has stopped. *Withdrawing and reinserting the catheter increase the risk of infection.*

FOLLOWING SELF-CATHETERISATION

For both female and male techniques, withdraw the catheter and wash it with soap and water. Store the catheter in a clean container. *The catheter can be reused until it is too soft or too hard to be directed into and through the urinary meatus.*

distension and relaxation of the muscles of the bladder promote reflex bladder activity. In addition, self-care fosters independence.

- Monitor residual urine throughout the bladder retraining program. *A residual urine amount of less than 80 mL after a triggered voiding is considered satisfactory.*
- Institute a bowel retraining program as follows:
  - Assess usual patterns of bowel elimination to establish best times for an individualised program.
  - Maintain a high-fluid, high-fibre diet.
  - Use stool softeners as prescribed; rectal suppositories and enemas may be used 30 minutes after meals to stimulate stronger peristalsis and facilitate evacuation.
  - Maintain an upright position if at all possible and ensure privacy.
  - If the person is unable to evacuate, digital stimulation or manual removal on a regular basis may be the most effective long-term management.

  A bowel retraining program to regulate the bowel through reflex activity may be instituted in the person with upper motor neuron injuries. The person with a lower motor neuron injury loses the defecation reflex and bowel retraining is more difficult (if not impossible).

Sexual dysfunction

Sexual intercourse is often still possible for the person with an SCI. In men, the general rule is that the higher the level of injury the greater the potential to have reflexogenic erections, although ejaculation or orgasm may not occur and fertility is usually lower as a result of a lack of temperature control of the testes. However, ejaculation may be stimulated and the sperm used to inseminate the person's partner so that fatherhood is a possibility. Men who have sacral-level injuries do not have reflexogenic erections but may have psychogenic erections. They are also more likely to remain fertile.

Women with an SCI generally do not have sensation during sexual intercourse, but pregnancy is possible. However, pregnant women with an SCI are at increased risk of autonomic dysreflexia during labour and delivery. Birth-control options should be discussed prior to discharge from the acute care setting.

A person with an SCI may be deeply concerned about alterations in sexual function. These concerns may lead to lowered self-esteem, altered self-image or changes in feelings about being an attractive and desirable person. Assess concerns and provide a climate that is receptive to discussion about sexuality. Examples of objectives for sexual counselling for the person with an SCI are that the person will understand how the injury has altered sexual functioning, be aware of alternative ways of achieving sexual pleasure and have a positive self-concept and body image.

- Include data about sexuality when obtaining the nursing history and database. *Sexuality is a private matter for most people and the person may not discuss it unless the nurse introduces the topic.*

- Provide accurate information about the effect of the SCI on sexual function. *Accurate information gives the person a realistic picture of how the injury will affect sexuality.*
- Initiate a discussion with the person and partner of alternative means of gaining sexual satisfaction; these include the use of vibrators and oral–genital and manual stimulation. *Alternatives to intercourse can meet sexual needs and help maintain the relationship with a significant other.*
- Refer for sexual counselling, if appropriate, or to local support groups where questions can be answered by others with similar experiences. *Knowing that others have had similar experiences can decrease social isolation and provide a means of learning alternative methods of sexual functioning.*

Low self-esteem

An SCI is often the result of sudden trauma. Within moments, a formerly independent, fully functioning individual is suddenly unable to move and faces enormous adjustments in social, economic and personal roles and relationships. Body image, self-esteem and role performance are all affected by the damage. As a result, the person often demonstrates behaviours that may be difficult for the nurse to handle: depression, denial and anger are seen in the period immediately after the injury. In addition to these responses, the young adult person may act out by making sexually overt statements.

- Encourage talking about all aspects of physical function and care. *Talking provides a safe outlet for fears and frustrations and also increases self-awareness. Acceptance of self facilitates rehabilitation.*
- Encourage self-care and independent decision making. *Participating in self-care can promote positive coping; making decisions decreases feelings of powerlessness.*
- Help identify strategies to increase independence in desired roles; include both short- and long-term goals. Discuss assistive devices (such as hand-operated motor vehicles). *Identifying strategies to increase independence in the future fosters a positive self-concept and motivates the person to achieve rehabilitation goals.*
- Include family members and important others in discussions. *The realisation that others do care and will continue to provide support is important in fostering positive self-regard.*
- Refer the person and family to support groups or for psychological counselling. *Adjustment to change is more likely when the person and family seek peer and professional assistance.*

Community-based care

Rehabilitation of the person with an SCI is an ongoing process that moves from intensive care to intermediate care, to rehabilitation, and then to community-based and home care. Nursing interventions are necessary at all points in the process to prevent the complications of altered physical mobility and body functions, and to teach the person and family measures that promote independence in self-care.

Discharge planning should be addressed even in the initial plan of care while the person is in the critical care setting. Advance planning ensures continuity of care when the person leaves the hospital setting.

The following should be included in teaching the person and family about care at home:

- self-care activities (ADLs, exercises, bowel and bladder programs, skin care)
- mobility (use of assistive devices: wheelchair, crutches, special motor vehicles)
- preparation of the home environment
- if the person is in a wheelchair, will steps, stairs, doors or carpeted floors present physical barriers?
- if a special bed is necessary, have arrangements been made and is it in the home?
- psychological support
- independent activities
- coping skills for the person and caregiver
- referral to a community health agency and physiotherapist for the person who is returning home

THE PERSON WITH A HERNIATED INTERVERTEBRAL DISC

A herniated intervertebral disc—also called a ruptured disc, herniated nucleus pulposus or a slipped disc—is a rupture of the cartilage surrounding the intervertebral disc with protrusion of the nucleus pulposus (see Figure 42.9). Perhaps few neuro-orthopaedic disorders are as challenging as those involving the intervertebral discs. The person with herniation (rupture) of a disc has not only excruciating pain but also limited mobility. These problems may in turn cause alterations in role function, coping and the ability to perform ADLs.

Incidence and prevalence

A herniated intervertebral disc may occur at any adult age. However, it is more common as people enter middle age and age-related changes occur. The nucleus pulposus loses fluid content and the discs are less able to absorb shocks. The discs become smaller and slip out of place more easily. Ageing causes degeneration in the annulus fibrosus and the posterior longitudinal ligaments, and the vertebrae and discs are less able to respond to movement and are more easily injured.

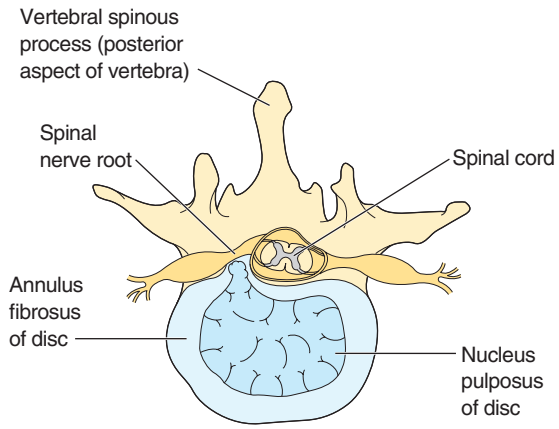

FIGURE 42.9 ■ A herniated intervertebral disc. The herniated nucleus pulposus is applying pressure against the nerve root

FAST FACTS

- Herniated intervertebral discs are more common in men than women.
- They occur most often in people between the ages of 30 and 50.
- The majority of herniated discs occur in the lumbar region (L4 or L5 to S1); when discs herniate in the cervical region, they most commonly do so at C6 to C7.
- Multiple herniations are not common, occurring in only about 10% of all people.

Source: Hickey (2013).

Pathophysiology

The intervertebral discs, located between the vertebral bodies, are made of an inner nucleus pulposus and an outer collar (the annulus fibrosus). The discs allow the spine to absorb compression by acting as shock absorbers. A herniated intervertebral disc occurs when the nucleus pulposus protrudes through a weakened or torn annulus fibrosus of an intervertebral disc (see Figure 42.9). This protrusion may occur anywhere along the vertebral column, but herniation of thoracic discs is uncommon. The protrusion may occur spontaneously or as a result of trauma, with trauma (such as lifting heavy objects or falling) causing about half of all cases. Rupture of the disc allows herniation of the nucleus pulposus in a posterolateral direction, with compression of the associated nerve root. The resulting pressure on adjacent spinal nerves causes characteristic manifestations, which vary with the location and the amount of protruding disc material (see the box below). Occasionally, the herniation is central rather than posterolateral, with pressure on the spinal cord.

The herniation may be abrupt or gradual. Lifting incorrectly or suddenly twisting the spine can cause rupture with immediate intense pain and muscle spasms. Gradual herniation is the result of degenerative changes, osteoarthritis or ankylosis spondylitis. People with a gradual herniation have a slow onset of pain and neurological deficits.

Lumbar disc manifestations

The classic manifestation of a ruptured lumbar disc is recurrent episodes of pain in the lower back. The pain typically radiates across the buttock and down the posterior leg, although it may be experienced only in the leg. **Sciatica** is a term used to describe lumbar back pain that radiates down the posterior leg to the ankle and is increased by sneezing or coughing (the result of pressure on nerve roots L4, L5, S1, S2 or S3, which give rise to the sciatic nerve). Sciatica may be elicited by straight leg raising: the person feels pain when lifting one leg while dorsiflexing the foot of that leg. Sciatica pain varies in intensity, ranging from mildly uncomfortable to excruciating. It is aggravated by a variety of positions and activities, including sitting, straining, coughing, sneezing, climbing stairs, walking and riding in a car.

Other manifestations include postural deformity, motor deficits, sensory deficits and changes in reflexes. In about 60% of people with ruptured lumbar discs, the normal lumbar lordosis is absent. When standing, the person typically has a slight forward tilt to the trunk, scoliosis of the lumbar spine, slight flexion of the hip and knee on the affected side and

MANIFESTATIONS A ruptured intervertebral disc

L4 TO L5 LEVEL (AFFECTS FIFTH LUMBAR NERVE ROOT)

- Pain in hip, lower back, posterolateral thigh, anterior leg, dorsal surface of foot, great toe
- Muscle spasms in affected areas
- Paraesthesia over lateral leg and web of great toe
- Foot drop (rare)
- Decreased or absent ankle reflex
- Cauda equina syndrome (with complete nerve root compression): bowel and bladder incontinence, paralysis of lower extremities

L5 TO S1 LEVEL (AFFECTS FIRST SACRAL NERVE ROOT)

- Pain in midgluteal region, posterior thigh, calf to heel, plantar surface of the foot to the fourth and fifth toes
- Paraesthesias in posterior calf and lateral heel, foot and toes
- Difficulty walking on toes

C5 TO C6 LEVEL (AFFECTS SIXTH CERVICAL NERVE ROOT)

- Pain in neck, shoulder, anterior upper arm, radial area of forearm, thumb
- Paraesthesia of forearm, thumb, forefinger and lateral arm
- Decreased biceps and supinator reflex
- Triceps reflex normal to hyperactive

paravertebral muscle spasms (Hickey, 2013). Motor deficits include weakness and, in some people, problems with sexual function and urinary elimination. Sensory deficits include paraesthesias and numbness. Knee and ankle reflexes are decreased or absent.

Cervical disc manifestations

Cervical discs that herniate laterally cause pain in the shoulder, neck and arm. Other manifestations of lateral cervical herniation include paraesthesias, muscle spasms and stiff neck, and decreased or absent arm reflexes. Central cervical herniations result in mild, intermittent pain; however, the person may also experience lower extremity weakness, unsteady gait, muscle spasms, urinary elimination problems, altered sexual function and hyperactive lower extremity reflexes.

INTERPROFESSIONAL CARE

Considerations for the person with a ruptured intervertebral disc include identifying the location of herniation and determining whether conservative treatment or surgery is indicated. Nursing care is directed towards preparing the person for diagnostic tests and providing teaching and care for the person who has either medical or surgical interventions.

Diagnosis

Diagnostic tests are ordered to differentiate the cause of back pain; for example, back and leg pain is also caused by spinal tumours, degenerative processes or abdominal diseases. Assessing pain is an important part of diagnosis. The tests include x-rays and CT scans of the lumbosacral or cervical area to identify skeletal deformities and narrowing of the disc spaces (see Chapter 40). Electromyography (EMG), which measures electrical activity of skeletal muscles at rest and during voluntary contraction, may be conducted to identify specific muscles affected by the pressure of the herniation on the nerve roots.

A myelogram with contrast medium is done to illustrate areas of herniation, although it does not provide the detail found with CT or MRI. However, myelography is diagnostic in 80–90% of all cases and is used both to rule out tumours and locate the herniation. Nursing implications for the care of a person having a myelogram are described in Chapter 40.

Medications

The person with a ruptured intervertebral disc is treated with medications to relieve pain and reduce swelling and muscle spasms. Pain is usually managed with NSAIDs (see Chapter 8). Muscle spasms are treated with muscle relaxants.

Treatments

A ruptured intervertebral disc may be treated conservatively or with surgery.

CONSERVATIVE TREATMENT A ruptured intervertebral disc is usually managed conservatively unless the person is experiencing severe neurological deficits. The goals of treatment are pain relief and healing of the involved disc by fibrosis. Conservative treatment is usually prescribed for 2 to 6 weeks. If the person continues to have pain after that time, surgery may be considered. The treatment regimen depends on the severity of the manifestations. Decreasing activity level with bed rest is no longer recommended; and in many cases, the person is advised to continue with normal activities while taking prescribed medications for pain, inflammation and muscle spasms.

Medications used to treat back pain include non-narcotic analgesics, anti-inflammatory drugs such as the NSAIDs, muscle relaxants and sedative–tranquillisers.

SURGERY Surgery is indicated for people who do not respond to conservative management or have serious neurological deficits. Several surgical interventions are used to treat a ruptured intervertebral disc. The type of surgery chosen depends on the location of the disc and the stability of the spinal column.

- A **laminectomy**, the type of surgery most often performed, is the removal of a part of the vertebral lamina. The surgery is done to relieve pressure on the nerves. It is often combined with removal of the protruding nucleus pulposus (*nuclectomy*). Nursing care for the person having a laminectomy is discussed in the box below. A *discectomy* is the removal of the nucleus pulposus of an intervertebral disc. Discectomy may be performed alone or with a laminectomy.
- Spinal fusion is the insertion of a wedge-shaped piece of bone or bone chips between the vertebrae to stabilise them. The bone is usually taken from a person donor site, such as the iliac crest. A spinal fusion may also be performed through a spinal implant with a device called a BAK (a hollow titanium cylinder with holes), which is packed with grafted bone from a donor site and placed in the space where a disc is removed. Although not appropriate for all people requiring a spinal fusion, this does facilitate a short hospital stay and convalescence.
- Foraminotomy is an enlargement of the opening between the disc and the facet joint to remove bony overgrowth compressing the nerve. The location and size of the incision vary according to the surgeon's preference and the location and size of the ruptured disc. The posterior approach is taken for lumbar surgery. Either the posterior or the anterior approach may be taken for cervical discs.
- Intradiscal electrothermal therapy (IDET) uses thermal energy to treat pain from a bulging spinal disc. A special needle is inserted into the disc and heated to a high temperature. The heat thickens and seals the disc wall and decreases bulging of the disc.
- A *microdiscectomy*, in which microsurgical techniques are used, is performed through a very small incision. This type of surgery decreases the possibility of trauma to surrounding structures during surgery and allows early postoperative mobility and a short hospital stay.

NURSING CARE OF THE PERSON having a posterior laminectomy

PREOPERATIVE TEACHING

- Demonstrate and ask the person to practise log-rolling; explain that it will be done by the nurses for the first day or two and then the person can do it alone. *To ensure healing, the spinal column must remain in alignment when turning and moving.*
- Explain the importance of taking pain medications regularly and of asking for them before the pain is severe. Include information about the possibility of the pain being much the same after surgery. *Pain is easier to control if medications are taken before the pain is severe. Pain may be the same following surgery for a herniated intervertebral disc because oedema due to surgery irritates and compresses the nerve roots.*
- Demonstrate the use of a fracture bedpan and ask the person to practise its use. The person usually must remain flat in bed for a period of time following surgery. *A fracture bedpan is more comfortable for the person who must lie flat.*
- Explain that the person may need to eat while lying flat. *This position prevents flexion of the spine.*
- Demonstrate and ask the person to demonstrate deep breathing, the use of the incentive spirometer and leg exercises. *These measures prevent respiratory and circulatory complications.*

POSTOPERATIVE CARE

- Maintain the person in a position that minimises stress on the surgical wound. For people with cervical laminectomy:
  a. Elevate the head of the bed slightly.
  b. Position a small pillow under the neck.
  c. Maintain the position of the cervical collar.
- For people with lumbar laminectomy:
  a. Keep the bed flat or elevate the head of the bed slightly.
  b. Place a small pillow under the head.
  c. Place a small pillow under the knees or use a pillow to support the upper leg when the person lies on one side.

  These positions minimise stress on the surgical wound and suture line. A cervical collar provides stability and prevents flexing or twisting the neck.
- Turn the person every 2 hours, using the log-rolling technique. Teach the person not to use the side rails to change position. Maintain proper body alignment in all positions. *The person's body is turned as a single unit (usually with a turning sheet) to avoid movement of the operative area. Pulling on the side rails puts stress on the operative area and may also cause misalignment of the vertebral column.*
- Monitor the person for signs of nerve root compression.
  a. Cervical laminectomy: assess hand grips and arm strength, ability to move the fingers and ability to detect touch.
  b. Lumbar laminectomy: assess leg strength, ability to wriggle the toes and ability to detect touch.

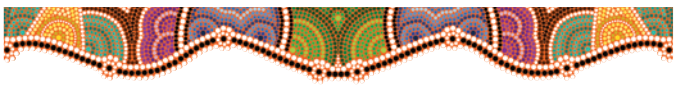
  Compare bilateral findings. Report muscle weakness or sensory impairment to the doctor immediately. *Loss of motor and sensory function may indicate nerve root compression.*
- Assess for haematoma formation as manifested by severe incisional pain that is not relieved by analgesics and decreased motor function. Report these findings immediately. *A haematoma may form at the surgical site. If untreated, it may cause irreversible neurological deficits including paraplegia and bowel/bladder dysfunctions (Hickey, 2013).*
- Assess for leakage of cerebrospinal fluid. Assess the dressing for increased moisture. Check the sheets for wetness when the person is lying supine; check for clear liquid running down the back when the person is sitting or standing. Gently palpate the sides of the wound to detect a bulge. Use a Dextrostrix strip to assess any leakage for the presence of glucose, a positive indicator of cerebrospinal fluid. *Although uncommon, leakage of cerebrospinal fluid greatly increases the risk of infection of the wound and of the meninges.*
- Assess for nerve root injury. Assess the person's ability to dorsiflex the foot (lumbar laminectomy) and the person's grip strength (cervical laminectomy). Assess the person who has had a cervical laminectomy for hoarseness. Report hoarseness and further assess the person's ability to swallow. *Nerve root compression may cause permanent damage, resulting in footdrop (in lumbar laminectomy) and hand weakness (in cervical laminectomy). Damage to the laryngeal nerve may cause permanent hoarseness. Impaired ability to swallow puts the person at risk of aspiration.*
- Assess for urinary retention. The person should void within 8 hours after surgery. If the doctor allows, let males stand to void. Compare intake and output for each 8-hour period. *All people who have received a general anaesthetic are at risk of urinary retention. The person who has had a lumbar laminectomy may have even more difficulty voiding as a result of stimulation of sympathetic nerves during surgery.*
- Assess for pain using a scale from 0 (no pain) to 10 (severe pain). Administer prescribed analgesics on a regular basis or teach the person to use patient-controlled analgesia (PCA), if prescribed. Discuss the person's concerns about pain that is unrelieved by surgery. *Compression of the nerve root over time results in oedema and inflammation. Because of surgery-induced oedema, the person is likely to experience either the same pain or perhaps more severe pain in the period immediately after surgery. This pain usually persists for several weeks after surgery. In addition, many people who have had a lumbar laminectomy have muscle spasms in the lower back, abdomen and thighs for the first few days after surgery.*
- Assess for infection by taking and recording vital signs at least every 4 hours; report increased body temperature. Assess the wound and dressing for signs of infection: increased redness, drainage, pain and pus. Use sterile technique to change dressings. *The surgical person is always at risk of infection; the person with a laminectomy is also at risk of arachnoiditis. This inflammation of the arachnoid layer of the spinal meninges*

(continued)

NURSING CARE OF THE PERSON having a posterior laminectomy (continued)

results from wound infection or contamination during surgery and may cause the formation of painful adhesions.

- Encourage deep breathing and the use of the incentive spirometer every 2 hours; coughing may be discouraged. *Anaesthesia and immobility depress respiratory function. Coughing may be discouraged because it can disrupt healing tissues, especially in the person having a cervical laminectomy.*
- Increase mobility as prescribed. (The time frame for ambulation is prescribed by the doctor; the routine here is representative.) People often sit on the side of the bed and dangle their legs the evening after surgery or the first day thereafter. Many people ambulate the first or second postoperative day. To help the person out of bed, first elevate the head of the bed. Then bring the person's legs over the side of the bed at the same time that the upper body moves into the upright position. *The person should not ambulate without assistance until they are no longer dizzy or weak. Early ambulation increases respiratory and circulatory function and decreases the risk of thrombophlebitis of the lower extremities. The vertebral column should remain in alignment while the person sits and stands. Safety must be considered throughout care.*



Nursing care

Nursing care for the person with a ruptured intervertebral disc may be provided through information in community and work settings, during conservative treatment and during pre- and postoperative treatment. The pain of the ruptured disc is often discouraging and debilitating and may well affect the person's ability to work.

Health promotion

Proper body mechanics may help prevent the occurrence of a ruptured intervertebral disc. Educating the person about the proper method of lifting and moving heavy objects should begin when children enter school. This information should also be given to all workers (including nurses) who have lifting as part of their responsibilities. The guidelines for proper body mechanics are as follows:

- Begin activities by spreading the feet apart to broaden the base of support.
- Use large muscles of the arms to lift and the legs to push when lifting.
- Work as closely as possible to the object that is to be lifted or moved.
- Slide, roll, push or pull an object rather than lift it.
- When lifting, bend the knees and lift up over your centre of gravity.
- When lifting, use a back support belt.

Assessment

The following data are collected through the health history and physical examination (see Chapter 40).

- *Health history:* type of employment, risk factors, pain (location, duration, intensity).
- *Physical assessment:* muscle strength and coordination, sensation, reflexes.

Nursing diagnosis and interventions

Nursing care for the person with a herniated intervertebral disc focuses largely on pain management, both during conservative management and after surgery.

Acute pain

People with a ruptured intervertebral disc experience acute back and leg pain. Acute pain may be related to preoperative muscle spasms or nerve root compression. After surgery, the person may have pain at the site of the incision and in the surgical area.

- Assess the degree of pain on a 0 to 10 scale (10 being greatest pain) and identify contributing and relieving factors. *Pain is a subjective experience. The nurse needs to assess it thoroughly before initiating interventions.*
- Use a firm mattress or place a board under the mattress. *A firm bed supports the spinal column and muscles.*
- Educate the person about avoiding turning or twisting the spinal column and to assume positions that decrease stress on the vertebral column (e.g. when in the supine position, flex the hips slightly). A small pillow may be placed under the knees (for the person with a herniated lumbar disc) or under the neck (for the person with a herniated cervical disc). *Correct body positions can decrease intradisc pressure.*
- Provide analgesic medications around the clock. *Intense pain can increase muscle spasms; maintaining serum levels of analgesics often prevents severe pain.*

CONSIDERATION FOR PRACTICE

It is important to maintain a constant level of pain relief. Healthcare providers have the responsibility of relieving pain with adequate medications.

Chronic pain

The person with a ruptured intervertebral disc often has pain for an extended period of time. Despite conservative treatment or previous surgery, pain may be ongoing or intermittent. If previous surgery has not relieved the pain, the person may be depressed or angry. Caring for a person with chronic pain is frustrating and the person is often regarded as difficult.

- Treat the person's reports of pain with respect. *The person is the one experiencing the pain and is thus the expert about it.*
- Do not refer to the person as being addicted to pain medication. *All types of pain medications may be used legitimately to manage pain.*

- Monitor the person carefully for any changes in condition. *Significant changes in the person's condition may go unrecognised when pain is present for a prolonged period of time.*

CONSIDERATION FOR PRACTICE

Although the person may develop tolerance to a narcotic analgesic, tolerance does not imply addiction.

- Maintain written plans of care for pain management that are individualised and ensure continuity of care. *When the person makes several visits (e.g. to an emergency department or a pain clinic), written records help caregivers determine what is effective in managing pain and what is not.*
- Teach the person alternative methods of pain management. *Consider the person's coping style when recommending methods. People who have a passive coping style are often better able to manage pain by depending on others, taking medications and resting. People with an active coping style are probably better able to manage pain by learning self-management methods, taking part in activities and staying busy.*
- Develop effective methods of improving rest and sleep. *Problems with rest and sleep make pain management more difficult. Sleeping poorly at night contributes to decreased motivation, confused thinking, depression and muscle aches.*
- Refer the person to a physiotherapist for an exercise program, if appropriate. *The person needs to know exactly what exercises to do, how many repetitions are recommended, for how long and how often. The person should not exercise to the point of causing increased pain.*
- Assess the need for referrals (and make them, if necessary) for the person who is depressed or anxious. *Anxiety and depression often are a part of long-term chronic pain, making pain management more difficult. Suggest that referrals for help with the frustration (rather than 'depression') may make a significant difference in the person's ability to manage pain.*

Constipation

The person with a ruptured intervertebral disc often has problems with constipation because of reduced mobility. Nursing interventions to alleviate and prevent constipation are important because straining to have a bowel movement can increase intradisc pressure, thus increasing pain.

- Assess the person's usual bowel routine, including diet, fluid intake and the use of laxatives or enemas. *Effective interventions are based on individualised needs.*

CONSIDERATION FOR PRACTICE

People who use laxatives or enemas for long periods of time may be dependent on those methods of having a bowel movement.

- Encourage a fluid intake of 2500 to 3000 mL per day unless contraindicated by the presence of renal or cardiac disease. *Adequate fluid intake facilitates the passage of faeces.*
- Increase fibre and bulk in the diet. If the person is unable to tolerate increased fibre, consult with the doctor about the use of stool softeners or bulk-forming agents. *Bulk and fibre promote regularity by retaining water in the large intestine.*

Community-based care

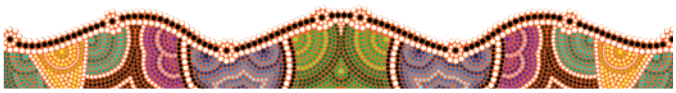
It is the nurse's responsibility to teach the person and family about chronic pain control, including specific interventions to alleviate pain. The nurse's role may be that of advocate and creative problem solver (see the 'Meeting individualised needs' box below). The following topics should be addressed:

- Often the goal is to control pain so that the person can perform normal ADLs, rather than to reach a pain-free state.

MEETING INDIVIDUALISED NEEDS Educating the person with a ruptured intervertebral disc

- Sleep on a firm mattress; use a bed board if necessary.
- When lying in the supine position, flex the knees to approximately a 45-degree angle with a small pillow and use a small pillow under the head.
- Avoid any activities that flex the spine, such as bending or lifting, and do not twist the back.
- Follow your diet to maintain body weight or to lose weight if needed.
- Follow the prescribed exercise program—for example:
  - a Lie flat on your back on the floor. Tighten your abdominal and buttock muscles and tilt your pelvis forward so that your lower back is flat on the floor. (This is called a *pelvic tilt.*) Hold the position for 3 seconds and repeat for the prescribed number of times.
  - b Lying on the back on a firm surface, press the feet to the floor, tighten the abdominal muscles and lift the upper half of the body off the floor. Hold the position for 3 seconds and repeat as prescribed.
  - c Lying on your back on a firm surface, bring your knees up to the chest. Put your hands around your knees and raise the buttocks off the floor. Repeat as prescribed.
  - d Sit upright on the floor or a firm surface. Keep one leg straight and bend the other knee. Reach for the toes of the straightened leg. Switch legs. Repeat as prescribed.
  - e Stand upright. Squat down, flexing the hips and knees. Straighten your back. Stand upright by straightening the knees. Repeat as prescribed.
- Wear flat-heeled shoes that provide good support.
- Use proper lifting techniques. For instance, squat and use your thigh muscles to lift an object from the floor and spread your feet to get a wide base of support when you lift while you are standing.

- Non-pharmacological methods of pain management include relaxation techniques, guided imagery, distraction, hypnosis and music. Joining a support group may be an effective intervention in coping with and managing pain.
- The person may be referred to a physiotherapist for education about body mechanics and back-strengthening exercises. Nurses should have the person demonstrate the exercises to reinforce teaching.



THE PERSON WITH A SPINAL CORD TUMOUR

Spinal cord tumours may be benign or malignant, primary or metastatic. They may arise at any level of the spinal column. Of all spinal cord tumours, 50% are thoracic, 30% are cervical and 20% are lumbosacral. They constitute about 0.5–1% of all tumours (Hickey, 2013). Tumours of the spinal cord are seen equally in men and women, and they most often occur between the ages of 20 and 60. They are rarely seen in the older adult.

Classification

Spinal cord tumours are classified by anatomical location as either intramedullary or extramedullary tumours. Intramedullary tumours, which make up about 10% of spinal tumours, arise from within the neural tissues of the spinal cord; those that occur include astrocytomas, ependymomas, glioblastomas and medulloblastomas (Papadakis & McPhee, 2015). Extramedullary tumours arise from tissues outside the spinal cord, with commonly occurring tumours including neurofibromas, meningiomas, sarcomas, chordomas and vascular tumours.

Extramedullary tumours are further categorised as intradural (arising from the nerve roots or meninges within the subarachnoid space) or extradural (arising from epidural tissue or the vertebrae outside the dura).

Tumours of the spinal cord are also classified as either primary or secondary (metastatic). Primary tumours, arising from the epidural vessels, spinal meninges or glial cells, have an unknown cause. Secondary tumours are metastatic in origin, most commonly the result of malignancies of the lung, breast, prostate, gastrointestinal tract or uterus.

Pathophysiology

Depending on their anatomical location, spinal cord tumours result in pathological changes as a result of compression, invasion or ischaemia secondary to arterial or venous obstruction. Extramedullary tumours (whether benign or malignant) alter normal function through compression of the spinal cord, with destruction of white matter and eventual filling of the space around the spinal cord. Cord compression interferes with normal blood flow and membrane potentials, altering afferent and efferent motor, sensory and reflex impulses. Compression of the spinal cord also causes oedema, which can ascend the cord and cause further neurological deficits. Intramedullary tumours both compress and invade. As the tumour grows within the cord, the cord also enlarges and distorts the white matter.

Manifestations

The manifestations of a spinal cord tumour depend on the anatomical location, level of occurrence, type of tumour and spinal nerves involved. General manifestations of a spinal cord tumour include pain, motor and sensory deficits, changes in bowel and/or bladder elimination, and changes in sexual function. Specific manifestations by anatomical level are outlined in the box below.

Pain is often the first manifestation of a spinal cord tumour. It is caused by compression of the spinal cord, tension on the spinal nerves or tumour attachment to the proximal dura (the covering of the spinal cord). The pain may be either localised or radicular. Localised pain is felt when pressure is applied over the spinous process of the involved area; this type of pain often accompanies metastatic tumours involving the vertebrae. Radicular pain is felt along the course of a nerve as a result of compression, irritation or tension of a nerve root. The pain is often made worse by any

MANIFESTATIONS Spinal cord tumours

CERVICAL CORD TUMOURS
- Ipsilateral arm motor involvement, followed by ipsilateral and contralateral leg involvement, followed by contralateral arm involvement
- Paresis of the arms and legs
- Stiffness of the neck
- Paraplegia
- Pain in the shoulders and arms
- Hyperactive reflexes

THORACIC CORD TUMOURS
- Paresis and spasticity of one leg, followed by paresis and spasticity of the other leg
- Pain in the back and chest
- Positive Babinski reflex
- Bowel and bladder dysfunction
- Sexual dysfunction

LUMBOSACRAL CORD TUMOURS
- Paresis and spasticity of one leg, followed by paresis and spasticity of the other leg
- Pain in the lower back, radiating to the legs and perineal area
- Loss of sensation in the legs
- Bowel and bladder dysfunction
- Sexual dysfunction
- Decreased or absent ankle and knee reflexes

activity that causes intraspinal pressure, such as sneezing or coughing.

Motor manifestations resulting from a spinal cord tumour include paresis and paralysis below the level of the tumour, spasticity and hyperactive reflexes. The Babinski reflex may be positive. These deficits are the result of involvement of the corticospinal tracts.

Many different sensory manifestations may occur, depending on the location and level of the tumour. Lateral tumour growth and compression affect the lateral spinothalamic tracts, causing pain, numbness, tingling and coldness. If the tumour involves the posterior columns, the senses of vibration and proprioception of body parts are affected.

Bladder and bowel elimination and sexual function are often affected. Bowel elimination deficits include constipation that may progress to paralytic ileus. Initial bladder elimination deficits include frequency, urgency and difficulty voiding. The deficits may progress to urinary retention and a neurogenic bladder. In addition, the male person may be impotent.

Syringomyelia is a complication of some spinal cord tumours. In this condition, a fluid-filled cystic cavity forms in the central intramedullary grey matter. This syndrome causes pain, motor weakness and spasticity.

INTERPROFESSIONAL CARE

The medical management of the person with a spinal cord tumour focuses first on diagnosis. Treatment depends on the type of tumour, its location and the person's condition.

Diagnosis

The person with a spinal cord tumour undergoes many of the same diagnostic tests as the person with a ruptured intervertebral disc. The tests used to identify the tumour include x-rays, CT scans, MRI and myelogram (see Chapter 40). A lumbar puncture of the person with a spinal cord tumour will demonstrate CSF that is commonly xanthochromic (having a yellow colour), has increased protein, has few to no cells and clots immediately. (This cluster of findings is called Froin's syndrome.)

Medications

The person with a spinal cord tumour is given medications to relieve pain and control oedema. If the pain is severe and the result of a metastatic tumour, narcotic analgesic may be administered via an epidural catheter. Pain management for the person with a spinal cord tumour is provided by narcotic analgesics (see Chapter 8). Steroids, such as dexamethasone, are administered to control oedema of the cord.

Surgery

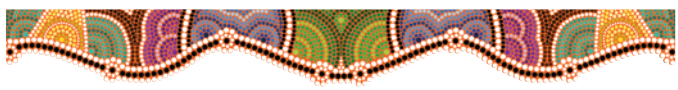
Intramedullary and intradural tumours are surgically excised when possible. Advances in microsurgical techniques and laser surgery have increased the possibility of tumour excision. Metastatic tumours may be partially excised to reduce cord compression; rapidly growing metastatic lesions may require surgical decompression to preserve motor, bowel or bladder function.

The surgical excision is made through a laminectomy. The person with a tumour involving more than two vertebrae often has a spinal fusion and may also have rods inserted to stabilise the spinal column.

Radiation therapy

Radiation therapy is used to treat metastatic spinal cord tumours for several different reasons. It may be used on an emergency basis to treat the person with rapidly progressing neurological deficits. It may be used to reduce pain. Radiation may also be used following surgical excision of as much tumour mass as possible.

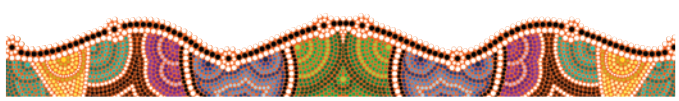
Radiation of the spinal cord may cause the development of radiation-induced myelopathy. This complication of radiation exposure occurs over time, with manifestations of *Brown–Séquard syndrome* (weakness or paralysis on one side of the body and loss of sensation on the opposite side) developing 12 to 15 months after therapy. The manifestations may progress to paraplegia, sensory loss and loss of bowel and bladder control (Hickey, 2013).



Nursing care

Nursing care for the person with a spinal cord tumour is individualised in accordance with the type of tumour and the type of treatment. The person with a benign tumour that is removed by surgery has different healthcare needs to the person with a metastatic tumour, even though they may have similar neurological deficits. The person with a spinal cord tumour (regardless of type) requires nursing care to monitor for neurological changes, to provide pain management and to manage motor and sensory deficits in order to preserve quality of life.

The assessments and nursing interventions for the person with a spinal cord tumour are similar to those described for the person with an SCI or who is undergoing surgery for a ruptured intervertebral disc. Following surgical treatment, the person may be transferred to a rehabilitation centre or may go home for the recovery period. Referrals for home care, occupational therapy and physiotherapy often help the person regain functional abilities. Teach family members how to move the person in the bed and from the bed to a chair. Also teach them how to provide physiotherapy, care for any appliances (such as an indwelling catheter) and prevent or treat constipation.



