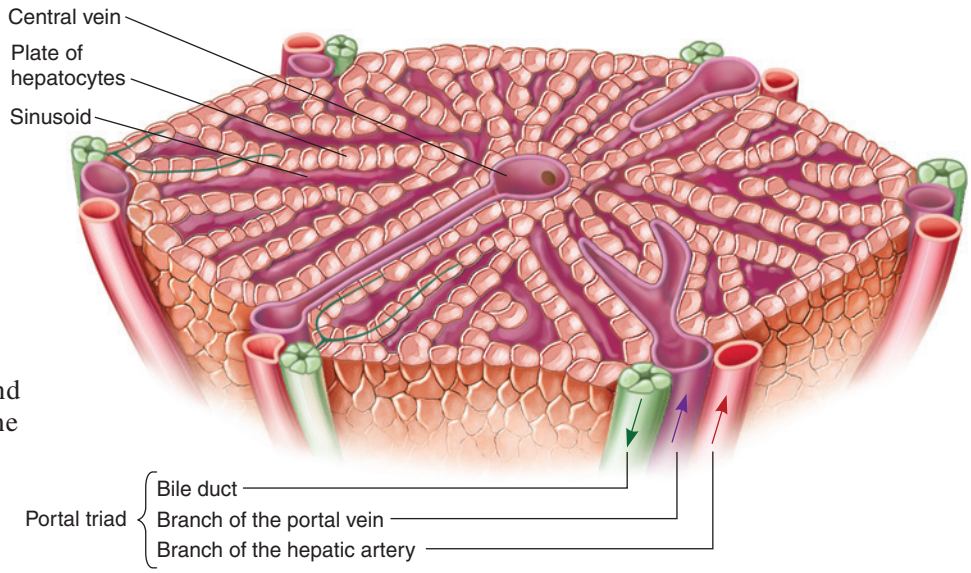
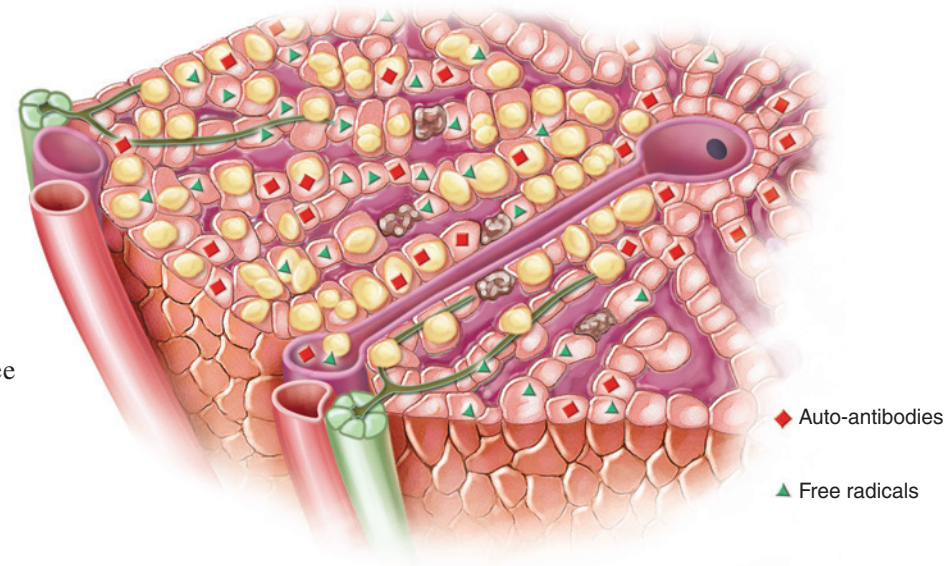
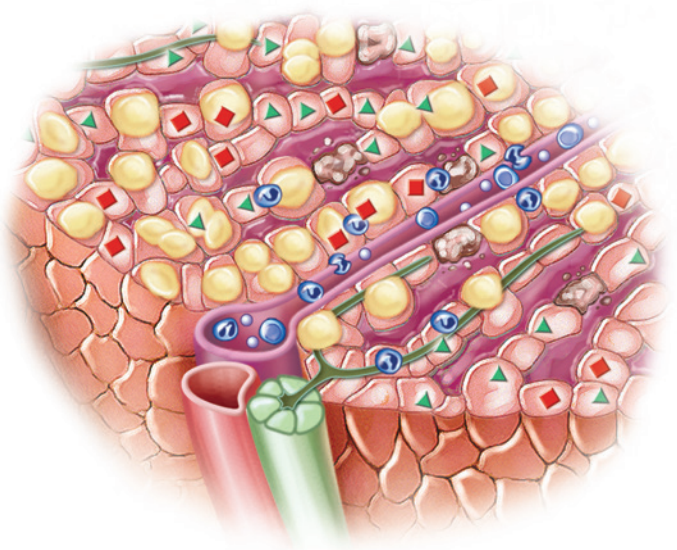
The liver contains multiple lobules made up of plates of hepatocytes, the functional cells of the liver, surrounded by small capillaries called sinusoids. These sinusoids receive a mixture of venous and arterial blood from branches of the portal vein and hepatic artery. Blood from the sinusoids drains into the central vein of the lobule. Hepatocytes produce bile, which drains outward to bile ducts.



Fatty liver

Ingested alcohol is primarily metabolised in the liver. Acetaldehyde, formed when alcohol is metabolised, damages hepatocytes and impairs the oxidation of fatty acids. As a result, fat accumulates within hepatocytes and liver lobules. Other alcohol metabolism by-products, including oxygen free radicals, promote inflammation and may stimulate autoantibody production.



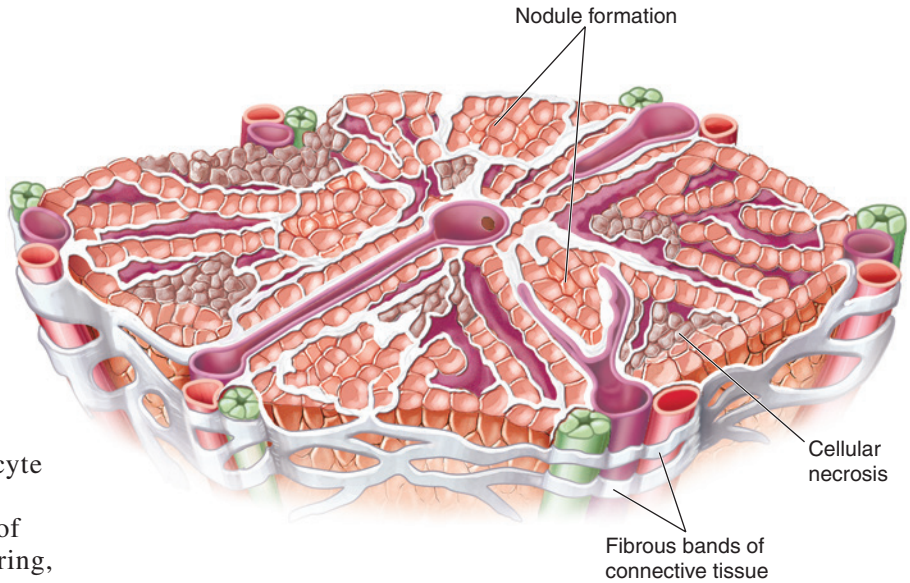


Alcoholic hepatitis

With continued alcohol intake, liver cells degenerate and spotty cellular necrosis occurs. Inflammatory cells such as polymorphonuclear leucocytes and lymphocytes infiltrate the lobule.

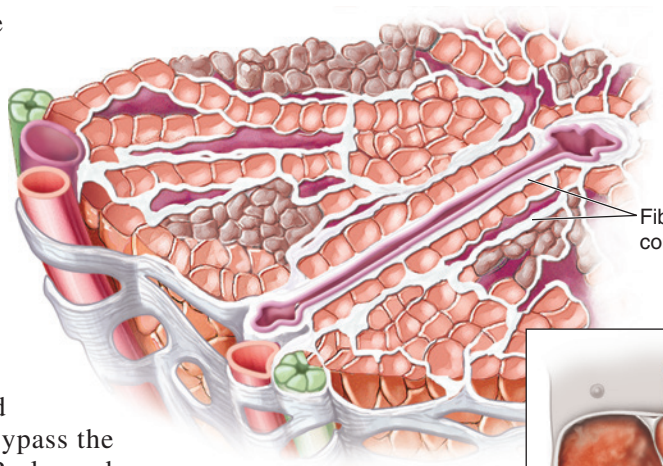
Alcoholic cirrhosis

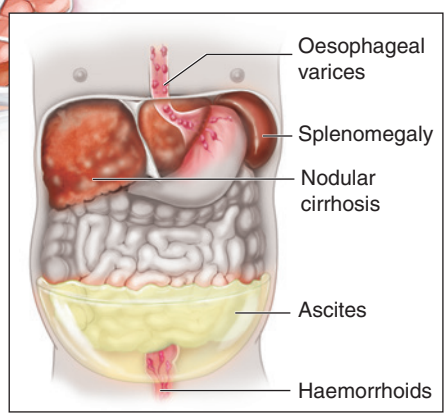
Cellular necrosis and inflammation transform some liver cells into fibroblasts that produce and deposit collagen. Web-like bands of connective tissue develop around the portal triads and central vein, eventually connecting with one another. Small islands of liver cells continue to regenerate, forming nodules. Hepatocyte destruction outpaces regeneration. As a result of cell loss, fibrosis and scarring, the liver shrinks and becomes hard and nodular.



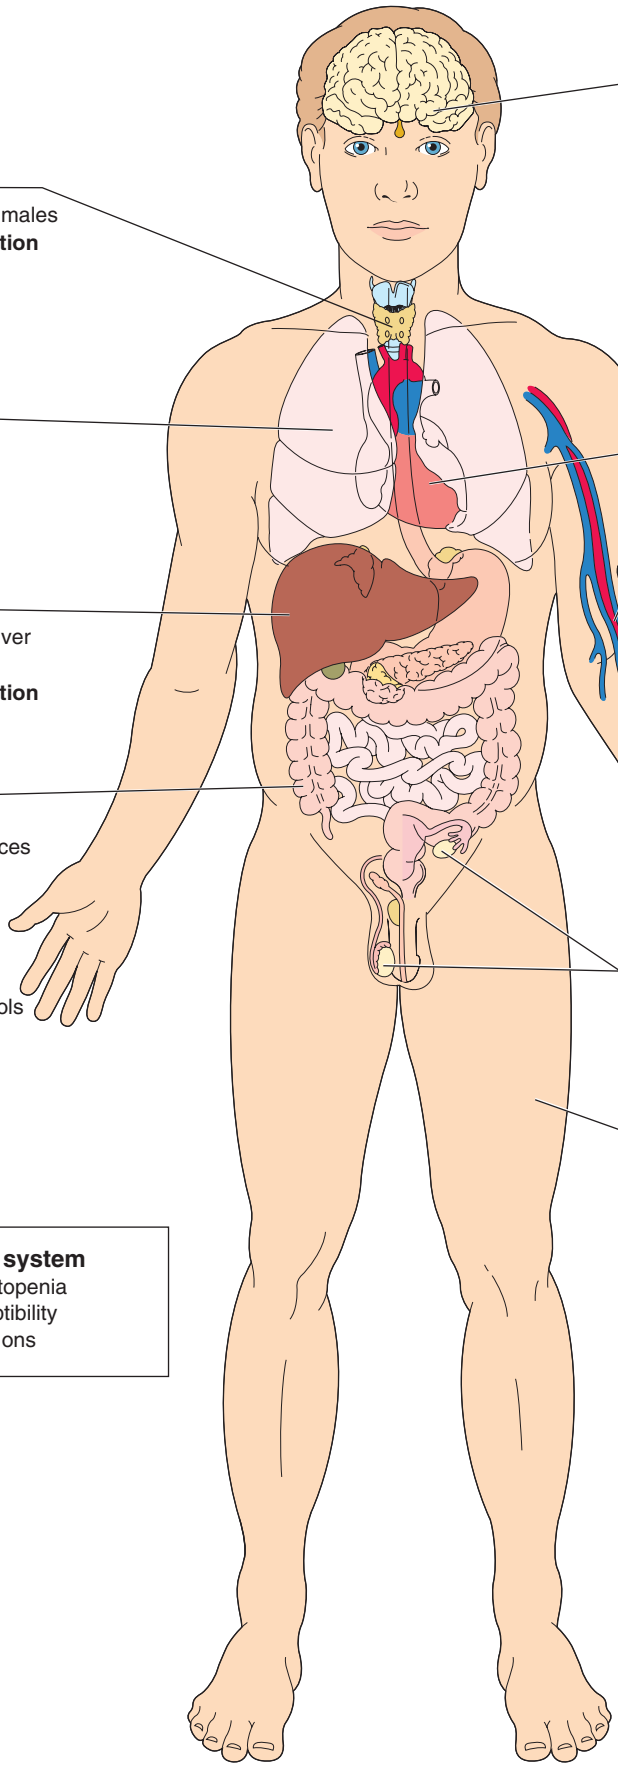
Portal hypertension

Bands of fibrotic scar tissue obstruct the sinusoids and blood flow from the portal vein to the hepatic vein. Pressure in the portal venous system, which drains the gastrointestinal tract, pancreas and spleen, increases. This increased pressure opens collateral vessels in the oesophagus, anterior abdominal wall and rectum, allowing blood to bypass the obstructed portal vessels. Prolonged portal hypertension leads to the development of (1) varices (fragile, distended veins) in the lower oesophagus, stomach and rectum; (2) splenomegaly (an enlarged spleen); (3) ascites (accumulation of fluid in the abdomen); and (4) hepatic encephalopathy (disrupted CNS function with altered consciousness).





MULTISYSTEM EFFECTS OF CIRRHOSIS



Neurological
- Portal systemic encephalopathy (agitation → lethargy → stupor → coma)
- Paraesthesias
- Sensory disturbances
- Asterixis ('liver flap')

Endocrine
- Gynaecomastia in males

Potential complication
- Diabetes mellitus

Respiratory
- Dyspnoea

Cardiovascular
- Bounding pulse
- Pulmonary hypertension
- Portal hypertension
- Arrhythmias

Hepatic
- Atrophic, nodular liver
- Splenomegaly

Potential complication
- Liver cancer

Haematological
- ↓ clotting factors
- Thrombocytopenia
- Anaemia

Potential complication
- Disseminated intravascular coagulation

Gastrointestinal

Oesophageal:
- Oesophageal varices

Stomach/intestines:
- Abdominal pain
- Anorexia
- Ascites
- Nausea
- Clay-coloured stools
- Peptic ulcers
- GI bleeding
- Haemorrhoids

Reproductive
- Oligomenorrhoea (female)
- Testicular atrophy (male)

Integumentary
- Jaundice (skin, sclera of eyes)
- Erythema of palms
- Spider angioma
- Decreased body hair
- Pruritis
- Ecchymoses
- Caput medusae (dilated veins around the umbilicus)

Immune system
- Leucocytopenia
- ↑ susceptibility to infections

Metabolic processes
- Fluid and electrolyte imbalances
  - Hypoalbuminaemia
  - Hypokalaemia
  - Hypocalcaemia
- Malnutrition
- Muscle wasting

PORTAL SYSTEMIC ENCEPHALOPATHY Portal systemic encephalopathy (*hepatic encephalopathy*) results from accumulation of neurotoxins in the blood and cerebral oedema. Ammonia, a by-product of protein metabolism, contributes to hepatic encephalopathy. Ammonium ion is produced as proteins and amino acids are broken down by bacteria in the intestinal tract. Normally, the ammonia produced is then converted by the liver to urea before entering the general circulation. As functional liver tissue is destroyed, ammonia can no longer be converted to urea and it accumulates in the blood. Other nervous system depressants, such as narcotics and tranquillisers, also can contribute to hepatic encephalopathy. Box 24.4 lists selected precipitating factors for hepatic encephalopathy. Accumulation of other metabolic toxins is thought to contribute as well.

Asterixis (liver flap), a muscle tremor that interferes with the ability to maintain a fixed position of the extremities and causes involuntary jerking movements, is an early sign of portal systemic encephalopathy. Asterixis primarily affects the upper extremities, but also may affect the tongue and feet. Asterixis is elicited by instructing the person to extend the arms and dorsiflex the wrists. If present, asterixis causes a downward flapping of the hands (see Figure 24.3). Changes in personality and mentation develop; agitation, restlessness, impaired judgment and slurred speech also are early manifestations of hepatic encephalopathy. As it progresses, confusion, disorientation and incoherence develop. Cerebral oedema that leads to increased intracranial pressure and cerebral hypoxia is the leading cause of death in people with portal systemic encephalopathy and liver failure.

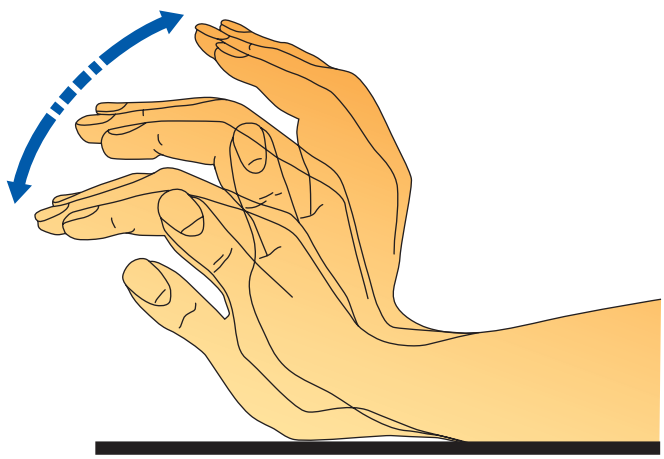


FIGURE 24.3 ■ Asterixis. Note the downward tremor of the hand on dorsiflexion of the wrist

BOX 24.4 Precipitating factors for hepatic encephalopathy

- High serum ammonia level
- Constipation
- Blood transfusions
- Gastrointestinal bleeding
- Medications: sedatives, tranquillisers, narcotic analgesics, anaesthetics
- Hypoxia
- High-protein diet
- Severe infection
- Surgery

HEPATORENAL SYNDROME Although the cause is unclear, renal failure with azotaemia (excess nitrogenous waste products in the blood), sodium retention, oliguria and hypotension may develop in people with advanced cirrhosis and ascites. Hepatorenal syndrome appears to be the result of imbalanced blood flow, leading to constriction of vessels leading to and within the kidneys. The syndrome may be precipitated by gastrointestinal bleeding, aggressive diuretic therapy or by an unknown cause.

SPONTANEOUS BACTERIAL PERITONITIS People with cirrhosis and ascites may develop bacterial peritonitis, even in the absence of known contamination of the peritoneal cavity or other specific risk factors (e.g. paracentesis). The inflammatory response to peritonitis worsens ascites by increasing the permeability of capillaries in the mesentery. The manifestations of spontaneous bacterial peritonitis may be subtle, with increased abdominal discomfort or pain, fever, increasing ascites, worsening encephalopathy and an overall decline in condition.

INTERPROFESSIONAL CARE

Care for the person with cirrhosis is holistic, addressing physiological, psychosocial and spiritual needs. The importance of including the family in the plan of care cannot be overemphasised, particularly if alcohol abuse is identified as the cause. Abstinence from alcohol is the cornerstone of treatment for alcoholic liver cirhossis (Bacon, 2012). Other treatment includes medications to help regulate protein metabolism, maintenance of fluid and electrolyte balance, and supportive therapies, including treatment of underlying problems such as malnutrition, anaemia, bleeding, encephalopathy, renal failure and infections.

Diagnosis

Studies to confirm the diagnosis of cirrhosis and identify its cause and effects are performed. Diagnostic tests may include the following:

- *Liver function studies* include *ALT*, *AST*, *ALP* and *GGT*. All may be elevated in cirrhosis, but usually not as severely as in acute hepatitis. Elevations in these enzymes may not correlate well with the extent of liver damage in cirrhosis.
- *FBC with platelets* is done. A low RBC count, haemoglobin and haematocrit demonstrate anaemia related to bone marrow suppression, increased RBC destruction, bleeding and deficiencies of folic acid and vitamin B_{12}. Platelets are low, related to increased destruction by the spleen. Leucopenia (low WBC count) also relates to splenomegaly.
- *Coagulation studies* show a prolonged prothrombin time due to impaired production of coagulation proteins and lack of vitamin K.

- *Serum electrolytes* are measured. Hyponatraemia is common, due to haemodilution. Hypokalaemia, hypophosphataemia and hypomagnesaemia also are frequently seen, related to malnutrition and altered renal excretion of these electrolytes.
- *Bilirubin* levels are usually elevated in severe cirrhosis, including both direct (conjugated) and indirect (unconjugated) bilirubin.
- *Serum albumin* levels show hypoalbuminaemia due to impaired liver production.
- *Serum ammonia* levels are elevated, because the liver fails to effectively convert ammonia to urea for renal excretion.
- *Serum glucose* and *cholesterol* levels frequently are abnormal in people with cirrhosis.
- *Abdominal ultrasound* is performed to evaluate liver size, detect ascites and identify liver nodules. Liver biopsy under ultrasound is useful to aid diagnosis; however, this is contraindicated in people who are still drinking alcohol (Bacon, 2012). Biopsy may be deferred if the bleeding time is prolonged (such as a prothrombin time (PT) greater than 3 seconds over the control). See the 'Diagnostic tests' box in Chapter 20 for nursing implications for a person having a liver biopsy. Figure 20.8 shows the site and position for liver biopsy.
- Endoscopy may be done to determine the presence of oesophageal varices.

More information about the above diagnostic tests and their nursing implications can be found in Chapter 20.

Medications

Medications are used to treat the complications and effects of cirrhosis; they do not reverse or slow the process of cirrhosis itself. Known hepatotoxic drugs and alcohol are avoided, as are drugs metabolised by the liver (e.g. barbiturates, sedatives, hypnotics and paracetamol). Several groups of drugs are commonly prescribed. See the 'Medication administration' box below for nursing responsibilities and teaching for commonly used drugs for people with cirrhosis.

- Diuretics reduce fluid retention and ascites. Spironolactone (Aldactone) is frequently the drug of first choice because it addresses one of the causes of ascites—increased aldosterone levels. If additional diuresis is necessary, a loop diuretic such as frusemide (Lasix) may be added to the regimen.
- Medications to reduce the nitrogenous load and lower serum ammonia levels are added when manifestations of hepatic encephalopathy develop. Two commonly administered medications are lactulose and neomycin. Both exert their effects locally, in the bowel. Lactulose reduces the number of ammonia-forming organisms in the bowel and increases the acidity of colon contents, converting ammonia into ammonium ion. Ammonium ion is not absorbable and is excreted in the faeces. Neomycin sulfate is a locally acting antibiotic that also reduces the number of ammonia-forming bacteria in the bowel.
- The beta-blocker nadolol (Corgard) may be given together with isosorbide mononitrate (Imdur, Monodur) to prevent rebleeding of oesophageal varices. This drug combination also lowers hepatic venous pressure.
- Ferrous sulfate and folic acid are given as indicated to treat anaemia. Vitamin K may be ordered to reduce the risk of bleeding. When bleeding is acute, packed RBCs, fresh frozen plasma or platelets may be administered to restore blood components and promote haemostasis.
- Antacids are prescribed as indicated. A drug regimen to treat *H. pylori* infection may also be effective (see Chapter 22).
- Oxazepam (Serepax), a benzodiazepine anti-anxiety/sedative drug, is not metabolised by the liver and may be used to treat acute agitation.

Treatments

Treatment of cirrhosis is supportive, directed at slowing the progression to liver failure and reducing complications.

NUTRITION Dietary support is an essential part of care for the person with cirrhosis. Dietary needs change as hepatic function fluctuates.

- Sodium intake is restricted to under 2 g/day and fluids are restricted as necessary to reduce ascites and generalised oedema. Fluids are often limited to 1500 mL/day. Fluid needs are calculated based on response to diuretic therapy, urine output and serum electrolyte values.
- Unless serum ammonia levels are high, a palatable diet with adequate kilojoules and protein is recommended. Previously protein was discouraged in people with encephalopathy; however, the negative impact of that restriction on overall nutrition is thought to outweigh the benefit (Bacon, 2012). The diet is high in kilojoules and includes moderate fat intake to promote healing. Parenteral nutrition is used as needed to maintain nutritional status when food intake is limited.
- Vitamin and mineral supplements are ordered based on laboratory values. Deficiencies in the B-complex vitamins, particularly thiamine, folate and B_{12}, and the fat-soluble vitamins A, D and E are common. These vitamins may need to be administered in a water-soluble form. People with alcohol-induced cirrhosis are at high risk of magnesium deficiency, which needs to be replaced.

COMPLICATION MANAGEMENT **Paracentesis**, aspiration of fluid from the peritoneal cavity, may be a diagnostic or a therapeutic procedure. It may be done therapeutically to relieve severe ascites that does not respond to diuretic therapy. The goal of paracentesis is to relieve respiratory distress caused by excess fluid in the abdomen. Ascites fluid may be withdrawn in moderate amounts of 500 mL to 1 L daily to reduce the risk of fluid and electrolyte imbalances. Large-volume paracentesis, withdrawal of 4 to 6 L of fluid at one time, may be used. Albumin is often administered intravenously during large-volume paracentesis to maintain intravascular volume as the pressure of the ascites fluid in the abdomen is relieved. Nursing implications for the person undergoing paracentesis are listed in Box 24.5. Figure 24.4 shows insertion sites and positioning during paracentesis.

Bleeding oesophageal varices are life threatening and require critical care management. Restoration of haemodynamic stability is the first priority. A central line is inserted and central venous and pulmonary artery pressures are monitored (see Chapter 30). Blood is given to restore blood volume, and fresh frozen plasma may be administered to restore clotting factors. Octreotide, a drug that constricts blood vessels in the

MEDICATION ADMINISTRATION The person with cirrhosis

DIURETICS

Spironolactone (Aldactone)
Frusemide (Lasix)

Spironolactone is a potassium-sparing diuretic that competes with aldosterone. It reduces ascites by increasing renal excretion of fluid and decreasing aldosterone levels. Frusemide is a loop diuretic that promotes the excretion of potassium. Drugs may be given in combination if serum potassium level permits.

Nursing responsibilities

- Monitor ECG, serum potassium, BUN, creatinine levels and hydration status.
- Weigh daily.
- Carefully monitor intake and output.
- Monitor for signs of hyperkalaemia if taking spironolactone alone: bradycardia; widening QRS, spiking T waves or ST segment depression on ECG; diarrhoea; and muscle twitching.
- Assess for hyponatraemia: confusion, lethargy, apprehension.

Health education for the person and family

- Maintain diet and fluid restrictions as prescribed.
- Report increases in weight or oedema.
- Immediately report signs of hyponatraemia, hyperkalaemia or hypokalaemia (see Chapter 9).
- Expect increased urinary output; take medications in morning hours to avoid nocturia.

LAXATIVES

Lactulose (Duphalac, Actilax)

Lactulose is a disaccharide laxative that is not absorbed by the gastrointestinal tract. It reduces the number of ammonia-producing bacteria and lowers the pH in the colon. The lower pH (increased acidity) converts ammonia to ammonium ion, a non-absorbable form that is excreted in the faeces. Lactulose also pulls water into the bowel lumen, increasing the number of daily stools.

Nursing responsibilities

- Assess bowel sounds and abdominal girth.
- Maintain accurate stool chart.
- Adjust dose to achieve two to four soft stools per day.
- Monitor electrolytes and hydration.

Health education for the person and family

- Drink adequate fluids.
- Report diarrhoea; if present, decrease dose. You should have an average of two to four stools per day.
- This drug may cause nausea. Continue taking the drug; taking it with crackers or a soft drink may reduce nausea.

ANTI-INFECTIVE AGENTS

Neomycin sulfate (Neosulf)

Neomycin sulfate is a non-systemic aminoglycoside antibiotic that reduces intestinal bacteria and decreases ammonia production in the bowel lumen. The drug may be administered as an oral or rectal preparation.

Nursing responsibilities

- Monitor hearing, renal and neurological functions. The drug is ototoxic, nephrotoxic and neurotoxic.
- Prior to administration, check for previous hypersensitivity reaction.
- Monitor intake and output.
- Monitor BUN and creatinine levels.
- If the person is taking digitalis, monitor levels; oral neomycin interferes with its absorption.

Health education for the person and family

- Report dizziness, tinnitus (ringing in ears), hearing loss, headaches, tremors or vision changes immediately.
- Keep follow-up appointments.
- Maintain fluids, avoid dehydration. (Teach signs of dehydration.)

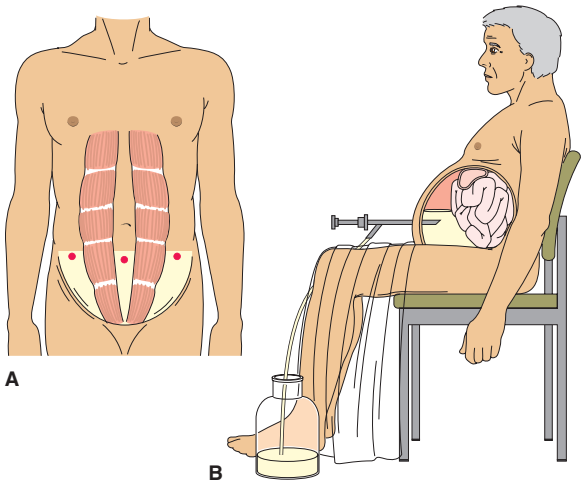

FIGURE 24.4 ■ Sites and position for paracentesis. *A*, Potential sites of needle or trocar insertion to avoid abdominal organ damage. *B*, The person sits comfortably; in this position, the intestines float back and away from the insertion site

gut, is given intravenously to reduce blood flow in the portal venous system. Vasopressin, a drug that produces generalised vasoconstriction, may also be used.

When the blood pressure and cardiac output have stabilised, upper endoscopy is performed to evaluate and treat the varices. During endoscopy, the varices may be banded or sclerosed to reduce the risk of recurrent bleeding. In *banding* (*variceal ligation*), small rubber bands are placed on varices to occlude blood flow. *Endoscopic sclerosis* involves injecting a sclerosing agent directly into the varices to induce inflammation and clotting. See Chapter 20 for the nursing implications of endoscopic investigation.

Balloon tamponade of bleeding varices may be used if bleeding cannot be controlled through vasoconstriction or if endoscopy is unavailable. A multiple-lumen nasogastric (NG) tube (such as a Sengstaken–Blakemore tube or a Minnesota tube) is inserted and the gastric and oesophageal balloons are inflated to apply direct pressure on the bleeding varices (see Figure 24.5). Tension is applied to the tube to further compress the varices. Balloon tamponade carries a number of risks,

BOX 24.5 Nursing implications for abdominal paracentesis

Preparation of the person

- Verify presence of an informed consent.
- Weigh prior to paracentesis.
- Assess vital signs for baseline.
- Have person void immediately prior to the test to avoid bladder puncture.
- Position seated, either on the side of the bed or in a chair, with feet supported.

Health education for the person and family

- Describe what to expect during and following paracentesis. Blood pressure is monitored during the procedure.
- The doctor will clean abdomen with Betadine and insert local anaesthesia. A small incision may be made and a needle or catheter is inserted to withdraw fluid. The needle is connected to tubing and a collection bottle; specimens may be sent to laboratory.
- A small dressing is placed over the puncture site after the needle is withdrawn. There may be some fluid leakage from the site.
- Salt-poor albumin may be given after the procedure to replace lost protein.

including aspiration, airway obstruction and tissue ischaemia and necrosis. An endotracheal tube is inserted prior to nasogastric intubation to support the airway and reduce the risk of aspiration. This short-term measure is used only until more definitive treatment can be done.

Transjugular intrahepatic portosystemic shunt (TIPS) is used to relieve portal hypertension and its complications of oesophageal varices and ascites. A channel is created through the liver tissue using a needle inserted transcutaneously (see Figure 24.6). An expandable metal stent is inserted into this channel to allow blood to flow directly from the portal vein into the hepatic vein, bypassing the cirrhotic liver. The shunt relieves pressure in oesophageal varices and allows better control of fluid retention with diuretic therapy. Stenosis and occlusion of the shunt are frequent complications. TIPS also increases the risk of developing hepatic encephalopathy (due to decreased perfusion of the liver and impaired ammonia metabolism) and may reduce long-term survival. It generally is used as a short-term measure until a liver transplant is performed.

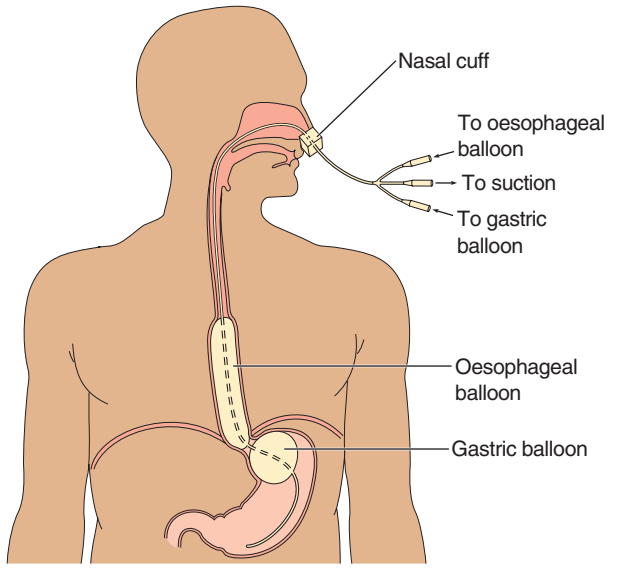

FIGURE 24.5 ■ Triple-lumen nasogastric tube (Sengstaken–Blakemore) used to control bleeding oesophageal varices

SURGERY **Liver transplantation** is indicated for some people with irreversible, progressive cirrhosis. A decline in functional status, increasing bilirubin levels, falling albumin levels and increasing problems with complications that respond poorly to treatment are indications for liver transplantation. Malignancy, active alcohol or drug abuse, and poor surgical risk are contraindications for the surgery. See the box below for nursing care of the person undergoing a liver transplant.

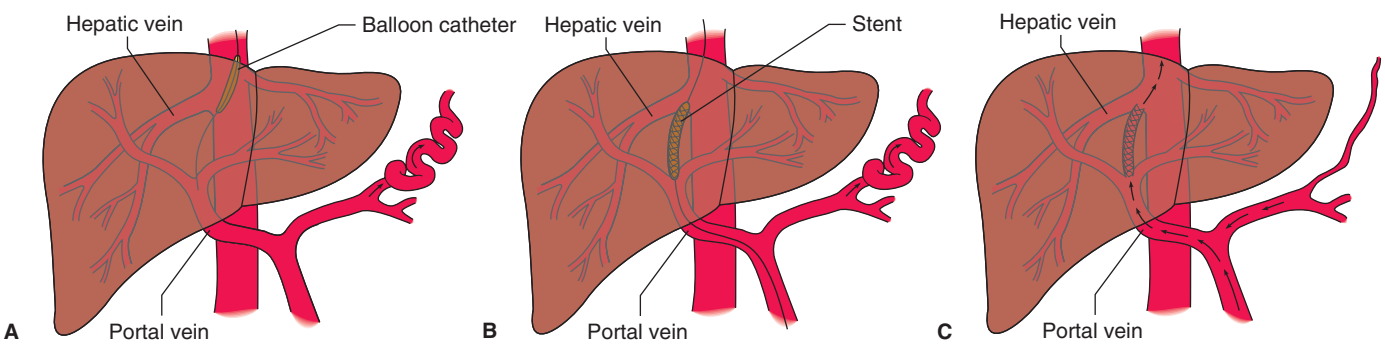

FIGURE 24.6 ■ Transjugular intrahepatic portosystemic shunt (TIPS). *A*, Guided by angiography, a balloon catheter inserted via the jugular vein is advanced to the hepatic veins and through the substance of the liver to create a portacaval (portal vein to vena cava) channel. *B*, A metal stent is positioned into the channel and expanded by inflating the balloon. *C*, The stent remains in place after the catheter is removed, creating a shunt for blood to flow directly from the portal vein into the hepatic vein

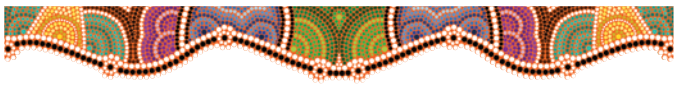


Nursing care

In addition to the nursing care discussed in this section, a nursing care plan for a person with alcoholic cirrhosis follows.

Health promotion

For most people, high-risk behaviours are the risk factors for cirrhosis. With all people (including children and young adults), stress the relationship between alcohol and drug abuse and liver disorders. While many people tolerate alcohol use in moderation with no adverse effects on the liver, excess alcohol use is the leading cause of cirrhosis. Injection drug use also is a significant risk factor, increasing the risk of contracting blood-borne hepatitis (B, C or D). These types of viral hepatitis can lead to chronic hepatitis and, ultimately, to cirrhosis. Discuss abstinence or safer sex practices as another measure to prevent viral hepatitis and potential liver damage.

Assessment

Assessment data related to cirrhosis include the following:

- *Health history:* current manifestations, including abdominal pain or discomfort, recent weight loss, weakness and anorexia; altered bowel elimination; excess bleeding or bruising; abdominal distension; jaundice, pruritus; altered libido or impotence; duration of symptoms; history of liver or gallbladder disease; pattern and extent of alcohol or injection drug use; use of other prescription and non-prescription drugs.
- *Physical assessment:* vital signs; mental status; colour and condition of skin and mucous membranes; peripheral pulses and presence of peripheral oedema; abdominal assessment including appearance, shape and contour, bowel sounds, abdominal girth, percussion for liver borders and palpation for tenderness and liver size.

Nursing diagnoses and interventions

Nursing care of the person with cirrhosis presents many challenges because liver function affects all body systems. The nurse is responsible for coordinating care among care providers. Many nursing diagnoses may apply. The diagnoses discussed in this section focus on problems with fluid and electrolyte balance, disturbed thought processes, risk of bleeding, skin integrity and nutrition.

Risk of excess fluid volume related to portal hypertension

Cirrhosis affects water and salt regulation due to portal hypertension, hypoalbuminaemia and hyperaldosteronism. Signs of fluid volume overload and portal hypertension may develop: ascites, peripheral oedema, internal haemorrhoids and varices, and prominent abdominal wall veins. Careful monitoring is necessary, because treatment measures can lead to further fluid and electrolyte imbalances.

- Weigh daily. Assess for jugular vein distension, measure abdominal girth daily and check for peripheral oedema. Monitor intake and output. *Careful assessment is important to detect fluid shifts.*
- Assess urine specific gravity. *Specific gravity measures the concentration of urine, an indicator of hydration.*
- Provide a low-sodium diet (500 to 2000 mg/day) and restrict fluids as ordered. *Excess sodium leads to water retention and can increase fluid volume, ascites and portal hypertension.*

CONSIDERATION FOR PRACTICE

Monitor the person with cirrhosis for signs of impaired renal function, such as oliguria, a fixed urine specific gravity of about 1.012, central oedema (around the eyes and of the face) and increasing serum creatinine and BUN levels. Such signs may indicate hepatorenal syndrome or acute renal failure from another cause.

Risk of disturbed thought processes due to hepatic encephalopathy

Accumulated nitrogenous waste products and other metabolites affect mental status and thought processes. Effects of hepatic encephalopathy can range from mild confusion to agitation to coma.

- Assess neurological status, including level of consciousness and mental status. Observe for signs of early encephalopathy: changes in handwriting, speech and asterixis. *Early identification of evidence of encephalopathy allows prompt intervention—subtle changes in neurological functioning are important!*
- Avoid factors that may precipitate hepatic encephalopathy. Avoid hepatotoxic medications and CNS-depressant drugs. *Cautious use of medications and close monitoring can eliminate iatrogenic causes of encephalopathy.*
- If possible, plan for consistent nursing care assignments. *Consistent care providers facilitate early identification of subtle neurological changes indicative of hepatic encephalopathy.*
- Administer medications or enemas as ordered to reduce nitrogenous products. Monitor bowel function and provide measures to promote regular elimination and prevent constipation. *Oral or rectally administered medications are ordered to reduce intestinal bacteria and the ammonia they produce. Regular bowel elimination promotes protein and ammonia elimination in the faeces.*
- Orientate to surroundings, person and place; provide simple explanations and reassurance. *Modification of verbal interactions to level of understanding and mental status may reduce anxiety and agitation.*

CONSIDERATION FOR PRACTICE

Closely monitor people who have experienced gastrointestinal bleeding for signs of hepatic encephalopathy. Blood in the intestinal tract is digested as a protein, increasing serum ammonia levels and the risk of hepatic encephalopathy.

NURSING CARE OF THE PERSON undergoing liver transplantation

PREOPERATIVE CARE

- Obtain a complete nursing history and physical examination. *A complete preoperative nursing assessment provides baseline data for comparison after surgery.*
- Provide routine preoperative care as ordered (see Chapter 3). *Preoperative care is similar to that provided for other people undergoing major surgery.*
- Discuss preoperative and postoperative expectations with the person and family. Introduce to the intensive care unit and discuss anticipated drainage tubes and supportive measures in the immediate postoperative period. Provide information about visiting policies and family accommodation (if available). *Preoperative teaching helps relieve anxiety in the person and family members. After a transplant people return from surgery to an intensive care or specialised care unit. Restrictions on the number of visitors and the time they may spend with the person are common.*
- Once a donor liver is located, check for evidence of infection; if no infection is present, begin preoperative antibiotics as ordered. *An acute or chronic infection may contraindicate liver transplantation as drugs given postoperatively to suppress rejection of the transplanted organ also impair the ability to fight infection.*

POSTOPERATIVE CARE

- Maintain airway and ventilatory support until awake and alert. *Until the new liver clears the anaesthesia, the person requires measures to support respirations and ventilation.*
- Monitor temperature and implement rewarming measures (such as warming blankets, heating lamps and head covers) as indicated. *The person often is hypothermic after liver transplant, necessitating careful rewarming while maintaining haemodynamic stability.*
- Frequently monitor haemodynamic pressures, including arterial blood pressure, central venous pressure and pulmonary artery pressures. *Postoperative fluid volume status may be difficult to determine without careful pressure measurements. The rate and type of fluids administered are determined by haemodynamic status.*
- Monitor urine output hourly; maintain careful intake and output records. Weigh daily. *Urine output and weight provide additional information about fluid volume status. In addition, renal function may be altered after liver transplant; acute renal failure is a significant risk. See Chapter 27 for more information about acute renal failure.*
- Monitor for signs of active bleeding, including excess drainage, increasing abdominal girth, bloody nasogastric drainage, black tarry stools, tachypnoea, tachycardia, diminished peripheral pulses or pallor. Report immediately. *Altered coagulation in the early postoperative period increases the risk of bleeding. Blood products to replace volume and clotting factors may be necessary.*
- Monitor serum electrolytes and laboratory values related to blood coagulation, liver function and renal function. Report abnormal results or significant changes immediately. *Electrolyte imbalances are common postoperatively. Altered liver or renal function tests may indicate rejection of the transplanted liver or acute renal failure. Other early signs of transplant rejection include fever, a drop in bile output or a change in bile colour and viscosity (Urden, Stacy & Lough, 2013).*
- Monitor neurological status. *With good function of the transplanted organ, mental status should clear within days of the transplant.*

HEALTH EDUCATION FOR THE PERSON AND FAMILY

- Teach how to reduce risk of infection and signs of infection to report.
- Instruct to recognise and report signs of organ rejection.
- Discuss all medications, including their purpose, schedule, adverse effects and potential long-term effects. Stress the importance of complying with all prescribed medications and postoperative precautions for the remainder of the person's life.
- Discuss possible changes in body image and psychological responses to receiving a transplanted organ. Refer to a social worker or support group as indicated.
- Refer for home health services for continued assessment and teaching.
- Stress importance of continued follow-up with transplant team and general practitioner.

Ineffective protection

Impaired coagulation, oesophageal varices and possible acute gastritis place the person with cirrhosis at significant risk of haemorrhage. Clotting is altered by vitamin K deficiency; impaired manufacture of coagulation factors II, VII, IX and X; and increased platelet destruction due to splenomegaly.

- Monitor vital signs; report tachycardia or hypotension. *Increased pulse and decreasing blood pressure may indicate hypovolaemia due to haemorrhage.*
- Institute bleeding precautions (see Box 24.6). *Preventive measures can decrease the risk of active bleeding.*
- Monitor coagulation studies and platelet count. *Report abnormal results. Coagulation studies help determine the risk of bleeding and the need for treatment.*

BOX 24.6 Bleeding precautions

- Prevent constipation.
- Avoid rectal temperatures or enemas.
- Avoid injections; if needed, use small-gauge needle and apply gentle pressure.
- Monitor platelet count, PT and APTT.
- Assess for bruised areas and areas of purpura.
- Apply pressure to bleeding sites. After venepuncture, apply direct pressure for at least 5 minutes.
- Use only a soft toothbrush.
- Avoid blowing nose.
- Assess oral cavity for bleeding gums.

NURSING CARE PLAN A person with alcoholic cirrhosis

Richard Wright is a 48-year-old divorced father of two teenagers. Mr Wright has been admitted to the community hospital with ascites and malnutrition. He has had three previous hospital stays for cirrhosis, the most recent 6 months ago.

ASSESSMENT

Mr Wright is lethargic but responds appropriately to verbal stimuli. He complains of 'spitting up blood the past week or so' and says, 'I'm just not hungry'. He has lost 9 kg since his previous admission. He is jaundiced and has petechiae and bruising on his arms and legs. Liz Mowdi, Mr Wright's nurse, notes pitting pre-tibial oedema. Abdominal assessment reveals a tight, protuberant abdomen with caput medusae. The liver margin is not palpable; the spleen is enlarged. Vital signs are T 37.7°C, P 110, R 24 and BP 110/70.

Abnormal laboratory results include WBC 3700/mm^3 (normal 4300 to 10 800/mm^3); RBC 4.0 million/mm^3 (normal 4.6 to 5.9 million/mm^3); platelets 75 000/mm^3 (normal 150 000 to 350 000/mm^3); serum ammonia 105 µm/dL (normal 35 to 65 µm/dL); total bilirubin 4.9 mcg/dL (normal 0.1 to 1.0 mcg/dL); and serum sodium 150 mEq/L (normal 135 to 145 mEq/L). Potassium, haemoglobin, haematocrit, total protein and albumin levels are markedly decreased. Liver enzymes are elevated. Blood urea nitrogen and creatinine levels are marginally elevated. Oxygen saturation (O_2 sat) is 88% (normal range: 96% to 100%) per pulse oximetry.

Endoscopy shows bleeding from gastric ulcer and the diagnosis of alcoholic cirrhosis with gastritis is made. Mr Wright is started on spironolactone, 25 mg PO q8h; lactulose, 30 mL prn until onset of diarrhoea, then 15 mL tds; and low-sodium diet; fluid restriction of 1500 mL/day.

DIAGNOSES

- *Risk of impaired gas exchange* related to pressure of ascites fluid on the diaphragm as manifested by tachypnoea and decreased oxygen saturation.
- *Risk of excess fluid volume* related to electrolyte imbalance and hypoalbuminaemia as manifested by ascites and peripheral oedema.
- *Risk of imbalanced nutrition: less than body requirements* related to anorexia and possible alcohol abuse as manifested by weight loss and low serum protein levels.
- *Risk of disturbed thought processes* related to effects of high ammonia levels as manifested by lethargy.
- *Risk of ineffective protection* related to impaired platelet formation and malnutrition.

PLANNING

- Teach the importance of activity, turning, coughing and deep breathing prior to the procedure.
- Encourage Mr Wright's family to visit at mealtimes to encourage oral intake.
- Ensure buzzer is kept by bedside at all times and encourage Mr Wright to alert nursing staff immediately if he experiences any signs of bleeding such as haematemesis or dizziness.
- Arrange for social work review for referral to community support services.

Expected outcomes

- Respiratory rate and SpO_2 will be within normal limits.
- Abdominal girth will decrease by 1 to 2 cm per day; peripheral oedema will decrease.
- Will gain 0.5 kg per week without evidence of increased fluid retention. Serum albumin levels will return to normal range.
- Will be alert and oriented; serum ammonia levels are within normal range.
- Will demonstrate no further evidence of active bleeding.
- Will verbalise willingness to join a community support group.

IMPLEMENTATION

- Weigh daily.
- Provide high-kilojoule, low-salt, low-protein diet with between-meal snacks.
- Maintain stool chart.
- Assign same nurses to care as much as possible to facilitate evaluation of mental status. Promptly report changes in status or laboratory values.
- Measure abdominal girth every 8 hours, marking level of measurement.
- Institute bleeding precautions.
- Elevate head of bed; assist to chair with legs elevated as tolerated. When resting in bed encourage to turn, cough and deep breathe every 2 to 4 hours.
- Include significant others in care and teaching.

EVALUATION

A week after admission, Mr Wright's ascites has decreased and no further active bleeding is noted. His serum protein levels have increased and his laboratory values are improving. No further bruising is noted during hospitalisation. Although he shows a 2 kg weight loss as excess water is eliminated, he is consuming 100% of his diet. His serum ammonia levels have returned to normal. On discharge, SpO_2 is 96%; respirations are 18. Lactulose will be continued on discharge.

Ms Mowdi provides both written and verbal information about the medication and cirrhosis, including measures to prevent complications. Mr Wright and his children express interest in Alcoholics Anonymous and are referred to this agency. Prior to discharge, follow-up appointments are made with a mental health team, social worker and a general practitioner.

CRITICAL THINKING IN THE NURSING PROCESS

1. Describe the relationship between portal hypertension, liver dysfunction and ascites.
2. What is the pathophysiological basis for hepatic encephalopathy? What are the nursing responsibilities related to lactulose and neomycin?
3. Design a nursing care plan for Mr Wright for the diagnosis *Ineffective coping*.

REFLECTION ON THE NURSING PROCESS

1. Outline what you have learned from this case study that you will apply to your future practice.
2. Mr Wright confides to you that he is worried about whether he will be able to completely abstain from alcohol. Reflect on how you would respond.

- Carefully monitor the person who has had bleeding oesophageal varices for evidence of rebleeding: haematemesis, haematochezia (bright blood in the stool) or tarry stools, signs of hypovolaemia or shock. *Rebleeding is common following variceal haemorrhage, especially within the first week.*

Impaired skin integrity

Severe jaundice with bile salt deposits on the skin may cause pruritus. Scratching related to the pruritus damages the skin and impairs its integrity. Malnutrition, particularly protein deficiency, and oedema also increase the risk of tissue breakdown and impaired skin integrity.

- Use warm water rather than hot water when bathing. *Hot water increases pruritus.*
- Use measures to prevent dry skin: apply an emollient or lubricant as needed to keep skin moist, avoid soap or preparations with alcohol, and do not rub the skin. *Dry skin contributes to pruritus.*
- If indicated, apply gloves to prevent scratching. *People with encephalopathy may not understand the need to refrain from scratching.*
- Institute measures to prevent skin and tissue breakdown: turn at least every 2 hours, use an alternating-pressure mattress and frequently assess skin condition. *Frequent position changes relieve pressure and promote circulation and tissue oxygenation.*
- Administer prescribed antihistamine (to relieve pruritus) cautiously. *Decreased liver function increases the risk of altered drug responses.*

Imbalanced nutrition: less than body requirements

The person with cirrhosis is at risk of malnutrition for a number of reasons: possible chronic alcohol use, anorexia, impaired vitamin and mineral absorption, and impaired protein metabolism. In addition, salt restrictions may make the diet less palatable and appealing to the person.

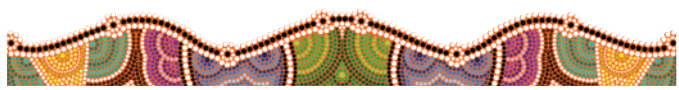
- Weigh daily. Instruct to weigh at least weekly at home. *Weight is a good indicator of both nutritional status and fluid balance. Short-term weight fluctuations tend to reflect fluid balance, while longer-term changes in weight are more reflective of nutritional status.*
- Provide small meals with between-meal snacks. *A small meal is more appealing for an anorexic person. Between-meal snacks help to maintain adequate kilojoule and nutrient intake.*
- Unless protein is restricted due to impending hepatic encephalopathy, promote protein and nutrient intake by providing nutritional supplements such as Ensure or instant breakfasts. *The sodium and protein content of all meals and snacks must be calculated when maintaining restrictions of these nutrients.*
- Arrange for consultation with a dietitian for diet planning while hospitalised and at home. *The dietitian can provide detailed instructions, sample menus and suggestions for improving the palatability of the diet and promoting intake.*

Community-based care

Cirrhosis is a chronic, progressive disease. As such, the person and family assume major roles in managing the disease and its manifestations, and in preventing complications. Teaching topics for home care include:

- The absolute necessity of avoiding alcohol and other hepatotoxic drugs. Suggest inpatient or community-based alcohol treatment programs and Alcoholics Anonymous as indicated.
- Diet and fluid intake restrictions and recommendations. Include suggestions to promote nutritional intake and increase the flavour of food when sodium is restricted.
- Prescribed medications; their timing, intended and adverse effects; and manifestations to report to the primary care provider.
- Bleeding precautions (see Box 24.6).
- Manifestations of potential complications to be reported to the primary care provider. Stress the importance of promptly reporting evidence of gastrointestinal bleeding for prompt intervention for potential haemorrhage.
- Skin care techniques to reduce pruritus and the risk of damage.
- Ways to manage fatigue and conserve energy.

Provide referrals for home health services, dietary consultation, social services and counselling as needed by the person and family. Suggest local support groups where available. If appropriate, suggest hospice services for the person with end-stage liver disease.



THE PERSON WITH CANCER OF THE LIVER

Primary liver cancer is a common malignancy worldwide although it only accounts for 1.2% of all cancers in Australia (AIHW, 2011; Carr, 2012). Hepatocellular carcinoma is common in parts of Asia and Africa which are associated with high endemic hepatitis B carrier rates (Carr, 2012). The incidence of primary liver cancer is three times higher in Australian men than it is in Australian women (AIHW, 2011). The prognosis for primary liver cancer is poor, in part because the disease is often advanced at the time of diagnosis. Metastasis to the liver from primary tumours of the lung, breast and gastrointestinal tract is relatively common.

Pathophysiology

About 80–90% of primary hepatic cancers arise from the liver's parenchymal cells (hepatocellular carcinoma); the remainder form in the bile ducts (cholangiocarcinoma). Regardless of the origin, the progress of the disease is similar. Several aetiological factors have been identified (see Box 24.7). Most primary liver cancer in the Australia is related to alcoholic cirrhosis, HBV or HCV.

BOX 24.7 Suspected causes of primary liver cancer

- Chronic hepatitis C infection
- Chronic hepatitis B infection
- Cirrhosis, regardless of type
- Chronic aflatoxin (a toxin produced by *Aspergillus* moulds) exposure
- Arsenic-contaminated water
- Carcinogens in food
- Possible hormonal factors (e.g. long-term use of androgens)

The underlying pathophysiology of primary liver cancer is damage to hepatocellular DNA. This damage may be caused by integration of HBV or HCV into the DNA or by repeated cycles of cell necrosis and regeneration that facilitate DNA mutations. HBV and aflatoxins damage a specific tumour suppressor gene, p53. Tumours may be limited to one specific area, may occur as nodules throughout the liver or may develop as surface infiltrates. The tumour interferes with normal hepatic function, leading to biliary obstruction and jaundice, portal hypertension and metabolic disruptions (hypoalbuminaemia, hypoglycaemia and bleeding disorders). It also may secrete bile products and produce hormones (paraneoplastic syndrome) that may lead to polycythaemia, hypoglycaemia and hypercalcaemia. Tumours usually grow rapidly and metastasise early.

Manifestations

Initial manifestations of liver cancer develop insidiously and often are masked by the presence of cirrhosis or chronic hepatitis. Weakness, anorexia, weight loss, fatigue and malaise are common early manifestations. Abdominal pain and a palpable mass in the right upper quadrant are common presenting symptoms. See the box below for manifestations of primary liver cancer. Ascites and jaundice may be present at diagnosis. Signs of liver failure with portal hypertension, splenomegaly and altered metabolism develop as the tumour progresses. People with advanced tumours have a median survival of 4 months, with or without treatment (Carr, 2012).

MANIFESTATIONS Primary liver cancer

- Malaise
- Anorexia
- Lethargy
- Weight loss
- Fever of unknown origin
- Jaundice
- Feeling of abdominal fullness
- Painful right upper quadrant mass
- Manifestations of liver failure

INTERPROFESSIONAL CARE

Liver tumours are identified by CT scans and MRI. A liver biopsy may be done to confirm the diagnosis and identify the tumour type or origin. See the 'Diagnostic tests' box in Chapter 20 for the nursing implications of liver biopsy. Serum alpha-fetoprotein (AFP) levels, normally low in non-pregnant adults, rise in most people with hepatocellular cancer.

Small, localised tumours may be surgically resected, offering the only viable chance for cure. Most tumours, however, have spread extensively or have distant metastasis at the time of diagnosis, so this is frequently not an option. Liver transplantation may be done; however, the tumour may recur in the transplanted organ.

Radiation therapy is used to shrink the tumour, decreasing pressure on surrounding organs and reducing pain. Chemotherapy may be used as primary treatment or adjunctive therapy. Direct continuous hepatic arterial infusion with an implanted pump has shown promise in prolonging survival rates. See Chapter 13 for nursing care for people receiving radiation therapy or chemotherapy.

Nursing care

Encourage people with risk factors for primary liver cancer to avoid alcohol and other substances that may further damage the liver. Urge them to discuss regular screening for liver tumours (such as serum AFP levels) with their general practitioner.

Both the person and the family need extensive nursing support. Controlling pain is a priority. Because of the poor prognosis, early referral for hospice services may be appropriate.

Nursing diagnoses, interventions and teaching for the person with liver cancer are similar to those for people with cirrhosis; see above.

THE PERSON WITH LIVER TRAUMA

Blunt or penetrating trauma to the abdomen can damage the liver. Liver trauma is frequently seen in combination with injuries to other abdominal organs. Motor vehicle crashes, stab or gunshot wounds, and iatrogenic sources such as liver biopsy are among the causes of these injuries.

Pathophysiology and manifestations

Liver trauma generally causes bleeding due to the vascularity of the organ. Liver injury may cause a surface haematoma, a haematoma within the liver parenchyma, laceration of liver

tissue or disruption of vessels leading to or from the liver. Severe bleeding can rapidly disrupt haemodynamic stability and lead to shock.

CONSIDERATION FOR PRACTICE

Bleeding due to liver trauma may not be immediately apparent. Instruct the person with apparent or potential liver trauma to immediately report light headedness, rapid heart rate, shortness of breath, thirst or increasing abdominal pain.

INTERPROFESSIONAL CARE

Diagnostic peritoneal lavage (DPL) may be used along with CT scan to diagnose liver trauma. The procedure is performed by making a small abdominal incision into the peritoneum (after the bladder has been emptied) and inserting a small catheter into the peritoneal cavity. If blood is immediately detected, the person is taken directly to surgery for abdominal exploration or transferred to a trauma facility where this surgery can occur. If frank bleeding is not apparent, a litre of isotonic fluid is instilled into the abdomen, then drained and sent for laboratory analysis.

A FAST (focused abdominal sonography in trauma) scan is more frequently used to identify free intraperitoneal fluid associated with liver injuries from blunt trauma. Unlike DPL, FAST scans are non-invasive, quick, and pose no risk to the person. DPL carries a 1–9.5% risk to the person, including perforation of a viscus, vascular laceration and wound complications (Christie-Large, Michaelides & James, 2008).

Intravenous fluids, fresh frozen plasma, platelets and other clotting factors are administered to restore blood volume and promote haemostasis. Haemodynamic status is closely monitored; continued instability may indicate a need for surgical intervention to control haemorrhage. Postoperative nursing care focuses on preventing pulmonary complications, such as atelectasis, and detecting and preventing infection.

Nursing care

Nursing care of the person with liver trauma focuses on fluid management and other supportive care related to shock. Keeping family members informed is an important aspect of care, especially during the period of haemodynamic instability. Diagnoses include the following:

- *Deficient fluid volume* related to haemorrhage.
- *Risk of infection* related to wound or abdominal contamination.
- *Ineffective protection* related to impaired coagulation.

THE PERSON WITH LIVER ABSCESS

Liver abscesses usually are bacterial or amoebic (protozoal) in origin. Bacterial abscesses may follow trauma or surgical procedures, including biopsy. Multiple or single abscesses occur most commonly in the right lobe. Amoebic abscesses most frequently occur following infestation of the liver by *Entamoeba histolytica*. Amoebic infestation is associated with poor hygiene, unsafe sexual practices or travel in areas where drinking water is contaminated.

Pathophysiology and manifestations

Following bacterial or amoebic invasion of the liver, healthy tissue is destroyed, leaving an area of necrosis, inflammatory exudate and blood. This damaged region becomes walled off from the healthy liver tissue. Pyogenic (bacterial) liver abscess may be caused by cholangitis or distant or intra-abdominal infections, such as peritonitis or diverticulitis. *Escherichia coli* is the most frequently identified causative organism. The onset of pyogenic abscess is usually sudden, causing acute symptoms such as fever, malaise, vomiting, hyperbilirubinaemia and pain in the right upper abdomen.

The infection pathway for amoebic hepatic abscesses usually is the portal venous circulation from the right colon. Generally, the onset of amoebic abscess is insidious.

INTERPROFESSIONAL CARE

Hepatic abscess is diagnosed through biopsy, hepatic aspirate, blood and faecal cultures, and CT scan and ultrasound studies. Therapy is based on identifying the causative organism through laboratory cultures. Pyogenic abscesses are treated with antibiotics to which the causative organism is sensitive.

Pharmacological agents used for amoebic hepatic abscess are the same as those used for intestinal amoebic infestation (see Chapter 23); combination therapy is commonly used. Two commonly used drugs for treating amoebic liver abscesses are metronidazole (Flagyl) and iodoquinol (Diquinol). Both medications can cause gastrointestinal symptoms. Bone marrow suppression is a risk with metronidazole.

If the abscess does not respond to antibiotic therapy, percutaneous aspiration or surgical drainage may be done. In these procedures, a *percutaneous closed-catheter drain* is placed in the abscess to promote drainage of purulent material.

Nursing care

A major aspect of nursing care is prevention; teaching people to avoid contaminated water and foods is especially important. Nursing interventions include teaching hikers to treat water and food handlers to wash hands thoroughly.

People who have a liver abscess require supportive care to prevent dehydration from the accompanying fever, nausea, vomiting and anorexia. Careful monitoring of fluid and electrolyte status is indicated, as are comfort measures for abdominal pain. Possible nursing diagnoses include the following:

- *Risk of deficient fluid volume* related to effects of prolonged fever and vomiting.
- *Deficient knowledge* related to transmission of amoebic abscess.
- *Activity intolerance* related to pain and weakness.

EXOCRINE PANCREAS DISORDERS

The pancreas is both an exocrine and an endocrine gland. It is made up of two basic cell types, each having different functions. The exocrine cells produce enzymes that empty through ducts into the small intestine, whereas the endocrine cells produce hormones that enter the bloodstream directly. Disorders of the exocrine pancreas affect the secretion and glandular control of digestive enzymes, whereas disorders of the endocrine pancreas affect the production of hormones necessary for normal carbohydrate, protein and fat metabolism. Disorders of the exocrine pancreas are discussed in this section of the chapter; diabetes mellitus, a disorder of the endocrine pancreas, is discussed in Chapter 19.

THE PERSON WITH PANCREATITIS

Pancreatitis, or inflammation of the pancreas, is characterised by release of pancreatic enzymes into the tissue of the pancreas itself, leading to haemorrhage and necrosis. Pancreatitis may be either acute or chronic.

Gallstones and chronic alcohol abuse account for 80% of acute pancreatitis causes (Nesvaderani, Eslick & Cox, 2015). The incidence of acute pancreatitis varies in different countries depending on the cause. In Australia, the estimated incidence is around 70 cases per 100 000 people.

The incidence of chronic pancreatitis is less clear, because many people with chronic pancreatitis do not have classic manifestations of the disease. People with pancreatitis may have long-term effects of the disease, with chronic changes in enzyme and hormone production.

Physiology review

Knowledge of the normal structure and functions of the exocrine pancreas is important to understand how inflammation affects it and the person. The exocrine pancreas consists of lobules of acinar cells. The acinar cells secrete digestive enzymes and fluids (pancreatic juices) into ducts that empty into the main pancreatic duct (the duct of Wirsung). The pancreatic duct joins the common bile duct and empties into the duodenum through the ampulla of Vater. (In some people the main pancreatic duct empties directly into the duodenum.) The epithelial lining of the pancreatic ducts secretes water and bicarbonate to modify the composition of the pancreatic secretions. Pancreatic enzymes are secreted primarily in an inactive form and are activated in the intestine, a modification that prevents digestion of pancreatic tissue by its own enzymes (Porth & Matfin, 2009). The pancreatic enzymes, with related functions, are as follows:

- proteolytic enzymes, including trypsin, chymotrypsin, carboxypolypeptidase, ribonuclease and deoxyribonuclease, which break down dietary proteins
- pancreatic amylase, which breaks down starch
- lipase, which breaks down fats into glycerol and fatty acids.

Pathophysiology

Acute pancreatitis

Acute pancreatitis is an inflammatory disorder that involves self-destruction of the pancreas by its own enzymes through autodigestion. The milder form of acute pancreatitis, *interstitial oedematous pancreatitis*, leads to inflammation and oedema of pancreatic tissue. It often is self-limiting. The more severe form, *necrotising pancreatitis*, is characterised by inflammation, haemorrhage and, ultimately, necrosis of pancreatic tissue.

Acute pancreatitis is more common in middle adults; its incidence is higher in men than in women. Acute pancreatitis is usually associated with gallstones in women and with alcoholism in men. Some people recover completely, others experience recurring attacks and still others develop chronic pancreatitis. The mortality and symptoms depend on the severity and type of pancreatitis: with mild pancreatic oedema, mortality is low; with severe necrotic pancreatitis, the mortality rate is high (Porth & Matfin, 2009).

Although the exact cause of pancreatitis is not known, the following factors may activate pancreatic enzymes within the pancreas, leading to autodigestion, inflammation, oedema and/or necrosis.

- Gallstones may obstruct the pancreatic duct or cause bile reflux, activating pancreatic enzymes in the pancreatic duct system.
- Alcohol causes duodenal oedema and may increase pressure and spasm in the sphincter of Oddi, obstructing pancreatic outflow. It also stimulates pancreatic enzyme production, thus raising pressure within the pancreas.

Other factors associated with acute pancreatitis include tissue ischaemia or anoxia, trauma or surgery, pancreatic tumours, third-trimester pregnancy, infectious agents (viral, bacterial or parasitic), elevated calcium levels and hyperlipidaemia. Some

medications have been linked with this disorder, including thiazide diuretics, oestrogen, steroids, salicylates and NSAIDs.