CHAPTER HIGHLIGHTS

- A stroke is a condition in which neurological deficits result from a sudden decrease in blood flow to a localised area of the brain. Strokes may be ischaemic or haemorrhagic. Ischaemic strokes result from a blockage of a cerebral artery by formation of a blood clot or by a clot or foreign substance (such as fat or bacteria) lodging in a blood vessel; they include transient ischaemic attacks, thrombotic strokes and embolic strokes. Haemorrhagic strokes occur when a cerebral blood vessel ruptures.
- Depending on the size and location of cerebral tissue damage, strokes may cause cognitive and behaviour changes, sensory–perceptual deficits, language disorders and motor deficits. Treatment of an ischaemic stroke with fibrinolytic therapy within 3 hours of the onset of manifestations may reverse damage to cerebral neurons.
- Nursing care is directed towards both prevention of a stroke through community-based education programs and interventions to promote recovery and decrease complications.
- Intracerebral haemorrhage may follow rupture of an intracranial aneurysm or arteriovenous malformation. Intracranial aneurysms occur at the site of a weakness in a cerebral blood vessel, while AV malformations are a tangled collection of dilated arteries and veins.
- Spinal cord injuries are almost always the result of trauma, with the main risk factors being age (young adults), gender (male) and alcohol or drug abuse. The causes of injury to the spinal cord include contusion, laceration, transection, haemorrhage and damage to spinal cord blood vessels.
- In a complete SCI, the motor and sensory pathways in the spinal cord are completely interrupted (transected), resulting in total loss of motor and sensory function below the level of the injury. In an incomplete SCI, the motor and sensory pathways are only partially interrupted, resulting in variable loss of function below the level of injury. Injuries of the spinal cord have the potential to affect movement, perception, sensation, sexual function and elimination.
- Spinal shock is the temporary loss of all reflexes (areflexia) below the level of injury. Manifestations of spinal shock include bradycardia, hypotension and flaccid paralysis.
- Autonomic dysreflexia is an exaggerated sympathetic response in the person with an SCI at or above the T6 level. Triggered by noxious stimuli (such as a blocked urinary catheter or a faecal impaction), this condition results in extreme hypertension and, if untreated, may cause seizures, stroke or a myocardial infarction.
- Rehabilitation of the person with an SCI is an ongoing process from intensive care to home care. Nursing interventions are necessary in all settings to promote independence in self-care.
- A herniated intervertebral disc is a rupture of the cartilage surrounding the intervertebral disc with protrusion of the nucleus pulposus. The main manifestation of lumbar discs is lower back and sciatic pain on the affected side. Cervical discs cause pain in the shoulder, neck and arm. A variety of medications, treatments and surgical procedures are available for the person.
- Spinal cord tumours may be benign or malignant, primary or metastatic. Depending on their size and location, they cause pathological changes in spinal cord function through compression, invasion or ischaemia.

CONCEPT CHECK

1 Which of the following manifestations would alert you to the possibility that a person has had a TIA?
1. sudden severe pain over the left eye
2. numbness and tingling in the corner of the mouth
3. complete paralysis of the right arm and leg
4. loss of sensation and reflexes in both legs

2 Although all of the following are risk factors for a stroke, which one is the greatest risk?
1. hypertension
2. heart disease
3. diabetes
4. high cholesterol levels

3 You have been assigned to care for a person who has had an acute ischaemic stroke of a left cerebral vessel. You read the chart and realise the person has contralateral deficits. What does this mean?
1. Both sides of the body are involved.
2. The person will have neurological deficits on the left side of the body.
3. The person will have neurological deficits on the right side of the body.
4. Deficits will be present below the level of the stroke.

4 What is the rationale for administration of a tissue plasminogen activator within the first 3 hours of a thrombotic stroke?
1. to reduce the risk of vasospasm
2. to decrease the risk of infection
3. to increase platelet aggregation
4. to cause fibrinolysis of the clot

5 Oxygen is often administered to the person who has had a stroke. Preventing hypoxia and hypercapnia through this treatment will lessen the risk of which complication?
1. fluid accumulation in the lungs
2. pulmonary emboli
3. increased intracranial pressure
4. rebleeding

6 What is the primary pathophysiological process of spinal shock?
1. temporary loss of reflex function below the level of injury
2. loss of control of cardiovascular mechanisms
3. exaggerated sympathetic response
4. damage to the lower motor neurons

7 A person has manifestations of autonomic dysreflexia. Which of these assessments would indicate a possible cause for this condition?
1. extreme hypertension
2. kinked catheter tubing
3. respiratory wheezes and stridor
4. skin breakdown over the coccyx

8 A person is admitted to the emergency department following a motor vehicle accident. An SCI at the cervical level is identified. What will be done to facilitate respirations?
1. No treatments are necessary.
2. Oxygen per nasal prongs will be administered.
3. The person will be placed on a ventilator.
4. The head of the bed will be elevated.

9 Many different medications may be given to the person with an acute SCI. Which of the following will possibly be administered? (Select all that apply.)

1 corticosteroids
2 vasopressors
3 antibiotics
4 analgesics
5 antihistamines

10 You are conducting a class at a factory to teach methods to prevent a ruptured intervertebral disc. What should be included? (Choose all that apply.)

1 Spread the feet apart to broaden the base of support.
2 Bend from the waist to lift articles from the floor.
3 Use large leg muscles to push when lifting.
4 Always lift articles rather than rolling or pushing them.
5 Work as closely as possible to the object to be moved.

CHAPTER 43

NURSING CARE OF PEOPLE WITH NEUROLOGICAL DISORDERS

LAURA MELLISH

KEY TERMS

LEARNING OUTCOMES

- Identify prevalence, incidence and risk factors for degenerative neurological, peripheral nervous system, cranial nerve and infection- and neurotoxin-caused neurological disorders.
- Explain the pathophysiology, manifestations, complications, interprofessional care and nursing care of people with neurological disorders.
- Compare and contrast the manifestations of the progressive stages of Alzheimer's disease.
- Discuss the purposes, nursing implications and health education for the person and their family of medications used to treat Alzheimer's disease, multiple sclerosis, Parkinson's disease and myasthenia gravis.
- Describe the procedures (thymectomy, percutaneous rhizotomy, plasmapheresis) used to treat selected neurological disorders.

CLINICAL COMPETENCIES

- Assess functional status of people with neurological disorders and monitor, document and report abnormal manifestations.
- Use evidence-based research to design nursing interventions specific to the needs of ageing people with multiple sclerosis.
- Determine priority nursing diagnoses, based on assessed data, to select and implement individualised nursing interventions for people with neurological disorders.
- Administer oral and injectable medications used to treat neurological disorders knowledgeably and safely.
- Provide skilled care to people having a thymectomy, percutaneous rhizotomy or plasmapheresis.
- Integrate interprofessional care into the care of people with neurological disorders.
- Provide appropriate teaching to facilitate safety and communication, prevent neurological infections and toxins (rabies, tetanus and botulism), and facilitate community-based acute and chronic self-care for healthcare needs resulting from neurological disorders.
- Revise the plan of care as needed to provide effective interventions to promote, maintain or restore functional health status for people with neurological disorders.

This chapter discusses a variety of neurological disorders. Included are degenerative disorders, peripheral nervous system disorders, cranial nerve disorders and disorders caused by neurotoxins and viruses. For many of the disorders, nursing care is based on similar nursing diagnoses. To avoid repeating those diagnoses and interventions for each disorder, they have been divided between the nursing care discussions as appropriate.

DEGENERATIVE NEUROLOGICAL DISORDERS

Degenerative neurological disorders affect the central nervous system and the peripheral nerves. By progressively disrupting cognitive processes or motor functions, disorders such as Alzheimer's disease, Parkinson's disease and multiple sclerosis strike at the core of an individual's sense of personal autonomy and wellbeing and can be psychologically and emotionally devastating to family members and caregivers.

Ongoing medical research into degenerative neurological disorders offers an increasing measure of hope to people and their families. The discovery of genetic or biochemical markers associated with some of these disorders is leading to the development of effective screening and diagnostic methods. In addition, new drugs may make it possible to halt the progression of the disorders in some people, transforming the disorders into manageable conditions. This chapter begins with a discussion of dementia, which is not a specific disease but rather a collection of manifestations caused by a variety of disorders that affect the brain.

DEMENTIA

Dementia affects multiple cortical functions, calculation, learning capacity, language and judgment. Impairments of cognitive function are usually accompanied by deterioration in emotional control, social behaviour and motivation. People with dementia lose their ability to solve problems and may also have personality changes such as agitation and hallucinations. All forms of dementia result from death of neurons and/or the loss of communication between the cells. Although the exact cause is not always known, many forms of dementia are characterised by abnormal structures in the brain called inclusions, and there is clearly a genetic component in the development of some kinds of dementia.

More than 342 800 people in Australia have dementia. Of these, three in 10 people are aged 85 and older. However, despite increased incidence in older people, dementia is not a normal part of ageing (Alzheimer's Australia, 2015a). The incidence of dementia in the Indigenous population is nearly five times greater than in the total Australian population. Dementia affects one in eight (12.4% of the population) Indigenous people aged 45 and older (Australian Indigenous HealthInfoNet, 2011).

Many different diseases and conditions may cause dementia, including Alzheimer's disease, vascular dementia, Huntington's disease, Creutzfeldt–Jakob disease, medications, metabolic disorders, poisoning and anoxia. Table 43.1 provides an overview of the most common causes of dementia. Doctors do not diagnose dementia unless two or more brain functions (such as memory, language skills, perception, reasoning or judgment) are significantly impaired without loss of consciousness.

Even though the actual cause of all dementias may not be known, factors that increase the risk of developing one or more kinds of dementia have been identified. These risk factors include advancing age, a family history of a disease that causes dementia, smoking and alcohol use, atherosclerosis, high cholesterol and plasma homocysteine levels, diabetes, mild cognitive impairment and Down syndrome.

TABLE 43.1 Common causes of dementia

NAME	CAUSE AND PRIMARY PATHOPHYSIOLOGY
Alzheimer's disease (the most common cause of dementia in people aged 65 and older)	Unknown cause; characterised by two abnormalities in the brain: amyloid plaques and neurofibrillary tangles.
Vascular dementia (the second most common cause of dementia)	Caused by brain damage from cerebrovascular and cardiovascular problems (usually strokes). May also be caused by cerebral blood vessel damage from genetic disorders, endocarditis, myeloid angiopathy, vasculitis and profound hypotension.
Lewy body dementia	Cause usually unknown, although familial cases have been reported. Cells die, and remaining cells in the substantia nigra contain abnormal structures called Lewy bodies.
Frontotemporal dementia	Nerve cells, especially in the frontal and temporal lobes, degenerate. In many people, abnormal tau protein accumulates in neurofibrillary tangles.

Although sometimes confused with dementia, people often experience other conditions that may mimic dementia. These include:

- age-related cognitive decline, resulting from slower information processing and mild memory impairment. With ageing, the brain often decreases in volume and some neurons are lost. These changes are normal and are not considered a part of dementia
- mild cognitive impairment, which may progress to dementia but is not severe enough to be initially diagnosed as such
- depression or other emotional problems, causing people to be passive, slow, confused or forgetful
- delirium, characterised by confusion, rapidly altering mental states, disorientation and possible personality changes. Delirium is usually caused by a treatable physical or mental health illness and, when treated, results in a full recovery.

THE PERSON WITH ALZHEIMER'S DISEASE

Alzheimer's disease (AD) (also called *dementia of Alzheimer type* or *senile disease complex*) is a form of dementia characterised by progressive, irreversible deterioration of general intellectual functioning. People with AD live about 8 to 10 years following diagnosis, although some live as long as 20 years. The cause of death is often aspiration pneumonia because of the loss of the ability to swallow late in the disease.

Memory loss is usually the first sign of Alzheimer's disease. Memory deficits are initially subtle and family members and friends may not suspect a problem until the disease progresses and manifestations become more noticeable. Family members and people with AD may also deny the manifestations and hide deficits until the person exhibits unsafe or extremely unusual behaviour. Progression of the disease varies, but the course is one of deteriorating cognition and judgment with eventual physical decline and total inability to perform activities of daily living (ADLs). With the loss of the ability to perform even the most basic ADLs, the burden of meeting the person's needs shifts to the caregiver.

Incidence and prevalence

Alzheimer's disease is the most common degenerative neurological disorder and the most common cause of cognitive impairment in older adults (Grossman & Porth, 2013). It accounts for up to 70% of cases of dementia in Australia, affecting adults in middle to late life (Alzheimer's Australia, 2015b).

Two types of AD exist*: familial AD* follows an inheritance pattern; *sporadic AD* has no obvious inheritance pattern. AD is further described as early onset (occurring in people younger than 65) and late onset (occurring in people aged 65 and older). Early-onset AD affects people aged 30 to 60, is relatively rare and often progresses more rapidly than late-onset AD.

Risk factors and warning signs

As one ages, the risk of developing AD increases. With numbers of older people increasing, the incidence of AD is predicted also to increase. The risk factors for AD are older age, family history and female gender. Warning signs are:

- memory loss that affects job skills
- difficulty performing familiar tasks
- problems with language
- disorientation to time and place
- poor or decreased judgment
- problems with abstract thinking
- misplacing things
- changes in mood or behaviour
- changes in personality
- loss of initiative.

Recognising early manifestations is important, because the cause of dementia (such as from depression or hypothyroidism) may be reversible. Further information can be obtained from Alzheimer's Australia. Dementia from AD is not reversible. Treatment, however, can maximise quality of life and allow the affected person to plan for the future.

FAST FACTS

- Scientists estimate that in 2050, one in every 85 people worldwide will be affected by AD (Western Australian Neuroscience Research Institute, 2014).
- AD usually occurs after the age of 65, with the risk increasing with age.
- Early-onset forms of AD, which are usually genetic, may appear as early as age 30.
- In Australia, one in 15 people over the age of 65, and almost one in four of all people over the of age 85, have AD (Neuroscience Research Australia, 2015).
- 2706 people died from AD in 2010, accounting for 1.9% of all registered deaths for that year. In 2010, female deaths (1865) due to AD were higher than male deaths (841); the median age at death was 87.3 years.

Source: Australian Bureau of Statistics (ABS) (2012). *Causes of death, Australia, 2010: Diseases of the nervous system (G00-G99).* (Cat. no. 3303.0). Retrieved from www.abs.gov.au/ausstats/abs@.nsf/Products/E9AE6DDF5D8153E9CA2579C6000F6FF6?opendocument.

Pathophysiology

Characteristic findings in the brains of AD people are loss of nerve cells and the presence of *neurofibrillary tangles* and *amyloid plaques* (see Figure 43.1). Neurofibrillary tangles result when *tau*, a kind of protein in the neurons, becomes distorted and twisted. Tau normally holds together the microtubules which guide nutrients and molecules to the end of the axon. In AD, tau changes and twists into pairs of filaments, which then join to form tangles. Because tau no longer maintains the transport system, communication is lost between neurons. Death of neurons may follow, contributing to the development of dementia.

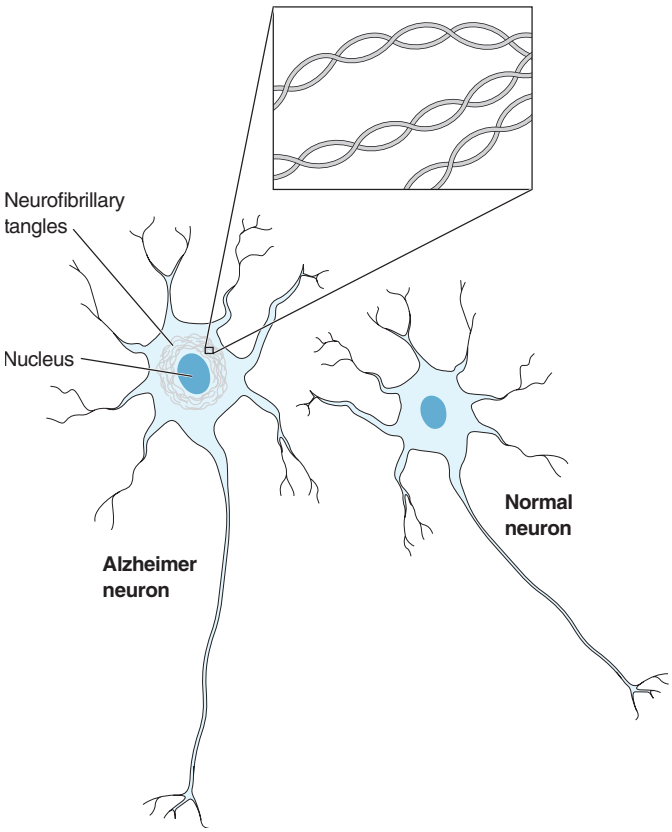

FIGURE 43.1 ■ Neuron with neurofibrillary tangles seen in Alzheimer's disease

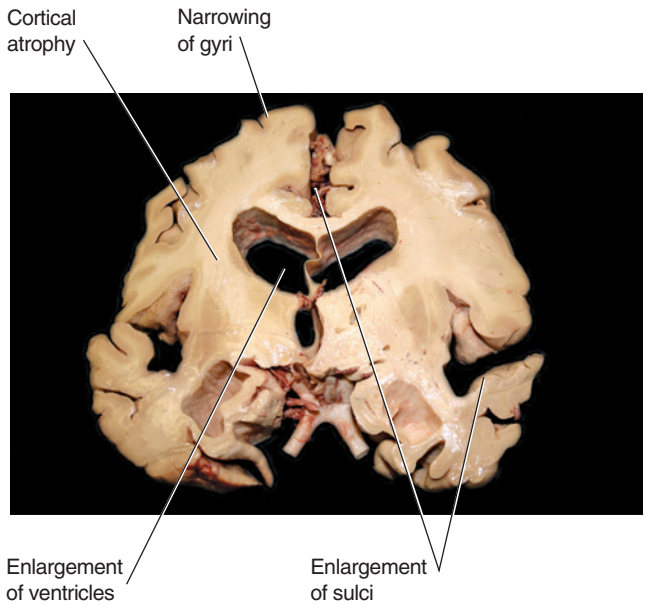

FIGURE 43.2 ■ Changes in neuroanatomy associated with Alzheimer's disease. Note areas of cortical atrophy, narrowing of the gyri, enlargement of sulci and ventricular dilation

Source: © Living Art Enterprises/Science Source.

Groups of nerve cells (especially the terminal axons) degenerate and clump around an amyloid core as plaques, and are found in the spaces between the neurons of the brain. These plaques, which develop first in areas used for memory and cognition, disrupt transmission of nerve impulses. The plaques consist primarily of insoluble deposits of beta-amyloid, a protein fragment from a larger protein called amyloid precursor protein, mixed with other neurons and non-nerve cells. It is not yet known if plaque formation causes AD or if plaques are a by-product of the AD process.

Blood flow to the affected areas of the brain is decreased. The brain atrophies and corresponding enlargement of ventricles and sulci is evident (see Figure 43.2). As AD progresses, more areas of the brain are affected, with manifestations correlating to those affected areas of the brain. For example, neuronal and neurotransmitter losses in the parietal lobe result in problems with perception and interpretation of environmental stimuli; deficits in the frontal lobe cause changes in personality and emotional lability.

AD is characterised by atrophy of the cortical area of the brain and loss of neurons, especially in the parietal and temporal lobes. With significant atrophy and loss of brain tissue, the ventricles enlarge (a form of hydrocephalus) (Grossman & Porth, 2013). Several structural and chemical changes in the brain occur with AD, especially in the hippocampus and the frontal and temporal lobes of the cerebral cortex. As AD destroys neurons in the hippocampus and related structures, short-term memory fails, and the ability to perform easy and familiar tasks declines. The effect of AD on neurons in the cerebral cortex is loss of language skills and judgment. Emotional outbursts and behaviour changes (such as wandering and agitation) begin to occur and become more frequent as the disease progresses. Eventually, other areas of the brain are affected; all affected areas begin to atrophy and the person becomes totally helpless and unresponsive.

The exact cause of AD is unknown. Theories include a decrease in choline acetyltransferase activity in the cortex and hippocampus. This enzyme is necessary for the synthesis of acetylcholine, a neurotransmitter associated with memory. The decrease in choline acetyltransferase is about equal to the severity of AD. Other theories include a mutation for encoding amyloid precursor protein and alteration in apolipoprotein E. Other possible causes are gene defects on chromosomes 14, 19 or 21, which may lead to clumping and precipitation of insoluble amyloid as plaques. The role of protein kinase C, the link between AD and aluminium, a viral cause, an autoimmune cause and mitochondrial defects that alter cell metabolism and protein processing are being studied.

Manifestations

Alzheimer's disease is classified into three stages based on the person's manifestations and abilities, as outlined in the box below. It is important to note that the progression of AD varies for each individual and may not precisely follow the model.

Stage 1 AD

In stage 1, a person typically appears physically healthy and alert, and cognitive deficits can go undetected unless thorough and periodic evaluations are performed. People may seem restless, forgetful or uncoordinated; they may lack spontaneity and be disoriented as to time and date. Usually, family members are the first to notice lapses in memory, subtle changes in personality or problems in doing simple calculations. People with AD and their families may consciously or unconsciously compensate for cognitive deficits by adjusting schedules and routines.

Stage 2 AD

In stage 2, memory deficits are more apparent and the person is less able to behave spontaneously. People may wander and get lost, even in their own homes. Although progression of manifestations continues and orientation to place and time deteriorates, people with AD may still have periods of mental lucidity and engage in time-oriented conversations. Generally, however, people become more confused and lose their sense of time, leading to changes in sleeping patterns, agitation and stress. They may demonstrate repetitive behaviour and eat ravenously. People with AD are less capable of making even simple decisions and adapting to environmental changes, and are often unable to carry out ADLs. **Sundowning** is another behavioural change, characterised by increased agitation, time disorientation and wandering behaviours during afternoon and evening hours; it is accelerated on overcast days.

Language deficits are common in stage 2. They include *paraphasia* (using the wrong word), *echolalia* (repetition of words or phrases) and *scanning speech*, in which the person appears to search for words. Eventually, *total aphasia* (absence of speech) may occur. Frustration and depression are common in people with AD as the full extent and implications of the deficits become obvious.

The person with AD slowly loses the ability to perform simple tasks required for hygiene or eating because sequencing of tasks is lost. For example, the person may open a can of soup but not remember to pour it into a pan to heat it. Instead, the person might place the can directly on the burner and leave the heat on high even after a smoke alarm sounds. The person with AD may falsely interpret the smoke alarm as a telephone ringing or an ambulance siren. Thus, safety is a high priority for the person in stage 2.

Sensorimotor deficits in stage 2 include *apraxia*, the inability to perform purposeful movements and use objects correctly; *astereognosis*, the inability to identify objects by touch; and *agraphia*, the inability to write properly. Problems related to malnutrition and decreased fluid intake, such as anaemia and constipation, may be evident. Sleep pattern disturbances are also common and are related to the loss of time orientation, sundowning phenomenon and depression.

Stage 3 AD

Stage 3 brings increasing dependence, with inability to communicate, loss of urinary and faecal continence, and progressive loss of cognitive abilities. Common complications include pneumonia, dehydration, malnutrition, falls, depression, delusions, seizures and paranoid reactions. People with AD are indifferent to food and lose weight. They are unable to recognise family or friends, or even themselves. The average life expectancy is 1 to 2 years from the onset of stage 3, although the individual may live as long as 10 years. Most people with AD are institutionalised during this final stage of the disease. Death frequently occurs from pneumonia secondary to aspiration.

INTERPROFESSIONAL CARE

There is no cure for AD and the main objective of care is to provide an environment that matches the person's functional abilities. Nurses, doctors, physical therapists and social workers collaborate with the person's family to provide the least restrictive environment in which the person can safely function.

MANIFESTATIONS Alzheimer's disease

STAGE 1: APPROXIMATELY 2TO 4YEARS

- Short-term memory loss: forgets location and names of objects and has difficulty learning new information; long-term memory is unaffected.
- Decreased attention span.
- Subtle personality changes: lacks spontaneity; denial, irritability and depression are possible.
- Mild cognitive deficits: attempts to adjust to and cover up memory loss.
- Visuospatial deficits: some problems with depth perception.

STAGE 2: APPROXIMATELY 2TO 12YEARS

- Impaired cognition: obvious memory deficits and confusion; loss of abstract thinking; astereognosis and agraphia; inability to do maths calculations; loss of ability to tell time and time disorientation, manifested as 'sundowning'; wandering behaviour.
- Personality changes: becomes easily agitated and irritable; may have delusions or hallucinations.
- Visuospatial deficits: is unable to dress self; has poor spatial orientation.
- Impaired motor skills: paces and is restless at times; motor apraxia is evident when using familiar objects.
- Impaired judgment: diminished social skills; inability to drive a car; inability to make decisions (e.g. choose clothing).

STAGE 3: APPROXIMATELY 2TO 4YEARS OR LONGER

- Cognitive abilities grossly decreased or absent: is usually disoriented to time, place and person.
- Communication skills usually absent: is frequently mute.
- Motor skills grossly impaired or absent: limb rigidity and posture flexion; bowel and bladder incontinence.

Diagnosis

Alzheimer's disease is diagnosed by ruling out causes for the person's manifestations. The only definitive method of diagnosis is postmortem examination of brain tissue. An extensive work-up is especially important because the dementia may be due to a reversible or treatable condition. For example, an older person's misuse of medications can lead to overdosing and resulting confusion. Other categories of conditions that may be considered and ruled out include depression, infection, hypothyroidism, dehydration, heart disease, stroke and chronic obstructive respiratory disease. Mental status is assessed with tests such as the Folstein Mini-Mental Status Examination (Folstein, 1975). This examination assesses areas of function such as the person's orientation to time, ability to repeat a series of words, ability to name objects and ability to follow written instructions.

National policies and practice guidelines for the early recognition and assessment of AD have been established by Alzheimer's Australia. A diagnosis of Alzheimer's disease requires the documented presence of dementia, onset between ages 40 and 90 years (most often after age 65), no loss of consciousness and absence of systemic or brain disorders that could cause mental changes.

Medications

There is no cure for AD, but some medications are effective in slowing the progression of the disease. Tacrine hydrochloride (Cognex) was the first medication specifically approved for the treatment of AD. Donepezil hydrochloride (Aricept) is used to treat mild to moderate AD dementia with some success. Rivastigmine tartrate (Exelon) is also used to treat mild to moderate AD manifestations. It improves the ability to carry out ADLs, decreases agitation and delusions, and improves cognitive function. Galantamine hydrobromide (Reminyl) is believed to increase the concentration of acetylcholine in the central nervous system (CNS) and is used as a treatment of mild to moderate AD. Memantine (Ebixa) improves cognitive function in moderate to severe AD and mild to moderate vascular dementia. Memantine acts by blocking receptors for glutamate, resulting in decreased calcium accumulation into neurons (increased calcium accumulation damages neurons). See the box below for information about selected medications used to treat AD.

Depression often accompanies AD and is treated with the appropriate medication. Antihistamines and tricyclic antidepressants that have high anticholinergic activity are usually avoided because they can increase AD manifestations. Occasionally, people with AD require tranquillisers such as thioridazine (Mellaril) or haloperidol (Serenace) to manage severe agitation. Other therapies under study to prevent or delay the onset of AD include antioxidants such as vitamin E, anti-inflammatory agents and antihypertensive drugs to lower hypertension.

Alternative and complementary therapy

The following types of alternative and complementary therapies may be used in treating the manifestations of AD:

- massage, which decreases agitation
- herbs:
  - ginkgo biloba and vitamin E, which are thought to improve cognition
  - huperzine A, a traditional Chinese medicine, which acts as an acetylcholinesterase inhibitor

MEDICATION ADMINISTRATION The person with Alzheimer's disease

CHOLINERGICS (PARASYMPATHOMIMETICS); CHOLINESTERASE INHIBITORS

Tacrine hydrochloride (Cognex)
Donepezil hydrochloride (Aricept)
Rivastigmine tartrate (Exelon)
Tacrine hydrochloride (Cognex)

In the early stages of AD, the pathological changes in neurons result in a deficiency of acetylcholine (a key neurotransmitter involved in cognitive functioning). Cholinesterase inhibitors slow the breakdown of acetylcholine release by the remaining intact neurons. In addition, rivastigmine tartrate inhibits the G1 form of acetylcholinesterase (found in higher levels in the brain of people with AD), so less acetylcholine is degraded. The drugs are used to improve memory in mild to moderate AD dementia.

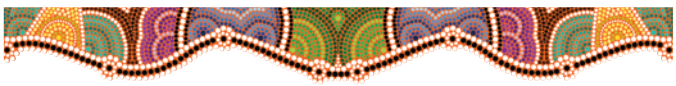
Nursing responsibilities

- Administer tacrine hydrochloride 1 hour before meals, if possible.
- Administer donepezil hydrochloride at bedtime.
- Administer rivastigmine tartrate (both capsules and liquid) with food. Liquid form may be administered undiluted or mixed with water, juice or soft drink. Stir to completely dissolve.
- Monitor for jaundice, increased bilirubin levels and other signs of liver involvement, such as rising serum aminotransferase (AST, ALT) levels. Therapy is usually decreased when the enzyme level exceeds four times normal limits and discontinued when the level reaches five times normal.
- Observe for gastrointestinal bleeding and gastric ulcer pain.
- Monitor for cholinergic-related problems: bladder outlet obstruction, seizures and slowed heart rate.
- Assist with ambulation because dizziness is a common side effect.
- Monitor glycaemic control in people with diabetes.
- Assess for improvement in AD symptoms, especially in reasoning, memory and ADLs.

Health education for the person and family

- Notify the healthcare provider promptly if jaundice, seizures, slowed heart rate, GI bleeding or difficulty in urinating occurs.
- Follow directions for times and instructions about administration of specific medication.
- Follow your healthcare provider's recommendation for periodic EEGs, blood tests and urine tests.
- These medications do not cure AD and will at some point become ineffective as the disease progresses.

- coenzyme Q10, an antioxidant that occurs naturally in the body
- supplements, such as zinc, selenium and evening primrose oil
- therapies involving art, music, sound and dance.



Nursing care

People with AD often require intensive, supportive nursing interventions directed at the physical and psychosocial responses to illness. Equally important, the nurse can facilitate the long-term support of these people by providing teaching and referrals to follow-up care in the community. A nursing care plan for the person with AD is found below.

Health promotion

Health promotion for the person with AD focuses on maintaining functional abilities and safety. If the person will be cared for at home, address safety considerations (see the box below) as well as the caregivers' abilities to meet the person's basic needs, such as maintaining hygiene and other ADLs. Adapt nursing interventions and teaching to the person's stage of Alzheimer's disease. Nurses also promote health in the caregiver; information about caregiver support systems and respite care should be provided.

Assessment

Collect the following data through the health history and physical examination (see Chapter 40). Further focused assessments are described with nursing interventions below.

- *Health history:* family member/caregiver support, living arrangements, ability to carry out ADLs, drug use, work history (e.g. exposure to metals), previous history of multiple strokes, brain injury or brain infection, family history of dementia, sleep pattern, changes in cognition and memory, ability to communicate, changes in behaviour.
- *Physical assessment:* height/weight, orientation, abstract reasoning, mental status.

Nursing diagnoses and interventions

During the early stage of AD, nursing care focuses on helping the person make minor adaptations to his or her environment. As the person becomes progressively unable to manage self-care tasks, more adaptations are required. Equally important, the caregiver needs much support—both physical and psychosocial—as the person becomes increasingly dependent.

Impaired memory

Impaired memory is an appropriate nursing diagnosis in stage 1 AD. At this stage, techniques to help with the memory loss should be included in teaching for both the person and the caregiver.

- Suggest complementary therapies, such as meditation, massage or exercise. *These activities can help reduce stress; stress can aggravate memory loss.*
- Suggest using a calendar, keeping lists of reminders or asking someone else to remind of appointments and events. *Written or verbal reminders are helpful if memory is impaired.*
- Recommend using a medication box labelled with days and times. A *medication box is a good way to remember to take medications.*

NURSING CARE PLAN A person with AD

Arthur and Ruth Joste, both aged 73, have been married for 47 years; he is a retired school teacher and she has been a homemaker. They have four children; two live in the same town and two live out of state. Arthur has noticed that he is having problems remembering friends' names and phone numbers; his wife has been asking him if he is driving in the correct direction when they go shopping.

Mrs Joste has severe osteoarthritis and is unable to lift heavy objects or perform all but light housekeeping tasks. For about 18 months, Mrs Joste has been aware of her husband's progressive cognitive decline, including forgetting current news from last night's TV news; miscalculating bank balances; neglecting his hygiene needs; and confusing their children's and grandchildren's names. The Jostes are referred to a neurologist for evaluation.

ASSESSMENT

Martha Spital, RN, assesses Mr Joste at the neurologist's office. She notes that he is unable to recall his home address without prompting, to name the correct date (although he does know the day of the week), to subtract serial 7s more than twice and to recall two of three objects. He is alert to his surroundings. Mrs Joste states that the problems seem to be getting worse with time and that she has had to 'cover up' mistakes for her husband. Mr Joste seems easily agitated and his wife reports that his sleep habits are 'jumbled'; he has long periods of wakefulness in the night-time hours.

Following a thorough evaluation and diagnostic testing to rule out other possible disorders, the neurologist tells the couple that Mr Joste has probable dementia of the Alzheimer's type. Both have feared this diagnosis; they want to know how they can be sure that Mr Joste has this disease and what they can do to prevent further decline. Both are obviously much saddened and they verbalise their feelings of being overwhelmed. The Jostes intend to remain in their home 'for as long as we can'.

NURSING CARE PLAN A person with AD (continued)

DIAGNOSES

- *Chronic confusion* related to deterioration of brain function and dementia manifested by forgetfulness.
- *Self-care deficits* related to forgetfulness and declining physical abilities, evidenced by poor hygiene.
- *Risk of injury* related to decreased orientation manifested by a decreased awareness of surroundings.
- *Disturbed sleep pattern* related to time disorientation, evidenced by periods of wakefulness.
- *Caregiver role strain* (wife) related to need to care for self and husband manifested by husband's increased need for assistance with ADLs.

PLANNING

Provide education about Alzheimer's disease, evaluate the environment, assess available support and determine needs in order to establish a management plan.

Expected outcomes

- The Joste family becomes aware of the characteristics of Alzheimer's disease and its progression.
- Remain free of injury.
- Navigate home environment with modifications as needed.
- Participate in grooming and hygiene activities with prompting and supervision.
- Obtain a minimum of 7 uninterrupted hours of sleep a night.
- Mrs Joste will participate in a minimum of two out-of-home activities a week.

IMPLEMENTATION

The community nurse, Eric Montane, RN, makes a home visit to evaluate the environment, assess available support and determine needs. He meets two of the Jostes' children, Dawn and Jay, who live in the same community and are willing to participate as much as possible in providing care and modifying the home.

Mr Montane discusses the importance of establishing and maintaining a consistent daily routine. He emphasises the importance of matching activities to Mr Joste's mental abilities to avoid frustration and increased agitation. Mr Montane recommends labelling drawers with their contents, such as Mr Joste's sock drawer. Labelling rooms may be necessary eventually.

Because his inability to comprehend and process information distresses and agitates Mr Joste, Mr Montane teaches the family to modify their communications to fit Mr Joste's cognitive ability, such as using simple, direct statements and directions.

Mr Montane recommends that family members keep background noise to a minimum because this may be a source of confusion.

After assessing the home, Mr Montane makes the following recommendations about safety:

- Remove throw rugs from hallways and tack down any remaining carpets.
- Secure the kitchen, bathroom and workshop cabinets, as well as the controls on the oven and stove.
- Modify the doors so that negotiating locks requires a two-step system of unlocking, such as with a deadbolt and a key.
- Provide extra lighting in dark areas, especially a night light in the bathroom.

Mr Montane explains that Mrs Joste will need assistance with housekeeping as Mr Joste continues to decline. Mr Montane provides referrals to community services, including Meals on Wheels, which can supply a daily meal. He also suggests that the Jostes obtain home care services to provide daily hygiene care. Most of the remaining home maintenance needs can be met with the children's help.

Mr and Mrs Joste and the two children attend the weekly local support group meetings for Alzheimer's disease and related disorders for approximately 3 months; thereafter, Mrs Joste attends with her daughter.

EVALUATION

Six months after the initial home visit and family planning session, Mr Joste:

- Has not had a fall, burn or other injury.
- Has periods of confusion when outside his home, but 90% of the time is oriented to place when at home.
- Has attended several support group meetings until 3 months ago. Currently, his wife attends weekly and a daughter occasionally accompanies her. She has continued to participate in their church and maintains contact with a few friends. She is finding it harder to leave her husband unattended for even a few minutes.
- Is able to clean and dress himself with prompting; he is not able to choose his own clothing. If hygiene articles are 'set up' (e.g. if the toothpaste is placed on the toothbrush), he remembers to perform the hygiene activity. The children have been replacing buttons and zippers with Velcro closures on his clothing.
- Sleeps an average of 6 hours a night with a 30-minute nap in the afternoon; this pattern is consistent with his previous sleep pattern.
- Has been more easily agitated for the past month. He wanders from room to room, apparently looking for something. These behaviours are worse in the evening and on cloudy days. Mrs Joste acknowledges her progressive inability to care for her husband.

CRITICAL THINKING IN THE NURSING PROCESS

1. Develop a tool to teach safety needs for the person and the family with Alzheimer's disease.
2. List five interventions to decrease agitation in cognitively impaired older adults; give three additional examples of activities suited to an older adult with AD who has osteoarthritis.

REFLECTION ON THE NURSING PROCESS

1. Outline what you have learned from this case study that you will apply to your future nursing practice.
2. Which education strategies could you use to ensure a person with AD receives adequate nutrition?

MEETING INDIVIDUALISED NEEDS **Safety interventions for the person with AD**

Decreasing the risk of falls

- Assess usual environment for hazards, such as throw rugs, electrical cords and slick floors.
- Observe areas of special concern, such as the bathroom, kitchen and stairs, and modify as needed; for example, provide skid-proof surfaces and mark stairs to show depth.
- Evaluate muscle strength and gait; consult a physiotherapist to plan exercises to increase strength and balance.
- Check shoes for fit and support.
- Enquire about alcohol use and medications that affect balance or cause mobility problems; for example, antihypertensive agents can cause dizziness with position changes.
- Use night lights and increase daytime lighting in dark areas such as hallways.
- Keep traffic areas free from clutter.

Decreasing the injuries related to cognitive impairments

- Secure items that may be mistakenly ingested, such as cleaning preparations and house plants.
- Modify potentially unsafe areas, such as unenclosed porches.
- Provide double-lock systems to outside doors and doors to rooms that are off limits.
- Protect from fire hazards; for example, make matches and cigarettes inaccessible.
- Fence the yard with a locked gate to prevent wandering.
- Modify the controls on the oven and stove.
- Adjust the water heater to a safe temperature.

General safety considerations

- Plan a calling system for emergencies; have children call at about the same time every day as a check.
- Ensure that the cognitively impaired family member has no access in the home to objects such as knives and guns.

- If safety is a concern (such as turning on the stove and forgetting it), suggest using alternatives such as a microwave. Program emergency numbers into the telephone. Ask the person to consider a personal emergency alarm system. *These measures can increase safety.*
- Suggest using cues, such as an alarm on a watch or a mobile phone, to trigger actions at designated times. *Cues are often helpful when memory loss is a problem.*

CONSIDERATION FOR PRACTICE

It may be necessary for the caregiver to arrange for the person's medications to be supplied by the pharmacy in a prearranged pack such as a Webster pack.

Chronic confusion

People with AD often have memory deficits that make functioning in a non-structured environment difficult. Many of the nursing interventions for this diagnosis need to be modified over time as the person continues to lose cognitive function.

- Label rooms, drawers and other items as needed. *Visual cues promote the highest possible degree of independence for the person.*
- Remove potential hazards (such as sharp knives or potentially harmful liquids or chemicals) from the environment. *Ensuring safety is a critical factor in providing care.*
- Keep environmental stimuli to a minimum: decrease noise levels; speak in a calm, low voice; and take an unhurried approach. *Minimising sensory input and maintaining a calm manner may decrease anxiety.*
- Begin each interaction by identifying yourself and calling the person by name. See Box 43.1 for other communication techniques. *These techniques provide information for the person with memory loss.*
- Limit questions to those that require a simple 'yes' or 'no' response. Questions need to be appropriate to the person's ability as decision-making and verbal skills decline.
- Orient to the environment, person and time as able, and place large, easy-to-read calendars and clocks in the

BOX 43.1 Communicating with the person with AD

- Face the person and talk directly to them; call the person by name.
- When first approaching the person, identify yourself.
- Use simple sentences and words with few syllables.
- Speak in a calm, low voice.
- Ask one question at a time. Use questions that require only a 'yes' or 'no' response.
- Keep non-verbal communication relaxed and parallel to the verbal communication.
- Avoid giving the impression of being in a hurry; try to have a relaxed approach.
- Observe for anxiety—wringing hands, pacing, darting eye movements—and alter your approach to decrease anxiety.
- Avoid arguing with people; do not insist on orienting person to reality; the person's point of reference may not be based in reality.
- Give plenty of time for the person with AD to process what you are trying to say; do not expect people to perform skills beyond their abilities.
- Repeat explanations in simple terms.

person's line of vision. Make references to the season or day of the week when conversing with the person. Orient the person according to their own level of ability. *Orienting to precise time may not be possible in the later stages of AD.*
- Provide boundaries by placing red or yellow tape on the floor. *Boundaries help the person stay within safe areas.*

CONSIDERATION FOR PRACTICE
Red and yellow are more easily seen by older adults.

- Provide continuity in nursing staff. *This not only promotes consistency of care for the person but also allows the nurse to determine more accurately changes in the person's condition.*
- Repeat explanations simply and as needed to decrease anxiety. *Loss of short-term memory leads to loss of a point of reference; eventually, people with AD think they are experiencing everything for the first time.*

Anxiety

Managing the AD person's behaviours associated with anxiety, restlessness and confusion is a major challenge confronting nurses and caregivers. Frequently, people are relatively calm in the morning hours, only to experience increasing periods of agitation in the afternoon and evening hours. The person with AD may even wake from the night's sleep with confusion, fearfulness or panic attacks.
- Monitor for early behaviours of fatigue and agitation. *Early assessment of problems results in prompt intervention to promote rest or to remove the person from the situation causing anxiety.*
- Remove from situations that are causing increased anxiety, such as noisy activities involving large groups. *High-stimulus situations may increase anxious feelings and agitation.*
- Keep daily routine as consistent as possible. *Providing a structured day enhances feelings of familiarity and decreases stress.*
- Schedule rest periods or quiet times throughout the day. *Fatigue contributes to anxiety and lowers the ability to tolerate stress.*
- Provide quiet activities, such as listening to music, in the afternoon or early evening. *Quiet activities may help decrease sundowning.*
- If confusion and agitation persist or escalate, assess for physical causes such as decreased oxygenation, infections, fatigue, constipation and electrolyte imbalance. *Physical factors can increase agitation in people with AD.*
- Use therapeutic touch or gentle hand massage. *These activities induce relaxation and have a calming effect.*

Hopelessness

As the person and their family recognise the effect of AD on their lives, they may feel a sense of hopelessness. They may not have the coping skills to deal effectively with the diagnosis and anticipated problems. The increasingly degenerative, irreversible nature of the disorder tends to diminish hope; only the ability to adapt to the many problems can restore it.
- Assess the person's and family's response to the diagnosis and understanding of AD; encourage expression of feelings. *Understanding the person/family's perspective enables the nurse to dispel myths about AD.*
- Provide realistic information about the disorder; provide information at the person/family's level of understanding. *The person and their family may need to have separate sessions. Factual information provides a foundation for decision making.*
- Avoid criticising or judging expressed feelings. *An environment accepting of the expression of real feelings promotes both further expression of feelings and willingness to discuss other issues.*
- Support positive family bonds and enhance communication between family members; promote mutual positive regard. *Strong family relationships can provide direction for living and convey willingness to share the burden.*
- Encourage the person to make as many decisions as possible. *Self-determination enhances a feeling of control over a situation and may give a sense of hope.*
- Encourage the person and their family to seek spiritual guidance that previously inspired hope. *The person's religious affiliation is a legitimate support system. Belief in a higher being can inspire hope beyond present circumstances.*

Caregiver role strain

Most caregivers of people with AD are spouses or other family members. Because AD is a chronic and eventually debilitating disorder, caregivers may feel overwhelmed by their responsibilities. The caregiving spouse faces not only the responsibility for the person's multiple physical demands but also economic and psychosocial stressors. An area that must be discussed is the ability and safety of the person in driving an automobile. Although it may be necessary, the loss of independence represented by the loss of the ability to drive may further trigger anxiety and anger. Fear of the future, loss of income, loss of companionship and a mate—combined with fatigue—make the caregiver vulnerable. Caregivers may become physically and mentally exhausted and socially isolated because of the overwhelming responsibilities of providing total care to the incapacitated family member.
- Teach the caregivers self-care techniques, such as taking rest periods and avoiding fatigue. *Fatigue adds to stress and potentially leads to poor decision making.*
- Have the caregivers list and regularly take part in physical activities they enjoy, such as walking or swimming. *Regular physical exercise decreases stress.*
- Refer the caregivers to local AD support groups. Suggest books pertinent to the subject. *Explicit suggestions in locating support systems and providing specific information promote coping.*

- Refer the caregivers to Meals on Wheels, home care, respite care and other community services. *Community agencies can relieve some of the daily care burdens, thus providing time for other activities. Programs that support caregivers have been shown to delay nursing home placement.*
- Ensure the family knows that hospice care is available during the end stages of AD. *Hospice services can support the family during this difficult time*.

Community-based care

Teaching for people and families initially centres on explaining the disorder and exploring available support systems. Anticipate the need to re-explain the disorder and its consequences because people and families may be in shock or denial during the initial period of the disease.

In addition to explaining the anticipated changes with AD, suggest practical solutions to identified problems. It is important to evaluate both the person and caregivers; interventions must be appropriate for the family's situation and resources. Maintaining the least restrictive environment that promotes safety for the person is a major goal of teaching. Using memory cues, such as labelling drawers to indicate the specific types of clothing and labelling rooms, can help orient the person and foster independence. Consistency in the environment and daily routine is an essential part of care. Emphasising realistic expectations means adjusting care and communication techniques to the person's level of ability.

Address the following topics for home care of the person and for the caregiver:

- Support groups and peer counselling are helpful in handling caregiver stress.
- A person with AD who is confused or agitated is not comfortable and is usually frightened.
- Plan care that matches the person's level of coping, using a consistent routine.
- Provide regular rest periods to decrease the person's stress and fatigue. (These do not increase night-time wandering.)
- Plan care for the caregiver. Periodic adult day care or respite care during the initial stages, with plans for increasing assistance to meet the person's daily needs as the disease progresses, may be sufficient. Referrals to the appropriate agency for long-term care, including skilled nursing facilities, may be indicated. Family members may need help adjusting to the idea of extended care but may be relieved to relinquish the physical care needs.

THE PERSON WITH MULTIPLE SCLEROSIS

Multiple sclerosis (MS) is a chronic demyelinating neurological disease of the CNS (brain, optic nerves and spinal cord), associated with an abnormal immune response to an environmental factor. The manifestations of MS vary according to the area of the nervous system affected. The initial onset may be followed by a total remission, making diagnosis difficult. In about 60% of people, MS is characterised by periods of exacerbation, when manifestations are highly pronounced, followed by periods of remission, when manifestations are not obvious. The end result, however, is progression of the disease with increasing loss of function.

Incidence and prevalence

The onset of MS is usually between 20 and 40 years of age, with three times as many women as men being diagnosed. MS is the most prevalent CNS demyelinating disorder and is a leading cause of neurological disability in young adults. MS is more common in Caucasians, especially those of northern European ancestry; however, MS does occur in people of African, Asian and Hispanic descent. A definite genetic factor has not been established but studies suggest that genetic factors may make some individuals more susceptible than others (MS Australia, 2015).

Pathophysiology

MS is believed to occur as a result of an autoimmune response to a prior viral infection in a genetically susceptible person. The infection, which is thought to occur early in life, activates T cells. T cells usually move in and out of the CNS across the blood–brain barrier but, for an unknown reason, they remain in the CNS in people with MS. The T cells facilitate infiltration by other leucocytes and an inflammatory process follows. Inflammation destroys myelin and oligodendrocytes (myelin-producing cells), leading to axon dysfunction.

Myelin sheaths are fatty, segmented wrappings that normally protect and insulate nerve fibres and increase the speed of transmission of nerve impulses. In multiple sclerosis, these myelin sheaths of the white matter of the spinal cord, brain and optic nerve are destroyed in patches, called *plaques*, along the axon (see the following 'Pathophysiology illustrated' feature). The demyelination of nerve fibres slows and distorts the conduction of nerve impulses and sometimes results in the total absence of impulse transmission. The neurons usually affected by MS are located in the spinal cord, brainstem, cerebral and cerebellar areas, and the optic nerve.

Both plaques and diffuse lesions form as demyelinating lesions. Plaques typically are scattered through the white matter of the CNS, although they may extend into adjacent grey matter. Early manifestations are the result of inflammatory oedema in and around the plaque and partial demyelination. These manifestations typically disappear within weeks after the initial episode. With progression of the disease, the demyelination and plaque formation result in scarring of glia (*gliosis*) and degeneration of axons. Continued loss of function leads to permanent disability, usually over about 20 years.

FAST FACTS

- Approximately 23 000 people in Australia have MS; the incidence is 2.5 million worldwide.
- Females are affected three times as often as males, and the incidence is highest in young adults under 55 years old.
- The disease occurs more commonly in temperate climates. This association is established by approximately age 15, and moving to or from a temperate climate after that age does not change it. In Australia, there is a significantly higher incidence of MS in Tasmania than in mainland Australia. No significant increase of disease incidence is noted in Indigenous Australians.

Sources: MS Australia (2015); Grossman & Porth (2013).

There are four classifications of MS: relapsing–remitting, primary progressive, secondary progressive and progressive–relapsing (see Box 43.2). Most people with MS present with the relapsing–remitting type.

Various stressors have been suggested as triggers for MS. These stressors include febrile states, pregnancy, extreme physical exertion and fatigue. These precipitating factors can also cause a relapse of the manifestations during the course of the disease.

Manifestations

The manifestations of MS vary according to the areas destroyed by demyelination and the affected body system (see the 'Multisystem effects of MS' feature below). Fatigue is one of the most disabling manifestations and affects almost all people with MS. The manifestations, categorised by the established syndromes of MS, are listed in the box below.

Brief attacks of manifestations are described as short lived or paroxysmal. Short-lived attacks of neurological deficits indicate the appearance or worsening of manifestations. Conditions that cause short-lived attacks include: (1) minor increases in body temperature or serum calcium concentrations (both increase the leakage of current through demyelinated neurons); and (2) functional demands that exceed conduction capacity. Paroxysmal attacks are sensory or motor manifestations that occur abruptly and last for only seconds or minutes; the manifestations are paraesthesias, dysarthria and ataxia, and tonic head turning. Paroxysmal attacks, which may occur many times a day, result from the direct transmission of nerve impulses between adjacent demyelinated axons.

BOX 43.2 Classifications of multiple sclerosis

Relapsing–remitting: the most common clinical course of MS, characterised by exacerbations (acute attacks) with either full recovery or partial recovery with disability.

Primary progressive: steady worsening of disease from the onset with occasional minor recovery.

Secondary progressive: begins as with relapsing–remitting, but the disease steadily becomes worse between exacerbations.

Progressive–relapsing: this rare form continues to progress from the onset but also has exacerbations.

MANIFESTATIONS Multiple sclerosis

MIXED OR GENERALISED TYPE (50% OF CASES)

- Visual deficits, with visual blurring, fogginess or haziness; impaired colour perception, decreased central visual acuity, area of diminished vision in the visual fields, acquired colour-vision deficit (especially to red and green) and an altered pupillary reaction to light.
- Brainstem lesions (cranial nerves III to XII) with nystagmus, dysarthria, deafness, vertigo, vomiting, tinnitus, facial weakness, decreased sensation, diplopia and eye pain; and cognitive dysfunctions involving concentration, short-term memory, word finding and planning.
- Mood alterations are manifested as depression more often than euphoria.

SPINAL TYPE (25% OF CASES)

- Weakness and/or numbness in one or both extremities (most often the legs).
- Upper motor neuron involvement is manifested by stiffness, slowness, weakness (spastic paresis).
- Bladder dysfunctions include urgency, hesitancy and incontinence.
- Bowel dysfunction is most often seen as constipation.
- Neurogenic impotence is noted.

CEREBELLAR TYPE (5% OF CASES)

- Manifestations of nystagmus, ataxia and hyptonia.

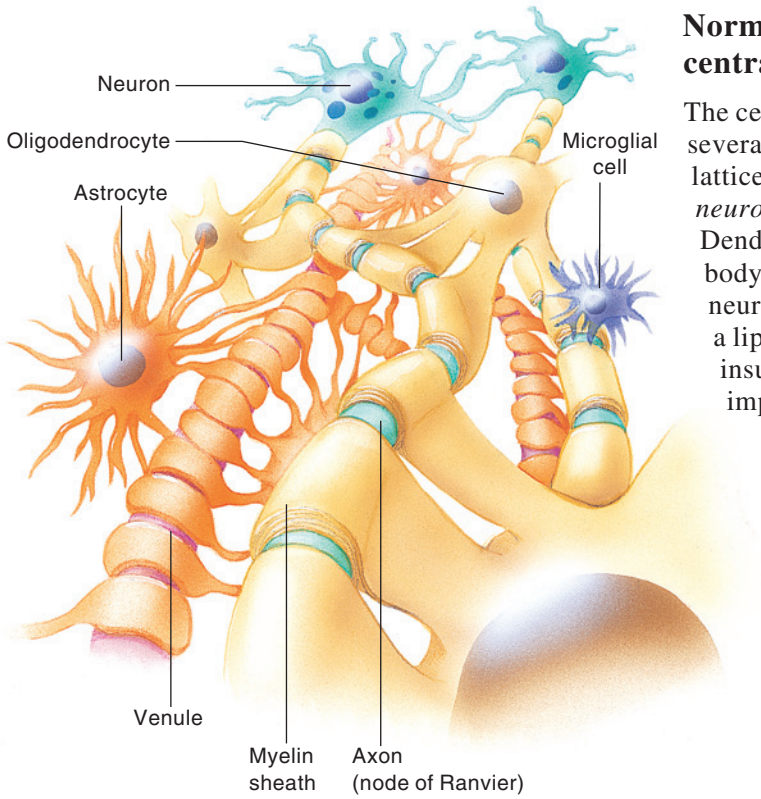
AMAUROTIC FORM (5% OF CASES)

- Blindness

INTERPROFESSIONAL CARE

Management of the person with MS varies according to the severity of the manifestations. The focus is on retaining the optimal level of functioning possible, given the degree of disability. Rehabilitation—physical, occupational/vocational and psychosocial—is a cornerstone of an interprofessional approach to treatment. During exacerbations, the focus of interventions shifts to controlling manifestations and quickly returning to remission.

Multiple sclerosis



Normal anatomy of the central nervous system

The central nervous system (CNS) is composed of several cell types arranged in a dense, interconnected lattice. The basic functional cell of the CNS is the *neuron*, which transmits electrochemical impulses. Dendrites, thin projections extending from the neuron body, receive impulses that are passed down the neuronal axon for transmission to other cells. Myelin, a lipid-protein substance, surrounds the axons, insulating them and speeding nerve impulse transmission.

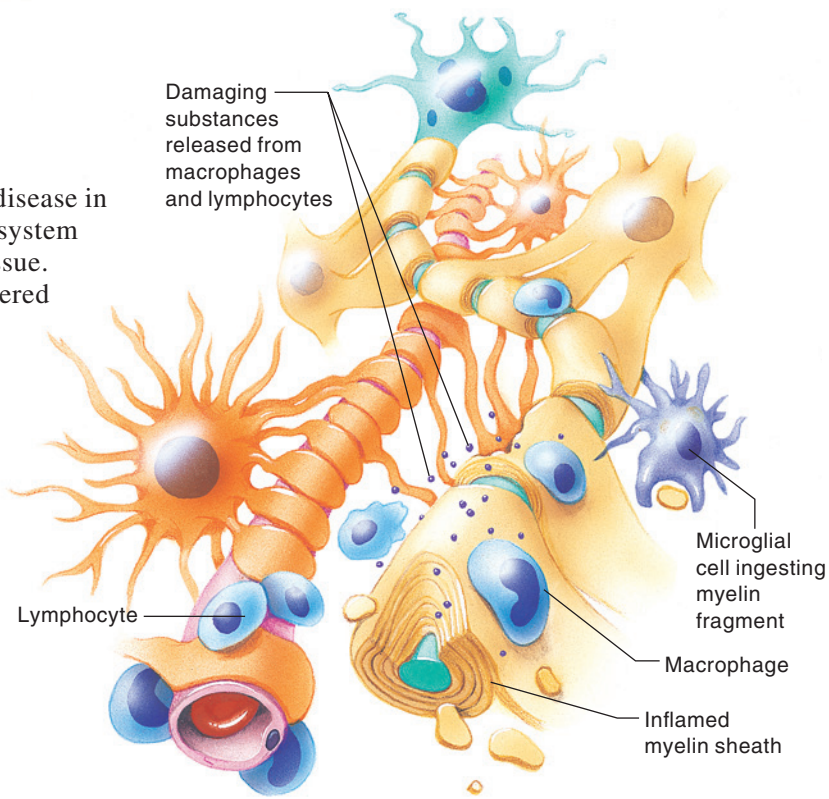
Neurons are surrounded by a network of cells:

- *Astrocytes* support neurons and connnect them to surrounding capillaries and venules.
- *Microglia* are motile phagocytic cells.
- *Oligodendrocytes* wrap concentric layers of myelin around nearby axons.

Acute attack

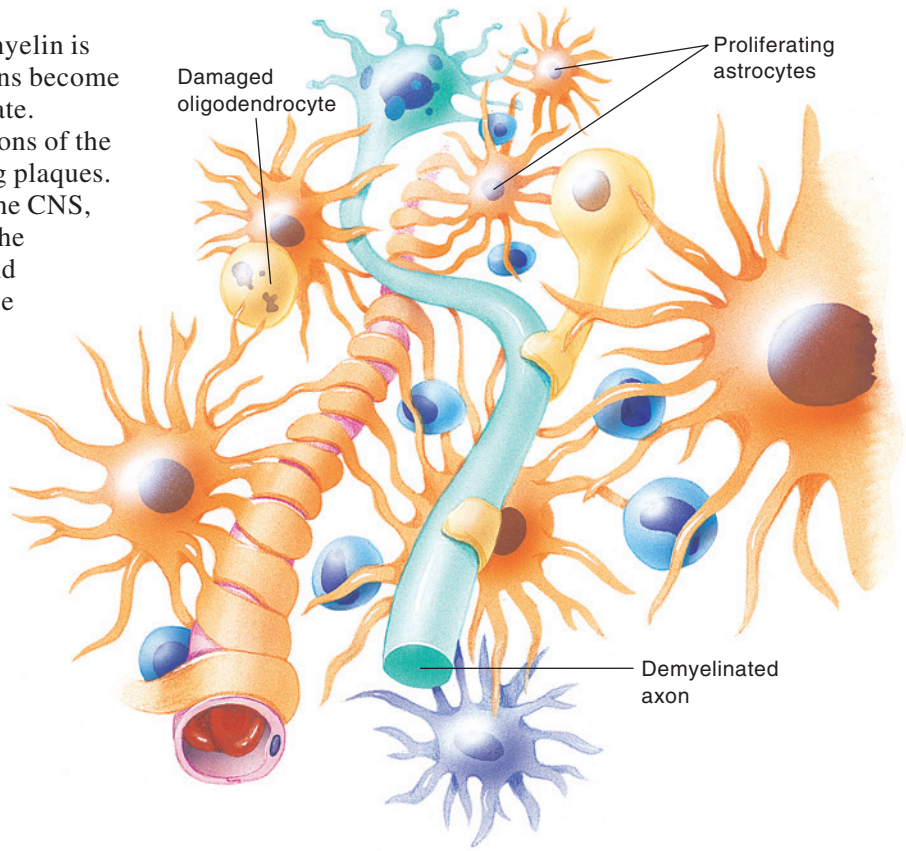
Multiple sclerosis (MS) is a demyelinating disease in which axonal myelin in the central nervous system is eroded, destroyed and replaced by scar tissue.

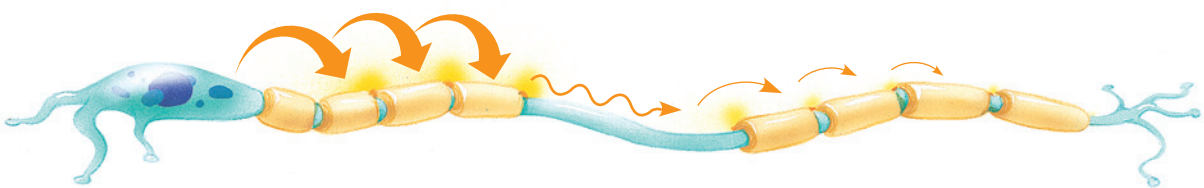
An autoimmune process apparently triggered by genetic and environmental factors is believed to cause inflammation of venules in the CNS. This disrupts the blood–brain barrier, allowing lymphocytes to enter CNS tissue. These lymphocytes proliferate and produce IgG, an antibody that attacks and damages myelin and causes the release of inflammatory chemicals and oedema. As the inflammation subsides, the myelin regenerates and manifestations of the disease subside.



Chronic lesion

After repeated inflammatory attacks, myelin is irreparably damaged. Segments of axons become totally demyelinated and may degenerate. Astrocytes proliferate in damaged regions of the CNS (a process called *gliosis*), forming plaques. The plaques are scattered throughout the CNS, appearing as grey or pinkish lesions. The relapsing-remitting character of MS and the scattered areas of damage within the CNS account for the variable nature of MS manifestations.

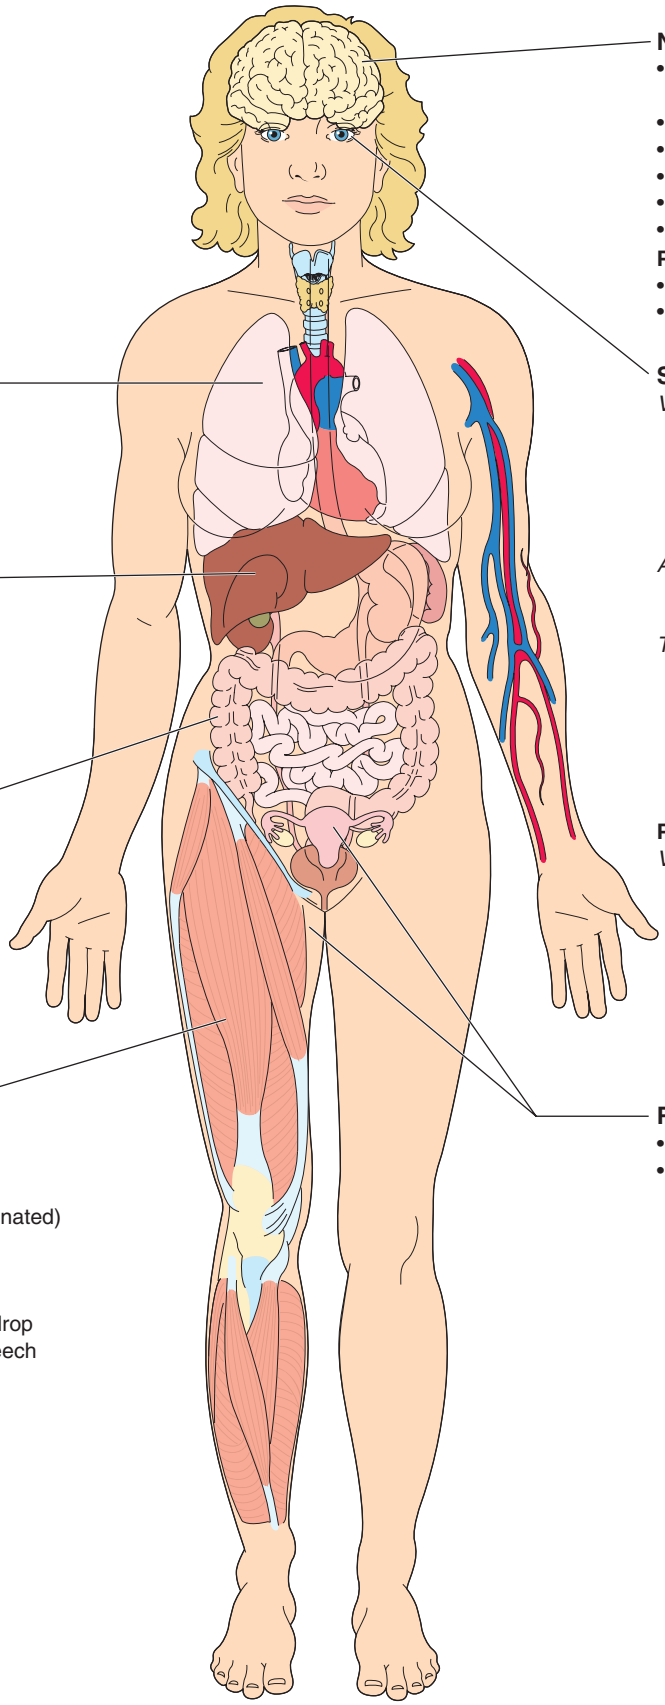




Abnormal nerve impulse transmission

In an undamaged neuron, nerve impulses travel down the axon by 'leaping' from one node of Ranvier to the next, thus greatly increasing the speed of impulse transmission. When nerve impulses travel down an axon damaged by MS, they are significantly slowed and weakened as they pass across the surface of demyelinated areas. Impulses may be blocked entirely when axons degenerate. The weakening or interruption of the transmission of nerve impulses and plaque formation within the CNS cause the manifestations of MS, including extremity weakness, paraesthesias, visual disturbances, bladder dysfunction and vertigo.

MULTISYSTEM EFFECTS OF MULTIPLE SCLEROSIS



Neurological
- Emotional lability (euphoria or depression)
- Forgetfulness
- Apathy
- Scanning speech
- Impaired judgment
- Irritability

Potential complications
- Convulsive seizures
- Dementia

Sensory

Visual
- Blurred vision
- Diplopia
- Nystagmus
- Visual field defects (blind spots)
- Eye pain

Auditory
- Vertigo
- Nausea

Tactile (especially hands or legs)
- Numbness
- Paraesthesias (tingling, burning sensation)
- Diminished sense of temperature
- Pain with spasms
- Loss of proprioception

Potential complication

Visual
- Blindness

Respiratory
- Diminished cough reflex

Potential complication
- Respiratory infections

Urinary
- Hesitancy
- Frequency
- Retention
- Reflex bladder emptying

Potential complications
- Recurring UTIs
- Incontinence

Gastrointestinal

Oral/oesophageal
- Difficulty chewing
- Dysphagia

Upper/lower GI
- Decreased or absent sphincter control
- Bowel incontinence
- Constipation

Musculoskeletal
- Fatigue
- Limb weakness
- Ataxic movements (shaky, irregular, uncoordinated)
- Intention tremors
- Spasticity
- Muscular atrophy
- Dragging of foot and foot drop
- Dysarthria with slurred speech

Reproductive
- Impotence (male)
- Loss of genital sensation

Diagnosis

Diagnosis of MS is challenging because the disease does not present uniformly. A diagnosis requires that the person has one of the following: (1) two or more exacerbations separated by 1 month or more and lasting more than 24 hours, followed by recovery; (2) a history of repeated exacerbations and remissions with or without complete recovery, followed by progressively more severe manifestations lasting for 6 months or more; or (3) slowly increasing manifestations for at least 6 months.

Diagnostic tests vary with the presenting complaints. Magnetic resonance imaging (MRI) with findings of lesions is the most definitive test available; however, it is only one of several laboratory and diagnostic tests that may be performed when establishing the diagnosis. Other tests (described in Chapter 40) include:

- Cerebrospinal fluid (CSF) analysis reveals an increased number of T lymphocytes that are reactive with antigens, indicating the presence of an immune response in the person (but is not specific to MS). Eighty per cent of people with MS have elevated levels of immunoglobulin G (IgG) in the CSF.
- Computed tomography (CT) scan of the brain shows atrophy and white matter lesions. In about 25% of people with MS, enlarged ventricles are visible on CT.
- Positron emission tomography (PET) scan measures brain activity. In people with MS the scan reveals areas with changes in glucose metabolism.
- Evoked response testing of visual, auditory or somatosensory impulses may show delayed conduction.

Medications

Medications slow the progression of MS and decrease the number of attacks. (See the 'Medication administration' box below.) Medications are used for a variety of reasons, including to treat manifestations, modify the course of the disease or interrupt the progression of the disease.

The medications used during an exacerbation are aimed at decreasing inflammation to inhibit manifestations and induce remission. Frequently, a combination of adrenal corticosteroid hormone (ACTH) and glucocorticoids is used to decrease inflammation and suppress the immune system. Immunosuppressive agents, including azathioprine (Imuran) and cyclophosphamide (Endoxan), are also used. Interferon and glatiramer acetate are used to reduce exacerbations in people with relapsing–remitting MS. Interferon alpha, beta and gamma (Roferon-A, Intron A, Wellferon, Imukin, Avonex or Rebif, Betaferon, Actimmune) enhance immune function, while glatiramer acetate (Copaxone) stimulates parts of the myelin basic protein to reduce the relapse rate of MS. Both drugs are given by injection and are usually well tolerated.

Other medications treat the manifestations of MS. Anticholinergics are administered for bladder spasticity; cholinergics are given if the person has a problem with urinary retention related to flaccid bladder. Depression is treated with antidepressant drugs.

Surgery

Surgery may be indicated for people who experience severe spasticity and deformity. However, physical therapy can prevent most severe problems. Foot drop from severe plantar flexion can be relieved with an Achilles tenotomy, a surgical procedure in which the Achilles tendon is transected.

Nutrition and fluids

Several diets involving manipulation of fats are currently under investigation. People with MS may be overweight because of their inability to ambulate; depression may contribute to the problem because people who are depressed tend to eat more. Ideally, the person should maintain a weight as close as possible to that recommended for the person's height and body type.

As MS progresses, the person's ability to prepare food and eat is compromised. Changes in muscle tone, tremor, weakness and ataxia all contribute to nutritional problems. Dysphagia also is a common problem. The diet must be adapted to accommodate changes in the person's ability to chew and swallow.

Rehabilitation

Physical and rehabilitative therapies are tailored to the person's level of functioning. The long-term goal is to enable the person to retain as much independence as possible. One major intervention is to maintain and increase existing muscle strength.

Spasticity is managed with stretching exercises, gait training and braces, splints or other assistive devices. To maintain balance, the person is encouraged to widen the base of support by standing with the feet slightly further apart. Walkers and canes may be weighted to provide support and balance for the ataxic person.

An interprofessional approach to rehabilitation will provide supportive services: speech therapy for problems with phonation, occupational therapy to maintain strength in the upper extremities and carry out ADLs, and occupational counselling. Referrals to a urologist are indicated for problems with urinary incontinence, urinary tract infections, retention and impotence. Consultation with a physiotherapist may be needed if the person develops chronic respiratory infections due to the inability to cough, move secretions or breathe deeply, especially with increased debilitation.

Nursing care

Because the disease most often affects young adults in the prime of life, the psychosocial and economic effect can be devastating. People with MS have to make adjustments to body image changes while simultaneously adapting to the altered relationships and decreased earnings usually encountered with the disease. A once-healthy spouse becomes wheelchair bound; a person once independent may eventually become dependent for even the most basic ADLs. The unpredictable course of MS is a challenge for long-term planning. A nursing care plan for the person with MS is given below.

- Suggest performing tasks in the morning hours. *Biorhythm studies indicate that people usually have greater energy reserves in the morning hours and diminished reserves in the afternoon.*

MEDICATION ADMINISTRATION The person with multiple sclerosis

IMMUNOMODULATORS

Interferon beta-1a (Avonex)
Interferon beta-1b (Betaferon)
Glatiramer acetate (Copaxone, Copolymer-1)

Interferon beta-1a, interferon beta-1b and glatiramer acetate are administered to people with relapsing–remitting MS to prolong the time of onset to disability. Their use is based on the assumption that MS is an immunologically mediated disease. Interferon beta-1b produces a decrease in the MS lesions in some people. Some people, however, develop a decrease in the absolute neutrophil count and increases in the levels of liver enzymes. Anxiety, confusion and depression with suicidal tendencies also have been reported. Other adverse reactions include pain, inflammation, hypersensitivity at the injection site and generalised flu-like manifestations. Some women experience menstrual disorders. Pregnant women should not take these medications.

Nursing responsibilities

- Assess baseline parameters to evaluate drug side effects: psychological profile, liver function tests and FBC with differential.
- Monitor FBC and liver function tests every 3 months or as prescribed.
- Assess injection site and report ulceration promptly. (Pain and redness are common reactions.)
- Evaluate the person's baseline neurological, sensory and motor function. Monitor changes in condition and function.
- Report if the person is pregnant or breastfeeding.

Health education for the person and family

- These drugs may cause depression and thoughts of suicide; report these feelings immediately to the healthcare provider.
- Administer medication within 3 hours of reconstitution. Rotate injection sites and avoid any areas that are red or show other skin reactions.
- Seek follow-up care to monitor neurological changes, FBC and liver function.
- Avoid prolonged exposure to sunlight.

ADRENAL CORTICOSTEROIDS

Adrenocorticotropic hormone (ACTH) (Acthar)
Prednisone (Deltasone, Meticorten, Predsone, Prednisolone)
Methylprednisolone (Depo-Medrol, Solu-Medrol)

Adrenal corticosteroids are used both to sustain a remission and to treat exacerbations of MS. ACTH is usually given to induce a remission; it is administered intravenously for 1 week and may be followed by oral prednisone therapy. Another protocol involves administering ACTH intravenously for 3 days followed by intramuscular injections every 12 hours for 1 week (Hickey, 2013). The drugs are given to suppress the immune system, which is implicated in the aetiology of MS. If the drug is used long term the usual steroid precautions are indicated, such as monitoring for glucose intolerance, osteoporosis and cataract formation. The drugs are used with caution in pregnant and lactating women.

MUSCLE RELAXANTS

Baclofen (Lioresal)
Dantrolene (Dantrium)
Diazepam (Valium)

Muscle relaxants are given to people with MS to relieve muscle spasms. Baclofen and diazepam act by suppressing CNS reflexes that regulate muscle activity; neither drug affects muscle strength. Baclofen therapy should be discontinued over 1 to 2 weeks; sudden withdrawal may cause seizures and paranoid ideation. In contrast to diazepam and baclofen, dantrolene acts directly on skeletal muscles and may affect muscle strength. Dantrolene may cause hepatotoxicity and should not be administered when hepatitis or cirrhosis is present.

Nursing responsibilities

- Evaluate baseline muscle strength and spasticity, range of movement and dexterity.
- Maintain safety or fall precautions; dizziness and drowsiness are common side effects.
- For the person taking dantrolene, monitor liver function tests (enzymes and bilirubin) for signs of hepatotoxicity.

Health education for the person and family

- These drugs may cause sedative effects. Take appropriate safety measures (e.g. avoid driving).
- Avoid CNS depressants (antihistamines, alcohol); they can increase the sedative effects of the medication.
- Continue follow-up care; if you are taking dantrolene, for example, liver function will need to be monitored.
- If you are taking baclofen, do not suddenly stop the medication.
- Increase fibre and fluids in the diet to prevent constipation.
- Change positions slowly to minimise dizziness and other effects of orthostatic hypotension.