Regardless of the precipitating factor, the pathophysiological process begins with the release of activated pancreatic enzymes into pancreatic tissue. Activated proteolytic enzymes—trypsin, in particular—digest pancreatic tissue and activate other enzymes such as phospholipase A, which digests cell membrane phospholipids, and elastase, which digests the elastic tissue of blood vessel walls. This leads to proteolysis, oedema, vascular damage and haemorrhage, and necrosis of parenchymal cells. Cellular damage and necrosis release activated enzymes and vasoactive substances that produce vasodilation, increase vascular permeability and cause oedema. A large volume of fluid may shift from circulating blood into the retroperitoneal space, the peripancreatic spaces and the abdominal cavity.

MANIFESTATIONS Acute pancreatitis develops suddenly, with an abrupt onset of continuous severe epigastric and abdominal pain. This pain commonly radiates to the back and is relieved somewhat by sitting up and leaning forward. The pain often is initiated by a fatty meal or excessive alcohol intake.

Other manifestations include nausea and vomiting, abdominal distension and rigidity, decreased bowel sounds, tachycardia, hypotension, elevated temperature, and cold, clammy skin. Within 24 hours, mild jaundice may appear. Retroperitoneal bleeding may occur 3 to 6 days after the onset of acute pancreatitis; signs of bleeding include bruising in the flanks (Turner's sign) or around the umbilicus (Cullen's sign). See the 'Manifestations' box below.

COMPLICATIONS Systemic complications of acute pancreatitis include intravascular volume depletion with acute tubular necrosis and renal failure (see Chapter 27 for more information about acute renal failure) and acute respiratory distress syndrome (ARDS). Acute renal failure usually develops within 24 hours after the onset of acute pancreatitis. Manifestations of ARDS may be seen 3 to 7 days after its onset, particularly in people who have experienced severe volume depletion. See Chapter 36 for more information about ARDS.

Localised complications include pancreatic necrosis, abscess, pseudocysts and pancreatic ascites. Pancreatic necrosis causes an inflammatory mass that may be infected. It may lead to shock and multiple organ failure. A pancreatic abscess may form late in the course of the disease (6 or more weeks after its onset), causing an epigastric mass and tenderness (McPhee, Papadakis & Tierney, 2008). Pancreatic pseudocysts, encapsulated collections of fluid, may develop both within the pancreas itself and in the abdominal cavity. They may impinge on other structures or may rupture, causing generalised peritonitis. Rupture of a pseudocyst or of the pancreatic duct can lead to pancreatic ascites. Pancreatic ascites is recognised by gradually increasing abdominal girth and persistent elevation of the serum amylase level without abdominal pain.

MANIFESTATIONS Acute and chronic pancreatitis

ACUTE PANCREATITIS
- Abrupt onset of severe epigastric and left upper quadrant pain; may radiate to back
- Nausea, vomiting; fever
- Decreased bowel sounds; abdominal distension and rigidity
- Tachycardia, hypotension; cold, clammy skin
- Possible jaundice
- Positive Turner's sign (flank bruising) or Cullen's sign (periumbilical bruising)

CHRONIC PANCREATITIS
- Recurrent epigastric and LUQ pain; radiates to back
- Anorexia, nausea and vomiting, weight loss
- Flatulence, constipation
- Steatorrhoea

Chronic pancreatitis

Chronic pancreatitis is characterised by gradual destruction of functional pancreatic tissue. In contrast to acute pancreatitis, which may completely resolve with no long-term effects, chronic pancreatitis is an irreversible process that eventually leads to pancreatic insufficiency. Alcoholism is the primary risk factor for chronic pancreatitis in the Australia. Malnutrition is a major worldwide risk factor. About 10–20% of chronic pancreatitis is idiopathic, with no identified cause. A genetic mutation on a gene associated with cystic fibrosis may play a role in these cases. Children or young adults with cystic fibrosis may develop chronic pancreatitis as well.

In chronic pancreatitis related to alcoholism, pancreatic secretions have an increased concentration of insoluble proteins. These proteins calcify, forming plugs that block pancreatic ducts and the flow of pancreatic juices. This blockage leads to inflammation and fibrosis of pancreatic tissue. In other cases, a stricture or stone may block pancreatic outflow, causing chronic obstructive pancreatitis. In chronic pancreatitis, recurrent episodes of inflammation eventually lead to fibrotic changes in the parenchyma of the pancreas, with loss of exocrine function. This leads to malabsorption from pancreatic insufficiency. If endocrine function is disrupted as well, clinical diabetes mellitus may develop.

MANIFESTATIONS Chronic pancreatitis typically causes recurrent episodes of epigastric and left upper abdominal pain that radiates to the back. This pain may last for days to weeks. As the disease progresses, the interval between episodes of pain becomes shorter. Other manifestations include anorexia, nausea and vomiting, weight loss, flatulence, constipation and steatorrhoea (fatty, frothy, foul-smelling stools caused by a decrease in pancreatic enzyme secretion).

COMPLICATIONS Complications of chronic pancreatitis include malabsorption, malnutrition and possible peptic ulcer disease. Pancreatic pseudocysts or abscesses may form or stricture of the common bile duct may develop. Diabetes mellitus may develop and there is an increased risk of pancreatic cancer. Narcotic addiction related to frequent, severe pain episodes is common.

INTERPROFESSIONAL CARE

Acute pancreatitis often is a mild, self-limiting disease. Treatment focuses on reducing pancreatic secretions and providing supportive care. Treatment to eliminate the causative factor is begun after the acute inflammatory process resolves. Severe necrotising pancreatitis may require intensive care management. Treatment for chronic pancreatitis often focuses on managing pain and treating malabsorption and malnutrition.

Diagnosis

The laboratory tests that may be ordered when pancreatitis is suspected are summarised in Table 24.4. Diagnostic studies include the following:

- *Ultrasonography* can identify gallstones, a pancreatic mass or pseudocyst.
- *CT scan* may be ordered to identify pancreatic enlargement, fluid collections in or around the pancreas, and perfusion deficits in areas of necrosis.
- *Endoscopic retrograde cholangiopancreatography (ERCP)* may be performed to diagnose chronic pancreatitis and to differentiate inflammation and fibrosis from carcinoma.
- *Magnetic endoscopic retrograde cholangiopancreatography (MRCP)* is a non-invasive procedure that does not use contrast media and is safer for people with known contrast adverse reactions.
- *Endoscopic ultrasonography* can detect changes indicative of chronic pancreatitis in the pancreatic duct and parenchyma.
- *Percutaneous fine-needle aspiration biopsy* may be performed to differentiate chronic pancreatitis from cancer of the pancreas; the cells that are aspirated are examined for malignancy.

More information about these tests and their nursing implications can be found in Chapter 20.

Medications

The treatment of acute pancreatitis is largely supportive. Early, aggressive fluid replacement with intravenous crystalloid fluids is recommended for mild to severe pancreatitis diagnoses. In additional the person should be kept nil by mouth until nausea, vomiting and pain dissipates. Narcotic analgesics such as morphine sulfate are used to control pain. Antibiotics may be prescribed to treat infection.

People with chronic pancreatitis also require analgesics, but are closely monitored to prevent drug dependence. Narcotics are avoided when possible. Pancreatic enzyme supplements are given to reduce steatorrhoea (see the 'Medication administration' box below). People with chronic pancreatitis may need to remain on pancreatic enzyme supplements for life. H_2 blockers such as cimetidine (Tagamet) and ranitidine (Zantac) and proton pump inhibitors such as omeprazole (Losec) may be given to neutralise or decrease gastric secretions. Octreotide (Sandostatin), a synthetic hormone, suppresses pancreatic enzyme secretion and may be used to relieve pain in chronic pancreatitis.

Treatments

NUTRITION Oral food and fluids are withheld during acute episodes of pancreatitis to reduce pancreatic secretions and promote rest of the organ. A nasogastric tube may be inserted and connected to suction. Intravenous fluids are administered for 48–72 hours to maintain vascular volume. If there is no improvement enteral feeding will be commenced via either a nasogastric or a nasojejunal tube. Enteral feeding is preferable to total parenteral nutrition (TPN) as it maintains gut barrier integrity, which reduces bacteria translocation risk, and is more physiological than TPN (Brenner & Krenzer, 2010; Greenberger, Conwell & Banks, 2012). Oral food and fluids are begun once the serum amylase

TABLE 24.4 Laboratory tests in exocrine pancreatic disorders

TEST	NORMAL VALUE	SIGNIFICANCE
Serum amylase	0–130 U/L (U = units)	Rises within 2 to 12 hours of onset of acute pancreatitis to three times normal. Returns to normal in 3 to 4 days.
Serum lipase	0–160 U/L	Levels rise to three times normal in acute pancreatitis; remain elevated for 7 to 14 days.
Serum trypsinogen	< 80 mcg/L	Elevated in acute pancreatitis; may be decreased in chronic pancreatitis.
Urine amylase	4–37 U/L/2 h	Urine amylase levels rise in acute pancreatitis.
Serum glucose	70–110 mg/dL	May be transient elevation in acute pancreatitis.
Serum bilirubin	0.1–1.0 mg/dL	Compression of the common duct may increase bilirubin levels in acute pancreatitis.
Serum alkaline phosphatase	30–95 U/L	Compression of the common duct may increase levels in acute pancreatitis.
Serum calcium	8.9–10.3 mg/dL or 4.5–5.5 mEq/L	Hypocalcaemia develops in up to 25% of people with acute pancreatitis.
White blood cells	4500–10 000/mm^3	Leucocytosis indicates inflammation and is usually present in acute pancreatitis.

MEDICATION ADMINISTRATION The person with chronic pancreatitis

PANCREATIC ENZYME REPLACEMENT

Pancrelipase

Pancrelipase enhances the digestion of starches and fats in the gastrointestinal tract by supplying an exogenous source of the enzymes protease, amylase and lipase. The drug promotes nutrition and decreases the number of bowel movements.

Nursing responsibilities

- Assess for allergy to pork protein.
- Monitor frequency and consistency of stools.
- Weigh every other day and record.
- Give with meals; if not enteric coated, H_2 antagonists or antacids may be given concurrently to prevent destruction of the enzymes by hydrochloric acid.
- Monitor for side effects: rash, hives, respiratory difficulty, haematuria, hyperuricaemia or joint pain.

Health education for the person and family

- Take with meals or snacks.
- If medicine is enteric coated, do not crush, chew or mix with alkaline foods (e.g. milk, ice-cream).
- Be sure to follow prescribed diet.
- Continue taking this drug until or unless advised by physician that it is no longer necessary.

levels have returned to normal, bowel sounds are present and pain disappears. A low-fat diet is ordered and alcohol intake is strictly prohibited.

SURGERY If the pancreatitis is the result of a gallstone lodged in the sphincter of Oddi, an *endoscopic transduodenal sphincterotomy* may be performed to remove the stone. When cholelithiasis is identified as a causative factor, a cholecystectomy is performed once the acute pancreatitis has resolved. Surgical procedures to promote drainage of pancreatic enzymes into the duodenum or resection of all or part of the pancreas may be done to provide pain relief in people with chronic pancreatitis. Large pancreatic pseudocysts may be drained endoscopically or surgically.

Nursing care

In addition to the nursing care discussed in this section, a nursing care plan for a person with acute pancreatitis is found below.

Health promotion

Teach people who abuse alcohol about the risk of developing pancreatitis. Advise abstinence to reduce this risk and refer to an alcohol treatment program or Alcoholics Anonymous.

Assessment

Assessment data related to acute or chronic pancreatitis include the following:

- *Health history*: current manifestations; abdominal pain (location, nature, onset and duration, identified precipitating factors); anorexia, nausea or vomiting; flatulence, diarrhoea, constipation or stool changes; recent weight loss; history of previous episodes or gallstones; alcohol use (extent and duration); current medications.
- *Physical assessment*: vital signs including orthostatic vitals and peripheral pulses; temperature; skin temperature and colour, presence of any flank or periumbilical ecchymoses; abdominal assessment including bowel sounds, presence of distension, tenderness or guarding.

Nursing diagnoses and interventions

Nursing care for the person with acute pancreatitis focuses on managing pain, nutrition and maintaining fluid balance.

Pain

Obstruction of pancreatic ducts and inflammation, oedema and swelling of the pancreas caused by pancreatic autodigestion cause severe epigastric, left upper abdominal or mid-scapular back pain. The pain often is accompanied by nausea and vomiting, abdominal tenderness and muscle guarding.

- Using a standard pain scale (see Chapter 8), assess pain, including location, radiation, duration and character. Note non-verbal cues of pain: restlessness or remaining rigidly still; tense facial features; clenched fists; rapid, shallow respirations; tachycardia; and diaphoresis. Administer analgesics on a regular schedule. *Pain assessment before and after analgesic administration measures its effectiveness. Administering analgesics on a regular schedule prevents pain from becoming established, severe and difficult to control. Unrelieved pain has negative consequences; for example, pain, anxiety and restlessness may increase pancreatic enzyme secretion.*
- Maintain NBM status and nasogastric tube patency as ordered. *Gastric secretions stimulate hormones that stimulate pancreatic secretion, aggravating pain. Eliminating oral intake and maintaining gastric suction reduce gastric secretions. Nasogastric suction also decreases nausea, vomiting and intestinal distension.*
- Maintain bed rest in a calm, quiet environment. Encourage use of non-pharmacological pain management techniques such as meditation and guided imagery. *Decreasing physical movement and mental stimulation decreases metabolic rate, gastrointestinal secretion, pancreatic secretions and resulting pain. Adjunctive pain relief measures enhance the effectiveness of analgesics* (see Chapter 8).

- Assist to a comfortable position, such as a side-lying position with knees flexed and head elevated 45 degrees. *Sitting up, leaning forward or lying in a foetal position tends to decrease pain caused by stretching of the peritoneum by oedema and swelling.*
- Remind family and visitors to avoid bringing food into the person's room. *The sight or smell of food may stimulate secretory activity of the pancreas through the cephalic phase of digestion.*

CONSIDERATION FOR PRACTICE

Regularly assess respiratory status (at least every 4 to 8 hours), including respiratory rate, depth and pattern; breath sounds; oxygen saturation and arterial blood gas results. Report tachypnoea, adventitious or absent breath sounds, oxygen saturation levels below 92%, $PaO_2 < 70$ mmHg or $PaCO_2 > 45$ mmHg. Severe abdominal pain causes shallow respirations and hypoventilation, and suppresses cough effectiveness, which can lead to pooling of secretions, atelectasis and pneumonia.

Imbalanced nutrition: less than body requirements

The effects of pancreatitis and its treatment may result in malnutrition. Inflammation increases metabolic demand and frequently causes nausea, vomiting and diarrhoea. At a time of increased metabolic demand, NBM status and gastric suction further decrease available nutrients. In the person with chronic pancreatitis, loss of digestive enzymes affects the digestion and use of nutrients.

- Monitor laboratory values: serum albumin, serum transferrin, haemoglobin and haematocrit. *Serum albumin, serum transferrin (which transports iron in the blood), haemoglobin and haematocrit levels are decreased in malnutrition. Decreased pancreatic enzymes affect protein catabolism and absorption; decreased transferrin affects iron absorption and transport, thereby decreasing haematocrit and haemoglobin levels.*
- Weigh daily or every other day. *Short-term weight changes (over hours to days) accurately reflect fluid balance, whereas weight changes over days to weeks reflect nutritional status.*
- Maintain stool chart; note frequency, colour, odour and consistency of stools. *Protein and fat metabolism are impaired in pancreatitis; undigested fats are excreted in the stool. Steatorrhoea indicates impaired digestion and, possibly, an increase in the severity of pancreatitis.*
- Monitor bowel sounds. *The return of bowel sounds indicates return of peristalsis; nasogastric suction usually is discontinued within 24 to 48 hours thereafter.*
- Administer prescribed intravenous fluids and/or enteral feeds. *Intravenous fluids are given to maintain hydration. Enteral feeds are used to provide fluids, electrolytes and kilojoules when fasting is prolonged (more than 2 to 3 days).*
- Provide oral and nasal care every 1 to 2 hours. *Fasting and nasogastric suction increase the risk of mucous membrane irritation and breakdown.*
- When oral intake resumes, offer small, frequent feedings. Provide oral hygiene before and after meals. *Oral hygiene decreases oral microorganisms that can cause foul odour and taste, decreasing appetite. Small, frequent feedings reduce pancreatic enzyme secretion and are more easily digested and absorbed.*

Risk of deficient fluid volume

Acute pancreatitis can lead to a fluid shift from the intravascular space into the abdominal cavity (third spacing). Third spacing of fluid may cause hypovolaemic shock, affecting cardiovascular function, respiratory function, renal function and mental status.

- Assess cardiovascular status every 4 hours or as indicated, including vital signs, cardiac rhythm, haemodynamic parameters (central venous and pulmonary artery pressures); peripheral pulses and capillary refill; skin colour, temperature, moisture and turgor. *These measurements are indicative of fluid volume status and are used to monitor response to treatment. Stable values are as follows: heart rate less than 100; blood pressure within 10 mmHg of baseline; central venous pressure 0–8 mmHg; pulmonary wedge pressure 8–12 mmHg; cardiac output approximately 5 L/min; and skin warm, dry, with good turgor and colour.* (See Chapter 10 for a full discussion of hypovolaemic shock.)
- Monitor renal function. Obtain hourly urine output; report if less than 30 mL per hour. Weigh daily. *Urine output of less than 30 mL per hour indicates decreased renal perfusion or acute renal failure, a major complication of acute pancreatitis. Weight changes are an effective indicator of fluid volume status.*
- Monitor neurological function, including mental status, level of consciousness and behaviour. *Hypotension and hypoxaemia may decrease cerebral perfusion, causing changes in mental status, decreased level of consciousness and changes in behaviour. In addition, alcohol withdrawal is a risk in the person with acute pancreatitis.*

Community-based care

The person with pancreatitis is often acutely ill and, along with family members, needs information about both hospital procedures and self-care at home following discharge. During the acute stage, keep explanations brief and simple.

Prior to discharge, teach the person and family about the disease and how to prevent further attacks of inflammation. Include the following topics as appropriate:

- Alcohol can cause stones to form, blocking pancreatic ducts and the outflow of pancreatic juice. Continued alcohol intake is likely to cause further inflammation and destruction of the pancreas. Avoid alcohol entirely.
- Smoking and stress stimulate the pancreas and should be avoided.
- If pancreatic function has been severely impaired, discuss appropriate use of pancreatic enzymes, including timing, dose, potential side effects and monitoring of effectiveness.
- A low-fat diet is recommended. Provide a list of high-fat foods to avoid. Crash dieting and binge eating also should

NURSING CARE PLAN A person with acute pancreatitis

Rose Schliefer is a 59-year-old wife, mother of three and grandmother of four. She has been hospitalised for the past 6 weeks for acute haemorrhagic pancreatitis and pseudocyst. The pancreatitis was caused by gallstones. Mrs Schliefer spent 3 weeks in intensive care and then underwent surgery to remove the gallstones and to insert drains into the pseudocyst. Prior to discharge, she had progressed to a soft, high-carbohydrate, low-fat diet; had all drains removed; and was able to walk in the hall. Mrs Schliefer was referred to the community nurses in her home town for continued follow-up.

ASSESSMENT

Lee Quinn, the community health nurse, assesses Mrs Schliefer at home after discharge. Mrs Schliefer is thin and appears anxious and tired. She states that she lost 13 kg in the hospital and now weighs only 46 kg. She is 168 cm tall. Her vital signs are within normal limits. Mrs Schliefer has a well-healed upper abdominal scar and two small wounds (from drains) on each side of her abdomen. The wounds are closed but still have scabs. Her skin is cool and dry and turgor is poor. She is alert and oriented and responds appropriately to questions. Blood glucose levels are normal. Mrs Schliefer states that her main problems are lack of energy and lack of appetite for the low-fat diet that has been ordered. Mrs Schliefer's husband and daughters express concern about their ability to provide care. Although they have been taught all about the disease and how to provide care, they still are not sure they know exactly what should be done now that Mrs Schliefer is at home.

DIAGNOSES

- *Fatigue* related to decreased metabolic energy production.
- *Imbalanced nutrition: less than body requirements* related to prolonged hospitalisation, dietary restrictions and impaired digestion.
- *Bathing/hygiene self-care deficit* (Level II: requires help of another person, supervision and teaching) related to decreased strength and endurance.
- *Risk of caregiver role strain* related to inexperience with care-giving tasks.

PLANNING

- Develop activity goals, incorporating small, incremental steps towards achieving goals. Instruct Mrs Schliefer to:
  - a. Rest in bed each day from 1 pm to 3 pm.
  - b. Eat six small meals a day with family members or friends.
  - c. Sit and rest quietly for 15 minutes before eating.
- Arrange for regular family discussions of concerns about future and goal setting and acknowledge family strengths.

Expected outcomes

- Set priorities for daily and weekly activities and incorporate a rest period into daily activity.
- Gain 0.5–1 kg per week.
- Bathe and maintain personal hygiene without assistance.
- Family members will verbalise comfort with providing necessary care.

IMPLEMENTATION

- Explain causes of fatigue. Review effects of pancreatitis, surgery and acute illness on energy levels.
- Mrs Schliefer indicates that she wants to cook a meal for the whole family. To reach this goal, she will:
  - a. Schedule the meal when her energy level is highest.
  - b. List actions necessary to prepare the meal and delegate difficult tasks to family members.
  - c. Ask her daughters to reorganise the kitchen to avoid unnecessary steps.
  - d. Plan the meal no sooner than the third week after being home.
- Discuss dietary restrictions and how to adapt them to usual diet.
- Advise to use shower chair and develop self-care goals for bathing and hygiene in small steps. Add self-care tasks gradually as tolerated.
- Discuss division of responsibilities for physical care, home maintenance and medical care with family members.

EVALUATION

One month after discharge, Mrs Schliefer and her family have established new routines based on her energy levels. Mrs Schliefer now fixes lunch because she feels best around midday. She and her husband share this time together without interruption. Mrs Schliefer still rests during the day but can now provide self-care. She has gained only 1 kg, but states that she is getting used to the new diet and that 'things are even starting to taste good without butter'. She also says that sitting quietly before meals is helpful and that she prefers eating six small meals a day. Mr and Mrs Schliefer and their daughters agree that their initial worries about Mrs Schliefer's care have been resolved now they all know what they must do and the future looks much brighter.

CRITICAL THINKING IN THE NURSING PROCESS

1. You are caring for a person who has acute pancreatitis and is also an alcoholic. Describe assessments that indicate the beginnings of withdrawal.
2. Discuss the pathophysiological basis of hypovolaemic shock in acute necrotic pancreatitis.
3. Outline a teaching plan that includes specific foods to omit and to include in a high-carbohydrate, low-protein, low-fat diet.
4. Develop a plan of care for the nursing diagnosis of *Impaired home maintenance*.

REFLECTION ON THE NURSING PROCESS

1. Outline what you have learned from this case study that you will apply to your future practice.
2. Reflect on Mrs Schliefer's discharge process from hospital. What could have been done differently to avoid her loss of appetite and fatigue at home?

be avoided as they may sometimes precipitate attacks. Spicy foods, coffee, tea or colas, and gas-forming foods stimulate gastric and pancreatic secretions and may precipitate pain. Avoid them if this occurs.

- Report symptoms of infection (fever of 38.5°C or more, pain, rapid pulse, malaise) because a pancreatic abscess can develop after initial recovery.

Refer to a dietitian or nutritionist for diet teaching as needed. If appropriate, refer to community agencies, such as Alcoholics Anonymous, or to an alcohol treatment program. Provide referrals to community or home health agencies, as needed, for continued monitoring and teaching at home.

THE PERSON WITH PANCREATIC CANCER

Pancreatic cancer accounts for about one-sixth of all deaths associated with cancers in Australia. It has a 5-year survival rate of less than 6%. Complete resection is the best hope for cure if the cancer is in the head of the pancreas. However, by the time of initial presentation most people already have advanced disease. Only about 30% of these people can be offered curative resection. If the cancer is in the body or tail of the pancreas, only about 10% of these people can be offered curative resection (Cancer Australia, 2015; Samra, Gananadha & Hugh, 2008).

In contrast to acute and chronic pancreatitis, alcohol abuse and gallstones are not identified risk factors for pancreatic cancer.

FAST FACTS

Identified risk factors for pancreatic cancer include:

- Cigarette smoking—the incidence is twice as high in smokers as in non-smokers
- Exposure to industrial chemicals or environmental toxins
- Chronic pancreatitis
- Diabetes mellitus
- Obesity; high-fat diet.

Pathophysiology and manifestations

Most cancers of the pancreas occur in the exocrine pancreas, are adenocarcinomas and cause death within 1 to 3 years after diagnosis.

Cancer of the pancreas has a slow onset, with manifestations of anorexia, nausea, weight loss, flatulence and dull epigastric pain. The pain increases in severity as the tumour grows. Other manifestations depend on the location of the tumour. Cancer of the head of the pancreas, which is the most common site, often obstructs bile flow through the common bile duct and the ampulla of Vater, resulting in jaundice, clay-coloured stools, dark urine and pruritus. Cancer of the body of the pancreas presses on the coeliac ganglion, causing pain that increases when the person eats or lies supine. Cancer of the tail of the pancreas often causes no symptoms until it has metastasised. Other late manifestations include a palpable abdominal mass and ascites. Because the manifestations are non-specific, up to 85% of people with cancer of the pancreas do not seek healthcare until the cancer becomes too far advanced for a cure.

INTERPROFESSIONAL CARE

Early cancers of the head of the pancreas may be resectable. A pancreatoduodenectomy (commonly called Whipple's procedure) is performed to remove the head of the pancreas, the entire duodenum, the distal third of the stomach, a portion of the jejunum and the lower half of the common bile duct. The common bile duct is then sutured to the end of the jejunum and the remaining pancreas and stomach are sutured to the side of the jejunum (see Figure 24.7). Radiation and chemotherapy are often used in addition to surgery.

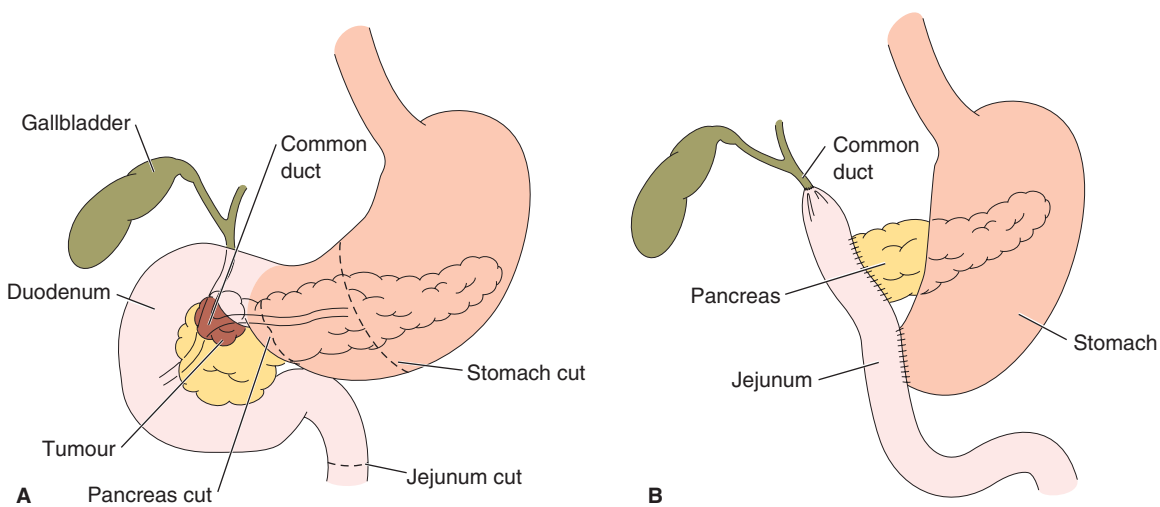


FIGURE 24.7 ■ Pancreatoduodenectomy (Whipple's procedure). *A*, areas of resection; *B*, appearance following resection

NURSING CARE OF THE PERSON undergoing Whipple's procedure

PREOPERATIVE CARE

- Provide routine preoperative nursing care as outlined in Chapter 3.
- Clarify teaching and learning as needed. Provide psychological support for person and family. *The person and family faced with a diagnosis of pancreatic cancer may require reinforcement of teaching as anxiety, fear and possible denial can interfere with learning.*

POSTOPERATIVE CARE

- Provide postoperative care as outlined in Chapter 3.
- Maintain in semi-Fowler's position. *Semi-Fowler's position facilitates lung expansion and reduces stress on the anastomosis and suture line.*
- Maintain low gastrointestinal suction. If drainage is not adequate, obtain an order to irrigate, using minimal pressure. Do not reposition nasogastric tube. *Pressure within the operative area from retained secretions increases intraluminal pressure and places stress on the suture line. Forceful irrigations and repositioning of the nasogastric tube may disrupt the suture line.*
- Maintain pain control using analgesics as prescribed (PCA, infusion or given on a regular basis). Assess effectiveness of pain management. *Doses higher than normal may be required if narcotic analgesics have been used prior to surgery to manage pain.*
- *Increased pain may indicate complications such as disruption of suture line, leakage from anastomosis or peritonitis. Adequate pain management increases resistance to stress, facilitates healing and increases the ability to cough, deep breathe and change position.*
- Assist with coughing, deep breathing and changing position every 1 to 2 hours. Splint incision during coughing and deep breathing. *The location of the incision makes coughing and deep breathing more painful. The prolonged surgical procedure, anaesthesia, location of incision and immobility increase the risk of retained secretions, atelectasis and pneumonia. Changing position facilitates drainage of secretions; effective coughing and deep breathing remove secretions and open distal alveoli.*
- Monitor for complications:
  a. Take vital signs every 2 to 4 hours or as indicated; immediately report changes (such as elevated temperature; hypotension; weak, thready pulse; increased or difficult respirations).
  b. Assess skin colour, temperature, moisture and turgor.
  c. Measure urinary output, gastrointestinal output and drainage from any other tubes; monitor amount and type of wound drainage.
  e. Assess level of consciousness.
  f. Monitor results of laboratory tests, especially arterial blood gases, haemoglobin and haematocrit.

The main potential complications following Whipple's procedure are haemorrhage, hypovolaemic shock and hepatorenal failure. *The assessments listed provide information about the person's status and alert the nurse to abnormal findings that signal the onset of these complications.*

Postoperative nursing care of the person undergoing Whipple's procedure is outlined above. Immediate postoperative care is often provided in the intensive care unit.

The person with pancreatic cancer has multiple problems requiring nursing care. Chapter 13 provides a discussion of care of the person with cancer. The nursing diagnoses and interventions discussed for the person with pancreatitis are also appropriate for the person with pancreatic cancer.

CHAPTER HIGHLIGHTS

- Gallstones (cholelithiasis) are common and often unrecognised until the person develops manifestations of biliary colic or acute cholecystitis. Laparoscopic cholecystectomy is the treatment of choice for symptomatic gallbladder disease.
- Hepatitis, inflammation of functional liver tissue, is usually a viral disease and therefore cannot be cured at this time. Preventing the spread of hepatitis through use of standard and body substance precautions is an important nursing responsibility.
- Hepatitis A, commonly transmitted via the faecal–oral route, is generally a self-limiting disease with few long-term sequelae. Some types of viral hepatitis, most notably hepatitis B and C, can become chronic and ultimately lead to liver failure and an increased risk of liver cancer. Hepatitis B and C can result in a carrier state in which the infected person has no symptoms of the disease, but can spread it to others.
- Alcohol abuse is a significant risk factor for liver and pancreatic disorders. Prevention, early identification and treatment of alcohol abuse reduce the risk of these disorders. Absolute abstinence from alcohol is an important part of the treatment plan for people with liver and pancreatic disorders.
- Cirrhosis leads to portal hypertension and liver failure, which, in turn, account for most of the manifestations and complications of the disorder. Complications, such as ascites, splenomegaly, oesophageal varices and hepatic encephalopathy, affect multiple body systems and significantly contribute to mortality and morbidity associated with cirrhosis.
- Bleeding from oesophageal varices may be massive, resulting in a medical emergency and requiring prompt control to maintain cardiac output.
- Acute pancreatitis often develops as a complication of gallstones. Acute pancreatitis often resolves with no long-term consequences. Chronic pancreatitis is more frequently related to alcohol abuse and can lead to continuing pain and digestive disruptions.

CONCEPT CHECK

1 When assessing the person admitted for a laparoscopic cholecystectomy, the nurse would expect to find:
1 a history of intermittent episodes of right upper quadrant pain
2 significant jaundice of the sclera and skin
3 complaints of recurrent heartburn and acid reflux
4 ascites and peripheral oedema

2 Which of the following does the nurse include in her teaching for a person with acute cholecystitis? (Select all that apply.)
1 Avoid consumption of foods high in fat, such as gravies and peanut butter.
2 Limit your intake to dry cracker biscuits and clear liquids during episodes of acute pain.
3 A low-carbohydrate diet such as the Atkins diet is recommended for weight loss.
4 Call your doctor if you develop severe abdominal pain and a temperature.
5 Surgery for gallstones is optional; they pose little risk when fat intake is minimal.

3 During an outbreak of hepatitis A traced to a food handler at a local restaurant, the nurse teaches staff at the restaurant that the most cost-effective means of protecting customers from further outbreaks is to:
1 insist that all food handlers be immunised against hepatitis A
2 test all new employees for hepatitis A antigen
3 wash hands thoroughly before handling food and after using the bathroom
4 use gloves for handling food if any cuts or scrapes are on hands

4 The nurse would evaluate teaching as effective when a person with chronic hepatitis C states which of the following?
1 'I will reduce my alcohol intake and use only paracetamol for pain relief.'
2 'I understand that I must return to the doctor every year for a follow-up liver biopsy.'
3 'Even though no treatment is available for this disease, I plan to live a long life.'
4 'I will avoid donating blood and will use barrier protection during sex.'

5 When evaluating for people possibly exposed to hepatitis A by a recently diagnosed person, the nurse inquires about:
1 sexual partners within the past 6 months
2 close household contacts within the past 4 weeks
3 food preparation activities since the development of jaundice
4 immunisation status of the person

6 A person hospitalised with cirrhosis, ascites and mild hepatic encephalopathy suddenly vomits 200 mL of bright red blood. Which of the following should the nurse do first?
1 Insert a nasogastric tube.
2 Place in Fowler's position.
3 Contact the physician.
4 Check stool for occult blood.

7 The nurse caring for a person scheduled for an abdominal paracentesis instructs the person to:
1 avoid eating or drinking fluid for 6 hours prior to the procedure
2 scrub the abdomen with antiseptic soap before the procedure
3 empty the bladder before the procedure
4 report excess flatus following the procedure to the physician

8 A person hospitalised with severe ascites due to cirrhosis develops a fever and confusion. The nurse should:
1 auscultate bowel sounds and palpate for abdominal tenderness
2 enquire about headache and check for nuchal rigidity
3 observe for neck vein distension and auscultate lung sounds
4 measure abdominal girth and percuss for shifting dullness

9 A 54-year-old woman admitted with acute pancreatitis says, 'I don't understand how I got this disease. I thought alcoholics got pancreatitis—I never drink.' Which of the following is the most appropriate response by the nurse?
1 'Was there a time in your life that you did drink heavily?'
2 'It also is prevalent in smokers; do you smoke cigarettes?'
3 'Gallstones also are a risk factor. We'll evaluate for them.'
4 'Intravenous drug use is a risk factor. Do you use drugs by injection?'

10 The nurse caring for a person returning to the unit following Whipple's procedure identifies which of the following as of highest priority in the plan of care?
1 referral to a smoking cessation program
2 frequent turning, coughing and deep breathing exercises
3 early mobilisation including ambulation as tolerated
4 maintaining patency of the nasogastric tube

UNIT 6 BUILDING CLINICAL COMPETENCE

Responses to altered gastrointestinal function

CLINICAL SCENARIO

You have been assigned to work with the following four people for the 0700 shift. Significant data obtained during report are as follows:

- Thomas Jones, aged 56, was transferred to your unit yesterday after treatment in the critical care unit for oesophageal varices. Significant history includes alcohol consumption (6 to 12 beers daily for several years) and smoking (2 packets per day for the past 30 years). Current vital signs are T 37.7°C, P 96, R 28, BP 150/90. He complains of abdominal tenderness and dyspnoea. He appears anxious and irritable.
- Ruth Green, aged 35, was admitted with right upper quadrant pain radiating to the left shoulder and a feeling of abdominal fullness. She has a history of cholelithiasis and cholecystitis. Her assessment reveals T 37.2°C, P 90, R 24, BP 140/84, with pallor, diaphoresis and complaints of nausea. She is scheduled for a cholecystectomy at 9 am.
- Tanya Cooper, aged 21, was admitted with dehydration, weakness and fainting. Her weight is 40.9 kg and height is 165 cm. Her vital signs are T 36.1°C, P 70, R 26, BP 90/56 mmHg with orthostatic BP 70/48 mmHg. She has a 3-year history of anorexia nervosa and laxative abuse. She has an IV of 0.9% NaCl with 20 mmol KCl infusing. She is to be monitored for food intake and watched for 1 hour after meals. She is ringing her call light to get up to the bathroom.
- Grace Freeman is a 36 year old who had a temporary colostomy formed 5 days ago following an abdominal injury from a motor vehicle crash. Vital signs at 0400 were T 36.8°C, P 78, R 14, BP 112/78. She buzzed for assistance because her colostomy bag is full and she needs help emptying it.

Critical thinking questions

1 In what order would you visit these people after report?

1. _____
2. _____
3. _____
4. _____

2 What top two priority nursing diagnoses would you choose for each of the people presented above? Can you explain, if asked, the rationale for your choices?

	Priority Nursing Diagnosis #1	Priority Nursing Diagnosis #2
Thomas Jones		
Ruth Green		
Tanya Cooper		
Grace Freeman		

3 You need to complete preoperative preparation on Mrs Green. Which of the following do you need to do?

1. Complete preoperative checklist, witness signed consent and administer preoperative medication when requested.
2. Explain the procedure, obtain informed consent and complete the preoperative checklist.
3. Sign the operative consent, explain complications of the procedure and take vital signs on call.
4. Obtain signed consent, discuss with the family the surgical procedure and have the person void prior to going to the OR.

4 Mrs Green understands the postoperative teaching done by the nurse when she states:

1. 'I will be on bed rest for two days after surgery.'
2. 'I will need to cough and deep breathe while splinting my incision.'
3. 'I will be able to begin eating when I return from surgery.'
4. 'I will be medicated for pain without having to request it.'

5 The nurse explains a diet of low-fat foods to Mrs Green. She understands this diet when she picks which meal plan?

1. eggs, sausage and toast
2. chicken, mashed potatoes and gravy and corn
3. grilled fish, tossed salad, peaches
4. hamburger with lettuce and tomato, chips

6 To prepare Mr Jones for an oesophagoscopy, the nurse institutes the following interventions:

1. Explain that it is not a painful procedure but he will be medicated for pain.
2. Keep Mr Jones NBM for 12 hours prior to the procedure.
3. Remove dentures and provide mouth care.
4. Place in a supine position with the head slightly hyperextended.

7 Which discharge instructions will the RN advise Mrs Freeman about regarding how to take care of the colostomy?

1. 'The types of foods you eat will not affect the colostomy output.'
2. 'Empty the colostomy pouch or replace the bag when it is half full.'
3. 'Irrigate the colostomy with water to stimulate the colon to empty.'
4. 'Cleanse the area around the stoma with deodorant soap to decrease odour.'

8 Which of the following is the most common initial manifestation of malignant tumours of the lower bowel?

1. rectal bleeding
2. diarrhoea
3. rectal pain
4. constipation

9 A person with severe diarrhoea may develop metabolic acidosis. Which arterial blood gases indicates metabolic acidosis?

1. pH 7.45, $PaCO_2$ 40 mmHg, bicarbonate 25 mEq/L
2. pH 7.28, $PaCO_2$ 30 mmHg, bicarbonate 19 mEq/L
3. pH 7.55, $PaCO_2$ 50 mmHg, bicarbonate 30 mEq/L
4. pH 7.33, $PaCO_2$ 36 mmHg, bicarbonate 24 mEq/L

10 Teaching appropriate constipation management includes which actions? (Select all that apply.)

1. Decrease dietary fibre.
2. Increase fluid intake.
3. Increase exercise activity.
4. Use bulk-forming laxatives.
5. Use enemas daily.

11 With Ms Cooper's history of anorexia for 3 years, which is a priority nursing intervention in the plan of care for her?

1. Monitor for cardiac arrhythmias due to electrolyte imbalances.
2. Monitor weight for loss or gain to determine effectiveness of nursing care.
3. Maintain close observation for at least 1 hour after meals.
4. Serve small, frequent meals, increasing serving size gradually.

12 In planning discharge for Ms Cooper, the family and person participate in teaching and diet counselling sessions. Which is the priority item for the family and Ms Cooper to follow after discharge?

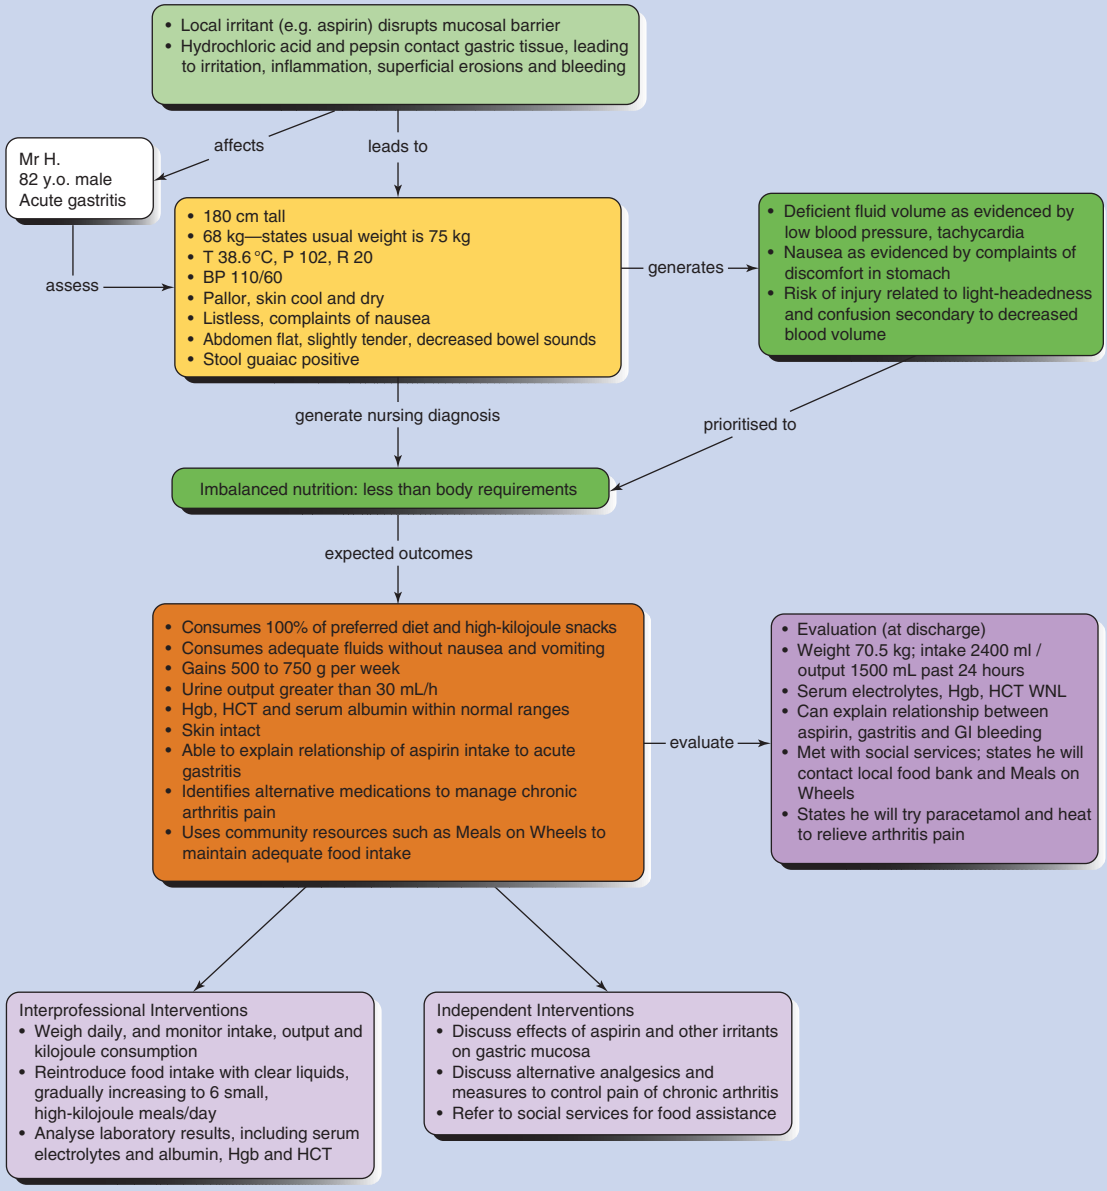
1. Monitor weight regularly to determine further weight loss.
2. Use rewards for food and kilojoule intake rather than weight gain.
3. Gradually increase the amount of food taken at meals.
4. Attend support groups for people with eating disorders.

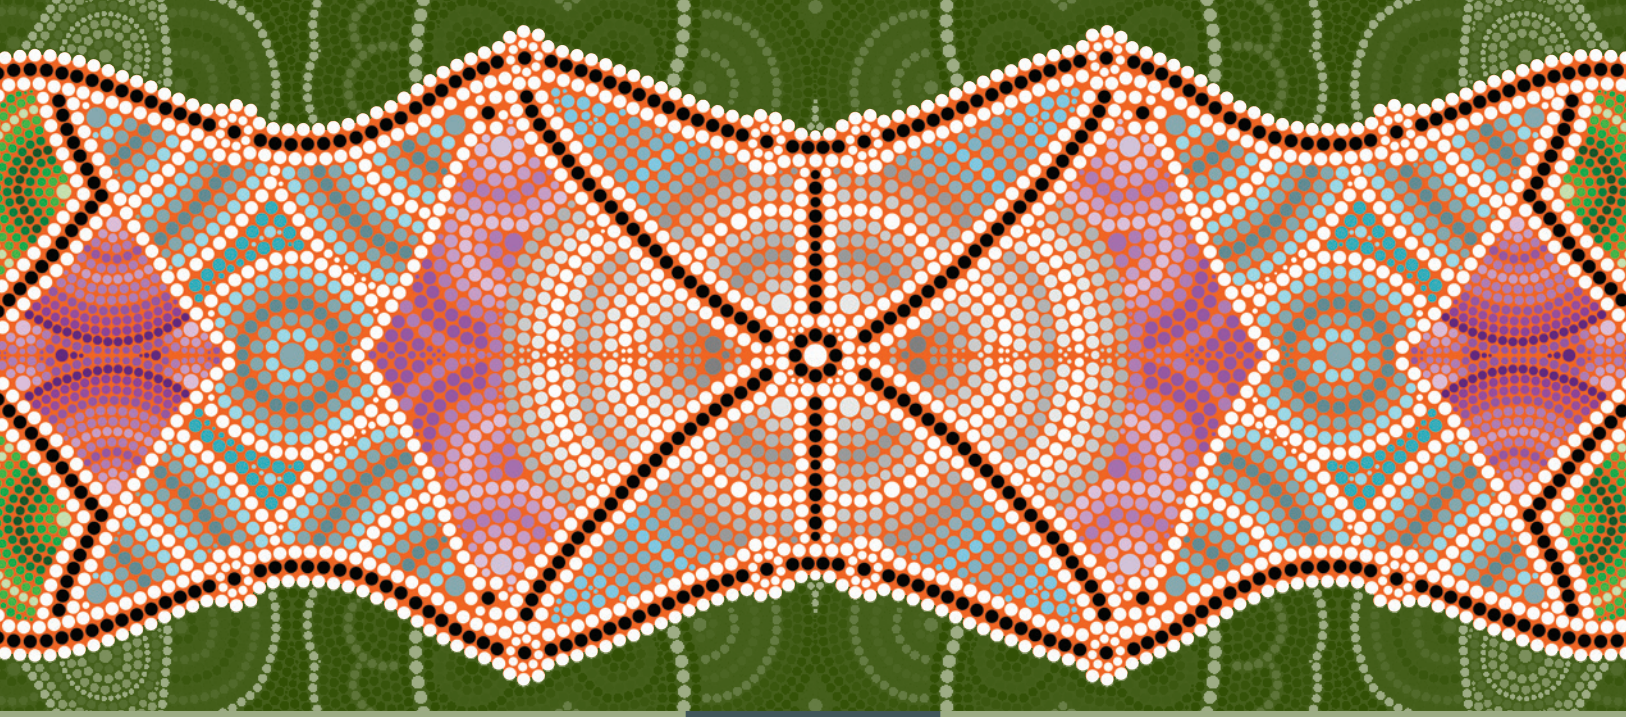
CASE STUDY

Lewis Haches, an 82-year-old white male, has a history of hypertension, degenerative arthritis and angina pectoris for which he takes frusemide, atenolol, extra-strength aspirin and glyceryl trinitrate. He states that his blood pressure is controlled when he takes his medications as prescribed. Lately, he has been having some financial difficulties and does not take his medications as often as he should. He lives with his 80-year-old wife, who also has health problems. He does the cooking and grocery shopping. He has a son who lives nearby who looks in on them every couple of days.

Mr Haches feels that he cooked some outdated food that made him ill. He states he has been trying to stretch their grocery budget by reducing their serving sizes and shopping less frequently. He says he has had nausea and loose, dark stools for the past 2 days. This morning, he is weak and dizzy and states he nearly fainted in the shower. He also states he has not been able to take his medications for the past 2 days and feels that his heart is beating too fast. His son brought him to the hospital because he was weak, confused and very pale when he checked on him prior to going to work in the morning.

Based on Mr Haches's medical diagnosis and treatment plan, *Imbalanced nutrition: less than body requirements* is identified as the priority nursing diagnosis at this time.





UNIT 7

RESPONSES TO ALTERED URINARY ELIMINATION

CHAPTER 25

A PERSON-CENTRED APPROACH TO ASSESSING THE RENAL SYSTEM

TRUDY DWYER, JENNIFER BORG, DIANE GOLDSWORTHY

KEY TERMS

albuminuria 838
calculi 835
chronic kidney disease (CKD) 831
creatinine 832
dysuria 834
glomerular filtration rate (GFR) 829
haematuria 834
micturition 833
nocturia 834
oliguria 834
polyuria 834
pyuria 834
urea 831

LEARNING OUTCOMES

- Describe the anatomy, physiology and functions of the renal system.
- Examine investigations, techniques and observations important for assessing a person's renal system function.
- Demonstrate accurate interpretation of normal and aberrant data obtained from assessment of a person's renal system.

CLINICAL COMPETENCIES

- Conduct and document a health history for people who have or are at risk of alterations in urinary elimination.
- Conduct and document a physical assessment of the renal system.
- Monitor the results of diagnostic tests and report abnormal findings.

EQUIPMENT NEEDED

- Urine specimen cup
- Disposable gloves

The functions of the renal system (also called the urinary system) are to regulate and maintain body fluids and electrolyte balance, to filter metabolic wastes from the bloodstream, to reabsorb needed substances and water into the bloodstream, and to eliminate metabolic wastes and water as urine. The renal system also indirectly maintains the body's the blood pressure, acid–base balance and an endocrine function. Any alteration in the structure or function of the renal system affects the whole body. In turn, healthy renal system function depends on the health of other body systems, especially the circulatory, endocrine and nervous systems.

ANATOMY, PHYSIOLOGY AND FUNCTIONS OF THE RENAL SYSTEM

The organs of the renal system are the paired kidneys (produce urine), the paired ureters (transport urine to the bladder), the urinary bladder (collects the urine) and the urethra (transports urine to outside the body) (see Figure 25.1). There are three major functions of the renal system:

1. *excretion*, the removal of wastes from body fluids
2. *elimination*, the elimination of these wastes from the body
3. *homeostatic regulation* of the volume and solute concentration of the plasma in the blood (Martini, Nath & Bartholomew, 2012).

Each structure is essential to the total functioning of the renal system.

THE KIDNEYS

The two kidneys are located outside the peritoneal cavity and on either side of the vertebral column at the levels of T_{12} to L_3. The left kidney is slightly superior to the right kidney. These highly vascular, bean-shaped organs are approximately 11.5 cm long, 5–7.5 cm wide, 2.5 cm thick and weigh about 150 g. The lateral surface of the kidney is convex; the medial

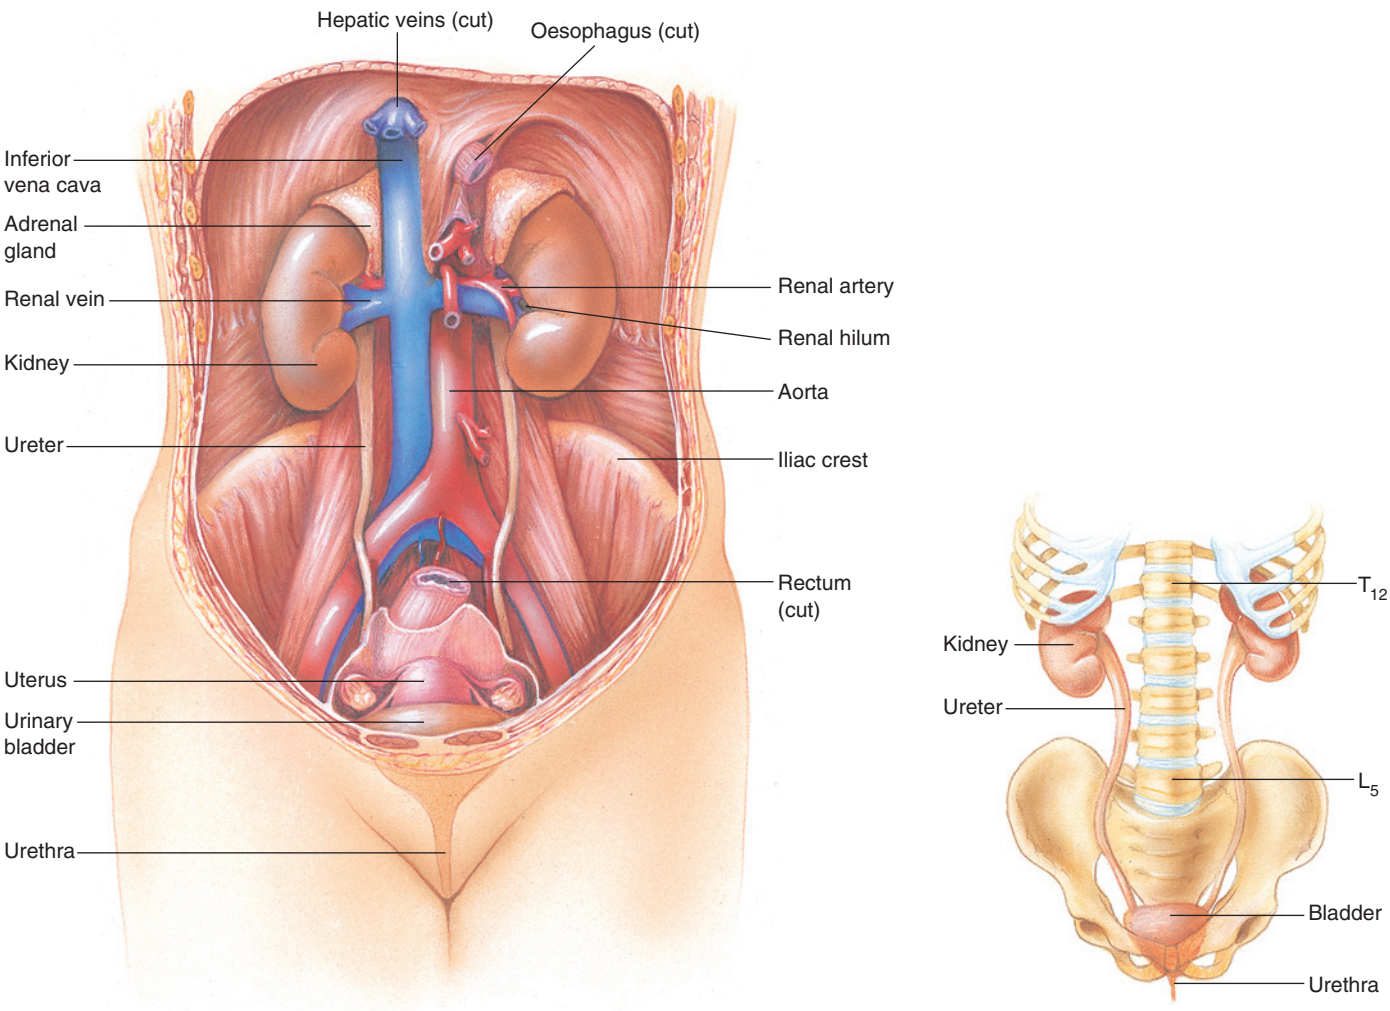


FIGURE 25.1 ■ The renal system. *A*, Anterior view of the renal system in a female. *B*, The kidneys are shown in relation to the vertebrae and ribs

surface is concave and forms a vertical cleft, the hilum. The ureter, renal artery, renal vein, lymphatic vessels and nerves enter or exit the kidney at the level of the hilum.

The kidney is supported by three layers of connective tissue: the outer renal fascia, the middle adipose capsule and the inner renal capsule. The renal fascia, made up of dense connective tissue, surrounds the kidney (and the adrenal gland, a discrete organ that sits on top of each kidney) and anchors it to surrounding structures. The middle adipose capsule is a fatty mass that holds the kidney in place and also cushions it against trauma. The inner renal capsule provides a barrier against infection and helps protect the kidney from trauma.

Internally, each kidney has three distinct regions: the cortex, medulla and pelvis. The outer region, or renal cortex, is light in colour and has a granular appearance (see Figure 25.2). This region of the kidney contains the glomeruli, small clusters of capillaries. The glomeruli bring blood to and carry waste products from the nephrons, the functional units of the kidney.

The renal medulla, just below the cortex, contains cone-shaped tissue masses called renal pyramids, formed almost entirely of bundles of collecting tubules. Areas of lighter-coloured tissue called renal columns are extensions of the cortex and serve to separate the pyramids. The collecting tubules that make up the pyramids channel urine into the innermost region, the renal pelvis.

The renal pelvis is continuous with the ureter as it leaves the hilum. Branches of the pelvis known as the major and minor calyces extend towards the medulla and serve to collect urine and empty it into the pelvis. From the pelvis, urine is channelled through the ureter and into the bladder for storage. The walls of the calyces, the renal pelvis and the ureter contain smooth muscle that moves urine along by peristalsis.

Each kidney contains approximately 1 million nephrons, which process the blood to make urine (see Figure 25.3). Each nephron consists of a renal corpuscle and a renal tubule (Martini et al., 2012). The renal corpuscle contains a tuft of capillaries called the glomerulus, which is completely

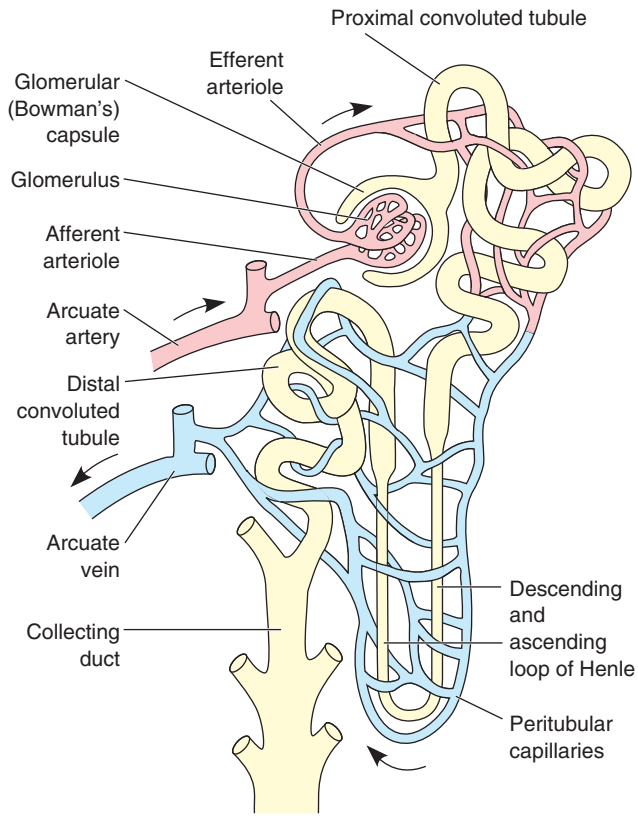

FIGURE 25.3 ■ The structure of a nephron, showing the glomerulus within the glomerular capsule

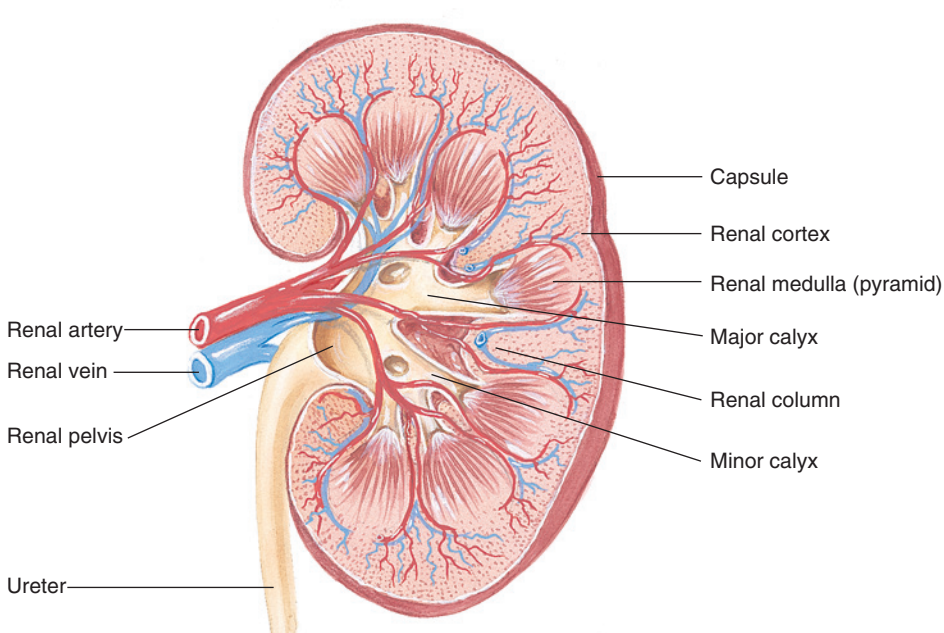

FIGURE 25.2 ■ Internal anatomy of the kidney

surrounded by the glomerular capsule (or Bowman's space). The renal tubule is a tubular passageway that may be up to 50 mm in length (Martini et al., 2012).

The endothelium of the glomerulus allows capillaries to be extremely porous. Thus, large amounts of solute-rich fluid pass from the capillaries into the capsule. This fluid, called the filtrate, is the raw material of urine. Filtrate leaves the capsule and is channelled into the renal tubule which consists of two convoluted (twisted or coiled) segments: the proximal convoluted tubule (PCT) and the distal convoluted tubule (DCT) (Martini et al., 2012). In the PCT of the nephron, microvilli on the tubular cells increase the surface area for reabsorption of substances from the filtrate into plasma in the peritubular capillaries. Substances moved by active transport include glucose, sodium, potassium, amino acids, proteins and vitamins. About 70% of the water in the filtrate, as well as chloride and bicarbonate, is reabsorbed by passive transport.

The filtrate then moves into the U-shaped loop of Henle where it is concentrated. The descending limb of the U is relatively thin and freely permeable to water, whereas the ascending segment is thick and thereby less permeable. The DCT receives filtrate from the loop of Henle. Although this segment is structurally similar to the PCT, it lacks microvilli and is more involved with secreting solutes into the filtrate than in reabsorbing substances from it. The collecting duct receives the newly formed urine from many nephrons and channels urine through the minor and major calyces of the renal pelvis and into the ureter.

The functions of the kidney are to:

- form urine
- balance solute and water transport
- excrete metabolic waste products
- conserve nutrients
- regulate acid–base balance
- secrete hormones to help regulate blood pressure, erythrocyte production and calcium metabolism.

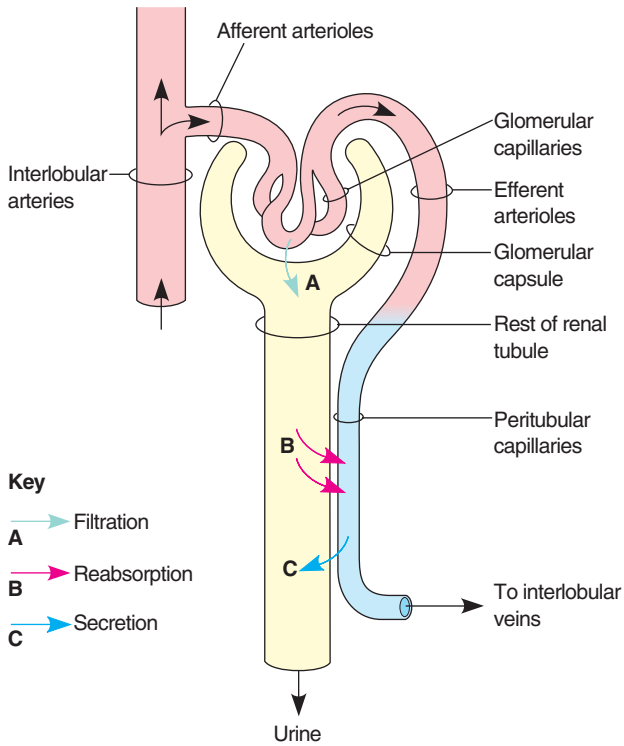

FIGURE 25.4 ■ Schematic view of the three major mechanisms by which the kidneys adjust to the composition of plasma: *A*, glomerular filtration; *B*, tubular reabsorption; and *C*, tubular secretion

Formation of urine

The complex structures of the kidneys process about 180 L of blood-derived fluid each day. Of this amount, only 1% is excreted as urine; the rest is returned to the circulation. (Normal and abnormal findings of urine on laboratory analysis are listed in Table 25.1.) Urine formation is accomplished entirely by the nephron through three processes: glomerular filtration, tubular reabsorption and tubular secretion (see Figure 25.4).

Glomerular filtration

Glomerular filtration is a passive, non-selective process in which hydrostatic pressure forces fluid and solutes through a membrane. The amount of fluid filtered from the blood into the capsule per minute is called the **glomerular filtration rate (GFR)**. Three factors influence this rate: the total surface area available for filtration, the permeability of the filtration membrane and the net filtration pressure.

The glomerulus is a far more efficient filter than most capillary beds, because the filtration membrane of the glomerulus is much more permeable to water and solutes than are other capillary membranes. In addition, the glomerular blood pressure is much higher, resulting in higher net filtration pressure.

Net filtration pressure is responsible for the formation of filtrate and is determined by two forces: hydrostatic pressure ('push') and osmotic pressure ('pull'). The glomerular hydrostatic pressure pushes water and solutes across the membrane. This pressure is opposed by the osmotic pressure in the glomerulus (primarily the colloid osmotic pressure of plasma proteins in the glomerular blood) and the capsular hydrostatic pressure exerted by fluids within the glomerular capsule. The difference between these forces determines the net filtration pressure, which is directly proportional to the GFR.

The normal GFR in both kidneys is 120 to 125 mL/min in adults or about 10% of the blood delivered to the glomeruli (Martini et al., 2012). This rate is held constant under normal conditions by intrinsic controls (or renal autoregulation). The myogenic mechanism, which responds to pressure changes in the renal blood vessels, controls the diameter of the afferent arterioles, thereby achieving autoregulation. An increase in systemic blood pressure causes the renal vessels to constrict, whereas a decline in blood pressure causes the afferent arterioles to dilate. These changes adjust the glomerular hydrostatic pressure and, indirectly, maintain the glomerular filtration rate. The GFR is difficult to measure so an estimated GFR (eGFR) is calculated from the serum creatinine (Kidney Health Australia (KHA), 2012). The eGFR is discussed in greater depth in Chapter 27.

TABLE 25.1 Normal and abnormal findings: urinalysis

CHARACTERISTIC OR COMPONENT	NORMAL RESULTS	ABNORMAL FINDING WITH POSSIBLE CAUSE
Colour	Light straw to amber-yellow	• Red, dark, smoky colour may be the result of blood in the urine (haematuria or menstrual blood). • Cloudy urine occurs from infection. • Colourless urine indicates very dilute urine, such as in overhydration, kidney disease, alcohol ingestion or diabetes insipidus. • Very dark yellow urine indicates dehydration and/or fever. • Red or red brown urine may be caused by medications such as phenytoin (Dilantin), chlorpromazine (Largactil) and phenolphthalein (Probanthine), and by beetroot, carrots, rhubarb or food colouring. • Purple urine may occur in people with permanent bladder catheters who have *Escherichia coli* infections. Sometimes called 'purple bag syndrome'. • Orange urine may be caused by fever, urobilin, nitrofurantoin (Macrodantin), sulfonamides and foods such as carrots and beetroot, or food colouring. • Blue or green urine is caused by *Pseudomonas* urinary tract infection, ingested substances such as amitriptyline (Endep), methylene blue, cimetidine (Tagamet), propofol (Diprivan) infusion and yeast concentrate. • Brown or black urine is caused by Lysol poisoning, melanin, bilirubin, methaemoglobin, herbal medicines such as cascara and injectable iron.
Appearance	Clear	• Hazy or cloudy urine indicates bacteria, pus, RBCs, WBCs, phosphates, prostatic fluid spermatozoa or urates. • Milky urine is the result of fats or pyuria. • Yellow foam results from bilirubin, bile or severe cirrhosis of the liver. • A dark yellow to brownish colour is seen with deficient fluid volume.
Odour	Aromatic	• Ammonia smell increases as urine stands outside the body. • Urinary tract infection (UTI) causes a foul or unpleasant odour, depending on the causative organism. • Asparagus causes a distinctive odour. • Mousy odours result from phenylketonuria. • Sweet or fruity odours occur in starvation and diabetic ketoacidosis.
pH	4.5–8.0	• < 4.5: metabolic acidosis, respiratory acidosis, diet high in protein or cranberries, ammonium chloride and mandelic acid. • > 8.0: bacteriuria, UTI, antibiotics (neomycin, kanamycin), sulfonamides, sodium bicarbonate, acetazolamide (Diamox), potassium citrate, vegetarian diet, low-carbohydrate diet and ingestion of citrus fruits.
Specific gravity	1.005–1.030	• < 1.005: diabetes insipidus, overhydration, renal disease, severe potassium deficit. • > 1.030: dehydration, fever, diabetes mellitus, vomiting, diarrhoea, contrast media.
Protein	2–8 mg/dL	• > 8 mg/dL: proteinuria, exercise, fever, stress, acute infection, kidney disease, lupus erythematosus, leukaemia, multiple myeloma, cardiac disease, toxaemia of pregnancy, sexual intercourse (in men), septicaemia, lead, mercury, neomycin, barbiturates, sulfonamides.
Glucose	Negative	• > 15 mg/dL or +4: diabetes mellitus, stroke, Cushing's syndrome, anaesthesia, glucose infusions, severe stress, infections, ascorbic acid, aspirin, cephalosporins and adrenaline.
Ketones	Negative	• +1 to +3: ketoacidosis, starvation, high-protein diet, severe exercise, exposure to cold, loss of carbohydrates.
RBCs	Rare	• > 2 per low-power field: kidney trauma, kidney diseases, renal calculi, cystitis, excess aspirin, anticoagulants, sulfonamides, menstrual contamination. *Note:* high false-positive rate of haematuria with 'dipstick testing'.
WBCs	3–4	• > 4 per low-power field: UTI, fever, strenuous exercise, kidney diseases.
Bilirubin	Negative	• Liver disease, biliary obstruction.
Urobilinogen	Low concentrations	• Liver disease such as hepatitis or cirrhosis or haemolytic conditions.
Casts	Occasional hyaline	• Fever, kidney diseases, heart failure.

The normal eGFR in the healthy adult is equal to or greater than 90 mL/min/1.73m^2 (KHA, 2012). Two aspects of the kidney are used to determine kidney function: eGFR and the presence of albuminuria (Department of Health, Victoria (DHV), 2012). **Chronic kidney disease (CKD)** is a general term used to refer to all conditions of the kidney (CKD stages 1–5) that last longer than 3 months (Australian Institute of Health and Welfare (AHIW), 2009).

Another intrinsic control of the GFR results from the renin–angiotensin mechanism at work in the kidneys. Special cells known as the juxtaglomerular apparatus are located in the distal tubules and respond to slow filtrate flow by releasing chemicals that cause intense vasodilation of the afferent arterioles. Conversely, an increase in the flow of filtrate promotes vasoconstriction, decreasing the GFR. A drop in systemic blood pressure often triggers the juxtaglomerular cells to release renin. Renin acts on a plasma globulin, angiotensinogen, to release angiotensin I, which is in turn converted to angiotensin II. As a vasoconstrictor, angiotensin II activates vascular smooth muscle throughout the body, causing systemic blood pressure to rise. Thus, the renin–angiotensin mechanism is a factor in renal autoregulation, even though its main purpose is the control of systemic blood pressure.

Glomerular filtration is also under an extrinsic control mechanism through the sympathetic nervous system. During periods of extreme stress or emergency, sympathetic nervous system stimulation causes strong constriction of the afferent arterioles and inhibits filtrate formation. The sympathetic nervous system also stimulates the juxtaglomerular cells to release renin, increasing systemic blood pressure.

Tubular reabsorption

Tubular reabsorption is a transepithelial process that begins as the filtrate enters the proximal tubules. In healthy kidneys, virtually all organic nutrients such as glucose and amino acids are reabsorbed. However, the tubules constantly regulate and adjust the rate and degree of water and ion reabsorption in response to hormonal signals. Reabsorption may be active or passive. Substances reclaimed through active tubular reabsorption are usually moving against electrical and/or chemical gradients. These substances, including glucose, amino acids, lactate, vitamins and most ions, require an ATP-dependent carrier to be transported into the interstitial space. In passive tubular reabsorption, which includes diffusion and osmosis, substances move along their gradient without expenditure of energy.

Tubular secretion

The final process in urine formation is tubular secretion, which is essentially reabsorption in reverse. Substances such as hydrogen and potassium ions, creatinine, ammonia and organic acids move from the blood of the peritubular capillaries into the tubules themselves as filtrate. Thus, urine consists of both filtered and secreted substances. Tubular secretion is important for disposing of substances not already in the filtrate, such as medications. This process eliminates undesirable substances that have been reabsorbed by passive processes and rids the body of excessive potassium ions. It is also a vital force in the regulation of blood pH.

Maintaining normal composition and volume of urine

Maintaining the normal composition and volume of urine involves a countercurrent exchange system. In this system, fluid flows in opposite directions through the parallel tubes of the loop of Henle and the vasa recta, tiny capillaries that run along the loop of Henle. Fluid is exchanged across these parallel membranes in response to a concentration gradient (see Figure 25.5). When the filtrate enters the proximal convoluted tubule, its osmolality (300 mOsm/kg) is the same as plasma and the interstitial fluid of the renal cortex. Note the following steps in the process:

1. The descending loop of Henle is highly permeable to water and allows chloride and sodium to enter the loop through diffusion. The hyperosmotic interstitium causes water to move out of the descending loop, so remaining filtrate becomes increasingly concentrated.
2. The lumen of the ascending loop of Henle is impermeable to water but allows chloride and sodium to move out into the interstitium of the medulla. As a result, the filtrate in the ascending loop becomes hypoosmotic and the medullary interstitium becomes hyperosmotic.
3. As the filtrate progresses through the ascending limb of the loop of Henle and enters the distal convoluted tubule, sodium and chloride are removed and water is retained. Thus, the filtrate becomes more dilute.
4. As the filtrate passes through the deep medullary regions, urea (an end product of protein metabolism and, along with water, the main constituent of urine) begins to diffuse out from the collecting tubules into the interstitial space and establishes a concentration gradient to facilitate water movement.
5. Some urea enters the ascending loop of Henle. Urea entering the vasa recta typically diffuses out again.

The dilution or concentration of urine is largely determined by the action of antidiuretic hormone (ADH), which is secreted by the posterior pituitary gland. ADH causes the pores of the collecting tubules to enlarge, so that increased amounts of water move into the interstitial space. As the end result, water is reabsorbed and urine is more highly concentrated. When ADH is not secreted, the filtrate passes through the system without further water reabsorption, so that the urine is more dilute.

Urine is composed, by volume, of about 95% water and 5% solutes. The largest component of urine by weight is urea. Other solutes normally excreted in the urine include sodium, potassium, phosphate, sulfate, creatinine, uric acid, calcium, magnesium and bicarbonate.

Clearing waste products

The kidneys excrete water-soluble waste products and other chemicals or substances from the body. This process is called renal plasma clearance, which refers to the ability of the kidneys to clear (cleanse) a given amount of plasma of a particular substance in a given time (usually 1 minute). The kidneys clear 25 to 30 g of **urea** (a nitrogenous waste product

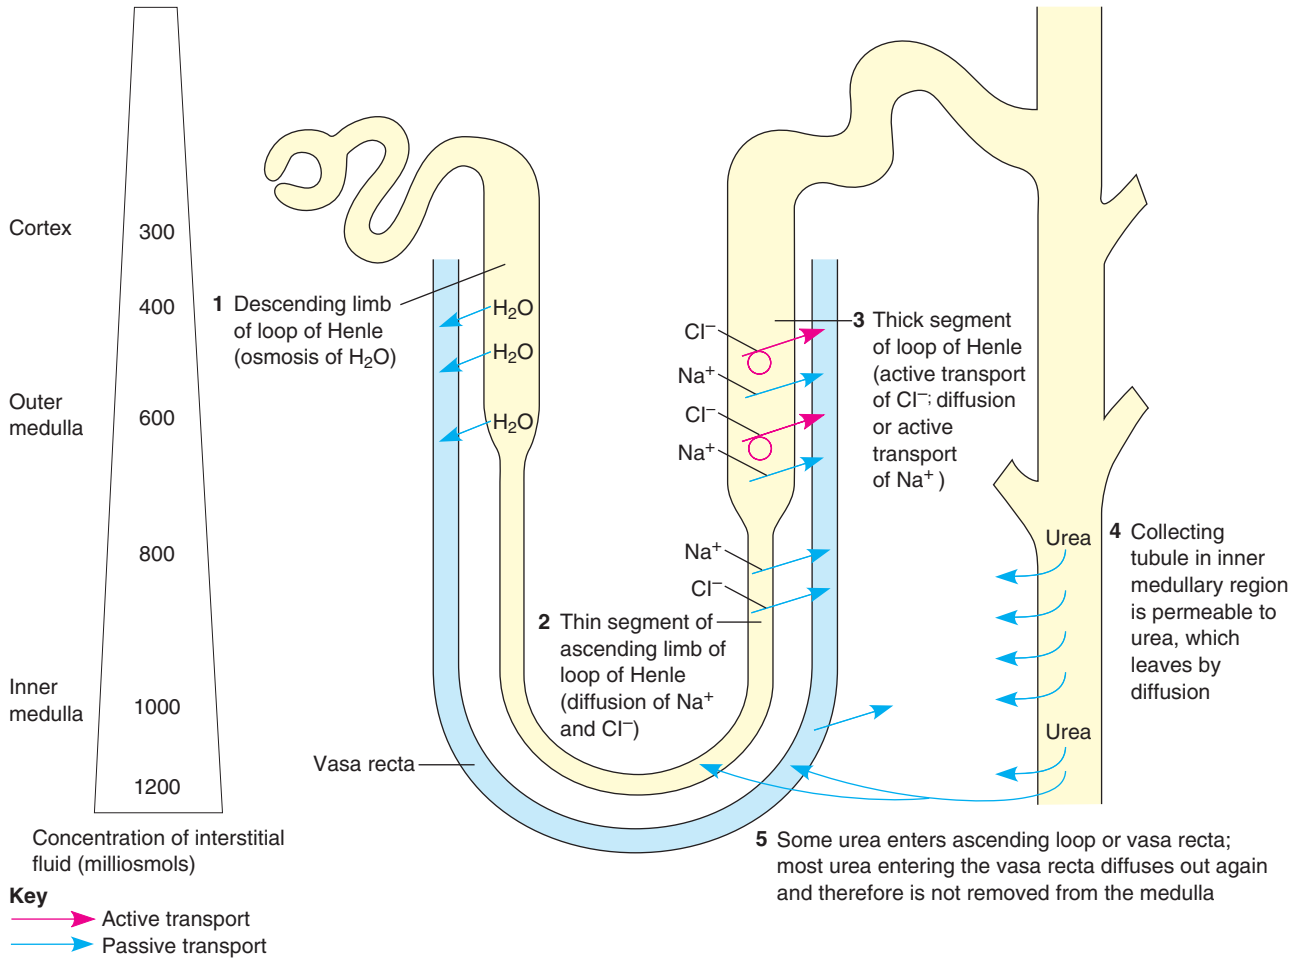

FIGURE 25.5 ■ The countercurrent exchange system is responsible for establishing and maintaining an osmotic gradient necessary to the composition, volume and pH of urine

formed in the liver from the breakdown of amino acids) each day. They also clear **creatinine** (an end product of creatine phosphate, found in skeletal muscle), uric acid (a metabolite of nucleic acid metabolism) and ammonia, as well as bacterial toxins and water-soluble drugs. Tests of renal clearance are often used to determine the GFR and glomerular damage.

Renal hormones

Hormones either activated or synthesised by the kidneys include the active form of vitamin D, erythropoietin and natriuretic hormone.

Vitamin D is necessary for the absorption of calcium and phosphate by the small intestine. In an inactive form, vitamin D enters the body either by dietary intake or through the action of ultraviolet rays on cholesterol in the skin. Activation occurs in two steps, the first in the liver and the second in the kidneys. The renal step is stimulated by parathyroid hormone, which in turn responds to a decreased plasma calcium level. High calcium and phosphate levels may lead to calcium deposits in the small capillaries in the eyes, lungs and heart. Calcium deposits increase the risk of cardiovascular disease over time (KHA, 2012).

Erythropoietin (EPO) stimulates the bone marrow to produce red blood cells in response to tissue hypoxia. The stimulus for the production of erythropoietin by the kidneys is decreased oxygen delivery to kidney cells.

The right atria of the heart releases natriuretic hormone in response to increased volume and stretch, as occurs in increased extracellular volume. This hormone inhibits ADH secretion, so that the collecting tubules are less porous and a large amount of dilute urine is produced.

THE URETERS

The ureters are bilateral tubes approximately 25 to 30 cm long. They transport urine from the kidney to the bladder through peristaltic waves originating in the renal pelvis. The wall of the ureter has three layers: an inner epithelial mucosa, a middle layer of smooth muscle and an outer layer of fibrous connective tissue.

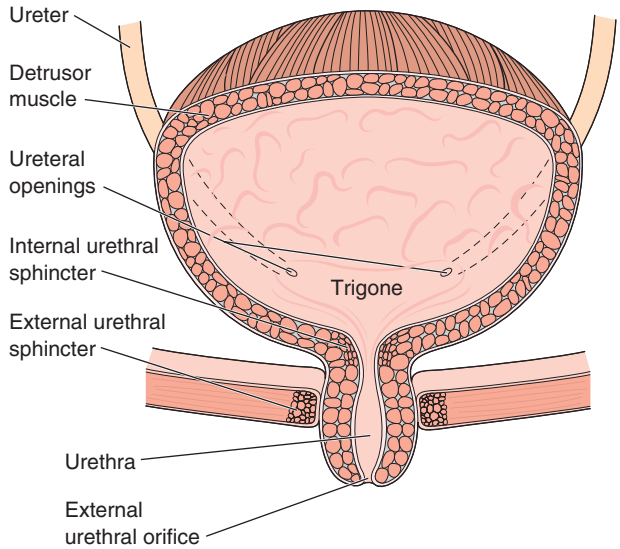

FIGURE 25.6 ■ Internal view of the urinary bladder and trigone

THE URINARY BLADDER

The urinary bladder is posterior to the pubic symphysis and serves as a storage site for urine. In males, the bladder lies immediately in front of the rectum; in females, the bladder lies in front of the vagina and the uterus. Openings for the ureters and the urethra are inside the bladder: the trigone is the smooth triangular portion of the base of the bladder outlined by these three openings (see Figure 25.6).

The layers of the bladder wall (from internal to external) are the epithelial mucosa lining the inside, the connective tissue submucosa, the smooth muscle layer and the fibrous outer layer. The muscle layer, called the detrusor muscle, consists of fibres arranged in inner and outer longitudinal layers and in a middle circular layer. This arrangement allows the bladder to expand or contract according to the amount of urine it holds.

The size of the bladder varies with the amount of urine it contains. In healthy adults, the bladder holds about 300 to 500 mL of urine before internal pressure rises and signals the need to empty the bladder through **micturition** (also called urination or voiding). However, the bladder can hold more than twice that amount if necessary. The bladder has an internal urethral sphincter that relaxes in response to a full bladder and signals the need to urinate. A second external urethral sphincter is formed by skeletal muscle and is under voluntary control.

THE URETHRA

The urethra is a thin-walled muscular tube that channels urine to the outside of the body. It extends from the base of the bladder to the external urinary meatus. In females, the urethra is approximately 3 to 5 cm long and the urinary meatus is anterior to the vaginal orifice. In males, the urethra is approximately 20 cm long and serves as a channel for semen as well as urine. The prostate gland encircles the urethra at the base of the bladder in males. The male urinary meatus is located at the end of the glans penis.

HEALTH ASSESSMENT, DIAGNOSTICS AND DOCUMENTATION

Renal system function is assessed by findings from a health assessment interview to collect subjective data, a physical assessment to collect objective data and diagnostic tests. Sample documentation of an assessment of renal system function is included in the box below.

Health assessment interview

A health assessment interview to determine problems with urinary structure and function may be conducted during a health screening, may focus on a chief complaint (such as burning on urination or difficulty starting the stream when urinating) or may be part of a total health assessment. As with alterations in bowel function, people with problems with renal system function may be embarrassed to talk about urinary elimination patterns. It is often helpful to discuss less personal information first.

LINKS TO NATIONAL PATIENT SAFETY STANDARDS

NSQHS Standard 9:
Recognising and Responding to Clinical Deterioration in Acute Health Care.

Essential element 4: Clinical communication

'Patient, family and carer concerns about possible deterioration are valued and acted on by the clinicians.' (Australian Commission on Safety and Quality in Health Care (ACSQHC), 2011)

People, their families and carers are well placed to identify the subtle signs of changes in a person's health. Identify opportunities for open communication such as conducting assessments in a private environment, discussing less personal information first, regular communication checks during healthcare team rounds and establishing an agreed communication process (written and verbal).

SAMPLE DOCUMENTATION

Assessment of renal system function

10/7/2014 NURS 1030 hrs — Home visit made to 66-year-old woman with end-stage chronic kidney disease. Skin pale and oral mucous membranes dry. 4+ oedema in ankles and feet. Eyelids swollen. Skin tight and shiny over abdomen and bilateral lower extremities. Abdomen distended and tender on light palpation; further palpation deferred. Urinary bladder not palpable. Urine output for past 24 hours is 15 mL.———— RN A Lam (A LAM RN)

Current urinary status should include the following data:

- colour, odour and amount of urine
- difficulty initiating a stream of urine
- frequency of urination
- painful urination (**dysuria**)
- excessive urination at night (**nocturia**)
- blood in the urine (**haematuria**)
- voiding scant amounts of urine (**oliguria**)
- voiding excessive amounts of urine (**polyuria**)
- discharge
- flank pain.

If you identify a problem with urinary elimination, analyse its onset, characteristics and course, severity, precipitating and relieving factors, and any associated symptoms, noting the timing and circumstances. For example, you may ask the following questions:

- Have you noticed any burning when you pass urine?
- Do you have difficulty starting to urinate?
- When did you first notice that you were unable to control the loss of urine from your bladder?

Further explore any abnormalities in the person's current renal status. Focus questions on changes in patterns of urination, changes in the urine and pain.

Assess changes in patterns of urination by asking the person: How many times a day do you urinate? Do you feel that you empty your bladder each time? How many times do you get up at night to urinate? Do you experience a very strong desire to urinate and feel that you just cannot wait? Have you noticed that you urinate small amounts of dark, strong-smelling urine?

Changes in the urine that should be explored include the presence of blood or a cloudy appearance of the urine. If the person has noticed blood, explore the use of medications (such as anticoagulants or dye-containing drugs) and other bleeding problems. Women may not understand that blood in the toilet or on toilet tissue after urination is normal during menstruation. Cloudy, foul-smelling urine often indicates infection (**pyuria**); ask the person about temperature elevations, chills and general malaise. Cloudy urine in men may result from retrograde ejaculation (when semen is discharged into the bladder instead of from the penis) during intercourse.

If the person reports pain, explore its location, duration and intensity. Kidney pain is experienced in the back and the costovertebral angle (the angle between the lower ribs and adjacent vertebrae) and may spread towards the umbilicus. Renal colic (pain in response to renal calculi moving through the ureter) is severe, sharp, stabbing and excruciating; often it is felt in the flank, bladder, urethra, testes or ovaries. Bladder and urethral pain is usually dull and continuous but may be experienced as spasms. The person with a distended bladder experiences constant pain increased by any pressure over the bladder.

Information about surgeries or other treatment of previous urinary problems is essential to the health history, as is a family history of altered structure or function. A family history of renal problems may be the first clue to abnormalities in the person's renal function. Explore information regarding family occurrence of end-stage renal disease, renal calculi and frequent infections, as well as related problems such as hypertension and diabetes mellitus.

Questions about lifestyle, diet and work history should explore cigarette smoking and/or exposure to toxic chemicals (to identify risks for cancer), usual fluid intake, type of fluid intake and self-care measures to replace fluids lost during work or physical activity in hot temperatures.

Interview questions categorised by functional health patterns are listed in the box below.

Physical assessment

The structure and function of the renal system is assessed by examination of the skin, abdomen, kidneys, bladder and urinary meatus. Guidelines for abdominal assessment are outlined in Chapter 20. Normal age-related findings for the older adult are summarised in Table 25.2. More information on the age-related changes in kidney function is presented in Table 27.2.

Physical assessment of the renal system may be performed as part of a total health assessment, as part of an abdominal assessment or as part of a back examination (for the kidneys). The techniques of inspection, auscultation, palpation and percussion are used.

Before beginning the assessment, ask the person to provide a clean urine specimen. Assess the specimen for colour, odour and clarity before sending to the laboratory.

Prior to the examination, collect all necessary equipment and explain the techniques to the person to decrease anxiety. Because the examination involves exposure of the genital area, give the person a gown and drape them appropriately to minimise exposure.

Guidelines for percussion and palpation of the kidneys are outlined in Box 25.1.

CONSIDERATION FOR PRACTICE

Auscultate immediately after inspection, because percussion or palpation may increase bowel motility and interfere with sound transmission during auscultation.

TABLE 25.2 Age-related renal system changes

AGE-RELATED CHANGE	SIGNIFICANCE
Kidneys: ↓ loss of renal mass, size of renal cortex and number of nephrons, ↓ growth of renal tissue, ↑ risk of atherosclerosis, all of which may result in atrophy of the kidneys (Abdel-Kader & Palevsky, 2009).	• Decreased renal blood flow. • Decreased GFR by about 50% between ages 20 and 90. eGFR of < 60 mL/min/1.73 m^2 is very common in older people (KHA, 2012).
Renal tubules: ↓ function, with less effective exchange of substances, water and sodium conservation, and ↓ plasma renin and aldosterone levels; ↑ vasoconstrictive response to stimuli (e.g. volume depletion) (Abdel-Kader & Palevsky, 2009).	• Risk of dehydration, hyponatraemia, hyperkalaemia, and nocturia. • Effects of medications may be altered (with decreased filtration). • Decreased reabsorption of glucose may result in proteinuria and glycosuria, which are not of major clinical significance.
Bladder: • Muscles weaken and bladder capacity decreases. • More difficult to empty bladder. • Delayed micturition reflex. Prostatic gland enlargement compressing the urethra (Martini et al., 2012).	• Urinary frequency, urgency and nocturia are more common with ageing. • Larger amounts of residual urine present after voiding. • Some stress incontinence may occur, especially in women who have had several children. • Urinary incontinence is not a normal outcome of ageing. • Urinary retention is more common.

Diagnostic tests

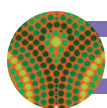
The results of diagnostic tests of renal system function are used to support the diagnosis of a specific disease, to provide information to identify or modify the appropriate medication or therapy, and to monitor the person's responses to treatment and nursing care interventions. Diagnostic tests used to assess the structures and functions of the renal system are described in the table below and summarised in the bulleted list that follows. More information is included in the discussion of specific disorders in Chapters 26 and 27.

- Urine may be tested through routine analysis, a urine culture, a post-voiding residual urine and a 24-hour collection for creatinine. Results of these tests include findings to serve as baseline data, to support diagnosis of various health problems, to evaluate the ability to empty the bladder of urine and to evaluate renal function.
- The ability to empty the bladder of urine may be evaluated by a portable bladder scan to evaluate for residual urine, uroflowmetry to measure the volume of urine voided per second and a cystometrogram (CMG) to evaluate bladder capacity, neuromuscular functions of the bladder, urethral pressures and causes of bladder dysfunction.
- Radiological examinations include an intravenous pyelogram, a retrograde pyelogram and a renal arteriogram or angiogram. These examinations are useful in visualising (via x-ray film) the urinary tract to identify abnormal size, shape and function of the kidneys, the kidney pelvis and ureters; and to detect renal **calculi** (stones), tumours or cysts.
- A cystoscopy allows direct visualisation of the bladder wall and urethra. During the procedure small stones can be removed, a sample of tissue may be taken for biopsy and a retrograde pyelogram may be done at the same time. If a contrast dye is instilled in the bladder, fistulas, tumours or ruptures can be identified.
- Non-invasive tests include a renal ultrasound, computed tomography (CT) scan, magnetic resonance imaging (MRI) and renal scan. These tests are used to identify and evaluate kidney size and structure, as well as renal or perirenal masses and obstructions. In addition, a renal scan may be used to evaluate kidney blood flow, perfusion and urine production.
- A kidney biopsy is done to obtain tissue to diagnose or monitor kidney disease.

The nurse should explain the procedure and required preparation, assess medication use that may affect the outcome of the tests, support the person during the examination as necessary, and document and monitor the results of the tests.

Genetic considerations

When conducting a health assessment interview and physical assessment consider the genetic influences on adult health (see 'Genetic considerations' below). Ask if family members have health problems affecting kidney function such as polycystic disease or diabetes mellitus. If data are found to indicate genetic risk factors or alterations, ask about genetic testing and refer for appropriate genetic counselling and evaluation. Chapter 8 provides further information about genetics in medical–surgical nursing.



GENETIC CONSIDERATIONS Renal system

- Adult polycystic kidney disease (APKD) is characterised by large cysts in one or both kidneys and a gradual loss of kidney tissue with resultant chronic kidney disease. There are three recognised forms: ~85% are called APKD1 and are linked to a familial chromosome 16 disorder; APKD2 (~15%) have an abnormality on chromosome 4; and the gene locus of APKD3 (rare) is yet to be identified.
- Chronic kidney disease (CKD) may be a complication of type 1 and type 2 diabetes mellitus (DM), but is seen more often in people with type 1 DM. Type 1 and type 2 DM are classified as multifactorial inheritance disorders because both genetic and environmental factors are necessary for onset of the disorder.

FUNCTIONAL HEALTH PATTERN INTERVIEW Renal system

FUNCTIONAL HEALTH PATTERN	INTERVIEW QUESTIONS AND LEADING STATEMENTS
Health perception–Health management	■ Have you ever had a bladder or kidney disease, injury or surgery? Describe. ■ If so, how was the problem treated? ■ Describe your usual intake of fluids for a 24-hour period. What type of fluids do you drink? ■ Have you ever smoked? If so, how many cigarettes per day? ■ Describe the problem you are having with your kidneys or bladder. ■ Are you taking medications for this or any other health problem? If so, what do you take and how often? ■ *For women*: Describe how you care for yourself when you urinate (e.g. direction of wiping with tissue). ■ If you have a surgical diversion of urine, describe how you care for yourself. (What skin and appliance care do you use? How often do you empty the bag?) ■ Do you wear or have you ever worn an external catheter, indwelling catheter or incontinence briefs? Explain. ■ Have you ever done self-catheterisation? If so, why and how often?
Nutritional–Metabolic	■ How much coffee, tea or alcohol do you drink in a 24-hour period? ■ Have you ever limited your fluid intake? Explain. ■ Do you limit the amount of salt you eat? Explain. ■ Do you have swelling in your ankles? If so, what do you do?
Elimination	■ How many times a day do you urinate? Do you have to get up at night to urinate? Has there been a change in your usual pattern of urination? ■ Do you experience a sudden urge to urinate? ■ Has there been a change in your urine, such as a change in amount, colour or odour? Have you ever noticed blood in your urine or on the tissue after you wipe? ■ Is it difficult for you to begin or end your flow of urine? ■ Have you ever had problems controlling your urine when you laugh, sneeze or cough? ■ Do you have any discharge from your urethra? Explain.
Activity–Exercise	■ Do your urinary problems interfere with your activities of daily living? Explain. ■ Describe your usual energy level. Has there been a change? Explain. ■ Have you ever been taught to do Kegel exercises to help you control your urination? If so, how often do you practise these?
Sleep–Rest	■ Does a problem with urination interfere with your ability to sleep and rest? Explain. ■ Has there been a change in the number of times you wake up at night to urinate? Explain.
Cognitive–Perceptual	■ Do you have any pain or burning when you urinate? ■ Have you experienced any tenderness or pain over the lower sides of your back or severe pain that spreads over your lower abdomen? If so, describe its location, intensity, aggravating factors and duration.
Self-perception–Self-concept	■ How does having this condition make you feel about yourself?
Role–Relationships	■ How does having this condition affect your relationships with others?
Sexuality–Reproductive	■ Has this condition interfered with your usual sexual activity?
Coping–Stress–Tolerance	■ Has having this condition created stress for you? ■ Have you experienced any kind of stress that makes this condition worse? Explain. ■ Describe what you do when you feel stressed.
Value–Belief	■ Describe how specific relationships or activities help you cope with this problem. ■ Describe specific cultural beliefs or practices that affect how you care for and feel about this problem. ■ Are there any specific treatments that you would not use to treat this condition?

BOX 25.1 Guidelines for physical assessment of the kidneys

Percussion of the kidneys

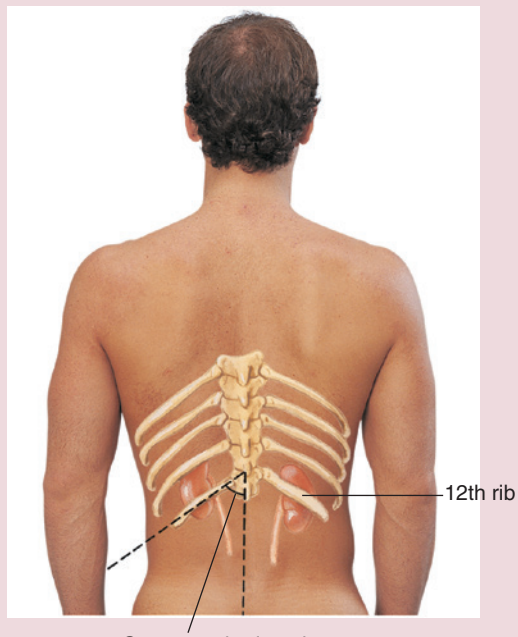
Percussion of the kidneys helps assess pain or tenderness. Assist the person to a sitting position and stand behind them. For indirect percussion, place the palm of your non-dominant hand over the costovertebral angle (see Figure A). Strike this area with the ulnar surface of your dominant hand, curled into a fist (see Figure B). For direct percussion, also strike the area over the costovertebral angle with the ulnar surface of your dominant hand, curled into a fist. Repeat the technique for the other kidney.

You should do percussion of the kidneys with only enough force so the person feels a gentle thud. Percussion is usually done at the end of the assessment.

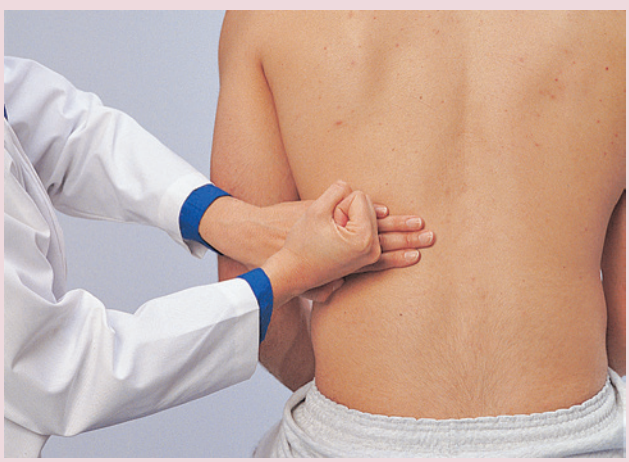
Palpation of the kidneys

Although the technique of palpation of the kidneys is outlined here, this technique is best performed by an advanced practitioner, because it involves deep palpation. In addition, the kidneys are difficult to palpate.

Assist the person to the supine position and stand at their right side. To palpate the left kidney, reach across the person and place your left hand under their left flank with your palm upward. Elevate the left flank with your fingers, displacing the kidney upward. Ask the person to take a deep breath and use the palmar surface of your right hand to palpate the kidney (see Figure C). Repeat the technique for the right kidney.



A Location of the kidneys and the costovertebral angle



B Percussing the kidney

C Palpating the left kidney

DIAGNOSTIC TESTS Renal system disorders

NAME OF TEST Serum urea

PURPOSE AND DESCRIPTION This blood test measures urea, the end product of protein metabolism. Increased levels may result from dehydration, vomiting, diarrhoea, GI bleeding, renal impairment, excessive protein catabolism or congestive cardiac failure. It may be decreased with protein deficiency in diet, dieresis and pregnancy.

Normal values: 3.0–8.0 mmol/L

RELATED NURSING CARE No special preparation is needed. If values are increased in a person who is dehydrated, they should return to normal with hydration. If not, this is an indicator of renal impairment.

(continued)

DIAGNOSTIC TESTS Renal system disorders (continued)

NAME OF TEST Serum creatinine

PURPOSE AND DESCRIPTION This blood test is used to diagnose renal impairment. Creatinine is a by-product of the breakdown of muscle and is excreted by the kidneys. Serum creatinine levels may rise when 50% or more nephrons are destroyed or there is acute muscle wasting. Levels may fall with chronic muscle wastage (such as muscular dystrophy, muscle sclerosis).

Normal values: Serum (adult female): 0.05–0.11. Serum (adult male): 0.06–0.12 mmol/L.

(Creatinine varies with size and muscle mass. Older adults may have decreased values due to decreased muscle mass.)

RELATED NURSING CARE No special preparation is needed. Values may be increased by antibiotics, ascorbic acid, L-dopa, methyldopa and lithium carbonate. Values are not affected by hydration status. Three to four hours after eating meat the plasma creatinine can double, so fasting prior to measurements may be recommended.

NAME OF TEST Estimated glomerular filtration rate (eGFR)

PURPOSE AND DESCRIPTION GFR is the best measurement of kidney function; the eGFR can estimate the GFR.

Normal values: GFR < 60 mL/min/1.73m^2 for 3 months. Normal findings and abnormal findings with causes are outlined in Table 25.1.

RELATED NURSING CARE eGFR may be unreliable if diet is vegetarian, high in protein or includes creatine supplements; in people with large muscle mass and amputees; in children under 18 years; and in those with severe liver disease.

NAME OF TEST Routine urinalysis (UA) (dipstick or ward urinalysis)

PURPOSE AND DESCRIPTION An examination of the constituents of a sample of urine to establish a baseline, to provide data for diagnosis or to monitor results of treatment. Normal findings and abnormal findings with causes are outlined in Table 25.1.

RELATED NURSING CARE Provide a clean specimen cup for a sample of urine. Note if the person is menstruating. Assess medications, fluid status and foods that might affect urinalysis results.

NAME OF TEST Urine culture (microscopy urine (MSU), clean-catch)

PURPOSE AND DESCRIPTION A culture of a urine sample to identify the causative organism of a urinary tract infection (UTI).

Normal value: < 10 000 organisms/mL (urine is sterile but urethra contains bacteria and a few WBCs).

Values of > 100 000 organisms/mL indicate UTI.

RELATED NURSING CARE Provide the person with sterile container. Ask women to separate labia with one hand and clean labia with other hand, using sterile cotton sponges saturated with a cleansing solution (may be 0.9% sodium chloride) and wiping three times front to back. Ask men to retract the foreskin and cleanse glans with three cotton sponges saturated with a cleansing solution, using a circular motion. After cleaning, ask the person to begin voiding and then collect specimen in the container (initial voiding will contain urethral contaminants). If the person is unable to void, it may be necessary to obtain a specimen with a urinary catheterisation.

NAME OF TEST Urinary albumin:creatinine ratio (ACR)

PURPOSE AND DESCRIPTION Used to detect albumin (a protein) in the urine. A marker of kidney damage is excessive amounts of albumin in the urine (**albuminuria**). The presence of albuminuria is determined by the albumin-to-creatinine ratio (ACR). Low levels of albumin in the urine are normal; the prevalence increases sharply from 65 years of age onwards (DHV, 2012). Other causes of transient elevations in urinary ACR include UTIs, diurnal variations in urinary excretion, non-steroidal anti-inflammatory drugs (NSAIDs), fluid overload and acute febrile illness (Phoon, 2012). Elevated ACR may occur when kidney damage is present.

Normal value: < 3.5 mg/mmol (Salem & Harvie, n.d.).

Albuminuria—Male: > 2.5 mg/mmol; Female: > 3.5mg/mmol

Microalbuminuria—Male: 2.5–25 mg/mmol; Female: 3.5–35 mg/mmol

Macroalbuminuria (moderate to severe CKD)—Male: > 25 mg/mmol; Female: > 35 mg/mmol (Salem & Harvie, n.d.; KHA 2015).

RELATED NURSING CARE This should be a first-void spot specimen. Albuminuria is said to be present if two out of three ACR results are positive (KHA, 2012). A routine 'dipstick' for protein in the urine is not recommended to investigate for CKD.

DIAGNOSTICTESTS Renal system disorders (continued)

NAME OF TEST Portable ultrasonic bladder scan

PURPOSE AND DESCRIPTION Used to obtain information about bladder volume or residual urine left in the bladder after voiding. Where possible, place the person in a supine position. Warm ultrasound gel and apply over the lower abdomen. The ultrasound probe is placed just above the pubic bone. Select 'male' on the machine if the person has had a hysterectomy. The scanner shows an outline of the bladder and displays the amount of urine in the bladder in millilitres. Obtain several readings and use the largest (the most accurate). Print the information, place it on the person's chart and document the residual urine amount.

RELATED NURSING CARE No special preparation is needed, but the test is usually not used for pregnant women. Remember the machine will measure any fluid collection in the suprapubic region such as ascites, haematoma or lymphocele. Report and monitor a residual of more than 100 mL or if the residual is greater than the amount voided. A urinary catheter may have to be inserted if the volume is greater than 600 mL, or if the person has not voided for 5 to 6 hours or is uncomfortable.

NAME OF TEST Creatinine clearance

PURPOSE AND DESCRIPTION A 24-hour urine test and a blood sample (collected at either the end or beginning of the 24-hour urine collection) are used to identify renal dysfunction and to monitor renal function.

Normal value: 90–125 mL/min

Calculation of estimated glomerular function rate (eGFR), using a single blood sample, is another straightforward method of estimating kidney function.

RELATED NURSING CARE Assess medications: drugs that may decrease the creatinine clearance measurement are steroids, aminoglycosides, thiazides, cimetidine, cisplatin and cephalosporins. Ascorbic acid, steroids, methyldopa (Aldomet), cefoxitin and diuretics can increase the result. Levels of creatinine are elevated in hypothyroidism, hypertension, pregnancy and exercise.

Obtain appropriate specimen container. Ask person to void and discard first voiding. Instruct the person, family and staff to then save all urine for a clearly designated 24-hour period, keeping the specimen in the fridge. If the person misses a sample, the test is invalid.

NAME OF TEST Uroflowmetry

PURPOSE AND DESCRIPTION This test measures the volume passed per second, maximum and average flow rate, and voiding time.

RELATED NURSING CARE Ask the person to increase fluid intake and refrain from voiding for several hours before the test to ensure a full bladder and a strong urge to void during testing. Tell the person they will be asked to urinate into a funnel. Residual urine may be measured following the test.

NAME OF TEST Micturating cysto-urethrogram (cystometrogram (CMG))

PURPOSE AND DESCRIPTION Conducted to evaluate bladder capacity and neuromuscular functions of the bladder, urethral pressures and causes of bladder dysfunction. A measured quantity of fluid (contrast media) is instilled into the bladder (via urethral catheter) and the filling capacity and voiding pressures are measured. The catheter is removed and a series of x-ray pictures are taken as the person micturates. A catheter may also be placed in the rectum during the test.

RELATED NURSING CARE Tell the person that the bladder will be filled and during filling they will be asked to describe the first urge to void and the sensation of being unable to delay urination any longer.

NAME OF TEST Intravenous pyelogram (IVP)

PURPOSE AND DESCRIPTION This radiological examination is done to visualise the entire urinary tract to identify abnormal size, shape and function of the kidneys, or to detect renal calculi (stones), tumours or cysts. A urinary catheter is placed into the bladder and a radiopaque substance is injected intravenously and a series of x-rays taken.

PERSON PREPARATION

- Assess knowledge and understanding of procedure, clarifying information as needed. The person may have to fast (from food); clear fluids allowed up to 2 hours prior to the procedure.
- Schedule IVP prior to any ordered barium test or gallbladder studies using contrast material.
- Assess if the person has any form of reaction to x-ray contrast dye, or an iodine or seafood allergy, or if they are asthmatic.
- Verify the presence of a signed consent for the procedure.
- Assess renal and fluid status, including serum osmolality, creatinine and urea results. Notify the doctor of any abnormal values.
- Instruct the person to follow preparation protocol. This may include pretest bowel preparation and fasting for 3 hours prior to the procedure.
- Obtain baseline vital signs and record.

(continued)

DIAGNOSTIC TESTS Renal system disorders (continued)

AFTER THE TEST

- Monitor vital signs and urine output.
- Report manifestations of delayed reaction to the contrast media such as dyspnoea, tachycardia, itching, hives or flushing.

HEALTH EDUCATION FOR THE PERSON AND FAMILY

- X-rays and a dye that is rapidly excreted in the urine are used to show the structures of the kidney, ureters and bladder. The test takes about 30 minutes.
- As the dye is injected, you may feel a transient warm flushing sensation along with possible nausea and a metallic taste.
- A wide band may be placed around your waist at some stage and tightened for a few minutes to stop the contrast from draining to the bladder through the ureters (the tubes joining the kidneys to the bladder).
- Notify your doctor immediately if you develop a rash, difficulty breathing, rapid heart rate or hives during or after the test.
- Increase fluid intake after the test is completed.

NAME OF TEST Retrograde pyelogram

PURPOSE AND DESCRIPTION This radiological test is done to evaluate the structures of the ureters and kidney pelvis. It may be performed alone or in conjunction with a cystoscopy. A contrast dye is injected through a catheter into the ureters and kidney pelvis and x-rays are taken.

RELATED NURSING CARE Nursing care for the person having a retrograde pyelogram is the same as that for people having an IVP.

NAME OF TEST Renal arteriogram or angiogram

PURPOSE AND DESCRIPTION This radiological test is done to visualise renal blood vessels in order to detect renal artery stenosis, renal thrombosis or embolism, tumours, cysts or aneurysm; to determine the causative factor for hypertension; and to evaluate renal circulation. A contrast medium is injected into the femoral artery.

RELATED NURSING CARE Assess for allergy to iodine, seafood or other contrast dye from other x-ray procedures. A laxative or cleansing enema may be required the night before and the person should be fasted for 8–12 hours prior to the test. Results may be affected by faeces, gas and barium sulfate. Anticoagulants should be discontinued.

After the test, pressure will be applied to the insertion site for up to 20 minutes to prevent bleeding. Continue to monitor for bleeding from the femoral artery, restrict activity for a day, assess peripheral pulses and monitor urine output.

NAME OF TEST Cystoscopy (cystogram), cystography

PURPOSE AND DESCRIPTION Direct visualisation of the bladder wall and urethra is accomplished by using a cystoscope. During the procedure small renal calculi can be removed from the ureter, bladder or urethra and tissue biopsy can be done. It also permits determination of the cause of haematuria or UTI. A stent may be inserted during the procedure to facilitate urinary drainage past an obstruction. A retrograde pyelogram may be done during the cystoscopy. By instilling a contrast dye into the bladder (*cystography*), neurogenic bladder, fistulas, tumours or ruptures can be identified.

PERSON PREPARATION

- Assess knowledge and understanding of the procedure, clarifying information as needed.
- Verify the presence of a signed consent for the procedure.
- Instruct in pre-test preparation as ordered, including prescribed laxatives the evening prior to the test and any ordered food or fluid restrictions.
- Administer sedation and other medications as ordered prior to the test.
- Immediately notify the doctor if your urine remains bloody for more than three voidings after the procedure or if you develop bright bleeding, low urine output, abdominal or flank pain, chills or fever.
- Warm baths, analgesic agents and antispasmodic medications may relieve discomfort after the procedure.
- Increase fluid intake to decrease pain and difficulty voiding and reduce the risk of infection.

HEALTH EDUCATION FOR THE PERSON AND FAMILY

- Cystoscopy is performed using either a local or general anaesthetic. You may feel some pressure or a need to urinate as the scope is inserted through the urethra into the bladder. The procedure takes approximately 15 to 30 minutes.
- Do not attempt to stand without assistance immediately after the procedure because you may feel dizzy or faint.
- Burning on urination for a day or two after the procedure is to be expected.

NAME OF TEST Renal ultrasound

PURPOSE AND DESCRIPTION This non-invasive test is conducted to detect renal or perirenal masses, identify obstructions and diagnose renal cysts and solid masses. It is done by applying a conductive gel to the skin and placing a small external ultrasound probe on the person's skin. Sound waves are recorded on a computer as they are reflected off tissues.

RELATED NURSING CARE No special preparation is indicated.

DIAGNOSTICTESTS Renal system disorders (continued)

NAME OF TEST CT scan of kidneys

PURPOSE AND DESCRIPTION The CT scan allows evaluation of kidney size, tumours, abscesses, suprarenal masses and obstructions. A contrast dye is injected intravenously, allowing increased visualisation of the density of renal tissue and masses in comparison to an ultrasound.

RELATED NURSING CARE Assess the person for allergies to iodine, x-ray contrast dye and seafood. Tell the person to fast for 4 hours prior to the test and that laxatives or enemas may be ordered to remove gas or faecal material from the bowel.

NAME OF TEST MRI of the kidneys

PURPOSE AND DESCRIPTION An MRI is used to visualise the kidneys by assessing computer-generated films of radiofrequency waves and changes in magnetic fields.

RELATED NURSING CARE Ask the person to remove all metal objects. Assess for metal implants. (Test may not be conducted if present.)

NAME OF TEST Renal scan

PURPOSE AND DESCRIPTION This test is done to evaluate kidney blood flow, location, size and shape; and to assess kidney perfusion and urine production. Radioactive isotopes are injected intravenously and radiation detector probes are placed over the kidneys to monitor activity in the kidneys. Radioisotope distribution in the kidneys is scanned and graphed. Non-functioning tissue, such as in tumours and cysts, appears as cold spots.

RELATED NURSING CARE Ask the person to drink several glasses of water prior to the test. Obtain weight and have the person void. After the procedure, increase fluid intake.

NAME OF TEST Renal biopsy

PURPOSE AND DESCRIPTION A renal biopsy is done to obtain tissue to diagnose or monitor kidney disease. The test is usually done by inserting a needle through the skin into the lower lobe of the kidney. It can also be done with CT, fluroscopy or ultrasound guidance.

PERSON PREPARATION

- Informed consent is required for a kidney biopsy. Answer questions and provide additional information as needed.
- Fast for 4 to 6 hours prior to the procedure.
- Continue to take all medications EXCEPT anticoagulants.
- Note haemoglobin, haematocrit and coagulation profile prior to the procedure.
- If the procedure is to be performed at the bedside, obtain biopsy tray and other necessary supplies.
- Following the procedure, apply a pressure dressing and position supine, for up to 4 hours, to help maintain pressure on the biopsy site.
- Monitor closely for bleeding during the first 24 hours after the procedure:
  a. Check vital signs frequently. Notify the doctor of tachycardia, hypotension or other signs of bleeding or shock.
  b. Monitor biopsy site for bleeding.
  c. Check haemoglobin and haematocrit, comparing with preprocedure values.
  d. Observe for and report complaints of flank or back pain, shoulder pain (caused by diaphragmatic irritation if haemorrhage occurs), pallor, light headedness.
  e. Monitor urine output for quantity and haematuria. Initial haematuria should clear within 24 hours.
- Monitor for other potential complications such as inadvertent penetration of the liver or bowel. Report abdominal pain, guarding and decreased bowel sounds.
- Encourage fluids during the initial post-procedure period.

HEALTH EDUCATION FOR THE PERSON AND FAMILY

- Local anaesthesia is used at the injection site. The procedure may be uncomfortable but should not be painful.
- When the needle is inserted, you will be instructed not to breathe to prevent kidney motion.
- The entire procedure takes approximately 10 minutes.
- Avoid coughing during the first 24 hours after the procedure. Strenuous activity such as heavy lifting may be prohibited for approximately 2 weeks after the procedure.
- Report any manifestations of complications, such as haemorrhage or urinary tract infection, to the doctor.

RENAL ASSESSMENTS

Technique/normal findings	Abnormal findings
Skin assessment Inspect the skin and mucous membranes, noting colour, turgor and excretions. *The colour of skin and mucous membranes should be even and appropriate to the person's age and race; skin should be dry with no visible excretions.*	■ Pallor of the skin and mucous membranes may indicate kidney disease with resultant anaemia. ■ Decreased turgor of the skin may indicate dehydration. ■ Oedema (generalised or in the lower extremities) may indicate fluid volume excess. (Changes in skin turgor may indicate renal insufficiency with either excess fluid loss or retention.) ■ An accumulation of uric acid crystals, called uraemic frost, may be seen on the skin of the person with late-stage kidney disease.
Abdominal assessment Inspect the abdomen, noting size, symmetry, masses or lumps, swelling, distension, glistening or skin tightness. *The abdomen should be slightly concave, symmetric, without distension or masses.*	■ Enlargements or asymmetry may indicate a hernia or superficial mass. ■ If the urinary bladder is distended, it rises above the pubic symphysis as a rounded mass. ■ Distension, glistening or skin tightness may be associated with fluid retention. ■ Ascites is an accumulation of fluid in the peritoneal cavity.
Urinary meatus assessment This technique is not part of a routine assessment, but it is an important component in caring for people with health problems of the renal system. Further discussion is included in Chapter 46. *For the male:* With the person in a sitting or standing position, compress the tip of the glans penis with your gloved hand to open the urinary meatus (see Figure 25.7). *For the female:* With the person in the dorsal lithotomy position, spread the labia with your gloved hand to expose the urinary meatus. *The urinary meatus should be midline and free of redness, lesions or discharge.*	■ Increased redness, swelling or discharge from the urinary meatus may indicate infection or sexually transmitted infection. ■ Ulceration of the urinary meatus may indicate a sexually transmitted infection. ■ Hypospadias is displacement of the urinary meatus to the ventral surface of the penis. ■ Epispadias is displacement of the urinary meatus to the dorsal surface of the penis.
Kidney assessment See Box 25.1 for assessment guidelines for percussion and palpation of the kidneys. Auscultate the renal arteries by placing the bell of the stethoscope lightly in the areas of the renal arteries, located in the left and right upper abdominal quadrants. *Bruits are not normally heard over the renal arteries.*	■ Systolic bruits ('whooshing' sounds) may indicate renal artery stenosis.
Percuss the kidneys for tenderness or pain. *No tenderness or pain should be elicited.*	■ Tenderness and pain on percussion of the costovertebral angle suggest glomerulonephritis or glomerulonephrosis.
Palpate the kidneys. The lower pole of the right kidney may be palpable with deep palpation; the remaining right kidney and the left kidney are normally not palpable. *If palpable, they should be non-tender, bilaterally of appropriate size and density, without palpable masses.*	■ A mass or lump may indicate a tumour or cyst. ■ Tenderness or pain on palpation may suggest an inflammatory process. ■ A soft kidney that feels spongy may indicate chronic renal disease. ■ Bilaterally enlarged kidneys may suggest polycystic kidney disease. ■ Unequal kidney size may indicate hydronephrosis.

FIGURE 25.7 ■ Inspecting the urinary meatus of the male

RENAL ASSESSMENTS (continued)

Technique/normal findings	Abnormal findings
Bladder assessment	
Percuss the bladder for tone and position. *The bladder should be midline without dullness.*	■ Dull percussion tone over the bladder of a person who has just urinated may indicate urinary retention.
Palpate the bladder (over the pubic symphysis and abdomen) for distension. *The bladder is normally not palpable.*	■ Distended bladder may be palpated at any point from the pubic symphysis to the umbilicus and is felt as a firm, rounded organ. It indicates urinary retention.

CONCEPT CHECK

1 What part of the kidney processes the blood to make urine?
1 ureter
2 medulla
3 pyramids
4 nephrons

2 A person has been vomiting for 4 hours. What hormone is increased as a result?
1 thyroxine
2 renin
3 aldosterone
4 ADH

3 What diagnostic test can be used to determine GFR as well as glomerular damage?
1 routine urinalysis
2 renal scan
3 creatinine clearance
4 renal biopsy

4 What gland encircles the male urethra at the base of the bladder?
1 spleen
2 pancreas
3 prostate
4 adrenal

5 The person tells you of having to get up to void several times a night. You record this finding as:
1 polyuria
2 nocturia
3 dysuria
4 haematuria

6 Which question would you ask a person prior to an IVP?
1 'Are you allergic to shellfish?'
2 'Do you have burning on urination?'
3 'Have you ever had kidney stones?'
4 'Why are you having this test?'

7 Before beginning the physical assessment of the renal system, you should ask the person to:
1 empty the bladder
2 take several deep breaths
3 provide a urine specimen
4 drink several glasses of water

8 Following surgery, an older adult has not voided for 12 hours. What assessment should you make?
1 Palpate for bladder distension.
2 Auscultate for bowel sounds.
3 Inspect for oedema of the urethra.
4 Percuss for gastric tympany.

9 Of the following health problems an older woman may have, which is not normally a part of ageing of the renal system?
1 increased risk of haematuria
2 decreased risk of infection
3 urine that is darker in colour
4 urinary incontinence

10 What assessment would you use to assess hydration status of a person?
1 auscultation of renal arteries
2 palpation for skin turgor
3 percussion for dullness over bladder
4 palpation of both kidneys

CHAPTER 26

NURSING CARE OF PEOPLE WITH URINARY TRACT DISORDERS

JENNIFER BORG, TRUDY DWYER, DIANE GOLDSWORTHY

LEARNING OUTCOMES

- Relate the interprofessional care and health management implications for a person with urinary tract infection to the pathophysiology of the condition.
- Explain the risk factors, course, pathophysiology and interventions required to competently care for a person with an obstruction of the urinary tract.
- Describe the interprofessional care and health management when caring for individuals experiencing various urinary flow disorders.

CLINICAL COMPETENCIES

- Assess the functional health status of people with urinary tract disorders, using data to determine priority nursing diagnoses and select individualised nursing interventions.
- Identify, report and document abnormal or unexpected assessments and their effect on personal status.
- Use evidence-based research to plan and implement nursing care for people with urinary tract disorders.
- Integrate the interprofessional plan of care into care for people with urinary tract disorders.
- Knowledgeably and safely administer prescribed medications and treatments for people with urinary tract disorders.
- Provide effective nursing care for people undergoing surgery of the urinary tract.
- Plan and provide appropriate teaching for prevention and self-care of urinary tract disorders.
- Evaluate personal responses, revising plan of care as needed to promote, maintain or restore functional health of individuals with urinary tract disorders.

KEY TERMS

The urinary system includes the kidneys, ureters, urinary bladder and urethra. This organ system can be affected by a variety of disorders, including congenital malformations, infections, obstructions, trauma, tumours and neurological conditions. Any portion of the system—from the kidney through to the urethra—can be affected, with serious or even life-threatening consequences unless the problem is appropriately diagnosed and treated. Kidney disorders that can affect urine production and waste elimination directly are discussed in the next chapter. Disorders of the **urinary drainage system** may obstruct urine flow or may affect the kidneys and urine production and elimination. The anatomy, physiology and nursing assessment related to the urinary tract are presented in Chapter 25.

When caring for people with urinary tract disorders, it is important to consider their modesty with respect to voiding, possible difficulty in discussing the genitals, embarrassment over exposure during examination and testing, and fear of changes in body image or function. These psychosocial issues may interfere with willingness to seek help, discuss treatment and learn about preventive measures.

Nursing interventions for people with urinary tract disorders are directed towards primary prevention, early detection and management of disorders through nursing care and health education.

THE PERSON WITH URINARY TRACT INFECTION

There were 2987 deaths in Australia in 2013 from diseases of the kidney and urinary tract with these being the tenth leading cause of death (Australian Bureau of Statistics, 2013). Untreated or poorly managed urinary tract infections (UTIs) may ultimately result in kidney damage, kidney failure and potentially, death (Kidney Health Australia (KHA), 2015). People who are diabetic or have nephritis or hypertensive vascular disease have an increased risk of developing end-stage or chronic kidney disease (CKD). Indigenous Australians have an even greater chance than non-Indigenous Australians with an almost 40% higher death rate from the disease (KHA, 2015).

Bacterial infections of the urinary tract are a frequent reason for seeking health services and are a contributing factor to CKD. In Australia, 1.6 in every 10 doctor consultations (1.1% of the population) was for urinary tract infection (Australian Institute of Health and Welfare (AIHW), 2008). Community-acquired UTIs are more common in women than males, are unusual in men under the age of 50 and may be symptomatic or asymptomatic.

Most community-acquired UTIs (80–90%) are caused by *Escherichia coli* (KHA, 2015), a common Gram-negative enteral bacteria. About 5–10% of symptomatic UTIs are caused by *Staphylococcus saprophyticus*, a Gram-positive organism. Catheter-associated UTIs often involve other Gram-negative bacteria such as *Proteus*, *Klebsiella*, *Serratia* and *Pseudomonas*.

Risk factors

A variety of factors can predispose to UTI (see Box 26.1). Some factors cannot be changed (e.g. ageing and the short urethra of the female); others may be a result of individual behaviour—for example, poor fluid intake or delaying going to the toilet, especially in the elderly.

BOX 26.1 Risk factors for UTI

Female
- Short, straight urethra
- Proximity of urinary meatus to vagina and anus
- Sexual intercourse
- Use of diaphragm and spermicidal compounds for birth control
- Pregnancy

Male
- Uncircumcised
- Prostatic hypertrophy
- Anal intercourse

Both
- Ageing
- Urinary tract obstruction
- Neurogenic bladder dysfunction
- Vesicoureteral reflux
- Genetic factors
- Catheterisation

In women, poor perineal hygiene or cleansing techniques after micturition or defecation may result in bacterial deposition close to the external urethral orifice. Sexual activity also increases the risk of UTI, because bacteria can be introduced into the bladder via the urethra during sexual intercourse. Use of spermicidal compounds with a diaphragm, cervical cap or condom alters the normal bacterial flora of the vagina and perineal tissues and further increases the risk of UTI. Some females lack a normally protective mucosal enzyme and have decreased levels of cervicovaginal antibodies to enterobacteria, further increasing their risk. Prostatic hypertrophy and bacterial prostatitis are risk factors among males, as is anal intercourse, although circumcision appears to have a protective effect. Congenital or acquired factors contributing to the risk of infection include urinary tract obstruction by tumours or calculi, structural abnormalities such as strictures, impaired bladder innervation, bowel incontinence and chronic diseases such as diabetes mellitus.

Instrumentation of the urinary tract (e.g. catheterisation or cystoscopy) is a major risk factor for UTI. The placement of the catheter prevents the flushing action of voiding and bacteria may ascend to the bladder either through the catheter lumen or via exudate between the urethral mucosa and the catheter. Even when performed under strict aseptic conditions, catheterisation can result in bladder infection. Research indicates that the risk of catheter-associated UTI is reduced when anaesthetic lubricating gels are inserted into the urethra prior to catheter insertion (Bardsley, 2005). Prophylactic antibiotics are not recommended at insertion or replacement of an indwelling urinary catheter unless otherwise recommended. Use of a local anaesthetic minimises the discomfort experienced by the patient (Australian & New Zealand Urological Nurses Society (ANZUNS), 2013).

Older individuals have an increased incidence of UTI. The greatest degree of increase is seen in men, as the ratio of female-to-male UTI in older adults changes from 50:1 to less than 5:1. An increased risk of urinary stasis, chronic disease states (such as diabetes mellitus) and an impaired immune response contribute to the higher incidence of UTI in the older adult. In men, the prostate typically hypertrophies with ageing, potentially resulting in urinary retention as the urethra narrows. Prostatic secretions are lessened, diminishing their protective, antibacterial effect. In older women, loss of tissue elasticity and weakening of perineal muscles often contribute to the development of a cystocele or rectocele. Resulting changes in bladder and urethral position increase the risk of incomplete bladder emptying.

FAST FACTS

- For females there is a 1 in 3 lifetime incidence of UTI (Jarvis, Chan & Gottlieb, 2014).
- In healthy adult men, however, UTIs are unusual and may prompt additional diagnostic testing.

Physiology review

The urinary tract is normally sterile above the urethra. Adequate urine volume, a free flow from the kidneys through the urinary meatus and complete bladder emptying are the most important mechanisms in maintaining sterility. Any pathogens that enter and contaminate the distal urethra are then washed out during voiding. Other defences for maintaining sterile urine include its normal acidity and the bacteriostatic properties of the bladder and urethral cells. The peristaltic activity of the ureters and a competent vesicoureteral junction help maintain sterility of the upper urinary tract. As the ureter enters the bladder, its distal portion tunnels between the mucosa and muscle layers of the bladder wall (see Figure 26.1). During voiding, increased *intravesicular* (within the bladder) pressure compresses the ureter, preventing **reflux** or backflow of urine towards the kidneys. In males, a long urethra and the antibacterial effect of zinc in prostatic fluid also help prevent contamination of this normally sterile environment.

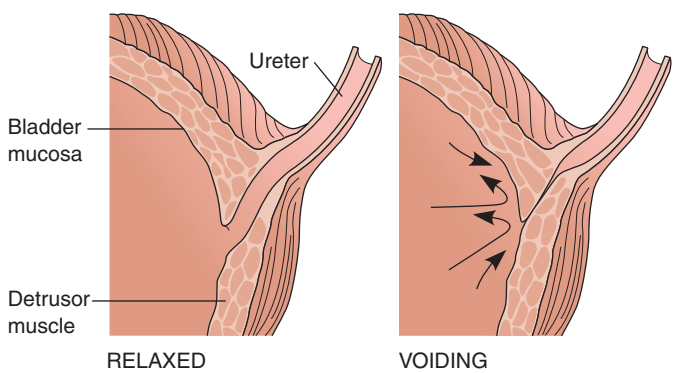

FIGURE 26.1 ■ A competent vesicoureteral junction. Note how increased intravesicular pressure during voiding occludes the distal portion of the ureter, preventing reflux

Pathophysiology and manifestations

Pathogens usually enter the urinary tract by ascending from the mucous membranes of the perineal area into the lower urinary tract. Bacteria that have colonised the urethra, vagina or perineal tissues are the usual source of infection (Porth & Matfin, 2009). From the bladder, bacteria may continue to ascend the urinary tract, eventually infecting the *parenchyma* (functional tissue) of the kidneys (Fauci et al., 2008). Haematogenous spread of infection to the urinary tract is rare. Infections introduced in this manner are usually associated with previous damage or scarring of the urinary tract. Bacteria introduced into the urinary tract may cause asymptomatic bacteriuria or an inflammatory response with manifestations of UTI.

Urinary tract infections can be categorised in several ways. Anatomically, UTIs may affect the lower or the upper urinary tract. Lower urinary tract infections include *urethritis*, inflammation of the urethra; *prostatitis*, inflammation of the prostate gland (discussed in Chapter 47); and **cystitis**, inflammation of the urinary bladder. The most common upper urinary tract infection is **pyelonephritis**, inflammation of the kidney and renal pelvis. The infection may involve superficial tissues such as the bladder mucosa or may invade other tissues such as prostate or renal tissues. Epidemiologically, UTIs are identified as community-acquired infections or **healthcare-associated infections** associated with catheterisation.

Cystitis

Cystitis, inflammation of the urinary bladder, is the most common UTI. The infection tends to remain superficial, involving the bladder mucosa. The mucosa becomes hyperaemic (red) and may haemorrhage (see Figure 26.2). The inflammatory response results in pus formation, causing the classic manifestations associated with cystitis. Typical presenting symptoms of cystitis include **dysuria** (painful or difficult urination), urinary frequency and **urgency** (a sudden, compelling need to

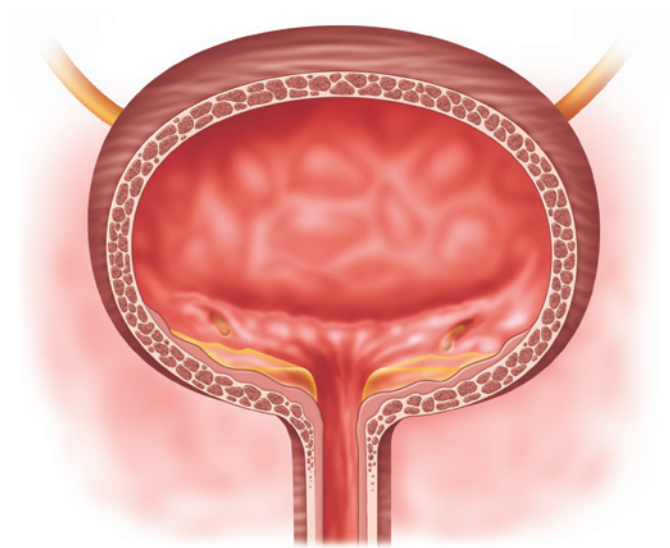

FIGURE 26.2 ■ Appearance of the bladder wall affected by cystitis

urinate), and **nocturia** (voiding two or more times at night). In addition, the urine may be foul smelling and cloudy (*pyuria*) or bloody (**haematuria**) because of mucus, excess white cells in the urine and bleeding of the inflamed bladder wall. Suprapubic pain and tenderness also may be present. See the box below for manifestations of cystitis.