IMMUNOSUPPRESSANTS

Azathioprine (Imuran)
Cyclophosphamide (Endoxan)

Immunosuppressants are given to people with MS because of the autoimmune component of the disease. Both medications can cause bone marrow suppression and increase the risk of cancer. Azathioprine may produce hepatitis. Toxic effects of cyclophosphamide include haemorrhagic cystitis, sterility and stomatitis.

Nursing responsibilities

- Monitor baseline parameters: FBC with platelet count and differential, urinalysis, liver function tests, hepatitis profile.
- Assess for anaemia: fatigue, lethargy, pallor.
- Watch for bleeding.
- Protect against and observe for subtle signs of infection.

Health education for the person and family

- Report infection, bleeding and anaemia immediately.
- Drink at least 2 L of fluid a day and observe urine for blood.
- Report jaundice immediately.
- Check oral cavity daily for changes or ulcers.
- Avoid becoming pregnant while taking these drugs.
- Obtain follow-up care, including frequent blood tests.

- Advise to avoid temperature extremes, such as hot showers or exposure to cold. *Maintaining a relatively constant body temperature may avoid exacerbation of the disorder. Heat can delay impulse transmission across demyelinated nerves, which contributes to fatigue.*
- Refer to the appropriate professionals to manage fatigue: stress management groups, support groups, occupational or physical therapist, as indicated. *Support groups and therapy can facilitate self-management and improve coping.*

Health promotion

Following an overview of the disorder, the person needs to understand how to prevent fatigue and exacerbations. Advise the person to avoid stress, extremes of cold and heat, high humidity, physical overexertion and infections. Because pregnancy can exacerbate manifestations, counselling about this risk is indicated. Also, address preventive measures to avoid risk of respiratory and urinary tract infections.

Assessment

Collect the following data through the health history and physical examination (see Chapter 40):

- *Health history:* history of childhood viral illnesses, geographical residence when a child, exposure to physical or emotional stressors (pregnancy/delivery, extremes of heat), medications, symptom onset, severity of manifestations.
- *Physical assessment:* affect, mood, speech, eye movements, gait, tremors, vision and hearing, reflexes, muscle strength and movement, sensation.

Nursing diagnoses and interventions

Interventions for the person with MS vary with the acuity of exacerbations and the presenting problems. Many nursing diagnoses relate to the inability to perform ADLs—for example, *Self-care deficit* and *Impaired home maintenance*. Others reflect problems with musculoskeletal changes or altered nerve conduction—for example, *Impaired physical mobility*, *Ineffective breathing pattern*, *Constipation* and *Functional urinary incontinence*. The nursing diagnoses discussed in this section are *Fatigue* and *Self-care deficit*.

Fatigue

Fatigue is an overwhelming, sustained sense of exhaustion and decreased capacity for physical and mental work at the usual level. Fatigue affects every aspect of the life of a person with ms: the ability to remain independent and perform self-care, sexual function, mobility, airway clearance and, ultimately, self-concept and coping. A great deal of teaching is needed to help the person and their family understand fatigue and how to adapt. People and their families need assistance managing fatigue in a society in which energy is highly valued.

- Assess degree of fatigue and identify contributing factors. *Fatigue is a subjective experience that needs to be evaluated thoroughly before planning can begin.*
- Arrange daily activities to include rest periods. *Rest is essential to manage feelings of fatigue; periods of relaxation may help replenish energy reserves.*

CONSIDERATION FOR PRACTICE

It is important to remember that the fatigue from chronic illnesses such as MS is very different from being 'tired', and that rest and sleep may not result in improvement.

- Ask the person to consider which activities are really necessary and to set priorities. *Prioritising activities promotes independence and self-control.*

Self-care deficit

People with MS may need assistance with bathing, toileting, dressing, grooming and feeding. The help needed can range from minimal guidance to total dependence. The person's ability to perform self-care activities is the gauge by which family members and caregivers need to adjust assistance. Self-care encompasses both the decisions about care and the provision of care; most people are capable of making decisions even after physical limitations prevent physical self-care. The need to maintain self-determination cannot be overemphasised and must be incorporated into each intervention. As the person with MS ages, there may be even more need for teaching to provide self-care.

- Assess the extent of the person's self-care deficit; refer to other health team members for assessment as appropriate. For example, refer to a speech pathologist to assess swallowing and gag reflex, if indicated. *An accurate assessment is crucial to individualising interventions.*
- Suggest adaptive devices, such as arm or wrist braces, as needed. *Meeting hygiene needs and feeding self are essential for positive self-concept, self-esteem and socialisation.*
- Teach to use assistive devices, such as plate guards; to modify consistency of foods; and to eat when energy level is better. If unable to buy and prepare meals, provide referral to Meals on Wheels. *Proper nutrition is basic to health; adapting utensils and foods can facilitate meeting nutritional needs.*
- Teach interventions related to altered bowel and bladder function: fluid intake of at least 2 L daily, bowel routine as indicated to prevent constipation, self-catheterisation skills as necessary. *Maintaining optimal bowel and bladder function decreases the risk of urinary tract infection and bowel impaction.*

Community-based care

The inconsistent and erratic nature of MS can make teaching for self-care difficult. Initial teaching focuses on a realistic explanation of MS. Referral to a support group early in the course of the disease is indicated. Social support can make a positive difference to a person's ability to cope with MS. Address the following topics in preparing the person for home care:

- various treatment options and their side effects
- information about medications, particularly steroid use, and about possible interactions with prescription or over-the-counter (OTC) medications

NURSING CARE PLAN A person with MS

George McMurphy, a 45 year old from Gosford, NSW, was diagnosed with MS approximately 5 years ago. He states that he probably had mild symptoms as long ago as 10 years. He works as a manager for a large grocery store chain near his home. He lives at home with his wife and two children, aged 12 and 15. Recently, Mr McMurphy has had increasing problems with urinary incontinence, lack of energy, weakness, extreme fatigue and altered mobility from spasticity in his leg muscles. He also has a fever, chest congestion and a cough productive of green sputum. He is admitted to the hospital for evaluation and treatment of pneumonia and exacerbation of his MS.

ASSESSMENT

Denise Miller, RN, primary care nurse, is assigned to care for Mr McMurphy. His main complaint is the inability to 'bring up all this sputum; I feel rotten from being so congested. I hate not being able to get to work and for my wife to have to tend to my personal needs'. Vital signs are as follows: BP 134/84, P 94, R 30, T 38.8°C. Mr McMurphy is admitted for an acute exacerbation of the disorder, probably triggered by pneumonia. He will be treated with ACTH and intravenous antibiotics during this admission.

DIAGNOSES

- *Ineffective airway clearance* related to lung infection and thick mucus, evidenced by tachypnoea and a productive cough.
- *Activity intolerance* related to fatigue and spasticity, evidenced by the inability to attend work and attend to own ADLs.
- *Self-care deficit: toileting, feeding and grooming* related to muscle weakness, evidenced by the inability to attend to own ADLs without assistance.

PLANNING

Management of symptoms of pneumonia and implementation of strategies to cope with an exacerbation of MS.

Expected outcomes

- Be able to clear airway.
- Have breath sounds clear to auscultation and pulse oximetry readings above 95%.
- Be able to ambulate using assistive devices, if needed.
- Perform self-care activities without becoming overly fatigued and tired.
- Verbalise methods to adapt daily routine to his level of tolerance.

IMPLEMENTATION

- Initiate pulmonary hygiene measures (e.g. incentive spirometry, turning, deep breathing and coughing, breathing exercises and postural drainage) at least every 2 hours. Assess lung sounds, oxygen saturation and ability to clear airway.
- Teach the importance of maintaining an oral fluid intake of at least 2 L per day to prevent tenacious sputum and urinary tract infections. Teach signs and symptoms of urinary and respiratory infections.
- Encourage participation in decision making about care.
- Assist with ADLs only as needed, based on level of fatigue and muscle weakness.
- Plan self-care activities so that they are performed during periods of peak level of energy; intersperse rest periods throughout the day.
- Refer to an MS support group.
- Refer to physical and occupational therapists for counselling regarding control of spasticity and possible splinting of spastic muscles.
- Consult a urologist for assessment of bladder incontinence; teach intermittent catheterisation. Alternatively, the use of an external condom catheter may be indicated.

EVALUATION

Mr McMurphy is discharged 3 days following admission. He states that he feels stronger; on discharge, he has no problem clearing his airway. Although he continues to pace his activities to avoid fatigue, his muscle strength and 'tiredness' have improved. He is able to complete ADLs unassisted.

Pulmonary function has returned to normal pre-hospitalisation levels: ABGs and pulse oximetry are within normal limits. Both Mr McMurphy and his wife have listed several ways to modify their daily routine to allow more rest and decreased stress. Follow-up visits to Mr McMurphy's primary care provider have been arranged and the McMurphys have been provided with information about the local MS support group.

CRITICAL THINKING IN THE NURSING PROCESS

1. Describe approaches the nurse could take to ensure that Mr McMurphy does not exceed his activity tolerance.
2. Develop a teaching plan for Mr McMurphy to help prevent future respiratory infections.

REFLECTION ON THE NURSING PROCESS

1. Which education and communication strategies could you suggest to reduce the risk of injury related to fatigue, muscle weakness and spasticity?
2. Outline what you have learned from this case study that you will apply to your future nursing practice.

THE PERSON WITH PARKINSON'S DISEASE

Parkinson's disease (PD) is a progressive, degenerative neurological disease characterised by tremor (shaking), muscle rigidity and bradykinesia (slowness of movement) (Grossman & Porth, 2013). People with PD are faced with multiple problems involving independence in ADLs, emotional wellbeing, financial security and relationships with caregivers.

Incidence and prevalence

PD is one of the most common neurological disorders affecting older adults. It is estimated that there are as many as 70 000 (one in every 340) Australians who currently have PD; of these, 53% are male and 47% are female. Eighty two per cent of people develop PD after the age of 65; however, 18% of people living with PD are of working age (15–64 years). The recent discovery of inherited forms of PD suggests a genetic role in the development of this disease (Deloitte Access Economics, 2015).

Parkinson's-like manifestations, called *secondary Parkinsonism*, may result from other disorders such as trauma, encephalitis, tumours, toxins and drugs. Drug-induced Parkinsonism, which is usually reversible, may occur in people taking neuroleptics, anti-emetics, antihypertensives and illegal designer drugs containing MPTP, a toxic chemical (Grossman & Porth, 2013). Carbon monoxide or cyanide poisoning can also cause secondary Parkinsonism. This discussion focuses on primary Parkinson's disease, the cause of which is unknown.

Pathophysiology

Coordinated, voluntary body movement is achieved through the actions of neurotransmitters in the basal ganglia of the brain. Some neurotransmitters facilitate the transmission of excitatory nerve impulses, while other neurotransmitters inhibit their transmission. Together, this system allows control of movement. A disturbed balance between excitatory and inhibitory neurotransmitters causes disorders of voluntary motor function, such as PD.

In PD, neurons in the cerebral cortex atrophy and are lost, the dopaminergic nigrostriatal (pigmented) pathway degenerates and the number of specific dopamine receptors in the basal ganglia decreases. These pathological processes cause a decrease in the production of dopamine (a neurotransmitter that helps regulate nerve impulses involved in motor function) from the substantia nigra. The usual balance of dopamine (an inhibitory neurotransmitter) and acetylcholine (an excitatory neurotransmitter) in the brain is disrupted and dopamine no longer inhibits acetylcholine. The failure to inhibit acetylcholine is the underlying basis for the manifestations of the disorder. PD has five stages, outlined in Box 43.3.

Manifestations

Parkinson's disease begins with subtle manifestations. People complain of feeling tired and seem to move more slowly; a slight tremor may accompany the fatigue. Over time, the manifestations progressively increase in severity. The manifestations and complications of PD are presented in the box below.

BOX 43.3 Stages of Parkinson's disease

1. Unilateral involvement only, usually with minimal or no functional impairment.
2. Bilateral or midline involvement, without impairment of balance.
3. First sign of impaired righting reflexes, evidenced as unsteadiness as the person turns or demonstrated when the person is pushed from standing equilibrium with the feet together and eyes closed. Functionally, the person is somewhat restricted in activities but may have some employment potential, depending on the type of employment. People are physically capable of leading independent lives and their disability is mild to moderate.
4. Fully developed, severely disabling disease; the person is still able to walk and stand unassisted but is markedly incapacitated.
5. Person is confined to bed or wheelchair unless aided.

MANIFESTATIONS AND COMPLICATIONS

Parkinson's disease

RELATED TO MOTOR DYSFUNCTION

- Non-intentional tremor
- Bradykinesia or akinesia
  a. Slowed movements; inability to initiate voluntary movements
  b. Slowed speech, low amplitude
  c. Poor articulation
  d. Decreased eye movements (i.e. blinking)
  e. Mask-like, expressionless face
- Rigidity
- Posture and gait disturbances
  a. Trunk tilted forwards
  b. Shuffling gait, propulsive at times
  c. Retropulsion
- Complications: falls, fractures, impaired communication, social isolation

RELATED TO AUTONOMIC SYSTEM DYSFUNCTION

- Skin problems
  a. Seborrhoea
  b. Excess sweating on face and neck, absence of sweating of trunk and extremities
  c. Mottled skin
- Heat intolerance
- Postural hypotension
- Constipation
- Complications: skin breakdown, dizziness, falls, constipation

RELATED TO COGNITIVE AND PSYCHOLOGICAL DYSFUNCTION

- Dementia
  a. Memory loss
  b. Lack of insight and problem-solving ability
  c. Declining intellectual abilities
- Anxiety
- Depression
- Complications: loss of ability to function, social isolation

Tremor

Tremor at rest is usually the first manifestation experienced, with one of the upper extremities more often affected. Resting tremors of the hand show a 'pill-rolling' motion of the thumb and fingers. (This name reflects the way in which medicinal pills were formed in the early days of medicine.) The tremor may be controlled with purposeful, voluntary movement and is worsened by stress and anxiety. People have progressive impairment in performing skills that require dexterity and fine muscle control, such as writing and eating.

Rigidity and bradykinesia

Manifestations related to motor and postural effects include rigidity, bradykinesia and uncoordinated movements. Rigidity (resulting from involuntary contraction of all skeletal muscles) makes both active and passive movement difficult. It is manifested as increased resistance to passive range of motion. Although the extremity moves, it does so in a jerky motion, called *cogwheel rigidity*. The first manifestation of rigidity may be muscle cramps in the toes or hands, but most often the person describes stiffness, heaviness or aching in muscles.

Bradykinesia, experienced as difficulty in starting, continuing or coordinating movements, is the most common and crippling manifestation. All striated muscles are affected, including those that involve chewing, swallowing and speaking. Slowed or delayed movements affect the eyes, mouth and voice, causing a mask-like face and softened or muffled voice. Disorders of swallowing result in problems with eating and with drooling. People have a staring gaze with minimal change in expression (see Figure 43.3). People describe being 'frozen' in place as voluntary movement is lost and they sit or lie in one position without movement for long periods of time. Movement is interspersed with freezing, brought about by turning, increasing the effort to move or making visual or touch contacts.

FIGURE 43.3 ■ In Parkinson's disease, the person's face lacks expression or animation

Source: Scott Houston/Corbis.

Abnormal posture

The loss of normal postural reflexes results in postural abnormalities, including disorders of postural fixation, equilibrium and righting. Involuntary flexion of the head and shoulders means the person with PD cannot maintain an upright position of the trunk when sitting or standing. This problem of postural fixation results in the characteristic stooped, forwards-leaning position. Disorders of equilibrium follow loss of postural fixation, with an inability to make adjustments when leaning or falling, increasing the risk of injury from falls. (The person usually falls backwards.) The person takes short, accelerated steps to try to maintain an upright position when walking.

Autonomic and neuroendocrine effects

Many manifestations result from the loss of functions controlled by the autonomic nervous system. Elimination problems include constipation and urinary hesitation or frequency. People may experience problems related to orthostatic hypotension, including dizziness with position change. Eczematous skin changes and seborrhoea are related to the increase in sweat gland activity secondary to increased sebotrophic hormone production.

Mood and cognition

Both depression and dementia are pathologies associated with PD. Depression occurs in half of all people, and one-third have dementia. Dementia, resulting from loss of cholinergic cells, loss of neurons, senile plaques, neurofibrillary tangles and amyloid changes in small blood vessels, occurs in 20% of people with PD and develops later in the disease (Grossman & Porth, 2013). The person has manifestations similar to the person with Alzheimer's disease, including confusion, disorientation, memory loss, distractibility and changes in abstraction and judgment. *Bradyphrenia* may also occur, resulting in slow thinking and a decreased ability to form thoughts, to plan or to make decisions.

Sleep disturbances

People with PD commonly have sleep disturbances, although they may experience decreased manifestations during sleep in the early stages. The ability to fall and stay asleep is affected by acetylcholine. Muscle rigidity may compromise sleep because of the inability to change position. This lack of muscle movement causes the person to awaken and consciously shift position.

Interrelated effects

Some of the manifestations that people with PD experience have multiple contributing factors. For example, constipation is common because of decreased peristalsis. However, decreased peristalsis is not the only cause: immobility, tremors (resulting in being unable to drink from a glass easily) and dietary changes from dysphagia all contribute to the problem of constipation.

Complications

The following complications are associated with PD:

- oculogyric crisis, in which the eyes become fixed with a lateral and upwards gaze
- paranoia and hallucinations, which may accompany dementia
- impaired communication due to changes in speech, handwriting and expressiveness
- falls from balance, posture and motor changes
- infections, such as pneumonia, related to immobility
- malnutrition related to dysphagia and inability to prepare meals
- altered sleep patterns due to loss of dopamine, levodopa side effects (nightmares, dreams) or side effects of anticholinergics (hyperreflexia, muscle twitching) and depression
- skin breakdown and pressure ulcers associated with urinary incontinence, malnutrition and sweat reflex changes
- depression and social isolation.

INTERPROFESSIONAL CARE

Prognosis is poor, owing to the progressive degeneration that ultimately affects multiple physiological systems and their function. Psychosocial effects are equally devastating and the family needs more support as the person's debilitation increases. Total disability is usually seen 10 to 20 years after diagnosis. The leading cause of death is pneumonia.

Diagnosis is based primarily on a thorough history and physical examination and is made based on having two of the following manifestations: tremor at rest, bradykinesia, rigidity and postural instability. Interventions vary with the clinical stage of the disorder and include medication, surgery and rehabilitation to retain the optimal level of functioning possible. An interprofessional approach is essential for people with PD.

Diagnosis

Diagnostic studies may support a potential diagnosis of PD; no test clearly differentiates PD from other neurological disorders (Hickey, 2013). However, a PET scan will show decreased uptake of 6-[18F]-fluorodopa.

Medications

The goal of drug therapy is to control manifestations to the extent possible. Generally, medications vary with the stage of the disease; however, response is individualised and guides the selection of medications. Types of drugs used include monoamine oxidase (MAO) inhibitors, dopaminergics, dopamine agonists and anticholinergics. Information about these drugs is presented in the 'Medication administration' box below.

Initially people are treated with selegiline (Carbex, Eldepryl), amantadine (Symmetrel) or anticholinergics. As the disease progresses, levodopa (Dopar, Larodopa) in combination with carbidopa (Lodosyn) is used in a medication named carbidopa–levodopa (Sinemet). Because levodopa eventually loses its effectiveness, dopamine agonists are added to increase its effectiveness. Eventually, pharmacotherapeutic agents lose their efficacy and the disease continues to progress despite treatment. Response to the drugs fluctuates; this phenomenon is called the 'on–off' response.

Bromocriptine (Parlodel) and pergolide (Permax), agents that inhibit the breakdown of dopamine, are used to delay progression of the disease. Catecholamine-O-methyl transferase (COMT) inhibitors (tolcapone (Tasmar) and entacapone (Comtan)) are used in conjunction with carbidopa–levodopa therapy to reduce the metabolism of levodopa, leading to more sustained dopaminergic stimulation of the brain. Selegiline (Eldepryl) increases dopaminergic activity and is used as an adjunctive therapy for people who have fluctuations in response, or become unresponsive, to levodopa.

Other medications may be used to treat problems related to PD. Antidepressants may be prescribed. Propranolol (Inderal) may be used to treat tremors; it should be used cautiously when people have orthostatic hypotension. Botulism toxin injections may be given to treat eyelid spasms and abnormal posturing (dystonia) involving the extremities.

Deep brain stimulation

Activa® tremor control therapy uses an implanted pacemaker-like device to deliver mild electrical stimulation to block the brain impulses that cause tremor, rigidity, stiffness, slowed movement and problems with walking. In this procedure, an insulated wire is surgically placed in the thalamus and connected to an implanted pulse generator (similar to an advanced cardiac pacemaker) near the clavicle. It is used only for people who cannot adequately control manifestations with medications (NINDS, 2015c).

Surgery

Pallidotomy is a surgical technique for Parkinson's disease and its results have been helpful for many people. In this procedure, the neurosurgeon locates the affected areas of the globus pallidus and destroys the involved tissue. As a result, people who could not previously ambulate are able to walk and tremors cease. The long-term effects are still being evaluated.

Stereotaxic thalamotomy (an x-ray is taken during neurosurgery to guide the insertion of a needle into a specific area of the brain) has been used only for people who do not respond to medications—generally, younger people with extreme unilateral tremor. The surgeon destroys a small amount of tissue by creating a lesion in the ventrolateral nucleus of the thalamus. This surgery decreases tremors and rigidity in the contralateral extremity.

Foetal tissue transplantation is a controversial surgical procedure limited to a few medical centres. In this procedure, brain cells from aborted foetuses are implanted into the brain in the hope that the new cells will grow and produce enough dopamine to restore some lost mobility.

Rehabilitation

Depending on their individual needs, people frequently benefit from rehabilitation therapy with a physiotherapist, social worker, psychologist and/or speech therapist.

Physiotherapists (PTs) can implement an individual exercise program to improve coordination, balance, gait and transfers.

MEDICATION ADMINISTRATION The person with Parkinson's disease

DOPAMINERGICS

Levodopa (Larodopa, Dopar)
Carbidopa–levodopa (Sinemet)
Amantadine (Symmetrel)

These drugs have their main effect on the akinesia of DP, improving mobility while decreasing muscle rigidity and tremor. Levodopa is a metabolic precursor of dopamine, but unlike dopamine it can cross the blood–brain barrier. Levodopa is converted to dopamine in the brain by decarboxylase, a catalytic enzyme, and stimulates dopamine receptors to balance the dopamine/acetylcholine concentrations. Carbidopa prevents decarboxylase from converting levodopa to dopamine in the peripheral tissues; therefore, carbidopa is frequently given in combination with levodopa. Amantadine is used to treat dyskinesia and also elevates mood.

Levodopa is avoided in people with narrow-angle glaucoma, severe angina pectoris, transient ischaemic attacks or melanoma. The 'on–off' phenomenon occurs after the person takes levodopa for several years; this phenomenon is characterised by unexpected dyskinesias and lack of symptom control.

Common side effects are nausea and vomiting; darkening of urine and sweat; dyskinesias, especially in the first few months of therapy; arrhythmias; orthostatic hypotension; and psychological reactions, such as hallucinations and vivid dreams. Older adults are particularly susceptible to psychological disturbances.

Nursing responsibilities

- Establish the person's baseline functional abilities in performing ADLs and administering the medication; assess motor control and coordination.
- To avoid adverse reactions, assess the person's overall health status before initiating therapy.
- Monitor medications known to cause adverse drug interactions: anticholinergics, pyridoxine and antipsychotic agents alter the effectiveness of levodopa; MAO-B inhibitors can cause severe hypertension because of their vasoconstrictive effects.
- Withhold levodopa for 8 hours prior to administering carbidopa–levodopa to avoid potentiating the effects of the circulating levodopa.

Health education for the person and family

- Levodopa may not take effect for several weeks to months.
- Do not alter dosages of medications; taking more of a medication may not result in better symptom control and can cause severe side effects.
- Your protein intake should be divided into equal amounts for the day's meals. Avoid foods high in pyridoxine, such as pork, beef, ham, avocado, beans and oatmeal.
- Levodopa may cause a darker colour of urine; however, this is harmless.
- To prevent side effects:
  - Prevent nausea by taking medication with food.
  - Change position slowly to avoid a drop in blood pressure and risk of falling.
  - Prevent constipation by increasing fluid intake and exercising regularly.
- Notify the healthcare practitioner if you begin to have difficulty making voluntary movements, or cardiac or psychological symptoms develop.
- Watch for the 'on–off' phenomenon, in which periods of symptom control alternate with periods when the drug fails to control symptoms.

MONOAMINE OXIDASE INHIBITORS

Selegiline (Eldepryl, Carbex)

Selegiline works by selectively inhibiting the enzyme that inactivates dopamine in the brain. It may be administered alone or as an adjunct therapy with levodopa: selegiline inhibits the enzyme system that would otherwise break down and destroy dopamine. This synergistic effect lasts approximately 1 to 2 years. The combination of selegiline and levodopa increases the adverse reactions of dopamine; nurses must be alert for orthostatic hypotension, changes in movement, hallucinations and confusion. These responses can be modified by lowering the dose of levodopa. Because it is highly selective for the MAO-A enzyme, selegiline does not have antidepressant effects like the MAO-B inhibitors. The risk of severe hypertension is low.

Nursing responsibilities

- Establish baseline functional abilities: motor control and movements, position changes, mental status.
- Monitor problems with insomnia.
- Assess for orthostatic hypotension; look for unsteadiness with position change and complaints of dizziness.
- Assess for hypertension, which can occur with higher than usual doses.

Health education for the person and family

- It is very important to take the medication as directed, especially the dose and time of administration.
- Notify the healthcare practitioner if insomnia occurs.
- Report signs of dizziness when changing positions or standing, changes in ability to move or psychological changes.
- Change positions slowly, especially when moving from a sitting to a standing position.
- Keep follow-up appointments for evaluation of the medication's effectiveness.

DOPAMINE AGONISTS

Bromocriptine (Parlodel)
Pergolide (Permax)
Pramipexole (Sifrol)
Ropinirole (Repreve)

Dopamine agonists act by directly activating dopamine receptors in the brain. They are frequently used in combination with levodopa therapy: when dopamine agonists are given with levodopa, they increase

MEDICATION ADMINISTRATION The person with Parkinson's disease (continued)

the therapeutic effects of levodopa and reduce fluctuations in motor symptoms. Adverse reactions are similar to those of levodopa: nausea, orthostatic hypotension and psychological disturbances are common. Nursing responsibilities, and personal and family teaching information, are similar to those for the dopaminergics.

COMT INHIBITORS

Tolcapone (Tasmar)
Entacapone (Comtan)

COMT inhibitors inhibit catechol-O-methyltransferase (COMT), which is responsible for metabolising dopamine. The concurrent administration of a COMT inhibitor with levodopa increases the amount of levodopa available to the brain to control Parkinson's disease.

Nursing responsibilities

- Monitor liver function test results and manifestations of liver impairment (dark urine, jaundice).
- Administer with food.
- If given concurrently with warfarin, monitor APTT and INR.

Health education for the person and family

- Avoid using alcohol and sedatives.
- Rise slowly from a sitting or lying position to avoid falling.
- Nausea is common at the beginning of therapy.
- Do not abruptly stop taking the medication.
- Report increased loss of muscle control, yellow skin or eyes, dark urine, hallucinations, severe diarrhoea.

ANTICHOLINERGICS

Benzhexol (Artane)
Benztropine (Cogentin)
Biperiden (Akineton)
Cycrimine (Pagitane)
Procyclidine (Kemadrin)
Chlorphenoxamine (Phenoxene)

Anticholinergics are effective in PD because they block the excitatory action of the neurotransmitter acetylcholine. They are frequently used during the early stages of the disease or when the person can no longer take levodopa. They may be given in combination with carbidopa–levodopa therapy. These medications ease drooling, tremors and rigidity; however, side effects are common and may include blurred vision, dry mouth, constipation, delayed gastric emptying, urinary retention, photophobia and tachycardia. Older adults are especially susceptible to heat stroke and psychological side effects, including confusion, depression, delusions and hallucinations. Anticholinergics should be tapered slowly when discontinued to avoid enhancing Parkinsonian symptoms.

Nursing responsibilities

- Perform baseline assessment for presence of glaucoma, cardiac dysfunction and prostatic hypertrophy.
- Note other medications, including OTC medications that have anticholinergic effects, such as antihistamines and tricyclic antidepressants.
- Monitor for side effects, especially changes in vision, elimination, gastric emptying and mentation.

Health education for the person and family

- Inform your healthcare practitioner if you begin taking any new medications or notice any new symptoms.
- Avoid overexposure to heat and take precautions to avoid heat stroke: drink fluids, keep cool and avoid strenuous activity on hot days.
- Drink adequate amounts of fluid to minimise constipation.
- Practise home safety to prevent falls associated with blurred vision.
- Avoid taking OTC antihistamines or sleeping aids; these have anticholinergic activity.
- Have the eyes examined annually to check for glaucoma; wear dark glasses if photophobia develops.
- Do not suddenly stop taking anticholinergics.

Preventing contractures is an important goal of exercise therapy. It is crucial that family and healthcare personnel permit the person adequate time to perform not only exercise regimens but also ADLs. Activities should not be rushed.

An occupational therapist (OT) helps the person adapt to changing abilities pertinent to work, self-care and recreational activities. Some rehabilitation centres assign OT personnel the responsibility of addressing the person's upper extremity functions while assigning PT personnel to manage lower extremity problems. For example, skills related to cooking and grooming would be supervised by the OT, whereas mobility and posture skills would be supervised by the PT.

Speech therapists frequently address not only the person's speech but also chewing and swallowing. These therapists evaluate people and plan treatment regimens. The challenge with people who have PD is that they have not only vocalisation problems but also dexterity deficits; speech therapists therefore must evaluate the potential benefits of assistive devices, such as a magic slate, voice synthesiser or computer, for each person.

Nursing care

The chronic and eventually debilitating nature of PD poses many challenges to people, families and healthcare professionals. Dependence due to declining physical and mental abilities is of major concern. In the early stages, most people are able to

remain at home, with the family assisting with or providing many of the person's ADL needs. As the disease progresses and the burden of care increases, the person and their family may prefer placement in a long-term care facility. A nursing care plan for the person with PD is given below.

Health promotion

Teaching preventive measures is extremely important when caring for people who have PD. Preventing malnutrition, falls and other environmental accidents, constipation, skin breakdown from incontinence or immobility, and joint contracture requires teaching and reinforcement.

In addition to incorporating information about safety needs, teach ways to prevent orthostatic hypotension when the person changes positions; some people may also benefit from wearing individually fitted compression hose. In addition, address safety considerations about proper administration of medications.

Assessment

Collect the following data through the health history and physical examination (see Chapter 40). Further focused assessments are described with nursing interventions. When assessing the older person, be aware of normal changes with ageing, outlined in Chapter 40.

NURSING CARE PLAN A person with PD

Walter Avneil, aged 78, was diagnosed with PD at age 64. His wife died 5 years ago and he has no other family living. Mr Avneil worked for more than 40 years as a mechanic in a large factory. He now lives in a residential aged care facility. During his last clinic visit for a review of his medications, the following assessment was made.

ASSESSMENT

Caucasian male with history of PD for the past 14 years. Skin oily and damp. Tremors in both hands and the lips. Gait is slow and shuffling, with a forwards-leaning posture. Speech slow and slurred. Face expressionless. Has lost 5 kg since last visit 3 months ago. Has been on levodopa with carbidopa since diagnosis. States his main problems are 'eating problems, bowel problems, walking problems'.

DIAGNOSIS

- *Constipation* related to lack of exercise, decreased food intake and effects of medications manifested by difficulty opening bowels.
- *Impaired verbal communication* related to lip tremors, slow/slurred speech and facial muscle involvement of PD, evidenced by difficulty communicating needs to others.
- *Poor nutrition* related to difficulty swallowing and chewing, evidenced by weight loss.
- *Impaired physical mobility* related to rigidity and bradykinesia, evidenced by slow, shuffling gait.

PLANNING

- Provide interventions to manage complications of PD.

Expected outcomes

- Have a soft stool at least every other day.
- Practise exercises provided by speech therapist twice a day.
- Increase number of kilojoules, fluids and fibre in diet provided at long-term facility.
- Improve joint mobility and ability to ambulate.

IMPLEMENTATION

- Discuss problems with bowel elimination with staff at long-term facility; suggest increasing fluids to 3 L per day and also increasing fibre in the diet, with oatmeal for breakfast and more fruit and vegetables at meals.
- Encourage exercises provided by speech therapist to improve speech and swallowing. If these are not effective, make a referral for another evaluation.
- Discuss diet plan with dietitian at the long-term care facility, including consistency of foods and number of kilojoules. Suggest dietitian be part of the swallowing evaluation by the speech therapist.
- Refer for physiotherapy and occupational therapy for a program to improve gait and joint mobility and to decrease risk of falling.

EVALUATION

In a return visit 3 months later, Mr Avneil reports that 'my bowels are working better'. He has gained 3.2 kg and the staff report that this is related to multiple factors, including practising his swallowing exercises, getting more exercise which stimulated his appetite and changing his diet to six small meals a day of soft or puréed foods. The staff are offering him liquids at meals and snack times and he usually drinks all they give him. His speech is not much improved. His posture and gait are somewhat better and he is doing the exercises provided by the physiotherapist and occupational therapist. Mr Avneil's functional abilities have improved so much that the staff are considering training sessions specific to care of residents with PD.

CRITICAL THINKING IN THE NURSING PROCESS

1. Although Mr Avneil did not mention it, the staff report that he is frustrated by not being able to dress himself. Which suggestions could you make to facilitate his independence?
2. Mr Avneil spends most of his time alone, although he enjoys the company of the other residents. List assessments and interventions you might provide to increase his diversional activity.
3. The loss of his wife and the debilitating effects of his disease increase Mr Avneil's risk of the nursing diagnosis of *Chronic sorrow*. What might you suggest the long-term staff do to reduce this risk?

REFLECTION ON THE NURSING PROCESS

1. Which communication and education strategies could you use to assist people with PD who are experiencing speech difficulties?
2. Outline what you have learned from this case study that you will apply to your future nursing practice.

- *Health history:* brain trauma, stroke, infection, exposure to heavy metals or carbon monoxide, medication and drug use, incontinence, constipation, weight loss, sweating, sleep problems, muscle pain, mood.
- *Physical assessment:* affect; appearance; speech, scalp, eyelashes and skin; drooling; tremor; coordination; posture; gait; muscle rigidity; mental status.

Nursing diagnoses and interventions

People with PD have complex and, ultimately, multisystem needs. Deficits in mobility and self-care are common. Psychosocial needs may include problems related to *Ineffective coping, Powerlessness* and *Disturbed body image*. Refer to the nursing care sections throughout this chapter for discussions of fatigue, self-care deficit, ineffective airway clearance and other pertinent diagnoses. This section focuses on the nursing diagnoses related to *Impaired physical mobility*, *Impaired verbal communication*, *Imbalanced nutrition: less than body requirements* and *Disturbed sleep pattern*.

Impaired physical mobility

People with PD have impaired mobility for several reasons, including tremors, gait-pattern disturbances and alterations in body positioning, such as forwards bending of the trunk. Poor self-esteem may contribute to the person's lack of motivation and willingness to be mobile.

- Suggest referral to a physiotherapist to develop an individualised exercise program. *A program specific to the person supplies motivation as well as helping the person maintain muscle tone, flexibility and mobility.*
- Request the physiotherapist teach caregivers how to do ROM exercises at least twice a day, emphasising the trunk, neck, arms, hips and legs. *Maintaining joint mobility promotes better function and strength, improving gait pattern. Consistent ROM exercises can prevent contractures.*
- Ask caregivers to ambulate the person at least four times a day if possible. *Exercise fosters independence and self-esteem.*
- Recommend assistive devices, such as lift chairs, canes, splints or braces, as indicated. *Adaptive equipment improves balance, protects joints and promotes proper anatomical positioning.*
- To promote mobility and safety:
  - Slightly elevate the back legs of chairs and raise the toilet seat to help rise from a sitting position to a standing position.
  - Wear shoes with Velcro closures.
  - Remove potential hazards, such as unanchored throw rugs.
  - Install handrails and non-skid surfaces in bathtubs and showers.
  - Ensure adequate lighting throughout the home and in outside areas, especially in areas where transfers are common.

    Safety measures prevent potential complications that may result from falls or other accidents and promote self-esteem through self-care.

CONSIDERATION FOR PRACTICE

Parkinson's disease is a disorder common in older adults, who are at greater risk of falls resulting from orthostatic hypotension, osteoporosis, poor vision and problems causing disorientation and confusion, such as Alzheimer's disease.

Impaired verbal communication

Diminished vocal amplitude and loss of muscular control can impair the person's ability to speak. Both caregivers and family members must remember to give people enough time for self-expression; an unhurried approach is recommended. Seek input from family members when determining alternative methods of communicating with the person.

- Assess current communication abilities in speech, hearing and writing. *Communication involves both sending and receiving messages.*
- Develop methods of communication appropriate to coordination abilities, such as a magic slate, flash cards with common phrases and pointing to objects. *Individualising a method of communication decreases anxiety and isolation.*
- Suggest referral to a speech pathologist to develop oral exercises and interventions that will facilitate speaking. *The muscles of speech and swallowing are affected by the PD process.*
- Remind the person to speak more loudly, if possible. *A low, monotonous voice is characteristic of the person with PD.*

Imbalanced nutrition: less than body requirements

Tremors, altered gait, and impaired chewing and swallowing can cause nutritional problems in the person with PD. As the disorder progresses, interventions for ensuring optimal nutrition need to be adapted to the person's functional abilities. Assess the person's swallow reflex before starting any feeding program. During the initial stages of the disorder, some people may have the nursing diagnosis of *Poor nutrition related to excess intake of kilojoules manifested by kilojoule intake exceeding energy expenditure.*

- Assess nutritional status and self-feeding abilities; suggest referral to an occupational or speech therapist, if needed. *An initial assessment of abilities ensures that interventions are personalised to the person's current functional abilities.*
- Teach caregivers how to prepare foods of proper consistency as determined by swallowing function. *The person may aspirate food that is too liquid.*
- Weigh weekly. *Early recognition of weight loss allows for intervention.*
- Teach eating methods to decrease tremors, such as holding a piece of bread in the hand that is not holding an eating utensil. *Non-intentional tremor may be reduced through purposeful activity.*
- Encourage diet that is high in bulk and fluids. *Several anti-Parkinson's medications and inactivity can cause constipation.*

Disturbed sleep pattern

Rigidity and weakness can cause people with PD to lose the ability to move and change positions during sleep. The resulting discomfort causes periods of wakefulness. Medications to treat PD contribute to sleep pattern disturbance; for example, levodopa can cause vivid dreams. Nurses can help in accurately assessing the sleep pattern disturbance and in planning interventions to improve or increase sleep time.

- Assess sleep pattern and existing conditions that may affect sleep, such as depression or pain. *People experiencing anxiety, depression and dementia have a difficult time falling asleep and may wake up more at night.*

CONSIDERATION FOR PRACTICE

Remember to assess pain status; lack of adequate pain control may interfere with sleep.

- Explain the disease process and the effects of decreased dopamine on the sleep–wake cycle. *Depending on the dosage, levodopa causes less REM sleep and deep sleep.*
- Review the person's medication. Bromocriptine and levodopa, especially if used with an anticholinergic, can cause vivid dreams. *Other medications (diuretics, theophylline, hypnotics) also may interfere with sleep.*
- Teach how to modify lifestyle activities that affect sleep:
  - Institute a routine of activities with limited rest periods during the day; avoid napping close to bedtime. Avoid strenuous exercise in the evening. *Daytime sleeping may contribute to decreased night-time sleeping. Vigorous exercise just before bedtime may act as a stimulant.*
  - Incorporate diet modifications, such as limiting caffeine and alcohol intake. *Caffeine is a stimulant and alcohol may cause early morning awakenings, increased daytime sleepiness and nightmares.*
  - Drink a glass of milk before bedtime. *Milk contains l-tryptophan, which produces sedative effects by shortening the time taken to fall asleep (sleep latency).*
  - Adapt the environment to aid sleep (e.g. darken the room and decrease noises). *Reducing environmental stimuli decreases external sleep disturbances.*

Community-based care

It is important for both the person and their family to maintain independence and self-care as long as possible. To maintain function and quality of life, the following topics should be addressed:

- realistic expectations
- equipment suppliers
- home environment conducive to using equipment
- referrals to speech therapist, occupational therapist, physiotherapist and dietitian
- gait training and exercises for improving ambulation, speech, swallowing and self-care
- increased fluid intake of 3 L/day and increased fibre in every meal
- stool softeners or laxatives as needed for bowel elimination
- swallowing during eating and taking medications. Have suction equipment available and know first aid treatment for choking:
  - Encourage the person to relax and breathe deeply.
    - Ask the person to cough.
    - If unsuccessful, bend the person well forwards and give 5 sharp blows between shoulder blades.
    - If still unsuccessful, place the person on their left side on the floor and call 000 for an ambulance.
  - Total blockage:
    - Lie the person on their left side on the floor.
    - Give 5 sharp blows between shoulder blades.
    - If unsuccessful, give 5 quick downward lateral chest thrusts (place one hand in the middle of the person's back for support and heel of other hand in the CPR compression position and give 5 chest thrusts, slower but sharper than compressions).
    - If still unsuccessful, call 000 for an ambulance and continue alternating 5 back blows with 5 chest thrusts until medical aid arrives (St John Ambulance Australia, 2014).
- foods that can be easily swallowed (such as puréed or soft foods) and feed six small meals a day if possible

THE PERSON WITH HUNTINGTON'S DISEASE

Huntington's disease (HD) is a progressive, degenerative, inherited neurological disease characterised by increasing dementia and chorea (jerky, rapid, involuntary movements). It is a single-gene autosomal dominant disease that causes localised death of neurons of the basal ganglia (Grossman & Porth, 2013). The exact cause is unknown, but postmortem studies have demonstrated a decrease in gamma-aminobutyric acid (GABA), an inhibitory neurotransmitter in the basal ganglia. There is also a decrease in acetylcholine levels, suggesting that the manifestations are the result of an imbalance in dopamine and acetylcholine. HD is a familial disease; each child of an HD parent has a 50% chance of inheriting the HD gene and, if they do, will eventually develop the disease (NINDS, 2015f). There is no cure for the disease. Huntington's disease causes progressive chorea, speech problems and dementia.

Because the person is usually asymptomatic until age 30 to 40, they may already have passed the gene to the next generation. The psychological effect is devastating to people and their families. The family not only experiences guilt from passing the disease from one generation to the next, but also is faced with the overwhelming long-term care needs of those affected. It is common for several family members to have the disease.

Pathophysiology

HD causes destruction of cells in the caudate nucleus and putamen areas of the basal ganglia. Other areas of the brain, such as the frontal lobes, may selectively atrophy. Several neurotransmitters and their receptors are decreased, including GABA and acetylcholine. The neurotransmitter dopamine is not affected in HD, but the decrease in acetylcholine results in a relative excess of dopamine in the basal ganglia. Whereas in PD a deficit of dopamine causes slow movement or lack of movement, in HD the opposite occurs: there is a relative excess of dopamine, causing excessive, uncontrolled movement.

Manifestations

Manifestations and complications primarily involve abnormal movement and progressive dementia (see the box below). The progression and sequence of manifestations varies somewhat; however, initially the psychological manifestations are more debilitating than the choreiform (rapid and jerky) movements.

Early signs of personality change include severe depression, memory loss with decreased ability to concentrate, emotional lability and impulsiveness. The person experiences frequent mood swings ranging from uncontrollable periods of anger to apathy. Eventually, signs of dementia, including disorientation, confusion and lack of sense of time, become evident and interfere with self-care.

Motor manifestations usually parallel personality and mood changes. The motor manifestations worsen with environmental stimuli and emotional stress but are absent when the person is sleeping. Initially, movement problems are described as 'fidgeting' or restlessness, followed by progressive worsening of abnormal movements. The choreiform movements, which begin in the face and arms and then involve the entire body, are manifested by facial grimaces, tongue protrusion, jerky movement of the distal arms or legs, and a rhythmic, lurching gait that almost resembles a dance. (The term *chorea* comes from *choreia*, the Greek word meaning 'dance'.) Gait changes cause uncoordinated movements and contribute to frequent falls.

The muscles of swallowing, chewing and speaking are affected, leading to dysphagia and dysarthria and associated problems with communication and nutrition. The person's constant movement and difficulty in swallowing contribute to weight loss and eventual cachexia. Breathing is impaired because the diaphragm is unable to move effectively.

The manifestations slowly progress over approximately 15 to 20 years after initial manifestations appear. Prognosis is poor, with inevitable debilitation and total dependence. Death usually results from aspiration pneumonia or another infectious process.

INTERPROFESSIONAL CARE

There is no cure for HD and treatment addresses the disease's manifestations. Nurses provide care to people with HD in a variety of community settings. Initially, people and families can manage care needs at home but, as the disease progresses, the person requires constant supervision, such as that provided in day respite facilities. Eventually, skilled long-term care is needed. People who develop acute problems may be hospitalised until the crisis is managed. Because of the inevitable total multisystem debilitation of people with Huntington's disease, nurses and other caregivers face many challenges.

MANIFESTATIONS AND COMPLICATIONS Huntington's disease

MOTOR EFFECTS

Early

- Restlessness
- 'Fidgety' feeling
- Minor gait changes—unsteady on feet
- Posture and positioning disturbances, frequent falls
- Inability to keep the tongue from protruding
- Slurred speech with poor articulation
- Complications: increasing problem with self-care activities, such as bathing, grooming, eating

Late

- Chorea—severely altered gait with irregular, uncontrollable movement; shoulders shrug arrhythmically
- Facial grimacing—raising of eyebrows, uncontrollable protrusion of the tongue
- Dysphagia
- Unintelligible speech
- Impaired diaphragmatic movement
- Complications: immobility, aspiration, choking and, eventually, total dependence, poor oxygenation, emaciation and cachexia

PSYCHOSOCIAL EFFECTS

Early

- Irritability
- Outbursts of rage alternating with euphoria
- Depression
- Complication: suicide

Late

- Decreasing memory
- Loss of cognitive skills
- Eventual dementia
- Complication: total dependence

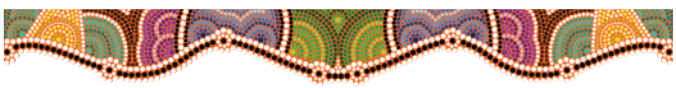
Diagnosis

Genetic testing is the only test available to diagnose people suspected of having HD. Both blood and amniotic fluid may be tested for the presence of a gene mutation on chromosome 4 using DNA analysis. The test can predict with 95% accuracy who is a carrier of the disease.

Medications

The following medications are given for the manifestations of HD:

- Antipsychotics, specifically phenothiazines and butyrophenones, are effective in HD because they block dopamine receptors in the brain. The therapeutic goal is to restore the balance between the neurotransmitters.
- Antidepressants are prescribed in the early stage of the disease; however, medications are no substitute for intense follow-up counselling for people and their families.



Nursing care

Nurses are faced with a multitude of challenges when caring for families who have Huntington's disease, including physiological, psychosocial and ethical problems. Physiological problems are related to the progressive and eventually debilitating nature of the disease. Psychosocial concerns occur as a result of the person's personality and mental changes, the family's responsibility for providing care and the guilt implicit in a genetically transmitted disease. Ethical difficulties relate to the genetic nature of the disease: DNA testing for the marker on chromosome 4 can determine whether the person is a carrier of the disease before they begin to exhibit manifestations. Children of people with HD are thus faced with the choice of finding out whether they will eventually be affected. If they choose not to be tested, they may pass the disease on to yet another generation; and if a foetus is affected they may face the decision of whether to undergo an abortion.

Nursing diagnoses and interventions

Initially, much of the nursing care focuses on teaching about the disease, psychological support and genetic counselling. As manifestations become more severe, nursing considerations centre on problems related not only to immobility and altered nutrition, but also to the increasing self-care deficits. Families and people experiencing HD face many psychosocial issues. Nurses must be prepared to listen actively as well as to provide comfort and encouragement throughout the lengthy illness. There are many possible nursing diagnoses for the person with HD; this section focuses on nursing diagnoses related to aspiration, nutrition, skin integrity and communication.

Risk of aspiration

Uncoordinated movements and swallowing and chewing problems put the person at high risk of aspiration.

- Maintain in an upright position while the person eats; support the head. *Proper positioning may prevent aspiration during meals.*
- Teach the first aid treatment for choking to caregivers and family members (see above). *Aspiration is a real possibility; caregivers must be prepared to re-establish the person's airway.*
- Provide food that is thick enough to manage, such as thick soups, mashed potatoes, stews or casseroles. *These foods are more readily tolerated and manipulated by the tongue than liquids.*
- Make sure food is swallowed before giving another spoonful of food. *The automatic phase of swallowing may be disrupted in the person with HD; providing adequate time and smaller bites may improve the ability to manipulate foods.*
- Provide a calm, relaxing eating environment. *Stress worsens choreiform movements and inappropriate behaviours.*

Poor nutrition

People with HD have unpredictable choreiform movements of the extremities and decreased ability to control muscles involved with chewing and swallowing. Families and caregivers are challenged to provide sufficient kilojoules to maintain the person in positive nitrogen balance.

- Evaluate current weight and nutritional status, including serum prealbumin and transferrin levels. *Establishing a baseline is crucial for meeting individual kilojoule, protein, vitamin and mineral needs.*
- Assess ability to swallow and manipulate eating utensils. *Aspiration is an ever-present danger that must be avoided; utensils may need to be adapted to the person's abilities, if the person is able to assist at all.*
- Continue feeding even if the person physically turns away from the meal. *Involuntary choreiform movements should not be interpreted as a refusal to eat.*
- Provide high-kilojoule, nutritious foods and sufficient snacks; request input from a dietitian. *The constant movement of HD increases kilojoule requirements.*
- Avoid milk; provide frequent oral hygiene. *Milk tends to thicken secretions. Decreasing thick secretions may improve ability to swallow and enable the person to ingest more kilojoules.*

Impaired skin integrity

Skin integrity is only one component of the person's general need for protection and avoidance of injury. Several factors increase the risk of impaired skin integrity, including poor nutritional status, eventual total immobility and incontinence.

- Evaluate the skin for actual and potential areas of breakdown. *Establishing a baseline is necessary to modify care and provide prophylactic protection of high-risk pressure areas.*
- Determine nutritional status, especially serum prealbumin level and vitamin, mineral and kilojoule intake. *Optimal nutritional status and positive nitrogen balance help prevent skin breakdown and formation of pressure ulcers.*

- Turn and inspect the skin at least every 2 hours, giving special consideration to areas that are most prone to breakdown, such as heels and coccyx. *Pressure points are particularly susceptible to skin breakdown.*
- Provide ROM exercises on a regular schedule in the daytime. *Movement stimulates circulation, which provides oxygenation and allows nutrients to reach muscles and skin.*
- Keep the skin clean and dry; pay particular attention to the perineal area if incontinent. *Skin in close proximity to the perineal area, such as the sacral area, is highly susceptible to breakdown due to exposure to wet, acidic urine and faecal material.*
- Place on an alternating-pressure mattress with foot board. *Decreasing pressure on bony prominences and preventing shearing forces serve to prevent skin breakdown.*
- Pad side rails and headrests of special chairs; have the person wear a helmet. *The person's violent movements can cause trauma to the head and extremities.*

Impaired verbal communication

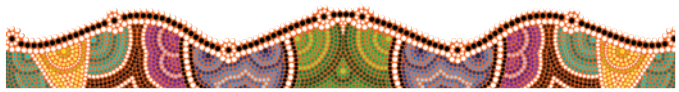
The inability to control muscles related to speech, swallowing and facial movement contributes to problems of verbal communication. Because HD affects fine motor movement, especially the distal portion of the extremities, the hands are not effective in communication. As the disease progresses, mental abilities are also compromised, making both receptive and expressive communication impossible.

- Choose alternative methods of communication while the person is able to participate. *Anticipatory planning may facilitate communication and decrease anxiety.*
- Continue to incorporate therapeutic communication techniques, even though the person is not responsive: maintain eye contact, use touch and talk directly to the person rather than to others in the room. *These techniques enhance the individual's dignity and self-worth.*
- Seek input from family about the person's usual preferences and how they are communicated; be alert for subtle cues. *Non-verbal communication techniques may be individualised and more readily recognised by the family member or caregiver who usually provides care.*
- Continue talking to the person, even though there is no apparent response. *Hearing may not be impaired, even though the person cannot speak.*

Community-based care

People with HD and their families may know how devastating the illness is because they may have cared for a parent or other close family member who had the illness. Many families are overwhelmed with just the thought of the physical and psychosocial debilitation that the disease brings. Fear, anxiety and hopelessness leading to depression are common reactions. Teaching ways to cope effectively with the psychosocial and physical changes is an integral part of the nurse's responsibilities. Referrals to appropriate agencies, such as adult day care centres, Huntington's Australia and local support groups or a psychologist, should be part of the nursing plan.

Another aspect of personal teaching concerns the genetic transmission of HD; refer people and family members to a geneticist. Nurses are frequently involved with clarifying information, especially concerning the transmission, course of illness and prognosis. A caring, sensitive approach is crucial. Information about transmission of an autosomal dominant trait is discussed in Chapter 7.



THE PERSON WITH MOTOR NEURONE DISEASE

Motor neurone disease (MND), also known as **amyotrophic lateral sclerosis (ALS)** or *Lou Gehrig's disease*, is a rapidly progressive and fatal degenerative neurological disease characterised by weakness and wasting of muscles under voluntary control, without any accompanying sensory or cognitive changes. The name is derived from the pathophysiological processes of muscle atrophy (*amyotrophy*), resulting from lower motor neuron involvement, and sclerosis of the corticospinal tract in the lateral column of the spinal cord, resulting from upper motor neuron involvement. Death results in 2 to 5 years after onset of the manifestations (although some people live 10 years or more), usually due to respiratory failure.

MND affects as many as 1900 people in Australia; on average, at least two people are diagnosed every day, and another 787 die of MND every year. In most cases, the disease occurs at random without clearly associated risk factors; however, about 10% of all cases are inherited in what is termed familial MND (Motor Neurone Disease Australia, 2013).

Most people are between 40 and 60 years of age at diagnosis; the incidence is higher in men in the earlier ages but becomes equal with women after menopause. Most of the health problems a person with MND encounters are related to swallowing and managing secretions, communication and dysfunction of the muscles used in respiration.

Pathophysiology

MND results from the degeneration and demyelination of both upper and lower motor neurons in the anterior horn of the spinal cord, brainstem and cerebral cortex. Death of the motor neurons results in axonal degeneration, demyelination, glial proliferation and scarring along the corticospinal tract. In the early stages of the disease, surviving motor neurons sprout new branches to reinnervate affected muscle fibres, preserving muscle strength. However, when more than half of the lower motor neurons are affected, reinnervation fails and weakness is evidenced.

Although the pathogenesis of MND is not clear, abnormal glutamate metabolism and hydrogen peroxide production are being studied. Echovirus RNA has also been isolated in spinal

cord tissue in some people with non-familial MND. Environmental factors, excess intracellular calcium and antibodies to calcium channels are also being researched.

Manifestations

The initial manifestations may relate to dysfunction of upper motor neurons, lower motor neurons or both. Dysfunction of upper motor neurons results in spastic, weak muscles with increased deep tendon reflexes. Dysfunction of lower motor neurons results in muscle flaccidity, paresis (weakness), paralysis and atrophy.

Weakness and paresis are common early manifestations. The weakness may initially affect only one muscle group. Manifestations vary according to the particular muscle group involved; *fasciculations* (twitching) of involved muscles are common in the early stage of the disorder. With the loss of muscle innervation, the muscles atrophy and paralysis results. Muscle mass decreases and people complain of progressive fatigue. Typically, the disease first affects the hands, then the shoulders, upper arms and, finally, the legs.

Increasing brainstem involvement causes progressive atrophy of the tongue and facial muscles with eventual dysphagia and dysarthria. Emotional lability and loss of control occur, but dementia is not part of the pathological progression of MND. Vision, hearing, sensation and cognitive ability usually remain intact. A summary of manifestations and complications is presented in the box below.

MANIFESTATIONS AND COMPLICATIONS MND

MUSCULOSKELETAL SYSTEM
- Weakness and fatigue
- 'Heaviness' of legs
- Fasciculations
- Uncoordinated movements, loss of fine motor control in hands
- Spasticity
- Paresis
- Hyperreflexia
- Atrophy
- Problems with articulation
- Complications: paralysis, loss of ability to perform ADLs, total immobility, aspiration, loss of verbal communication

RESPIRATORY SYSTEM
- Dyspnoea
- Difficulty clearing airway
- Complications: pneumonia, eventual respiratory failure

NUTRITIONAL EFFECTS
- Difficulty chewing
- Dysphagia
- Complication: malnutrition

EMOTIONAL EFFECTS
- Loss of control, lability
- Complication: depression

INTERPROFESSIONAL CARE

Because many treatable disorders may cause manifestations similar to those that appear in the initial stage of MND, a thorough evaluation is required. Once MND is diagnosed, the primary goal is to support the person and their family in meeting physical and psychosocial needs, particularly as the disease progresses.

Medical and nursing care for people with MND is primarily supportive. Referral for home health management is indicated. Occupational, physical, speech and respiratory (physiotherapy) are major supportive and rehabilitative treatments. As the disorder progresses and swallowing becomes ineffective, a gastrostomy tube may be necessary to provide adequate nutritional intake. Ventilatory assistance should be discussed with people before the need occurs.

Diagnosis

There is no specific test to diagnose MND. Rather, diagnosis is made based on manifestations and tests to rule out other diseases. A number of disorders may mimic early MND, including hyperthyroidism, hypoglycaemia, compression of the spinal cord, toxic agents, infections and neoplasms.

Medications

Riluzole (Rilutek), an antiglutamate, is the first medication developed to treat MND. It inhibits the presynaptic release of glutamic acid in the CNS and protects neurons against the excitotoxicity of glutamic acid. This oral medication is administered without food at the same time each day. People are regularly monitored for liver function, blood count, blood chemistries and alkaline phosphatase. They should be warned to report any febrile illness to their healthcare provider and to avoid alcohol.

Nursing care

Nursing care focuses on current health problems and on anticipating future difficulties. As with other disorders causing incapacitation and dependence, individualised nursing goals and interventions relate to decreasing complications, especially those associated with loss of muscular function and immobility; promoting independence to the extent possible; initiating referrals, particularly to a support group for both the person and their family; and providing physical and psychosocial support as indicated.

Of special consideration is planning for the person's eventual inability to communicate. Because the person's eye muscles and movements remain intact, signals can be prearranged before the loss of speech.

Nursing diagnoses and interventions

Two nursing diagnoses that frequently apply to people with MND are *Risk of disuse syndrome* and *Ineffective breathing pattern*.

Risk of disuse syndrome

People with MND are at risk of developing problems associated with bed rest not only because they cannot move and reposition themselves, but also because they frequently have altered nutritional and hydration status. Nursing interventions focus on preventing skin breakdown and infections such as urinary tract infections.

- Assess current condition for baseline parameters, particularly skin over bony prominences, lung sounds and vital signs. *Understanding the person's current condition allows accurate future assessment and realistic planning.*
- Assess skin; provide skin care and obtain an alternating-pressure mattress. *Pressure points are at risk of breakdown; early detection is crucial to instituting appropriate care.*
- Institute active ROM exercises, as the person is able. Perform passive ROM exercises every 2 hours, when the person is turned. *Contractures can develop within a week because extensor muscles are weaker than flexor muscles.*
- Maintain positive nitrogen balance and hydration status: monitor prealbumin levels, haemoglobin and haematocrit levels, and urine specific gravity. *Adequate protein is required to maintain osmotic pressure and prevent oedema; positive nitrogen balance promotes optimal body functioning.*
- Monitor for manifestations of infection; for example, assess urine, especially if a urinary catheter is present. *Urinary catheters place people at high risk of sepsis; bed rest places the person at greater risk of urinary stasis.*

CONSIDERATION FOR PRACTICE

Urinary tract infection is indicated by cloudy, foul-smelling urine, pain on urination, fever and general malaise.

Ineffective breathing pattern

As the muscle weakness of MND continues, people become less able to breathe. The respiratory muscles are affected and people eventually may require ventilatory assistance. The nurse must initiate measures to support the existing respiratory effort.

- Obtain a baseline assessment of breathing pattern, air movement and oxygen saturation. *Assessments indicating the person's current condition provide data to plan individualised interventions.*
- Turn at least every 2 hours. *Movement enhances the ability to move pulmonary secretions and prevents stasis.*
- Elevate the head of the bed at least 30 degrees, suction as indicated and provide oxygen. *This supports ventilation and enhances lung expansion as the person's condition changes.*
- Monitor temperature and lung sounds routinely; obtain sputum culture as indicated. *Early detection of a possible infectious process leads to prompt treatment.*

CONSIDERATION FOR PRACTICE

A pulmonary infection is indicated by respiratory difficulty, crackles and/or wheezes, cough productive of yellow or green sputum, fever and malaise.

Community-based care

Initial teaching centres on explaining the disease process, expected course and prognosis. Referral to a social worker to determine home care needs and financial assistance is helpful. Counselling and referrals to a home health agency, dietitian and physiotherapist, and speech and occupational therapists can help the family meet the person's changing needs and abilities. The realistic anticipation of needs cannot be overemphasised.

As the person becomes more debilitated, family members or other care providers focus on preventing complications. For example, family members need to know how to suction the person and perform the first aid treatment for choking to prevent aspiration. Teaching the family how to prevent problems related to immobility is a primary consideration for the nurse.

LINKS TO NATIONAL PATIENT SAFETY STANDARDS

NSQHS Standard 10:
Preventing Falls and Harm from Falls.

'The intention of this standard is to reduce the incidence of patient falls and minimise harm from falls.' (Australian Commission on Safety and Quality in Health Care (ACSQHC), 2012, p. 66)

Implementing this standard is achieved by the establishment of systems and procedures that aim to eliminate preventable falls and reduce harm resulting from falls that may occur. This includes the development of falls-related policies and procedures; thorough screening and assessment to identify people at increased risk of falls; the implementation of evidence-based falls-prevention strategies; and communicating with patients, families and carers about identified falls risks, and collaborating to develop suitable falls-prevention plans.

Individuals with degenerative neurological disorders are at risk of falls due to the progressive nature of these conditions. These conditions increase a person's risk of falls due to the development of increased confusion, disorientation, fatigue and tremors; decreased motor control; unsteady gait; and loss of balance. The implementation of systems that address prevention of falls and harm from falls is essential to the safety and wellbeing of people with degenerative neurological conditions.

Source: © Australian Commission on Safety and Quality in Health Care.

Another focus of teaching is basic care needs, such as care required to meet elimination needs. Teach families methods to establish a bowel routine, considerations related to a urinary catheter and the need to promptly report manifestations of an infection.

Throughout the early stage and continued care of the person with MND and their family, much consideration is given to psychosocial concerns. Depression, anger and denial may be initial reactions; refer the person and their family to an MND support group, social worker, psychologist or psychiatrist as indicated.

PERIPHERAL NERVOUS SYSTEM DISORDERS

Many aetiological agents are responsible for peripheral nervous system disorders. Autoimmune disorders, viruses, environmental toxins such as heavy metals, and nutritional deficiencies can affect the peripheral nervous system.

THE PERSON WITH MYASTHENIA GRAVIS

Myasthenia gravis is a chronic autoimmune neuromuscular disorder characterised by fatigue and severe weakness of skeletal muscles. People experience periods of remission and exacerbation, and mild forms of the disorder exist. Weakness may remain limited to a few muscle groups, especially the ocular muscles, or may become generalised with all muscles eventually becoming weakened.

Women are affected three times more frequently than men. The average age of onset for women is 28 and men is 42 (Muscular Dystrophy Foundation Australia, 2012). Treatment with anticholinesterase medications has greatly improved the prognosis and symptom management.

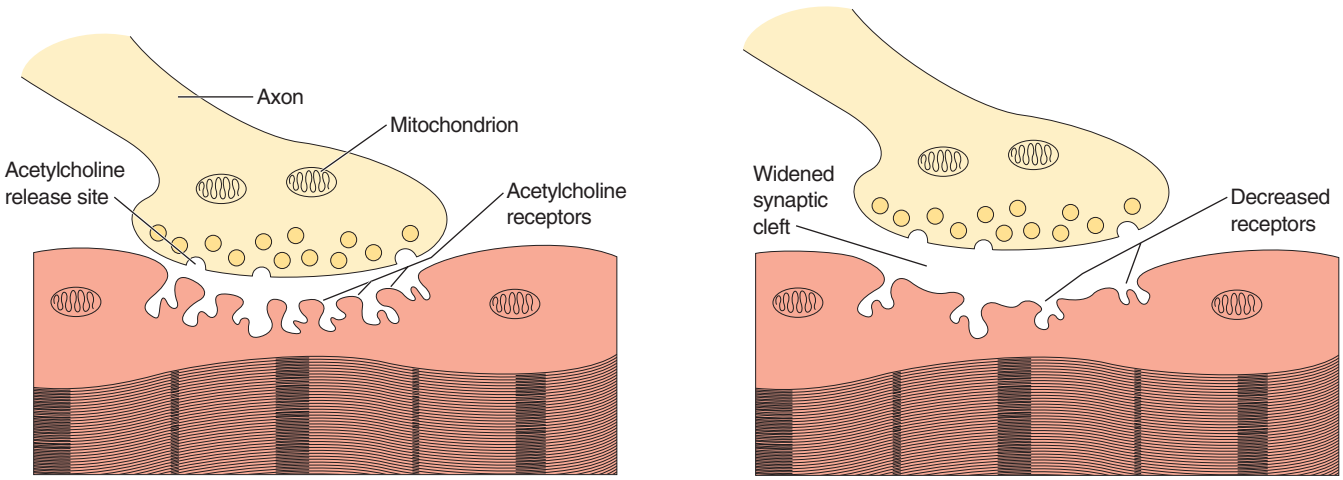
Pathophysiology

The axons of motor neurons divide as they enter skeletal muscles and each axonal ending forms a neuromuscular junction. Although the axonal ending and the muscle fibre are extremely close, they are separated by the synaptic cleft. The transmission of nerve impulses from the nerve to the muscles occurs at the neuromuscular junctions. The neurotransmitter acetylcholine is released from the axonal ending, crosses the synaptic cleft, attaches to acetylcholine receptors on the muscle fibre and stimulates the muscle.

In myasthenia gravis, antibodies destroy or block neuromuscular junction receptor sites, resulting in a decreased number of acetylcholine receptors. Structural changes also result in diminished acetylcholine uptake. The net result is a decrease in the muscle's ability to contract despite a sufficient amount of acetylcholine. A comparison of a normal neuromuscular junction and one affected by myasthenia gravis is shown in Figure 43.4.

In about 75% of people with myasthenia gravis, the thymus gland, which is usually inactive after puberty, continues to produce antibodies because of hyperplasia of the gland or because of tumours. It is believed that the thymus is a source of autoantigen that triggers an autoimmune response in myasthenia gravis. The exact mechanism and reason for the thymus gland's antibody production are unknown.

Myasthenia gravis is sometimes associated with a tumour of the thymus, thyrotoxicosis (hyperthyroidism), rheumatoid arthritis and lupus erythematosus. The disorder is often diagnosed



A Normal neuromuscular junction

B Myasthenia gravis

FIGURE 43.4 ■ *A*, A normal neuromuscular junction and *B*, one showing the changes seen in myasthenia gravis. These changes interfere with the transmission of nerve impulses to the muscle

when a person seeks treatment for a coincidental infection that exacerbates manifestations. Exacerbations may also occur before the menstrual period and during or soon after pregnancy.

Manifestations

The manifestations of myasthenia gravis correspond to the muscles involved. Initially, the eye muscles are affected and the person experiences either diplopia (unilateral or bilateral double vision) or ptosis (drooping of the eyelid) (see Figure 43.5). Next, the facial, speech and mastication muscles become weak and people may have periods of dysarthria and dysphagia. Fatigue is evident even when the person tries to eat a meal; the muscles of chewing tire and the person is forced to stop eating momentarily. A smile becomes a snarl or grimace, and the voice is weak with a muffled nasal quality. Problems performing fine motor movements of the hands, such as writing, appear early in the disease.

As the disease progresses, the muscles of the neck and extremities are affected. When the muscles of the neck become affected, the head juts forward. Deep tendon reflexes are usually normal, however, even in weak muscles. Fatigue and weakness are exacerbated with stress, fever, overexertion and exposure to heat, and are relieved by rest. Manifestations vary on a daily basis. Manifestations and complications of myasthenia gravis are listed in the box below.

Complications

Complications are directly related to the degree of muscle weakness and the specific muscles involved. For example, when the pharyngeal and palatal muscles are affected, the person cannot manage swallowing and may aspirate food or fluids. The person is at increased risk of pneumonia because weakness of the diaphragm and muscles of respiration compromises gas exchange. People with myasthenia gravis can develop life-threatening emergencies, including myasthenic crisis and cholinergic crisis.

Myasthenic crisis

Myasthenic crisis is a sudden exacerbation of motor weakness putting the person at risk of respiratory failure and aspiration. Myasthenic crisis most often is due to undermedication, missed doses of medication or a developing infection. Manifestations of myasthenic crisis include tachycardia, tachypnoea, severe respiratory distress, dysphagia, restlessness, impaired speech and anxiety.

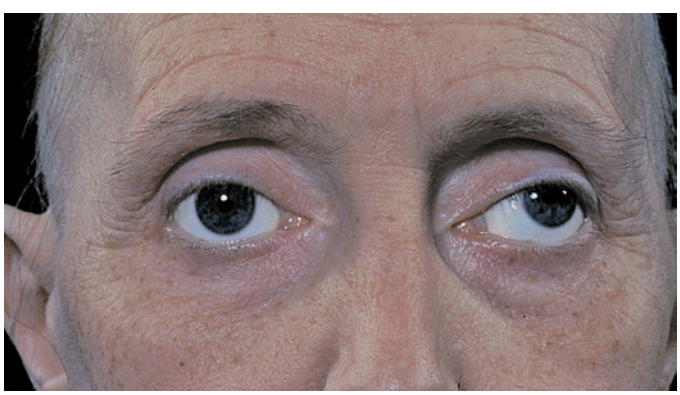


FIGURE 43.5 ■ In myasthenia gravis, the person experiences unilateral weakness of the facial muscles. Note the drooping of one eyelid

Source: Wellcome Image Library/Custom Medical Stock Photo.

MANIFESTATIONS AND COMPLICATIONS

Myasthenia gravis

OCULAR AND FACIAL
- Ptosis
- Diplopia
- Facial weakness
- Dysphagia
- Dysarthria
- Complications: difficulty closing eyes, aspiration, impaired communication and nutrition

MUSCULOSKELETAL
- Weakness and fatigue
- Decreased function of hands, arms, legs and neck muscles
- Complications: inability to perform ADLs and self-care activities, complications related to immobility, myasthenic and cholinergic crises

RESPIRATORY
- Weakening of intercostal muscles
- Decrease in diaphragm movement
- Breathlessness and dyspnoea
- Poor gas exchange
- Complications: decreasing ability to walk, eat and perform other ADLs, pneumonia

NUTRITIONAL
- Inability to chew and swallow
- Decreasing ability to move tongue
- Impairment of fine motor movements: inability to feed self
- Complications: weight loss, dehydration, malnutrition, aspiration

Cholinergic crisis

Cholinergic crisis is the result of overdosage with the anticholinesterase (cholinergic) medications used to treat myasthenia gravis. Gastrointestinal manifestations, severe muscle weakness, vertigo and respiratory distress are signs of cholinergic crisis. Both types of crises are emergency, life-threatening situations; people frequently require ventilatory assistance. Differentiation is based on the person's response to edrophonium chloride (Tensilon). In myasthenic crisis the test is positive; in cholinergic crisis the test is negative (see the discussion that follows under 'Diagnosis').

INTERPROFESSIONAL CARE

Care of the person with myasthenia gravis focuses on providing appropriate treatment, preventing complications and supporting the person and their family in meeting physical and psychosocial needs, especially as the disease progresses.

Diagnosis

Diagnostic tests are conducted following a thorough history and physical examination, with special attention to the facial, oculomotor, laryngeal and respiratory muscles. Diagnostic tests include the anticholinesterase (Tensilon) test, nerve stimulation studies and an analysis of antiacetylcholine receptor antibodies.

In the Tensilon test, the person is injected with edrophonium chloride, a short-acting anticholinesterase. People with myasthenia gravis show a significant improvement in muscle strength that lasts approximately 5 minutes. This test is also used to differentiate myasthenic crisis (caused by insufficient medication, so the person shows improvement with the drug) from cholinergic crisis (caused by overmedication, so the person does not show improvement).

Single-fibre electromyography can detect delayed or failed neuromuscular transmission in muscle fibres supplied by a single nerve fibre. Serum assay of circulating acetylcholine receptor antibodies, if increased, is diagnostic of myasthenia gravis with a sensitivity of 80–90%.

Medications

The primary group of medications used to treat myasthenia gravis is the anticholinesterases. These drugs act at the neuromuscular junction and allow acetylcholine to concentrate at the receptor sites, thus promoting muscle contraction. Pyridostigmine (Mestinon) is the most commonly used acetylcholinesterase inhibitor for myasthenia gravis. The person's decrease in manifestations guides dosage.

Immunosuppression with glucocorticoids, typically prednisone, is another pharmacological therapy aimed at improving muscle strength. People must be aware of the need to stay on the drug at the prescribed dose to determine the least amount required for efficacy. If people do not respond to prednisone alone, it may be combined with other immunosuppressive agents, such as cyclosporin or azathioprine (Imuran). Medications used to treat myasthenia gravis are discussed in the 'Medication administration' box below.

Surgery

Approximately 75% of people with myasthenia gravis have dysplasia of the thymus gland. Therefore, thymectomy is often

MEDICATION ADMINISTRATION The person with myasthenia gravis

ANTICHOLINESTERASES/CHOLINESTERASE INHIBITORS

Neostigmine (Prostigmin)
Ambenonium (Mytelase Caplets)
Pyridostigmine (Mestinon, Regonol)
For diagnosis: edrophonium chloride (Tensilon)

Cholinesterase inhibitors are used in myasthenia gravis to enhance the effects of acetylcholine at the remaining skeletal muscle receptors. Cholinesterase inhibitors do not cure or change the underlying pathophysiological processes, but they can provide effective, lifelong improvement of symptoms. Because the cholinesterase inhibitors are non-selective, the neuromuscular, muscarinic and ganglionic junctions are each affected.

Adjusting the dose to obtain maximum benefit with minimal side effects is a major consideration when administering cholinesterase inhibitors. Initially, small doses are given, followed by incremental increases until optimal muscle strength is obtained. The dose may need to be adjusted when activities result in symptoms of undermedication, such as increased ptosis. Severe undermedication results in myasthenic crisis. Although a sustained-release form of pyridostigmine is available for bedtime use, it should not be used during the day because of its inconsistent absorption.