Cystitis occurs most frequently in adult females, usually because of colonisation of the bladder by bacteria normally found in the lower gastrointestinal tract. These bacteria gain entry by ascending the short, straight female urethra. In addition to the risk factors listed above, personal hygiene practices and voluntary urinary retention can contribute to the risk of UTI in women.

Older people may not experience the classic symptoms of cystitis. Instead, they often present with non-specific manifestations such as nocturia, incontinence, confusion, behaviour change, lethargy, anorexia or 'just not feeling right'. Fever and hypothermia may also be present.

Although the bacteriostatic effect of prostatic fluid and a longer urethra provide an effective barrier to bladder infection for adult males, the prostatic hypertrophy commonly associated with ageing increases the risk of cystitis in elderly males. An enlarged prostate can impede urine flow, leading to incomplete bladder emptying and urinary stasis. Bacteria are not completely flushed with voiding, allowing colonisation of the bladder.

Cystitis is usually uncomplicated and readily responds to treatment. Severe or prolonged infection may lead to sloughing of bladder mucosa and ulcer formation; when left untreated, the infection can ascend to involve the kidneys. Chronic cystitis can also lead to bladder stones (discussed later in this chapter).

Catheter-associated UTI

At least 20% (Wynne et al., 2014) of hospitalised people with indwelling urinary catheters develop bacteriuria. The longer the catheter remains in place, the greater the risk of infection. Bacteria, including *E. coli*, *Proteus*, *Pseudomonas* and *Klebsiella*, reach the bladder either by migrating through the column of urine within the catheter or by moving up the mucous sheath of the urethra outside the catheter (Fauci et al., 2008). Bacteria enter the catheter system at the connection between the catheter and drainage system or through the emptying tube of the drainage bag. Colonisation of perineal skin by bowel flora is a common source of infection in catheterised women.

Catheter-associated UTIs are often asymptomatic. Gram-negative bacteraemia is the most significant complication associated with these. Most catheter-associated UTIs resolve quickly when the catheter is removed and a short course of antibiotics is given. Intermittent catheterisation carries a lower risk of infection than does an indwelling catheter and is preferred for those who are unable to empty their bladder by normal voiding.

Pyelonephritis

Pyelonephritis is inflammation of the renal pelvis and parenchyma, the functional kidney tissue. *Acute pyelonephritis* is a bacterial infection of the kidney; *chronic pyelonephritis* is associated with repeated non-bacterial infections and inflammatory processes that may be metabolic, chemical or immunological in origin.

ACUTE PYELONEPHRITIS Acute pyelonephritis usually results from an infection that ascends to the kidney from the lower urinary tract. Asymptomatic bacteriuria or cystitis can lead to acute pyelonephritis. Risk factors include pregnancy (because of slowed ureteral peristalsis), urinary tract obstruction and congenital malformation. Urinary tract trauma, scarring, calculi (stones), kidney disorders such as polycystic or hypertensive kidney disease, and chronic diseases such as diabetes may also contribute to pyelonephritis. *Vesicoureteral reflux*, a condition in which urine moves from the bladder back towards the kidney, is a common risk factor in children who develop pyelonephritis and is also seen in adults when bladder outflow is obstructed.

The infection spreads from the renal pelvis to the renal cortex. The pelvis, calyces and medulla of the kidney are primarily affected, with white blood cell (WBC) infiltration and inflammation. The kidney becomes grossly oedematous. Localised abscesses may develop on the cortical surface of the kidney. As with cystitis, *E. coli* is the organism responsible for 80–90% (KHA, 2015) of the cases of acute pyelonephritis. Other organisms commonly found include *Proteus* and *Klebsiella*, bacteria that normally inhabit the intestinal tract.

The onset of acute pyelonephritis is typically rapid, with chills and fever, malaise, vomiting, flank pain, costovertebral tenderness, urinary frequency and dysuria (see the 'Manifestations' box below). Symptoms of cystitis also may be present. The older adult may present with a change in behaviour, acute confusion, incontinence or a general deterioration in condition.

CHRONIC PYELONEPHRITIS Chronic pyelonephritis involves chronic inflammation and scarring of the tubules and interstitial tissues of the kidney and is a common cause of chronic renal failure. It may develop as a result of ascending

MANIFESTATIONS Cystitis

- Dysuria
- Pyuria
- Frequency
- Haematuria
- Urgency
- Suprapubic discomfort
- Nocturia

MANIFESTATIONS Acute pyelonephritis

URINARY
- Urinary frequency
- Dysuria
- Pyuria
- Haematuria
- Flank pain
- Costovertebral tenderness

SYSTEMIC
- Vomiting
- Diarrhoea
- Acute fever
- Shaking chills
- Malaise

UTIs or other conditions that damage the kidneys, such as hypertension, vascular conditions, severe vesicoureteral reflux or obstruction of the urinary tract.

The person with chronic pyelonephritis may be asymptomatic or have mild manifestations such as urinary frequency, dysuria and flank pain. Hypertension can develop as kidney tissue is destroyed.

FAST FACTS

- The most common route of entry for a urinary tract infection is ascending, from colonisation of the perineal tissues by faecal bacteria (usually *E. coli*), through the urethra, into the bladder (cystitis) and possibly kidney tissue (pyelonephritis).

INTERPROFESSIONAL CARE

Treatment of UTI focuses on eliminating the causative organism, preventing relapse or reinfection, and identifying and correcting any contributing factors. Drug treatment with antibiotics and urinary anti-infectives is commonly used. In some cases, surgery may be indicated to correct contributing factors.

Diagnosis

Laboratory testing for UTI includes:

- *Urinalysis*, to assess for pyuria, bacteria and blood cells in the urine. A bacteria count greater than 10×10^6/L suggests infection. Rapid tests for bacteria in the urine include using a *nitrite dipstick* (which turns pink in the presence of bacteria) and the *leucocyte esterase test*, which is positive in the presence of WBCs (neutrophils), indicating infection or inflammation.

  Urine should be a midstream clean-catch specimen in a sterile container. If necessary, catheterisation or 'mini-cath', with aseptic technique, may be used. However, catheterisation should be avoided if possible to reduce the risk of further infection. (A 'Diagnostic tests' box for nursing care related to collecting a urinalysis specimen is included in Chapter 25.)
- *Gram stain of the urine* may be done to identify the infecting organism by shape and characteristic (Gram-positive or Gram-negative).
- *Urine culture and sensitivity* tests may be ordered to identify the infecting organism and the most effective antibiotic. Culture requires 24 to 72 hours, so treatment to eliminate the most common organisms may be initiated without culture followed by antibiotic therapy according to sensitivity results.
- *WBC with differential* may be done to detect typical changes associated with infection, such as *leucocytosis* (elevated WBC) and increased numbers of neutrophils.

In men and in adult women with recurrent infections or persistent bacteriuria, additional diagnostic testing may be ordered to evaluate for structural abnormalities and other contributing factors:

- *Intravenous pyelography (IVP)* is used to evaluate the structure and excretory function of the kidneys, ureters and bladder. As the kidneys clear an intravenously injected contrast medium from the blood, the size and shape of the kidneys, their calyces and pelvises, the ureters and the bladder can be identified and structural or functional abnormalities, such as vesicoureteral reflux, may be detected.
- *Antegrade pyelogram* is used when an IVP fails to identify an obstruction in the ureters or bladder. Contrast medium is injected into the collecting system of the kidney and renal flow is monitored by radiology.
- *Computed tomography (CT scan)* may be used in preference to IVP for identifying renal calculi. It uses a radiation beam to build a three-dimensional picture of the renal system.
- *Ultrasound* is a non-invasive technique that utilises sound waves to visualise soft tissue masses, obstructions, some renal calculi and renal blood flow.
- *Micturating cystogram (MCU)* is a procedure conducted on infants or children, and involves instilling contrast medium into the bladder, then using x-rays to assess the bladder and urethra when filled and during voiding. This study can detect structural or functional abnormalities of the bladder and urethral strictures. This test has a lower risk of allergic response to the contrast dye than IVP.
- *Cystoscopy*, direct visualisation of the urethra and bladder through a cystoscope, may be used to diagnose conditions such as prostatic hypertrophy, urethral strictures, bladder calculi, tumours, polyps or diverticula, and congenital abnormalities. A tissue biopsy may be obtained during the procedure and other interventions performed (e.g. stone removal or stricture dilation).
- *Manual pelvic* or prostate examinations are performed to assess for structural changes of the genitourinary tract, such as prostatic enlargement, cystocele or rectocele.

Nursing implications for these diagnostic procedures are presented in Chapter 25.

Medications

Most uncomplicated infections of the lower urinary tract can be treated with a short course of antibiotic therapy. Upper urinary tract infections, in contrast, usually require longer treatment (2 or more weeks) to eradicate the infecting organism.

Short-course therapy (either a single antibiotic dose or a 3-day course of treatment) reduces treatment cost, increases compliance and has a lower rate of side effects. Single-dose therapy is associated with a higher rate of recurrent infection and continued vaginal colonisation with *E. coli*, making a 3-day course of treatment the preferred option for uncomplicated cystitis. Oral trimethoprim (TMP) or cephalexin as a first choice may be ordered (Jarvis et al., 2014). Treatment for acute uncomplicated cystitis should be individualised when choosing an antibiotic, as no single agent is considered best (Gilbert & Weiner, 2013).

Men and women with pyelonephritis, urinary tract abnormalities, stones or a history of previous infections with antibiotic-resistant infections may be prescribed a variety of drugs including cephalexin, amoxicillin/clavulanic acid, trimethoprim or ciprofloxacin as a 7- to 10-day course. Those with severe illness may need hospitalisation for initial parenteral treatment, changing to oral therapy when there is clinical improvement. Drugs used for severe illness or sepsis associated with UTI

include ciprofloxacin, gentamicin or ceftriaxone (Rocephin), or amoxicillin/ampicillin. (See Chapter 11 for the nursing implications for antibiotic therapy.)

The outcome of treatment for UTI is determined by follow-up urinalysis and culture. *Cure*, as evidenced by no pathogens present in the urine, is the desired outcome. When therapy fails to eradicate bacteria in the urine, it is known as unresolved bacteriuria. *Persistent bacteriuria* or *relapse* occurs when a persistent source of infection causes repeated infection after initial cure. *Reinfection* is the development of a new infection with a different pathogen following previous successful UTI treatment (McPhee, Papadakis & Rabow, 2012).

CONSIDERATION FOR PRACTICE

Follow-up urine culture should be performed 10 days to 2 weeks following completion of antibiotic therapy for UTI to ensure bacterial eradication from the urinary tract.

Individuals experiencing frequent symptomatic UTIs may be treated with prophylactic antibiotic therapy with a drug such as TMP or nitrofurantoin (Furadantin, Macrodantin). TMP and nitrofurantoin do not achieve effective plasma concentrations at recommended doses, but do reach effective concentrations in the urine. Nitrofurantoin also may be used to treat UTI in pregnant women. Nursing implications for these urinary anti-infectives are outlined in the 'Medication administration' box below.

Antibiotics and urinary anti-infectives are not generally recommended to treat asymptomatic bacteriuria in catheterised people. The recommended treatment for catheter-associated UTI is removal of the indwelling catheter followed by a 10- to 14-day course of antibiotic therapy to eliminate the infection.

Surgery

Surgery may be indicated for recurrent UTI if diagnostic testing indicates calculi, structural anomalies or strictures that contribute to the risk of infection. Table 26.1 lists major causes of urinary tract obstruction that may contribute to UTI.

Stones or *calculi* in the renal pelvis or in the bladder are an irritant and provide a matrix for bacterial colonisation. Treatment may include surgical removal of a large calculus from the renal pelvis or cystoscopic removal of bladder calculi. *Percutaneous*

MEDICATION ADMINISTRATION Urinary anti-infectives

URINARY ANTI-INFECTIVES

Nitrofurantoin (Furadantin, Macrodantin)
Trimethoprim (Bactrim, Triprim)

Urinary anti-infectives are usually used prophylactically to prevent recurrence of UTI in those with frequent symptomatic infections. Nitrofurantoin may be used to treat UTI in pregnant women but only if medically essential.

Nursing responsibilities

- Ensure adequate fluid intake (1500 to 2000 mL/day) to maintain a urine output of at least 1500 mL of urine per 24 hours. Do not overhydrate.
- Administer with meals to minimise GI side effects, such as nausea, gastric upset and abdominal cramping.
- Trimethoprim is contraindicated for use in people with renal or hepatic impairment; nitrofurantoin is contraindicated for those with impaired renal function. Report abnormal laboratory values such as elevated creatinine or BUN, decreased eGFR, bilirubin, alanine aminotransferase (ALT), aspartate aminotransferase (AST) and lactic dehydrogenase (LDH).
- Monitor for skin irritations, rash, nausea, vomiting and fever. If bruising or unusual bleeding occurs, discontinue the drug and notify the doctor.
- Use with caution in older or chronically ill people. Monitor closely for adverse effects.
- Do not administer trimethoprim to pregnant women unless essential because of possible adverse effects on the foetus.
- Monitor the person taking nitrofurantoin for an acute or chronic pulmonary reaction with manifestations of dyspnoea, cough, chills, fever and chest pain. Discontinue the drug and notify the doctor.
- Nitrofurantoin may cause peripheral neuropathy, especially in older individuals and adult diabetics. Notify the doctor if symptoms develop.
- Nitrofurantoin oral suspension may stain the teeth; therefore, instruct the person to rinse the mouth thoroughly after administering.
- Monitor for signs of phenytoin toxicity (sedation, ataxia and increased blood levels) if trimethoprim is given concurrently. Phenytoin doses may need to be reduced.

Health education for the person and family

- These drugs are used with good hygiene practices to prevent UTI recurrence. Take as directed even when no symptoms are present, until the course is completed.
- Drink six to eight glasses of water a day (2500–3500 mL) while taking these drugs.
- Take the drug with meals or food to reduce gastric effects; however, avoid milk products because they may interfere with absorption.
- Trimethoprim should not be taken during pregnancy. Contact your doctor before attempting to become pregnant.
- Contact your doctor if you develop any of the following: chest pain, difficulty breathing, cough, chills and fever; numbness and tingling or weakness of the extremities; rash or pruritus (itching), bruising or bleeding.
- If you are taking an oral suspension of nitrofurantoin, rinse your mouth thoroughly after each dose to avoid staining the teeth.
- Nitrofurantoin turns the urine brown. This is not harmful and disappears when the drug is discontinued.
- If you are taking trimethoprim along with phenytoin (Dilantin) or a related anticonvulsant, contact your doctor if you become sedated or begin to stagger.

TABLE 26.1 Major causes of urinary tract obstruction by location

LOCATION	OBSTRUCTIVE PROCESS
Kidney pelvis	Calculi (stones) Polycystic kidney disease Infection and scarring
Ureters	Calculi Scarring and stricture Congenital defects or strictures External processes such as pregnancy, tumours, lymph node enlargement
Bladder	Neurogenic bladder Tumours Calculi and other foreign bodies
Urethra	Benign prostatic hypertrophy Tumours Scarring and stricture Trauma

ultrasonic pyelolithotomy or *extracorporeal shock wave lithotripsy* (described in the next section of this chapter) may be used instead of surgery to crush and remove stones. (See the 'Diagnostic tests' box in Chapter 25 for nursing care related to cystoscopy.)

Ureteroplasty, surgical repair of a ureter, may be indicated for structural abnormality or stricture of a ureter. This may be combined with a ureteral reimplantation if vesicoureteral reflux is present. The person returns from these surgeries with an indwelling urinary catheter (Foley or suprapubic) and a **ureteral stent** (a thin catheter inserted into the ureter to provide for urine flow and ureteral support) which remains in place for 3 to 5 days. Care of those with a ureteral stent is outlined in the box below.

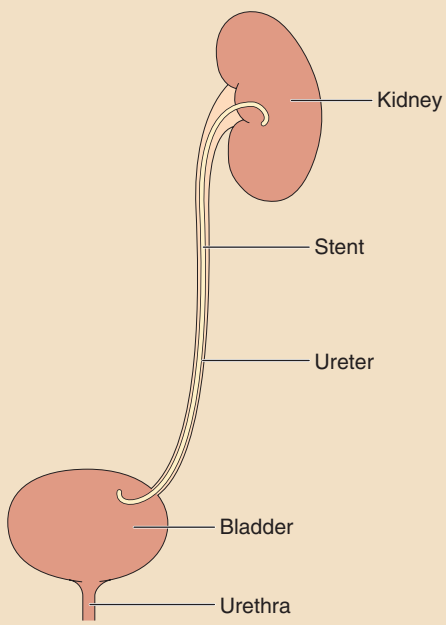
Complementary therapies

Complementary therapies such as aromatherapy or herbal preparations, particularly cranberry juice, have been advocated for use in conjunction with antibiotics to treat UTI. However, despite being recommended for prevention and treatment of UTI, cranberry juice and capsule studies have been inconclusive as to their effectiveness. While some studies have shown there may be benefits from cranberry juice, in controlled studies cranberry juice does not prevent UTIs (KHA, 2015). There are also risks of interaction between cranberry juice and other drugs—for example, warfarin. People who wish to take herbal remedies should consult their doctor because of drug interaction risks.

NURSING CARE OF THE PERSON with a ureteral stent

Ureteral stents are used to maintain patency and promote healing of the ureters (see figure below). A stent may be temporary, used during and after a surgical procedure, or it may be used for longer periods in individuals with ureteral obstruction due to tumours, strictures or other causes.

Stents may be positioned during surgery or cystoscopy. They are made of a non-toxic material such as silicone or polyurethane, with side drainage holes placed along the length of the stent. Stents are radiopaque for easy radiographic identification and one or both ends of the stent may be pigtail or J shaped to prevent migration or dislodgement.



- Label all drainage tubes, including stents, for easy identification. Attach each catheter and stent to a separate closed drainage system. *Careful labelling allows close monitoring of output from all sources and reservoirs. Separate drainage systems minimise the risk of infection.*
- If the stent has been brought to the surface, secure it and maintain its position. The stent is usually placed in the renal pelvis. *It is important to secure it well to prevent trauma to the kidney, inadvertent removal of the stent and ureter obstruction.*
- Monitor urine output, including colour, consistency and odour. Monitor for signs of infection, bleeding, fever, tachycardia, pain, haematuria and cloudy or foul-smelling urine. *The stent facilitates urine flow but may become obstructed because of bleeding, calculi or sediment. Obstruction may result in hydronephrosis and kidney damage. The stent itself is a foreign body in the urinary tract and can increase the risk of UTI.*
- Maintain fluid intake, encouraging the use of fluids that acidify urine, such as low-sugar apple, cranberry and blueberry juice. *The stent can precipitate calculus formation as well as UTI. Increasing fluid intake and acidifying the urine help to prevent these complications.*
- For an indwelling stent, stress the need for regular follow-up to monitor for and prevent complications such as UTI and calculi. *The person with an indwelling stent may tend to forget that the stent is in place and become lax in compliance with follow-up and preventive measures.*

Nursing care

Health promotion

Teach measures to prevent UTI to all sexually active women, particularly young ones. Encourage the maintenance of a generous fluid intake of 2000–2500 mL per day, increasing intake during hot weather or strenuous activity. Discuss the need to avoid voluntary urinary retention, emptying the bladder every 3 to 4 hours. Instruct women to cleanse the perineal area from front to back after voiding and defecating. Teach to void before and after sexual intercourse to flush out bacteria introduced into the urethra and bladder. Teach measures to maintain the integrity of perineal tissues: avoid bubble baths, feminine hygiene sprays and vaginal douches; wear cotton briefs, avoid synthetic materials as they may irritate the perineal and vaginal mucosa. Postmenopausal women may be advised to use hormone replacement therapy or oestrogen cream. Avoid excess intake of milk and milk products, non-acidic fruit juices and sodium bicarbonate (baking soda), which is an alkaline substance.

Assessment

Focused assessment data for the person with a UTI include the following:

- *Health history:* current symptoms, including frequency, urgency, burning on urination, voidings per night; colour, clarity and odour of urine; other manifestations such as lower abdominal, back or flank pain, nausea or vomiting, fever; duration of symptoms and any treatment attempted; history of previous UTIs and their frequency; possibility of pregnancy and type of birth control used; chronic diseases such as diabetes; current medications and any known allergies.
- *Physical examination:* general health; vital signs including temperature; abdominal shape, contour, tenderness to palpation (especially suprapubic); percuss for costovertebral tenderness (see Box 25.1).

See Chapter 25 for complete nursing assessment of the urinary system.

Nursing diagnoses and interventions

General health, abilities for self-care and risk factors that may contribute to UTI are considered when planning and implementing nursing care for the person with a UTI. Priority nursing diagnoses focus on comfort, urinary elimination and teaching/learning needs. A nursing care plan for the person with cystitis can be found below.

Pain

Pain is a common manifestation of both lower and upper UTI. Urinary tract pain is caused primarily by distension and increased pressure within the tract. The severity of the pain is related to the rate at which inflammation and distension develop.

In cystitis, inflammation causes a sensation of fullness; dull, constant suprapubic pain; and possibly lower back pain. The inflamed bladder wall and urethra cause dysuria, pain and burning on urination. Bladder spasms may develop, causing periodic severe, stabbing discomfort. Pain associated with pyelonephritis is often steady and dull, localised to the outer abdomen or flank region. Urological disorders rarely cause central abdominal pain.

- Assess pain: timing, quality, intensity, location, duration and aggravating and alleviating factors. *A change in the nature, location or intensity of the pain could indicate an extension of the infection or a related but separate problem.*
- Teach or provide comfort measures such as warm baths, warm packs or heating pads, and balanced rest and activity. Systemic analgesics, urinary analgesics or antispasmodic medication may be used as ordered. *Warmth relaxes muscles, relieves spasms and increases local blood supply. Because pain can stimulate a stress response and delay healing, it should be relieved when possible.*
- Increase fluid intake unless contraindicated. *Increased fluid dilutes urine, reducing irritation of the inflamed bladder and urethral mucosa.*
- Instruct to notify primary care provider if pain and discomfort continue or intensify after therapy is initiated. *Pain and discomfort in voiding typically are relieved within 24 hours of the initiation of antibiotic therapy. Continued discomfort may indicate a complicated UTI or other urinary tract disorder.*

CONSIDERATION FOR PRACTICE

The older adult with a UTI may not complain of dysuria with a UTI. Be alert for other manifestations of UTI such as incontinence or cloudy or foul-smelling urine. Inflammatory and immune responses tend to diminish with ageing, reducing the irritative effects of UTI symptoms.

Impaired urinary elimination

Inflammation of the bladder and urethral mucosa affects the normal process and patterns of voiding, causing frequency, urgency and burning on urination, as well as nocturia. Urine may be tinged with blood, cloudy and foul smelling. The person with short- or long-term urinary retention requires additional measures in assessing for and preventing UTI. (See the section on urinary retention later in this chapter.)

- Monitor (or give instructions to monitor) colour, clarity and odour of urine. *Urine should return to clear yellow within 48 hours, unless drug therapy causes a change in the colour of urine. If clarity does not return, further investigation may be necessary.*

CONSIDERATION FOR PRACTICE

Provide for close, easy access to a bedpan, urinal, commode or bathroom. Make sure that lighting is adequate and that pathways are free of obstacles. Frequency, urgency and nocturia increase the risk of urinary incontinence and, importantly, of injury due to falls, particularly in the older or debilitated individual.

NURSING CARE PLAN A person with cystitis

Marja Waisanen is a 25-year-old second-year university student. She was recently married and lives in an apartment with her husband near the university she attends. Mrs Waisanen has never been pregnant and uses a diaphragm for birth control. She presents at the local family planning clinic complaining of lower back pain, frequency, urgency and burning on urination that began the day before.

ASSESSMENT

Patricia Purcel, RN, admits Mrs Waisanen to the clinic and completes an assessment. Mrs Waisanen denies having had similar symptoms in the past or ever having been diagnosed with a urinary tract infection. The data collected show a constant dull ache that does not change with movement. Mrs Waisanen feels the need to urinate almost constantly, but experiences difficulty in starting her stream, with a burning pain and cramping when voiding. She reports getting up four times the night before to urinate. She denies painful intercourse and states that her last menstrual period began 2 weeks previously. A physical examination reveals: BP 112/68; P 90 and regular, T afebrile. Suprapubic tenderness was noted but no flank or costovertebral angle tenderness. A clean-catch urine specimen shows haematuria, multiple WBCs and a bacteria count greater than 10^6/L.

After assessing for allergies and diabetes, Mrs Waisanen was prescribed trimethoprim (TMP) 160/800 mg PO bd for 3 days and paracetamol 1 g PO every 4 hours as needed for pain; with a maximum of 4 g per day. She was also advised to increase her fluid intake to at least 3000 mL every day to flush out the urinary system.

Mrs Waisanen is instructed to return to the clinic in 7 days for a follow-up urine culture or sooner if her symptoms do not improve.

DIAGNOSES

- *Pain* related to infection and inflammatory process in the urinary tract.
- *Impaired urinary elimination* related to inflammation as evidenced by frequency, urgency, nocturia and dysuria.
- *Deficient knowledge* related to lack of information about risk factors for UTI.

PLANNING

- Plan for effective pain management.
- Plan for elimination of burning on urination.
- Plan for effective psychological care.
- Plan to monitor for fluid balance.
- Plan for incorporating health prevention activities into daily routine.

Expected outcomes

- Relief of lower back pain and burning on urination.
- Regains a normal voiding pattern without frequency, urgency, nocturia and abnormal urine characteristics.
- Verbalises understanding of the disease process, related risk factors, follow-up instructions and symptoms of any recurrence indicating the need for medical attention.

IMPLEMENTATION

- Teach comfort measures: warm baths, a heating pad on low heat applied to her lower back or abdomen, rest, increased fluid intake, avoiding caffeinated beverages and taking paracetamol as ordered.
- Advise to avoid the use of antacids when taking trimethoprim-sulfamethoxazole and to take the medication on an empty stomach.
- Advise to stop taking the medication and return to doctor if rash and/or skin irritation occurs which may signify allergic response to medication.
- Advise to refrain from sexual intercourse until infection and inflammation have cleared to avoid further irritation of inflamed tissues.
- Discuss the possible relationship between using a diaphragm for birth control and UTI in women.
- Discuss dietary and hygiene practices to prevent UTI, symptoms indicating the need for further intervention and the risks of under treatment.
- Suggest how strategies designed to prevent further attacks of UTI can be incorporated into daily activities.
- Ensure details of Mrs Waisanen's history, diagnosis, treatment and response are recorded on the appropriate documents.

EVALUATION

On her follow-up visit, Mrs Waisanen reports that her symptoms and urine cleared within about a day after starting the antibiotic and she has had no further problems. She has seen her healthcare practitioner to change her birth control to oral contraceptives, increased her intake of fluid and vitamin C, and no longer puts off urinating until she 'has time to go'.

CRITICAL THINKING IN THE NURSING PROCESS

1. Which physiological and psychosocial factors put Mrs Waisanen at risk of developing a UTI?
2. Why is it necessary to ascertain whether or not Mrs Waisanen had allergies or diabetes? What would be the implications of these for the prescribed treatment?
3. Why was it appropriate to use short-course therapy for Mrs Waisanen? What was the importance of advising her to return if the symptoms did not clear?

REFLECTION ON THE NURSING PROCESS

1. Compare and contrast the benefits and disadvantages to short-course therapy versus conventional therapy for UTI in this case.
2. What are the potential dangers of repeated attacks of UTIs and why is it important to prevent these?
3. What lessons from this scenario could be used in health education programs to promote awareness of UTI and its treatment?

- Instruct to avoid caffeinated drinks, including coffee, tea and cola; citrus juices; drinks containing artificial sweeteners; and alcoholic beverages. *Caffeine, citrus juices and artificial sweeteners irritate bladder mucosa and the detrusor muscle, and can increase urgency and bladder spasms.*

- Use strict aseptic technique and a closed urinary drainage system when inserting a straight or indwelling urinary catheter. Insert indwelling catheters to the full recommended length (5–6 cm in women and 15–25 cm in men) until urine flows before inflating the balloon. Never inflate the balloon until urine flows freely and stop if pain is felt. *Bacteria colonising the perineal tissues or on the nurse's hands can be introduced into the bladder during catheterisation. Aseptic technique reduces this risk. Inflation of the balloon while in the urethra damages urethral tissues and can cause significant discomfort. See the 'Translation to practice' box below for evidence-based practice for catheterisation.*

CONSIDERATION FOR PRACTICE

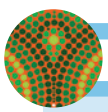
In males, fully insert the catheter to the 'Y' connection; in females, 2.5 cm beyond the point of urine flow (SUNA, 2014).

- When possible, use intermittent straight catheterisation to relieve urinary retention. Remove indwelling urinary catheters as soon as possible. *Using intermittent straight catheterisation allows the bladder to fill and completely empty in a more normal manner, maintaining physiological function. The risk of infection associated with an indwelling catheter is about 3–5% per day of catheterisation* (Fauci et al., 2008; Gilbert & Weiner, 2013).

Promoting health maintenance

The person with a urinary tract infection is at an increased risk of future UTI and needs to understand the disease process, risk factors, measures needed to prevent recurrent infection, diagnostic procedures required and appropriate home care. In addition, once the symptoms of UTI are relieved, individual motivation to continue the treatment plan declines. Failure to complete the full course of therapy and recommended follow-up can lead to continued bacteriuria and recurrent infections.

- Teach how to obtain a midstream clean-catch urine specimen. *Ninety per cent of urethral bacteria are cleared in the first 10 mL of voided urine; a midstream specimen is representative of urine in the bladder. Cleansing of the urinary meatus and perineal area reduces contamination of the specimen by external cells and bacteria.*
- Assess knowledge about the disease process, risk factors and preventive measures. *The individual may have little understanding of UTI, its causes and contributing factors.*
- Discuss the prescribed treatment plan and the importance of taking all prescribed antibiotics.
- Help the person develop a plan for taking medications, such as taking them with meals (unless contraindicated) or setting out all doses for the day in the morning. *Missed doses of antibiotic can result in lowered therapeutic blood levels and reduced effectiveness. Taking medication in association with meals helps with remembering doses.*



TRANSLATION TO PRACTICE Evidence-based practice: catheterisation

Insertion of an indwelling (retention) catheter is performed in hospitals and long-term care facilities. The location of the female urethral meatus presents a challenge to maintaining catheter sterility during insertion, whereas the anatomy of the male urethra presents a different set of challenges. Best practice guidelines for inserting the catheter in females is to insert the catheter until urine flows, then advance the catheter a further 2–4 cm to ensure the balloon is clear of the urethra; for males insert the catheter until resistance is felt at the first sphincter, then continue to the Y bifurcation. Ensure the retention balloon is well within the urinary bladder prior to its inflation (ANZUNS, 2013). Insertion to any lesser distance is inadequate to ensure safe balloon inflation without potential damage to the urethra.

IMPLICATIONS FOR NURSING

Nursing fundamentals and skills texts recommend inserting the catheter from 15.25 cm into the male urethra until urine flows. To ensure safe practice and reduce the risk of injury and discomfort, insert a retention catheter to the bifurcation before inflating the balloon.

SAFETY ALERT

Maintain the closed urinary drainage system and use aseptic technique when emptying the catheter drainage bag. Maintain gravity flow, preventing reflux of urine into the bladder from the drainage system. Bacteria can enter the drainage system when its integrity is interrupted as, for example, when disconnecting the catheter from the drainage system or during emptying of the drainage bag. Bacteria can ascend the column of urine to the bladder, causing UTI.

- Provide perineal care on a regular basis and following defecation. Use antiseptic preparations only as ordered. Regular cleansing of perineal tissues reduces the risk of colonisation by bacteria from the bowel or other sources. *While antiseptic solutions may be ordered for catheter care, they can dry perineal tissues and reduce normal flora, increasing the risk of colonisation by pathogens and therefore should not be routinely used.*

CRITICAL THINKING IN PERSON-CENTRED CARE

1. Why is insertion of a urinary catheter frequently a more uncomfortable and difficult procedure for a male than a female? What nursing measures or techniques can be used to reduce this discomfort?
2. Sterile technique is generally used when catheterising people in acute care settings. However, those who require intermittent catheterisation to empty their bladder typically use clean technique. Would clean technique be appropriate in an acute or long-term care setting? Why or why not?

Source: ANZUNS (2013).

CONSIDERATION FOR PRACTICE

Symptoms are largely relieved within 24 to 48 hours of starting antibiotic therapy; however, bacteria may remain in the urinary tract. Completing the prescribed regimen is important to prevent recurrent infections and resistant bacteria.

- Instruct to keep appointments for follow-up and urine culture. *Follow-up urine culture, often scheduled 7 to 14 days after completion of antibiotic therapy, is vital to ensure complete eradication of bacteria and prevention of relapse or recurrence.*
- Teach measures to prevent future UTI (see the preceding 'Health promotion' section). *Keep urine dilute and acidic and void regularly to flush bacteria out of the bladder and urethra. The proximity of the female urethral meatus to the vagina and anus increases the risk of bacterial contamination, especially during intercourse. Bubble baths, feminine hygiene sprays, synthetic fibres and douches may dry and irritate perineal tissues, promoting bacterial growth. Maintain adequate fluid intake to ensure renal function and production of urine.*

Community-based care

Because both upper and lower urinary tract infections are usually managed in the community, health education is the most important nursing intervention. Provide instruction on the following topics:

- Risk factors for UTI and how to minimise or eliminate these factors through increased fluid intake, regular elimination and personal hygiene measures.
- Early manifestations of UTI and the importance of seeking medical intervention promptly.
- Maintaining optimal immune system function by attending to contributory physical and psychosocial stressors, such as lack of adequate rest, poor nutrition and high levels of emotional stress.
- The importance of completing the prescribed treatment and keeping follow-up appointments.
- Minimising the risk of UTI when an indwelling urinary catheter is necessary:
  a. Use alternatives to an indwelling catheter when possible. For urinary incontinence, try scheduled toileting, incontinence pads or external catheters if possible. For urinary retention, teach the person or a family member to perform straight catheterisation every 3 to 4 hours using clean technique.
  b. Teach care measures such as perineal care, managing and emptying the collection chamber, maintaining a closed system and bladder irrigation or flushing if ordered when an indwelling catheter is necessary.

THE PERSON WITH URINARY CALCULI

Urinary calculi, stones in the urinary tract, are the most common cause of upper urinary tract obstruction (Porth & Matfin, 2009). The term **lithiasis** means 'stone formation'; when the stones form in the kidney, it is known as *nephrolithiasis*; when they form elsewhere in the urinary tract (e.g. the bladder), it is called *urolithiasis*. Stones may form and obstruct the urinary tract at any point (see Figure 26.3). In the Australia, the United States and other industrialised countries, renal or kidney stones are the most common.

Incidence and risk factors

Urolithiasis is the third most common urological condition. It affects more males (1:10) than females (1:35) and in Australia the Indigenous population is at greater risk than non-Indigenous Australians. The incidence may vary according to geographical areas. Most people affected are in young or middle adulthood.

Although the majority of stones are idiopathic (having no demonstrable cause), a number of risk factors have been identified. The greatest risk factor for stone formation is a prior personal or family history of urinary calculi. A genetic predisposition towards the accumulation of certain mineral substances in the urine or a congenital lack of protective factors may explain the familial link. Other identified risk factors include dehydration with resultant increased urine concentration, immobility and excess dietary intake of calcium, oxalate or proteins. Gout, hyperparathyroidism and urinary stasis or repeated infections also contribute to calculus formation.

Physiology review

Normally, a balance exists in the kidneys between the need to conserve water and to eliminate poorly soluble materials such as calcium salts. This balance is affected by factors such as diet, environmental temperature and activity. Protective inorganic and organic substances in the urine, such as pyrophosphate, citrate and glycoproteins, normally inhibit stone formation.

Pathophysiology

Three factors contribute to urolithiasis: supersaturation, nucleation and lack of inhibitory substances in the urine.

When the concentration of an insoluble salt in the urine is very high (supersaturated), crystals may form. Usually, these crystals disperse and are eliminated because the chemical bonds holding them together are weak. However, a nucleus of crystals may develop stable bonds to form a stone with crystals forming around an organic matrix or mucoprotein nucleus. The stimulus required to initiate crystallisation in supersaturated urine may be minimal. Ingesting a meal high in insoluble salt, or decreased fluid intake as occurs during sleep, allows the concentration to increase to the point where salt precipitation occurs, and stones are formed and grow. When fluid intake is adequate, no stone growth occurs. The acidity or alkalinity of the urine and the presence or absence of calculus-inhibiting compounds also affect lithiasis.

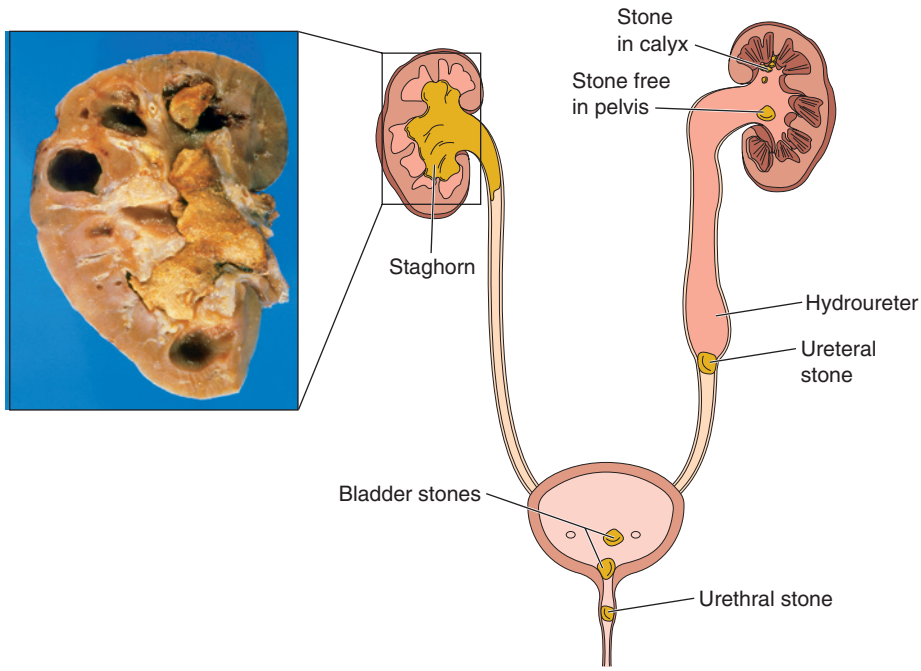


FIGURE 26.3 ■ Development and location of calculi within the urinary tract

Source: Image © Dr E. Walker/Science Source.

Most (75–80%) kidney stones are *calcium stones*, composed of calcium oxalate and/or calcium phosphate. These stones are generally associated with high concentrations of calcium in the blood or urine. *Uric acid stones* develop when the urine concentration of uric acid is high. They are more common in men and may be associated with gout. Genetic factors contribute to the development of uric acid stones and calcium stones. *Struvite stones* are associated with UTI caused by urease-producing bacteria such as *Proteus*. These stones can become very large, filling the renal pelvis and calyces, and are often called *staghorn stones* because of their shape. *Cystine stones* are rare and are associated with a genetic amino acid metabolic defect. The types of renal calculi, contributing factors and recommended dietary modifications are listed in Table 26.2.

Manifestations

The symptoms caused by urinary calculi vary with their size and location (see the 'Manifestations' box below). Manifestations

TABLE 26.2 Risk factors and interventions for renal calculi

STONE TYPE AND INCIDENCE	RISK FACTORS	MANAGEMENT
Calcium phosphate and/or oxalate 75–80%	Hypercalciuria and hypercalcaemia: hyperparathyroidism, immobility, bone disease, vitamin D intoxication, multiple myeloma, renal tubular acidosis, prolonged steroid intake, alkaline urine, dehydration, inflammatory bowel disease	Pharmacology: thiazide diuretics, phosphates, calcium-binding agents Dietary: limit foods high in calcium and oxalate, increase foods that acidify urine Other: increase hydration, exercise
Struvite 15–20%	UTIs, especially *Proteus* infections	Pharmacology: antibiotic therapy for UTI Other: surgical intervention or lithotripsy to remove stone
Uric acid 5–10%	Gout, increased purine intake, acid urine	Pharmacology: potassium citrate, allopurinol Dietary: low-purine diet Other: increase hydration
Cystine (uncommon)	Genetic defect, acid urine	Pharmacology: penicillamine, sodium bicarbonate Dietary: sodium restriction Other: increase hydration

develop as a result of obstructed urine flow with resulting distension, and tissue trauma caused by passage of the rough-edged, crystalline stone.

FAST FACTS

- Most urinary stones form in the renal pelvis and are composed primarily of calcium salts.
- Loss of calcium from the bones (e.g. due to immobility, osteoporosis) and dehydration are major risk factors for urinary stones.

Calculi affecting the kidney calyces and pelvis may cause few symptoms. If the stone has gradually or partially obstructed urinary flow, dull, aching flank pain may be present, but renal calculi may be silent, without symptoms. Bladder calculi may cause few symptoms other than dull suprapubic pain on exercise or after voiding.

Renal colic—acute, severe flank pain on the affected side—develops when a stone obstructs the ureter, causing ureteral spasm. The pain of renal colic may radiate to the suprapubic region, groin and external genitals (the scrotum or labia). The severity of the pain often causes a sympathetic response with associated nausea, vomiting, pallor and cool, clammy skin.

Manifestations of UTI, including chills and fever, frequency, urgency and dysuria, may accompany urinary calculi at any level. Trauma to the urinary tract by the calculi may cause gross or microscopic haematuria. Gross haematuria may also be the only sign of bladder stones.

Complications

Urinary stones may obstruct urine flow at any point of the urinary tract, leading to complications such as hydronephrosis and urinary stasis with subsequent infection.

MANIFESTATIONS Urinary calculi

KIDNEY STONES
- Often asymptomatic
- Dull, aching flank pain
- Microscopic haematuria
- Manifestations of UTI

URETERAL STONES
- Renal colic
- Acute, severe flank pain on affected side
- Often radiates to suprapubic region, groin and external genitals
- Nausea, vomiting, pallor and cool, clammy skin

BLADDER STONES
- May be asymptomatic
- Dull suprapubic pain, possibly associated with exercise or voiding
- Gross or microscopic haematuria
- Manifestations of UTI

Obstruction

Stones can obstruct the urinary tract at any point from the calyces of the kidney to the distal urethra, impeding the outflow of urine. If the obstruction develops slowly, there may be few or no symptoms, whereas sudden obstruction (e.g. blockage of a ureter by a passing stone) may cause severe manifestations. Urinary tract obstruction can ultimately lead to renal failure. The degree of obstruction, its location and the duration of impaired urine flow determine the effect on renal function.

HYDRONEPHROSIS The kidneys continue to produce urine, causing increased pressure and distension of the urinary tract behind the obstruction. **Hydronephrosis**, distension of the renal pelvis and calyces, and *hydroureter*, distension of the ureter, are possible results. If the pressure is unrelieved, the collecting tubules, proximal tubules and glomeruli of the kidney are damaged, causing a gradual loss of renal function.

Acute hydronephrosis typically causes colicky pain on the affected side. The pain may radiate into the groin. Chronic hydronephrosis develops slowly and may have few manifestations other than dull, aching back or flank pain. When hydronephrosis is significant, a palpable mass may be felt in the flank region. Haematuria and signs of UTI such as pyuria, fever and discomfort may occur. Gastrointestinal symptoms such as nausea, vomiting and abdominal pain may accompany hydronephrosis (see the 'Manifestations' box). In severe cases, shock caused by pain may develop and urgent treatment may be necessary.

INFECTION The urinary stasis associated with partial or complete obstruction increases the risk of urinary infection in the upper or lower urinary tract.

MANIFESTATIONS Acute and chronic hydronephrosis

ACUTE
- Acute, colicky pain; may radiate into groin
- Haematuria, pyuria
- Fever
- Nausea, vomiting, abdominal pain

CHRONIC
- Dull, aching flank pain
- Haematuria, pyuria
- Fever
- Palpable flank mass

INTERPROFESSIONAL CARE

Management of urinary calculi focuses on relieving acute symptoms, destroying or removing stones, and preventing further stone formation. Asymptomatic stones (those not causing pain, infection or obstruction) are treated conservatively.

Diagnosis

Laboratory and diagnostic tests that may be ordered when urinary calculi are suspected include the following:

- *Urinalysis* to assess for haematuria and the possible presence of WBCs and crystal fragments. The urine pH is helpful in identifying the type of stone.
- *Chemical analysis* of any stones passed in the urine determines the type of stone and suggests measures to prevent further stone formation. Retrieving stones or teaching the person to do so is a nursing responsibility. All urine is strained and may be saved. Any visible stones or sediment is sent for analysis.
- *Urine calcium*, *uric acid* and *oxalate* levels measure the amount of these substances excreted over a 24-hour period and may be assessed to help identify possible causes of lithiasis. Elevated calcium levels occur in hyperparathyroidism, Cushing's syndrome and osteoporosis, all of which may contribute to lithiasis. Uric acid levels may be elevated in people with gout and those at risk of forming uric acid calculi. Urine oxalate excretion may help to differentiate calcium oxalate from calcium phosphate stones.
- *Serum calcium*, *phosphorus* and *uric acid* levels may be obtained to help identify factors contributing to calculus formation.
- *X-ray* (kidneys, ureters and bladder) of the lower abdomen that requires no special preparation. Calculi may be identified as opacities in the kidneys, ureters and bladder.
- *Renal ultrasound* is a non-invasive test that uses reflected sound waves to detect stones and evaluate the kidneys for possible hydronephrosis.
- *Computed tomography (CT) scan* of the kidney, with or without contrast medium, directed at the kidney from many angles to provide a computer-generated photograph that shows calculi, ureteral obstruction and other renal disorders.
- *IVP* may be done to visualise the kidneys, ureters and bladder after injection of a contrast medium. IVP may be done when x-rays, renal ultrasonography and CT scan fail to demonstrate clear evidence of urinary calculi. (See 'Diagnostic tests, intravenous pyelogram (IVP)' in Chapter 25.)
- *Cystoscopy* is used to visualise and possibly remove calculi from the urinary bladder and distal ureters.

Nursing implications and care for people undergoing these tests and procedures are outlined in Chapter 25.

Medications

An acute episode of renal colic is treated with analgesia and hydration. A narcotic analgesic such as morphine sulfate is given, often intravenously, to relieve pain and reduce ureteral spasm. Indomethacin, a non-steroidal anti-inflammatory drug (NSAID), given as a suppository, may reduce the amount of narcotic analgesia required for acute renal colic. Oral or intravenous fluids reduce the risk of further stone formation and promote urine output.

After analysis of the calculus, various medications may be ordered to inhibit or prevent further lithiasis. A thiazide diuretic, frequently prescribed for calcium calculi, acts to reduce urinary calcium excretion and is very effective in preventing further stones. Potassium citrate alkalinises urine by raising the pH and is often prescribed to prevent stones that tend to form in acidic urine (uric acid, cystine and some forms of calcium stones). See Table 26.2 for other preparations related to types of stones. Nursing responsibilities focus on teaching the person about the prescribed medication, its importance in preventing further stone formation and potential adverse effects.

Nutrition and fluid management

Diet modifications are often prescribed to change the character of the urine and prevent further lithiasis.

Increased fluid intake of 2500 to 3000 mL per day is recommended, regardless of stone composition. A fluid intake to ensure the production of approximately 2000 to 2500 mL of urine a day prevents the stone-forming salts from becoming concentrated enough to precipitate. Fluid intake should be spaced throughout the day and evening. Some authorities recommend that drinking one to two glasses of water at night helps to prevent concentration of urine during sleep.

Recommended dietary changes may include reduced intake of the primary substance forming the calculi. For calcium stones, dietary calcium and vitamin-D-enriched foods are limited. Limiting vitamin D inhibits the absorption of calcium from the GI tract. Calcium stones may be a calcium phosphate salt, calcium oxalate or a combination of both; therefore, phosphorus and/or oxalate may also be limited in the diet.

The person with uric acid stones requires a diet low in purines. Organ meats, sardines and other high-purine foods may be limited.

In addition to limiting certain foods, the diet may be modified to maintain a urinary pH that does not promote lithiasis. Uric acid and cystine stones tend to form in acid urine. Foods that tend to alkalinise the urine may be recommended. Because alkaline urine promotes formation of calcium stones and urinary tract infections, the diet may be modified to lower the pH of the urine. Foods that affect urinary pH and foods high in various stone components are summarised in Table 26.3.

TABLE 26.3 Teaching people with urolithiasis: possible food and fluid modifications

Foods high in calcium	Beans and lentils, chocolate and cocoa, dried fruits, canned or smoked fish except tuna, flour, milk and milk products
Foods high in oxalate	Asparagus, beer and colas, beetroot, cabbage, celery, chocolate and cocoa, fruits, green beans, nuts, tea, tomatoes
Purine-rich foods	Goose, organ meats, sardines and herring, venison; moderate in beef, chicken, crab, pork, salmon, veal
Acidifying foods	Cheese, cranberries, eggs, grapes, meat and poultry, plums and prunes, tomatoes, whole grains
Alkalinising foods	Green vegetables, fruit (except as noted above), legumes, milk and milk products, rhubarb

Surgery

Treatment of existing calculi depends on the location of the stones, the extent of obstruction, renal function, the presence or absence of UTI, and the individual's general state of health. In general, a stone is removed if it is causing severe obstruction, infection, unrelieved pain or serious bleeding (Fauci et al., 2008).

Lithotripsy, using sound or shock waves to crush a stone, is the preferred treatment for urinary calculi. Several techniques are available. **Extracorporeal shock wave lithotripsy (ESWL)** is a non-invasive technique for fragmenting kidney stones using shock waves generated outside the body. Acoustic shock waves are aimed under fluoroscopic guidance at the stone (see Figure 26.4). These shock waves travel through soft tissue without causing damage, but shatter the stone as its greater density stops their progress. Repeated shock waves pulverise the stone into fragments small enough to be eliminated in the urine. The procedure may require 30 minutes to 2 hours to complete. Intravenous sedation generally is adequate to maintain comfort during the procedure (Doherty, 2009). See the box below for nursing care of the person undergoing a lithotripsy procedure.

Lithotripsy also may be performed using a percutaneous ultrasonic or laser technique. *Percutaneous ultrasonic lithotripsy* uses a nephroscope inserted into the kidney pelvis through a small flank incision (see Figure 26.5). The stone is fragmented using a small ultrasonic transducer and the fragments are removed through the nephroscope. *Laser lithotripsy* is an alternative to ultrasonic lithotripsy. Laser beams are used to disintegrate the stone, without damaging soft tissue. A nephroscope or a ureteroscope (passed up the ureter from the bladder during cystoscopy) is used to guide the laser probe into direct contact with the stone.

A double J stent may be inserted into the affected ureter to maintain its patency following ESWL or other lithotripsy procedures. (See the box below for 'Nursing care of the person having lithotripsy'.)

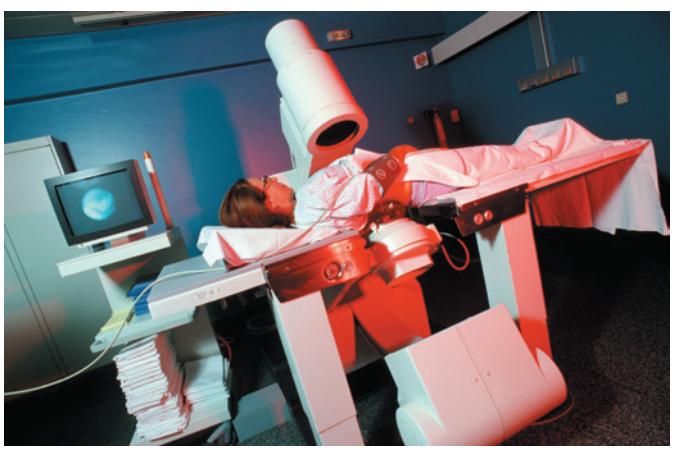

FIGURE 26.4 ■ Extracorporeal shock wave lithotripsy. Acoustic shock waves generated by the shock wave generator travel through soft tissue to shatter the urinary stone into fragments, which are then eliminated in the urine

Source: PHANIE/Science Source.

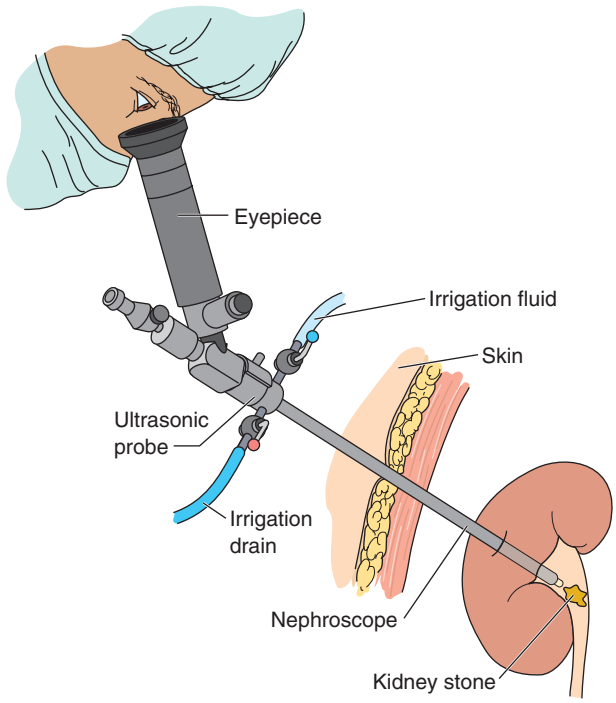

FIGURE 26.5 ■ Percutaneous ultrasonic lithotripsy. A nephroscope is inserted into the renal pelvis and ultrasonic waves are used to fragment the stone. The fragments are then removed through the nephroscope

On rare occasions, surgical intervention is necessary to remove a calculus in the renal pelvis or ureter. *Ureterolithotomy* is incision in the affected ureter to remove a calculus. *Pyelolithotomy* is incision into and removal of a stone from the kidney pelvis. A staghorn calculus that invades the calyces and renal parenchyma may require a *nephrolithotomy* for removal. See Chapter 3 for care of the person having surgery.

Bladder stones may be removed using an instrument passed through a cystoscope to crush the stones. The remaining stone fragments are then irrigated out of the bladder using an acid solution to counteract the alkalinity that precipitated stone formation.

Nursing care

Nursing care for the person with urolithiasis is directed at providing for comfort during acute renal colic, assisting with diagnostic procedures, ensuring adequate urinary output and teaching information necessary to prevent future stone formation.

Health promotion

Discuss the importance of maintaining an adequate fluid intake with all people. Stress the need to increase fluid intake during warm weather and strenuous exercise or physical labour. Discuss the relationship between weight-bearing activity and retention of calcium in the bones. Encourage the maintenance

NURSING CARE OF THE PERSON having lithotripsy

PREOPERATIVE CARE

- Assess knowledge and understanding of the procedure, providing information as needed. *Anxiety is reduced and recovery is enhanced and hastened when the individual is fully prepared for surgery*.
- Follow directions from the radiology department, doctor or anaesthetist for withholding food and fluids and for bowel preparation prior to surgery. Conscious sedation, general anaesthesia or spinal anaesthesia may be required, depending on the procedure. *Faecal material in the bowel may impede fluoroscopic visualisation of the kidney and stone.*

POSTOPERATIVE CARE

- In the initial period, monitor vital signs frequently. *The kidney is highly vascular; therefore, haemorrhage and resulting shock are potential complications of lithotripsy. Bleeding may be internal or retroperitoneal and difficult to detect.*
- Monitor amount, colour and clarity of urine output. *Urine is often bright red initially, but bleeding should diminish within 48 to 72 hours. Cloudy urine may indicate the presence of an infection.*
- Maintain placement and patency of urinary catheters. Anchor ureteral catheters or nephrostomy tubes securely. Irrigate gently if ordered. *A kinked or plugged catheter may result in hydroureter, hydronephrosis and kidney damage. Decreased urinary output and flank pain are possible symptoms of obstructed urine flow. Excessive force in irrigation may cause trauma and bleeding.*
- Ensure fluid intake of at least 3 L per day to promote urine production and to flush the renal system.

HEALTH EDUCATION FOR THE PERSON AND FAMILY

- Prepare for discharge by teaching care of the indwelling catheter, urine-collection device and incision site (if present). Teach signs and symptoms to report: urine leakage from incision for more than 4 days, symptoms of infection, pain, bright haematuria. *If discharged with dressings and catheters in place, the individual and family need necessary information to provide self-care.*
- Teach measures to reduce the risk of further lithiasis. Prevention of stone formation is important to preserve renal function, as many people *have repeated episodes of lithiasis and renal colic. Dietary advice may be required.*

of physical activity as much as possible to prevent bone resorption (loss) and possible hypercalciuria.

Instruct people with known gout to maintain a generous fluid intake so as to produce at least 2000 mL of urine every day. Discuss the risk of lithiasis with individuals who have frequent UTIs and teach measures to reduce the incidence of UTI and the risk of lithiasis.

Assessment

Obtain subjective and objective assessment data specific to urolithiasis:

- *Health history:* complaints of flank, back or abdominal pain, radiation, characteristics and timing, aggravating or relieving factors; other symptoms such as nausea and vomiting; possible contributing factors such as dehydration; previous or family history of kidney stones; current or previous treatment measures.
- *Physical examination:* general appearance including position, vital signs; skin colour, temperature, moisture, turgor; abdominal, flank or costovertebral tenderness; amount, colour and characteristics of urine (presence of haematuria, bacteria, pyuria, pH).

Nursing diagnoses and interventions

See the nursing care plan that follows this section for additional nursing diagnoses and interventions.

Acute pain

Pain is the primary outward manifestation of urolithiasis, particularly when a stone lodges within a ureter causing acute obstruction and distension. Invasive and non-invasive procedures to remove or crush stones also may be painful. People undergoing surgery also experience incisional pain.

CONSIDERATION FOR PRACTICE

The intensity of renal colic pain can cause a vasovagal response with resulting hypotension and syncope. Always provide for the person's personal safety and ensure they are not at risk from shock in this situation.

- Assess pain using a standard pain scale and its characteristics. Administer analgesia as ordered and monitor its effectiveness. *The intensity, type of pain and its responsiveness to analgesia provide valuable clues as to its cause. Regular administration of prescribed analgesics controls pain more effectively than waiting until pain becomes intolerable. Administering an ordered NSAID on a routine schedule may significantly reduce the need for narcotic analgesia for those with renal colic.*
- Unless contraindicated, encourage fluid intake and ambulation for people with renal colic. *Increased fluids and ambulation encourage urinary output, thereby facilitating movement of the calculus through the ureter and decreasing pain.*
- Use non-pharmacological measures such as positioning, moist heat, relaxation techniques, guided imagery and diversion as adjunctive therapy for pain relief. *Adjunctive pain relief measures can enhance the effectiveness of analgesics and other prescribed treatment.*
- If surgery has been performed, monitor urinary output, catheters, incision and wound drainage. *Pain may be a symptom of proximal distension due to a blocked catheter. Infection or haematoma at the surgical site can significantly increase perceived pain.*

Impaired urinary elimination

Obstruction of the urinary tract is the primary problem associated with urolithiasis. Obstruction can ultimately lead to stasis, infection or irreversible renal damage.

- Monitor amount and character of urine output. If catheterised, measure output hourly. Document any haematuria, dysuria, frequency, urgency and pyuria. Strain all urine for stones, saving any recovered stones for laboratory analysis. *The amount of urine output helps determine possible urinary tract obstruction and adequacy of hydration. Gross or microscopic haematuria is often associated with calculi and with procedures used to remove stones, such as cystoscopy or lithotripsy. A change in the amount of haematuria may indicate stone passage or a complication. Dysuria, frequency, urgency and cloudy urine are symptoms of UTI, often associated with urolithiasis. Antibiotic therapy may be required. Analysis of stones recovered from the urine can direct measures to prevent further lithiasis.*

CONSIDERATION FOR PRACTICE

A stone that completely obstructs the ureter can lead to hydronephrosis and kidney damage on the affected side. Report symptoms of hydronephrosis such as dull flank pain or aching and changes in renal function studies (BUN and serum creatinine). Because the other kidney continues to function, urine output may not fall significantly with obstruction of one ureter. A rising BUN and serum creatinine may be early signs of renal failure.

- Maintain patency and integrity of all catheter systems. Secure catheters well, label as indicated and use sterile technique for all ordered irrigations or other procedures. *A kinked or plugged catheter, particularly a ureteral catheter or nephrostomy tube, may damage the urinary system. Labelling catheters can prevent mistakes such as inappropriate irrigation or clamping. Any catheter increases the risk of infection; aseptic technique in all procedures reduces this risk.*

Deficient knowledge

The person with urolithiasis has multiple learning needs. These include information about the disease and its possible consequences, any diagnostic or therapeutic procedures performed and strategies to prevent future lithiasis.

- Assess understanding and previous learning. *Relating information to previously learned material enhances retention and understanding.*
- Present all information in a manner appropriate to knowledge base, developmental and educational level, and current needs. *Learning is an active process that requires the individual's participation. Tailoring teaching to the individual increases involvement.*
- Educate about all diagnostic and treatment procedures. *Knowing what to expect reduces anxiety, enhances compliance and hastens recovery.*
- If the person will be managed in the community, educate to:
  a. Collect and strain all urine, saving any stones.
  b. Report stone passage to the doctor and deliver the stone for analysis.
  c. Report any changes in the amount or character of urine output to doctor.

  When pain can be managed with oral analgesics, urinary stones are managed in the community. The individual needs to know how and why to collect the calculus and indicators of complications, such as reduced urine output and cloudy or bloody urine.
- Teach measures to prevent further urolithiasis:
  a. Increase fluid intake to 2500 to 3500 mL per day.
  b. Follow recommended dietary guidelines.
  c. Maintain activity level to prevent urinary stasis and bone resorption.
  d. Take medications as prescribed.
  e. Obtain prompt treatment for any further urinary infections.
  f. Avoid too much tea or coffee, and reduce salt in the diet. Restrict carbonated drinks such as cola and beer to 1000 mL per week as these contain phosphoric acid, a precursor to calculi formation.

  The risk of recurrent lithiasis is approximately 50%; however, this risk can be reduced by measures to prevent conditions favouring stone formation.
- Teach about the relationship between urinary calculi and UTI, emphasising preventive measures and the importance of prompt treatment. *Urinary tract infection promotes urolithiasis and thus requires prompt treatment to reduce this risk.*

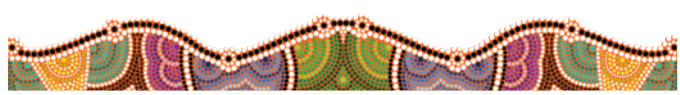
Community-based care

The person with urinary calculi needs to know how to manage existing stones and what to do to reduce the risk of future stone formation. Discuss the following topics to prepare the person and family for home care:

- importance of maintaining a fluid intake adequate to produce 2000 to 2500 mL of urine per day
- prescribed medications, their management and potential adverse effects
- dietary recommendations
- prevention, recognition and management of UTI
- any further diagnostic or treatment measures planned.

If the person is to be discharged with dressings, a nephrostomy tube or a catheter, educate the individual and family about the following:

- how to change dressings, maintaining aseptic technique
- assessment of the wound and skin for healing and possible complications such as infection or skin breakdown
- how to manage drainage systems and maintain their patency
- emptying drainage bags and assessing urine output
- recommendations for follow-up care and when to contact the doctor.



NURSING CARE PLAN A person with urinary calculi

Richard Leton, aged 44, owns a small business. He is admitted to the medical unit from the emergency department after awakening at 4 am with severe right-sided pain. His FBC is normal and urinalysis reveals microscopic haematuria, but no protein or bacteria. A renal ultrasound shows a 4–5 mm stone partially obstructing the right ureter.

The admitting nurse notes that Mr Leton is pale, diaphoretic and very anxious. He complains of nausea and asks for an emesis basin. Mr Leton received 4 mg of intravenous morphine sulfate approximately 2.5 hours ago. He denies pain at this time but says, 'I'm scared to death that it'll come back. I couldn't even move, it hurt so bad.'

ASSESSMENT

Mr Leton's history reveals no previous episodes of renal calculi. He felt well until the pain awakened him during the night. He admits that he has been working under a deadline to complete a construction project and that he probably has not been drinking enough fluids, 'considering how hot it's been'. Physical assessment findings include T 38.0°C, P 98, R 24 and BP 160/86. Colour is pale to ashen, skin cool and moist. His abdomen is firm with moderate tenderness in the right upper outer quadrant. The doctor orders an IV of 5% dextrose in normal saline at 200 mL/h until nausea is relieved, then PO fluids of at least 3000 mL/24 h; morphine sulfate 2 to 10 mg IV prn for pain; indomethacin (Indocid) 50 mg per rectal suppository q8h; promethazine (Phenergan) 25 mg PO or per suppository q6h prn for nausea; activity to tolerance; and strain all urine, sending recovered stones for analysis.

DIAGNOSES

- *Anxiety* related to anticipation of recurrent severe pain.
- *Risk of imbalanced nutrition: less than body requirements* related to nausea.
- *Acute pain* related to partial obstruction of right ureter by calculus.
- *Impaired urinary elimination* related to partial obstruction of ureter by calculus.
- *Deficient knowledge* related to lack of information about disease process, contributing factors and management.

PLANNING

- Plan interventions to reduce pain and anxiety.
- Plan interventions to reduce nausea and facilitate adherence to increased fluid intake.
- Develop collaboratively a nutrition and fluid education program.

Expected outcomes

- Demonstrate reduced anxiety by relaxed facial expression, vital signs within his normal range and ability to rest when not disturbed.
- Consume at least 50% of diet and 100% of ordered fluids without nausea or vomiting.
- Request analgesia as needed at onset of pain; report effective pain relief.
- Maintain urine output of 2500 mL/24 h with no signs of infection or obstruction (such as increased pain, dysuria, pyuria or haematuria).
- Demonstrate an understanding of the process of urolithiasis and contributing factors.
- Verbalise knowledge of dietary, fluid intake and other measures required to reduce risk of future stone formation.

IMPLEMENTATION

- Reassure that measures to prevent further episodes of renal colic are being implemented and that medication is available to relieve pain promptly.
- Assess the effectiveness of analgesia and its adverse effects, especially nausea.
- Maintain IV as ordered until oral fluid intake exceeds 200 mL of fluid per hour while awake.
- Measure and strain all urine. Assess urine for colour, clarity and odour.
- Teach about urolithiasis and its risk factors, especially as they relate to Mr Leton.
- Teach the importance of maintaining a high fluid intake, especially when working outdoors in hot weather; recommended dietary modifications and their rationale; ordered medications and their effects; how to identify and prevent UTI; and symptoms that should be reported to the doctor.