Cholinesterase inhibitors should not be administered to people experiencing obstruction of the intestinal or urinary tract. Caution is advised when administering these drugs to people with asthma, hyperthyroidism, bradycardia or peptic ulcer disease. Cholinesterase inhibitors can cross the placenta; reproductive counselling is indicated.

Nursing responsibilities

- Obtain a baseline assessment of muscle strength and abilities, concentrating on swallowing and ptosis.
- Administer the medication parenterally if the person has dysphagia. Check the dose of the medication carefully when changing from oral to parenteral routes.
- Evaluate the effectiveness of the medication and document the response—for example, time when fatigue occurs in relation to activities.
- Promptly recognise and respond to manifestations of excessive stimulation of muscarinic receptors: excess salivation, urinary urgency, bradycardia, gastrointestinal hypermotility, diaphoresis. Atropine can be administered to combat these manifestations. Respiratory depression and failure can occur and require mechanical ventilation.
- Have a muscarinic antagonist (e.g. physostigmine) readily available to treat poisoning.

Health education for the person and family

- Balancing symptom control with dosage is crucial; record time of dose and response in a journal. Note the time of day when fatigued and any adverse effects, such as excess salivation, sweating, slow heartbeat and diarrhoea.
- Take the medication about 30 minutes prior to meals to enhance swallowing and chewing.
- Report manifestations of myasthenic crisis immediately: severe muscle weakness, fast heartbeat, restlessness, difficulty breathing and increasing difficulty swallowing or speaking.
- Report slow heartbeat, increased salivation or sweating, and/or decreased blood pressure immediately.
- Review possible causes of myasthenic crisis: physical or emotional stress, infection or reduction in the medication dosage.
- Wear or carry MedicAlert® identification.

NURSING CARE OF THE PERSON having a thymectomy

PREOPERATIVE CARE

- Reinforce the doctor's explanation of the procedure and prepare the person for chest tubes and tracheostomy. *Realistic preparation of what to expect postoperatively encourages compliance and allays anxiety.*
- Anticipate the need for alternative communication. *The person may have a tracheostomy; preoperative planning facilitates communication after surgery.*
- Allow sufficient time for questions. Thymectomy is a major surgery requiring either a thoracotomy and sternal split, or a transcervical approach. *The person is usually anxious and adequate time must be allocated to preoperative instruction.*

POSTOPERATIVE CARE

- Provide meticulous pulmonary hygiene: turning, deep breathing and coughing at least every 2 hours; use an incentive spirometer. *Regardless of surgical approach, measures are aimed at preventing pulmonary complications of atelectasis and pneumonia.*
- People with a thoracotomy and sternal split procedure will require care of the anterior chest tube. *Observe for complications, such as pneumothorax. Air may enter the thoracic cavity—be alert for sudden chest pain and dyspnoea, decreased breath sounds and early signs of shock, such as restlessness.*
- Manage pain with scheduled analgesic therapy. *Maintaining a therapeutic blood level of analgesic provides better pain control than waiting until the person requests medication, as on a prn basis.*

recommended for people younger than 60. The two surgical approaches used are the transcervical approach, which is considered less invasive, and the transsternal approach. The latter approach allows a more extensive removal of the gland; however, it also poses more potential complications because it involves splitting the sternum.

Preoperatively, people may be tapered from steroid therapy. Usually, pyridostigmine is administered to prevent muscular manifestations during the perioperative period. Postoperative nursing care focuses on preventing complications and controlling pain. Nursing implications for the person undergoing thymectomy are presented in the box above. Remission is obtained in about 40% of people but may take several years to achieve. Refer to Chapter 35 for care of the person having a thoracotomy and chest tubes. A tracheostomy may be required when the diaphragm or intercostal muscles are involved.

Plasmapheresis

Plasma exchange in myasthenia gravis may be used in conjunction with other therapies; for example, it may be performed prior to surgical intervention. The goal of therapy is to remove the antiacetylcholine receptor antibodies, thus improving severe muscle weakness, fatigue and other manifestations. The procedure is frequently performed when respiratory muscle involvement is evident. See the box below for nursing care of the person having plasmapheresis.

NURSING CARE OF THE PERSON having plasmapheresis

PREPROCEDURE CARE

- Teach about the procedure and what to expect, including what the machine looks like, the need for arterial and venous insertion sites, and the length of time of the procedure (2 to 5 hours). *Giving information, answering questions and addressing concerns decrease anxiety.*
- Check with the doctor about withholding medications until after the procedure. *Medications may be removed from the body as an incidental part of the plasmapheresis process.*
- Assess vital signs and weight. *Baseline parameters are necessary to evaluate for fluid imbalances and response to therapy.*
- Assess FBC, platelet count and clotting studies. *People undergoing plasmapheresis are at high risk of anaemia and coagulation problems secondary to haemolysis of cells.*
- Check blood type and cross-match for replacement blood products. *Hypersensitivity reactions can occur and close monitoring is important.*

CARE DURING AND AFTER THE PROCEDURE

- Observe for dizziness or hypotension. *Hypovolaemia is a complication of plasma exchange, especially during the procedure when up to 15% of the person's blood volume is in the cell separator.*
- Apply pressure dressing to access site(s). *Direct pressure helps decrease or prevent bleeding.*
- Monitor for infection and bruises at the intravenous port site. *The site of vascular access is at risk of complications and must be routinely and carefully assessed for signs of infection and bleeding or haematoma formation.*
- Monitor electrolytes and signs of electrolyte loss. Report imbalances and replace electrolytes as ordered. Observe for circumoral tingling, Chvostek's and Trousseau's signs if calcium levels are low, and cardiac arrhythmias and leg cramps if potassium levels are low. *Hypocalcaemia and hypokalaemia may occur. Hypocalcaemia occurs because the anticoagulant citrate dextrose binds with calcium.*
- Re-evaluate pre-procedure laboratory data, especially FBC, platelet count and clotting times. *The cell-separating process can damage cells; anticoagulation is part of the procedure.*

Nursing care

Because avoiding fatigue is a major part of teaching for myasthenia gravis, it is important to incorporate interventions to enhance rest and conserve energy (see Box 43.4). For example, suggest sitting while preparing meals and performing hygiene and grooming. Anticipating problems such as impaired communication, and developing alternative solutions, can be helpful in promoting independence. A nursing care plan for the person with myasthenia gravis is given below.

Nursing diagnoses and interventions

Nursing care of people with myasthenia gravis focuses not only on present problems but also on anticipated needs. Preventing myasthenic and cholinergic crises, and providing psychological support to people and families, are two important aspects of care. Individualised care depends on the specific therapy instituted. This section discusses the nursing diagnoses related to ineffective airway clearance and impaired swallowing; other nursing diagnoses that commonly apply, such as *Fatigue*, are addressed in other sections of this chapter.

Ineffective airway clearance

The underlying causes of ineffective airway clearance for the person with myasthenia gravis include poor cough mechanism, decreased rib cage expansion, diminished diaphragm movement and decreased expiratory effort. The following interventions require particular attention if the person undergoes a thymectomy.

- Assist with turning, deep breathing and coughing at least every 2 hours. Teach proper coughing techniques; use an incentive spirometer every 2 hours while the person is awake. *Position changes promote lung expansion; coughing helps clear secretions from the tracheobronchial tree.*
- Place in a semi-Fowler's position. *This position expands the lungs and alleviates pressure from the diaphragm; these are especially important considerations if the person is obese.*
- Maintain hydration status and monitor for dehydration; use a humidifier as needed. If needed, teach family how to perform percussion, postural drainage and suction. *Interventions to liquefy secretions, such as ensuring a daily fluid intake of up to 2500 mL (perhaps via feeding tube or parenteral route), help the person mobilise and expectorate sputum.*
- Monitor lung sounds, the rate and character of respirations, and pulse oximetry readings at least every 4 hours or as indicated by the person's condition. *Frequent assessments are critical to early identification of ineffective respirations and oxygenation of tissues.*

Impaired swallowing

People with myasthenia gravis have weakness of the laryngeal and pharyngeal muscles involved with swallowing. Alterations in swallowing place the person at risk of poor nutrition as well as possible aspiration. Family members need to be included in teaching, particularly the person who prepares and assists with meals.

- Assess the ability to safely manage various consistencies of foods; consult with a speech therapist for evaluation. *Dysphagic people are at risk of aspiration; matching food consistency to the person's ability to swallow enhances safety.*
- Plan meals to promote medication effectiveness. *Pyridostigmine should be given 30 minutes before the meal to provide optimal muscle strength for swallowing and chewing.*
- Have the person eat slowly, using small bites of food. Schedule meals during periods when the person is adequately rested; develop a daily schedule incorporating rest periods. *Fatigue may add to dysphagia, putting the person at greater risk of aspiration.*
- If necessary, give cues while eating, such as 'Chew your food thoroughly; swallow.' *Keeping the person focused may enhance swallowing.*
- Teach caregivers the first aid treatment for choking and how to suction. *Knowing specific measures to take in case of aspiration decreases both the person's and the family's anxiety and promotes confidence in managing potential problems.*

BOX 43.4 Personal and family teaching: myasthenia gravis

- Schedule periods of rest and avoid stress; conserve energy when possible.
- Avoid cigarette smoke, alcohol and beverages with quinine (e.g. tonic water).
- Take medications as prescribed. If manifestations change, consult the doctor; the dose may need to be adjusted.
- Avoid extremes of temperature; an environment that is too hot or too cold may cause an exacerbation of myasthenia gravis.
- Avoid people with upper respiratory infections; infections can result in an exacerbation and extreme weakness.

Community-based care

Teaching for the person and family with myasthenia gravis focuses on prevention and recognition of crisis situations, understanding the disorder and methods for coping with both physical and psychosocial problems. Setting realistic goals with the person and family provides opportunities for self-assessment and promotes active participation in rehabilitation.

Address the following topics:

- the importance of maintaining consistency in medication dosage and management
- realistic expectations

NURSING CARE PLAN A person with myasthenia gravis

Kirsten Avis, a 44-year-old homemaker and mother of two teenage sons, was diagnosed with myasthenia gravis 2 years ago. She takes an anticholinesterase medication, pyridostigmine (Mestinon), four times a day. Over the past month she has been experimenting with decreasing the dose of her pyridostigmine because she has 'felt so good'. She was prescribed 60 mg of pyridostigmine three times a day before meals and one-half of a long-acting 180 mg pyridostigmine tablet at night.

Three days ago, she began having chills and fever and her myasthenic symptoms became markedly worse. Mrs Avis is easily fatigued and has been experiencing increasing weakness, bilateral ptosis and mild dysphagia in the late afternoon and evenings. She is admitted to the hospital.

ASSESSMENT

Lela Silva, RN, is caring for Mrs Avis. Physical examination of Mrs Avis reveals severe muscle weakness bilaterally in her hands, arms and thorax. Her voice is nasal and she speaks slowly; the longer she speaks, the more difficult it becomes to understand her. She is anxious and dyspnoeic. Her complaints of weakness, dysphagia, dysarthria, problems with mobility and ptosis are more pronounced later in the day. Vital signs are as follows: BP 138/88, P 88, R 28, T 39°C.

Some improvement in muscle weakness is noted following a restful night's sleep; however, the respiratory distress is more evident and Mrs Avis is increasingly restless. She is moved to the critical care unit for advanced monitoring and possible ventilatory assistance. The medical diagnosis is myasthenic crisis secondary to pulmonary infection.

DIAGNOSES

- *Impaired gas exchange* related to ineffective breathing pattern and muscle weakness, evidenced by dyspnoea, restlessness and fatigue.
- *Risk of aspiration* related to dysphagia, manifested by difficulty swallowing.
- *Fatigue* related to increased energy needs from muscular involvement, manifested by limb weakness and mobility difficulties.

PLANNING

- Management of pulmonary infection and exacerbated symptoms of myasthenia gravis.

Expected outcomes

- Pulse oximetry readings will be maintained at 92% or above.
- No aspiration will occur.
- Will verbalise decreasing fatigue when performing ADLs.
- Will state the correct method of medication dosing and demonstrate how she will maintain schedule.

IMPLEMENTATION

Mrs Avis's manifestations improve following administration of edrophonium chloride (Tensilon) to verify myasthenic crisis. She is placed on oxygen by mask and suctioned as needed; equipment for possible intubation and ventilation is made readily available. She is placed in a semi-Fowler's position and vital signs are assessed every 5 minutes during the acute exacerbation. The nurses in the critical care unit remain in constant attendance throughout the crisis period and provide explanations to Mrs Avis in an effort to decrease her stress and to avoid further severity of manifestations.

Three days after the crisis period, Mrs Avis is moved to a progressive nursing care unit. Nurses follow up on teaching her the manifestations of both myasthenic and cholinergic crises. They discuss the need to wear MedicAlert® identification and review medication administration techniques with Mrs Avis. The nurses emphasise in particular that Mrs Avis must not split time-released medications.

Within 5 days, Mrs Avis's condition stabilises and her weakness decreases sufficiently to allow discharge home. Although her temperature has returned to normal and her respiratory status has improved, she still has a productive cough. Oral antibiotics are prescribed for 2 weeks, after which she will have a follow-up visit with her GP. She is instructed to seek treatment promptly if respiratory symptoms or temperature indicate recurrence of infection.

EVALUATION

Mrs Avis is discharged without developing aspiration pneumonia or any symptoms of aspiration. Her airway was maintained throughout the myasthenic crisis and her pulse oximetry readings remained above 92% once oxygen therapy was initiated. On discharge, pulse oximetry is above 95% without oxygen therapy. Mrs Avis states that her fatigue and weakness have significantly improved.

Both Mrs Avis and her husband are able to explain the difference between myasthenic and cholinergic crises and to identify methods to avoid both problems. Mrs Avis correctly relates her proper medication regimen and makes an appointment for a follow-up visit with her doctor.

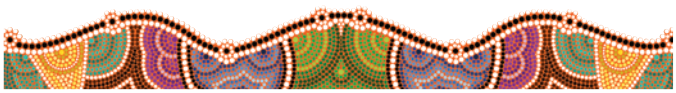
CRITICAL THINKING IN THE NURSING PROCESS

1. What is the rationale for administering Tensilon to evaluate a myasthenic crisis?
2. Develop a plan to assist Mrs Avis to avoid fatigue when preparing and eating meals.
3. Which factors contributed to Mrs Avis's diagnosis of myasthenic crisis?

REFLECTION ON THE NURSING PROCESS

1. Which communication and education strategies could you use to reduce fatigue related to the performance of ADLs and daily tasks?
2. Outline what you have learned from this case study that you will apply to your future nursing practice.

- methods to avoid fatigue and undue stress; specific measures for avoiding upper respiratory infections and exposure to extreme heat or cold
- birth control measures or referral for counselling (Pregnancy can exacerbate manifestations; also, medications used to control myasthenia gravis, such as neostigmine bromide (Prostigmin), cross the placenta.)
- referral to support groups
- helpful resources such as:
  - The Australian Myasthenic Association: www.myasthenia.org.au
  - National Institute of Neurological Disorders and Stroke (NINDS): www.ninds.nih.gov.



THE PERSON WITH GUILLAIN–BARRÉ SYNDROME

Guillain–Barré syndrome (GBS) is an acute inflammatory demyelinating disorder of the peripheral nervous system characterised by an acute onset of motor paralysis (usually ascending). The classification of Guillain–Barré subtypes includes acute inflammatory demyelinating polyradiculoneuropathy, acute axonal motor neuropathy and acute motor and sensory axonal neuropathy.

GBS is one of the most common peripheral nervous system disorders, affecting about 1 to 2 people per 100 000 in Australia (Guillain–Barré Syndrome Association of NSW, 2014). The cause is unknown, but precipitating events include a respiratory or gastrointestinal viral or bacterial infection 1 to 3 weeks prior to the onset of manifestations, surgery, viral immunisations and other viral illnesses. In 60% of cases, *Campylobacter jejuni* is identified as the cause of the preceding infection. Approximately 90% of people with GBS have a spontaneous recovery with little or no residual disabilities.

The disease is characterised by progressive ascending flaccid paralysis, accompanied by paraesthesias and numbness. About 20% of people have respiratory involvement to the point that ventilatory assistance is required. GBS is often a medical emergency.

Pathophysiology

The primary pathophysiological process in GBS is the destruction of myelin sheaths covering the axons of peripheral nerves. The demyelination is thought to be the result of both a humoral- and a cell-mediated immunological response. The loss of myelin results in poor conduction of nerve impulses, causing sudden muscle weakness and loss of reflex response. Other manifestations occur when nerve conduction to various muscles is interrupted. The stages of GBS and their usual manifestations are presented in Box 43.5.

Manifestations

Muscles, sensory nerves and cranial nerves are commonly affected in people with GBS. Most people experience symmetrical muscle weakness, initially in the lower extremities. The weakness and sensory loss then ascends to the upper extremities, torso and cranial nerves. Sensory involvement includes severe pain, paraesthesia and numbness. Cognition and level of consciousness are not affected. Facial nerve involvement results in the inability to change facial expressions and close the eyes. Muscles involved with chewing, swallowing and speaking may be affected.

Paralysis of intercostal and diaphragmatic muscles may alter respiratory function. These people require ventilatory assistance and supportive care. Involvement of the autonomic nervous system is characterised by fluctuating blood pressure, cardiac arrhythmias and tachycardia, paralytic ileus, syndrome of inappropriate antidiuretic hormone secretion and urinary retention.

The weakness usually plateaus or improves by the fourth week. Strength then improves slowly over weeks or months. Women who have had GBS are at increased risk of relapse in the first trimester of pregnancy.

BOX 43.5 Stages of Guillain–Barré syndrome

I. Acute stage
- Characterised by severe and rapid weakness, especially in the lower extremities; loss of muscle strength progressing to quadriplegia and respiratory failure; decreasing deep tendon reflexes; decreasing vital capacity; paraesthesias, numbness; pain, especially nocturnal; facial muscle involvement (inability to wrinkle forehead or change expressions).
- Involvement of the autonomic nervous system manifested by bradycardia, sweating, fluctuating blood pressure (notably hypotension) which may last for 2 weeks.

II. Stabilising/plateau stage
- Occurs 2 to 3 weeks after initial onset.
- Marks the end of changes in condition; characterised by a 'levelling off' of symptoms.
- Generally, the labile autonomic functions stabilise.

III. Recovery stage
- May take from several months to 2 years.
- Marked by improvement in symptoms.
- Generally, muscle strength and function return in descending order.

INTERPROFESSIONAL CARE

Interventions during the acute phase (1 to 3 weeks) focus primarily on ensuring oxygenation via ventilatory assistance and preventing complications from immobility. Rehabilitation time to regain muscle strength and function varies; most people return to full pre-syndrome muscle function within 6 months to 2 years.

Care of the person with GBS requires a team approach. From the initial acute phase through rehabilitation, many members of the healthcare team are involved. An accurate and rapid diagnosis is needed to ensure prompt supportive treatment, particularly if there is respiratory involvement combined with widespread paralysis.

Diagnosis

Diagnosis of GBS is made after a thorough history and clinical examination. It must be differentiated from several disorders, among them influenza, heavy metal poisoning, Lyme disease and cranial haemorrhage. Diagnosis is made based on manifestations, history of a recent viral infection, elevated CSF protein levels and electromyography studies reflecting decreased nerve conduction. Although there is no specific test to diagnose this syndrome, several findings support and confirm the diagnosis.

Medications

No medications are available for the specific treatment of GBS. Other medications may be prescribed to provide support or prophylaxis or to combat concurrent problems; for example, antibiotics may be prescribed for urinary tract or respiratory infections. Morphine is commonly administered to control muscle pain. Anticoagulation therapy is usually instituted to prevent thromboembolic complications, such as deep venous thrombosis and pulmonary embolism, which are associated with prolonged bed rest. If hypotension is a problem, vasopressors are prescribed.

Surgery

Tracheostomy is performed if respiratory failure occurs. People who need ventilatory support are usually able to be weaned after 2 to 3 weeks, but the time frame varies greatly. When the person's vital capacity reaches 8 to 10 mL/kg, they may be weaned from the ventilator (Hickey, 2013). Insertion of a temporary pacemaker may be indicated for bradycardia.

Plasmapheresis

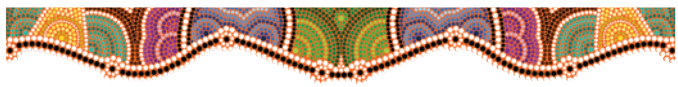
Plasma exchange has been beneficial, particularly when performed within the first 2 weeks of the syndrome's development. Antibodies are removed and immunosuppressive agents are administered concurrently. People typically have five exchanges during an 8–10-day period.

Nutrition and fluids

Nutritional support for the person who is immobilised for prolonged periods of time is crucial. Maintaining positive nitrogen balance, ensuring sufficient fluid intake and electrolyte balance, and ensuring recommended kilojoule intake are goals of therapy. When swallowing problems occur, total parenteral nutrition may be indicated if feeding via a nasogastric or gastrostomy tube is ineffective.

Physiotherapy and occupational therapy

Long-term physiotherapy and occupational therapy are crucial to recovery. People with GBS usually require prolonged rehabilitation care, which begins during the acute phase and focuses on preventing complications and limiting the effects of immobility. The severe muscle atrophy and loss of muscle tone require that people relearn many functions and skills, such as walking. Compromise in respiratory function may delay physical rehabilitation; people need positive reinforcement when they make even small gains in their progress. Continued attention to pain control is essential because paraesthesia and pain can interfere with physical therapy.



Nursing care

Many of the nursing interventions for people with Guillain–Barré syndrome involve monitoring neurological function, preventing problems of immobility, ensuring adequate hydration and nutrition, and promoting respiratory function. Anticipating needs of both the person and their family is an important aspect of care. For example, developing an alternative method of communication before it is necessary may decrease anxiety. It is important that nursing care focuses on preventing complications that may be fatal by following a rigorous predetermined schedule for turning and respiratory care (e.g. coughing, deep breathing, suctioning), using strict aseptic technique and providing continuous psychosocial support.

Nursing diagnoses and interventions

Anxiety and powerlessness are major nursing considerations. The person is almost always admitted to the critical care unit for care and is mentally alert but suddenly mute, ventilator dependent and immobile. Refer to previous nursing care sections in this chapter for interventions related to anxiety, imbalanced nutrition, impaired swallowing, impaired verbal communication and ineffective airway clearance. This section focuses on the nursing diagnoses related to pain and risk of impaired skin integrity.

Acute pain

Pain experienced with GBS varies. Frequently, there is a 'stocking–glove' pattern, with pain in the hands, feet and legs. Pain and tenderness in muscles can be severe; interventions must be individualised to personal needs. The intense pain combined with altered sensations leads to anxiety; nursing interventions can make a difference in breaking the cycle of increasing pain that leads to increased anxiety and in turn causes more pain.

- Listen to the description of pain; determine presence of triggers or a pattern. *Acknowledging the person's perception of pain is a basis for treatment; listening establishes trust.*
- Use a pain scale for determining extent of pain. *Consistent measurement is essential to evaluate degree of pain and effectiveness of intervention.*
- Use complementary therapies to help manage pain:
  - application of heat/cold
  - guided imagery
  - relaxation techniques
  - massage.

Presenting options for managing pain gives the person control over the situation and helps reduce anxiety. Non-invasive interventions may augment the therapeutic benefit of medications.

- Provide analgesics as indicated; administer on a regular schedule rather than waiting until pain becomes severe. *Anticipating and managing pain before it becomes severe decreases anxiety and averts the cycle of increased anxiety leading to increased pain.*
- Monitor for side effects of analgesics, particularly respiratory depression; assess respirations and lung sounds. Perform routine pulmonary care measures and monitor for aspiration. *People with GBS have weakened thoracic muscles; frequent respiratory monitoring is indicated.*

Risk of impaired skin integrity

During the acute and plateau stages of GBS, people are at risk of problems related to immobility and malnutrition. Impaired skin integrity is one such problem. Preventing areas of skin breakdown is important. Prophylactic interventions will help ensure that ingested protein and kilojoules are used to maintain ideal body weight and other body functions rather than to heal an avoidable problem. Implicit in interventions is maintenance of adequate nutrition.

- Inspect bony prominences and provide skin care at least every 2 hours. Reposition the person and clean, dry and lubricate the skin as needed. *These activities stimulate circulation and ensure even distribution of body weight; baseline observations allow discovery of early signs of altered integrity.*
- Pad bony prominences, such as sacral area, heels and elbows. *This decreases shearing tears on these pressure points.*
- Use an alternating-pressure mattress or water bed. *Relieving pressure stimulates circulation and promotes oxygenation of tissues.*
- Monitor for incontinence and provide thorough skin care following each episode of incontinence. *Urine is caustic to the skin and the moisture promotes skin breakdown.*

Community-based care

People and family members are frequently stunned by the rapid deterioration of function and by fear that the paralysis will be permanent. Regularly reinforce teaching because the person's high anxiety level may interfere with listening and understanding. When possible, include the person and their family in decision making; for example, seek their input when planning a daily schedule of care that incorporates various therapies.

Teaching the rationales for preventive measures reinforces the person's and family's understanding and may promote compliance during the lengthy rehabilitation. For example, because of autonomic nerve involvement, people need to be monitored for cardiac arrhythmias and taught to avoid changing position suddenly to prevent orthostatic hypotension.

Referrals to appropriate therapists are a component of anticipating needs; speech, nutritional, occupational and physical therapists are an integral part of rehabilitation. Another focus of care is teaching both the person and their family; incorporate explanations for interventions aimed at promoting self-care. For further information, refer the person and their family to the Guillain–Barré Syndrome Association in their state.

CRANIAL NERVE DISORDERS

Disorders of the cranial nerves may be caused by intracranial trauma or by pathological processes. The pairs of cranial nerves, described in Chapter 40, are numbered in the order in which they arise in the brain and are named according to their anatomical characteristic or primary function. The most common cranial nerve disorders are those affecting the trigeminal (cranial nerve V) and the facial (cranial nerve VII) nerves. These disorders, discussed in the following sections, result primarily in pain or loss of sensory or motor function.

THE PERSON WITH TRIGEMINAL NEURALGIA

Trigeminal neuralgia, also called *tic douloureux*, is a chronic disease of the trigeminal cranial nerve (V) that causes severe facial pain. The trigeminal nerve has three divisions: the ophthalmic, the maxillary and the mandibular (see Figure 43.6). The ophthalmic division supplies the forehead, eyes, nose, temples, meninges, paranasal sinus and part of the nasal mucosa. The maxillary division supplies the upper jaw, teeth, lip, cheeks, hard palate, maxillary sinus and part of the nasal mucosa. The mandibular division supplies the lower jaw, teeth, lip, buccal mucosa, tongue, part of the external ear and the meninges. Sensory fibres of the nerve conduct impulses for touch, pain and temperature; motor fibres innervate the temporal and masseter muscles used for chewing and lateral movement of the jaw. The maxillary and mandibular divisions are the divisions of the trigeminal nerve affected in almost all cases of this disorder.

Trigeminal neuralgia occurs more commonly in middle-aged and older adults, and affects women more often than men.

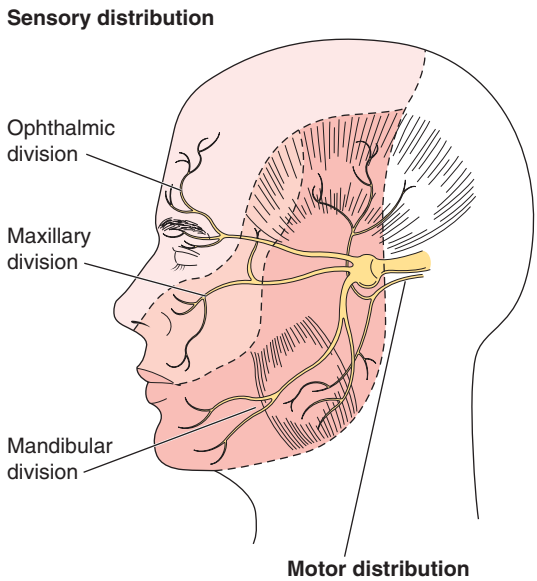


FIGURE 43.6 ■ Sensory and motor distribution of the trigeminal nerve. The three sensory divisions are ophthalmic, maxillary and mandibular

Pathophysiology

The actual cause of trigeminal neuralgia is unknown; however, contributing factors include irritation from flu-like illnesses, trauma or infection of the teeth or jaw, and pressure on the nerve by an aneurysm, a tumour or arteriosclerotic changes of an artery close to the nerve (Hickey, 2013).

Stimulating specific areas of the face, called *trigger zones*, may initiate the onset of pain. These trigger zones usually parallel the distribution of the nerve and typically follow a track leading from just over the eyebrow to the ridge of the cheekbone, along the nasolabial fold, around the corner of the mouth and down the side of the chin. The episodes of pain are initiated by many factors, including light touch, eating, swallowing, talking, sneezing, shaving, chewing gum, brushing the teeth or washing the face. Other factors that may trigger a pain episode include changes in temperature and exposure to wind. In an attempt to control the pain, people may refuse to wash, shave, eat or talk.

The episodes of pain may recur for several weeks or months. The disease then spontaneously goes into remission and the person is free of pain for periods lasting from days to years. As the person grows older, the remissions tend to become shorter and a dull ache may be present between episodes of acute pain.

Manifestations

Trigeminal neuralgia is characterised by brief (lasting a few seconds to a few minutes), repetitive episodes of sudden severe (usually unilateral) facial pain. The pain may occur as often as hundreds of times a day to as infrequently as a few times a year. The pain is experienced over the surface of the skin. It most often begins near one side of the mouth and rises towards the ear, eye or nostril on the same side of the face. People describe the pain as stabbing or lightning-like, and often respond to the pain by wincing or grimacing.

INTERPROFESSIONAL CARE

There are no specific diagnostic tests for trigeminal neuralgia. The disorder is diagnosed by the characteristic location and type of pain. The disorder is treated by pharmacological or surgical interventions.

Medications

The drug most useful in controlling the pain is the tricyclic anticonvulsant carbamazepine (Tegretol). If carbamazepine is ineffective, other medications such as the anticonvulsants phenytoin (Dilantin) or gabapentin (Neurontin) or the skeletal muscle relaxant baclofen (Lioresal) may be used. These drugs are administered to decrease paroxysmal afferent impulses and stop the pain. Drugs in this category may cause side effects of dizziness, nausea and drowsiness. Liver function, bone marrow function and blood levels of the medications should be monitored on a regular basis.

Surgery

If medications do not control the pain, surgical procedures may be performed, including various types of *rhizotomy*—the surgical severing of a nerve root. Closed surgical interventions by percutaneous rhizotomy involve inserting a needle through the cheek into the foramen ovale at the base of the brain and partially destroying the trigeminal nerve with glycerol (an alcohol), by radiofrequency-induced heat or by balloon compression of the trigeminal ganglion. These procedures carry less risk and result in shorter hospital stays than open procedures, but there is a possibility of recurrence of pain. Following surgery, the person may have some facial numbness, but there usually is no residual paralysis. The involved side of the face is insensitive to pain. The person will have some loss of facial sensation (e.g. to temperature and/or touch) and is at risk of loss of the corneal reflex. Closed procedures provide long-term pain relief and are well tolerated by the older adult. Nursing care of the person undergoing a percutaneous rhizotomy is presented in the box below.

It has been found that some structural abnormalities (such as an artery or vein compressing the nerve) may cause the neuralgia and, if so, decompression and separation of the blood vessel from the nerve root produce lasting relief of the pain (Papadakis & McPhee, 2015). The Jannetta procedure involves locating and lifting the involved vessel and placing a small piece of silicone sponge between the vessel and the nerve. Possible complications of the procedure include headache and facial pain.

Nursing care

Nursing care for the person with trigeminal neuralgia involves teaching self-management at home after medical or surgical intervention. Primary personal concerns are managing pain, maintaining nutrition and preventing injury.

NURSING CARE OF THE PERSON having a percutaneous rhizotomy

POSTOPERATIVE CARE

- Follow routine postoperative interventions for people having surgery (see Chapter 3).
- Monitor cranial nerve function every 2 to 4 hours:
  a. Assess the corneal reflex by lightly touching the cornea with a gauze square. If the reflex is intact, the person will blink. *Severing the ophthalmic division of the trigeminal nerve destroys the corneal reflex and leaves the cornea at risk of dryness and injury.*
  b. Assess the facial nerve by asking the person to blow out the cheeks, wrinkle the forehead, frown, wink and close both eyes tightly. Test taste by placing bitter, salty and sweet substances on the anterior portion of the tongue. *Facial weakness is evidenced by changes in movement in the involved side of the face. The facial nerve also innervates the anterior two-thirds of the tongue.*
  c. Assess the function of the oculomotor muscles by asking the person to follow your finger through the cardinal positions of vision (see Chapter 44). *The eyes should move together; alterations in movement indicate an abnormal response.*
  d. Assess the motor portion of the trigeminal nerve by asking the person to clench the teeth while you palpate the tightness of the contracted masseter and temporal muscles. *Loss of motor function is indicated by loss of bulk and tightness of these muscles.*
  e. Apply as prescribed an ice pack to the jaw on the operative site. *Cold decreases bleeding and swelling.*
  f. Teach the person to avoid rubbing the eye on the involved side. *Loss of the corneal reflex removes protection because the person no longer has the sensation of pain in the involved eye. Rubbing the eye could cause corneal abrasions.*

Nursing diagnoses and interventions

Interventions for managing pain and improving nutritional intake are addressed here; teaching to prevent injury following surgery is discussed in the following 'Meeting individualised needs' box.

Acute pain

The person with trigeminal neuralgia has excruciating pain and often avoids ADLs and socialising with others in an attempt to prevent the onset of pain. Pain management is fully discussed in Chapter 8. Nursing interventions for pain in people with this disorder focus on strategies for self-management.

- Identify factors that trigger an attack and discuss strategies to avoid these precipitating factors. *Most people can clearly identify trigger zones and triggering factors. Identification is the first step in pain control.*
- Determine usual response to pain. *Sensitivity and reaction to pain are influenced by previous experiences with pain and by age, gender, emotional factors and cultural background.*
- Assess factors that affect the ability to influence pain tolerance, including the knowledge and cause of the pain, the meaning of the pain, the ability to control the pain, cultural background and support systems. *Pain tolerance, which is the duration and intensity of pain a person is willing to endure, differs greatly between individuals and may also vary within particular people in different situations.*
- Monitor the effects of the medication prescribed for the neuralgia. *If the prescribed medication does not provide relief, other medications or methods of treatment may be used to control the pain.*

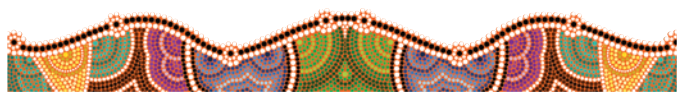
Risk of altered nutrition: less than body requirements

People often refuse to eat during periods of pain attacks, fearing that the movements of chewing may precipitate the pain. In addition, the chronic nature of the illness often causes depression, which may depress the appetite.

- Monitor dietary intake and weight at each visit and ask the person to keep a weekly weight record. *Ongoing assessments are necessary for early detection of nutritional deficiencies.*
- Discuss the temperature and consistency of foods eaten and suggest referral to a dietitian if necessary. *Hot or cold foods may trigger an attack; soft, warm or cool foods are less likely to act as triggers.*
- Suggest chewing on the unaffected side of the mouth. *Chewing on the unaffected side is less likely to trigger an attack of pain and so facilitate food intake.*
- If unable to tolerate oral food, tube feedings may be necessary. *Adequate kilojoules and nutrients for metabolic processes are essential.*

Community-based care

The person with trigeminal neuralgia who is receiving medical treatment and providing self-care at home requires teaching about the disease process, medication(s) being taken and ways to reduce the incidence of attacks or pain. Diet teaching and assistance with self-management of pain are also important. For example, if the home setting is draughty and attacks of pain are triggered by wind blowing across the face, it may be necessary to encourage the person to put weather stripping around windows and doors. To prevent injury to affected areas, the topics in the 'Meeting individualised needs' box below should be addressed.



THE PERSON WITH BELL'S PALSY

Bell's palsy, also called *facial paralysis*, is a disorder of the seventh cranial (facial) nerve, characterised by unilateral paralysis of the facial muscles. The facial nerve is

MEETING INDIVIDUALISED NEEDS Teaching for home care of trigeminal neuralgia

Eye care

- Do not rub the eyes; use artificial tears four times a day if the eyes are dry or irritated.
- Wear an eye patch at night.
- Wear protective sunglasses or goggles when outside, working in dusty areas, mowing the lawn and using any type of spray material (e.g. hair spray, cleaning materials, paint, insecticides).
- Remember to blink frequently.
- Check your eyes for redness or swelling each day.
- Schedule regular eye examinations.

Face and mouth care

- Chew on the unaffected side of the mouth.
- Avoid eating hot foods or drinking hot liquids.
- After every meal, brush your teeth and inspect the inside of your mouth for food that may collect between the gums and cheek.
- Have regular dental examinations; you will not be able to feel pain associated with gum infection or tooth decay.
- Use an electric razor to shave the face.
- Protect your face from very cold or windy conditions.

primarily a motor nerve that supplies all the muscles associated with expression on one side of the face. The sensory component innervates the anterior two-thirds of one side of the tongue.

This disorder can occur at any age but is seen most often in people aged between 15 and 60. The incidence is equal in men and women. The majority of people recover completely within 2 weeks to 6 months, and most recover without any treatment. Of those remaining, many recover some function but have some permanent facial paralysis; these people are usually older, have diabetes mellitus or have more severe manifestations, such as vertigo, a sensitivity to noise and deep head pain (NINDS, 2015b).