EVALUATION

Mr Leton passed the obstructing stone the evening after admission and is discharged the following day. On discharge, he states he has no pain or nausea, his urine is clear and pale yellow, and urinalysis is normal. Laboratory analysis shows that the calculus was calcium. Mr Leton is able to affirm the importance of continuing a high fluid intake. He confirms that he will reduce his intake of calcium-rich foods, such as milk and milk products, and that he will increase his intake of foods to acidify his urine. He is able to list foods to include in his diet and comments: 'You can be sure I'll follow my diet, drink my water and make sure I don't get an infection. I hope to never feel pain like that again!'

CRITICAL THINKING IN THE NURSING PROCESS

1. What factors contributed to the onset and timing of Mr Leton's ureteral colic?
2. What is the rationale for administering indomethacin, an NSAID, to a person with ureteral colic?
3. Why did the nurse include a nursing intervention to assess for a relationship between Mr Leton's nausea, his pain and the ordered analgesic agent?

REFLECTION ON THE NURSING PROCESS

1. Reflect on the educational strategies offered to Mr Leton and consider how you could incorporate these into your work day to prevent a reoccurrence for people at risk.
2. Considering the case study above, identify what new knowledge you have gained that will enhance how you deliver care to a person with ureteral colic.

THE PERSON WITH A URINARY TRACT TUMOUR

A malignancy can develop in any part of the urinary tract; however, 90% develop in the bladder, about 8% develop in the renal pelvis and only 2% develop in the ureter or urethra (Fauci et al., 2008). When diagnosed early, the 5-year survival rate for bladder cancer is 94% (American Cancer Society (ACS), 2009).

Incidence and risk factors

The incidence of bladder cancer is higher in people who smoke or are over the age of 65, and is three times higher in men than in women. Women experience poorer outcomes and survival (Patel et al., 2015).

Two main factors are implicated in the development of bladder cancer: the presence of carcinogens in the urine, and chronic inflammation or infection of bladder mucosa. Cigarette smoking is the primary risk factor for bladder cancer. The risk in smokers is twice that of non-smokers (ACS, 2009). The chemicals and dyes used in the plastics, rubber and cable industries; substances in the work environment of textile workers, leather finishers, spray painters and petroleum workers; and the chronic use of phenacetin-containing analgesic agents also are associated with a higher risk. Additional risk factors for bladder cancer include residence in an urban area, chronic UTIs and bladder calculi. The parasite *Schistosoma haematobium*, endemic to Egypt and the Sudan, also increases the risk of bladder cancer (Porth & Matfin, 2009). The risk of bladder cancer appears to be reduced by increasing the intake of fluids and vegetables (ACS, 2009).

FAST FACTS

The main risk factors for bladder cancer are:

- Male gender, age > 55, residence in urban area
- Cigarette smoking
- Occupational exposure to dyes or solvents
- Chronic UTI or bladder calculi
- Long-term use of cyclophosphamide

Pathophysiology

Most urinary tract malignancies arise from epithelial tissue. Transitional epithelium lines the entire tract from the renal pelvis through to the urethra. Carcinogenic products of nicotine metabolism and cigarette smoke are stored in the bladder then excreted in urine. It is possible the presence of carcinogens in bladder urine may cause abnormal bladder cell development. Squamous cell carcinoma of the urinary tract occurs less frequently than transitional epithelial cell tumours.

Urinary tract tumours begin as non-specific cellular alterations that develop into either flat or papillary lesions. These lesions may be either superficial or invasive. About 75% of bladder tumours are papillary lesions (*papillomas*), a polyp-like structure attached by a stalk to the bladder mucosa (see Figure 26.6). Papillomas are generally superficial, non-invasive tumours that bleed easily and frequently recur (Fauci et al., 2008). They rarely progress to become invasive and the prognosis for recovery is good.

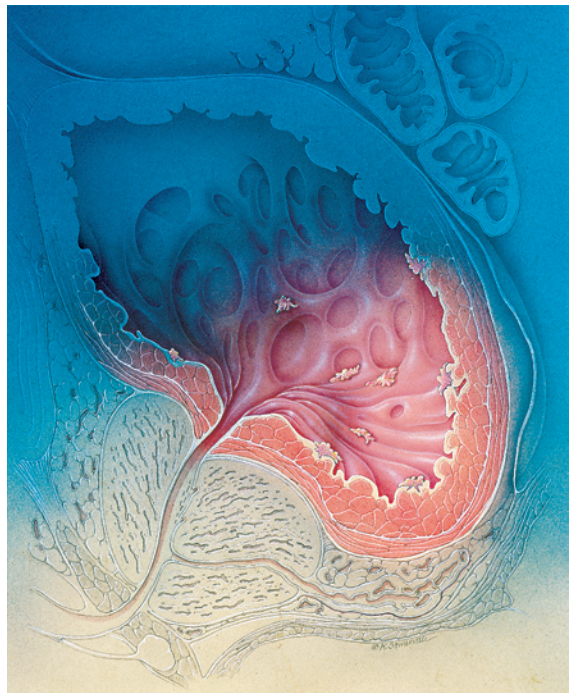


FIGURE 26.6 ■ Papillary transitional cell carcinoma of the urinary bladder

Source: Custom Medical Stock Photo, Inc.

Carcinoma in situ (CIS), which occurs less frequently, is a poorly differentiated flat tumour that invades directly and is associated with a poorer prognosis. Bladder tumours are rated by their cell type and grade. Grade I tumours are highly differentiated and rarely progress to become invasive, whereas grade III tumours are poorly differentiated and usually progress (Fauci et al., 2008). The staging of bladder tumours is outlined in Table 26.4. See Chapter 13 for more information about tumour grading and staging. When metastasis occurs, the pelvic lymph nodes, lungs, bones and liver are most commonly involved.

Manifestations

Painless haematuria is the presenting sign in 75% of urinary tract tumours. Haematuria may be gross or microscopic and is often intermittent, causing delay in seeking treatment (Porth & Matfin, 2009). Inflammation surrounding the tumour occasionally causes manifestations of a urinary tract infection, including frequency, urgency and dysuria. Ureteral tumours may cause colicky pain from obstruction. Tumours of the urinary tract typically cause few outward signs and may not be discovered until obstructed urine flow causes flank pain or renal failure.

CONSIDERATION FOR PRACTICE

Intermittent painless haematuria is the most common presenting symptom of bladder cancer. Instruct all people with painless haematuria to contact their doctor for follow-up testing.

TABLE 26.4 Bladder tumour staging

DEPTH OF INVOLVEMENT	TNM (TUMOUR, NODE, METASTASIS) STAGE	TUMOUR INVOLVEMENT
Superficial	T_a	Limited to the bladder mucosa
	T_1	Involvement of the bladder mucosa and submucosal layers
Invasive	T_2	Invasion of superficial muscle of bladder wall
	T_{3a}	Deep muscle invasion
	T_{3b}	Involvement of perivesicular fat
	$T_{3–4}N_+$	Regional (pelvic) lymph node involvement
	$T_{3–4}M_1$	Metastasis to distant lymph nodes or organs

INTERPROFESSIONAL CARE

Treatment of the person with a tumour of the urinary tract focuses on removing or destroying the cancerous tissue, preventing further invasion or metastasis and maintaining renal and urinary function.

Diagnosis

When a urinary tract tumour is suspected, the following diagnostic tests may be ordered:

- *Urinalysis* is done to evaluate for haematuria. Gross or microscopic haematuria is often the first indicator of a neoplasm in the urinary tract.
- *Urine cytology*, microscopic examination of cells in the urine, is performed to identify abnormal cells (tumour or pretumour cells). Periodic urine cytology is recommended for those at high risk of bladder cancer or its recurrence due to carcinogen exposure.
- *Ultrasound of the bladder* is a non-invasive test to detect bladder tumours. No dye is required and there is no exposure to radiation.
- *Intravenous pyelography* is used to evaluate the structure and function of the kidneys, ureters and bladder. IVP may reveal a rigid deformity of the bladder wall, obstruction of urine flow at the point of the tumour, or bladder filling or emptying defects.
- *Cystoscopy* and *ureteroscopy* allow direct visualisation, assessment and biopsy of lesions of the urethra, bladder or ureters using a lighted scope inserted through the urethra. Cystoscopy or ureteroscopy with biopsy allows definitive diagnosis of urinary tract tumours.
- *CT scan* or *MRI* is primarily used to evaluate tumour invasion or metastasis if suspected.
- See Chapter 25 for nursing care related to these diagnostic tests.

Medications

Immunological or chemotherapeutic agents administered by intravesical instillation (into the bladder) may be used either as the primary treatment for bladder cancer when multiple early lesions are present or to prevent recurrence following endoscopic tumour removal. Bacillus Calmette-Guérin (BCG; BCGLive, TheraCys) is a suspension of attenuated *Mycobacterium bovis* used to treat carcinoma in situ (CIS) and recurrent bladder tumours. Instillation into the bladder causes a local inflammatory reaction that eliminates or reduces superficial tumours. Systemic mycobacterial infection is a rare complication of intravesical BCG therapy that may require antituberculin treatment (McPhee et al., 2012). Other chemotherapeutic agents also may be administered intravesically, including doxorubicin, mitomycin C and interferon. Bladder irritation, frequency, dysuria and contact dermatitis are possible adverse reactions to intravesical chemotherapy. Suppression of bone marrow function also can occur as a result of intravesical treatment.

Radiation therapy

Radiation is an adjunctive therapy used in the treatment of urinary tumours. Although radiation alone is not curative, it can reduce tumour size prior to surgery and is used as palliative treatment for inoperable tumours and those who cannot tolerate surgery. Radiation therapy also is used in combination with systemic chemotherapy to improve local and distant relapse rates (McPhee et al., 2012) (see Chapter 13).

Surgery

A number of surgical procedures, ranging from simple resection of non-invasive tumours to removal of the bladder and surrounding structures, are used to treat urinary tract tumours. Indications for each procedure and specific nursing implications are outlined in Table 26.5.

Transurethral tumour resection may be performed by excision, *fulguration* (destruction of tissue using electric sparks generated by high-frequency current) or *laser photocoagulation* (use of light energy to destroy abnormal tissue). Laser surgery carries the lowest risk of bleeding and perforation of the bladder wall. Following cystoscopic tumour resection, individuals are followed at 3-month intervals for tumour recurrence. Recurrences may develop anywhere in the urinary tract, including the renal pelvis, ureter or urethra (Fauci et al., 2008).

Cystectomy, surgical removal of the bladder, is necessary to treat invasive cancers. Partial cystectomy may be done to remove a solitary lesion; however, radical cystectomy is the standard treatment for invasive tumours. The bladder and adjacent muscles and tissues are removed. In men, the prostate and seminal vessels are also removed, resulting in impotence. In women, a total hysterectomy and bilateral salpingo-oophorectomy

TABLE 26.5 Surgical procedures to treat bladder tumours

PROCEDURE	INDICATIONS	NURSING IMPLICATIONS
Transurethral resection of bladder tumour	Diagnose and treat superficial bladder tumours having low rate of recurrence; control bleeding	Maintain continuous bladder irrigation postoperatively; monitor for excessive bleeding; ensure catheter patency. Increase fluids to 2500–3000 mL/day. Give stool softeners to prevent straining.
Partial cystectomy	Resect solitary, isolated tumour at stage T_2 or T_3 not involving trigone	Maintain patency of urethral and/or suprapubic catheter to make sure suture lines are free of pressure; monitor for excess bleeding.
Complete or radical cystectomy	Remove large, invasive tumours; involvement of trigone	Permanent urinary diversion is required. Maintain patency and position of stents; urethral catheter may be in place to drain pelvic cavity.

(removal of the uterus, fallopian tubes and ovaries) accompanies the procedure, causing sterility. At the time of surgery, a **urinary diversion** is created to provide for urine collection and drainage. Either an *ileal conduit* (see Figure 26.7A) or a *continent urinary diversion* (see Figure 26.7B) is created to collect and drain urine. Table 26.6 describes the most frequently used urinary diversion techniques.

Surgical procedures to remove tumours involving other portions of the urinary tract vary according to the site and stage of the tumour. When the distal ureter is involved, the tumour may be resected and the ureter implanted into the opposite ureter to provide for drainage. A proximal ureteral tumour necessitates removal of the ureter and kidney on the affected side.

See the box below for nursing care of the person undergoing tumour resection and a urinary diversion.

Nursing care

The person who undergoes treatment for a tumour of the urinary tract has many nursing care needs because of alterations in the functional health patterns of elimination, health perception–health management, cognitive–perceptual, self-perception–self-concept, role–relationships and coping–stress–tolerance.

Health promotion

Encourage all individuals not to smoke. Provide referral to smoking cessation programs or clinics for those who wish to give up smoking. Encourage people at high risk of developing bladder cancer (see above) to have periodic examinations, including urinalysis and urine cytology.

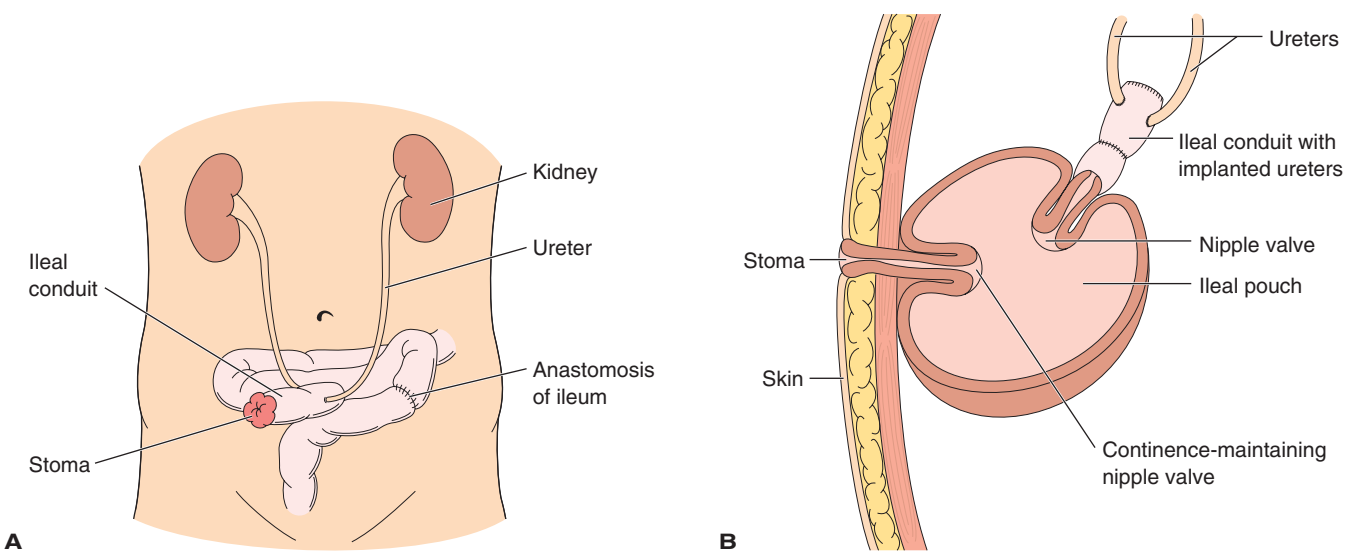

FIGURE 26.7 ■ Common urinary diversion procedures. *A*, Ileal conduit. A segment of ileum is separated from the small intestine and formed into a tubular pouch with the open end brought to the skin surface to form a stoma. The ureters are connected to the pouch. *B*, A continent urinary diversion. A segment of ileum is separated from the small intestine and formed into a pouch. Nipple valves are formed at each end of the pouch by intussuscepting tissue backwards into the reservoir to prevent leakage

TABLE 26.6 Urinary diversion procedures

PROCEDURE	DESCRIPTION	NURSING CONSIDERATIONS
Ileal conduit	Portion of ileum is isolated from small intestine, leaving vascular, lymphatic and neural connections intact; ileum is formed into pouch with open end brought to surface to form a stoma; ureters are inserted into pouch.	Most common urinary diversion. Continuous urine drainage necessitates appliance. Postoperative oedema may interfere with urine output. Risk of infection is less than for cutaneous ureterostomy, but potential for reflux is high. Good skin care vital because of constant contact with urine.
Continent internal ileal reservoir or continent ileal bladder conduit (Kock pouch)	Pouch is created as for ileal conduit but nipple valves are formed by intussuscepting tissue backwards into a reservoir to connect pouch to the skin and ureters to the pouch; filling pressure closes valves, preventing leakage and reflux.	Drainage collection device not necessary. The person must be willing and able to perform clean intermittent self-catheterisation every 2 to 4 hours. Continence valve mechanism may fail, requiring surgery for revision.
Indiana pouch (continent diversion)	A portion of the terminal ileum, ascending colon and caecum is isolated from the bowel with vascular and neural connections intact. Reservoir is formed from colon and caecum; portion of the ileum is brought to the surface to form nipple valve and stoma or is attached to urethral stump.	As for Kock pouch. The person must be able and motivated to manage self-catheterisation. Reservoir may absorb urea and electrolytes, resulting in imbalances. Significant portion of bowel is required to form pouch and stoma.
Ileocystoplasty	Section of the ileum is isolated and formed into U shape. Ureters are implanted in upper portion of the U. Urethra is anastomosed to central section.	Appropriate for men only because urethra is removed with cystectomy in women. Allows the person to void by relaxing pelvic muscles and using Valsalva manoeuvre.

Assessment

Nursing assessment related to urinary tract cancer includes both subjective and objective information:

- *Health history:* risk factors; history of haematuria or manifestations of UTI (dysuria, frequency, urgency, pyuria); lower abdominal discomfort or flank pain.
- *Physical examination:* general health; abdominal tenderness; urine for analysis.

Nursing diagnoses and interventions

Maintaining urinary output is the priority nursing care focus for the person with a bladder tumour. For additional potential nursing diagnoses and interventions for those with a bladder tumour, see the nursing care plan that follows.

Impaired urinary elimination

Whether the person has undergone transurethral resection of a bladder tumour or radical cystectomy with urinary diversion, urinary elimination is altered at least temporarily.

- Monitor urine output from all catheters, stents and tubes for amount, colour and clarity hourly for the first 24 hours postoperatively, then every 4 to 8 hours. *Decreased urine output may indicate impaired catheter or drainage system patency. Prompt intervention is necessary to prevent hydronephrosis. A change in colour or clarity may indicate a complication such as haemorrhage or infection.*
- Label all catheters, stents and their drainage containers. Maintain separate closed gravity drainage systems for each. *Clear identification of each tube can prevent errors in irrigating and calculating outputs. Separate closed systems minimise the risk and extent of potential bacterial contamination and resultant infection.*

CONSIDERATION FOR PRACTICE

Promptly report urine output of less than 30 mL per hour. This may indicate low vascular volume or renal insufficiency. Prompt intervention is vital to restore cardiac output and prevent acute kidney injury (previously known as acute renal failure).

- Secure ureteral catheters and stents with tape; prevent kinking or occlusion; and maintain gravity flow by keeping drainage bag below the level of the kidneys. *Impaired urine flow can lead to urinary retention and distension of the bladder, a newly created reservoir or the renal pelvis (hydronephrosis).*

CONSIDERATION FOR PRACTICE

Using aseptic techniques, strictly follow guidelines for irrigating catheters. Catheters placed in the kidney pelvis are irrigated using gentle pressure and small amounts of fluid (10 to 15 mL) to avoid damaging renal tissues.

- Encourage fluid intake of 3000 mL per day. Increased fluid intake maintains a high urinary output, reducing the risk of infection. *Dilute urine is less irritating to the skin surrounding the stoma site. Electrolyte reabsorption from reservoirs may increase risk of calculi; high fluid intake and urine output reduce this risk.*
- Encourage activity to tolerance. *Ambulation promotes drainage of urine from reservoirs and helps prevent calcium loss from bones, which could precipitate calculus formation.*

CONSIDERATION FOR PRACTICE

Monitor urine output closely for first 24 hours after stents or ureteral catheters are removed. Oedema or stricture of ureters may impede output, leading to hydronephrosis and kidney damage.

Risk of impaired skin integrity

The skin surrounding the stoma site of an ileal conduit is at risk of irritation and breakdown. Because urine is acidic and contains high concentrations of electrolytes, it has a corrosive effect on skin. In addition, adhesives and sealants used to prevent pouch leakage may irritate the skin.

- Assess peristomal skin for redness, excoriation or signs of breakdown. Assess for urine leakage from catheters, stents or drains. Keep the skin clean and dry. Change wet dressings. *Intact skin is the first line of defence against infection. Impaired skin integrity may lead to local or systemic infection and impaired healing.*
- Ensure gravity drainage of urine collection device or empty bag every 2 hours. *Overfilling of the collection bag may damage the seal, allowing leakage and contact of urine with skin.*
- Change urine collection appliance as needed, removing any mucus from stoma. See Box 26.2 for care of a urinary stoma. *Meticulous care and protection of skin surrounding stoma can maintain integrity and prevent breakdown.*

Disturbed body image

A radical cystectomy and urinary diversion affect the person's body image. In most cases, an abdominal stoma is created, requiring either a drainage appliance or regular catheterisation of the stoma to drain urine. Removal of the prostate and seminal vesicles or the uterus and ovaries leaves the person sterile. If radiation or chemotherapy is planned as adjunctive therapy, the individual may experience hair loss, stomatitis, nausea and vomiting, or other disturbing side effects of therapy.

- Use therapeutic communication techniques to help the person deal with the situation by actively listening and responding to the individual's and the family's concerns. *People must know that their feelings and concerns are respected and valued. Denial, anger, guilt, bargaining or depression are common during the grieving process for the person's disordered body and normal for those undergoing a significant change in body image.*
- Recognise and accept behaviours that indicate use of coping mechanisms, encouraging adaptive mechanisms. *The person may initially use defensive coping mechanisms such as denial, minimisation and dissociation from the immediate situation to reduce anxiety and maintain psychological integrity. Adaptive mechanisms include learning as much as possible about the surgery and its effects, practising procedures, setting realistic goals and rehearsing various alternative outcomes.*
- Encourage looking at, touching and caring for the stoma and appliance as soon as possible. Allow the person to proceed gradually, providing support and encouragement. *Accepting the stoma as part of the self is vital to adapting to the changed body image and is indicated by a willingness to begin self-care.*
- Discuss concerns about returning to usual activities, perceived relationship changes and resumption of sexual relations. Provide referral to the support group or provide for contact with someone who has successfully adjusted to a urinary diversion. *Individuals and families may be reluctant to discuss topics of concern. An atmosphere of openness and acceptance facilitates expression of concerns and anxieties related to the changed body image.*

Risk of infection

Diagnostic instrumentation procedures, surgical manipulation and disruption of normal urinary tract defence mechanisms increase the risk of ascending urinary tract infection. When an ileal conduit or artificial bladder is created using bowel tissue, the normal bacteriostatic activity of bladder mucosa is lost. In addition,

BOX 26.2 Urinary stoma care

- Gather all supplies: a clean, disposable pouch; liquid skin barrier or barrier ring; 4 × 4 gauze squares; stoma guide; adhesive solvent; clean gloves; and a clean washcloth.
- Assess knowledge, learning needs and ability and willingness to assist with procedure. Explain the procedure as needed.
- Use standard precautions.
- Remove old pouch, pulling gently away from skin. Warm water or adhesive solvent may be used to loosen the seal if necessary.
- Assess stoma. Normally the stoma is bright red and appears moist. Report a dark purple, black or very pale stoma to the doctor. Slight bleeding with cleansing is normal, especially in the immediate postoperative period.
- Prevent urine flow during cleaning by placing a rolled gauze square or tampon over the stoma opening.
- Cleanse skin around the stoma with soap and water; rinse and pat or air dry.
- Use the stoma guide to determine correct size for the bag opening and/or protective ring seal. Trim the bag or seal as needed.
- Apply skin barrier; allow to dry.
- Apply the bag with an opening no more than 1 to 2 mm wider than outside of stoma. Allow no wrinkles or creases where the bag contacts the skin. Smooth side edges and lower edges first to ensure smooth fit.
- Connect bag to the urine-collection device. Dispose of old pouch, used supplies and gloves appropriately. Wash hands.
- Chart procedure, including stoma appearance and response of the person.

NURSING CARE OF THE PERSON having a cystectomy and urinary diversion

PREOPERATIVE CARE

- Provide routine preoperative care as outlined in Chapter 3.
- Assess knowledge of the proposed surgery and its long-term implications, clarifying misunderstandings and discussing concerns. *Those having surgery for cancer of the urinary tract are trying to cope with a diagnosis of cancer and may not fully understand the surgery and its potential effects. Open discussion can reduce the need for postoperative analgesia, facilitate postoperative recovery and adjustment.*
- Begin teaching about postoperative tubes and drains, self-care of stoma and control of drainage and odour. *Postoperative physiological and psychological stressors may interfere with learning. A basic understanding of what to expect in the way of tubes, drains and procedures reduces stress in the immediate postoperative period. Preoperative teaching can enhance recall and postoperative learning.*
- Refer to the Continence Nurse Advisor to help prepare the person physically and psychologically for the outcomes of surgery and changed body image.
- Assist in identifying a stoma site, avoiding folds of skin, bones, scar tissue and the waistline or belt area. The site should be visible and accessible for manipulation. Be sure to consider the person's occupation and style of clothing. *Stoma placement is a vital component of adjustment and self-care. Care is taken to place the stoma away from areas of constant irritation by clothing or movement. It should be located so that the person can cover and disguise the collecting device, maintain the seal to prevent leakage and effectively cleanse and maintain the site.*
- Perform bowel-preparation activities as ordered. *Bowel preparation is done to prevent faecal contamination of the peritoneal cavity and to decompress the bowel during surgery.*

POSTOPERATIVE CARE

- Provide routine postoperative care (see Chapter 3).
- Monitor intake and output carefully, assessing urine output every hour for the first 24 hours, then every 4 hours or as ordered. Call the doctor if urine output is less than 30 mL per hour. *Tissue oedema and bleeding may interfere with urinary output from stoma, catheters or drains. Maintenance of urine outflow is vital to prevent hydronephrosis and possible renal damage. A urine output of at least 30 mL per hour is necessary for effective renal function.*
- Assess colour and consistency of urine. Expect pink or bright red urine fading to pink and then clearing by the third postoperative day. Urine may be cloudy due to mucus production by bowel mucosa. *Bright red blood in the urine from a urinary diversion may indicate haemorrhage, necessitating further surgery. Excessive cloudiness or foul-smelling urine may indicate infection.*
- Assess size, colour and condition of the stoma and surrounding skin every 2 hours for the first 24 hours, then every 4 hours for 48 to 72 hours. Expect the stoma to initially appear bright red and slightly oedematous. Slight bleeding during cleansing is normal. *Compromised circulation causes the stoma to appear pale, grey or cyanotic, or to blanch when touched. Other complications, such as infection or impaired healing, may be evidenced by a change in the appearance of the stoma or incision.*
- Irrigate the ileal diversion catheter with 30 to 60 mL of normal saline every 4 hours or as ordered. *Mucus produced by the bowel wall may accumulate in the newly devised reservoir or obstruct catheters.*
- Monitor serum electrolyte values, acid–base balance and renal function tests such as BUN and serum creatinine. *Reabsorption of electrolytes from reservoirs created by portions of bowel may result in electrolyte imbalance and metabolic acidosis. Optimal renal function is necessary to maintain a normal state of homeostasis.*

HEALTH EDUCATION FOR THE PERSON AND FAMILY

- Teach the person and family about stoma and urinary diversion care, including odour management, skin care, increased fluid intake, pouch application and leakage prevention, self-catheterisation for those with continent reservoirs and signs of infection and other complications. *The ability to provide self-care is a significant factor in the adjustment to a changed body image. Teaching family members facilitates acceptance and adjustment. The family also needs this knowledge in case illness or disability interferes with the self-care capacity.*
- Ensure the Continence Nurse Advisor is available for counselling, guidance and support for the person and family in the postoperative period.

NURSING CARE PLAN A person with a bladder tumour

Ben Hussain is a 61-year-old car salesman. He is married and has five children, all of whom are grown and living away from home. A week ago Mr Hussain became alarmed when his urine was bright red. He called his doctor, who ordered urinalysis and urine cytology which revealed gross haematuria and poorly differentiated abnormal cells. Cystoscopy and tissue biopsy confirmed a tumour involving the bladder trigone area. Mr Hussain was admitted for a radical cystectomy and continent urinary diversion.

ASSESSMENT

Mr Hussain's admission history, obtained by the Registered Nurse, indicated that he had lost 4–7 kg during the last few months. He smoked two to three packets of cigarettes a day for 40 years, but cut back to a packet a day about a year ago, saying he could not quit smoking entirely. He drinks five to six cups of coffee daily and consumes a moderate amount of alcohol, averaging three to four drinks a day. Mr Hussain says that he is 'a little nervous about surgery and what

NURSING CARE PLAN A person with a bladder tumour (continued)

they're going to find'. The nurse notes that he fidgets and talks rapidly throughout their interview. Mr Hussain also expresses concern about how he will handle the pain after surgery, because he had never been hospitalised before his cystoscopy. Physical assessment findings include T 36.7°C, P 84, R 18 and BP 154/86. Examinations of the skin, neuromuscular and cardiac systems show no abnormalities. Auscultation of lung fields showed scattered expiratory crackles. Bowel sounds were very active; Mr Hussain explained that he began taking his bowel-preparation laxative the day before admission. Slight tenderness was noted in the suprapubic region and Mr Hussain's urine was clear and bright pink. CBC and chemistry screening results were within normal limits. Surgery was planned for 9 am the following day.

DIAGNOSES

- *Anxiety* related to undetermined extent of disease and fear of pain.
- *Deficient knowledge* related to care and management of continent urinary diversion.
- *Impaired urinary elimination* related to cystectomy and urinary diversion.
- *Risk of impaired gas exchange* related to smoking history and effects of anaesthesia.

PLANNING

- Plan education to reduce anxiety and concerns around surgery.
- Plan to include family in education sessions.
- Plan adequate pain reduction interventions.
- Plan a collaborative quit smoking and alcohol-reduction intervention programs.

Expected outcomes

- Verbalise decreased feelings of anxiety.
- Demonstrate appropriate postoperative pain relief through subjective reports of pain severity and objective findings.
- Be able to care for urinary diversion and surrounding skin prior to discharge.
- Demonstrate self-catheterisation of stoma using appropriate technique prior to discharge.
- Maintain normal urine output with acceptable colour and clarity and no signs of infection.
- Maintain adequate gas exchange as evidenced by good skin colour, O_2 saturation greater than 95% and clear lung sounds on auscultation.

IMPLEMENTATION

- Spend as much time as possible with Mr Hussain and his family preoperatively, answering questions fully and encouraging expression of fears and anxieties.
- Reinforce teaching given by the Continence Nurse Advisor and ensure that Mr Hussain understands his condition, the surgery and his postoperative plan of care.
- Provide verbal explanations supported by printed material and application examples when appropriate.
- Administer postoperative analgesia on a regular basis for the first 48 to 72 hours. Monitor for objective signs of unrelieved pain.
- Explain all procedures related to stoma and diversion care as they are being performed.
- Encourage Mr Hussain to look at the stoma and touch it when ready.
- Teach stoma and skin care, as well as self-catheterisation, emphasising measures to prevent skin irritation and urinary tract infection.
- Monitor urine output, colour, clarity and consistency every hour for first 24 hours, then every 4 hours for 24 hours, then every 8 hours. Report output of less than 30 mL per hour, bright bleeding, excessively cloudy or foul-smelling urine.
- Assist with use of incentive spirometer to promote respiratory function every hour while awake. Ambulate as soon as possible. Assess lung sounds every 4 hours, reporting increased crackles or diminished breath sounds.
- Refer Mr and Mrs Hussain to a local stoma group on discharge.

EVALUATION

On discharge, Mr Hussain has performed self-catheterisation and stoma and skin care several times. His wife also is able to catheterise the stoma and demonstrate skin care. His urine is pale yellow and slightly cloudy. Mr Hussain is ambulating independently and using oxycodone (Percocet) twice a day for pain relief. His lungs are clear and he is very proud of having 'survived' 7 days without a cigarette. He says, 'Now I'm going to try for 7 weeks, then 7 months, then 7 years without a cigarette!' A community care referral is made to continue supporting Mr Hussain in caring for his diversion and appliance at home.

CRITICAL THINKING IN THE NURSING PROCESS

1. How does cigarette smoking contribute to the increased risk of urinary tract tumours?
2. Suppose Mr Hussain had become confused, disoriented and tremorous, and had begun to experience visual hallucinations 2 to 3 days postoperatively. What would you suspect the cause to be? What would be the appropriate response?
3. Develop a plan of care for Mr Hussain for the nursing diagnosis *Risk of sexual dysfunction*.

REFLECTION ON THE NURSING PROCESS

1. Reflect on how Mr Hussain's attitudes towards smoking, alcohol and caffeine intake may have influenced his adherence and contribution to planned education programs.
2. How has involvement of the family in education programs influenced Mr Hussain's adherence to the programs?

the peristaltic action of the ureters may be disrupted and the vesicoureteral junction no longer prevents urine reflux. Adjunctive chemotherapy or radiation treatments may impair normal immune function and further increase the risk of infection.

- Maintain separate closed drainage systems, keeping drainage bags lower than the kidney, and prevent loops or kinks in drainage tubing, which impede urine flow. *Although urine is sterile when it leaves the kidney, bacteria grow rapidly in it. Therefore, prevention of urine reflux is essential to preventing UTI.*
- Monitor for signs of infection: elevated temperature, cloudy or foul-smelling urine, haematuria, general malaise, back or abdominal pain, and nausea and vomiting. *Infection undermines the healing process. Early detection and treatment help prevent long-term consequences such as chronic pyelonephritis.*

CONSIDERATION FOR PRACTICE

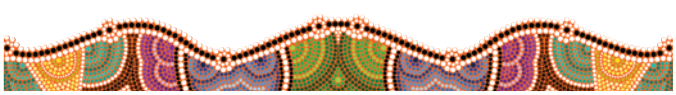
Impaired immune capability (due to ageing or the effects of chemotherapy) and urine cloudiness (related to the effects of urine on ileal mucosa) can mask signs of UTI such as fever and altered urine clarity. Be alert for more generalised manifestations, such as increased fatigue and malaise.

- Teach signs and symptoms of infection and self-care measures to prevent UTI. The person with a cystectomy and ileal diversion, urostomy or continent reservoir is at risk of UTI for life because of impaired urinary defence mechanisms. *Using clean or aseptic technique in providing care, increasing fluid intake and using measures to acidify urine minimise this risk to a certain degree but do not eliminate it.*

Community-based care

The need for individual and family teaching for the person who has had surgery to treat a urinary tract tumour is significant. For many, surgery means a lifelong change in urinary elimination. Even the individual who has undergone transurethral excision of bladder tumours requires follow-up cystoscopy on a regular basis and needs to be alert for signs of tumour recurrence.

The person who has had a urinary diversion needs teaching about care of the stoma and surrounding skin, prevention of urine reflux and infection, signs and symptoms of UTI and renal calculi, and, in some cases, self-catheterisation using clean technique. Referral to community health services will be an important aid to the individual and family in adapting to their changed situation and the impact on their lifestyles.



THE PERSON WITH URINARY RETENTION

Urinary retention, incomplete emptying of the bladder, can lead to overdistension of the bladder, poor detrusor muscle contractility and inability to urinate. If the problem persists, hydroureter and hydronephrosis can result.

Physiology review

Normally, bladder emptying is controlled by the interaction of muscle tone and the autonomic nervous system. The sympathetic nervous system (SNS) relaxes the detrusor muscle, allowing the bladder to fill with urine. The internal sphincter, a continuation of the detrusor muscle, remains closed during filling. Pressures within the bladder remain low during filling, in contrast to high sphincter and urethral pressures. Voluntary muscles of the external sphincter and pelvic floor help maintain these high pressures. When the bladder contains 150 to 300 mL of urine, signals from stretch receptors in the bladder wall are transmitted to the spinal cord and cerebral cortex. Reflexive bladder emptying can be consciously inhibited. During *micturition* (bladder emptying), parasympathetic stimulation causes the detrusor muscle of the bladder fundus to contract, opening the internal sphincter. The external sphincter then relaxes, allowing urine to flow out.

Pathophysiology

Either mechanical obstruction of the bladder outlet or a functional problem can cause urinary retention. Benign prostatic hypertrophy (BPH) is a common cause; difficulty initiating and maintaining urine flow is often the presenting complaint in men with BPH. Acute inflammation associated with infection or trauma of the bladder, urethra or perineal tissues may also interfere with micturition. Scarring due to repeated urinary tract infection can lead to urethral stricture and a mechanical obstruction. Bladder calculi may also obstruct the urethral opening from the bladder.

Surgery, particularly abdominal or pelvic surgery, may disrupt detrusor muscle function, leading to urine retention. Drugs also may interfere with its function. Anticholinergic medications such as atropine, glycopyrrolate (Robinul), propantheline bromide (Pro-Banthine), hyoscine (Buscopan) and others can lead to acute urinary retention and bladder distension. Other drugs with anticholinergic side effects may also cause urinary retention. Among these are anti-anxiety agents such as diazepam (Valium), antidepressant and tricyclic drugs such as imipramine (Tofranil), antiparkinsonian drugs, antipsychotic agents and some sedative/hypnotic drugs. In addition, antihistamines common in over-the-counter cough, cold, allergy and sleep-promoting drugs have anticholinergic effects which may interfere with bladder emptying. Diphenhydramine (Benadryl) is an example of a non-prescription antihistamine.

Voluntary urinary retention (particularly common among nurses!) may lead to overfilling of the bladder and a loss of detrusor muscle tone.

Manifestations

The person with urinary retention is unable to empty the bladder completely. Overflow voiding or incontinence may occur, with 25 to 50 mL of urine eliminated at frequent intervals. Assessment reveals a firm, distended bladder that may be displaced to one side of midline. Percussion of the lower abdomen reveals a dull tone, reflective of fluid in the bladder.

Severe urinary retention with resulting bladder distension impairs the ability of the vesicoureteral junction to prevent

backflow of urine into the ureters (see Figure 26.1 earlier in the chapter). Reflux of urine from the distended bladder distends the ureters (hydroureter) and kidneys (hydronephrosis). Hydronephrosis impairs renal function and acute kidney injury can result. See Chapter 27 for more information about acute kidney injury (previously known as acute renal failure).

INTERPROFESSIONAL CARE

Urinary retention is confirmed using a bladder scan or by inserting a urinary catheter (if possible) and measuring the urine output. Use of a bladder scan is preferred to reduce the risk of UTI (Teng et al., 2005).

An indwelling urinary catheter or intermittent straight catheterisation can prevent urinary retention and overdistension of the bladder. Cholinergic medications such as bethanechol chloride (Urocarb), which promote detrusor muscle contraction and bladder emptying, may be used. A medication with no anticholinergic side effects may be substituted when urinary retention is related to drug therapy.

Mechanical obstructions are treated by removing or repairing the obstruction when possible. Resection of the prostate gland may be done for urinary retention related to BPH. Bladder calculi are removed and measures to prevent their formation are instituted.

Nursing care

Health promotion measures to prevent urinary retention include monitoring urine output in at-risk individuals and evaluating drug regimens for medications known to interfere with detrusor muscle function. Pay particular attention to elimination when these drugs are ordered for (or used by) those with BPH or if there is known mechanical obstruction of urine flow.

Nursing diagnoses and interventions

Impaired urinary elimination

Nursing measures to promote urination include placing the individual in normal voiding position and providing for privacy. Additional measures include running water, placing the person's hands in warm water, pouring warm water over the perineum or taking a warm sitz bath.

In acute urinary retention, catheterisation may be necessary to relieve bladder distension and prevent hydronephrosis. Use a relatively small catheter (14 Fr. for a man, 12 Fr. for a woman). A coudé-tipped catheter is passed more easily in the older man with an enlarged prostate. Using 2% lignocaine gel (10 mL injected into the male urethra or 6 mL injected into the female urethra) reduces discomfort during catheterisation and the risk of catheter-associated infection and promotes pelvic muscle relaxation (Bardsley, 2005). Carefully observe the person as the distended bladder drains for signs of discomfort or shock.

Home care for the person with urinary retention varies, depending on the cause. Some people may be taught intermittent self-catheterisation. Instruct all those who have experienced urinary retention to avoid over-the-counter drugs that affect micturition, especially those with an anticholinergic effect (allergy and cold medications, and many non-prescription sleep aids). Other home care measures include double-voiding (urinate, remain on the toilet for 2 to 5 minutes, then urinate again), scheduled voiding, or, when other measures fail, an indwelling catheter. When an indwelling catheter is necessary, teach the person and family to use clean technique when changing from overnight bag to leg bag and to promptly report signs of UTI to the primary care provider.

CONSIDERATION FOR PRACTICE

Some people may experience a vasovagal response, becoming pale, sweaty and hypotensive if the bladder is rapidly drained (decompression). Draining urine in 500 mL increments and clamping the catheter for 5 to 10 minutes between increments may prevent this response. Haematuria also may occur with rapid bladder decompression. Promptly notify the doctor if haematuria develops.

THE PERSON WITH A NEUROGENIC BLADDER

The neurological connections influencing bladder filling, the perception of fullness and the need to void, and bladder emptying are complex. Disruption of the central or peripheral nervous systems may interfere with normal mechanisms, causing **neurogenic bladder**.

Pathophysiology

As noted in the physiology section on urinary retention, bladder filling and emptying are controlled by the central nervous system (CNS). This neurological control can be disrupted at any level: the cerebral cortex (voluntary impulses), the micturition centre of the midbrain, the spinal cord tracts or the peripheral nerves of the bladder itself.

Spastic bladder dysfunction

A simple reflex arc exists between the bladder and the spinal cord at levels S_2 to S_4. The stimulus of more than 400 mL of urine in the bladder causes reflex contraction of the detrusor muscle and bladder emptying unless voluntary control (cerebral input) is used to suppress it. Disruption of CNS transmission above the sacral spinal cord segment typically leads to *spastic neurogenic bladder*. Both sensory and voluntary control of urination is interrupted partially or totally, while the sacral reflex arc remains intact. The stimuli generated by bladder filling causes frequent spontaneous detrusor muscle contraction and involuntary bladder emptying. Spinal cord injury above the sacral segment is the most

common cause of a spastic bladder. Other causes include stroke, multiple sclerosis and other CNS lesions (Porth & Matfin, 2009).

Flaccid bladder dysfunction

Damage to the sacral spinal cord at the level of the reflex arc, the cauda equina or the sacral nerve roots causes loss of detrusor muscle tone and a *flaccid neurogenic bladder*. The perception of bladder fullness is lost and the bladder becomes overdistended, with weak and ineffective detrusor muscle contractions. Flaccid neurogenic bladder is seen with myelomeningocele and during the spinal shock phase of a spinal cord injury above the sacral region. During the spinal shock phase, all reflex activity below the level of spinal cord injury is suppressed.

Peripheral neuropathies may also cause bladder atony and overfilling. Either sensory or motor pathways (or both) may be disrupted, leading to incomplete bladder emptying and large residual volumes after voiding (Porth & Matfin, 2009). Diabetes mellitus is the most common cause of peripheral bladder neuropathy. Other causes include multiple sclerosis, chronic alcoholism and prolonged overdistension of the bladder.

INTERPROFESSIONAL CARE

Management of a neurogenic bladder focuses on maintaining continence and avoiding complications associated with overfilling or incomplete emptying of the bladder. Because self-care is the goal, teaching is a primary intervention for the healthcare team.

Diagnosis

The following diagnostic tests may be ordered for the person with a neurogenic bladder:

- *Urine culture* to detect possible urinary tract infection related to impaired bladder function.
- *Urinalysis* and *serum creatinine* and *BUN* to evaluate renal function. See the diagnostic tests table in Chapter 25 for normal BUN and creatinine levels. Ascending infection or hydronephrosis resulting from bladder overfilling and vesicoureteral reflux can damage the kidneys. Impaired renal function may lead to blood cells or protein in the urine and elevated BUN and creatinine levels.
- *Post-void catheterisation* to measure residual urine. Amounts greater than 50 mL may indicate ineffective detrusor muscle contractions, common in a neurogenic bladder.
- *Cystometrography* to evaluate bladder filling and the detrusor muscle tone and function. See Chapter 25 for nursing care of the person undergoing cystometrography.

Medications

Medications may be prescribed to increase or decrease the contractility of the detrusor muscle, to increase or decrease the tone of the internal sphincter, or to relax the external urethral sphincter.

Bethanechol (Urocarb), a cholinergic drug, stimulates detrusor muscle contraction in a flaccid neurogenic bladder. It is generally used to manage short-term urinary retention (e.g. following surgery or childbirth). It may be used in combination with bladder-training techniques to promote complete emptying of a neurogenic bladder. Anticholinesterase drugs such as neostigmine also may be used to increase detrusor muscle tone.

Anticholinergic drugs (parasympathetic blockers) relax the detrusor muscle and contract the internal sphincter, increasing bladder capacity in people with spastic bladder dysfunction. Oxybutynin (Ditropan) and tolterodine (Detrol) inhibit the muscarinic effects of acetylcholine on smooth muscle, reducing detrusor muscle spasticity and promoting bladder filling. Other anticholinergic drugs also may be used, including propantheline (Pro-Banthine) or flavoxate (Urispas). Dry mouth, blurred vision and constipation are potential adverse effects of anticholinergic medications. See the 'Medication administration' box below for drugs used to modify detrusor muscle activity.

Nutrition

Dietary measures to reduce the risk of UTI and urinary calculi may be suggested for the person with a neurogenic bladder. A moderate to high fluid intake and a diet that acidifies the urine are helpful. Cranberry juice is recommended to maintain urine acidity. See Table 26.3 for additional foods to include or avoid in the diet to help prevent UTI and urolithiasis. The timing of fluid intake may be regulated to promote continence.

Bladder retraining

Individuals with a spastic neurogenic bladder may use measures to stimulate reflex voiding, allowing scheduled toileting. Techniques include using trigger points—for example, stroking or pinching the abdomen, inner thigh or glans penis. Pulling pubic hairs, tapping the suprapubic region or inserting a gloved finger into the rectum and gently stretching the anal sphincter can also stimulate urination.

Credé's method (applying pressure to the suprapubic region with the fingers of one or both hands), manual pressure on the abdomen and the Valsalva manoeuvre (bearing down while holding the breath) promote bladder emptying for the person with a spastic or flaccid bladder.

CONSIDERATION FOR PRACTICE

Increasing lower abdominal and bladder pressure with Credé's method can stimulate autonomic dysreflexia in some people with spinal cord injuries. Autonomic dysreflexia is a medical emergency in which the blood pressure rises rapidly due to SNS stimulation.

See Chapter 42 for a discussion of autonomic dysreflexia.

The person with a flaccid bladder may require catheterisation to completely empty the bladder. An indwelling catheter may be used initially, but intermittent catheterisation is preferred. Clean intermittent self-catheterisation is performed every 3 to 4 hours to prevent overdistension of the bladder (see Procedure 42.1).

Surgery

Surgery may be required when urination cannot be effectively managed using more conservative measures. *Rhizotomy*, or destruction of the nerve supply to the detrusor muscle or the external sphincter, may be used for those with hyperreflexia or spasticity. Urinary diversion is another surgical technique used when conservative management fails. Implantation of an artificial sphincter may be useful for some people with neurogenic bladder. See Table 26.6 for urinary diversion techniques and above for nursing care of those undergoing a urinary diversion.

MEDICATION ADMINISTRATION The person with a neurogenic bladder

ANTICHOLINERGIC DRUGS TO TREAT SPASTIC BLADDER

Oxybutynin (Ditropan, Ditropan XL)
Tolterodine (Detrol, Detrol LA)
Propantheline bromide (Pro-Banthine)
Flavoxate hydrochloride (Urispas)

Anticholinergic drugs inhibit the response to acetylcholine, relaxing the detrusor muscle and increasing internal sphincter tone. The combination of detrusor relaxation and internal sphincter contraction increases the bladder capacity of those with spastic or hyperreflexive neurogenic bladder. Of these medications, tolterodine has the most specific effects on the detrusor muscle with fewer anticholinergic side effects.

Nursing responsibilities

- Assess for contraindications, such as glaucoma, gastrointestinal or urinary tract obstruction, severe ulcerative colitis or toxic megacolon, unstable cardiovascular status or myasthenia gravis.
- Observe for the desired effect of increased bladder capacity with decreased incontinence and spasm.
- Monitor for possible interaction with other drugs such as narcotic analgesics, antiarrhythmic medications, antihistamines, antidepressants or psychoactive drugs.
- Monitor heart rate and blood pressure, especially when given to people with known cardiovascular disease.
- Assess for adverse effects such as urinary hesitancy or retention, arrhythmias, mental status changes and gastrointestinal disturbances.

Health education for the person and family

- Promptly report eye pain, rapid heartbeat, difficulty breathing, rash or hives, or changes in mental function to your primary care provider.
- These drugs may cause drowsiness or blurred vision. Use caution when driving, operating machinery or performing other tasks requiring mental acuity.
- Boiled sweets help relieve dry mouth associated with these drugs.
- Do not use alcohol or non-prescription antihistamines while taking these drugs.

CHOLINERGIC DRUGS TO STIMULATE MICTURITION

Bethanechol chloride (Urocarb)

- Bethanechol stimulates the parasympathetic nervous system, increasing detrusor muscle tone and producing a contraction strong enough to initiate micturition. It is used primarily to treat acute postoperative and postpartum urinary retention.

Nursing responsibilities

- Assess for contraindications, including hypersensitivity, hyperthyroidism, peptic ulcer disease, asthma, significant bradycardia or hypotension, coronary heart disease, epilepsy and parkinsonism.
- Do not give to individuals who have had recent gastrointestinal or bladder surgery, or those with possible gastrointestinal or urinary tract obstruction.
- Give oral forms on an empty stomach to reduce the risk of nausea and vomiting.
- Administer parenteral bethanechol (Urocarb) subcutaneously. Keep atropine, the antidote for bethanechol overdose or toxicity, available.
- Observe for desired effect within 30 to 60 minutes after oral administration, 5 to 15 minutes after injection.
- Assess for adverse effects such as malaise, headache, abdominal cramping, nausea, hypotension with reflex tachycardia, wheezing and dyspnoea.

Health education for the person and family

- Take the medication 1 hour before or 2 hours after meals.
- Use caution when rising from a recumbent or sitting position; you may feel dizzy or light headed.

Nursing care

Nursing care of the person with a neurogenic bladder is directed towards promoting urinary drainage and continence, preventing complications, and teaching the person and family self-care techniques.

Assessment

Nursing assessment for neurogenic bladder includes obtaining a complete nursing history, focusing on information related to CNS or spinal cord injury or disease, as well as disorders that affect the peripheral nervous system (e.g. diabetes). Ask about measures used to stimulate or control urination. Inspect and palpate the lower abdomen and suprapubic region for tenderness or bladder distension. Percuss the suprapubic region for a dull percussion tone indicative of a full bladder. Dullness up to the level of the umbilicus indicates at least 500 mL of urine in the bladder (Gray, 2000). Assess urine for colour, clarity and odour. Collect a specimen for analysis as indicated.

Nursing diagnoses and interventions

Although each person has individual nursing care needs, examples of nursing diagnoses appropriate for those with a neurogenic bladder include the following:

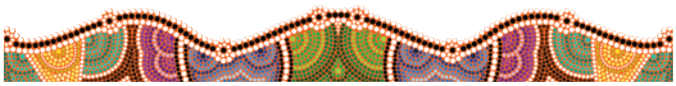
- *Impaired urinary elimination* related to impaired bladder innervation.
- *Self-care deficit: toileting* related to neurological injury.
- *Risk of impaired skin integrity* related to urinary incontinence.
- *Risk of infection* related to impaired urination reflex.

Community-based care

Include the following in teaching for the person with a neurogenic bladder and family members:

- measures to stimulate reflex voiding and promote bladder emptying

- use of prescribed medications, including desired and adverse effects and interactions with other drugs
- manifestations of UTI or urolithiasis and measures to reduce the risk of these complications.



THE PERSON WITH URINARY INCONTINENCE

The most common manifestation of impaired bladder control is **urinary incontinence (UI)**, or involuntary urination. UI can have a significant impact on individuals, leading to physical problems such as skin breakdown, maceration, infection and rashes. Psychosocial consequences include embarrassment, isolation and withdrawal, feelings of worthlessness and helplessness, and depression.

Incidence and prevalence

According to the Continence Foundation of Australia (CFA) (2012), approximately 37% of Australian women and 13% of Australian men are affected by urinary incontinence. An estimated 65% of older women visiting their general practitioner reported UI and in nursing homes the incidence is about 77% (CFA, 2012). The actual prevalence of urinary incontinence is nearly impossible to determine. Embarrassment and the availability of products to protect clothing and prevent detection contribute to people not seeking evaluation of and treatment for incontinence.

Pathophysiology

Urinary continence requires a bladder able to expand and contract, and sphincters that can maintain a urethral pressure higher than that in the bladder. Incontinence results when the pressure within the urinary bladder exceeds urethral resistance, allowing urine to escape. Any condition causing higher than normal bladder pressures or reduced urethral resistance can potentially result in incontinence. Relaxation of the pelvic musculature, disruption of cerebral and nervous system control, and disturbances of the bladder and its musculature are common contributing factors.

Incontinence may be an acute, self-limited disorder or it may be chronic. The causes may be congenital or acquired, reversible or irreversible. Congenital disorders associated with incontinence include *epispadias* (absence of the upper wall of the urethra) and *meningomyelocele* (a neural tube defect in which a portion of the spinal cord and its surrounding meninges protrude through the vertebral column). CNS or spinal cord trauma, stroke and chronic neurological disorders such as multiple sclerosis and Parkinson's disease are examples of acquired, irreversible causes of incontinence. Reversible causes include acute confusion, medications such as diuretics or sedatives, prostatic enlargement, vaginal and urethral atrophy, UTI and faecal impaction.

FAST FACTS

- Urinary incontinence is especially common among older individuals. Although the prevalence of UI increases in older adults, it is *not* a normal consequence of ageing and it can be treated.
- Over 70% of women suffer from UI as a result of childbirth and the menopause.
- The incidence of UI in males increases with age, especially in the 80+ age group.

Incontinence is commonly categorised as stress incontinence, urge incontinence (also known as overactive bladder), overflow incontinence and functional incontinence. Table 26.7 summarises each type with its physiological cause and associated factors. *Mixed incontinence*, with elements of both stress

NURSING CARE OF THE OLDER ADULT Minimising the risk of UTI and UI

Older adults have a higher incidence of two common urinary tract disorders: urinary tract infection and urinary incontinence.

URINARY TRACT INFECTION

Ageing affects the normal protective mechanisms which prevent UTI. The pH of urine increases with ageing, allowing bacteria to grow and multiply more readily. Glucosuria, more common in older adults due to the higher incidence of diabetes, facilitates bacterial growth. Incomplete bladder emptying and urinary retention are more common due to problems such as prostatic hypertrophy in men, bladder prolapse in women and neurogenic bladder in both sexes. Changes in vaginal pH in women post menopause and decreased prostatic secretions in men may also contribute to an increased incidence of UTI.

While many UTIs in older adults are asymptomatic and self-limited, infections can lead to bacteraemia, sepsis and shock. Manifestations of UTI in the elderly include dysuria, urgency, frequency, incontinence, occasional haematuria and confusion. Symptoms such as fever, chills and flank pain and tenderness may be absent. Dementia may make diagnosis more difficult.

URINARY INCONTINENCE

Urinary incontinence, the involuntary loss of urine, is a common problem in older adults. While incontinence should never be considered a *normal* consequence of ageing, age-related changes contribute to its development. Bladder capacity tends to decline with age and involuntary bladder muscle contractions are more common. In women, decreased oestrogen levels and pelvic muscle relaxation decrease bladder outlet and urethral resistance pressures. Decreased oestrogen also causes atrophic vaginitis and urethritis, with manifestations of dysuria and urgency. Other risk factors for UI in older adults include impaired mobility and chronic degenerative diseases, impaired cognition, medications, low fluid intake, diabetes and stroke.

ASSESSING FOR HOME CARE

Assessment for urinary problems in the older adult focuses on risk factors, the extent and manifestations of the disorder, and contributing factors. Using clear language, ask about problems with urine loss, its frequency and any contributing factors. Enquire about frequency, urgency and burning on urination. Identify current medications and the

NURSING CARE OF THE OLDER ADULT **Minimising the risk of UTI and UI (continued)**

time of day each is taken. Assess patterns of fluid intake and output. Assess the abdomen for evidence of bladder distension or tenderness. Perform a mental status examination if indicated.

Assess the home environment (whether in the community or a residential living facility) for possible barriers to urinary elimination:

- inadequate lighting, particularly at night
- narrow doorways that may interfere with access to the toilet
- inadequate toilet facilities
- physical placement of toilet facilities resulting in long walks for disabled or incapacitated individuals
- the need for mobility aids such as safety bars, a raised toilet seat or a bedside commode.

TEACHING FOR HOME CARE

Discuss the following points to help prevent UTI and UI in the older adult:

- Maintain a generous fluid intake. Reduce or eliminate fluid intake after 7 pm in the evening to reduce nocturia.
- Wear comfortable clothing that is easy to remove for toileting.
- Maintain good hygiene, but do not bathe more often than necessary. Frequent bathing and feminine hygiene sprays or douches may dry perineal tissues, increasing the risk of UTI or UI.
- Perform pelvic muscle exercises (Kegel exercises) several times a day to increase perineal muscle tone.
- Reduce consumption of caffeine-containing beverages (coffee, tea, colas), citrus juices and artificially sweetened beverages containing aspartame.
- Use behavioural techniques such as scheduled toileting, habit training and bladder training to reduce the frequency of incontinence. *Scheduled toileting* is toileting at regular intervals (e.g. every 2 to 4 hours). *Habit training* is toileting the person on a schedule that corresponds with the normal pattern. *Bladder training* gradually increases the bladder capacity by increasing the intervals between voidings and resisting the urge to void.
- See your primary care provider regularly for a pelvic or prostate examination to assess for physical abnormalities.
- For women, discuss possible benefits and risks of hormone replacement therapy, physical therapy, incontinence aids or surgery to treat incontinence.
- Report a change in urine colour, odour or clarity, or symptoms such as burning, frequency or urgency, to your primary care provider.

and urge incontinence, is common. *Total incontinence* is loss of all voluntary control over urination, with urine loss occurring without stimulus and in all positions.

Incontinence is associated with an increased risk of falls, fractures, pressure ulcers, urinary tract infection and depression. It contributes to the stress of caregivers and may be a factor in institutionalising the affected person.

INTERPROFESSIONAL CARE

Urinary incontinence management is directed at identifying and correcting the cause if possible. If the underlying disorder cannot be corrected, techniques to manage urine output can often be taught.

Evaluation for incontinence begins with a complete history, including the duration, frequency, volume and associated circumstances of urine loss. A voiding diary (see Figure 26.8) is often used to collect detailed information. The history also includes information about chronic or acute illnesses, previous surgeries and current medication use, both prescription and over the counter.

Physical assessment includes abdominal, rectal and pelvic assessment, as well as evaluation of mental and neurological status, mobility and dexterity. Findings often associated with incontinence in women include weak abdominal and pelvic muscle tone, cystocele or urethrocele, and atrophic vaginitis. In men, an enlarged prostate gland is the physical finding most commonly associated with incontinence.

See the 'Translation to practice' feature below on evidence-based practice for diagnosing urge incontinence using specific personal assessment data.

Diagnosis

- *Urinalysis* and *urine culture* using a clean-catch specimen are done to rule out infection and other acute causes of incontinence.

TABLE 26.7 Types of urinary incontinence

	DESCRIPTION	PATHOPHYSIOLOGY	CONTRIBUTING FACTORS
Stress	Loss of urine associated with increased intra-abdominal pressure during sneezing, coughing, lifting. Quantity of urine lost is usually small	Relaxation of pelvic musculature and weakness of urethra and surrounding muscles and tissues leads to decreased urethral resistance	• Multiple pregnancies • Decreased oestrogen levels • Short urethra, change in angle between bladder and urethra • Abdominal wall weakness • Prostate surgery • Increased intra-abdominal pressure due to tumour, ascites, obesity
Urge	Involuntary loss of urine associated with a strong urge to void	Hypertonic or overactive detrusor muscle leads to increased pressure within bladder and inability to inhibit voiding	• Neurological disorders such as stroke, Parkinson's disease, multiple sclerosis; peripheral nervous system disorders • Detrusor muscle overactivity associated with bladder outlet obstruction, ageing or disorders such as diabetes
Overflow	Inability to empty bladder, resulting in overdistension and frequent loss of small amounts of urine	Outlet obstruction or lack of normal detrusor activity leads to overfilling of bladder and increased pressure	• Spinal cord injuries below S_2 • Diabetic neuropathy • Prostatic hypertrophy • Faecal impaction • Drugs, especially those with anticholinergic effect
Functional	Incontinence resulting from physical, environmental or psychosocial causes	Ability to respond to the need to urinate is impaired	• Confusion or dementia • Physical disability or impaired mobility • Therapy or sedation • Depression • Regression

- *Post-voiding residual (PVR) volume* is measured to determine how completely the bladder empties with voiding. Less than 50 mL PVR is expected; when 100 mL or more is obtained, further testing is indicated.
- *Cystometrography* is used to assess neuromuscular function of the bladder by evaluating detrusor muscle function, pressure within the bladder and the filling pattern of the bladder. The person describes sensations and any urge to void as sterile water or saline is instilled into the bladder. Normally, the urge to void is perceived at 150 to 450 mL and the bladder feels full at 300 to 500 mL. Bladder pressure and volume are recorded on a graph. When the bladder is full, the individual voids and intravesical pressure is noted during voiding.
- *Uroflowmetry* is a non-invasive test used to evaluate voiding patterns. The uroflowmeter, contained in a funnel, measures the rate of urine flow, the continuous flow time and the total voiding time.
- *IVP* may be ordered to evaluate structure and function of the upper and lower urinary tract.
- *Cystoscopy* or *ultrasonography* may be ordered to identify structural disorders contributing to incontinence, such as an enlarged prostate or a tumour.

Nursing implications for the specialised studies for urinary incontinence are outlined in Chapter 25.

Medications

Both stress and urge incontinence may improve with drug treatment.

When incontinence is associated with postmenopausal atrophic vaginitis, oestrogen therapy may be effective. Both systemic oestrogens and local creams are used.

People with urge incontinence may be treated with preparations that increase bladder capacity. The primary drugs used to inhibit detrusor muscle contractions and increase bladder capacity include oxybutynin (Ditropan and Ditropan XL), an anticholinergic drug, and tolterodine (Detrol and its longer-acting form, Detrol LA), a more specific antimuscarinic agent. These drugs can be taken once or twice a day and have fewer side effects than less specific anticholinergic drugs. Drugs with anticholinergic effects are contraindicated for the person with acute glaucoma. Urinary retention is a potential side effect that must be considered when these drugs are used (see the 'Medication administration' box above).

Surgery

Surgery may be used to treat stress incontinence associated with cystocele or urethrocele and overflow incontinence associated with an enlarged prostate gland.

Suspension of the bladder neck, a technique that brings the angle between the bladder and urethra closer to normal, is effective in treating stress incontinence associated with urethrocele in 80–95% of individuals. A laparoscopic, vaginal or abdominal approach may be used to perform this surgery. Care of the person with a bladder neck suspension is outlined below.

Prostatectomy, using either the transurethral or suprapubic approach, is indicated for the person who is experiencing overflow incontinence as a result of an enlarged prostate gland and urethral obstruction. Care of the person with a prostatectomy is outlined in Chapter 47.

Other surgical procedures of potential benefit in the treatment of incontinence include implantation of an artificial sphincter, formation of a urethral sling to elevate and compress

Your Daily Voiding Diary **Date** _____

This diary will help you and your healthcare team identify factors causing bladder control problems. Choose a 24-hour period when you can record your fluid intake (type and amount), urine output and episodes of urine leakage, any strong urge to void just prior to leaking, and your activity when leak episodes occur. The line below illustrates how to use your diary.

Time	Fluid Intake		Urine Output	Leaks	Urge	Activity
	Amount	Type			Yes No	
7 am	2 cups	coffee	sm (med) lg	(sm) med lg	Yes	walking
			sm med lg	sm med lg

the urethra, and augmentation of the bladder with bowel segments to increase bladder capacity.

Complementary therapies

Biofeedback and relaxation techniques may help reduce episodes of urinary incontinence. Biofeedback uses electronic monitors to teach conscious control over physiological responses of which the individual is not normally aware. Developing awareness of perceptible information allows the person to gain voluntary control over urination. Biofeedback is widely used to manage urinary incontinence.

Nursing care

Health promotion

Although urinary incontinence rarely causes serious physical effects, it frequently has significant psychosocial effects and can lead to lowered self-esteem, social isolation and even institutionalisation (Lauver et al., 2004). Get the word out—inform all people that UI is not a normal consequence of ageing and that treatments are available. To reduce the incidence of UI, teach all women to perform pelvic floor muscle (Kegel) exercises (see Box 26.3) to improve perineal muscle tone. Advise women to seek advice from their women's healthcare or primary care practitioner about using topical or systemic hormone therapy during menopause to maintain perineal tissue integrity. Advise older men to have routine prostate examinations to prevent urethral obstruction and overflow incontinence. Pelvic floor muscle exercises also may benefit men who experience UI following prostatectomy, but evidence supporting this is limited (Moore & Gray, 2004).

Assessment

Nursing assessment for the person with urinary incontinence includes both subjective and objective data:

- *Health history:* voiding diary; frequency of incontinent episodes, amount of urine loss and activities associated with incontinence; methods used to deal with incontinence; use of Kegel exercises or medications; any chronic

TRANSLATION TO PRACTICE Evidence-based practice: urinary incontinence

While an accurate diagnosis of stress urinary incontinence often is made based on clinical data, motor urge incontinence has been more difficult to diagnose accurately without urodynamic investigations. This presents difficulty for nurses and nurse practitioners planning care for incontinent individuals when urological testing is not feasible or readily available. A model developed by Gray et al. (2001) may be useful to address this problem in cognitively intact adults. By comparing personal data with urodynamic testing results, this team of researchers identified factors predictive of motor urge incontinence. These factors included age, gender and three key symptoms: diurnal frequency (urinating more often than every 2 hours while awake), nocturia (awakening with urge to urinate more than once per night if under age 65, twice per night if over age 65) and urge incontinence (urine loss associated with a strong desire to urinate). The presence of all three symptoms was more than 92% predictive of motor urge incontinence in study participants of all ages (range 18 to 89; median 61) and both genders.

IMPLICATIONS FOR NURSING

Asking specific questions about urinary tract symptoms can facilitate accurate identification of the nursing diagnosis *Urinary incontinence: urge*. Accurate diagnosis is vital to planning and implementing appropriate care measures and achieving the desired outcome of continence. Successful treatment promotes self-esteem and provides positive reinforcement for continuing planned strategies.