Pathophysiology

The exact cause of the disorder is unknown, although inflammation of the nerve and a relationship to the herpes simplex virus have been suggested (Papadakis & McPhee, 2015).

Manifestations

The onset of Bell's palsy is usually sudden and almost always involves one side of the face. Pain behind the ear or along the jaw may precede the paralysis. The person initially notices numbness or stiffness of one side of the face that distorts the appearance. As the disease progresses, the distortion becomes more obvious and the face appears asymmetrical. The facial paralysis causes the entire side of the face to droop and the person cannot wrinkle the forehead, close the eye or pucker the lips on the affected side (see Figure 43.7). When the person attempts to smile, the lower facial muscles are pulled to the opposite side of the face. Some people have only mild manifestations, whereas others have complete facial paralysis. People often believe they have had a stroke. Manifestations of Bell's palsy are listed in the 'Manifestations' box.

MANIFESTATIONS Bell's palsy

- Paralysis of the facial muscles on one side of the face
- Paralysis of the upper eyelid with loss of the corneal reflex on the affected side
- Loss or impairment of taste over the anterior portion of the tongue on the affected side
- Increased tearing from the lacrimal gland on the affected side

FIGURE 43.7 ■ The person with Bell's palsy shows the typical drooping of one side of the face

Source: © Dr P. Marazzi/Science Source.

INTERPROFESSIONAL CARE

There are no definitive laboratory or diagnostic tests for Bell's palsy, nor are there any specific treatments. Treatment includes medications and physiotherapy. Recent studies have shown that antiviral drugs such as aciclovir combined with an anti-inflammatory drug such as prednisone may be effective by limiting damage to the nerve. Physiotherapy to stimulate the facial nerve and help maintain muscle tone may help prevent permanent contractures before recovery takes place. Moist heat applied to the affected side of the face may decrease pain.

Nursing care

Although people provide self-care at home, the nurse plays a key role in teaching the person and their family about Bell's palsy and how to prevent injury and maintain nutrition. The person is often anxious about their appearance and may require counselling if any deficits in facial expression become permanent. The following topics should be addressed:

- Use artificial tears four times a day to lubricate the eye; wear an eye patch or tape the eye shut at night. Wear sunglasses or goggles when outside, working in dusty conditions and using any type of spray.
- Massage combined with warm, moist heat often is effective in relieving the pain.
- A soft diet that does not require chewing and six small meals a day are helpful. Chew slowly on the unaffected side and avoid hot foods. Clean the mouth and carefully inspect the area between the gums and cheek for food after each meal.
- As function returns, practise wrinkling the forehead, closing the eyes, blowing air out of the puckered mouth and whistling for 5 minutes three or four times a day.

DISORDERS RESULTING FROM INFECTIONS AND NEUROTOXINS

A variety of disorders of the nervous system may have infectious or toxic causes. Although these disorders are not common, those included here require significant nursing care when they do occur.

THE PERSON WITH CREUTZFELDT–JAKOB DISEASE

Creutzfeldt–Jakob disease (CJD) (also called *spongiform encephalopathy*) is a rapidly progressive, degenerative, neurological disease that causes brain degeneration without inflammation. The disease is transmissible and progressively fatal. The causative agent is believed to be an abnormal form of a cellular glycoprotein known as the prion protein. Transmission of the agent is by direct contamination with infected neural tissue, such as during eye and brain surgery. The injection of contaminated human growth hormone from cadaveric pituitaries has also been implicated.

A different form of the disease, called *variant CJD (vCJD)* is also a rare, degenerative, fatal brain disorder, but is not the same as the classic form of CJD. New variant CJD, referred to as 'mad cow disease', is believed to result from consumption of cattle products contaminated with bovine spongiform encephalopathy (BSE). This form primarily affects young adults. Because the illness is fatal and is associated with infected cattle, severe restrictions have been placed on the importation of cattle, sheep and goats, and on products from these animals, from countries in which BSE is known to exist.

Both forms of CJD occur worldwide, but clusters occur in several areas, more often in England, Chile and Italy. The incidence is approximately one case per 1 million Australians every year (NSW Health, 2012). Classic CJD affects adults over the age of 50; vCJD affects younger adults. The median age of death for people with classic CJD is 68 years. In contrast, the median age of death with vCJD is 28 years.

Pathophysiology

Creutzfeldt–Jakob disease is characterised by degeneration of the grey matter of the brain. The spongiform degeneration (involving the formation of tiny holes and resembling a sponge) produces severe dementia, myoclonus (muscle contractions) and characteristic changes in brain waves. On autopsy or biopsy of brain tissue, the brain shows loss of neurons and a proliferation of astrocytes (indicating destruction of nearby neurons).

Manifestations

The disease has characteristic stages and manifestations. The onset is characterised by memory changes, an exaggerated startle reflex, sleep disturbances and nervousness. The person then experiences rapid deterioration in motor, sensory and language function. Tremors, hyperreflexia, rigidity and a positive Babinski reflex are often present, and confusion progresses to dementia in almost all cases. People in the terminal state are comatose and exhibit decorticate and decerebrate posturing. The median duration of illness for CJD is 4 to 5 months; the median duration of illness for vCJD is 13 to 14 months (Centers for Disease Control and Prevention (CDC), 2015).

INTERPROFESSIONAL CARE

No specific treatment is available to stop or slow the progression of CJD. Collaborative interventions focus on the disease's manifestations. The disease is diagnosed by a thorough neurological examination, specific EEG changes and a CT scan. However, the final diagnosis of CJD can be made only by postmortem examination. It is often difficult to differentiate this disease from Alzheimer's disease, especially in the early stages.

Nursing care

The nurse may identify the manifestations of CJD when conducting a health history and total physical assessment. Include questions about familial history, cultural and geographical risk, and high-risk occupations or procedures in the history. Assessment of mental function, reflexes and cranial nerve function may provide information to assist in diagnosis.

Nursing care focuses on maximising comfort, preventing injury, preventing transmission and providing support. The following guidelines are useful in designing the plan of care:

- Although comfort is difficult to assess in people with impaired cognitive function, interventions that provide a quiet environment and analgesia are important.
- Communication is essential, even if the person is unable to respond.
- Institute seizure precautions and pad side rails.
- Provide skin care, changes in position and pressure-relief mattresses to decrease the risk of pressure ulcers, venous stasis and pneumonia.
- Use standard precautions for blood and body fluids when providing care. Disinfect surfaces with a solution of 5% bleach. Sterilise contaminated equipment by autoclave or soak in 5% bleach solution for 1 hour. Label all specimens as biohazardous. Teach staff members and family members guidelines for care, including careful handwashing. However, it is not necessary to place the person in isolation.
- Provide time for family members to verbalise grief and loss, which may be manifested as anger and frustration with the healthcare system.
- Provide information to family members about all procedures and the plan of care.
- Refer family members to sources of support, such as social services and the appropriate clergy.

THE PERSON WITH POSTPOLIOMYELITIS SYNDROME

Postpoliomyelitis syndrome is a complication of a previous infection by the poliomyelitis virus. This disease was epidemic in the 1940s and 1950s, but has largely been eradicated through immunisation with oral live trivalent virus vaccine. It is estimated that up to 4 million Australians were affected by poliomyelitis (Polio NSW, 2013). These people have struggled for years to rehabilitate themselves and lead productive lives. Now, as they reach retirement age, they are again experiencing manifestations which may be physically and psychologically incapacitating.

The poliomyelitis virus destroys some of the motor cells of the anterior horn cells of the spinal cord, causing neuromuscular effects that range from mild to severe flaccid paralysis and atrophy. The primary cause of death is respiratory arrest (Papadakis & McPhee, 2015).

Manifestations of motor neuron degeneration and weakness may emerge 10 to 40 years after the initial infection. Most people with postpoliomyelitis syndrome initially had a more severe case of polio and required hospitalisation, contracted the disease after the age of 10, required ventilator assistance for respiration and had paralysis in all four extremities. The incidence is slightly higher in women. As the population ages, it is projected that the number of older adults with postpoliomyelitis syndrome will increase.

Pathophysiology

The pathophysiological process in postpoliomyelitis syndrome is not known.

Manifestations

The manifestations of postpoliomyelitis syndrome include fatigue, muscle and joint weakness, loss of muscle mass, respiratory difficulties and pain. The manifestations are most often seen in muscles affected by the initial infection, but new muscle groups may also be affected. In addition to neuromuscular manifestations, the person may experience cold intolerance, dizziness, headaches, urinary incontinence and sleep disorders.

INTERPROFESSIONAL CARE

Postpoliomyelitis syndrome is diagnosed by a previous history of polio and the current manifestations. Diagnostic studies of nerve conduction, muscle strength and pulmonary function determine current physical status. Treatment addresses the manifestations and often involves physical physiotherapy and pulmonary rehabilitation programs.

Nursing care

The person with postpoliomyelitis syndrome faces the challenge of unexpected physical changes. People are often anxious about how others will react or what the future holds. Respiratory

dysfunction may result in the need for oxygen. Muscular weakness and decreased pulmonary function may make walking difficult, if not impossible. ADLs, independent self-care and careers are threatened.

Many people have not fully recovered psychologically from having polio and may respond to a recurrence of manifestations with denial and disbelief. Older people may not know they had polio as children. Nurses are responsible for assessing and identifying the manifestations of postpoliomyelitis syndrome. It is essential to question middle to older adults about a past history of polio when conducting the health history and to ask specific questions about manifestations that the person may be experiencing.

The nurse individualises teaching to meet the physical and psychosocial needs of the person and their family. The nurse should provide candid explanations and teach the person how to prevent fatigue, promote optimal respiratory function, meet self-care needs, modify ADLs and maintain safety. Follow-up care with nurses, doctors, physiotherapists, respiratory therapists and counsellors is indicated. Referral to a support group can make a positive difference in the person's and family's ability to cope with the disorder.

THE PERSON WITH RABIES

Rabies is a rhabdovirus infection of the central nervous system transmitted by infected saliva that enters the human body through a bite or an open wound. It is a fatal viral encephalitis that causes tens of thousands of deaths worldwide each year, with more than 15 million people worldwide receiving post-exposure vaccination (World Health Organization (WHO), 2015). Rabies does not currently occur in Australia, but a rabies-like virus, called the lyssavirus (which is lethal to humans), is carried by Australian animals such as bats and flying foxes; therefore, understanding the effects remains important to Australians (NSW Health, 2013). Rabies is a critical illness that almost always causes death if untreated. The rabies virus is carried by both wild and domestic animals, including bats, skunks, foxes, raccoons, cats and dogs. After an incubation period that may last from 10 days to many years (the norm is 3 to 7 weeks), the virus travels to the brain of the infected animal via the nerves. It multiplies and migrates to the salivary glands.

Pathophysiology

The person with rabies usually has a history of an animal bite but may also become infected through an abrasion or open wound that is exposed to the infected saliva. The virus spreads from the wound to local muscle cells and then invades the peripheral nerves. It eventually travels to the central nervous system. The incubation period in humans varies according to the severity and location of the bite. For example, bites on the face may result in manifestations in 10 days to a few weeks, whereas bites on the lower extremities may incubate for as long as 1 year.

Manifestations

The manifestations occur in stages. During the initial—or prodromal—stage, the site of the wound is painful and then exhibits various paraesthesias. The infected person is anxious, irritable and depressed. General manifestations of infection (such as headache, loss of appetite and sore throat) may appear. The person may also have increased sensitivity to light and sounds, and the skin is especially sensitive to changes in temperature.

The prodromal stage is followed by an excitement stage. The infected person has periods of excitement that alternate with periods of quiet. Attempts to drink cause such painful laryngospasms that the person refuses to drink (a phenomenon called *hydrophobia*). Large amounts of thick, tenacious mucus are present. The person experiences convulsions, muscle spasms and periods of apnoea. If untreated, death occurs approximately 7 days from the onset of manifestations and is usually due to respiratory failure.

INTERPROFESSIONAL CARE

Sick animals should be euthanised and their brains examined for presence of the rabies virus, which is detected by fluorescent antibody testing. The blood of an infected person can also be tested with the same diagnostic study to demonstrate the presence of rabies antibodies.

Nursing care

Nursing care for people with rabies is provided in a critical care unit, with the person in a quiet, darkened room to decrease stimulation as much as possible. The person requires interventions to maintain the airway, maintain oxygenation and control seizures. Standard precautions are essential, because the rabies virus is present in the saliva of the person. If an open wound of a healthcare provider is contaminated with infected saliva, the provider must receive post-exposure immunisations.

Health promotion

Personal and family teaching focuses on the importance of providing proper care of wounds, seeking immediate medical attention for animal bites and obtaining treatment after any suspicious bite.

Because the untreated disease is almost always fatal, the best intervention is prevention. Preventive activities include:

- Immunisation of those at risk of injury from bats (i.e. bat handlers, vets and wildlife officers).
- Local treatment of animal bites and scratches:
  - Carefully and thoroughly clean and flush wounds with soap and water to remove the saliva and dilute the viral exposure.
  - Immediately take the person with the bite for emergency treatment.

- Post-exposure care:
  - Human rabies immunoglobulin (RIG) is administered for passive immunisation. A dose of 20 units/kg of the immunoglobulin is infiltrated around the wound and the rest is administered intramuscularly. At the same time, an inactivated human diploid cell vaccine (HDCV) is administered intramuscularly, with 1 mL given on the day of exposure and on days 3, 7, 14 and 28 after exposure (WHO, 2013). HRIG and HDCV should never be given in the same syringe or at the same site. Local and mild systemic reactions include itching, tenderness, headaches, muscle aches and nausea.
  - If RIG is not available, equine rabies antiserum may be administered after testing the person for horse serum sensitivity.

THE PERSON WITH TETANUS

Tetanus, more commonly called *lockjaw*, is a disorder of the nervous system caused by a neurotoxin elaborated by *Clostridium tetani*. This anaerobic bacillus lives in the soil. Spores of the bacillus enter the body through open wounds contaminated with dirt, street dust or faeces (animal or human). The wounds may result from punctures, scratches or abrasions, bee stings, abortions, surgery, trauma, burns or intravenous drug use. Incidence is highest in people who have never been immunised, the very young who are not fully immunised and older adults whose immunity has been lost. Tetanus has a high mortality rate, with death occurring in approximately three in every 100 cases (Department of Health, 2015). Contaminated lesions of the head and face are more dangerous than those in other parts of the body.

Pathophysiology

When the spores of *C. tetani* enter the open wound, they germinate and produce a toxin called tetanospasmin. The incubation period averages 8 to 12 days but can range from 5 days to 15 weeks (Papadakis & McPhee, 2015). The toxins are absorbed by the peripheral nerves and carried to the spinal cord, where they block the action of inhibitory enzymes at spinal synapses and interfere with transmission of neuromuscular impulses. As a result, even minor stimuli cause uncontrolled muscle spasms.

Manifestations

The manifestations begin with pain at the site of the infection. The infected person has stiffness of the jaw and neck, and dysphagia. There is often profuse perspiration and drooling from increased salivation. As the infection progresses, the person experiences hyperreflexia, spasms of the jaw muscles (*trismus*) or facial muscles, and rigidity and spasms of the abdominal, neck and back muscles. Generalised tonic seizures are caused by even minor stimuli and the person assumes a typical opisthotonic position during the seizures: the head is retracted, the back is arched and the feet are extended. The muscle spasms are painful. The person may be unable to breathe from spasms of the glottis and respiratory muscles. Despite these physical effects, the person has no change in mental status.

The complications of tetanus include urinary retention and airway obstruction from the spasms. Cardiac and respiratory failure are late, life-threatening complications.

INTERPROFESSIONAL CARE

There are no specific diagnostic tests for tetanus; diagnosis is based on manifestations. Tetanus is completely preventable by active immunisation. Immunisation for children includes tetanus toxoid, administered as part of the diphtheria-pertussis-tetanus (DPT) immunisation series. In adults, immunisation is obtained by administering tetanus toxoid as two doses 4 to 6 weeks apart, with a third dose in 6 to 12 months. All individuals should have a booster dose every 10 years throughout life, or at the time of a major injury if the last booster dose was given more than 5 years prior to the injury.

If a wound is contaminated, or if the person's immunisation status is uncertain, passive immunisation with tetanus immune globulin is administered. Active immunisation with tetanus toxoid is begun at the same time. The wound is carefully and thoroughly debrided and antibiotics are administered.

The person with tetanus requires intensive care in an area of minimal stimulation. Penicillin is administered to help destroy the toxin-producing organism. Muscle spasms and seizures are controlled by chlorpromazine (Largactil) or diazepam (Valium), often combined with a sedative. Anticoagulants may be prescribed to prevent venous thrombosis. In severe cases, seizures and spasms are controlled with paralysis by a curare-like medication and airway obstruction is managed by mechanical ventilation.

Nursing care

Nursing care for the person with tetanus is intensive and focuses on assessments and interventions to promote safety, prevent injury, maintain nutrition and maintain pulmonary and cardiovascular function. The person usually requires in-hospital care for 2 to 5 weeks. The nursing care plan commonly includes the following:

- Place in a quiet, darkened room to decrease stimuli that cause muscle spasms and seizures.
- Provide only necessary physical care and do so during periods of maximal sedation to decrease tactile stimulation that causes muscle spasms.
- Maintain oxygenation through mechanical ventilator and frequent suctioning of secretions.
- Maintain intravenous access for the administration of fluids and medications.
- Administer prescribed antibiotics, anticonvulsants and sedatives. In the case of cardiovascular complications, administer prescribed beta-adrenergic blocking agents such as propranolol (Inderal).

- Provide adequate nutrition through prescribed nutritional support, such as total parenteral nutrition.
- Monitor respiratory and cardiovascular status and provide immediate interventions for respiratory or cardiovascular failure.
- Monitor fluid and electrolyte status. Ensure adequate fluid intake to maintain hydration and urinary output.
- Monitor urinary output, which should be maintained at 1.5 to 2 L per day.
- Monitor for the hazards of immobility, including constipation, pneumonia, deep venous thrombosis and pressure ulcers.

Health promotion

Tetanus is a preventable disorder and nurses have a major role in promoting immunisations for all children and for educating adults about the need for booster doses. The older population is especially at risk of never having been immunised or for letting immunisations lapse. Information for this age group can be provided through activities such as community health fairs and programs at senior citizen groups.

It is also necessary to teach the proper care of wounds. All wounds, no matter how small, should be thoroughly washed with soap and water. All foreign material should be carefully flushed out or removed from a wound, and medical care should be sought for wounds that are more extensive or contaminated.

THE PERSON WITH BOTULISM

Botulism is food poisoning caused by ingestion of food contaminated with a toxin produced by the bacillus *Clostridium botulinum*. This anaerobic spore-forming bacillus is found in the soil. Most cases of botulism occur from eating improperly canned or cooked foods, especially home-canned vegetables and fruits, smoked meats and vacuum-packed fish. The mortality rate is high if the disease is untreated.

Pathophysiology

The toxins liberated by *C. botulinum* are absorbed by the gastrointestinal tract and bound to nerve tissues. They block the release of acetylcholine from nerve endings and thus cause respiratory paralysis due to paralysis of skeletal muscles.

Manifestations

Manifestations appear 12 to 36 hours after ingestion of the contaminated food. They usually begin with visual disturbances such as diplopia, loss of accommodation and fixed, dilated pupils. Ptosis is often present. Gastrointestinal manifestations include nausea and vomiting, diarrhoea, dysphagia and dry mouth. Involvement of the larynx is manifested by dystonia (impaired muscle tone). Paralysis of all muscle groups progresses throughout the body, with respiratory paralysis causing death if the person is not placed on a mechanical ventilator. There is no effect on mental status.

INTERPROFESSIONAL CARE

Infection with the *Clostridium* toxin is verified by laboratory analysis of the serum and stool and of suspected food, if possible. If botulism is suspected, the local Public Health Unit should be notified for assistance with laboratory assays and procuring botulism antitoxin. All people who may have eaten the contaminated food must be located and observed.

Any toxins in the gastrointestinal system are removed by cathartics, enemas and gastric lavage. The person with respiratory paralysis is placed on a mechanical ventilator and may require a tracheostomy. Botulism antitoxin is administered to eradicate toxins in the circulation. Nutritional support is often provided with total parenteral nutrition. Intravenous fluids are administered to prevent dehydration and renal failure. If ventilation can be maintained, the person often recovers without further neurological deficits.

Nursing care

The person with botulism is hospitalised and interventions focus on monitoring for respiratory failure and providing ventilatory assistance if necessary. Ongoing assessments are also made for manifestations of paralytic ileus and urinary retention. The person will be nil by mouth until able to swallow and breathe; therefore, hydration and nutritional status are monitored. Teach the person and their family that fatigue and weakness may persist for up to a year. During this time, the person may need to modify ADLs and take rest periods throughout the day.

Health promotion

Education of the public to prevent botulism is important. Address the following topics at health fairs and community programs:

- Home-canned foods must be processed in a pressure cooker rather than in boiling water because the organism is difficult to kill.
- Do not eat home-processed foods that have a change in colour, are soft, contain gas bubbles or have a bad odour.
- Always heat both home-processed and commercial foods at temperatures over 120°C or boil for 10 minutes before tasting or eating them.
- Discard home-processed or commercially canned or bottled foods with defective seals.
- Discard commercially prepared canned foods that are damaged or have bulging sides or leaking contents.

CHAPTER HIGHLIGHTS

- Alzheimer's disease (AD) is a form of dementia (a disease of the brain) of older adults with progressive irreversible deterioration of general intellectual functioning. The disease is characterised by atrophy of brain tissue, loss of neurons, neurofibrillary tangles and amyloid plaques. AD finally leaves the person unable to communicate, maintain continence and recognise self or others. Caregivers need much teaching and support not only to provide care but also to avoid caregiver burden.
- Multiple sclerosis (MS) is a chronic demyelinating neurological disease of the CNS (brain, optic nerves and spinal cord). Occurring in young to middle-aged adults, it is believed to be due to an autoimmune response to a prior viral infection. The loss of myelin leads to axon dysfunction, which slows and distorts nerve impulses. Medications (ACTH, immunosuppressive agents, interferon and glatiramer acetate) are used to slow the progression of the disease, decrease the number of exacerbations and treat manifestations.
- Parkinson's disease (PD) is a progressive degenerative neurological disease characterised by tremor, muscle rigidity and bradykinesia. The loss of voluntary motor control is the result of pathological processes resulting in a decrease of dopamine (an inhibitory neurotransmitter) so that it can no longer inhibit acetylcholine (an excitatory neurotransmitter). Medications are used to treat manifestations and include MAO inhibitors, dopaminergics, dopamine agonists and anticholinergics. Other treatments include deep brain stimulation and surgery.
- Huntington's disease (HD) (chorea) is a progressive, degenerative, inherited neurological disease characterised by increasing dementia and chorea. There is an excess of dopamine, causing excessive, uncontrolled movement.
- Motor neurone disease (MND) is a rapidly progressive and fatal degenerative disease characterised by weakness and wasting of voluntary control muscles, but without sensory or cognitive changes. The person eventually loses the ability to communicate and breathe. Riluzole, antiglutamate medication, is used to treat (but not cure) manifestations.
- Myasthenia gravis (MG) is a chronic autoimmune peripheral nervous system disorder characterised by fatigue and severe skeletal muscle weakness. It results from a decreased number of acetylcholine receptors at the neuromuscular junction, so muscles are unable to contract. Life-threatening emergencies include myasthenic crisis (sudden increase in motor weakness) and cholinergic crisis (from an overdose of the anticholinesterase medications used to treat MG).
- Guillain–Barré syndrome (GBS) is an acute inflammatory demyelinating disease of the peripheral nervous system characterised by an acute onset of flaccid motor paralysis that begins in the lower extremities and ascends to involve the upper extremities, torso and cranial nerves. Paralysis of intercostal and diaphragmatic muscles often necessitates ventilatory assistance. The acute phase lasts from 1 to 3 weeks, followed by recovery, which takes from 6 months to 2 years.
- Cranial nerve disorders include trigeminal neuralgia (tic douloureux) and Bell's palsy. Trigeminal neuralgia is a chronic disorder of cranial nerve V and causes severe facial pain. Bell's palsy is an acute disorder of cranial nerve VII, characterised by unilateral paralysis of the facial muscles. People provide self-care at home and require teaching to help prevent complications.
- Neurological disorders resulting from neurotoxins or viruses include Creutzfeldt–Jakob disease, postpoliomyelitis syndrome, rabies, tetanus and botulism. Community-based health education can not only provide information but can also prevent illness in the case of rabies, tetanus and botulism.

CONCEPT CHECK

1 Which of the following statements is true of dementia? (Choose all that apply.)
1. Dementia is a general term used to describe manifestations of damage or death of neurons.
2. Dementia is the term used to describe the cognitive and behavioural manifestations of AD.
3. Dementia is an acute disorder resulting from an injury to the brain.
4. Dementia is the primary manifestation of Guillian–Barré syndrome.

2 Which manifestation is usually the first indication of the onset of AD?
1. inability to perform ADLs
2. sundowning at night
3. subtle memory deficits
4. inability to communicate

3 Which of the following nursing diagnoses is appropriate for people with MS, regardless of type or severity?
1. *Fatigue*
2. *Risk of aspiration*
3. *Acute pain*
4. *Impaired gas exchange*

4 You are preparing information to teach a person about medications for MS. Which drugs would you expect to be used?
1. antibiotics
2. antihistamines
3. interferon
4. levodopa

5 Which of the following topics is important when teaching a young adult with MS?
1. how to prevent sexually transmitted infections
2. how pregnancy can improve manifestations
3. what can be done to cure the disease
4. why it is important to avoid extremes of heat and cold

6 The manifestations of Parkinson's disease are the result of:
1. autoimmune responses to a viral infection
2. the failure of dopamine to inhibit acetylcholine
3. effects of a neurotoxin
4. a genetic defect

7 When teaching care at home for the person with PD, what would be a major area to discuss with caregivers?
1. preventing an overdose of medications
2. avoiding daily baths and showers
3. preventing falling
4. increasing appetite

8 Which drug classification is the medication used to treat MND?
1 dopamine agonist
2 anticholinergic
3 anti-inflammatory
4 antiglutamate

9 You are preparing a teaching plan for a person with Bell's palsy. What information would you include?
1 'You will experience severe facial pain during attacks.'
2 'The disease affects your muscles so you can't walk.'
3 'One side of your face will not move normally.'
4 'Be sure to boil all home-canned foods before eating them.'

10 How can the nurse prevent tetanus?
1 Teach safe food preparation techniques.
2 Promote immunisation for adults and children.
3 Demonstrate proper disposal of soiled dressings.
4 Promote immunisation of household pets.

UNIT 11 BUILDING CLINICAL COMPETENCE

Responses to altered neurological function

CLINICAL SCENARIO

You have been assigned to work with the following people on a neurological hospital unit. Significant data obtained during report are as follows:

- Sam Kwon is a 74-year-old male who was admitted from the emergency department to the neurology ward last night. Mr Kwon was found by family in his home. He was unable to speak or move the right side of his body and continues to experience paralysis on the right side in both his arm and his leg. He is aphasic with facial drooping, but is able to nod his head to communicate. Mr Kwon has a known history of hypertension, CHF and type 2 diabetes controlled by oral hypoglycaemic medications. He has smoked a packet of cigarettes a day for 40 years. BP is now 140/105, P 98, R 24. Lungs reported to have crackles in the bases. He is receiving 2 L of oxygen via nasal prongs. A swallowing evaluation has been ordered to be done today.
- Jane Thomas is a 56-year-old female. She was admitted 4 days ago and underwent a lumbar laminectomy. She was able to ambulate with assistance on day 2 after surgery and now reports no dizziness on ambulation. Her leg strength has progressively increased since surgery. She has equal sensation and is able to wriggle her toes on both feet. Pain is controlled at her desired level of 2 to 3 on a scale of 1 to 10 with oral medications.
- Cesar Phillips is a 39-year-old male, admitted 4 days ago after experiencing paralysis and severe headache at work. He has been diagnosed with stroke following an MRI. He has a history of smoking one packet of cigarettes per day and hypertension. His wife reported that he had stopped taking his blood pressure medication due to the side effects of impotence. Mr Phillips is awake and alert, but has exhibited impulsive behaviour and agnosia. He also has a difficult time remembering words and neglects the left side of his body in ADLs. BP had been 130/85 at the beginning of last shift but has increased to 170/110. He received an additional prn blood pressure medication 1.5 hours ago.
- Tonya Walton is a 29-year-old female. She was involved in a car crash 12 hours before her admission 5 days earlier. She developed a headache, drowsiness, confusion and pupil enlargement several hours after the crash. Following an MRI, Ms Walton underwent intracranial surgery to evacuate a subdural haematoma. She has been complaining of a headache that has increased in intensity from a 2 to a 6 on a scale of 1 to 10 on the previous shift. She received two Nurofen ES tabs 1 hour ago. BP was 140–150 systolic and 90–100 diastolic for most of the shift. Her BP at the time of the Nurofen administration was 175/115. She has not experienced any changes in her neuro assessment except for the increasing headache and blood pressure elevation.

Critical thinking questions

1 In what order would you visit these people after report?

1. _____
2. _____
3. _____
4. _____

2 Which two top-priority nursing diagnoses would you choose for each of the people presented above? Can you explain, if asked, the rationale for your choices?

	Priority Nursing Diagnosis #1	Priority Nursing Diagnosis #2
Sam Kwon		
Jane Thomas		
Cesar Phillips		
Tonya Walton		

3 After completing Mr Kwon's beginning-of-shift baseline assessment, which assessment would be your next priority?

1. rhythm strip interpretation
2. intake and output
3. heart sounds
4. level of pain

4 You are completing the beginning-of-shift assessment for Mr Phillips. Which changes would best indicate that the plan initiated by the previous shift was effective?

1. Mr Phillips no longer has a craving for cigarettes.
2. Mr Phillips's respiratory rate is 18–20.
3. Mr Phillips's pain score is now 1–2.
4. Mr Phillips's blood pressure has decreased to 145/90.

5 What are the top two education priorities for Jane Thomas as you plan for discharge? (Select all that apply.)

1. appropriate exercise
2. pain management
3. weight control
4. incision care
5. importance of rest

6 You review the lab reports for Jane Thomas. You are most interested in the results for which of the following studies? (Select all that apply.)

1. white blood cell count
2. red blood cell indices
3. serum sodium
4. haemoglobin
5. haematocrit
6. osteocalcin
7. prealbumin

7 You are completing the beginning-of-shift assessment for Ms Walton. Which changes would best indicate that the plan initiated by the previous shift was effective?

1. Ms Walton has no neurological changes or deterioration.
2. Ms Walton's BP is 142/94.
3. Ms Walton's pain score is now 1–2.
4. Ms Walton's dressing is dry and intact.

8 If you re-evaluated Ms Walton and her headache pain had not decreased, what should be your next priority?

1. Reposition Ms Walton on her left side with the head of the bed flat.
2. Call the doctor about Ms Walton's report of increasing headache.
3. Decrease stimuli in the room by darkening the room and limiting noise.
4. Check the prn orders to evaluate if a stronger pain medication has been ordered.

9 If you were planning an effective team meeting with all disciplines that should be collaborating to provide care and a discharge plan for Mr Phillips, which six disciplines should be represented and why?

1. _____
2. _____
3. _____
4. _____
5. _____
6. _____

10 Review the five steps of the abbreviated neurological assessment as outlined in the text. What are three findings you would expect when conducting a neuro check with Mr Kwon?

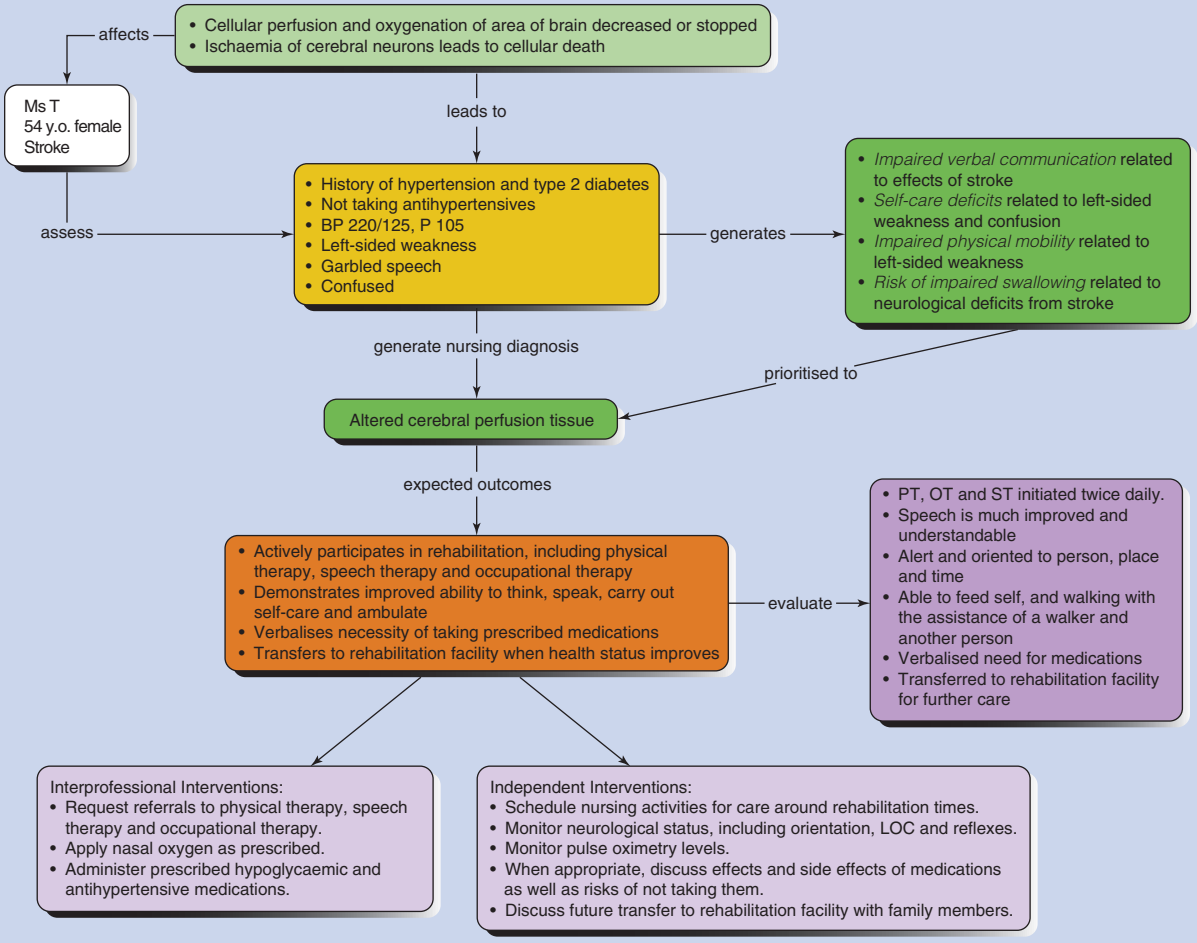
1. _____
2. _____
3. _____

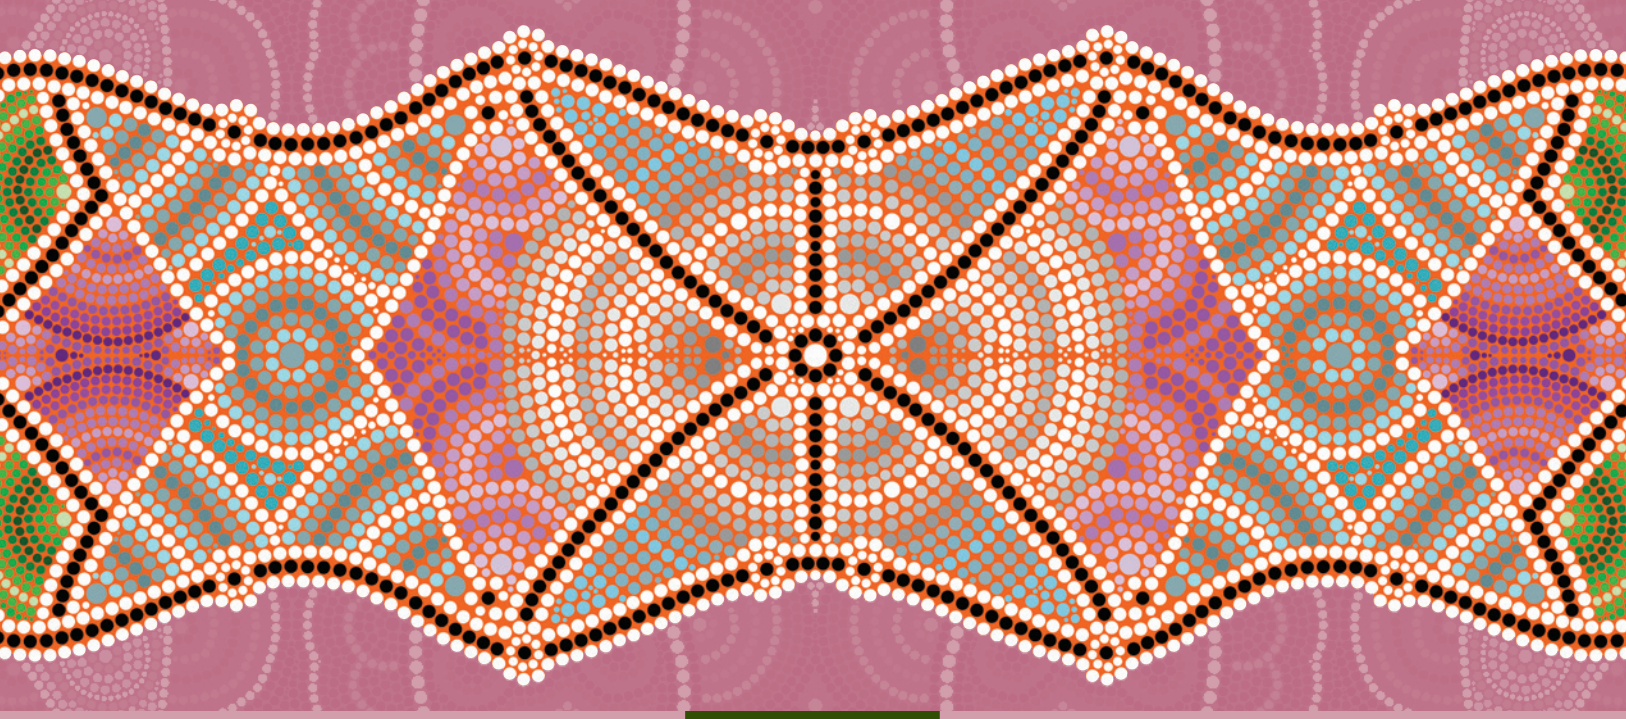
CASE STUDY

Shirley Tayler is a 54-year-old Indigenous Australian female. She was admitted 2 days earlier after being diagnosed with a stroke. She lives with her husband of 34 years and her 14-year-old grandson. Her grandson found her lying on the kitchen floor when he got home from school. When he asked her what had happened, she was unable to say words that were clear or understandable. He tried to help her stand up, but was unable to because she was extremely weak in her left side. He called 000 and an ambulance transported her to the emergency department. Her blood pressure when the ambulance arrived was 220/125, P 105, R 24, and she was very anxious and spoke garbled words loudly at the paramedics. She was diagnosed with acute stroke after evaluation at the hospital and was admitted for treatment. Mrs Tayler has a history of hypertension and type 2 diabetes. She recently stopped taking her blood pressure medication because it made her feel 'tired'.