CRITICAL THINKING IN PERSON-CENTRED CARE

1. What nursing care measures and person-centred teaching will you provide for the person with stress incontinence that may not be appropriate or necessary for the person with urge incontinence but not stress incontinence?
2. Identify circumstances in which it may not be possible or feasible to have the person undergo urodynamic testing to differentiate stress, urge or mixed (stress and urge) incontinence.
3. The individuals in this study lived independently in the community and were cognitively intact. Can the data in this study be generalised to people residing in a long-term care facility? Can the results be applied to all types of incontinence? Why or why not?

Source: A model for predicting motor urge urinary incontinence by Gray et al., (2001). *Nursing Research*, *50*(2), 116–122.

BOX 26.3 Pelvic floor muscle (Kegel) exercises

Particularly important for postpartum, menopausal or post-vaginal hysterectomy women.

- Identify the pelvic muscles with these techniques:
  a. Stop the flow of urine during voiding and hold for a few seconds.
  b. Tighten the muscles at the vaginal entrance around a gloved finger or tampon.
  c. Tighten the muscles around the anus as though resisting defecation.
- Perform exercises by tightening pelvic muscles, holding for 10 seconds and relaxing for 10 to 15 seconds. Continue the sequence (tighten, hold, relax) for 10 repetitions.
- Keep abdominal muscles and breathing relaxed while performing exercises.
- Initially, exercises should be performed twice per day, working up to four times a day.
- Encourage exercising at a specific time each day or in conjunction with another daily activity (such as bathing or watching the news). Establish a routine because these exercises should be continued for life.

diseases, related surgeries; effects of incontinence on usual activities, including social activities.

- *Physical examination:* physical and mental status, including any physical limitations or impaired cognition; inspect, palpate and percuss abdomen for bladder distension; inspect perineal tissues for redness, irritation or tissue breakdown; observe for bulging of bladder into vagina when bearing down; assess pelvic muscle tone as indicated.

Nursing diagnoses and interventions

In planning nursing care, consider the person's mental status, mobility and motivation. Behavioural techniques can be effective, but require long-term commitment and the physical and mental capability to use them.

Nursing care and modification of routines can restore continence fully or partially even in the institutionalised person. Scheduled toileting, bladder training and prompted voiding, combined with positive reinforcement such as praise, can reduce the need for nappies, incontinence pads and indwelling catheters.

See the nursing care plan that follows for additional nursing diagnoses and interventions for the person with urinary incontinence.

Urinary incontinence: stress and/or urge

Exercises to strengthen pelvic floor muscles, dietary modifications and bladder training programs often are effective to restore and maintain continence.

- Instruct to keep a voiding diary, recording the time and amount of all fluid intake and urinary output, status at the time of voiding (dry or wet) and on arising from sleep and

NURSING CARE OF THE PERSON having a bladder neck suspension

PREOPERATIVE CARE

- Provide routine preoperative care and teaching as outlined in Chapter 3.
- Discuss the need to avoid straining and the Valsalva manoeuvre postoperatively. Suggest measures such as increasing fluid and fibre intake and using a stool softener to prevent postoperative constipation. *Straining and increased abdominal pressure during the Valsalva manoeuvre may place excessive stress on suture lines and interfere with healing.*

POSTOPERATIVE CARE

- Provide routine postoperative care as outlined in Chapter 3.
- Monitor urine output, including quantity, colour and clarity. Expect urine to be pink initially, gradually clearing. *Bright red urine, excessive vaginal drainage or incisional bleeding may indicate haemorrhage. Instrumentation of the urinary tract increases the potential for UTI; cloudy urine may be an early sign.*
- Maintain stability and patency of suprapubic and/or urethral catheters. Secure catheters in position. *Maintaining bladder decompression eliminates pressure on suture lines. Preventing movement or pulling of catheters reduces the risk of resultant pressure on surgical incisions.*
- Carefully monitor urine output after catheter removal. *Difficulty voiding is common following catheter removal. Early intervention to prevent bladder distension is important to prevent pressure on suture lines.*
- If the urethral or suprapubic catheter will remain in place on discharge, teach proper care to the person and family members as needed. *Appropriate self-care and early recognition of problems reduce the risk of significant complications.*

activities. *Voiding diaries provide valuable information for identifying the type of incontinence and possible measures to reduce or eliminate incontinent episodes.*

- Teach pelvic floor muscle exercises (see Box 26.3). Instruct to consciously tighten pelvic muscles when the need to void is perceived and to relax the abdomen while walking to the bathroom. *Improved pelvic muscle strength helps retain urine and prevent stress incontinence by increasing urethral pressure. Exercises also decrease abnormal detrusor muscle contractions, decreasing pressure within the bladder.*

CONSIDERATION FOR PRACTICE

Do not advise people who have difficulty emptying the bladder completely to stop urine flow while voiding to identify pelvic floor muscles. Repeated interruption of micturition can interfere with complete bladder emptying and increase the risk of UTI.

- Using the person's voiding diary, suggest dietary and fluid intake modifications to reduce stress and urge incontinence. Include limiting caffeine, alcohol, citrus juice and artificial sweetener consumption; limiting fluid intake to no less than 1.5 to 2.0 L per day; and limiting evening fluid intake. *Caffeine, alcohol and citrus juices are bladder irritants and tend to promote detrusor instability, increasing the risk of urge incontinence. Artificial sweeteners may also irritate the bladder. Fluid intake of 1.5 to 2.0 L per day is adequate to maintain health for most people; excess fluid may increase stress incontinence if bathroom facilities are not readily available.*

CONSIDERATION FOR PRACTICE

Limiting total fluid intake to less than 1.5 to 2.0 L per day is not recommended for those with urinary incontinence. Inadequate fluid increases urine concentration, leading to bladder wall irritation and possibly increasing problems of urge incontinence.

Self-care deficit: toileting

Functional incontinence may be the predominant problem in an institutionalised older adult. Limited mobility, impaired vision, dementia, lack of access to facilities and privacy, and tight staffing patterns increase the risk of incontinence in previously continent residents. The primary problem in functional incontinence is an outside factor that interferes with the ability to respond normally to the urge to void. An immobilised person may wet the bed if a call light is not within reach; a person with Alzheimer's disease may perceive the urge to void but be unable to interpret its meaning or respond by seeking a bathroom. For these people, self-care deficit in toileting is a primary problem.

- Assess physical and mental abilities and limitations, usual voiding pattern and ability to assist with toileting. *A thorough assessment allows planned interventions to address specific needs and promote independence.*
- Provide assistive devices as needed to facilitate independence, such as raised toilet seats, grab bars, a bedside commode or night-lights. *Fostering independence in toileting bolsters self-concept and maintains a positive body image.*
- Plan a toileting schedule based on the person's normal elimination patterns to achieve approximately 300 mL of urine output with each voiding. *Allowing the bladder to fill to a point at which the urge to void is experienced and then emptying it completely helps maintain normal bladder capacity and bacteriostatic functions.*
- Position for ease of voiding—sitting for females, standing for males—and provide privacy. *Normal positioning, usual toileting facilities and privacy enhance the ability to void on schedule and empty the bladder completely.*
- Adjust fluid intake so that the majority of fluids are consumed during times of the day when the person is most able to remain continent. Unless fluids are to be restricted, maintain a fluid intake of at least 1.5 to 2.0 L per day. *An adequate fluid intake is vital to promote hydration and*

urinary function. Overly concentrated urine can irritate the bladder, increasing incontinence.

- Assist with clothing that is easily removed (e.g. elastic-waist pants or loose dresses). Velcro and zipper fasteners may be easier to use than snaps and buttons. *Clothing that is difficult to remove can increase the risk of incontinence for those with mobility problems or impaired dexterity.*

Social isolation

Urinary incontinence increases the risk of social isolation due to embarrassment, fear of not having ready access to a bathroom, body odour or other factors. Social isolation can, in turn, increase problems of incontinence because normal cues and relationships are lost and the need to remain dry is less strongly felt.

- Assess reasons for and extent of social isolation. Verify the degree of social isolation with the person or significant other. Do not assume that social isolation is only related to urinary incontinence. *Other problems frequently associated with ageing (such as a hearing deficit) may be primary or contributing factors.*
- Refer the person for urological examination and incontinence evaluation. *People who assume that urinary incontinence is a normal part of the ageing process may not be aware of treatment options.*
- Explore alternative coping strategies with the person, significant other, staff and other healthcare team members. *Protective pads or shields, good perineal hygiene, scheduled voiding and clothing that does not interfere with toileting can enhance continence.*

Community-based care

Because urinary incontinence is a contributing factor in the institutionalisation of many older people, person-centred teaching and family teaching can have a significant impact on maintaining independence and residence in the community. Address possible causes of incontinence and appropriate treatment measures. Refer for urological examination if not already completed. Discuss fluid intake management, perineal care and products for clothing protection.

NURSING CARE PLAN A person with urinary incontinence

Anna Giovanni, a 76-year-old retired teacher, has been widowed for 10 years and lives alone. Mrs Giovanni's eldest daughter expresses concern that her mother seems increasingly reluctant to leave her apartment to visit friends and family. She reports a strong odour of urine throughout her mother's apartment and that her mother's bed is often wet. She is worried about needing to place her mother in a nursing home if she cannot continue to live independently.

ASSESSMENT

The community nurse visits Mrs Giovanni to assess her situation. Mrs Giovanni admits that she has problems with urine leakage when laughing and coughing and has a strong urge to void on hearing the sound of running water. At night, her urge to void is so strong that she often cannot reach the bathroom in time. Mrs Giovanni does not have a history of UTIs, neurological disorders or difficulty with her bowels. She had a hysterectomy at age 52 and was on hormone replacement therapy for about 10 years afterwards. She is taking digoxin 0.125 mg daily, frusemide 40 mg twice daily and potassium chloride 20 mEq three times daily for mild heart failure.

Physical assessment reveals a moderate cystourethrocele and atrophy of vaginal and vulvar tissues. Moderate perineal dermatitis is also noted and her pelvic floor strength is weak. Urinalysis is within normal limits and postvoiding residual urine is 5 mL.

Analysis of Mrs Giovanni's voiding diary shows moderate consumption of tea and juices throughout the day, nine day-time voidings and four night voidings with an average volume of about 250 mL per void. She notices urine leakage most often in the late afternoon and at night. The community nurse identifies stress incontinence with an urgency component and decides to try a conservative approach before referring Mrs Giovanni for further testing and possible doctor referral for cystourethrocele repair. Oestrogen cream, tolterodine (Detrol) and a barrier cream to treat Mrs Giovanni's vulvitis are prescribed.

DIAGNOSES

- *Stress urinary incontinence* related to weak pelvic floor musculature and tissue atrophy.
- *Urge urinary incontinence* related to excess intake of caffeine and citrus juices.
- *Impaired skin integrity* related to constant contact of urine with perineal tissues.
- *Ineffective coping* related to inability to control urine leakage.

PLANNING

- Plan interventions to facilitate a return of normal bladder function.
- Plan interventions that foster a resumption of previous levels of social activity.

Expected outcomes

- Remain dry between voidings and at night.
- Demonstrate improved perineal muscle strength.
- Regain and maintain perineal skin integrity.
- Return to her previous level of social activity.

IMPLEMENTATION

- Teach how to identify pelvic floor muscles and how to perform Kegel exercises.
- Suggest drinking decaffeinated tea and non-citrus fruit juices (grape, apple and cranberry).
- Encourage to minimise fluid intake after evening meal.

NURSING CARE PLAN A person with urinary incontinence (continued)

- Change evening dose of frusemide from 9 pm to 3 pm.
- Instruct to void by the clock, gradually increasing intervals from every 45 to 60 minutes to every 2 to 2.5 hours. Advise to maintain shorter voiding intervals for 2 to 3 hours after frusemide doses.
- Teach to how to cleanse perineal area, wiping front to back after each voiding or incident of urine leakage.
- Introduce commercial products available for clothing and furniture protection, encouraging experimentation to identify the most helpful product(s).
- Provide a commode for bedside at night and adequate lighting to prevent injury.
- Schedule follow-up visits and evaluations to reinforce teaching.

EVALUATION

Three months after her initial visit, Mrs Giovanni states that she is doing very well, experiencing only occasional leakage of small amounts of urine, primarily when sneezing, coughing or laughing. She finds a minipad adequate for protection and is often able to remain dry all day. She has had no further problems with enuresis since changing her evening frusemide dose to late afternoon and limiting her fluids after dinner. She can make it to the bathroom and no longer needs the bedside commode. Her perineal tissue is intact and she demonstrates improved muscle strength. Anna's daughter says her mother is beginning to resume her normal social activities and that she is no longer worried about her mother's ability to care for herself independently.

CRITICAL THINKING IN THE NURSING PROCESS

1 What factors in Mrs Giovanni's medical history and current medication regimen contributed to her nighttime incontinence?
2 What is the rationale for including an intervention to teach Mrs Giovanni about perineal cleansing as part of her care plan?

REFLECTION ON THE NURSING PROCESS

1 Outline what you have learned from Mrs Giovanni's situation that you could apply to your future practice.
2 What educational strategies would you give Mrs Giovanni's family to prevent her developing social isolation related to the urinary incontinence?

CHAPTER HIGHLIGHTS

- Urinary tract infections are very common and are a leading complication among hospitalised individuals. Short-course antibiotic therapy is appropriate for uncomplicated infections of the lower urinary tract that are not associated with the presence of an indwelling urinary catheter.
- Teach people about perineal hygiene and the importance of maintaining adequate fluid intake as measures to help prevent UTI.
- Urinary calculi can obstruct the urinary tract at any level and cause significant pain as they move from the kidney through the ureter. Instruct those who have had a renal stone to maintain a generous fluid intake particularly during exercise and warm weather, to reduce the risk of further stone formation.
- The risk of bladder cancer is greater among men than women and cigarette smoking is the most significant risk factor for bladder cancer. Most tumours can be resected transurethrally if diagnosed early, before spreading to deeper layers of the bladder wall, the lymph nodes and adjacent tissue.
- When resection of the urinary bladder is necessary, a urinary diversion is created to collect urine. A collection appliance must be worn constantly on an ileal conduit; when a continent urinary diversion is created, the pouch is emptied by intermittent catheterisation of the stoma.
- Urinary retention may occur as a result of some medications, neurological damage or disease, or obstruction (e.g. an enlarged prostate gland). If the underlying condition cannot be treated, medications or intermittent catheterisation are used to promote bladder emptying.
- Older adults, in particular, are at risk of urinary incontinence, a treatable condition. A health history, voiding diary and diagnostic testing are used to establish the type of urinary incontinence and direct treatments such as surgery, pelvic floor muscle exercises, medications and scheduled toileting.

CONCEPT CHECK

1 A 30-year-old male presents to the urgency clinic complaining of concentrated bright yellow urine and of discomfort in his lower back area. The assessment reveals no significant nursing history. Additional questions the nurse should ask include:
   1 'Have you had any injury to your abdominal area?'
   2 'When did you first notice your urine's colour?'
   3 'How often do you void?'
   4 'How much fluid do you drink each day?'

2 The man volunteers the information that he has just started cycling, has been following a strict high-level exercise program and has a high-protein diet. His fluid intake is about 1 L per day. The nurse should then ask:
   1 'Do you take any prescribed medications?'
   2 'How much exercise do you have each day?'
   3 'How long have you been on this exercise program?'
   4 'Do you take any additional supplements, e.g. vitamins?' (Multi-vitamins will colour urine orange.)

3 After an assessment and a nursing history nothing of significance is noted except mild tenderness over the lower back area. The man admits he has been taking multivitamins because he wanted to improve his physical performance. The nurse recommends the man:
   1 reduces the amount of exercise he does on a daily basis
   2 applies a warm pack to his lower back when he rests
   3 stops taking the multivitamin medication until his urine returns to a normal colour
   4 increases his fluid intake to at least 3 L per day

4 A 58-year-old woman presents at her doctor's with symptoms of frequency, urgency, nocturia, dysuria and cloudy, rust-coloured urine for the third time in the past 2 years. The nurse should plan to include which of the following in her teaching for this woman? (Select all that apply.)
1 return to the office in 10 days for follow-up culture
2 preprocedure instruction for an IVP
3 the potential benefits of oestrogen vaginal cream
4 recommendations for perineal cleansing
5 recommendations for screening cystoscopy

5 Recognising the risk of urolithiasis in the immobilised person, the nurse appropriately plans to:
1 administer a calcium supplement
2 regularly monitor urine pH
3 maintain an indwelling urinary catheter
4 increase fluid intake to 3000 mL per day

6 A person admitted with possible kidney stones develops sudden complaints of acute crampy pain on the left side that radiates into the groin. He is nauseated and vomits clear fluid. On voiding, his urine is pink. The nurse should:
1 obtain a bladder scan to assess for residual urine
2 administer the prescribed narcotic analgesic
3 notify the doctor
4 strain all urine

7 The nurse teaching a group of community members about wellness and disease prevention includes which of the following as a measure to reduce the risk of bladder cancer?
1 Do not start smoking. If you smoke, stop.
2 Avoid using hair dyes and pesticides in the home.
3 Limit your intake of coffee and other caffeinated beverages.
4 Empty your bladder every 2 hours.

8 A person remarks to the nurse that his urine occasionally appears pink. He wonders if this is anything to be concerned about. The nurse should:
1 instruct the man to notify his doctor if he develops pain or difficulty voiding
2 advise the man to make an appointment to see his doctor
3 instruct the man to record if the urine is pink following exercise
4 tell the man to increase his fluid intake to 4 L per day

9 The nurse caring for a person in the spinal shock phase following spinal cord injury appropriately plans to:
1 insert a Foley catheter to accurately measure output
2 stimulate voiding using Credé's method
3 assess for urinary retention following each voiding
4 catheterise with a straight catheter every 3 to 4 hours

10 The nurse implements a nursing care necessary for this individual with a Foley catheter in place to:
1 maintain the closed system of drainage tubing and collection bag to prevent ascending infection
2 irrigate the person with 1% neosporin solution three times a daily
3 clamp the catheter for 1 hour every 4 hours to maintain the bladder's elasticity
4 maintain the drainage tubing and collection bag below bladder level to facilitate drainage by gravity

CHAPTER 27

NURSING CARE OF PEOPLE WITH KIDNEY DISORDERS

PAUL BENNETT, PETER SINCLAIR, MONICA SCHOCH

LEARNING OUTCOMES

- Discuss the course, implications and health management options for a person with acute kidney injury.
- Relate the pathophysiology, clinical manifestations and possible interventions required for a person with chronic kidney disease to the pathophysiology of the condition.
- Discuss the risk factors, implications and health management and treatment options for a person who has end-stage kidney disease.

CLINICAL COMPETENCIES

- Assess the functional health status of people with kidney disease.
- Monitor, document and report unexpected or abnormal manifestations in people with kidney disease.
- Provide appropriate and effective nursing care for people undergoing dialysis, surgery involving the kidneys or kidney transplant.
- Based on assessment data, determine priority nursing diagnoses and interventions for people with kidney disease.
- Plan and implement evidence-based nursing care for people with kidney disease using research and best practices.
- Collaborate with the person and other members of the interprofessional team to prioritise and implement care.
- Provide teaching appropriate to both people with kidney disease and their personal circumstances.
- Evaluate responses to care, revising the plan of care as needed to promote, maintain or restore functional health status for people with kidney disease.

KEY TERMS

The internal environment of the body normally remains in a relatively constant or *homeostatic* state. One of the easiest ways to reflect on the nursing roles necessary when looking after a person with renal insufficiency is to recall the functions of the kidney (see Table 27.1) and then consider how we support the loss of those functions.

RENAL INSUFFICIENCY: TOWARDS A NEW UNDERSTANDING

Renal insufficiency is a broad term that describes any condition in which the kidneys are unable to remove accumulated metabolites from the blood, leading to altered fluid, electrolyte and acid–base balance. The cause may be an acute insult or a primary kidney disorder, or may be secondary to a systemic disease or urological defects.

Before we continue to explore the many facets of renal insufficiency it is important to understand the disease trajectory of any kidney-related disorder and the meanings of the terms used to describe them. One point to note when reviewing the renal literature is that there has been a change in the past few years as to how we describe renal insufficiency. You may note that some literature uses the term 'chronic renal failure' or 'acute renal failure' whereas more modern texts use the terms 'chronic kidney disease' and 'acute kidney injury or dysfunction', respectively. These changes in terminology reflect the changes in our understanding of both the illness trajectory and the pathophysiology of renal insufficiency, and that in fact, more often than not, there is a disease process occurring and not merely 'renal failure'.

The sub-types of renal insufficiency are described as either acute, chronic or end-stage. **Acute kidney injury (AKI)** is characterised by a rapid onset of symptoms that are potentially reversible with prompt intervention that addresses the initial cause of the injury. Chronic kidney disease, by contrast, is a largely silent disease that presents as an insidious irreversible decline in renal function. A more detailed definition of chronic kidney disease (CKD) will be discussed later in this chapter. People with CKD are also at high risk of acute episodes, which is referred to as 'acute on chronic kidney disease'. As the phrase suggests, an acute injury is superimposed on a background of CKD. For example, a person with a history of CKD may become dehydrated and experience a rapid decline in renal function which may be reversible with adequate rehydration.

TABLE 27.1 Functions of the kidney

EXCRETORY	REGULATORY	HORMONAL/ METABOLIC
Removal of metabolic waste products	Maintain fluid and electrolyte balance Maintain acid–base balance Regulate blood pressure	Activation of vitamin D Erythropoietin production Renin production

There is often some confusion in the literature when the terms 'chronic kidney disease' and 'end-stage kidney disease' are used interchangeably. This use is incorrect, as the final stage of chronic kidney disease, when the glomerular filtration rate falls below 15 mL/min, sees its description change to 'end-stage kidney disease' to denote the terminal phase of the disease trajectory. It is at this stage that the person must choose to undergo a kidney replacement therapy or to withdraw from active treatment.

FAST FACTS

- Acute kidney injury has a sudden onset and is often reversible with prompt treatment.
- Chronic kidney disease is a slowly progressive and often silent disease that is irreversible.
- End-stage kidney disease is the final stage of the CKD continuum.

AGE-RELATED CHANGES IN KIDNEY FUNCTION

Structural and functional changes occur in the ageing kidney. Structurally, the number of nephrons decreases. Glomeruli in the renal cortex (see Chapter 25 for a review of normal kidney structure and function) are lost with ageing, reducing kidney mass. Because of the large functional reserve of the kidneys, however, renal function remains adequate unless additional stressors affect the renal system. Any additional stressors such as hypotension, exposure to nephrotoxic drugs or an inflammatory process such as glomerulonephritis may precipitate an acute episode in the older adult. The **glomerular filtration rate (GFR)**, the amount of filtrate made by the kidneys per minute, declines due to age-related factors affecting the renovascular system (such as arteriosclerosis, decreased renal vascularity and decreased cardiac output). By age 80, the GFR may be less than half of what it was at age 30. Serum creatinine levels may rise slowly. Because older adults have less muscle mass, they produce less creatinine. Likewise, the urea may remain within normal limits.

Age-related changes in renal function have significant implications. The kidneys are less able to concentrate urine and compensate for increased or decreased salt intake. When combined with the diminished effectiveness of antidiuretic hormone (ADH) and a reduced thirst response, both common in ageing, this decreased ability to concentrate urine increases the risk of dehydration. Potassium excretion may be decreased because of lower aldosterone levels. As a result, fluid and electrolyte imbalances are more common and potentially critical in older people.

Decreased GFR in the older adult also reduces the clearance of drugs excreted through the kidneys. This reduced clearance prolongs the half life of drugs and may necessitate lower drug doses and longer dosing intervals. Common medications affected by decreased GFR include:

- cardiac drugs: digoxin
- antibiotics: aminoglycosides, tetracyclines, cephalosporins
- histamine H_2 antagonists: cimetidine
- hypoglycaemic agents: metformin.

TABLE 27.2 Nursing implications of age-related changes in kidney function

FUNCTIONAL CHANGE	EFFECT	IMPLICATIONS
Decreased GFR	Decreased clearance of drugs excreted primarily through the kidneys increases drug half life and blood levels and risk of drug toxicity.	Monitor carefully for signs of toxicity, especially when administering contrast media, amphotericin B, digoxin, aminoglycoside antibiotics, tetracyclines, vancomycin, cimetidine and cephalosporin antibiotics.
Decreased number of functional nephrons; lower levels of aldosterone; increased resistance to ADH	Decreased ability to conserve water and sodium; impaired potassium excretion; and decreased hydrogen ion excretion, resulting in reduced ability to compensate for acidosis.	Monitor for dehydration and hyponatraemia; maintain fluid intake of 1500 to 2500 mL/day unless contraindicated; monitor for hyperkalaemia, especially if taking a potassium-sparing diuretic, heparin, ACE inhibitor, beta-blocker or NSAID; increased risk of acidosis.
Reduced numbers of functional nephrons	Decreased renal reserve with increased risk of acute injury.	Avoid giving nephrotoxic drugs if possible; monitor urine output and blood chemistries for early signs of renal failure.

When caring for older adults or any person at risk of chronic kidney disease, it is especially important to monitor drugs that are toxic to the renal tubules. Age-related changes in renal function and related nursing implications are summarised in Table 27.2.

THE PERSON WITH ACUTE KIDNEY INJURY

The use of the term 'AKI' suggests some form of structural injury to the renal parenchyma, yet classifications of AKI such as RIFLE (Risk, Injury, Failure, Loss, End-stage kidney disease) and the Acute Kidney Injury Network (AKIN) criteria (see Table 27.3) define AKI in terms of functional decreases. In basic terms, AKI manifests as a rapid decline in renal function with uraemic symptoms and fluid and electrolyte imbalances. The deterioration in renal function sees an increase in serum creatinine levels. However, what is important in terms of outcomes for people experiencing AKI is the context and environment in which the insult to the kidney occurs as this is directly associated with mortality and morbidity.

AKI is a broad clinical syndrome, which includes both direct injury to the kidney and the acute impairment of function. Even an increase in serum creatinine of only 26.5 µmol/L (0.3 mg/dL) in a 48-hour period is associated with higher mortality rates (Kellum & Lameire, 2013).

Incidence and risk factors

Approximately 5–7% of all people hospitalised develop AKI; the incidence jumps to as high as 30% in critical care units, with an associated mortality rate as high as 60% (Fauci et al., 2008). The reason these rates are so high has previously been attributed to the populations affected by AKI (i.e. older people and the critically ill), but recent evidence suggests that AKI itself may have an independent and deleterious effect on morbidity and mortality (Obermüller et al., 2014). However, a longitudinal Australian study has reported that although the incidence of AKI is increasing, mortality rates are steadily declining (Bagshaw, George & Bellomo, 2007).

Major trauma or surgery, infection, haemorrhage, severe heart failure, severe liver disease and lower urinary tract obstruction are risk factors for AKI. Drugs and radiological contrast media that are toxic to the kidney (*nephrotoxic*) also increase the risk of AKI. Older adults develop AKI more frequently due to a higher incidence of serious illness, hypotension, major surgeries, diagnostic procedures and treatment with nephrotoxic drugs. The older adult also may have some degree

TABLE 27.3 Comparison of AKI staging by RIFLE and AKIN systems

RIFLE STAGES[a]	RIFLE SERUM CREATININE INCREASE[b]	RIFLE AND AKIN URINE OUTPUT CRITERIA[c]	AKIN SERUM CREATININE INCREASE[b]	AKIN STAGES
Risk	≥ 150–200%	< 0.5 mL/kg per h for > 6 h	≥ 0.3 mg/dL or ≥ 150%	1
Injury	> 200–300%	< 0.5 mL/kg per h for >12 h	> 200–300%	2
Failure	> 300%	< 0.3 mL/kg per h for ≥ 24 h or anuria ≥ 12 h	≥ 300%[d] or acute RRT	3

[a] The remaining RIFLE stages are Loss (persistent acute renal failure = complete loss of kidney function > wk) and ESKD (> 3 mo).
[b] Serum creatinine increase from baseline.
[c] Urine output criteria are identical in the corresponding RIFLE and AKIN stages.
[d] Or if baseline > 4 mg/dL then increase ≥ 0.5 mg/dL; RRT = renal replacement therapy.

of pre-existing renal insufficiency associated with ageing (Chronopoulos, Cruz & Ronco, 2010).

The most common causes of AKI are ischaemia and exposure to nephrotoxic agents. The kidney is particularly vulnerable to both due to the amount of blood that passes through it. A fall in blood pressure or volume can result in ischaemic injury to the kidney tissues. Alternatively, nephrotoxins in the blood damage kidney tissue directly.

Physiology review

The functional unit of the kidneys, the nephron (see Figure 25.3), produces urine through three processes: glomerular filtration, tubular reabsorption and tubular secretion. In the *glomerulus*, a filtrate of water and small solutes is formed. The solute concentration of this filtrate is equal to that of plasma, with the exception of large molecules such as plasma proteins and blood cells. The GFR is affected by blood volume and pressure, the autonomic nervous system and other factors. From the glomerulus, the filtrate flows into the *tubules*, where its composition is changed by the processes of *tubular reabsorption* and *tubular secretion*. Most water and many filtered solutes such as electrolytes and glucose are reabsorbed. Metabolic waste products such as urea, hydrogen ion, ammonia and some creatinine are secreted into the tubule for elimination. By the time urine exits the collecting duct into the renal pelvis, 99% of the filtrate has been reabsorbed.

Pathophysiology

Acute kidney injury is categorised as being prerenal, intrinsic or postrenal. The incidence of prerenal AKI accounts for about 40–55% of all AKI cases (Sharfuddin et al., 2011). In *prerenal AKI*, hypoperfusion leads to kidney dysfunction without directly affecting the integrity of kidney tissues. *Intrinsic* (or *intrarenal*) *AKI*, due to direct damage to functional kidney tissue, is responsible for approximately 50% of reportable cases. Urinary tract obstruction with resulting kidney damage is the precipitating factor for *postrenal AKI* and is the least common form (~5%) (Sharfuddin et al., 2011). Table 27.4 summarises the causes of AKI. See also 'Pathophysiology illustrated: Acute kidney injury' below.

Prerenal AKI

Prerenal AKI results from any condition that decreases renal blood flow, causing subsequent hypoperfusion of the kidney; as a result, it is also termed 'volume responsive AKI'. Renal blood flow can be decreased though renovascular obstruction (e.g. renal artery stenosis), during surgical procedures or as a result of any condition that significantly decreases vascular volume, cardiac output or systemic vascular resistance. The kidney's natural response is to use its own autoregulatory system in an attempt to restore renal blood flow. The afferent and efferent arterioles dilate and constrict, respectively, while the enzyme angiotensinogenase (more commonly known as renin) is simultaneously released to activate the renin–angiotensin system to stimulate the production of the potent vasoconstrictor angiotensin II. Angiotensin II has multiple functions, including the constriction of the efferent arterioles, which increases the pressure within the glomeruli. It also facilitates the release of aldosterone from the adrenal cortex to increase sodium and chloride reabsorption. The ensuing increase in plasma sodium stimulates the secretion of antidiuretic hormone from the posterior pituitary gland, which increases water reabsorption and assists peripheral vasoconstriction. The sum effect of these autoregulatory features of the kidney is a decrease in urine production and an increase in circulating blood volume, which collectively increase blood pressure. The unfortunate by-product of this autoregulation is that urea reabsorption also occurs, which sees a corresponding elevation in serum urea levels. If these autoregulatory mechanisms are unsuccessful and renal perfusion is not restored, the continuing ischaemia can lead to acute tubular necrosis.

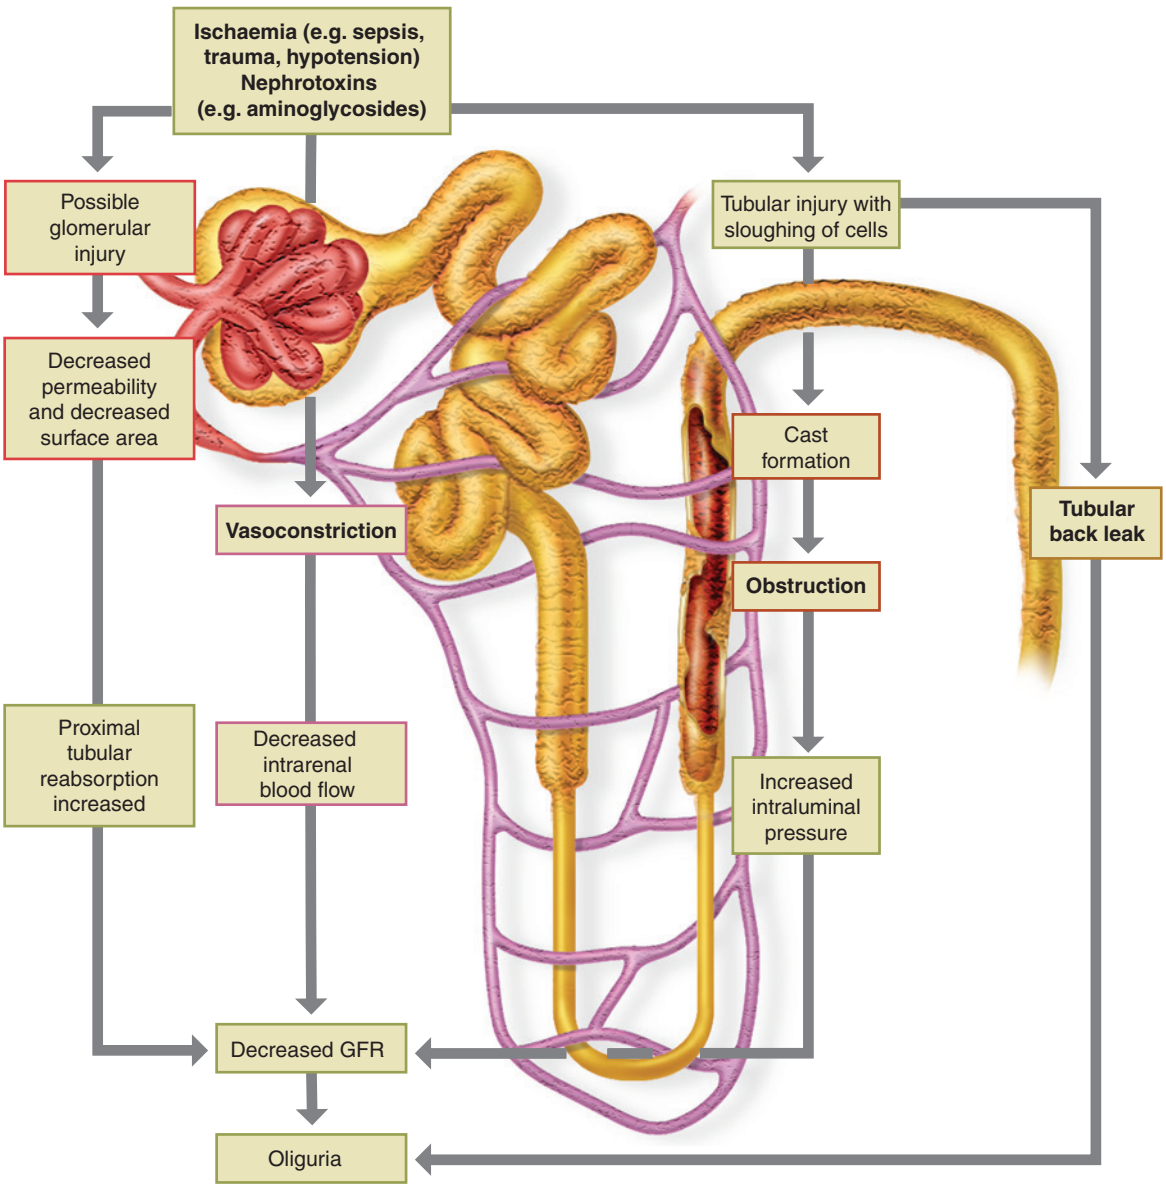
The kidneys normally receive 20–25% of the cardiac output to maintain the GFR. A drop in renal blood flow to less than 20% of normal causes the GFR to fall. As the filtration of substances by the glomeruli is reduced, less reabsorption of substances in the tubule is required. As a result, the kidney cells require less energy and oxygen, their metabolism slows and they effectively go to sleep (Grossman & Porth, 2014).

TABLE 27.4 Causes of acute kidney injury

	CAUSE	EXAMPLES
Prerenal	Hypovolaemia	Haemorrhage, dehydration, excess fluid loss from GI tract, burns, wounds, sepsis
	Decreased cardiac output	Heart failure, cardiogenic shock
	Altered vascular resistance	Sepsis, anaphylaxis, vasoactive drugs
	Renovascular obstruction	Renal artery stenosis, aneurysm, trauma, emboli, thrombi
Intrarenal	Glomerular/microvascular injury	Glomerulonephritis, disseminated intravascular coagulation, vasculitis, hypertension, toxaemia of pregnancy, haemolytic uraemic syndrome
	Acute tubular necrosis	Ischaemia due to conditions associated with prerenal failure; toxins such as drugs, heavy metals; haemolysis, rhabdomyolysis (muscle cell breakdown)
	Interstitial nephritis	Acute pyelonephritis, toxins, metabolic imbalances, idiopathic
Postrenal	Ureteral obstruction	Calculi, carcinoma, external compression Prostatic hypertrophy, calculi, carcinoma, stricture, blood clot, neuropathy

Acute kidney injury

The initial kidney injury is usually associated with an acute condition such as sepsis, trauma and hypotension, or the result of treatment for an acute condition with a nephrotoxic medication. Injury to the kidney can occur because of glomerular injury, vasoconstriction of capillaries or tubular injury. All consequences of injury lead to decreased glomerular filtration and oliguria.



FAST FACTS

- Prerenal AKI is common, particularly in trauma, surgical and critically ill people.
- Restoration of blood pressure and blood flow to the kidneys rapidly reverses prerenal AKI.
- If not promptly identified and treated, prerenal AKI leads to ischaemic acute tubular necrosis and intrinsic AKI.

Intrinsic (intrarenal) AKI

Intrinsic or intrarenal failure is characterised by acute damage to the renal parenchyma and nephrons. The major structures of the kidney that may be affected are the blood vessels, the glomerulus, the tubules and the interstitium. Intrarenal causes include diseases of the kidney itself, such as acute glomerulonephritis and **acute tubular necrosis (ATN)**, the most common intrinsic cause of AKI.

Acute glomerulonephritis

Acute **glomerulonephritis** can be caused by a number of different factors; however, the key feature is inflammation of the glomerulus which can decrease renal blood flow and cause AKI. Acute glomerulonephritis can result from infection, immunological abnormalities, drugs, toxins and systemic diseases such as lupus erythematosus. Acute post-streptococcal glomerulonephritis (also known as acute proliferative glomerulonephritis) is a common cause of glomerulonephritis. Infection of the pharynx or skin with group A beta-haemolytic *Streptococcus* is the usual initiating event for this disorder. Staphylococcal or viral infections, such as hepatitis B, mumps or varicella (chickenpox), can lead to a similar post-infectious acute glomerulonephritis (Huether, 2010). This primarily childhood disease can also affect adults. See 'Pathophysiology illustrated: acute glomerulonephritis' below.

MANIFESTATIONS AND COMPLICATIONS Post-infectious acute glomerulonephritis is characterised by an abrupt onset of **haematuria**, **proteinuria**, salt and water retention, and evidence of uraemic symptomology occurring 10 to 14 days after the initial infection. The urine often appears brown or cola-coloured. Salt and water retention increase extracellular fluid volume, leading to hypertension and oedema. The oedema is primarily noted in the face, particularly around the eyes (*periorbital* oedema). Dependent oedema, affecting the hands and upper extremities in particular, may also be noted. Other manifestations may include fatigue, anorexia, nausea and vomiting, and headache. See the 'Manifestations' box below.

The older adult may have less apparent symptoms. Nausea, malaise, arthralgias and proteinuria are common manifestations; hypertension and oedema are seen less often. Pulmonary infiltrates may occur early in the disorder, often due to worsening of a pre-existing condition such as heart failure.

The prognosis for adults with acute post-infectious glomerulonephritis is less favourable than it is for children. The symptoms may resolve spontaneously within 10 to 14 days. Full recovery is usual in children, whereas approximately only 60% of adults recover completely, decreasing to 25% in the older population. The remainder have persistent symptoms and some have permanent kidney damage (Rodriguez-Iturbe et al., 2007; Nasr et al., 2011).

ACUTE TUBULAR NECROSIS ATN is characterised pathologically by structural damage to the tubular epithelial cells and cell death if the insult is not reversed promptly. Nephrons are particularly susceptible to injury from ischaemia or exposure to nephrotoxic agents. Prolonged ischaemia is the primary cause of ATN. When ischaemia and nephrotoxin exposure occur concurrently, the risk of ATN and tubular dysfunction increases. See Figure 27.1 for the pathogenesis of acute kidney injury due to ATN. Risk factors for ischaemic ATN include major surgery, severe hypovolaemia, sepsis, trauma and burns. The impact of ischaemia resulting from vasodilation and fluid loss in sepsis, trauma and burns is often compounded by toxins and inflammatory markers released by bacteria or from damaged tissue (Koyner & Murray, 2009).

Ischaemia lasting more than 2 hours causes severe and irreversible damage to kidney tubules with patchy cellular necrosis and sloughing. The GFR is significantly reduced as a result of (1) ischaemia, (2) activation of the renin–angiotensin system, and (3) tubular obstruction by cellular debris, which raises the pressure in the glomerular capsule.

Common nephrotoxic agents associated with ATN include the aminoglycoside antibiotics and radiological contrast media. Research has demonstrated AKI to be a common problem in the hospitalised and ambulatory population and the term contrast-induced AKI (CI-AKI) is proposed for people who develop AKI following intravenous radiological contrast media. Many other drugs (e.g. NSAIDs, antineoplastics and some immunosuppressants), heavy metals such as mercury and gold, and some common chemicals such as ethylene glycol (antifreeze) are also potentially toxic to the renal tubule. The risk of ATN is higher when nephrotoxic drugs are given to older people or those with pre-existing renal insufficiency and when used concomitantly with other nephrotoxic agents. Dehydration also increases the risk by increasing the toxin concentration in nephrons (Kidney Disease: Improving Global Outcomes (KDIGO), 2012a).

Nephrotoxins destroy tubular cells by both direct and indirect effects. As tubular cells are damaged and lost through necrosis and sloughing, the tubule becomes more permeable. This increased permeability results in filtrate reabsorption, further reducing the ability of the nephron to eliminate wastes.

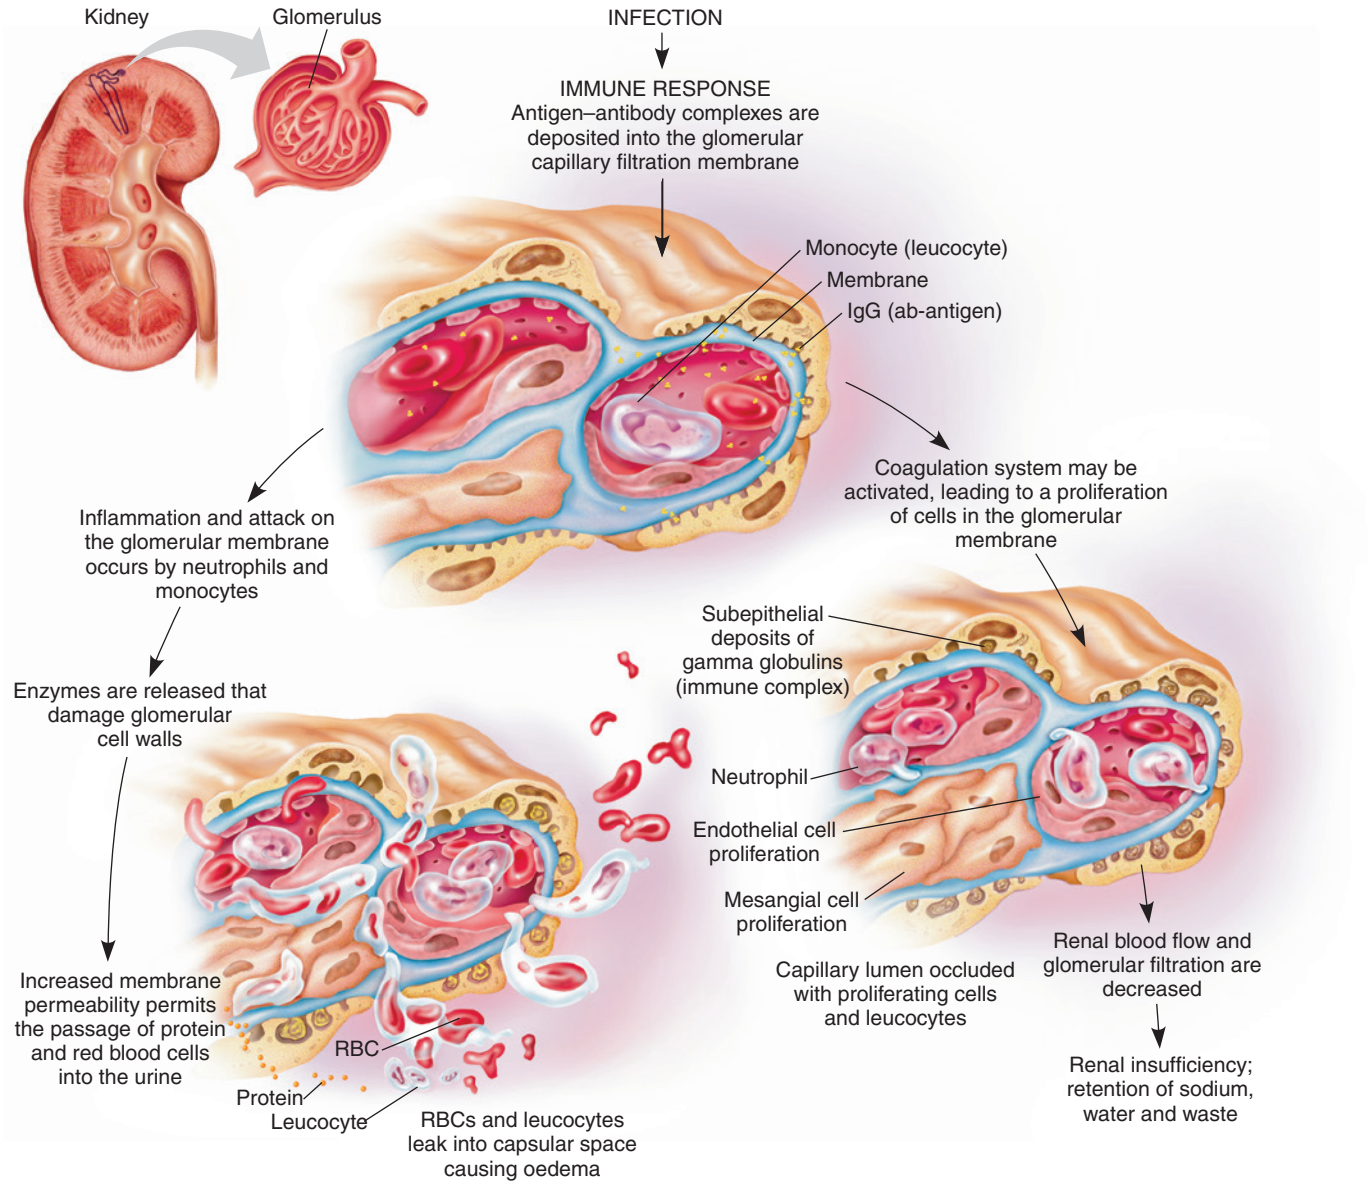
Rhabdomyolysis is a pathological syndrome that is characterised by damage to skeletal muscle fibres, which causes the release of excess myoglobin. Myoglobin is a protein that acts as the oxygen reservoir for muscle fibres, much as haemoglobin does for the blood. Muscle trauma and other factors can precipitate rhabdomyolysis. The myoglobin obstructs renal tubules, causing ischaemic injury, and contains an iron pigment that directly damages the tubules. Common causes of rhabdomyolysis include crush injuries, strenuous exercise, drug overdose and infection. Although no epidemiological data exists in Australia, 15–33% of people experiencing rhabdomyolysis will develop AKI. It accounts for between 7% and 15% of all cases of AKI in the United States (Melli, Chaudhry & Comblath, 2005; Russell, 2005). Renal injury occurs secondary to the myoglobin-induced tubule obstruction, renal hypoperfusion and intratubular cast formation. Prompt intervention with fluid resuscitation and urinary alkalinisation will minimise the impact of AKI and contribute to positive outcomes.

MANIFESTATIONS Acute glomerulonephritis

- Haematuria, cola-coloured urine
- Proteinuria
- Salt and water retention
- Oedema, periorbital and facial, dependent oedema
- Hypertension
- Uraemia
- Fatigue
- Anorexia, nausea and vomiting
- Headache

Acute glomerulonephritis

Infection from group A beta-haemolytic *Streptococcus* causes an immune response that causes inflammation and damage to the glomeruli. Protein and red blood cells are allowed to pass through the glomeruli. Blood flow to the glomeruli is reduced due to obstruction with damaged cells and renal insufficiency results, leading to the retention of sodium, water and waste.



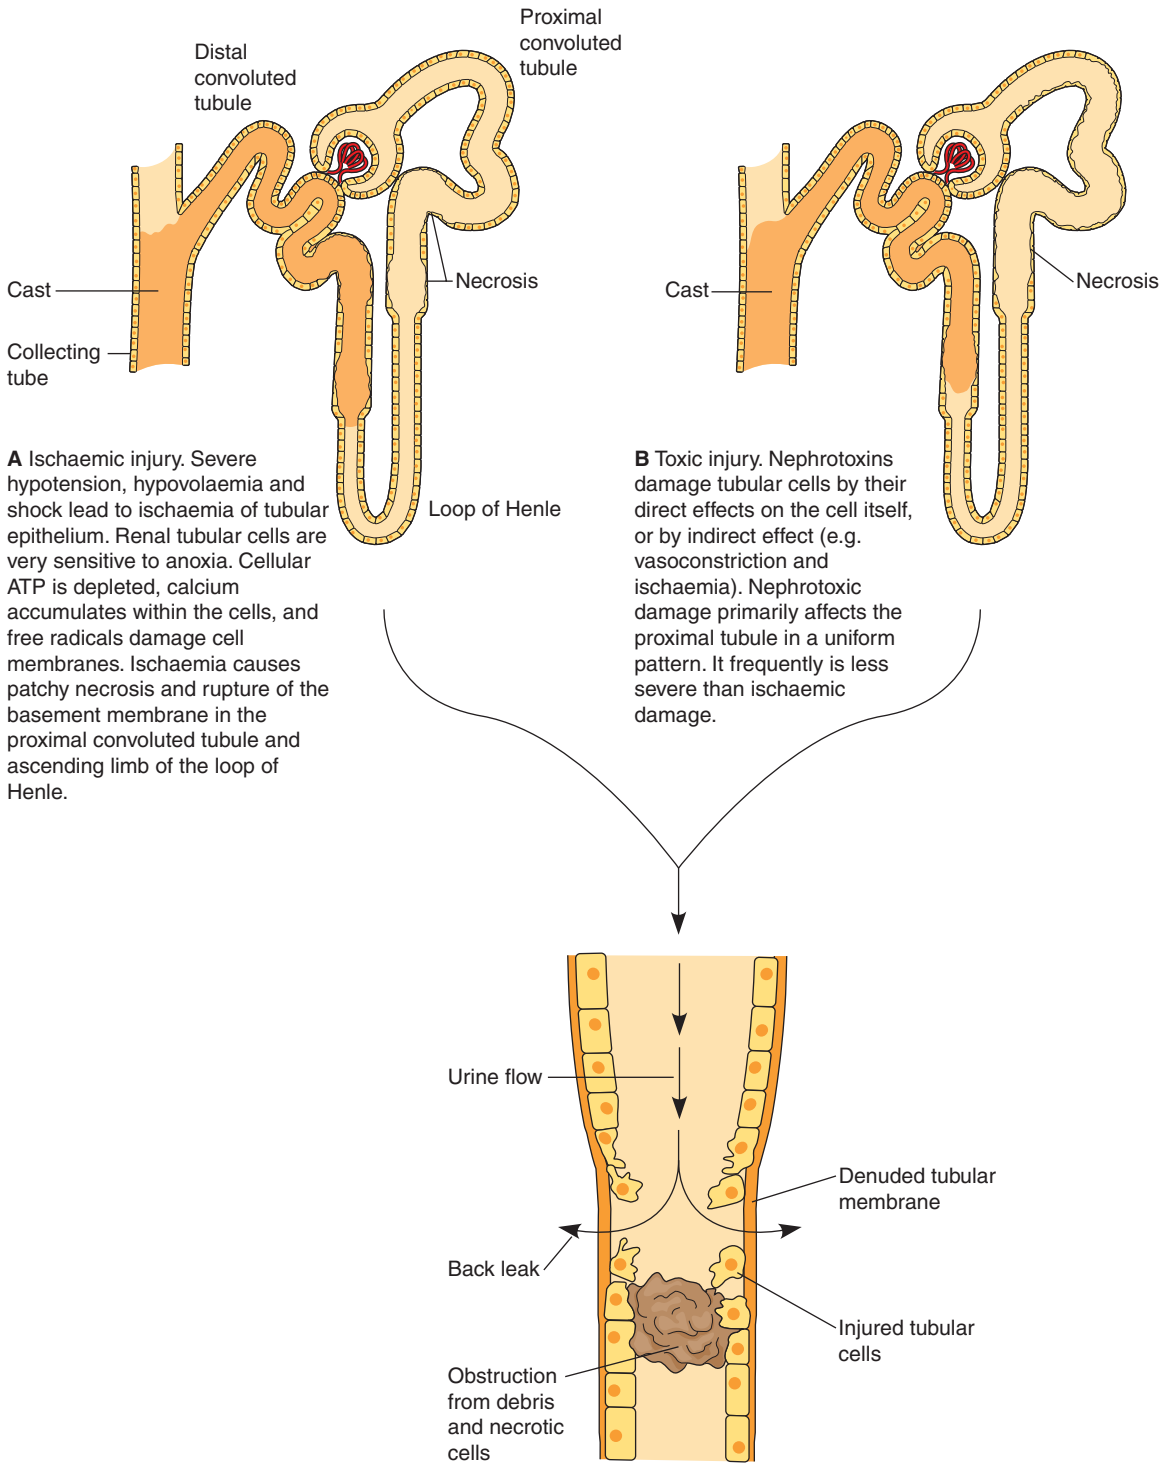
Postrenal AKI

Obstructive causes of acute kidney injury are classified as postrenal. Any condition that prevents urine excretion can lead to postrenal AKI. Benign prostatic hypertrophy is the most common precipitating factor. Others include renal or urinary tract calculi and tumours. See Chapter 26 for further discussion of urinary tract obstruction.

FAST FACTS

Clues for identifying pre-existing CKD in people with suspected AKI:

- Review biochemistry history: does the person currently have an elevated parathyroid hormone or is there a record of elevated serum creatinine levels anywhere in their patient history?
- Renal ultrasound revealing small kidneys with decreased cortical width is consistent with a history of CKD.
- Does the person have a long-standing history of uraemic symptoms?



A Ischaemic injury. Severe hypotension, hypovolaemia and shock lead to ischaemia of tubular epithelium. Renal tubular cells are very sensitive to anoxia. Cellular ATP is depleted, calcium accumulates within the cells, and free radicals damage cell membranes. Ischaemia causes patchy necrosis and rupture of the basement membrane in the proximal convoluted tubule and ascending limb of the loop of Henle.

B Toxic injury. Nephrotoxins damage tubular cells by their direct effects on the cell itself, or by indirect effect (e.g. vasoconstriction and ischaemia). Nephrotoxic damage primarily affects the proximal tubule in a uniform pattern. It frequently is less severe than ischaemic damage.

C Injured tubular cells release intracellular debris, which combines with proteins within the tubules to form casts. These casts, together with sloughed necrotic cells, occlude the tubular lumen, increasing tubular pressure and disrupting the flow of glomerular filtrate. Glomerular filtration slows. The increased pressure pushes filtrate out of the damaged tubule into interstitial tissues (back leak). Renal blood flow and glomerular filtration may be further reduced by intrarenal angiotension II release and vasoconstriction.

FIGURE 27.1 ■ Acute tubular necrosis. In ATN, tubular epithelial cells are destroyed by either ischaemic or toxic injury

Clinical course and manifestations of acute kidney injury

Not all people with AKI experience an identical clinical course; however, more often than not it progresses as a continuum through four phases: initiation, maintenance, diuretic and recovery.

Initiation phase

The *initiation phase* may last hours to days. It begins with the initiating event (e.g. haemorrhage) and ends when tubular injury occurs. If AKI is recognised and the initiating event is effectively treated during this phase, the prognosis is good. The initiation phase of AKI has few manifestations; in fact, it is often identified only when manifestations of the maintenance phase develop.

Maintenance phase

The *maintenance phase* of AKI is characterised by a significant fall in GFR and tubular necrosis. **Oliguria** may develop, although many people continue to produce normal or near-normal amounts of urine (non-oliguric AKI). Even though urine may be produced, the kidney cannot efficiently eliminate metabolic wastes, water, electrolytes and acids from the body during the maintenance phase of AKI. Uraemic symptoms, fluid retention, electrolyte imbalances and metabolic acidosis develop. These abnormalities are more severe in oliguric AKI than non-oliguric AKI. Up to 50% of AKI is non-oliguric, which generally reflects a less severe insult and is associated with a more favourable prognosis than in people with oliguric AKI.

During the maintenance phase, salt and water retention cause oedema, increasing the risk of heart failure and pulmonary oedema. Impaired potassium excretion leads to hyperkalaemia. When the serum potassium level is greater than 6.0 to 6.5 mmol/L, manifestations of its effect on neuromuscular function develop. These include muscle weakness, nausea and diarrhoea, electrocardiographic changes, arrhythmias and possible cardiac arrest. Other electrolyte imbalances include hyperphosphataemia and hypocalcaemia. Metabolic acidosis results from impaired hydrogen ion elimination by the kidneys.

Anaemia develops after several days of AKI due to suppressed erythropoietin secretion by the kidneys. Immune function is often impaired, increasing the risk of infection, and is one of the leading causes of mortality in AKI. Other manifestations of the maintenance phase include:

- oedema and hypertension due to salt and water retention
- confusion, disorientation, agitation or lethargy, hyperreflexia and possible seizures or coma due to uraemic toxicity and electrolyte and acid–base imbalances
- anorexia, nausea, vomiting and decreased or absent bowel sounds
- uraemic syndrome if AKI is prolonged (see the section on chronic kidney disease that follows).

Diuretic phase

The diuretic phase, if it occurs, can last up to 1 to 2 weeks. An increase in diuresis occurs because patency within the renal tubules is re-established. Nephrons have not recovered functionally and still cannot concentrate urine; and the solutes previously retained, such as urea and sodium, promote an osmotic effect, thus increasing urine output. It is crucial during this phase that the nurse ensures that fluid intake matches urine output so that renal perfusion is maintained. As the diuretic phase ends, urea and creatinine levels begin to decrease and electrolyte imbalances begin to resolve, and the kidneys start to regain their ability to regulate hydrogen and bicarbonate ion exchange. This sees the commencement of the recovery phase.

Recovery phase

The recovery phase of AKI is characterised by the fibrous scar tissue laid down within the glomerular basement membrane during the initial insult being replaced with a more contractile scar tissue. This process of tubular cell regeneration and repair sees a gradual return of the GFR to normal or pre-AKI levels. Serum creatinine, urea, potassium and phosphate levels remain high and may continue to rise in spite of increasing urine output. Renal function improves rapidly during the first 5 to 25 days of the recovery phase and continues to improve for up to a year.

FAST FACTS

The classification of urine output:

- Anuria: no urine output
- Oliguria: less than 400 mL/day
- Polyuria: greater than 2500 mL/day

Diagnostics

Diagnostic tests are used to identify the cause of acute kidney injury and monitor its effects on homeostasis:

- *Urinalysis* often shows the following abnormal findings in acute kidney injury:
  a. Urine-specific gravity is typically higher in prerenal AKI as the kidney attempts to conserve water, and lower in intrinsic AKI as the tubules are unable to concentrate the filtrate. However, urine osmolality provides a more accurate measurement.
  b. Proteinuria if glomerular damage is the cause of AKI.
  c. The presence of RBCs (due to glomerular dysfunction), WBCs (related to inflammation) and renal tubular epithelial cells (indicating ATN).
  d. Cell casts, which are protein and cellular debris moulded in the shape of the tubular lumen. (In AKI, RBCs, WBCs and renal tubular epithelial casts may be present. Brownish pigmented casts and positive tests for occult blood indicate haemoglobinuria or myoglobinuria.)
- *Serum creatinine* and *urea* are used to evaluate renal function. In AKI, serum creatinine levels increase rapidly, within 24 to 48 hours of the onset. Creatinine levels generally peak within 5 to 10 days. Creatinine and urea levels tend to increase more slowly when urine output is maintained. The onset of recovery is marked by a halt in the rise of the serum creatinine and urea. eGFR is an inaccurate marker to evaluate kidney function in AKI as the formula used to determine GFR relies on a steady-state creatinine level and does not account for

fluctuating or rapid changes in creatinine levels. It is also important to note that eGFR has not been validated in children or the Indigenous population.

- *Serum electrolytes* are monitored to evaluate the fluid and electrolyte status. The serum potassium rises at a moderate rate and is often used to indicate the need for dialysis. Hyponatraemia is common, due to the water excess associated with AKI.
- *Arterial blood gases* often show a metabolic acidosis due to the kidneys' inability to adequately eliminate metabolic wastes and hydrogen ions (see Chapter 9).
- *FBC* shows reduced RBCs, moderate anaemia and a low haematocrit. AKI affects erythropoietin secretion and RBC production. Iron and folate absorption may also be impaired, further contributing to anaemia.

INTERPROFESSIONAL CARE

Identifying people at risk and preventing acute kidney injury should be a goal for health professionals, especially for people in high-risk groups. Treatment goals for acute kidney injury are to: (1) identify and correct the underlying cause, (2) prevent additional kidney damage, (3) restore the urine output and kidney function, and (4) compensate for renal impairment until kidney function is restored.

Maintaining an adequate vascular volume, cardiac output and blood pressure is vital to preserve kidney perfusion. The nursing team is ideally placed to facilitate the coordination of interprofessional care and is able to notify the treating team of any changes in status and to identify the need for timely referral to other members of the healthcare team. AKI is a serious life-threatening illness that requires multidisciplinary collaboration, agreed guidelines and implementation to deliver high-quality care (Sedgewick, 2011).

Medications

The primary focus in drug management for acute kidney injury is to restore and maintain renal perfusion and volume homeostasis, correct biochemical imbalances and eliminate nephrotoxic agents from the treatment regimen.

Intravenous fluids and blood volume expanders are given as needed to restore renal perfusion. Low or 'renal' dose dopamine has been historically administered via intravenous infusion to increase renal blood flow. Dopamine is a sympathetic neurotransmitter that improves cardiac output and dilates blood vessels of the mesentery and kidneys when given in low therapeutic doses. However, recent research has shown that low-dose dopamine may worsen renal perfusion in critically ill people (Lauschke et al., 2006).

If restoration of renal blood flow does not improve urinary output, a loop diuretic such as frusemide may be given with intravenous fluids. The purpose is twofold. First, if nephrotoxins are present, the combination of fluids and potent diuretics may, in effect, 'wash out' the nephrons, reducing toxin concentration. Second, re-establishing urine output may prevent oliguria and reduce the degree of uraemic toxin accumulation and fluid and electrolyte imbalances. Frusemide also may be used to manage salt and water retention associated with AKI.

Aggressive hypertension management limits renal injury when AKI is associated with disorders such as toxaemia and pregnancy-induced hypertension. ACE inhibitors or other antihypertensive medications are used to control arterial pressures.

All drugs that are either directly nephrotoxic or that may interfere with renal perfusion may be discontinued. NSAIDs, nephrotoxic antibiotics and other potentially harmful drugs are avoided throughout the course of acute kidney injury. When a nephrotoxic drug or substance must be used, the risk of AKI can be reduced by using the minimum effective dose, maintaining hydration and eliminating other known nephrotoxins from the medication regimen.

People with kidney injury are at an increased risk of GI bleeding; this is related to the stress response and impaired platelet function. The cause is likely due to the combined effect of uraemic toxins, medications like warfarin or heparin, or coexisting GI tract pathologies. Histamine H_2-receptor antagonists or proton pump inhibitors are used to prevent GI haemorrhage. These drug classes protect the gastric mucosa by profoundly reducing gastric acid secretion. Antacids are used infrequently due to the inconvenience of dosing, whereas the other drug classes afford more convenient administration routes and less dosing intervals. It is worth noting that there has been an increase in reported cases linking episodes of acute interstitial nephritis with the use of proton pump inhibitors (Brewster & Perazella, 2007).

Hyperkalaemia may require active intervention in combination with the restriction of dietary potassium intake. Serum levels of greater than 6.0–6.5 mmol/L are treated to prevent cardiac effects of hyperkalaemia. With significant hyperkalaemia, calcium chloride, sodium bicarbonate or insulin and glucose may be given intravenously to reduce serum potassium levels by moving potassium into the cells. A potassium-binding exchange resin such as calcium resonium may be given orally or by enema. This agent removes potassium from the body by exchanging sodium for potassium, primarily in the large intestine. When given orally, it is often co-administered with an aperient to prevent constipation. Rectally, it is instilled as a retention enema, allowed to remain in the bowel for approximately 30 to 60 minutes and then irrigated out using a tap-water enema.

Hyperphosphataemia is generally managed conservatively in AKI unless it is severe and there is a clinically significant reduction in serum calcium. Generally it is only when the episode of AKI is protracted that oral phosphate binders are initiated (see the CKD section on medications later in this chapter for a more comprehensive review of phosphate binders).

Because many drugs are eliminated from the body by the kidney, drug dosages may need to be adjusted. Doses within the usual range can lead to potentially toxic blood levels, because their elimination is slowed and half life prolonged. Nursing implications for medications commonly prescribed for the person with AKI are summarised in the 'Medication administration' box below.

MEDICATION ADMINISTRATION The person with acute kidney injury

LOOP DIURETICS

Frusemide
Ethacrynic acid

The loop diuretics, named for their primary site of action in the loop of Henle, are *high-ceiling diuretics*: the response increases with increasing doses. These are highly effective diuretics used in early AKI to re-establish urine flow and convert oliguric renal failure to non-oliguric renal failure. Loop diuretics may be given with intravenous dopamine to promote renal blood flow. In ATN secondary to exposure to a nephrotoxic agent, loop diuretics are often used to clear the toxin from the nephrons more rapidly. Loop diuretics cause potassium wasting, which is generally not a concern in AKI because renal dysfunction impairs normal potassium elimination.

Nursing responsibilities

- Assess weight and vital signs for baseline data.
- Monitor intake and output, daily weight (or more frequently as ordered), vital signs, skin turgor and other indicators of fluid volume status frequently.
- Assess for postural hypotension because these potent diuretics can lead to hypovolaemia.
- Monitor laboratory results, especially serum electrolyte, glucose, urea and creatinine levels.
- Administer by mouth or, if ordered, by intravenous injection:
  a. Frusemide undiluted at a rate of no more than 20 mg per minute
  b. Ethacrynic acid 50 mg diluted with 50 mL of normal saline at a rate of no more than 10 mg per minute
- Assess response. Urine output typically increases within 10 minutes after intravenous administration.
- Monitor hearing and for complaints such as tinnitus. High doses of loop diuretics increase the risk of ototoxicity, especially with ethacrynic acid. These effects may be reversible if detected early and the drug is discontinued.
- Avoid administering concurrently with other ototoxic agents, such as aminoglycoside antibiotics and cisplatin.

Health education for the person and family

- Unless contraindicated, maintain a fluid intake that is equal to the previous day's urine output plus 500–700 mL to allow for insensible losses.
- Rise slowly from lying or sitting positions, because a fall in blood pressure may cause light headedness.
- Administer in the morning and at lunchtime if ordered twice a day, to avoid sleep disturbance.
- Take with food or milk to prevent gastric distress.
- NSAIDs interfere with the effectiveness of loop diuretics and should be avoided.

ELECTROLYTES AND ELECTROLYTE MODIFIERS

Calcium chloride
Calcium gluconate
Sodium bicarbonate
Calcium polystyrene sulfonate

Calcium chloride or gluconate and sodium bicarbonate are administered intravenously in the initial management of hyperkalaemia. Calcium can also be administered to correct hypocalcaemia and reduce hyperphosphatemia. (Calcium and phosphate have a reciprocal relationship in the body; as the level of one rises, the level of the other falls.) Sodium bicarbonate helps to correct acidosis and move potassium back into the intracellular space. Calcium polystyrene sulfonate is used to remove excess potassium from the body by exchanging calcium ions for potassium in the large intestine.

Nursing responsibilities

- Assess serum electrolyte levels prior to and during therapy. Report rapid shifts or adverse responses to the treating team.
- Administer as appropriate:
  a. Intravenous calcium chloride at less than 1 mL per minute; intravenous calcium gluconate at 0.5 mL per minute. Inject into a large vein through a small-bore needle; avoid infiltration because extravasation of intravenous solution will cause tissue necrosis.
  b. Intravenous sodium bicarbonate infusion over 4 to 8 hours; oral tablets as prescribed.
  c. Calcium polystyrene sulfonate as an oral solution can be taken with a laxative to prevent constipation or as a retention enema mixed with warm water. Leave in the bowel for 30 to 60 minutes; irrigate using a small tap-water enema.
- Monitor for adverse reactions, such as arrhythmias, electrolyte imbalances and metabolic alkalosis.

Health education for the person and family

- Intravenous calcium may make you light headed; remain in bed for at least 30 minutes after administration.
- Do not take sodium bicarbonate tablets with milk.
- Retain the calcium polystyrene sulfonate enema as long as possible.

Fluid management

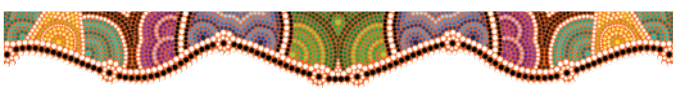
Once vascular volume and renal perfusion is restored, fluid intake is usually restricted. The allowed daily fluid intake is calculated by allowing 500–700 mL for insensible losses (respiration, perspiration, bowel losses) and adding the amount excreted as urine (or lost in vomitus) during the previous 24 hours. For example, if a person with AKI excretes 325 mL of urine in 24 hours, they are allowed a fluid intake allowance (including oral and intravenous fluids) of 825 mL for the next 24 hours. Fluid balance is carefully monitored, using accurate weight measurements and strict fluid balance charts as the primary indicators.

Nutrition

Nutritional management is critical in supporting the person with AKI. AKI is associated with the accumulation of electrolytes and fluids and the accelerated breakdown of body proteins (*catabolism*) which creates a negative nitrogen balance. Poor nutritional status is associated with increased mortality and morbidity; people with malnutrition are at higher risk of sepsis and

haemorrhage. Managing nutritional intake remains a challenge in which the determinants of treatment requirements are based not on the degree of renal insufficiency, but on the cause of the AKI and the degree of catabolism experienced. People in hypercatabolic states experience multiple metabolic sequelae, including insulin resistance, hormonal alterations and metabolic acidosis. The goal of nutritional management is to maintain lean body mass through the provision of adequate kilojoule and nutritional intake, and to restore immunocompetence and an anabolic state (Fiaccadori & Cremaschi, 2009). Early referral to the dietitian is essential in order to provide comprehensive and timely management of the individual's nutritional status. Nutritional requirements are highly individualised and are influenced by the cause and treatment of the AKI. Due to the well-established association of malnutrition with morbidity and mortality, protein restriction is not recommended. It is recommended that a non-catabolic person with AKI who is not on dialysis receive between 0.8 and 1.0 g/kg/day of protein. For those receiving kidney replacement therapy higher amounts are recommended (KDIGO, 2012b). Dietary proteins should be of high biological value (rich in essential amino acids). Carbohydrates are increased to maintain adequate kilojoule intake and provide a protein-sparing effect.

Parenteral nutrition providing amino acids, concentrated carbohydrates and fats may be instituted when the individual with AKI cannot tolerate enteral nutrition or consume an adequate diet (e.g. due to impaired gut function, nausea, vomiting or underlying critical illness). The disadvantages of parenteral nutrition in these instances are the high volume of fluid required and the risk of infection through the central venous access.



Nursing care

Health promotion

Acute kidney injury often can be prevented by measures that maintain fluid volume and cardiac output and reduce the risk of exposure to nephrotoxins.

- Carefully monitor critically ill, postoperative and other people who are at high risk of early signs of hypovolaemia (low urine output, altered mental status or changes in vital signs, skin colour or temperature).
- Report significant decreases in urine output and other evidence of decreased cardiac output.
- Maintain intravenous fluids as ordered.
- Alert the treating team if you note that the individual is receiving more than one nephrotoxic drug or if a nephrotoxic drug is ordered for a person who is dehydrated.
- Closely observe people receiving blood or blood cells for early signs of transfusion reaction and intervene appropriately.

Assessment

Both subjective and objective data are useful when assessing the person with acute kidney injury:

- *Health history:* complaints of anorexia, nausea, weight gain or oedema; recent exposure to a nephrotoxin such as an aminoglycoside antibiotic or radiological procedure using an injected contrast medium; previous transfusion reaction; chronic diseases such as diabetes, heart failure or kidney disease.
- *Physical examination:* vital signs, including temperature; urine output (amount, colour, clarity, specific gravity, presence of blood cells or protein); weight; skin colour, peripheral pulses; presence of oedema (periorbital or dependent); lung sounds, heart sounds and bowel tones.

Nursing diagnoses and interventions

The person with acute kidney injury has numerous nursing care needs related not only to the renal dysfunction but also to the underlying condition that precipitated it. Priority nursing care needs relate to fluid volume alterations, appetite and nutrition, and teaching/learning. For additional nursing diagnoses and interventions, see the nursing care plan below.

Excess fluid volume

In AKI, the kidneys often cannot excrete adequate urine to maintain a normal extracellular fluid balance. Fluid retention is greater in oliguric renal failure than in non-oliguric failure. Rapid weight gain and oedema indicate fluid retention. In addition, heart failure and pulmonary oedema may develop.

- Maintain hourly intake and output records. *Accurate intake and output records help guide therapy, especially fluid restrictions.*
- Weigh daily. Use standard technique (same scale, time, clothing or coverings) to ensure accuracy. *Rapid weight changes are an accurate indicator of fluid volume status, particularly in the oliguric person.*
- Assess vital signs at least every 4 hours. *Hypertension, tachycardia and tachypnoea may indicate excess fluid volume.*

CONSIDERATION FOR PRACTICE

Frequently assess breath and heart sounds, neck veins for distension and back and extremities for oedema. Report abnormal findings. Adventitious breath sounds (crackles), abnormal heart sounds such as an S_3 or S_4 gallop, distended neck veins and peripheral oedema may indicate hypervolaemia, heart failure or pulmonary oedema.

- If not contraindicated, place in semi-Fowler's position *to enhance cardiac and respiratory function.*
- Report abnormal serum electrolyte values and manifestations of electrolyte imbalance. People with AKI are at particular risk of the following electrolyte imbalances:
  a. *Hyperkalaemia* due to impaired potassium excretion. Manifestations include irritability, nausea, diarrhoea, abdominal cramping, muscle weakness, cardiac arrhythmias and ECG changes.
  b. *Hyponatraemia* due to water retention. Manifestations include nausea, vomiting and headache, with possible central nervous system (CNS) manifestations of lethargy, confusion, seizures and coma. The body's natural physiological response post surgery is to retain sodium and water.

c. *Hyperphosphataemia* due to decreased phosphate excretion. Manifestations include hyperreflexia, paraesthesias and possible tetany secondary to hypocalcaemia.

AKI impairs electrolyte and water excretion, causing multiple electrolyte imbalances.

- Restrict fluids as ordered. Provide frequent mouth care and strategies to decrease thirst drive (chewing gum, boiled lollies). If ice chips are allowed, include the water content (approximately one-half of the total volume) as intake. *Fluids are restricted to minimise fluid retention and complications of fluid volume excess.*
- Administer medications with meals. *Giving oral medications with meals minimises ingestion of excess fluids.*
- Turn frequently and provide good skin care. *Oedema decreases tissue perfusion and increases the risk of skin breakdown.*

Imbalanced nutrition: less than body requirements

Anorexia and nausea associated with any form of renal insufficiency often interfere with oral intake and nutrition. In addition, the disease process leading to AKI may contribute to increased nutritional needs for healing and decreased food intake.

- Monitor and record food intake, including the amount and type of food consumed. *A detailed intake record helps guide decisions about nutritional status and necessary supplements.*
- Weigh daily. Weight changes over time (days to weeks) reflect nutritional status, while rapid weight changes are more reflective of fluid volume status. *In AKI, weight may remain stable or increase due to fluid retention even though tissue mass is being lost.*
- Arrange for dietary consultation to plan meals within prescribed limitations that consider individual food preferences. *Diets restricted in protein, salt and potassium can be unpalatable; intake and appetite improve when preferred foods are included as allowed.*
- Engage in planning daily menus in line with dietary allowances. *Participation in meal planning increases the individual's sense of control and autonomy.*
- Allow family members to prepare meals within dietary restrictions. Encourage family members to eat with the person. *Familiar foods and social interaction encourage eating and increase enjoyment of meals.*
- Provide frequent, small meals or between-meal snacks. *These measures promote food intake in people who are fatigued or anorexic.*
- Administer anti-emetics as ordered and provide mouth care prior to meals. *Nausea and a metallic taste in the mouth, common manifestations of uraemia, can decrease food intake.*
- Administer parenteral nutrition as ordered if the person is unable to eat or tolerate enteral nutrition. *Preventing or slowing tissue catabolism is important for the people with AKI.*

CONSIDERATION FOR PRACTICE

Intravenous lines and parenteral nutrition solutions can increase the risk of infection. Monitor sites carefully for signs of infection or inflammation and adhere to local policy for line replacement.

Deficient knowledge

The person with AKI has multiple learning needs. These include information about AKI, diagnostic and laboratory studies, management strategies and implications for the recovery period.

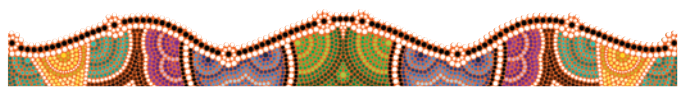
- Assess anxiety level and ability to comprehend instruction. Tailor information and presentation to developmental level and physical, mental and emotional status. *The person with AKI may be critically ill or have uraemic effects that hinder learning. During the initial stages of AKI it may be necessary to limit information to immediate concerns.*
- Assess knowledge and understanding. *To enhance understanding and retention, relate information presented to previous learning.*
- Teach about diagnostic tests and therapeutic procedures. *Teaching reduces anxiety and improves understanding and cooperation.*
- Discuss dietary and fluid restrictions. *These measures may be continued after discharge.*
- If discharge is planned prior to the recovery phase of AKI, teach the signs and symptoms of complications, such as fluid volume excess or deficit, heart failure and electrolyte imbalances. *As kidney function returns, urine output increases, but the concentrating ability of the nephrons and electrolyte excretion remain impaired. This impaired function increases the risk of excess fluid loss, possible dehydration, postural hypotension and electrolyte imbalance.*
- Teach how to monitor weight, blood pressure and pulse. *These are important means of assessing fluid status.*
- Instruct to avoid nephrotoxic agents for up to 1 year following an episode of AKI. *During recovery, nephrons remain vulnerable to damage by nephrotoxins such as NSAIDs, some antibiotics, radiological contrast media and heavy metals. Because alcohol can increase the nephrotoxicity of some materials, discourage alcohol intake.*

Community-based care

Quite often people develop AKI when they are critically ill. Critical illness and the resulting state of personal and family crisis can impair learning and retention of information. Include family members in teaching during the initial stages to promote understanding of what is happening and the reasons for specific treatment measures. Inclusion of the family reduces their anxiety and provides a valuable resource for reinforcing key health education points about care after discharge.

Teaching needs for home care include:

- avoiding exposure to nephrotoxins, particularly those in over-the-counter products
- preventing infection and other major stressors that can slow healing
- monitoring weight, blood pressure and pulse
- manifestations of relapse
- continuing dietary restrictions
- knowing when to contact the GP or present to the local emergency department.



NURSING CARE PLAN A person with acute kidney injury

Sharon Jones is driving home late one evening when she loses control of her car trying to avoid hitting a kangaroo on the road. Her car strikes a tree and rolls into a deep ditch beside the road, out of sight of passing cars. The wreck is not discovered until 8 hours later. On arrival at the accident scene, the paramedics find Ms Jones hypotensive: BP 90/60, P 120, R 24 and GCS 11/15. She appears disorientated and in severe pain, with a fractured right femur and multiple facial fractures. 1 L of crystalloid is infused, analgesia administered and oxygen applied. After immobilising Ms Jones's neck and back and extricating her from the car, they apply a traction splint to her leg and transport her to the local hospital.

ASSESSMENT

Upon arriving at the high dependency unit Ms Jones is more responsive, her pain score is 4/10 and GCS is 14/15. Lexi Ballinger, RN, obtains a nursing history on Ms Jones's admission and notes no significant medical history and nil known allergies. Ms Jones is not currently taking prescription or non-prescription drugs. Physical assessment findings on admission to the unit include T 36.3°C, P 100, R 18 and BP 124/68. Skin pale, cool and dry, with multiple scrapes and contusions on her face and extremities. A linear bruise is noted on her chest and abdomen from the seat belt. Lung sounds clear, heart tones normal and abdomen tender but soft to palpation. Right leg alignment maintained with skeletal traction. One unit of whole blood was infused in the emergency department. An indwelling urinary catheter and nasogastric tube were in situ.

During the first few hours after admission, Ms Ballinger notes that Ms Jones's hourly output has dropped from 55 mL to 45 mL to 28 mL of clear yellow urine. The resident medical officer is notified and orders a 500 mL intravenous fluid challenge, 40 mg frusemide IV, urinalysis, serum urea, creatinine and electrolytes. The fluid challenge and frusemide sees only a slight increase in urine output. Urinalysis results show a specific gravity of 1.010 and the presence of WBCs, red and white cell casts, and tubular epithelial cells in the sediment. Ms Jones's blood results reveal: urea 10 mmol/L; creatinine 133 µmol/L and potassium 5.9 mmol/L. The resident medical officer diagnoses probable acute kidney injury and orders sodium polystyrene sulfonate 15 g TDS. In addition, the physician orders aluminium hydroxide, 10 mL every 2 hours per nasogastric tube and ranitidine 50 mg intravenously every 8 hours.

DIAGNOSES

- *Acute pain* related to injuries sustained in accident.
- *Anxiety* related to admission to the high dependency unit.
- *Risk of excess fluid volume* related to impaired renal function.
- *Impaired physical mobility* related to skeletal traction.
- *Ineffective protection* related to injuries and invasive procedures.

PLANNING

- Plan for effective pain management.
- Plan for effective psychological care.
- Plan to monitor for bleeding, fluid balance and respiratory distress.
- Plan for skin care, pressure ulcer prevention and to prevent infection.

Expected outcomes

- Report adequate pain control.
- Verbalise reduced anxiety.
- Maintain stable weight and vital signs within normal range.
- Maintain skin integrity.
- Use the trapeze appropriately to adjust position in bed while maintaining body alignment.
- Remain free of infection, bleeding or respiratory distress.

IMPLEMENTATION

- Maintain PCA.
- Assess frequently for pain control and response to analgesia.
- Encourage expression of thoughts, feelings and fears about condition and placement in the critical care unit.
- Document vital signs and heart and lung sounds at least every 4 hours.
- Weigh daily as tolerated by pain.
- Document hourly intake and output.
- Restrict fluids as ordered, including diluents for all intravenous medications as intake.
- Assist with mouth care every 3 to 4 hours; allow frequent rinsing of mouth, and ice chips as allowed.
- Assist with position changes at least every 2 hours; teach use of the overhead trapeze.
- Monitor frequently for signs of infection, bleeding or respiratory distress.

EVALUATION

After just over 3 days of oliguria, Ms Jones's urine output increases. By the end of the fourth day she is excreting 60 to 80 mL/h of urine. Although her urea and creatinine levels remain slightly elevated, they never reach a critical point and dialysis is not required. She is transferred from the high dependency unit on the fourth day after admission. When Ms Jones is able to begin eating, she is placed on a low-potassium diet, restricted to 60 g of protein. Her renal function gradually improves. By discharge, the results of her renal function studies, including urea and serum creatinine, are nearly normal. Ms Jones verbalises an understanding of the need to avoid nephrotoxic agents such as NSAIDs in order to prevent another insult to her kidneys and agrees to be followed up by her GP in 2 weeks.

CRITICAL THINKING IN THE NURSING PROCESS

1. What was the most likely specific precipitating factor for Ms Jones's acute kidney injury? Did anything else contribute to her risk?
2. Why did the physician prescribe aluminium hydroxide and ranitidine? Consider both the acute kidney injury and Ms Jones's placement in the high dependency unit.
3. Ms Jones is at risk of respiratory distress related to potential fluid volume excess. How does her fractured femur further contribute to risk of respiratory distress?
4. Develop a care plan for Ms Jones for the nursing diagnosis of *Deficient diversional activity*.

REFLECTION ON THE NURSING PROCESS

1. Consider the case study above and identify what new knowledge you have gained that will enhance the care you deliver to a person with AKI.
2. Reflect on a time you have provided education in the clinical setting. What are some of the key factors you would need to consider when educating Ms Jones about avoiding nephrotoxic agents?

THE PERSON WITH KIDNEY TRAUMA

Despite the kidneys being relatively well protected by the rib cage and back muscles, kidney trauma due to blunt force or penetrating injury remains the most frequent urological trauma (Santucci & Bartley, 2010). The majority of kidney trauma is managed successfully without surgery, but prompt diagnosis and treatment is essential and can be lifesaving in the event of major damage.

Pathophysiology and manifestations

Blunt force is the most common cause of kidney injury. Falls, motor vehicle accidents and sports injuries can damage the kidney. The injury may be minor, resulting in a contusion or small haematoma, or more serious, resulting in laceration or other damage. The kidney may fragment or 'shatter', causing significant blood loss and urine extravasation. Tearing of the renal artery or vein may cause rapid haemorrhage, with shock and possible death.

Gunshot wounds, knife wounds, impalement injuries and fractured ribs are more likely to require surgical intervention including nephrectomy (Santucci et al., 2004). Minor penetrating injuries may lacerate the capsule or renal cortex. Major injuries include laceration or destruction of renal parenchyma or the vascular supply.

The primary manifestations of kidney trauma are haematuria (gross or microscopic), flank or abdominal pain, and oliguria or anuria. There may be localised swelling, tenderness or ecchymoses in the flank region. Retroperitoneal bleeding from the kidney may cause Turner's sign, a bluish discolouration of the flank. Signs of shock may be present, including hypotension, tachycardia, tachypnoea, cool and pale skin, and an altered level of consciousness.

INTERPROFESSIONAL CARE

The radiology team plays a crucial role in differentiating between cases that require immediate surgical intervention or conservative management. In blunt force trauma, renal imaging is indicated if there is suspected trauma (e.g. following a blunt injury or falling from a height) associated with either gross haematuria or microhaematuria with concurrent shock. Renal imaging is used immediately in penetrating trauma unless severe haemodynamic instability warrants urgent surgical intervention (Heyns, 2004). Haemoglobin and haematocrit levels fall in significant renal injury with haemorrhage. Haematuria is typically noted on urinalysis and aspartate transaminase (AST) levels rise within 12 hours of significant renal trauma. Renal ultrasound is used to diagnose bleeding and kidney damage. It is non-invasive but lacks the resolution afforded by a CT scan. An abdominal CT scan with contrast medium may be done to visualise renal structures to establish a definitive diagnosis. Renal angiogram has been replaced by CT as a diagnostic tool but may be performed for suspected renal artery thrombosis where stenting or percutaneous embolisation may be required (Heyns, 2004).

Treatment of minor kidney injuries is generally conservative, including bed rest, regular observation of vital signs, abdominal symptomology and full blood count. In these injuries, bleeding is typically minor and self-limiting, as opposed to major or critical trauma where immediate treatment focuses on controlling haemorrhage and treating or preventing shock. Major lacerations may require surgical repair or partial or total **nephrectomy** (removal) of the affected kidney (McCombie et al., 2014).

Nursing care

Nursing care for people who have experienced renal trauma focuses on timely and accurate assessment and appropriate intervention to preserve life and prevent complications. A urine specimen for analysis should be obtained when kidney trauma is suspected. Monitor level of consciousness, vital signs, skin colour and temperature, and urine output for possible signs of shock. See Chapter 10 for additional nursing care measures for the person who has had a traumatic injury or who develops shock.

THE PERSON WITH A RENAL TUMOUR

Renal tumours are classified as benign or malignant, primary or metastatic. Benign renal tumours are infrequent and are often found only on autopsy. In 2011, renal cell carcinoma accounted for 2.4% of all adult cancers in Australia (Australian Institute of Health and Welfare (AIHW), 2015a). Most primary renal tumours arise from renal cells; a primary tumour also may develop in the renal pelvis, although less frequently. Metastatic lesions to the kidney are associated with lung and breast cancer, melanoma and malignant lymphoma.

Males are affected by renal cancer more than females by a 2:1 ratio. The highest incidence is seen in people over the age of 55 years. Risk factors include smoking, obesity, prolonged time on dialysis, environmental exposure and genetic predisposition. The chronic irritation associated with renal calculi may also contribute (Kidney Health Australia (KHA), 2015).

Pathophysiology and manifestations

The most prevalent renal tumours are renal cell carcinomas, which develop in the renal cortex. The tumour, which can range in size up to several centimetres, has clearly defined margins and contains areas of ischaemia, necrosis and haemorrhage. Renal tumours tend to invade the renal vein and often have metastasised when first identified. Metastases tend to occur in the lungs, bone, lymph nodes, liver and brain (Fauci et al., 2008; Grossman & Porth, 2014).

Renal tumours are often silent, with few manifestations. The classic triad of symptoms—gross haematuria, flank pain and a palpable abdominal mass—is seen in only about 10% of people

with renal cell carcinoma. Haematuria, often microscopic, is the most consistent symptom. Systemic manifestations include fever without infection, fatigue and weight loss; see the box below.

The tumour may produce hormones or hormone-like substances, including parathyroid hormone, prostaglandins, prolactin, renin, gonadotropins and glucocorticoids. These substances produce *paraneoplastic syndromes*, with additional manifestations such as hypercalcaemia, hypertension and hyperglycaemia. The progression of renal cell carcinomas varies from prolonged periods of stable disease to very aggressive. Table 27.5 outlines the staging and prognosis for renal cell cancers.

TABLE 27.5 Renal cell cancer staging

STAGE	EXTENT OF TUMOUR	PROGNOSIS
I	Confined to the kidney capsule	> 90% 5-year survival
II	Invasion through the capsule but confined to local fascia	85% 5-year survival
III	Renal vein or inferior vena cava involvement (IIIA), local lymph node (IIIB) and local lymph nodes and vessels (IIIC)	60% 5-year survival
IV	Spread to nearby organs or distant metastases	≤ 10% 5-year survival

Source: Adapted from *Harrison's principles of internal medicine* (17th ed.) by A. S. Fauci et al. (eds) (2008). New York: McGraw-Hill.

INTERPROFESSIONAL CARE

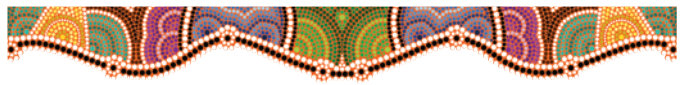
Haematuria is often the only initial manifestation of renal cancer; its presence indicates a need for further diagnostic studies. Commonly used imaging studies are discussed later in this chapter.

Radical nephrectomy is the treatment of choice for kidney tumours. In a radical **nephrectomy**, the adrenal gland, upper ureter, fat and fascia surrounding the kidney, as well as the entire kidney, are removed. Regional lymph nodes may also be resected. Although nephrectomy can be done using a laparoscopic approach, laparotomy primarily is used for radical nephrectomy. Nursing care for the person having a nephrectomy is summarised in the box below.

No effective treatment is available for advanced renal carcinoma with metastases. Biological therapies such as interferon or interleukin-2 have been used, but rarely achieve a durable effect. No chemotherapy drug consistently causes tumour regression in more than 20% of individuals (Fauci et al., 2008).

MANIFESTATIONS Renal tumours

- Microscopic or gross haematuria
- Flank pain
- Palpable abdominal mass
- Fever
- Fatigue
- Weight loss
- Anaemia or polycythaemia



Nursing care

Nursing diagnoses and interventions

Nursing care focuses on needs related to the cancer diagnosis and to the surgical intervention. Postoperative pain may be significant and the risk of respiratory complications is high. The remaining kidney must be protected from damage to preserve renal function. Psychologically, the person may grieve the loss of a major organ and the diagnosis of cancer.

Pain

The size and location of the incision used for a radical nephrectomy (see Figure 27.2) make pain management a challenge. Intercostal blocks, patient-controlled analgesia (PCA) or routine analgesic administration can effectively relieve the discomfort. Nursing care focuses on assessing pain relief, providing supportive measures to enhance analgesia and ensuring that pain or the fear of pain does not lead to respiratory complications.

- Assess frequently for adequate pain relief. Use a standard pain scale and non-verbal signs such as grimacing, tense body position, apparent dozing, elevated pulse, change of blood pressure or rapid, shallow respirations. Notify the physician of inadequate pain relief. *The person may assume that pain is to be expected or may fear becoming addicted to analgesics. Careful questioning and assessment allow effective pain management. Responses to analgesics are individual and the prescribed dose may need to be adjusted.*
- Assess the incision for inflammation or swelling, and drainage catheters and tubes for patency. *An obstructed catheter can lead to hydronephrosis, haematoma or abscess, increasing incisional pain.*
- Use adjunctive pain relief measures such as positioning, diversional activities, management of environmental stimuli, guided imagery and relaxation techniques. *These can enhance the effects of analgesia.*

CONSIDERATION FOR PRACTICE

Assess for abdominal distension, tenderness and bowel sounds. Intra-abdominal bleeding, peritonitis or paralytic ileus can cause pain that may be confused with incisional pain.

Ineffective breathing pattern

The location of the incision combined with the respiratory depressant effects of narcotic analgesics increases the risk of respiratory complications in the person who has had a nephrectomy.

- Position to promote respiratory excursion, using semi-Fowler's position and side-lying positions as allowed and tolerated. *Lung expansion is improved in semi-Fowler's and Fowler's positions.*

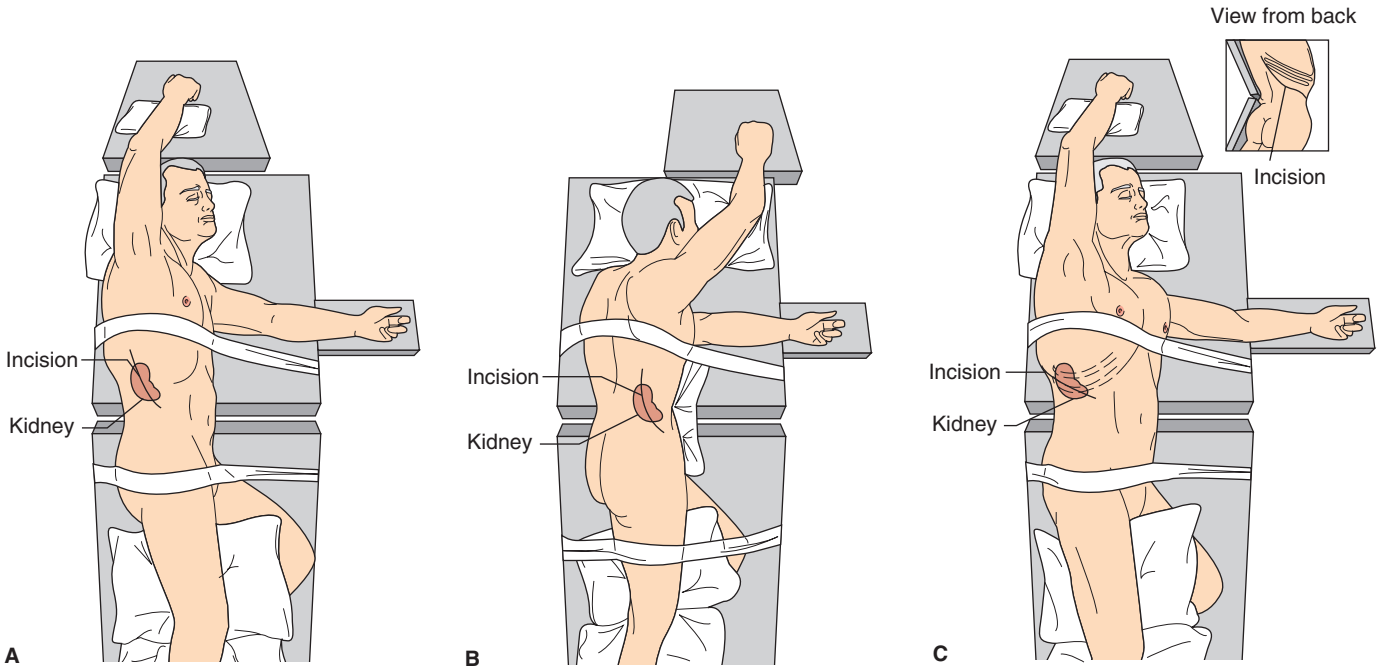


FIGURE 27.2 ■ Incisions used for kidney surgery: *A*, flank; *B*, lumbar; and *C*, thoracoabdominal

NURSING CARE OF THE PERSON having a nephrectomy

PREOPERATIVE CARE

- Provide routine preoperative care as outlined in Chapter 3.
- Report abnormal laboratory values to the surgical team. *Bacteriuria, blood coagulation abnormalities or other significant abnormal values may affect surgery and postoperative care.*
- Discuss operative and postoperative expectations as indicated, including the location of the incision and anticipated tubes, stents and drains. *Preoperative teaching about postoperative expectations reduces anxiety for the person and family during the early postoperative period.*

POSTOPERATIVE CARE

- Provide routine postoperative care as described in Chapter 3.
- Frequently assess urine colour, amount and character, noting any haematuria, pyuria or sediment. Promptly report any significant decreases in urine output or changes in colour or clarity. *Preserving function of the remaining kidney is critical; frequent assessment allows early intervention for potential problems.*
- Note the placement, status and drainage from ureteral catheters, stents, nephrostomy tubes or drains. Label each clearly. Maintain gravity drainage; irrigate only as ordered. *Maintaining drainage tube patency is vital to prevent potential hydronephrosis. Bright bleeding or unexpected drainage may indicate a surgical complication.*
- Support the grieving process and adjustment to the loss of a kidney. Loss of a major organ leads to a body image change and grief response. *When renal cancer is the underlying diagnosis, the person may also grieve the loss of health and potential loss of life.*
- Provide the following home care instructions for the person and family:
  a. The importance of protecting the remaining kidney by preventing UTI, renal calculi and trauma. See Chapter 26 for measures to prevent UTI and calculi. *Damage to the remaining kidney by UTI, renal calculi or trauma can lead to renal failure.*
  b. Maintain a fluid intake of 2000 to 2500 mL per day. *This important measure helps prevent dehydration and maintain good urine flow.*
  c. Gradually increase exercise to tolerance, avoiding heavy lifting for a year after surgery. Participation in contact sports is not recommended to reduce the risk of injury to the remaining kidney. Lifting is avoided to allow full tissue healing. *Trauma to the remaining kidney could seriously jeopardise renal function.*
  d. Care of the incision and any remaining drainage tubes, catheters or stents. *This routine postoperative instruction is vital to prepare the person for self-care and prevent complications.*
  e. Report abnormal signs and symptoms to the treating team, including manifestations of UTI (dysuria, frequency, urgency, nocturia, cloudy, malodorous urine) or systemic infection (fever, general malaise, fatigue), redness, swelling, pain or drainage from the incision or any catheter or drain tube site. *Prompt treatment of postoperative infection is vital to allow continued healing and prevent compromise of the remaining kidney.*

- Change position frequently, ambulate as soon as possible. *These measures promote lung expansion and the movement of mucus out of airways.*
- Encourage frequent (every 1 to 2 hours) deep breathing, spirometer use and coughing. *Assist to splint the incision. These measures promote alveolar ventilation, gas exchange and airway clearance.*

CONSIDERATION FOR PRACTICE

Assess respiratory status frequently, including rate and depth, cough, breath sounds, oxygen saturation and temperature. Pneumothorax on the operative side is common. Early identification and intervention can prevent major respiratory complications.

Risk of impaired urinary elimination

Surgery involving the urinary tract increases the risk of altered renal function and urine elimination. In addition, removal of one kidney dictates extra caution to maintain renal circulation, a sterile urinary tract and free urine flow.

- Monitor vital signs, central venous pressure (CVP) and urine output every 1 to 2 hours initially, then every 4 hours. *Hypovolaemia due to haemorrhage, diuresis or fluid sequestering (third spacing) reduces blood flow to the kidney and increases the risk of renal ischaemia with possible acute tubular necrosis and acute kidney injury.*
- Frequently assess the amount and nature of drainage on surgical dressings and from drainage tubes, stents and catheters. Measure and record output from each drain or catheter separately. *Frequent and accurate assessment of drainage helps to identify excess bleeding, abnormal fluid loss, infection or other potential surgical complications.*

CONSIDERATION FOR PRACTICE

Prevent kinking, twisting or tension on drains and tubes. Do not clamp. Notify the surgical team immediately if any tube becomes dislodged. It is vital to maintain the patency of drains, particularly any affecting the remaining kidney, to prevent the excess pressure of hydronephrosis.

- Maintain fluid intake with intravenous fluids until oral intake is resumed. Encourage an intake of 2000 to 2500 mL per day if not contraindicated. *A liberal fluid intake prevents dehydration, helps to dilute any nephrotoxic substances and promotes good urinary output.*
- Use strict aseptic technique in caring for all urinary catheters, tubes, stents, drains and incisions. *Asepsis is vital to prevent infection and possible compromise of the remaining kidney.*
- Following catheter removal, assess frequently for urinary retention. Notify the physician if the person is unable to void within 4 to 6 hours or if manifestations of retention (distended bladder, discomfort, urinary dribbling) develop. *Maintenance of urine output is vital to prevent stasis and possible complications such as infection and hydronephrosis.*
- Monitor laboratory results, including urinalysis, serum urea, creatinine and electrolytes. Report abnormal findings to the treating team. *Abnormal values may indicate early acute kidney injury; prompt intervention is necessary to preserve renal function.*

Anticipatory grieving

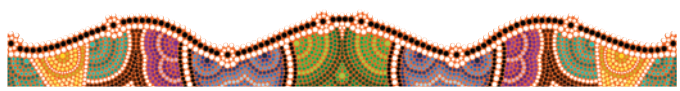
The person having a radical nephrectomy for renal cancer not only loses a major organ but also has to adjust to the diagnosis of cancer. Although the prognosis for recovery may be good, many people perceive cancer as always fatal. Providing support during the initial stages of grieving can improve physical recovery, psychological coping and eventual adaptation.

- Work to develop a trusting relationship with the person and family. *Trust increases the nurse's effectiveness in helping them work through the process of grieving.*
- Listen actively, encouraging the person and family to express fears and concerns. *As they begin to express their concerns, person and family can begin to deal more effectively with them.*
- Assist the person and family to identify strengths, past experiences and support systems. *These resources can be employed in working through the grieving process.*
- Demonstrate respect for cultural, spiritual and religious values and beliefs; encourage use of these resources to cope with losses. *Value and belief systems can provide a structure and form for dealing with the grieving process.*
- Encourage discussion of the potential impact of loss on the person and the family structure and function. Assist family members to share concerns with one another. *Sharing of fears and concerns among family members promotes involvement and support of the entire family unit so that the individual is not left to cope alone.*
- Refer to cancer support groups, social services or counselling as appropriate. *Support groups and counselling services provide additional resources for coping.*

Community-based care

If renal cancer was detected at an early stage and cure is anticipated, teaching for home care focuses on protecting the remaining kidney. Include the following measures to prevent infection, renal calculi, hydronephrosis and trauma:

- Maintain a fluid intake of 2000 to 2500 mL per day, increasing the amount during hot weather or strenuous exercise.
- Urinate when the urge is perceived and before and after sexual intercourse.
- Properly clean the perineal area.
- Watch for symptoms of UTI and understand the importance of early and appropriate evaluation and intervention.
- If the person is an older adult male, he should watch for symptoms of prostatic hypertrophy, a major cause of urinary tract obstruction. Stress the importance of routine screening examinations.
- Avoid contact sports such as football or hockey; use measures to prevent motor vehicle accidents and falls, which could damage the kidney.



THE PERSON WITH A CONGENITAL KIDNEY MALFORMATION

Congenital kidney disorders can affect the form and/or function of the kidney. Functional congenital kidney disorders are usually identified in childhood or adolescence. If function is not affected, congenital malformations may be detected only coincidentally. Malformations include agenesis, hypoplasia, alterations in kidney position and fusion anomalies such as horseshoe kidney.

Agenesis, absence of the kidney, and *hypoplasia*, underdevelopment of the kidney, typically affect only one of these paired organs. Renal function remains normal unless the unaffected kidney is compromised. Abnormal kidney position affects the ureters and urine flow, potentially leading to urinary stasis, increased risk of UTI and lithiasis or stone formation (see Chapter 26).

One in every 400 to 500 people has *horseshoe kidney*, making it one of the most common renal malformations (Kumar & Burton, 2007). Failure of the embryonic kidneys to ascend normally can result in a single, horseshoe-shaped organ. The two kidneys are fused at either the upper or lower pole (usually the lower). This malformation does not typically affect renal function; however, because the ureters cross the fused poles, there is an increased risk of *hydronephrosis* or distension of the renal pelvis and calyces with urine (see Chapter 26). Recurrent UTI and renal calculi are also common in people with horseshoe kidney.

Renal ultrasound and intravenous pyelography are used to diagnose horseshoe kidney. Correction of the abnormality is rarely necessary, although surgical resection of the isthmus (connection between the kidneys) may be done to relieve ureteral obstruction or allow access to the abdominal aorta, which lies behind it.

Nursing care for people with horseshoe kidney or other congenital malformations is primarily educational. Because abnormal kidney shape or position increases the risk of infection and stone formation, teach the person to maintain a fluid intake of at least 2500 mL per day. Emphasise the importance of avoiding dehydration by increasing fluids during hot weather and strenuous exercise. Teach hygiene practices such as perineal cleansing and voiding before and after intercourse to help prevent UTI. Teach the early manifestations of UTI and instruct to seek treatment promptly to prevent infection of the kidney. See Chapter 26.

THE PERSON WITH CHRONIC KIDNEY DISEASE

Although the kidneys usually recover from acute injury, many chronic conditions lead to progressive renal tissue destruction and loss of function. Nephron units are lost and renal mass decreases, with progressive deterioration of glomerular filtration, tubular secretion and reabsorption. This process of chronic kidney disease (CKD) may progress slowly for many years without being recognised. Eventually, the kidneys are unable to excrete metabolic wastes and regulate fluid and electrolyte balance adequately, a condition known as end-stage kidney disease (ESKD), the final stage of CKD.

A person is described as having **chronic kidney disease (CKD)** if they have a GFR < 60 mL/min/1.73 m^2 for more than 3 months with or without evidence of kidney damage, *or* evidence of kidney damage (with or without decreased GFR) for more than 3 months including microalbuminuria, proteinuria, glomerular haematuria or any anatomical or pathological abnormality. There are five stages of chronic kidney disease (see Figure 27.3) and, in Australia, one in 10 adults has indications of CKD including decreased GFR and microalbuminuria (Australian Bureau of Statistics, 2012).

Conditions causing CKD typically involve diffuse, bilateral disease of the kidneys with progressive destruction and scarring of the entire nephron. As indicated in Table 27.6, diabetic nephropathy continues to be the leading cause of ESKD in all population groups in Australia and New Zealand, and in fact in most of the Western world. Glomerulonephritis and hypertension follow as the next two main causes of ESKD, and in many people these disorders coexist (ANZDATA Registry, 2015).

CKD is a growing public health concern in Australia and New Zealand (KHA, 2015). Although data exist that enable us to report the incidence and prevalence of ESKD, it is much harder to report the same with CKD. This is due largely to its asymptomatic nature and, as such, incidence and prevalence

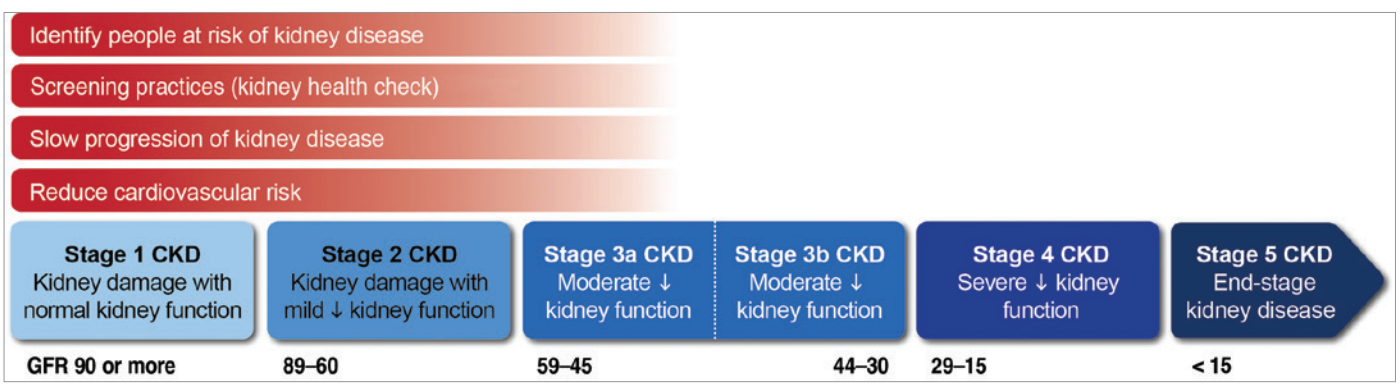


FIGURE 27.3 ■ Stages of chronic kidney disease

Source: Nephrology Educators Network.

TABLE 27.6 Pathophysiology of primary disease leading to end-stage kidney disease in the Australian population (2014)

CAUSE (% OF PEOPLE)	EXAMPLES
Diabetic nephropathy (35%)	Multifactorial. Changes in the glomerular basement membrane lead to sclerosis of the glomerulus and gradual destruction of the nephron.
Glomerulonephritis (19%)	Bilateral inflammatory process of the glomeruli leads to ischaemia, nephron loss and shrinkage of the kidney.
Hypertension (14%)	Long-standing hypertension damages the vasculature supplying the kidneys and leads to renal arteriosclerosis and ischaemia, resulting in glomerular destruction and tubular atrophy.
Polycystic kidney disease (6%)	Multiple bilateral cysts gradually destroy normal renal tissue by compression.
Reflux nephropathy (2%)	Results from chronic infection (pyelonephritis) commonly associated with an obstructive or neurological process and vesicoureteral reflux. The end result is renal scarring, atrophy and dilated calyces.

estimations are made from epidemiology studies and national self-reported surveys (Green & Ryan, 2009).

CKD was the leading cause of 2678 deaths in Australia in 2012 (AIHW, 2013). These figures do not accurately reflect the burden of CKD as the majority of people with CKD die of a cardiovascular-related illness rather than CKD per se. The burden of CKD in Australia has led to the development of a national CKD strategy with six national priority actions (see Box 27.1). Many area health services have now put into action CKD management programs to identify and screen people at risk, implement risk reduction and prevention strategies, and prevent its progression while managing the co-morbid associations of CKD.

The incidence of **end-stage kidney disease (ESKD)**, the terminal phase of CKD, is increasing, particularly in older adults. In 2013, 2544 and 546 people in Australia and New Zealand respectively began receiving treatment for ESKD. That same year, in Australia, a total of 11 774 people with ESKD underwent dialysis, with a further 9696 people maintaining functioning kidney transplants (ANZDATA Registry, 2015). The cumulative cost of treatment for all current and new cases of ESKD from 2009 to 2020 is projected to be between approximately $11.3 billion and $12.3 billion (Cass et al., 2006). This cost excludes not only the financial costs incurred by people undertaking kidney replacement therapy, but also the immeasurable costs and burden placed on their lifestyle.

BOX 27.1 National CKD strategy and national priority actions

- Risk reduction and prevention of CKD
- Early detection and management of CKD
- Management of advanced CKD
- Dialysis
- Organ donation and transplantation
- Indigenous Australians

Source: Kidney Health Australia (2008).

The burden of kidney disease on Indigenous peoples

Chronic kidney disease (CKD) exemplifies the differences in health equality with CKD death rates seven and 11 times higher for male and female Indigenous Australians than for non-Indigenous Australians (AIHW, 2009). Although exact comparisons are confounded by different age distributions, the incidence of CKD is still much higher in Indigenous than non-Indigenous Australians. In the more remote Indigenous communities, the incidence of ESKD is more prevalent than the national incidence; this often requires the need to relocate in order to receive dialysis treatment (Preston-Thomas, Cass & O'Rourke, 2007).

The burden of chronic illness on Indigenous Australians is reflected in the burden of kidney replacement therapy being required 10 years earlier than for non-Indigenous Australians, and death rates at an earlier age being more likely the result of cardiovascular, endocrine, metabolic, respiratory and nutrition-related illness than for non-Indigenous Australians (McDonald & Russ, 2003). Several factors contribute to this increased burden of kidney disease, including poorer socioeconomic conditions, higher rates of physical and behavioural risk factors, and poorer educational attainment. Indigenous Australians have additional risk factors that predispose them to CKD more than non-Indigenous Australians. These include higher rates of post-streptococcal childhood infections and prenatal elements that lead to lower nephron numbers due to reduced nephron endowment (Hoy et al., 2006; White, Hoy & McCredie, 2001).

The burden for Indigenous people can be increased when they are required to leave their lands for complex healthcare treatment in a distant Australian city. Nurse researchers Burnette and Kickett (2009) found that Aboriginal people undertaking dialysis away from their homes had overwhelming feelings of disempowerment related to their dependence on health professionals and dialysis treatment, perceived lack of education and the requirements of the foreign hospitalisation experience. Thus, the prevention or identification of early-stage

CKD in Indigenous populations is critical to ensure people receive appropriate management to delay, minimise or halt disease progression.

Physiology review

The glomeruli are the filtering units of the kidney, with each glomerulus consisting of a tuft of capillaries surrounded by a thin, double-walled capsule (Bowman's capsule) (see Figure 25.3). About 20% of the resting cardiac output flows through the glomeruli of the kidneys, forming approximately 180 L of plasma ultrafiltrate each day. More than 99% of this filtrate is reabsorbed in the renal tubules. The rate of glomerular filtration is controlled by opposing forces: the pressure and amount of blood flowing through the glomeruli promote filtration, and the pressure in Bowman's capsule and colloid osmotic (*oncotic*) pressure of the blood oppose it. The total surface area of glomerular capillaries also affects the GFR. The glomerular capillary membrane has three layers: the capillary endothelial layer, the basement membrane and the capsule epithelial layer. Water and the smallest solutes (such as electrolytes) pass freely across this membrane, whereas larger molecules (such as plasma proteins) are retained in the blood.

Pathophysiology

In the early stages of CKD, as nephrons are damaged the remaining functional nephrons hypertrophy. Glomerular capillary flow and pressure increase in these nephrons and more solute particles are filtered to compensate for lost renal mass. This increased demand predisposes the remaining nephrons to glomerular sclerosis (scarring), resulting in their eventual destruction. This process of continued loss of nephron function may continue even after the initial disease process has resolved (Longo et al., 2012).

Haematuria, microalbuminuria and proteinuria are manifestations of glomerular capillary membrane damage, which allows blood cells and proteins to escape from the blood into the glomerular filtrate. Haematuria may be either gross or microscopic. Microalbuminuria (30–300 mg/day), the precursor to proteinuria, may be detected early on in the disease process but this is highly reliant on screening practices and the type of testing methodology utilised. The degree of albuminuria can be measured with a simple early morning spot urine test to determine the albumin:creatinine ratio (ACR). Proteinuria is measured similarly with a protein:creatinine ratio (PCR) and is considered an important indicator of glomerular injury, because it increases progressively with increased glomerular damage. Loss of plasma proteins leads to hypoalbuminaemia (low serum albumin levels), which in turn reduces the plasma oncotic pressure (osmotic pressure created by plasma proteins), leading to oedema.

As plasma proteins are lost, the forces opposing filtration diminish and the amount of filtrate increases. The increased flow of filtrate stimulates the renin–angiotensin–aldosterone mechanism (see Chapter 25), producing vasoconstriction and a fall in GFR. Increased aldosterone production causes salt and water retention, which further contributes to oedema. As the GFR falls, filtration and elimination of nitrogenous wastes, including urea, decrease. Oliguria, urine output of less than 400 mL in 24 hours, may result from the decreased GFR. Hypertension results from fluid retention and disruption of the renin–angiotensin system, a key regulator of blood pressure.

Table 27.6 outlines common pathological processes causing CKD that lead to ESKD in Australia.

The course of CKD is variable, progressing over a period of months to many years. In stage 1 the GFR remains essentially normal or slightly elevated as a result of a hyperperfusive state whereby unaffected nephrons compensate for the lost nephrons. As the disease progresses to stage 2 the GFR falls to between 89 and 60 mL/min and the individual remains asymptomatic. Any further insult to the kidneys at this stage (such as infection, dehydration, exposure to nephrotoxins or urinary tract obstruction) can further reduce function and precipitate the onset of an acute decline in renal function. Stage 3 is characterised by a moderate decrease in renal function with a GFR of between 59 and 30 mL/min. The serum creatinine and urea may begin to rise and the person may begin to notice some feelings of tiredness, itchiness or loss of appetite, but it is not unusual to remain asymptomatic. Stage 4 sees a severe decrease in renal function with the GFR declining to between 28 and 15 mL/min. Symptomology of this decreased function, including increased tiredness, shortness of breath and general malaise, may be enough to prompt the individual to schedule a visit to their general practitioner if they have not already been diagnosed with CKD. In end-stage kidney disease, the final stage of CKD, the GFR is less than 15 mL/min and kidney replacement therapy is necessary to sustain life (see Figure 27.3).

Diabetic nephropathy

Diabetic nephropathy is one of the main microvascular complications of diabetes mellitus (DM) which sees the combination of haemodynamic, genetic and metabolic sequelae contribute to the development of increased vascular permeability at the glomerular basement membrane. Diabetic nephropathy is the leading cause of ESKD in Australia and New Zealand, with type 2 representing the majority of diabetic nephropathy cases requiring kidney replacement therapy (ANZDATA Registry, 2015). ESKD resulting from diabetic nephropathy is seen more frequently in Indigenous populations and those with type 2 DM due to a higher prevalence of type 2 DM in the community.

The characteristic lesion of diabetic nephropathy is glomerulosclerosis and thickening of the glomerular basement membrane. Hyperglycaemia impairs the ability of afferent and efferent arterioles and glomerular capillaries to regulate glomerular pressure and respond to systemic changes in blood pressure. As the disease progresses, the glomerular capillary lumen narrows, reducing the surface area for glomerular filtration. Arteriosclerosis, a common feature of long-term diabetes and hypertension, contributes to the disease process, as do nephritis and tubular lesions. Pyelonephritis, inflammation of the kidney, is also implicated in the development of diabetic nephropathy. A further discussion is found in Chapter 19.

Diabetic nephropathy progresses from a stage of hyperfiltration to early stage glomerular damage signified by microalbuminuria, which is typically seen within 10 to 15 years after the

onset of diabetes. If this damage is not detected early or is poorly controlled it will lead to overt proteinuria (within 15 to 20 years of the initial diagnosis) and decreased GFR, and may also see the concomitant development of hypertension. Eventually ESKD will develop and the individual will require kidney replacement therapy to sustain life.

Glomerulonephritis

Glomerulonephritis (GN) affects both the structure and function of the glomerulus, disrupting glomerular filtration, and is the second leading cause of ESKD in Australia (ANZDATA Registry, 2015). Histologically, glomerular involvement may be diffuse, involving all glomeruli, or focal, involving some glomeruli while others remain essentially normal. GN can present as either an acute or chronic condition and describes any disease that is mediated by either an inflammatory or immune mechanism that affects the glomerulus. Circulating antigen–antibody immune complexes formed during the initiating event become trapped in the glomerular membrane, leading to an inflammatory response. The complement system is activated and vasoactive substances and inflammatory mediators are released. Endothelial cells proliferate and the glomerular membrane swells and becomes permeable to plasma proteins and blood cells (see Figure 27.4). This increased permeability causes the manifestations common to glomerular disorders: haematuria, proteinuria and oedema.

The taxonomy of GN sometimes causes confusion as it attempts to classify the histopathological characteristics of the disease (e.g. focal segmental GN), the clinical presentation (e.g. nephrotic syndrome) or the aetiology of the disease (e.g. autoimmune) (Chadban & Atkins, 2005). From an aetiological perspective, GN is described as either primary, where the disease is immunological or idiopathic in origin, or secondary, where it is associated with a multisystem disease or hereditary condition. Systemic lupus erythematosus (SLE) and Goodpasture's syndrome are frequently implicated in secondary glomerular disorders. The most appropriate way to classify GN and avoid any potential confusion is according to its clinical presentation (Chadban & Atkins, 2005). In this way the treating team is able to identify the priorities for management.

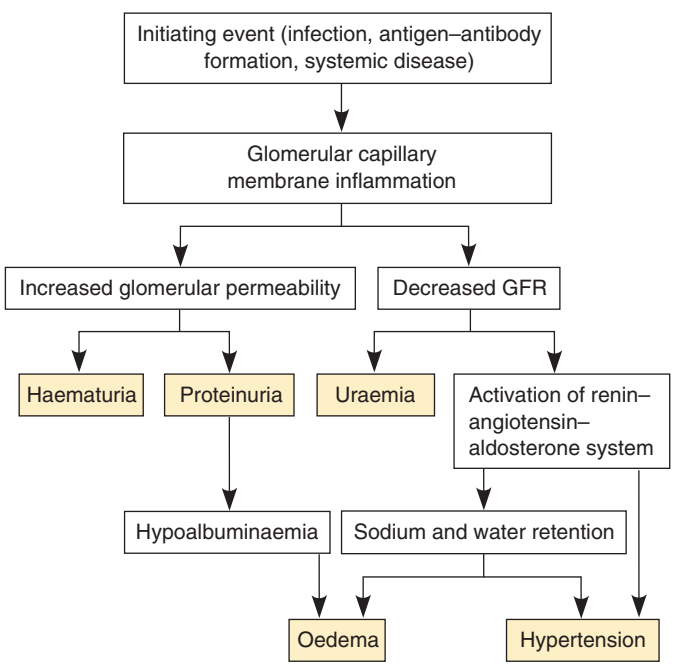

FIGURE 27.4 ■ The pathogenesis of glomerulonephritis

FAST FACTS

- Glomerulonephritis is the second leading cause of CKD in Australia.
- Haematuria and microalbuminuria are early manifestations of CKD.
- IgA mesangioproliferative GN is the most common histologically proven form of glomerulonephritis in Australia, followed by focal sclerosing GN.

In Australia, the major primary glomerular disorders include IgA mesangioproliferative GN, rapidly progressive glomerulonephritis, focal sclerosing glomerulonephritis and nephrotic syndrome (ANZDATA Registry, 2015). Goodpasture's syndrome and lupus nephritis are the most common secondary forms of glomerular disease.

IGA MESANGIOPROLIFERATIVE GLOMERULONEPHRITIS IgA mesangioproliferative glomerulonephritis, or IgA nephropathy (IgAN) as it is more commonly known, is characterised by the deposition of the antibody immunoglobulin A in the glomerular mesangium. IgAN has a highly variable course which can range from a benign condition to either a chronically slow or rapidly progressive disease. Children and young adults generally present with haematuria post respiratory tract infection or gastrointestinal illness; adults present later in the disease trajectory with proteinuria, haematuria and hypertension (Wyatt & Julian, 2013). Renal biopsy is diagnostic of IgAN and therefore early biopsy is essential in order to implement appropriate treatment to retard the progression of the disease.

RAPIDLY PROGRESSIVE GLOMERULONEPHRITIS *Rapidly progressive glomerulonephritis (RPGN)* is characterised by manifestations of severe glomerular injury without a specific, identifiable cause. This type of glomerulonephritis often progresses to renal failure within months. It may be idiopathic (primary) or secondary to a systemic disorder such as SLE or Goodpasture's syndrome. It affects people of all ages.

In RPGN, glomerular cells proliferate and, together with macrophages, form crescent-shaped lesions that obliterate Bowman's space (Porth, 2011). Glomerular damage is diffuse, leading to a rapid, progressive decline in renal function. Irreversible renal failure often develops over weeks to months (Longo et al., 2012).

People with RPGN typically present with complaints of weakness, nausea and vomiting. Some may relate a history of flu-like illness preceding the onset of the glomerulonephritis. Other symptoms include oliguria and abdominal or flank pain. On urinalysis, haematuria and massive proteinuria are noted. People with RPGN are often treated with plasma exchange as an adjunct to immunosuppressive therapy (see Box 27.2).

BOX 27.2 Therapeutic plasma exchange

Therapeutic plasma exchange (**plasmapheresis**), a procedure performed by highly trained nurses to remove disease-mediating antibodies from the plasma, is used in conjunction with immunosuppressive therapy to treat RPGN and Goodpasture's syndrome. Blood is removed from the person via a large vein or central venous device and then the plasma containing the glomerular-damaging antibodies is separated and discarded using either centrifugal or membrane separation technologies. The RBCs are then returned to the person along with albumin or human plasma to replace the plasma removed. This procedure is usually done in a series of treatments. It is not without risk and informed consent is required. Procedural complications are mainly associated with the type of technology used to achieve plasma separation. The most common complications are transfusion reactions, citrate toxicity (with centrifugal methods), altered coagulation status, vascular access infection and hypotension secondary to fluid volume shifts.

Nephrotic syndrome

Nephrotic syndrome is a group of clinical findings as opposed to a specific disorder. It is characterised by massive proteinuria, hypoalbuminaemia, hyperlipidaemia and oedema. A number of disorders can affect the glomerular capillary membrane, changing its porosity and allowing plasma proteins to escape into the urine.

With plasma protein loss in the urine and resulting hypoalbuminaemia, the oncotic pressure of the plasma falls. Fluid shifts from the vascular compartment to interstitial spaces, causing the oedema characteristic of nephrotic syndrome. Salt and water retention, possibly due to activation of the renin–angiotensin system, contribute to the oedema. Oedema may be severe, affecting the face and periorbital area as well as dependent tissues (see Figure 27.5).

Loss of plasma proteins stimulates the liver to increase albumin production and lipoprotein synthesis. As a result, serum triglyceride and low-density lipoprotein (LDL) levels increase, as do urine lipids (*lipiduria*). Hyperlipidaemia increases the risk of atherosclerosis in people with nephrotic syndrome.

Thromboemboli (mobilised blood clots) are a relatively common complication of nephrotic syndrome. Loss of clotting and anti-clotting factors along with plasma proteins disrupts coagulation pathways and increases the risk of renal venous thrombosis, deep venous thrombosis and pulmonary embolism. Renal venous thrombosis can cause flank or groin pain on one or both sides, gross haematuria and a reduced GFR (Porth, 2011).

Nephrotic syndrome usually resolves without long-term effects in children. The prognosis for adults is less optimistic because the syndrome often occurs secondarily to another disorder. Many adults do not recover completely, experiencing persistent proteinuria and, potentially, progressive renal impairment.

Goodpasture's syndrome

Goodpasture's syndrome is a rare autoimmune disorder of unknown aetiology. It is characterised by formation of antibodies to the glomerular basement membrane. These antibodies may also bind to alveolar basement membranes, damaging alveoli and causing pulmonary haemorrhage. Goodpasture's syndrome usually affects young men aged between 18 and 35, although it can occur at any age and affect women as well.

FIGURE 27.5 ■ Severe oedema characteristic of nephrotic syndrome

Source: © MedicImage/Alamy Stock Photo.

Although the glomeruli may be nearly normal in appearance and function in Goodpasture's syndrome, extensive cell proliferation and crescent formation characteristic of rapidly progressive glomerulonephritis are more common. Renal manifestations include haematuria, proteinuria and oedema. Rapid progression through the CKD continuum may occur. Alveolar membrane damage can lead to mild or life-threatening pulmonary haemorrhage. Cough, shortness of breath and haemoptysis (bloody sputum) are early respiratory manifestations.

Lupus nephritis

Systemic lupus erythematosus (SLE) is an inflammatory autoimmune disorder affecting the connective tissue of the body. Between 60% and 80% of people with SLE develop manifestations of nephritis (Longo et al., 2012). Immune complexes that form within the glomerular capillary wall are the usual trigger for glomerular injury in SLE. Manifestations of lupus nephritis range from microscopic haematuria to massive proteinuria. Its progression may be slow and chronic or *fulminant*, with a sudden onset and the rapid development of renal disease. Most people with minimal or mild lesions survive for at least 10 years. Improved management of the underlying disease, immunotherapy, dialysis and renal transplantation have significantly improved the prognosis in recent years.

THE PERSON WITH A RENOVASCULAR DISORDER

Renal function is dependent on an adequate supply of blood. Blood supports renal cell metabolism and is vital to kidney function, the nephron in particular. The kidney can regulate fluid, electrolyte and acid–base balance, and serve as a major organ of excretion, only when its blood supply is sufficient. Vascular disorders, therefore, can have a significant impact on renal function.

Hypertension

Hypertension, sustained elevation of the systemic blood pressure, can result from or cause kidney disease. In 2013, it was the cause of 14% of all cases of end-stage kidney disease in Australia (ANZDATA Registry, 2015).

Prolonged hypertension damages the walls of arterioles and accelerates the process of atherosclerosis. This damage primarily affects the heart, brain, kidneys, eyes and major blood vessels. In the kidney, arteriosclerotic lesions develop in the *afferent* (leading into) and *efferent* (going out of) arterioles and the glomerular capillaries. The glomerular filtration rate declines and tubular function is affected, resulting in proteinuria and microscopic haematuria.

Malignant hypertension is a rapidly progressive form of hypertension that can develop in people with untreated primary hypertension. Here, the diastolic pressure is in excess of 120 mmHg and may be as high as 150 to 170 mmHg. Malignant hypertension affects less than 1% of people with hypertension; it is more common in African Americans than in people of European ancestry. Untreated, malignant hypertension causes a rapid decline in renal function due to vessel changes, renal ischaemia and infarction.

Approximately 5–10% of hypertension is a manifestation of an underlying disease and is termed 'secondary hypertension'. Renal vascular disease and diseases of the renal parenchyma, such as diabetic nephropathy, are commonly associated with secondary hypertension. Ensuring blood pressure lies within normal limits is vital to prevent kidney damage. When hypertension is secondary to kidney disease, adequate blood pressure control is an integral step in attempting to retard the decline in kidney function. Hypertension and its management are discussed in depth in Chapter 31.

Renal artery occlusion

Renal arteries can be occluded by either a primary process affecting the renal vessels or by emboli, clots or other foreign material. Risk factors for acute renal artery thrombosis (formation of a blood clot in the renal artery) include severe abdominal trauma, vessel trauma from surgery or angiography, aortic or renal artery aneurysms, and severe aortic or renal artery atherosclerosis. Emboli from the left side of the heart can travel via the aorta to occlude the renal artery. Emboli may form as a result of atrial fibrillation (irregular and uncoordinated electrical activity of the atria), following myocardial infarction, as vegetative growths on heart valves associated with bacterial endocarditis or from fatty plaque in the aorta.

Renal arterial occlusion may be asymptomatic when the occlusion develops slowly and the affected vessels are small. Acute occlusion leading to ischaemia and infarction typically causes sudden, severe localised flank pain, nausea and vomiting, fever and hypertension. Haematuria and oliguria may occur. In the older person, the new onset of hypertension or worsening of previously controlled hypertension may signal renal artery thrombosis.

Laboratory studies reveal leucocytosis (elevated WBCs) and elevated renal enzyme levels, including aspartate transaminase (AST) and lactic dehydrogenase (LDH). These enzymes, normally present in renal cells, are released into the circulation when cells necrose and die. With bilateral arterial occlusion and infarction, renal function deteriorates rapidly, leading to acute kidney injury (Longo et al., 2012).

Surgery to restore blood flow to the affected kidney may be indicated for acute occlusion. Management usually is more conservative, using anticoagulant therapy, hypertension control and supportive treatment.

Renal vein occlusion

A thrombus (clot) formed in a renal vein can occlude the vessel. The cause of the thrombus often is unclear. In adults, renal venous thrombosis usually occurs with nephrotic syndrome. Other predisposing factors include pregnancy, oral contraceptive use and certain malignancies.

Gradual or acute deterioration of renal function may be the only manifestation of renal vein occlusion. If the thrombus breaks loose, it can become a pulmonary embolism. The definitive diagnosis is made by visualising the thrombus through renal venography.

Thrombolytic drugs such as streptokinase or tissue plasminogen activator (tPA) may be given to dissolve or break up the thrombus. Anticoagulant therapy also is used to prevent further clotting and pulmonary emboli. Renal function often improves with treatment.

Renal artery stenosis

Renal artery stenosis is narrowing of the artery that supplies blood to the kidney; it can be uni- or bilateral. Quite often a person can go through life with unilateral renal artery stenosis undetected; however, this is not always the case.

Atherosclerosis with gradual occlusion of the renal artery lumen by plaque is the primary cause of renal artery stenosis in men. In younger women, the most common cause is fibromuscular dysplasia, structural abnormalities involving the intimal, medial or adventitial layers of the arterial wall.