The pathophysiology of a stroke is dependent on location of the causative factor, size of tissue affected and time of loss of cellular perfusion and oxygenation. Time is critical when it involves compromised perfusion to any organ and the brain is no exception. Cerebral neuron cellular metabolism is severely affected within 4 to 5 minutes of compromised perfusion. Compromised cellular metabolism leads to glucose, glycogen and adenosine triphosphate depletion and sodium–potassium pump failure. Wherever sodium goes, water follows. When the sodium–potassium pump fails, the sodium in the cell draws water into the cell, resulting in oedema. Additionally, cerebral vessel walls also swell, further compromising blood and oxygen supply. Severe or prolonged ischaemia leads to cellular death. The manifestations of a stroke include, but are not limited to, motor deficits, elimination disorders, sensory–perceptual deficits, communication disorders and behavioural changes. The manifestations are always sudden in onset, focal and usually unilateral. Typically, a stroke is manifested by weakness of the face, arm and leg; loss of vision in one eye; speech and swallowing problems; and difficulties with balance. There are many different complications of a stroke, including increased intracranial pressure, coma, death, chronic long-term confusion and intellectual changes.

The nursing diagnosis of *Ineffective cerebral tissue perfusion* is appropriate for implementing care for Mrs Tayler.





UNIT 12

RESPONSES TO ALTERED VISUAL AND AUDITORY FUNCTION

CHAPTER 44

A PERSON-CENTRED APPROACH TO ASSESSING THE EYE AND EAR

CHAPTER 45

NURSING CARE OF PEOPLE WITH EYE AND EAR DISORDERS

CHAPTER 44

A PERSON-CENTRED APPROACH TO ASSESSING THE EYE AND EAR

KAMAREE BERRY

KEY TERMS

accommodation 1663
cerumen 1672
convergence 1664
corneal reflex 1661
hyperopia 1668
myopia 1668
nystagmus 1668
presbyopia 1668
ptosis 1669
pupillary light reflex 1662
refraction 1663

LEARNING OUTCOMES

- Describe the anatomy, physiology and functions of the eye and ear.
- Explain the physiological processes involved in vision, hearing and equilibrium.
- Identify specific topics for consideration during a health history interview of the person with health problems of the eye or ear.
- Describe normal variations in assessment findings for the older adult.
- Identify abnormal findings that may indicate impairment in the function of the eye and the ear.

CLINICAL COMPETENCIES

- Conduct and document a health history for people having or at risk of alterations in the structure or functions of the eye and ear.
- Monitor the results of diagnostic tests and report abnormal findings.
- Conduct and document a physical assessment of the structure and/or functions of the eye and ear.

EQUIPMENT NEEDED

- Visual acuity charts
- Opaque eye cover
- Pen
- Penlight
- Cotton-tipped applicator
- Ophthalmoscope
- Otoscope
- Tuning fork

Vision and hearing allow us to experience the world in which we live. The eyes and ears provide pathways for visual and auditory stimuli to reach the brain, while specialised structures within the ear help maintain position sense and equilibrium. Deficits in vision and hearing may limit self-care, mobility, safety, independence, communication and relationships with others.

ANATOMY, PHYSIOLOGY AND FUNCTIONS OF THE EYES

The eyes are complex structures that contain 70% of the sensory receptors of the body.

Each eye is a sphere measuring about 2.5 cm in diameter, surrounded and protected by a bony orbit and cushions of fat. The primary functions of the eye are to encode the patterns of light from the environment through photoreceptors and to carry the coded information from the eyes to the brain. The brain gives meaning to the coded information, allowing us to make sense of what we see. Both extraocular and intraocular structures are considered parts of the eye.

Extraocular structures

Although the extraocular structures of the eye are outside the eyeball, they are vital to its protection. These structures are the eyebrows, eyelids, eyelashes, conjunctiva, lacrimal apparatus and extrinsic eye muscles (see Figure 44.1).

The eyebrows shade the eyes and keep perspiration away from them. The eyelids are thin, loose folds of skin covering the anterior eye; they protect the eyes from foreign bodies, regulate the entry of light into the eye and distribute tears by blinking. The eyelashes are short hairs that project from the top and bottom borders of the eyelids. An unexpected touch to the eyelashes initiates the blinking reflex to protect the eyes from foreign objects.

The conjunctiva is a thin, transparent membrane that lines the inner surfaces of the eyelids and folds over the anterior surface of the eyeball. The palpebral conjunctiva lines the upper and lower eyelids, whereas the bulbar conjunctiva loosely covers the anterior sclera (the white part of the eye). The conjunctiva is a mucous membrane that lubricates the eyes. The lacrimal apparatus is composed of the lacrimal gland, the puncta, the lacrimal sac and the nasolacrimal duct. Together, these structures secrete, distribute and drain tears to cleanse and moisten the eye's surface.

The six extrinsic eye muscles control movement of the eye, allowing it to follow a moving object and move precisely. The muscles also help maintain the shape of the eyeball. The cranial nerves control the extrinsic muscles (see Figure 44.2).

Intraocular structures

The intraocular structures transmit visual images and maintain homeostasis of the inner eye. Those in the anterior portion of each eyeball are the sclera and the cornea (forming the outermost coat of the eye, known as the fibrous tunic), the iris, the pupil and the anterior cavity (see Figure 44.3).

Sclera and cornea

The white sclera lines the outside of the eyeball it protects and provides its shape. The sclera gives way to the cornea over the iris and pupil which is transparent, avascular and sensitive to touch. The cornea forms a window that allows light to enter the eye and is a part of its light-bending apparatus. When the cornea is touched, the eyelids blink (**corneal reflex**) and tears are secreted.

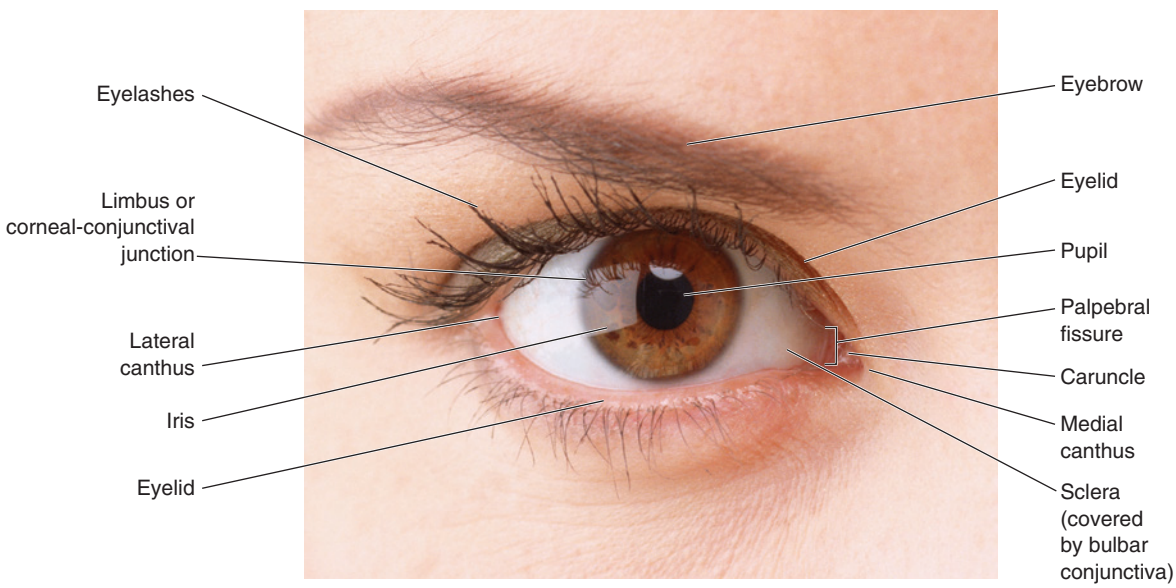


FIGURE 44.1 ■ Accessory and external structures of the eye

C

Name	Controlling cranial nerve	Action
Lateral rectus	VI (abducens)	Moves eye laterally
Medial rectus	III (oculomotor)	Moves eye medially
Superior rectus	III (oculomotor)	Elevates eye or rolls it superiorly
Inferior rectus	III (oculomotor)	Depresses eye or rolls it inferiorly
Inferior oblique	III (oculomotor)	Elevates eye and turns it laterally
Superior oblique	IV (trochlear)	Depresses eye and turns it laterally

FIGURE 44.2 ■ Extraocular muscles. *A*, Lateral view of the right eye. *B,* Superior view of the right eye. *C*, Innervation of the extraocular muscles by the cranial nerves

Iris

The iris is a disc of muscle surrounding the pupil and lying between the cornea and the lens. The iris gives the eye its colour and regulates light entry by controlling the size of the pupil. The pupil is the dark centre of the eye through which light enters. The pupil constricts when bright light enters the eye and when it is used for near vision; it dilates when light conditions are dim and when the eye is used for distance vision. In response to intense light, the pupil constricts rapidly in the **pupillary light reflex**.

Aqueous fluid

The anterior cavity is made of the anterior chamber (the space between the cornea and the iris) and the posterior chamber (the space between the iris and the lens). The anterior cavity is filled with aqueous humour, a clear fluid which constantly forms and drains to maintain a relatively constant pressure of 15 to 20 mmHg in the eye. The canal of Schlemm, a network of channels that circles the eye in the angle at the junction of the sclera and the cornea, is the drainage system for fluid moving between the anterior and posterior chambers. Aqueous humour provides nutrients and oxygen to the cornea and the lens.

Internal chamber

The intraocular structures that lie in the internal chamber of the eye are the lens, posterior cavity, vitreous humour, ciliary body, uvea and retina.

The lens is a biconvex, avascular, transparent structure located directly behind the pupil. It can change shape to focus and refract light onto the retina. The posterior cavity lies behind the lens. It is filled with a clear gelatinous substance, the vitreous humour, which supports the posterior surface of the lens, maintains the position of the retina and transmits light. The uvea, also called the vascular tunic, is the middle layer of the eyeball. This pigmented layer has three components: the iris, ciliary body and choroid. The ciliary body encircles the lens and, along with the iris, regulates the amount of light reaching the retina by controlling the shape of the lens. Most of

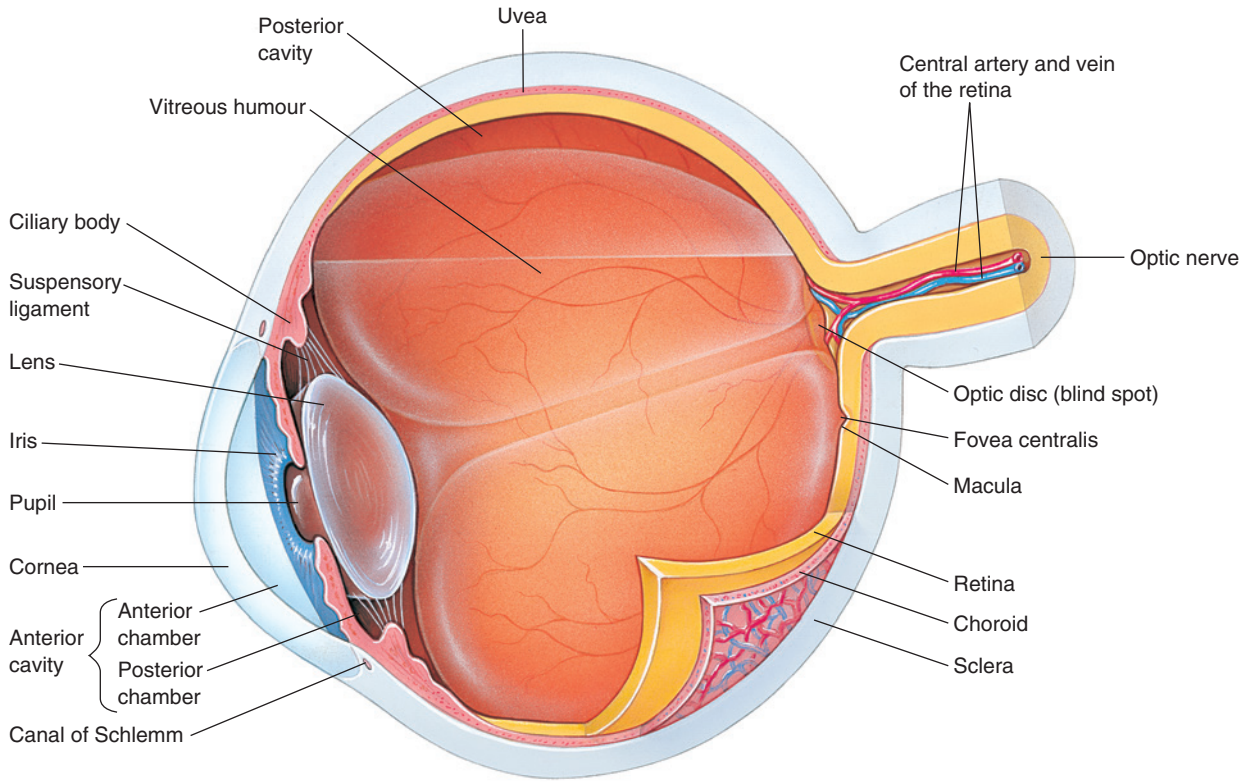

FIGURE 44.3 ■ Internal structures of the eye

the uvea is made up of the choroid, which is pigmented and vascular. Blood vessels of the choroid nourish the layers of the eyeball and its pigmented areas absorb light, preventing it from scattering within the eyeball.

The retina is the innermost lining of the eyeball. It has an outer pigmented layer and an inner neural layer. The outer layer, next to the choroid, serves as the link between visual stimuli and the brain. The transparent inner layer is made up of millions of light receptors in structures called rods and cones. Rods enable vision in dim light as well as peripheral vision and cones enable vision in bright light and the perception of colour. The optic disc, a cream-coloured round or oval area within the retina, is the point at which the optic nerve enters the eye. The slight depression in the centre of the optic disc is called the physiological cup. Located laterally to the optic disc is the macula, a darker area with no visible blood vessels and which contains primarily cones. The fovea centralis is a slight depression in the centre of the macula that contains only cones and is a main receptor of detailed colour vision.

The visual pathway

The optic nerves are cranial nerves formed of the axons of ganglion cells. The two optic nerves meet at the optic chiasma, just anterior to the pituitary gland in the brain. At the optic chiasma, axons from the medial half of each retina cross to the opposite side to form pairs of axons from each eye. These pairs continue as the left and right optic tracts (see Figure 44.4). The crossing of the axons results in each optic tract carrying information from both eyes. The left optic tract carries visual information from the lateral half of the retina of the left eye and the medial half of the retina of the right eye, whereas the right optic tract carries visual information from the lateral half of the retina of the right eye and the medial half of the retina of the left eye.

The ganglion cell axons in the optic tracts travel to the thalamus and synapse with neurons, forming pathways called optic radiations. The optic radiations terminate in the visual cortex of the occipital lobe and the nerve impulses that originated in the retina are interpreted here.

The visual fields of each eye overlap considerably and each eye sees a slightly different view. Because of this overlap and the crossing of the axons, information from both eyes reaches each side of the visual cortex, which then fuses the information into one image. This fusion of images accounts for the ability to perceive depth; however, depth perception depends on visual input from two eyes that focus well.

Refraction

Refraction is the bending of light rays as they pass from one medium to another of different optical density. As light rays pass through the eye, they are refracted at several points: as they enter the cornea; as they leave the cornea and enter the aqueous humour; as they enter the lens; and as they leave the lens and enter the vitreous humour. At the lens, the light is bent so that it converges at a single point on the retina. The focusing of the image is called **accommodation**. Because the lens is convex, the image projected on to the retina (the real image) is upside down and reversed from left to right. This real image is coded as electric signals that are sent to the brain; the brain

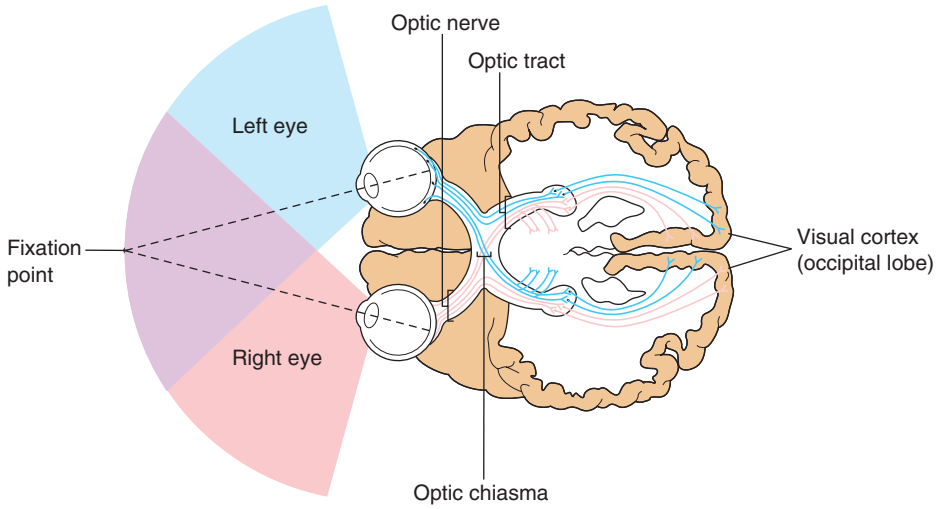

FIGURE 44.4 ■ The visual fields of the eye and the visual pathways to the brain

then decodes the image so that the person perceives it as it occurs in space.

The eyes are best adapted to see distant objects. Both eyes fix on the same distant image and do not require any change in accommodation. For people with emmetropic (normal) vision, the distance from the viewed object at which the eyes require no accommodation is 6 metres. This point is called the far point of vision. To focus for near vision, the eyes must instantly accommodate the lens, constrict the pupils and converge the eyeballs. Accommodation is accomplished by contraction of the ciliary muscles. This contraction reduces the tension on the lens capsule so that it bulges outwards to increase the curvature. This change in shape also achieves a shorter focal length, another requirement for focusing close images on the retina. The closest point on which a person can focus is called the near point of vision; in young adults with normal vision this is usually 20 to 25 cm. Pupillary constriction helps eliminate most of the divergent light rays and sharpens focus. **Convergence** (the medial rotation of the eyeballs so that each is directed towards the viewed object) allows the focusing of the image on the retinal fovea of each eye.

ASSESSING THE EYES

Structures and functions of the eyes are assessed by findings from a health assessment interview to collect subjective data, a physical assessment to collect objective data and diagnostic tests.

Health assessment interview

To determine problems with the eyes and vision, a health assessment interview may be conducted during a health screening. It may focus on a chief complaint, such as blurred vision or an eye infection, or may be part of a complete health assessment. If the person has a health problem involving one or both eyes, analyse its onset, characteristics and course, severity, precipitating and relieving factors, and any associated symptoms, noting the timing and circumstances. For example, ask the person:

- Describe the type of pain you experience in your eyes. When did it begin? How long does it last?
- Have you noticed rings of colour around streetlights at night?
- When did you first notice having difficulty reading the paper?

Throughout the interview, be alert to non-verbal behaviours, such as squinting and/or abnormal eye movements, that may suggest problems with eye function. Explore problems such as watery, irritated eyes or changes in vision. Assess the person's use of corrective eyewear and care of eyeglasses or contact lenses. If the person uses eye medications, ask about the type, purpose, frequency, dose and duration of use. When taking the history, find out about eye trauma, surgery or infections, as well as the date and results of the last eye examination. In addition, ask the person about a medical history of diabetes, hypertension, thyroid disorders, glaucoma, cataracts and eye infections. Include questions about a family history of myopia (nearsightedness) or presbyopia (farsightedness), cancer of the retina, colour blindness and any other eye or vision disorders.

Collect information about environmental and/or work exposure to irritating chemicals, sport participation or hobbies that pose the risk of eye injury and the use of protective eyewear during dangerous activities such as sawing wood or using a lawn trimmer.

Interview questions categorised by functional health patterns are listed in the 'Functional health pattern interview' table below.

Physical assessment of the eyes and vision

Physical assessment of the eyes and of visual acuity may be performed as part of a total assessment or separately for people with known or suspected eye problems. The eyes and vision are primarily assessed through inspection of external structures and assessment of visual fields and visual acuity, extraocular muscle function and internal structures. Palpation—for example, of a blocked lacrimal duct—may be used if a problem is identified. Prior to the examination, explain the techniques to the person to decrease anxiety. The person may sit or stand

FUNCTIONAL HEALTH PATTERN INTERVIEW The eye

FUNCTIONAL HEALTH PATTERN	INTERVIEW QUESTIONS AND LEADING STATEMENTS
Health perception–Health management	■ Describe your vision. Rate it on a scale of 1 to 10, with 10 being excellent vision. Is it the same in both eyes? If not, which eye is better?
	■ Describe your current vision problems. How have these been treated?
	■ What eye medications do you use? What type and how often?
	■ Have you ever had eye surgery? Provide details.
	■ Describe the type of corrective lens that you wear. Are you satisfied with this appliance? How do you care for it?
	■ Describe how you care for your eyes each day.
	■ Do you wear sunglasses when you are outside?
	■ When was your last eye examination? Have you been tested for glaucoma?
Nutritional–Metabolic	■ Do you have any redness, swelling, watering or dryness of your eyes?
Activity–Exercise	■ Does your vision problem interfere with your usual activities of daily living? Provide details.
	■ Do you wear protective goggles when you take part in activities that increase the risk of injury to your eyes (such as at work or when operating machinery at home)?
Sleep–Rest	■ Does your eye problem interfere with your ability to rest or sleep (e.g. pain)? If so, what do you do?
Cognitive–Perceptual	■ Do you have any difficulty focusing on objects? If so, do you have more difficulty with near objects or distant objects?
	■ Is your vision blurry? Do you see halos around lights? Do you see flashes of light or 'floaters'? Do you see double?
	■ Do you have pain in or around your eyes? If so, describe its location, intensity, what makes it worse and how long it lasts. How do you treat it?
Self-perception–Self-concept	■ Has this problem with your eyes affected how you feel about yourself?
Role–Relationships	■ How has having this condition affected your relationships with others?
	■ Has having this condition interfered with your ability to work? Provide details.
	■ Has anyone in your family had problems with eye disease? Provide details.
Sexuality–Reproductive	■ Has this condition interfered with your usual sexual activity?
Coping–Stress–Tolerance	■ Has having this condition created stress for you? If so, does your health problem seem to be more difficult when you are stressed?
	■ Have you experienced any kind of stress that makes the condition worse? Provide details.
	■ Describe what you do when you feel stressed.
Value–Belief	■ Describe how specific relationships or activities help you cope with this problem.
	■ Describe specific cultural beliefs or practices that affect how you care for and feel about this problem.
	■ Are there any specific treatments that you would not use to treat this problem?

during the assessment. Normal age-related findings for the older adult are summarised in Table 44.1.

Assessing visual fields

Visual fields are tested to assess the functioning of the macula and peripheral vision. The visual fields of the examiner (which must be normal to perform this assessment) are used as the standard. To measure visual fields, sit directly opposite the person at a distance of 45 to 60 cm. Ask the person to cover one eye with the opaque cover while you cover your own eye opposite to the person (e.g. if the person covers the right eye, you cover your left eye.) Ask the person to look directly at you. Move the penlight from the periphery towards the centre from right to left, above and below, and from the middle of

TABLE 44.1 Age-related changes in the eye

AGE-RELATED CHANGE	SIGNIFICANCE
The lens:	
• ↓ elasticity, decreasing focus and accommodation for near vision (presbyopia). • ↑ density and size, making lens more stiff and opaque. • Yellowing of the lens and changes in the retina affect colour perception.	Most older adults require corrective lenses to accommodate close and detailed work. Increased opacity leads to the development of cataracts. As cataracts develop, they increase sensitivity to glare and interfere with night vision.
The cornea:	
• Fat may be deposited around the periphery and throughout the cornea.	A partial or complete white circle may form around the cornea (arcus senilis). Lipid deposits in the cornea cause vision to be blurred.
• ↓ corneal sensitivity.	Decreased sensitivity increases the risk of injury to the eye.
The pupil:	
• ↓ size and responsiveness to light pupil; sphincter hardens.	Increased light perception threshold and difficulty seeing in dim light or at night means increased light is needed to see adequately.
The retina and visual pathways:	
• Visual fields narrow. • Photoreceptor cells are lost. • Rods work less effectively. • Macular degeneration is a risk. • Depth perception is distorted. • Adaptation to dark and light takes longer.	Peripheral vision is decreased and central vision may be lost from macular degeneration. Increased risk of falls as a result of changes in depth perception and adaptation to changes in light. Vision progressively declines with age.
The lacrimal apparatus:	
• ↓ reabsorption of intraocular fluid. • ↓ production of tears.	Increased risk of developing glaucoma and eyes feel and look dry.
The posterior cavity:	
• Debris and condensation become visible. • Vitreous body may pull away from the retina.	Vision is blurred and distorted and 'floaters' are often seen by the older adult.

each of these directions. Both you and the person should see the penlight enter the field of vision at the same time, if the examiner has normal peripheral vision.

The central visual field may be assessed with an Amsler grid (see Figure 44.5). The most basic form has black lines on a white grid, forming squares (boxes) that measure 5 mm with a black dot in the centre of the grid. The Amsler grid is useful for identifying early changes in vision from macular degeneration and diabetes mellitus. To use the Amlser grid, ask the person to hold the grid at normal reading distance (about 30 to 35 cm), cover one eye and stare at the centre dot. Ask the person if any of the lines look crooked or bent, if any of the boxes are different in size or shape, and if any of the lines are wavy, missing, blurry or discoloured. Repeat with the other eye. The test should be conducted before the pupils are dilated and the person should be wearing their best correction lenses.

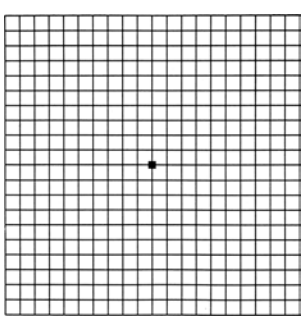

FIGURE 44.5 ■ The Amsler grid

Diagnostic tests

The results of diagnostic tests of the structure and functions of the eyes are used to support the diagnosis of a specific injury, disease or vision problem; to provide information to identify and/or modify the appropriate medications or assistive devices used to treat the disease or problem; and to help nurses monitor the person's responses to treatment and nursing care interventions. Diagnostic tests of the eye, especially for vision testing, are most often conducted in a health-care provider's office. Diagnostic tests to assess the structure and functions of the eyes are described in the 'Diagnostic tests' box below and summarised in the following list. More information is included in the discussion of specific injuries or diseases in Chapter 45.

- Refractive errors (with prescription for corrective lenses) are evaluated by retinoscopy and/or refractometry. Pupils must be dilated for accurate diagnosis.

DIAGNOSTIC TESTS Eye disorders

NAME OF TEST Refraction, retinoscopy, refractometry

PURPOSE AND DESCRIPTION Used to measure refractive error. Either a hand-held retinoscope or an instrument with multiple lenses is used; with the latter method, the person chooses lenses that provide the best vision.

RELATED NURSING CARE No special preparation is needed; advise the person that pupils will be dilated with medication and may be enlarged for several hours.

NAME OF TEST Tonometry

PURPOSE AND DESCRIPTION Used to diagnose increased intraocular pressure in glaucoma. A variety of methods are used, ranging from a hand-held instrument (tonometer) to a computerised component of the device used to evaluate refraction. The cornea is anaesthetised prior to being touched with the device.

Normal value: 10–22 mmHg.

RELATED NURSING CARE No special preparation is needed.

NAME OF TEST Computed tomography (CT) scan of the eye

PURPOSE AND DESCRIPTION Radiological examination used to identify foreign objects or tumours within the eyeball or orbit.

RELATED NURSING CARE No special preparation is needed.

NAME OF TEST Fluorescein angiography

PURPOSE AND DESCRIPTION Fluorescein solution is injected IV to evaluate blood vessels in the eye in conditions such as diabetes, macular degeneration or vessel occlusion.

RELATED NURSING CARE Informed consent is required for this test. Note current medications and notify the doctor if the person is pregnant. Inform the person that a hot flush and transient nausea may be experienced when the dye is injected. Monitor for anaphylactic hypersensitivity responses that may occur. Fluorescent yellow urine and a yellow skin colour may be noted for 1–2 days after the procedure; these are not considered harmful.

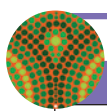
- Tonometry is used to identify and evaluate increased intraocular pressure, characteristic of glaucoma.
- A CT scan may be used to identify foreign objects or tumours of the eye.
- Fluorescein angiography is used to evaluate blood vessels in the eye in conditions such as diabetes, macular degeneration or vessel occlusion.

Regardless of the type of diagnostic test, the nurse may be responsible for explaining the procedure and any special preparation needed, assessing any medication use that might affect the outcome of the tests, supporting the person during the examination as necessary, documenting the procedures as appropriate and monitoring the results of the tests.

Genetic considerations

When conducting a health assessment interview and a physical assessment, it is important for the nurse to consider genetic influences on the health of the adult, as several diseases of the eyes have a genetic component. During the health assessment interview, ask about a family history of glaucoma and/or blindness.

During the physical assessment, assess for any manifestations that might indicate a genetic disorder (see the accompanying 'Genetic considerations' box). If the data are found to indicate genetic risk factors or alterations, ask about genetic testing and refer for appropriate genetic counselling and evaluation. Chapter 7 provides further information about genetics in medical–surgical nursing.



GENETIC CONSIDERATIONS
Eye disorders

- *Glaucoma* is a term used for a group of diseases that damage the optic nerve and cause blindness. Approximately 300 000 people in Australia may suffer from glaucoma, with nearly half of them not being aware that they suffer from this disease (Centre for Eye Research in Australia, 2014).
- Gyrate atrophy of the choroid and retina is a genetic disorder resulting in a progressive vision loss, with total blindness occurring between ages 40 and 60.
- Best disease is a familial disorder found most often in Caucasians who originated in Europe. It leads to gradual loss of vision, beginning during the teenage years.
- Retinitis pigmentosa may be transmitted in an autosomal recessive, dominant or X-linked pattern. It results in progressive night blindness, with loss of visual acuity and peripheral vision.

EYE AND VISION ASSESSMENTS

Vision assessment

Visual acuity is assessed with an eye chart such as the Snellen or the E chart for testing distance vision, and the Rosenbaum chart for testing near vision. The Snellen chart contains rows of letters in various sizes, with standardised numbers at the end of each row. The number at the end of the row indicates the visual acuity of a person who can read the row at a distance of 6 metres. If the person is unable to read or does not read English, use the E chart to test visual acuity. The top number at the end of the row is always 6, representing the distance between the person and the chart. The bottom number is the distance (in metres) at which a person with normal vision can read the line. A person with normal vision can read the row marked 6/6. To conduct the assessment, ask the person to stand 6 metres from the chart in a well-lit area. Ask the person to cover one eye with an opaque cover or with the palm of their hand (see Figure 44.6). Then ask the person to read each row of letters, moving from largest letters to the smallest ones that the person can see. Measure visual acuity in the other eye the same way and then assess visual acuity while the person has both eyes uncovered. You may test the person who wears corrective lenses with and without the lenses.

The Rosenbaum chart is held at a distance of from 30 to 35 cm from the eyes, with visual acuity measured in the same manner as with the Snellen chart (see Figure 44.7). A gross estimate of near vision may also be assessed by asking the person to read from a magazine or newspaper.

FIGURE 44.6 ■ Testing distant vision using the Snellen eye chart

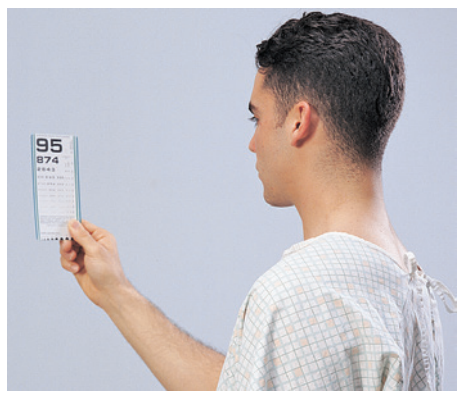


FIGURE 44.7 ■ Testing near vision using Rosenbaum eye chart

Technique/normal findings	Abnormal findings
Vision	
Assess distant vision using the Snellen or E chart. *When standing 6 metres from the chart, the person can read the smallest line of letters with or without corrective lenses (recorded as 6/6).*	■ Changes in distant vision are most commonly the result of **myopia** (nearsightedness). For example, a reading of 6/9 indicates impaired distance vision. A person has to stand 6 metres from the chart to read a line that a person with normal vision could read 9 metres from the chart.
Assess near vision, using a Rosenbaum chart or a card with newsprint held 30 to 35 cm from the person's eyes. *Normal near visual acuity is 35/35 with or without corrective lenses.*	■ Changes in near vision, especially in people over age 45, can indicate **presbyopia**, impaired near vision resulting from a loss of elasticity of the lens related to ageing. In younger people, this condition is referred to as **hyperopia** (farsightedness).
Eye movement assessment	
Assess the cardinal fields of vision to gain information about extraocular eye movements. Ask the person to follow a pen or your finger while keeping the head stationary. Move the pen or your finger through the 6 fields one at a time, returning to the central starting point before proceeding to the next field (see Figure 44.8). *The eyes should move through each field without involuntary movements.*	■ Failure of one or both eyes to follow the object in any given direction may indicate extraocular muscle weakness or cranial nerve dysfunction. ■ An involuntary rhythmic movement of the eyes, **nystagmus**, is associated with neurological disorders and the use of some medications.

Technique/normal findings	Abnormal findings
The cover–uncover test is a test for strabismus, a weakening of a muscle that causes one eye to deviate from the other when the person is focusing on an object. To conduct the test, hold a pen or your finger about 300 cm from the eyes and ask the person to focus on that object. Cover one of the person's eyes and note any movement in the uncovered eye; as you remove the cover, assess for movement in the eye that was just uncovered. Repeat the procedure with the other eye. *The uncovered eye should remain fixed straight ahead. The covered eye should remain fixed straight ahead after being uncovered.*	 FIGURE 44.8 ■ The six cardinal fields of vision
Assess convergence. Ask the person to follow an object as you move it towards the person's eyes. *Normally both eyes converge towards the centre.*	■ Failure of the eyes to converge equally on an approaching object may indicate a neuromuscular disorder or improper eye alignment.
Assess the corneal light reflex. Direct a light source onto the bridge of the nose from 30 to 40 cm. *Observe for equal reflection of the light from each eye.*	■ Reflections of the light from different sites on the eyes reveal improper alignment.
Pupils	
Observe pupil size and equality. *Pupils should be of equal size, 3 to 5 mm.*	■ Pupils that are unequal in size may indicate a severe neurological problem, such as increased intracranial pressure.
Assess direct and consensual pupil response. Ask the person to look straight ahead. Shine a light obliquely into one eye at a time. Observe for constriction of the pupil in the illuminated eye. Test both eyes. To test consensual pupil response, again shine a light obliquely into one eye at a time as the person looks straight ahead. Observe constriction of the pupil in the opposite eye. *The normal direct and consensual pupillary response is constriction.*	■ Failure of the pupils to respond to light may indicate degeneration of the retina or destruction of the optic nerve. ■ A person who has one dilated and unresponsive pupil may have paralysis of the oculomotor nerve. ■ Some eye medications may cause unequal dilation, constriction or inequality of pupil size. Morphine and narcotic drugs may cause small, unresponsive pupils and anticholinergic drugs such as atropine may cause dilated, unresponsive pupils.
Test for accommodation. Hold an object at a distance of approximately 600 cm from the person. The pupils should dilate. Ask the person to follow the object as you bring it to within a few centimetres of the person's nose. *The pupils should constrict and converge as they change focus to follow the object.*	■ Failure of accommodation along with lack of pupil response to light may signal a neurological problem. ■ Lack of response to light with appropriate response to accommodation is often seen in people with diabetes.
External eye