Renal artery stenosis is suspected when hypertension develops before age 30 or after age 50 with no prior history of high blood pressure. An epigastric bruit (murmur) and other manifestations of vascular insufficiency may also be present. The affected kidney appears small and atrophied on renal ultrasound. Renal angiography uses radiological contrast dye injected into the renal arteries to allow visualisation of renal blood vessels.

Polycystic kidney disease

Polycystic kidney disease (PKD), a hereditary disease characterised by cyst formation and massive kidney enlargement, affects both children and adults. This disease has two forms: the autosomal dominant form, which affects adults; and the autosomal recessive form, which is present at birth (Porth, 2011). Autosomal recessive PKD is rare. It usually is diagnosed prenatally or in infancy. Autosomal dominant PKD is relatively common and accounts for approximately 6% of

people with ESKD in Australia (ANZDATA Registry, 2015). This section focuses on autosomal dominant PKD, the more common adult form of the disorder.

Pathophysiology

Renal cysts are fluid-filled sacs affecting the nephron, the functional unit of the kidneys. The cysts may range in size from microscopic to several centimetres in diameter and affect the renal cortex and medulla of both kidneys. As the cysts fill, enlarge and multiply, the kidneys also enlarge. Renal blood vessels and nephrons are compressed and obstructed and functional tissue is destroyed (see Figure 27.6).

Although the name suggests the disease affects the kidneys, polycystic kidney disease is actually a systemic disease process and manifests with both renal and non-renal abnormalities. Often cysts develop elsewhere in the body, including the liver, spleen, pancreas and other organs. Diverticular disease of the colon is common and may lead to perforation of the bowel (Longo et al., 2012). Up to 10% of people affected experience subarachnoid haemorrhage from a type of congenital intracranial aneurysm.

Manifestations

Polycystic kidney disease is slowly progressive. Symptoms usually develop by age 40 to 50. Common manifestations include flank pain, microscopic or gross haematuria, proteinuria, and *polyuria* and *nocturia*, as the concentrating ability of the kidney is impaired. Urinary tract infection and renal calculi are common, as cysts interfere with normal urine drainage. Most people will develop hypertension from disruption of renal vessels. The kidneys become palpable, enlarged and knobby. Symptoms of renal insufficiency typically develop in approximately 60% of people by the age of 70. The progression to ESKD tends to occur more rapidly in men than in women.

GENETIC CONSIDERATIONS
Adult polycystic kidney disease

- In approximately 50% of cases, parents with autosomal dominant PKD will pass on the faulty gene to their offspring.
- Approximately 90% of cases are inherited as an autosomal dominant trait; the remaining 10% are due to spontaneous mutations.
- In autosomal recessive PKD, both parents must carry the defective gene and have a 25% chance of their child inheriting this disease.

MANIFESTATIONS AND COMPLICATIONS OF CKD

Uraemia

Uraemia, which literally means 'urine in the blood', refers to a group of symptoms associated with the decline in renal function generally in the final stages of the disease trajectory. In uraemia, fluid and electrolyte balance is altered, the regulatory and endocrine functions of the kidney are impaired, and accumulated metabolic waste products affect essentially every other organ system (Longo et al., 2012; Porth, 2011).

Early manifestations of uraemia include nausea, apathy, weakness and fatigue, symptoms that may be dismissed as a viral infection or just being run down. The multisystem effects of uraemia are illustrated below.

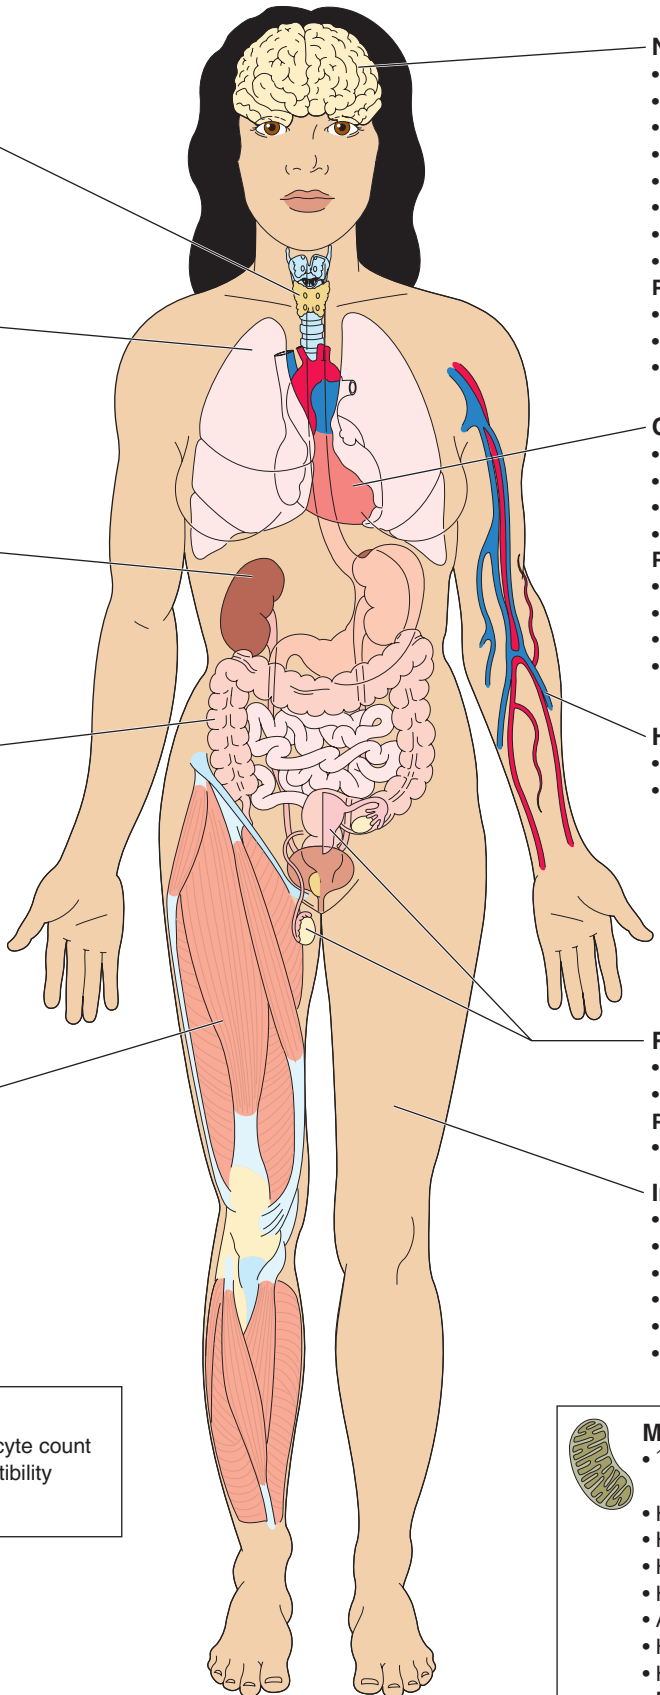
Fluid and electrolyte effects

Loss of kidney function impairs its ability to regulate fluid, electrolyte and acid–base balance. In the early stages of CKD, impaired filtration and reabsorption lead to proteinuria, haematuria and decreased urine-concentrating ability. Salt and water are poorly conserved and the risk of dehydration increases. Polyuria, nocturia and a fixed specific gravity of 1.008 to 1.012 are common (Porth, 2011). As the GFR decreases and renal function deteriorates further, sodium and water retention are common, necessitating salt and water restrictions.

Hyperkalaemia develops as kidney disease progresses. Manifestations of hyperkalaemia, such as muscle weakness, paraesthesias and ECG changes, are not usually seen until the GFR is less than 5–10 mL/min. Phosphate excretion is also impaired, leading to hyperphosphataemia and hypocalcaemia. Reduced calcium absorption due to impaired vitamin D activation also contributes to hypocalcaemia. Hypermagnesaemia develops with advancing kidney disease; magnesium-containing antacids are avoided for this reason.

As kidney disease advances, hydrogen-ion excretion and buffer production are impaired, leading to metabolic acidosis. Respiratory rate and depth increase (Kussmaul's respirations) to compensate for metabolic acidosis. Although metabolic acidosis is often asymptomatic, other possible manifestations include general malaise, weakness, headache, nausea and vomiting, and abdominal pain (see Chapter 9).

MULTISYSTEM EFFECTS OF URAEMIA



Endocrine
- Hyperparathyroidism
- Glucose intolerance

Respiratory
- Pulmonary oedema
- Pleuritis
- Kussmaul's respirations

Urinary
- Proteinuria
- Haematuria
- Fixed specific gravity
- Nocturia
- Oliguria, anuria

Gastrointestinal
- Anorexia
- Nausea and vomiting
- Gastroenteritis
- Hiccups
- Abdominal pain
- Uremic fetor

Potential complications
- Peptic ulcer
- GI bleeding

Musculoskeletal
- Osteodystrophy
- Bone pain
- Spontaneous fractures

Neurological
- Apathy
- Lethargy
- Headache
- Impaired cognition
- Insomnia
- Restless leg syndrome
- Gait disturbances
- Paraesthesias

Potential complications
- Seizures
- Decreased LOC
- Coma

Cardiovascular
- Hypertension
- Oedema
- Coronary heart disease
- Arrhythmias

Potential complications
- Pericarditis
- Pericardial effusion
- Cerebrovascular disease
- Heart failure

Hematological
- Anaemias
- Impaired clotting

Reproductive
- Amenorrhoea (female)
- Impotence (male)

Potential complication
- Spontaneous abortion

Integumentary
- Pallor
- Uraemic skin colour (yellow-green)
- Dry skin, poor turgor
- Pruritis
- Ecchymoses
- Uraemic 'frost'

Immune system
- Diminished leucocyte count
- Increased susceptibility to infection

Metabolic processes
- ↑ urea and serum creatinine
- Hyperkalaemia
- Hyperphosphataemia
- Hypocalcaemia
- Hypermagnesia
- Acidosis
- Hyperlipidaemia
- Hyperuricaemia
- Malnutrition

Cardiovascular effects

In 2013, cardiovascular causes were attributed as the leading cause of deaths in dialysis-dependent people in Australia and New Zealand (ANZDATA Registry, 2015). A combination of malnutrition, inflammatory processes, atherosclerosis, hypertension, hyperlipidaemia and glucose intolerance all contribute to the increased cardiovascular burden on people with kidney disease (Tonbul et al., 2006). Cerebral and peripheral vascular manifestations of atherosclerosis are also seen.

Systemic hypertension is a common complication of ESKD. Hypertension results from excess fluid volume, increased renin–angiotensin activity, increased peripheral vascular resistance and decreased prostaglandins. Increased extracellular fluid volume also can lead to oedema and heart failure. Pulmonary oedema may result from heart failure and increased permeability of the alveolar capillary membrane.

Retained metabolic toxins can irritate the pericardial sac, causing an inflammatory response and signs of pericarditis. *Cardiac tamponade*, a potential complication of pericarditis, occurs when inflammatory fluid in the pericardial sac interferes with ventricular filling and cardiac output.

Haematological effects

Anaemia is a common sequela in CKD and its cause is multifactorial. The kidneys produce erythropoietin, a hormone that controls RBC production. In kidney disease, erythropoietin production declines. Retained metabolic toxins further suppress RBC production and contribute to a shortened RBC lifespan. Nutritional deficiencies (iron and folate) and increased risk of blood loss from the GI tract also contribute to anaemia. (See Chapter 32 for more information on anaemia.)

Anaemia contributes to symptoms such as fatigue, weakness, depression and impaired cognition. It also affects cardiovascular function, as the heart's natural response to anaemia is to increase cardiac output which leads to increased cardiac remodelling and left ventricular hypertrophy. As such, anaemia is associated with an increased risk of cardiovascular disease.

People with kidney disease are at increased risk of bleeding disorders such as ecchymoses, epistaxis and GI bleeding. The combination of anaemia, platelet abnormalities, drug interactions, impaired platelet–vessel wall interaction and circulating uraemic toxins in the blood are all associated with this increased risk.

Immune system effects

Uraemia increases the risk of infection. High levels of urea and retained metabolic wastes impair all aspects of inflammation and immune function. The WBC declines, humoral and cell-mediated immunity are impaired and phagocyte function is defective. Both the acute inflammatory response and delayed hypersensitivity responses are affected (Porth, 2011). Fever is suppressed, often delaying the diagnosis of infection.

Gastrointestinal effects

Anorexia, nausea and vomiting are the most common early symptoms of uraemia. Hiccups also are commonly experienced. Gastroenteritis is frequent. Ulcerations may affect any level of the GI tract and contribute to an increased risk of GI bleeding. Peptic ulcer disease is particularly common in people with uraemia *Uraemic fetor*, a urine-like breath odour often associated with a metallic taste in the mouth, may develop. Uraemic fetor can further contribute to anorexia.

Neurological effects

Uraemia alters both central and peripheral nervous system function. CNS manifestations occur early and include changes in mentation, difficulty concentrating, fatigue and insomnia. Psychotic symptoms, seizures and coma are associated with advanced uraemic encephalopathy.

Peripheral neuropathy is also common in advanced uraemia. Both the sensory and motor tracts are involved. The lower limbs are initially affected. 'Restless leg syndrome', sensations of crawling or creeping, prickling or itching of the lower legs with frequent leg movement, increases during rest. Paraesthesias and sensory loss typically occur in a 'stocking-glove' pattern. As uraemia progresses, motor function is also impaired, causing muscle weakness, decreased deep tendon reflexes and gait disturbances.

Musculoskeletal effects

Hyperphosphataemia and hypocalcaemia associated with uraemia stimulate parathyroid hormone secretion. Parathyroid hormone causes increased calcium resorption from bone. In addition, osteoblast (bone-forming) and osteoclast (bone-destructing) cell activity is affected. This bone resorption and remodelling, combined with decreased vitamin D synthesis and decreased calcium absorption from the GI tract, lead to *renal osteodystrophy*. Osteodystrophy is characterised by oste*omalacia,* softening of the bones, and *osteoporosis*, decreased bone mass. Bone cysts may develop. Manifestations of osteodystrophy include bone tenderness, pain and muscle weakness, which all increase the risk of spontaneous fractures (Porth, 2011).

Endocrine and metabolic effects

Accumulated waste products of protein metabolism are a primary factor involved in the effects and manifestations of uraemia. Serum creatinine and urea levels are significantly elevated. Uric acid levels are increased, contributing to an increased risk of gout.

Tissues become resistant to the effects of insulin in uraemia, leading to glucose intolerance. High blood triglyceride levels and lower than normal high-density lipoprotein (HDL) levels contribute to the accelerated atherosclerotic process.

Reproductive function is affected. Pregnancies are rarely carried to term and menstrual irregularities are common. Reduced testosterone levels, low sperm counts and impotence affect men with ESKD.

Dermatological effects

Anaemia and retained pigmented metabolites cause pallor and a yellowish hue to the skin in uraemia. Dry skin with poor turgor, a result of dehydration and sweat gland atrophy, is common. Bruising and excoriations are frequently seen. Metabolic wastes not eliminated by the kidneys may be deposited in the skin, contributing to itching or pruritus. In advanced uraemia, high levels of urea in the sweat may result in *uraemic frost*, crystallised deposits of urea on the skin.

INTERPROFESSIONAL CARE

Management of chronic kidney disease regardless of its aetiology focuses on identifying and slowing the progression of the underlying disease process, preserving renal function, preventing and managing complications, and providing psychological support. This aim is achieved through the collaboration of all members of the healthcare team.

Diagnostics

Laboratory and diagnostic testing are valuable to identify the cause of CKD, monitor kidney function and evaluate the efficacy of treatment. A number of tests and procedures may be performed to determine the underlying renal disease. (See Table 27.7 for normal laboratory values for commonly requested blood and urine tests.) Once the diagnosis is established, renal function is monitored primarily through blood levels of metabolic wastes and electrolytes. Imaging investigations provide information about the size and shape of the kidneys, possible tumours or cysts, the nature of the renal parenchyma and the presence of any obstruction. See Chapter 25 for the nursing implications of selected tests.

The following studies may be ordered to help identify the underlying cause or aetiology:

- *eGFR* provides an estimation of the glomerular filtration rate. eGFR is used to evaluate renal function and may be reduced despite serum creatinine levels being in the normal range.
- *Urea* is the end product of protein metabolism. It is created by the breakdown and metabolism of both dietary and body proteins. Urea is eliminated from the body by filtration in the glomerulus; minimal amounts are reabsorbed in the renal tubules. Glomerular diseases interfere with filtration and elimination of urea nitrogen, causing blood levels to rise. Increased protein catabolism (destruction), which may occur with GI bleeding or tissue breakdown, can also raise the urea level.
- *Serum creatinine* measures the amount of creatinine in the blood. Creatinine is the metabolic by-product of muscle metabolism and is produced in relatively constant amounts by skeletal muscles. It is excreted entirely by the kidneys, making serum creatinine a good indicator of kidney function. Normal values are lower in the older adult because of decreased muscle mass.
- *Serum electrolytes* are monitored throughout the course of CKD because impaired kidney function alters their excretion. The serum sodium may be within normal limits or low because of water retention. Potassium levels are elevated but usually remain below 6.5 mmol/L. Serum phosphate is elevated and the calcium level is decreased. Metabolic acidosis is identified by a low pH, low CO_2 and low bicarbonate levels.
- *Full blood count (FBC)* provides information about the degree of anaemia, with most people with stage 4 and 5 CKD

TABLE 27.7 Changes in laboratory values associated with kidney disease

TEST	NORMAL VALUE	ASSOCIATED WITH KIDNEY DISEASE
Urea, serum	3.5–7.2 mmol/L Slightly higher in older adults	Elevated in hypovolaemia, AKI, later stages of CKD Decreased in hypervolaemia and malnutrition
Creatinine, serum	Female: 50–110 µmol/L Male: 60–120 µmol/L Slightly lower in older adults	Elevated in hypovolaemia, AKI, later stages of CKD
eGFR	> 90 mL/min (young adults) eGFR declines naturally with age	See Figure 27.3 eGFR is not validated for use in children, Indigenous populations or AKI
Serum albumin	33–41 g/L	Decreased in nephrotic syndrome
Serum electrolytes	Potassium 3.7–5.2 mmol/L Sodium 136–144 mmol/L Calcium 2.18–2.49 mmol/L Ionised calcium 1.16–1.30 mmol/L Phosphorus 0.88–1.46 mmol/L	Increased in renal insufficiency Decreased in nephrotic syndrome Decreased in later stages of CKD and malabsorption Elevated in hypocalcaemia and later stages of CKD
Haemoglobin	115–165 g/L	Decreased in later stages of CKD. Target concentration of 110 g/L for stage 4 and 5 CKD/ESKD
Red blood cell count	Female: 3.8–5.8 x 10^{12}/L Male: 4.5–6.5 x 10^{12} /L	Decreased in later stages of CKD
Urinary ACR	Female: 3.5–35 mg/mmol Male: 2.6–25 mg/mmol Female: > 35 mg/mmol Male: > 25 mg/mmol	Microalbuminuria Macroalbuminuria
Urinary PCR	> 30 mg/mmol	Proteinuria
Urine red blood cells	< 2–3/HPF; no RBC casts	Present in glomerular disorders

showing decreased haematocrit, haemoglobin, RBCs and platelets.

- *Erythrocyte sedimentation rate (ESR)* is a general indicator of inflammatory response. It is generally elevated in conditionals such as vasculitis, acute post-streptococcal glomerulonephritis and lupus nephritis.
- *C-reactive protein (CRP)* is a non-specific inflammatory marker and is used to indicate the presence of inflammatory states. It may be elevated in infective processes and in lupus nephritis.
- *Urinalysis* often reveals red blood cells (RBCs) and proteins in the urine of people with CKD. These substances, which normally are too large to enter glomerular filtrate, escape due to the increased permeability of the glomerular basement membrane.

In CKD, urinary specific gravity may be fixed at approximately 1.010, equivalent to that of plasma. This fixed specific gravity is due to impaired tubular secretion, reabsorption and urine concentrating ability. Abnormal proteins (e.g. Bence-Jones proteins), blood cells and cellular casts may also be noted in the urine.

- *Albumin:creatinine (ACR)* and *protein:creatinine ratio (PCR)* evaluates the urinary excretion of either albumin or protein and is considered best practice in the primary screening of CKD.
- *24-hour timed urine* enables the measurement of urinary protein and/or creatinine excretion over a 24-hour time period. Urine creatinine levels decrease when renal function is impaired because it is not effectively eliminated from the body.
- *Urine microbial culture and sensitivity* may be ordered to identify any urinary tract infection that may hasten the progress of CKD.
- *Throat or skin cultures* detect infection by group A beta-haemolytic *Streptococcus.* Although post-streptococcal glomerulonephritis typically follows the acute infection by 1 to 2 weeks, treatment to eradicate any remaining organisms is initiated to minimise antibody production.
- *Antistreptolysin O (ASO) titre* and other tests detect streptococcal exoenzymes (bacterial enzymes that stimulate the immune response in acute post-streptococcal glomerulonephritis). Other titres such as antistreptokinase (ASK) or antideoxyribonuclease B (ADNAase B) may be obtained as well.
- *Kidney biopsy*, microscopic examination of kidney tissue, assists in determining the cause of CKD, its prognosis and appropriate treatment. It is usually done percutaneously, by inserting a biopsy needle through the skin into the kidney to obtain a tissue sample. Open biopsy, which requires surgery, may also be done. Biopsy is not justified when clinical evidence makes diagnosis almost certain—for example, polycystic kidney disease. Other contraindications include small kidneys, single kidney, uncontrolled blood pressure and/or uraemia.
- *Kidney, ureter, bladder (KUB) ultrasound* is considered a first-line imaging technique and is used to evaluate kidney size and identify potential obstructions. It is a useful non-invasive technique to differentiate acute kidney injury from chronic kidney disease. In AKI, the kidneys may be enlarged, whereas they typically appear small and shrunken with decreased cortical width in CKD. Ultrasound can also detect renal masses and differentiate polycystic kidney disease from renal carcinoma.
- *Kidney scan*, a nuclear medicine procedure, allows visualisation and functional assessment of the kidneys after intravenous administration of a radioisotope.
- *Intravenous pyelogram (IVP)*, *retrograde pyelography* or *antegrade pyelography* may also be used to evaluate kidney structure and function. Radiological contrast media are used with extreme caution because of their potential nephrotoxicity. Retrograde pyelography, in which contrast dye is injected into the ureters, and antegrade pyelography, in which the contrast medium is injected percutaneously into the renal pelvis, are preferred because they have fewer nephrotoxic effects than IVP.
- *Renal angiography* is used to investigate and evaluate renal blood flow and the major vasculature of the kidney and affords the opportunity for simultaneous interventional procedures such as stenting or angioplasty.
- *Computed tomography (CT) scan* is used to detect and differentiate renal masses such as cystic disease or tumours. CT can determine tumour density, local extension of the tumour and any regional lymph node or vascular involvement.
- *Bone density scan* is used to assess bone mineral density; see Chapter 37 for more information.

See Chapter 25 for nursing implications of tests used in renal medicine.

CONSIDERATION FOR PRACTICE

People with pre-existing kidney disease, volume depletion or advanced age are at high risk of contrast nephropathy if exposed to radiocontrast. Alert the treating team prior to any imaging procedure that requires radiocontrast if person is in high-risk category. Preventative methods surround adequate hydration. If not contraindicated, ensure the person remains well hydrated pre and post procedure.

Medications

Chronic kidney disease affects both the pharmacokinetic and pharmacodynamic effects of drug therapy. Many medications are excreted primarily by the kidney. The half life and plasma levels of many drugs increase in chronic kidney disease. Drug absorption may be decreased when phosphate-binding agents are administered concurrently. Proteinuria can significantly reduce plasma protein levels, leading to toxicity when highly protein-bound drugs are given. In addition, any potentially nephrotoxic agent is avoided or used with extreme caution in people with CKD. Dose reductions may be required and/or dosing intervals are lengthened in CKD according to individual GFR.

As renal function declines, medications become an integral component of replacing diminished renal function. Medications are used to treat underlying disorders, reduce inflammatory processes, manage symptoms and attempt to retard the progression of CKD.

Diuretics such as frusemide may be prescribed to reduce extracellular fluid volume and oedema. Diuretic therapy can also reduce hypertension and lower potassium levels. Thiazides such as hydrochlorothiazide, which are commonly used in combination with some antihypertensive classes, are less effective as diuretics when the eGFR falls below 25–30 mL/min but still remain effective in reducing hypertension as they reduce blood pressure through a vasodilatory effect.

ANTIHYPERTENSIVE AGENTS Antihypertensive agents are used to maintain the blood pressure within normal levels, slow the progression of CKD and prevent complications of coronary heart disease and cerebral vascular disease. Angiotensin-converting-enzyme (ACE) inhibitors are preferred, although any class of antihypertensive agent may be prescribed (see Chapter 31). ACE inhibitors may be ordered to reduce protein loss associated with nephrotic syndrome. These drugs reduce proteinuria and slow the progression of renal disease in the kidney. Angiotensin receptor blockers such as irbesartan have also been shown to have a renoprotective benefit independent of blood pressure control, particularly in the reduction of microalbuminuria in people with diabetic nephropathy (Ravera et al., 2005).

DRUGS FOR ACID–BASE IMBALANCE AND ELECTROLYTE DISTURBANCES Other drugs may be used to manage electrolyte imbalances and acid–base imbalances. Sodium bicarbonate may be used to correct mild acidosis.

If the serum potassium rises to dangerously high levels, a combination of bicarbonate, insulin and glucose may be given intravenously to promote potassium movement into the cells. Sodium polystyrene sulfonate (Resonium), a potassium-ion exchange resin, can be given either orally or rectally (as an enema).

PHOSPHATE BINDERS AND AGENTS FOR RENAL OSTEODYSTROPHY Oral phosphate binding agents such as calcium carbonate are taken with food to lower serum phosphate levels and before or after food to normalise serum calcium levels. Aluminium hydroxide has a stronger phosphate binding potency but its use is limited by complications such as encephalopathy and osteodystrophy associated with long-term administration (McPhee, Papadakis & Tierney, 2008). Non-calcium phosphate binders such as sevelamer and lanthanum have the advantage that they are not themselves absorbed from the gut, so have less potential to cause problems with accumulation. They have shown benefits in reducing coronary calcification (Block et al., 2007). Vitamin D analogues such as calcitriol may be given to improve gastrointestinal calcium absorption and normalise calcium levels. Bisphosphonates such as alendronate are contraindicated when the eGFR falls below 35 mL/min and are also contraindicated in hypocalcaemia. Cinacalcet belongs to a drug class termed 'calcimimetic' as it imitates calcium at the parathyroid gland to decrease output of parathyroid hormone due to secondary hyperparathyroidism. This slows down excessive bone turnover and remodelling and lowers the chance of harmful metastatic calcification.

ERYTHROPOIETIN STIMULATING AGENTS AND MEDICATIONS USED IN ANAEMIA Folic acid and iron supplements are given to combat anaemia associated with chronic kidney disease due to impaired erythropoiesis and shortened red blood cell survival. A multivitamin preparation is also often prescribed because anorexia, nausea and dietary restrictions may limit nutrient intake. Recombinant human erythropoietin stimulates the proliferation and differentiation of erythroid progenitors, which in turn increase haemoglobin synthesis and accelerate the release of reticulocytes (young RBCs) from the bone marrow. There are five erythropoietin stimulating agents (ESAs) currently on the Australian market. These are epoetin alfa (Eprex), epoetin beta (NeoRecormon), epoetin lambda (Novicrit), methoxy polyethylene glycol-epoetin beta (Mircera) and darbepoetin (Aranesp). There is little difference between the agents in terms of efficacy and the choice is governed by factors such as frequency and route of administration.

ANTIBIOTICS Antibiotics, usually from the penicillin family, are prescribed for the person with post-streptococcal glomerulonephritis to eradicate any remaining bacteria, removing the stimulus for antibody production. Nephrotoxic antibiotics such as aminoglycosides are avoided but will be administered in cases where the benefit outweighs the risk. Both vancomycin and gentamicin are renally cleared so redosing is titrated according to serum levels.

ANALGESIA Non-steroidal anti-inflammatory medications such as ibuprofen are avoided due to their nephrotoxic nature. Pethidine is avoided altogether as its metabolite is renally cleared and accumulation will cause seizures. Morphine is also avoided due its metabolite, M6G, accumulating in kidney disease but may be given once or twice for acute pain episodes such as chest pain. Fentanyl and oxycodone are generally preferred due to the liver metabolising them into inactive metabolites.

IMMUNOSUPPRESSANTS Aggressive immunosuppressive therapy is used to treat acute inflammatory processes such as rapidly progressive glomerulonephritis, Goodpasture's syndrome and exacerbations of SLE. When begun early, immunosuppressive therapy significantly reduces the risk of end-stage kidney disease. Corticosteroids such as prednisolone are often used in large doses for several months, sometimes in combination with other immunosuppressants such as azathioprine and cyclophosphamide. Corticosteroids may also be used to induce remission of nephritic syndrome. However, in post-streptococcal glomerulonephritis they may actually worsen the condition so are usually avoided. See the transplant section of this chapter and Chapter 12 for more information about corticosteroids and other immunosuppressive drugs.

Nutrition and fluid management

As renal function declines, the elimination of water, solutes and metabolic wastes is impaired. Accumulation of these wastes in the body leads to uraemic symptoms. Instituted early in the course of CKD, dietary modifications can reduce uraemic symptoms and help prevent complications.

TABLE 27.8 Foods high in potassium or phosphate and some low-value alternatives

HIGH POTASSIUM	LOW POTASSIUM
Fruit and vegetable juices (except cranberry, lemon), bananas, apricots, plums, dried fruit, nuts and seeds, legumes, potatoes, avocados, tomatoes and tomato paste	Cranberry juice, apples, pears, blueberries, lychees, green beans, zucchinis, onions, strawberries, raspberries, lettuce, lemons
HIGH PHOSPHATE	**LOW PHOSPHATE**
Milk, eggs, cheese, meats, offal, poultry, fish, cola drinks and soy	Pasta, rice, corn cereals, popcorn, green beans, non-cola-based drinks and cordial

Unlike carbohydrates and fats, the body is unable to store excess proteins. Unused dietary proteins are degraded into urea and other nitrogenous wastes, which are then eliminated by the kidneys. Protein-rich foods also contain inorganic ions such as hydrogen ion, phosphate and sulfites that are eliminated by the kidneys. Consequently, dietary protein intake should be assessed by a renal dietitian with a bias towards optimising nutritional status.

A daily protein intake of 0.6 g/kg of ideal body weight provides the amino acids necessary for tissue repair in order to maintain body composition for people with CKD, provided the protein is of high biological value (Fouque & Mitch, 2014). Carbohydrate and fat intake may need to be increased to maintain ideal body weight and energy requirements, and is dependent on the rate of physical activity.

Water and sodium intake are regulated to maintain the extracellular fluid volume at normal levels. Water intake of 1000 to 2000 mL per day is generally recommended to maintain water balance. Sodium is restricted to 100 mmol or 2300 mg per day initially and equates to the equivalent of a 'no added salt' diet. More stringent water and sodium restrictions may be necessary as CKD progresses. The person is instructed to monitor weight daily and report any weight gain in excess of 2 kg over a 2-day period.

When the GFR falls to less than 10 to 20 mL/min, potassium and phosphorus intake may also be restricted. Potassium intake is generally limited to 1 mmol/kg of ideal body weight per day. The person is cautioned to avoid using salt substitutes, which typically contain high levels of potassium chloride. See Table 27.8 for foods high in potassium and phosphorus and some low-potassium and low-phosphorus alternatives.

Nursing care

The clinical setting, whether it is in the community or a secondary or tertiary referral hospital, determines the nursing care.

Upon diagnosis of CKD, regardless of the clinical setting, the teaching of self-management principles begins. The principal nursing diagnosis at this time may be *Deficient knowledge* in relation to understanding of disease process and measures to help preserve kidney function. The nurse, in partnership with the person, should establish priorities for management and collaborate with other members of the interprofessional team as required. Ensure that the person and family understand and are able to discuss the following topics:

- information about the disease and the prognosis
- prescribed treatment, including activity and diet restrictions; the use and potential effects, both beneficial and adverse, of all medications
- risks, manifestations, prevention and management of complications such as oedema and infection
- signs, symptoms and implications of declining renal function
- measures to prevent further kidney damage, including eliminating modifiable risk factors and avoiding nephrotoxic drugs
- community resources, such as home care providers and support groups.

Teach people with CKD about the underlying pathology of their specific disease process, its treatment and usual course. Discuss measures to maintain optimal renal function and the importance of avoiding additional insults to their kidneys. Include extra information about preventing UTI (such as hygiene measures) and early manifestations of UTI. Stress the importance of seeking treatment to prevent further kidney damage. Advise to avoid drugs that are potentially toxic to the kidneys and to check with the primary care provider before taking any new drug, including over-the-counter and complementary medicines.

For those with polycystic kidney disease, discuss the potential benefits of genetic counselling and screening of family members for evidence of the disease. This is particularly important if renal transplantation is contemplated and family members are potential donors.

Health promotion

Measures to reduce the risk of CKD focus on preventing kidney disease, particularly in those with diabetes and hypertension. Deal with modifiable risk factors promptly, including the maintenance of a healthy BMI and smoking cessation. Promote early and effective treatment of all infections, particularly skin and pharyngeal infections caused by streptococcal bacteria. Discuss measures to reduce the risk of urinary tract infections and stress the importance of prompt treatment to eradicate the infecting organism. Discuss the relationship between diabetes, hypertension and kidney disease. The rates of obesity in Australia are of particular concern given that increased BMI is linked as an independent risk factor for type 2 diabetes, hypertension and cardiovascular disease. Emphasise that maintaining blood glucose levels and blood pressure within the recommended ranges reduces the risk of adverse effects on the kidneys. Reiterate the importance of avoiding drugs and

substances that are potentially toxic to the kidneys. Ensure that all people with reduced renal function are well hydrated, particularly when a nephrotoxic drug is prescribed or anticipated. Finally, encourage people approaching ESKD to investigate options for early transplantation to avoid long-term dialysis. In liaison with the 'living related' transplant team discuss the option of a living donor and renal allotransplantation.

Assessment

Review Chapter 25 for complete assessment of the renal and urinary systems. Focused assessment data related to CKD include the following:

- *Health history:* complaints of facial or peripheral oedema or weight gain, fatigue, nausea and vomiting, headache, general malaise, abdominal or flank pain; cough or shortness of breath; changes in amount, colour or character of urine (e.g. frothy urine); history of skin or pharyngeal streptococcal infection, diabetes, SLE or kidney disease; current medications.
- *Physical examination:* general appearance; vital signs; weight; presence of periorbital, facial or peripheral oedema; skin for lesions, infection; inspect throat, obtain culture as indicated; urine specimen for colour, character, odour.

Nursing diagnoses and interventions

Nursing care is supportive and educational. Monitoring renal function and fluid volume status is a key component of care, as is protecting the person from infection. Both manifestations of CKD and its treatment can interfere with a person's ability to maintain usual roles and responsibilities.

Excess fluid volume

Excess fluid volume and resulting oedema are common manifestations of glomerular disorders. When proteins are lost in the urine, the oncotic pressure of plasma falls and fluid shifts into the interstitial spaces. The body responds to this fluid shift by retaining sodium and water to maintain intravascular volume, leading to excess fluid volume.

- Monitor vital signs, including blood pressure, apical pulse, respirations and breath sounds, at least every 4 hours. Report significant changes. *Excess fluid increases the cardiac workload and the blood pressure. Tachycardia may result. Associated electrolyte imbalances can cause arrhythmias. Increased pulmonary vascular pressure can lead to pulmonary oedema, tachypnoea, dyspnoea and crackles (rales) in the lungs.*
- Record fluid intake and output as indicated. *Accurate fluid balance records help determine fluid volume status.*

CONSIDERATION FOR PRACTICE

Weigh daily, using consistent technique (time of day, scale and clothing). Accurate daily weights are the best indicator of approximate fluid balance.

- Monitor serum electrolytes, haemoglobin and haematocrit, urea, creatinine and eGFR. *Glomerular disorders affect fluid balance and may alter electrolyte balance as well, potentially leading to complications such as cardiac arrhythmias (see Chapter 9). Increased intravascular volume can result in low haemoglobin and haematocrit values. Urea, creatinine and eGFR provide information about renal function.*
- Maintain fluid restriction as ordered. Offer ice chips (in limited and measured amounts) and frequent mouth care to relieve thirst. With the person, develop a fluid intake schedule. *Fluids may be restricted to reduce fluid overload, oedema and hypertension. Ice chips and frequent mouth care moisten mucous membranes and help relieve thirst while maintaining oral tissue integrity. Including the person in planning fluid intake promotes a sense of control and understanding of the treatment regimen.*

CONSIDERATION FOR PRACTICE

Carefully monitor and regulate intravenous infusions; include fluid used to dilute IV medications as intake. Significant 'hidden' fluid intake can occur with intravenous medication administration.

- Arrange dietary consultation regarding sodium- or protein-restricted diets. Include the person and dietitian in planning to allow individualisation of the diet to person preferences. *The glomerular disorder may reduce appetite; considering food preferences can help maintain adequate nutrition.*
- Monitor for desired and adverse effects of prescribed medications. *Diuretic therapy helps reduce excess fluid volume; however, glomerular disorders can affect the person's response to treatment. In addition, diuretics can exacerbate the electrolyte imbalances and muscle weakness often associated with glomerular disorders.*
- Provide frequent position changes and good skin care. *Perfusion may be altered by tissue oedema, increasing the risk of breakdown.*

Fatigue

Fatigue is a common manifestation of CKD. Anaemia, loss of plasma proteins, headache, anorexia and nausea compound this fatigue. The ability to maintain usual physical and mental activities may be impaired.

- Schedule activities and procedures to provide adequate rest and energy conservation. Prevent unnecessary fatigue. *Adequate rest and energy conservation reduce fatigue and improve the person's ability to tolerate and cope with required treatments and activities.*
- Assist with ADLs as needed. *The goal is to conserve limited energy reserves.*
- Discuss the relationship between fatigue and the disease process with the person and family. *Understanding the nature of the disease and associated fatigue helps the person and family cope with reduced energy and comply with prescribed rest.*
- Reduce energy demands with frequent, small meals and short periods of activity. Limit the number of visitors and visit length. *Small, frequent meals reduce the energy*

needed for eating and digestion. Limiting visitors and visit length helps conserve energy. In addition, nurses can assist the fatigued person who may be reluctant to ask visitors to leave.

Ineffective protection

People with CKD are at high risk of infection. The use of some drug classes in specific treatments can depress the immune system further. The anti-inflammatory effect of corticosteroids may also mask early symptoms of infection.

CONSIDERATION FOR PRACTICE

Monitor vital signs, temperature and mental status every 4 hours. An elevated temperature may indicate infection; anti-inflammatory drugs may moderate this response, however. Tachycardia, increasing lethargy or confusion may be the initial signs of infection.

- Assess frequently for other signs of infection such as purulent wound drainage, productive cough, adventitious breath sounds and red or inflamed lesions. Monitor for manifestations of UTI, such as dysuria, frequency and urgency, and cloudy, foul-smelling urine. *Early identification and treatment of infection is important to prevent systemic complications in the susceptible person.*
- Monitor FBC, focusing on the WCC and differential. *An elevated WCC and increased numbers of immature white cells in the blood (left shift) may be early indicators of infection.*
- Use standard precautions and good handwashing technique. Protect from cross-infection by providing a private room and restricting ill visitors. *People with decreased resistance to infection need increased protection.*
- Avoid or minimise invasive procedures. *Maintaining the protective skin barrier is especially important for the person with altered immune status.*
- If catheterisation is required, use sterile intermittent straight catheterisation or maintain a closed drainage system for an indwelling catheter. Prevent urine reflux from the drainage system to the bladder or the bladder to the kidneys by ensuring a patent, gravity flow system. *The urinary tract is a frequent entry point for infection, particularly in the hospitalised person. Maintaining strict asepsis during catheterisation is vital. Intermittent catheterisation is associated with a lower risk of UTI than an indwelling catheter.*
- Provide a nutritionally sound diet with complete proteins. *A well-balanced, nutritionally sound diet is important to maintain nutritional status and support immune function.*
- Teach measures to prevent infection. *Care is often provided in the home, requiring the person and family to use appropriate infection control measures.*

Ineffective role performance and anticipatory grieving

Strategies to support people with ineffective role performance and anticipatory grieving are similar and revolve around support processes. The manifestations and treatment of CKD can affect the ability to maintain usual roles and activities. In addition, the person may express feelings associated with the loss of function and lifestyle. Fatigue and muscle weakness may limit physical and social activities. If uraemia is present, malaise, nausea and mental status changes can interfere with role function. Facial and periorbital oedema affect the person's self-esteem and may lead to isolation.

- Establish a strong therapeutic relationship. *It is important to gain the person's trust and confidence to afford them the opportunity to share their feelings.*
- Encourage self-care and participation in decision making. *Increased autonomy helps to restore self-confidence and reduce powerlessness.*
- Provide time for verbalisation of thoughts and feelings; listen actively, acknowledging and accepting fears and concerns. *Adequate time and active listening encourage expression of concerns and the effect of the disease or treatments on daily life. This helps the person deal with the illness, its treatment and associated losses.*
- Support coping skills, helping the person identify personal strengths. *This support helps the person gain confidence.*
- When possible, enlist the support of family, other people and friends. *These people can provide physical, psychological, emotional and social support.*
- Discuss the effect of the disease and treatments on roles and relationships, helping identify potential changes in roles, relationships and lifestyle. Help the person and family develop a plan for alternative behaviours and relationships, encouraging the person to maintain usual roles to the extent possible. *Developing a plan helps reduce the strain of role changes and maintain a sense of dignity and control.*
- Provide accurate and optimistic information about the disorder and its short- and long-term effects. *The person and family need accurate information to plan for the future.*
- Evaluate the need for additional support and social services for the person and family. Provide referrals as indicated. *Depending on the person and family strengths, the severity of the disorder and its treatment and prognosis, ongoing social support services may be necessary to facilitate coping and adaptation.*

Community-based care

Whereas hospital-based care is focused on treating the complications of CKD symptomology, community care is focused on primary prevention, screening practices and the teaching of self-management principles. The cornerstone of any primary prevention program is the screening of people in 'at-risk' categories (see Box 27.3). Screening programs, whether they are opportunistic or systematic, assist in identifying people with CKD and afford the opportunity to initiate timely intervention to prevent the progression to ESKD. Nurses are ideally placed to identify at-risk people and implement screening strategies to identify people with CKD. One of the wonders of screening strategies for CKD is that they are predominantly non-invasive and non-expensive (see Box 27.4). Urinalysis and blood pressure measurements are key screening techniques for detecting

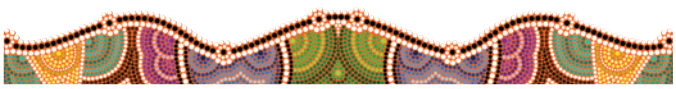
BOX 27.3 Major risk factors for chronic kidney disease (CKD)

- Diabetes
- High blood pressure
- Aged over 60 years
- Smoking
- Obesity
- Family history of kidney disease
- Aboriginal or Torres Strait Islander origin
- Established cardiovascular disease

BOX 27.4 The kidney health check

1. Blood test for eGFR to check kidney function
2. Urine test for albumin:creatinine ratio (ACR)
3. Check blood pressure for presence of hypertension

glomerular dysfunction (i.e. microalbuminuria or proteinuria) and hypertension. Kidney function can also be measured through eGFR from a simple blood test. CKD is progressive in nature; its course is generally lengthy but may also progress rapidly in some cases.



THE PERSON WITH END-STAGE KIDNEY DISEASE

Kidney replacement therapy

Kidney replacement therapy (KRT) (previously referred to as renal replacement therapy (RRT)), used to treat end-stage kidney disease (ESKD), is provided through haemodialysis, peritoneal dialysis or kidney transplantation. ESKD is reached when glomerular function decreases to a level of less than 15 mL/min (AIHW, 2015d). In Australia, dialysis and transplantation have been available since the early 1960s. The first dialysis was performed in Brisbane in 1954 (Dique, 1955). The first successful transplant was performed in Adelaide in 1965 (Lawrence, 1994).

KRT involves considerable individual and healthcare burdens. Australia has followed the worldwide trend and seen an approximate annual increase of 6% in the number of people receiving dialysis treatment, although this has stabilised somewhat from 2006 to 2013 (ANZDATA Registry, 2015). The greatest increase since 1989 has been in the elderly with a 13-fold increase in the number of people over 75 years of age receiving dialysis (AIHW, 2012). In 2013, a record high 882 kidney transplants were performed in Australia; however, Australia's organ donation rates remain relatively low compared with countries such as Spain, Portugal and the United States (ANZDATA Registry, 2015). The numbers of people receiving KRT will likely increase by 80% from 2011 to 2020 (AIHW, 2012) placing an enormous burden on future Australian healthcare resources.

Dialysis

Dialysis is the diffusion of solute molecules across a semipermeable membrane from an area of higher solute concentration to one of lower concentration. It is used to remove excess fluid and metabolic waste products in kidney failure. During dialysis, blood is separated from a dialysis solution by a semipermeable membrane. Both haemodialysis and peritoneal dialysis rely on the principle of diffusion to remove wastes from people during KRT. For the person who is not a candidate for kidney transplantation, or who has had a transplant failure, dialysis is life sustaining.

Of the 11 774 people receiving dialysis at the end of 2013, 80% were receiving haemodialysis and 20% were receiving peritoneal dialysis (ANZDATA Registry, 2015). Care involving dialysis is by far the most common reason for same-day separations in Australia (AIHW, 2012). Unfortunately, there are significantly higher rates of admission for dialysis in the Indigenous and lower socioeconomic populations (AIHW, 2012).

Both peritoneal dialysis and haemodialysis can be undertaken safely at home. Although home dialysis therapy is the preferred treatment of clinicians and resources have been increased (Lauder et al., 2011; Ludlow et al., 2011), rates have not increased significantly over the past 10 years (Fortnum & Ludlow, 2014). Home dialysis can be performed more frequently and can suit the person's lifestyle (Chow & Tran, 2012). In saying this, factors such as employment and availability of a dialysis centre become the primary factors influencing the choice of haemodialysis or peritoneal dialysis (Bennett, Schatell & Shah, 2015; Sinclair, 2008).

People on long-term dialysis have a higher risk of complications and death than the general population. Mortality rates are generally higher with older age, diabetes, Indigenous status and coronary artery disease; however, crude 1-year mortality rates in this group have decreased from 0.14 to 0.10 over the past 10 years (ANZDATA Registry, 2015). Although dialysis and transplantation can provide lifesaving treatment they are not the only options for people with ESKD, with supportive care more frequently being provided.

Supportive care

The decision to initiate dialysis is not easy as dialysis only manages the symptoms of ESKD and is not a cure. Although many people on dialysis still maintain jobs, dialysis requires considerable support from healthcare professionals and significant others as people can be challenged with the day-to-day stress that accompanies dialysis treatment (Josland, 2013). Many people live with constant lethargy, never feeling truly well and may feel powerless because of their dependence on others for treatment (Tallis, 2005). In the end, the person may choose supportive care rather than undergoing dialysis or transplantation.

Supportive care in the ESKD context describes the active therapy that is delivered without dialysis or transplantation. Given the often high symptom burden in ESKD, renal supportive care includes appropriate symptom management, care coordination and ongoing education for patients, families and health professional staff (Josland, 2013). Although supportive care is increasingly being offered in Australia and globally,

patients commonly report a greater emphasis on dialysis and transplant over supportive care (Moustakas, Bennett & Tranter, 2015). Given that the quality of life is often compromised by dialysis and the mortality rates over 65 years are comparable to supportive care (Jassal & Watson, 2011), supportive care is a legitimate therapy option for any person with ESKD.

Haemodialysis

Haemodialysis uses the principles of diffusion and ultrafiltration to remove electrolytes, waste products and excess water from the body. Blood is pumped from the person via a vascular access to the dialyser (see Figure 27.7). The porous membranes of the dialyser allow small molecules such as water, glucose and electrolytes to pass through, but block larger molecules such as serum proteins and blood cells. The **dialysate**, a solution of approximately the same composition and temperature as normal extracellular fluid, passes along the other side of the membrane allowing small solute molecules to move freely across the membrane by diffusion.

The direction of movement for any substance is determined by the concentrations of that substance in the blood and the dialysate. Electrolytes and waste products such as urea and creatinine diffuse from the blood into the dialysate. Essential electrolytes such as calcium or potassium may be added to the dialysate to reduce excessive removal. Excess water is removed by creating a negative pressure on to the blood moving through the dialyser. This process is known as **ultrafiltration**.

Haemodialysis is predominantly performed three times a week, varying from 3 to 8 hours per treatment with the majority of people receiving 4 to 5 hours per treatment or 12 to 15 hours per week (ANZDATA Registry, 2015). Haemodialysis is performed most frequently in satellite, or community, settings that are nurse run and require little nephrologist management input (Bennett, 2011). The most frequent complications during dialysis (intradialytic) are hypotension and muscle cramps (Bradshaw, Ockerby & Bennett, 2011). Infection, malnutrition and vascular access problems are common long-term complications of haemodialysis.

Following are complications associated with haemodialysis:

- Hypotension, the most frequent complication during haemodialysis, is related to changes in serum osmolality, rapid removal of fluid from the vascular compartment, vasodilation and other factors.
- Bleeding is related to altered platelet function associated with uraemia and the use of heparin during dialysis.
- Infection (local or systemic) is related to WBC damage and immune system suppression. *Staphylococcus aureus* septicaemia is commonly associated with contamination of the vascular access site.

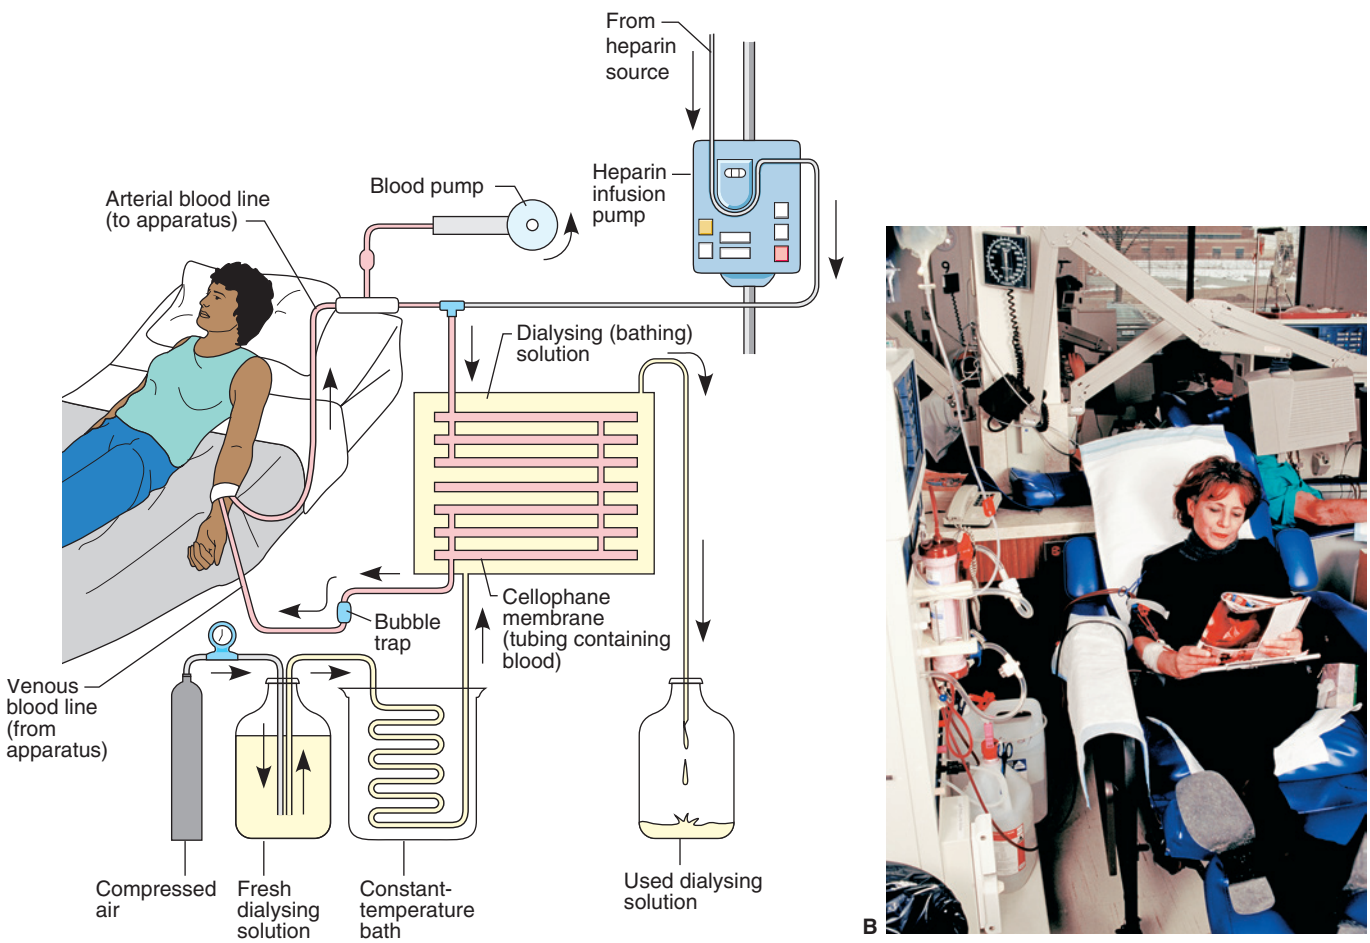


FIGURE 27.7 ■ *A*, The components of a haemodialysis system. *B*, A person receiving haemodialysis

Source: B, © Carolyn A. McKeone/Science Source.

See the box below for nursing care for the person undergoing intermittent haemodialysis.

Haemodiafiltration combines the processes of haemodialysis and greater ultrafiltration in an attempt to better mimic the function of the healthy kidney (Hill et al., 2015). Large amounts of fluid are infused into the dialysis blood circuit and then removed through the haemofilter. Thus both diffusion and convection occurs in this process. The advantage of haemodiafiltration is the greater amount of wastes that can be removed through increased convection. Continuous haemodiafiltration, known as CVVHDF, is used in acutely ill people through continuous therapy.

Vascular access

Access to the blood is required for haemodialysis and is commonly termed 'vascular access'. Vascular access can be in the form of arteriovenous fistula (AVF), arteriovenous graft (AVG) or central venous dialysis catheter (CVDC). AVF is the preferred vascular access with decreased complications compared with grafts and catheters. In 2013 in Australia, prevalent haemodialysis access comprises AVFs 78%, grafts 7% and CVDCs 15%; however, over 50% of all people commencing haemodialysis commence with a CVDC (ANZDATA Registry, 2015).

Arteriovenous fistulae are created by surgically creating an opening (fistula), from an artery to a vein. In preparation for fistula formation, the access limb should not be used for venipuncture prior to the surgical construction of the AVF. The most common vessels used are the radial artery and cephalic vein; however, upper arm veins and arteries can be used. It takes approximately 4 to 6 weeks for the pressure in the artery to engorge or enlarge the veins. Once the veins are large enough and are providing an adequate blood flow, the fistula can be used

NURSING CARE OF THE PERSON undergoing intermittent haemodialysis

PRE-DIALYSIS CARE

- Assess vital signs, including the most appropriate blood pressures (lying, sitting and standing), pulse, respirations and lung sounds. *These data provide baseline information to help evaluate the effects of haemodialysis. Hypertension or hypotension may indicate excess fluid volume. The person who is hypotensive may not tolerate rapid fluid volume changes during dialysis. Abnormal heart sounds (e.g. a gallop or murmur) and changes in heart rate or rhythm may indicate excess fluid volume or electrolyte imbalance. Fluid overload may also cause dyspnoea, tachypnoea and rales or crackles in the lungs.*
- Record weight. *Weight changes are an indicator of fluid volume and nutritional status and assist in determining amount of ultrafiltration required.*
- Assess vascular access site for a palpable pulsation or vibration and an audible bruit and for inflammation. *Infection and thrombus formation are the most common problems affecting the access site in haemodialysis people.*
- Alert all staff to avoid using the extremity with the vascular access site (or the non-dominant arm, if long-term access has not been established) for blood pressures or venipuncture. *These procedures may damage vessels and lead to failure of the arteriovenous fistula.*

INTRADIALYTIC CARE

- Assess and document vital signs during dialysis treatment. *Fluid removal may lead to hypotension.*
- Assess and treat other signs of volume depletion such as cramp, nausea and vomiting. Reset fluid loss as required. *Hypotension may lead to cramp and/or nausea and vomiting.*
- Respond to dialysis machine blood circuit alarms. *Arterial pressure and/or venous pressure may indicate access or volume status complications.*
- Assess access sites for signs of bleeding. *Dialysis anticoagulation may contribute to bleeding around access sites.*
- Use aseptic technique during cannulation technique and when accessing the blood circuit. *Poor aseptic technique may lead to infection.*

POST-DIALYSIS CARE

- Assess and document vital signs, weight and vascular access site condition. *Rapid fluid and solute removal during dialysis may lead to orthostatic hypotension, cardiopulmonary changes and weight loss.*
- Review urea, serum creatinine, serum electrolyte and haemoglobin levels between dialysis treatments. *These values help determine the effectiveness of the treatment, the need for fluid and diet restrictions, and the timing of future dialysis sessions. If the anaemia associated with kidney failure does not improve with dialysis, erythropoietin stimulating agents (ESAs), iron and folate supplements may be needed.*
- Assess for dialysis disequilibrium syndrome, with headache, nausea and vomiting, altered level of consciousness and hypertension. *Rapid changes in urea, pH and electrolyte levels during dialysis may lead to cerebral oedema and increased intracranial pressure.*
- Assess for other adverse responses to dialysis, such as dehydration, nausea and vomiting, or muscle cramps. *Excess fluid removal and rapid changes in electrolyte balance can cause fluid deficit, nausea, vomiting and seizure activity.*
- Assess for bleeding at the access site or elsewhere. Use standard precautions at all times. *Kidney failure and heparinisation during dialysis increase the risk of bleeding.*
- Provide psychological support and listen actively. Address concerns and accept responses such as anger and depression. Reinforce person and family strengths in coping with kidney failure and haemodialysis. *Grieving is a normal response to loss of organ function. The person may feel hopeless or helpless and resent dependence on a machine. The nurse can help the person and family work through these responses and focus on positive aspects of living.*
- Refer to social services and counselling as indicated. *People with kidney failure may need additional support services to help them adapt to and live with their disease.*

LINKS TO NATIONAL PATIENT SAFETY STANDARDS

NSQHS Standard 9:
Recognising and Responding to Clinical Deterioration in Acute Health Care

'The intention of this standard is to ensure a patient's deterioration is recognised promptly, and appropriate action is taken.' (ACSQHC, 2011, p. 60)

Implementing this standard is achieved by the establishment of systems to assist with recognition, initiating appropriate responses and ensuring meaningful and appropriate communication between all individuals involved in a person's care (including patients, families and carers).

Comprehensive and ongoing assessment of a person's renal function should be undertaken and documented as frequently as clinically necessary to facilitate rapid, responsive action in the event of a person's deterioration. Treatment may be pharmacological, but may also include acute renal replacement therapy. Advanced planning should be undertaken prior to the potential rapid renal deterioration to ensure treatment decisions are patient centred.

Source: © Australian Commission on Safety and Quality in Health Care.

for taking and replacing blood during dialysis. A functional AVF has a palpable pulsation and a bruit on auscultation. Accurate measurement of blood flow through the fistula can be assessed using ultrasound techniques (Schoch et al., 2008).

Historically the recommended cannulation technique for AVFs was the 'rope-ladder' technique where, ideally, a new site was used up and down the fistula to avoid fistula aneurysm, creating a rope-ladder look. Recent shifts in cannulation techniques have occurred with the increased popularity of the 'buttonhole' or 'constant site' technique. This technique involves the repeated use of the same track or tunnel to access blood from the AVF, culminating in the use of blunt needles. Although not appropriate for all people on dialysis (Moist & Nesrallah, 2014), the buttonhole technique may decrease pain and anxiety related to cannulation (Verhallen, Kooistra & van Jaarsveld, 2007).

Arteriovenous graft is the alternative if AVF construction is not possible, most commonly due to poor blood vessel condition. AVGs are most commonly made of polytetrafluoroethelene (PTFE) material. The graft is surgically implanted and connects the artery and the vein. Blood flows through the graft from the artery to the vein, providing sufficient blood flow for haemodialysis. AVGs can be constructed in the arm or leg. Unlike AVFs, grafts can often be used soon after surgery but have a higher infection and thrombosis rate than AVFs (Moist & Al-Jaishi, 2013). The HeRO Graft is a further option that is showing early successes; it involves traversing higher vein stenosis with the outflow directly into the central venous circulation (Nassar et al., 2014).

Central venous dialysis catheters are predominantly double-lumen catheters inserted into the jugular, subclavian or femoral vein (see Figure 27.8). If prolonged vascular access is required, a double-cuffed tunnelled catheter may be inserted (Hill et al., 2015). Design of CVDCs is constantly evolving; however, in all CVDCs blood is drawn into the catheter through small openings in the proximal portion of the catheter and returned to the circulation through an opening in the distal end of the catheter to minimise recirculation of the blood that has just been dialysed.

The two most frequent complications of a CVDC are infection and clotting. To reduce the risk of infection, strict aseptic technique is vital in caring for CVDC sites (Chu, Adams and Crawford, 2013). To reduce intraluminal clotting, insertion of anticoagulant (heparin, sodium citrate) following the dialysis procedure is required. Importantly, the anticoagulant lock needs to be removed prior to the next treatment to avoid unnecessary anticoagulation of the already acutely ill person.

Peritoneal dialysis

Peritoneal dialysis is more frequently being used as the first treatment of choice. This is related to the increased independence and increased maintenance of residual kidney function (McCarthy et al., 2010). Peritoneal dialysis uses the highly vascular peritoneal membrane, which surrounds the surfaces of the peritoneal cavity, as the dialysing surface (see Figure 27.9). Warmed sterile dialysate is instilled into the peritoneal cavity through a Tenckhoff catheter inserted into the peritoneal cavity. Metabolic waste products and excess electrolytes diffuse into the dialysate while it remains in the abdomen. Water movement is

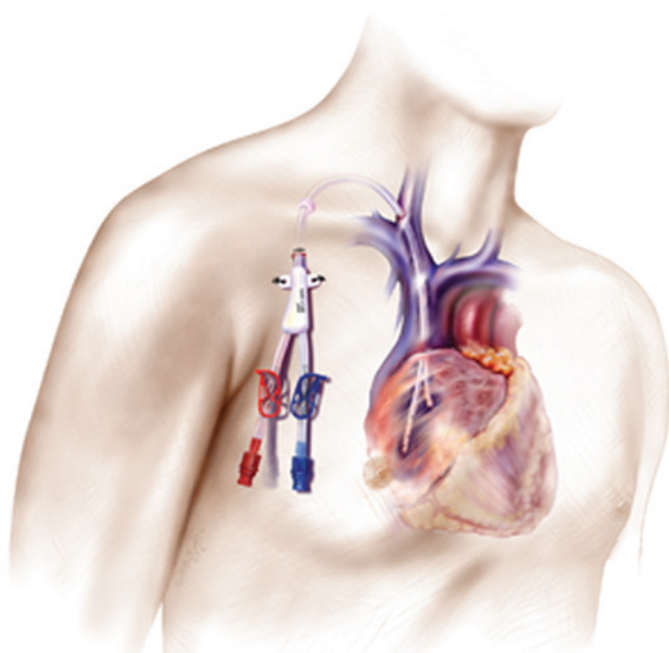

FIGURE 27.8 ■ Central venous dialysis catheter

controlled using dextrose-based fluids as osmotic agents to draw it into the dialysate, a process known as ultrafiltration. The two most common forms of peritoneal dialysis are continuous ambulatory peritoneal dialysis and automated peritoneal dialysis.

In peritoneal dialysis, heparinisation and vascular complications associated with an arteriovenous fistula are avoided and often residual renal function is better maintained. The clearance of metabolic wastes is slower but more continuous, avoiding rapid fluctuations in extracellular fluid composition and associated symptoms. More liberal intake of fluids and nutrients is often possible for the person with peritoneal dialysis. While glucose absorbed from dialysate can increase blood glucose levels in the person with diabetes, regular insulin can be added to the infusion to manage hyperglycaemia. The majority of people on peritoneal dialysis are able to self-manage the treatment regimen, affording a greater sense of autonomy and reducing any potential feelings of helplessness (Al Wakeel et al., 2009).

The major complication of peritoneal dialysis is peritonitis, where infection of the peritoneum occurs. This can severely limit the effect of peritoneal dialysis, decrease the life of the peritoneum and cause life-threatening infection if not treated early (Evans, 2012). Other long-term complications include exit site infection, mechanical flow restrictions and abdominal pain. (See the box below for nursing care for the person undergoing peritoneal dialysis.) The presence of an indwelling peritoneal catheter may cause a body image disturbance; however, the presence of an AVF in haemodialysis may also be a disturbance.

Continuous ambulatory peritoneal dialysis (CAPD) is performed manually and is most commonly performed at home. Two- to three-litre bags of dialysate fluid are infused into the abdomen and left to dwell for prescribed intervals. The fluid is then drained by gravity out of the peritoneal cavity into a sterile bag. This process of dialysate infusion, dwell time of the solution in the abdomen and drainage is repeated four to five times per day and is often referred to as 'exchanges'. No special equipment is needed. Excess fluid and solutes are removed more gradually in CAPD, minimising large blood pressure and solute variations. Depending on comfort, clearance and ultrafiltration measures, people receiving CAPD may leave a bag of dialysate fluid in their peritoneum overnight.

Automated peritoneal dialysis (APD) uses a machine (see Figure 27.10) to cycle dialysate fluid in and out of the peritoneum over a continuous period of 8 to 12 hours. This is most commonly undertaken overnight and at home. This allows the person receiving APD to cap off their catheter during the day. CAPD and APD can be combined, with some people undertaking one or two exchanges in the middle of the day while still receiving APD overnight (George, 2009).

FAST FACTS

- Infective complications of peritoneal dialysis are the second most common cause of technique failure after social reasons.
- A diagnosis of peritonitis is established if the person presents with two or more of the following: cloudy effluent with a WCC > 100 µL (with a neutrophil count > 50%), abdominal pain, fever or positive Gram stain.
- Fungal peritonitis generally requires the removal of the Tenckhoff catheter and temporary haemodialysis.

Continuous renal replacement therapy

Continuous renal replacement therapy (CRRT) is used for people with acute kidney injury (AKI) and is most commonly undertaken in a critical care or high-dependency setting. Initially, people with AKI typically undergo continuous haemodialysis, then intermittently as indicated. Intermittent haemodialysis is not used if the person is haemodynamically unstable (e.g. with hypotension or low cardiac output). Access to a blood flow of at least 200 mL/min is required for CRRT (see Figure 27.11), predominantly using a double-lumen venous catheter.

In CRRT, blood is continuously circulated through a highly porous haemofilter from artery to vein, or vein to vein, for a period of 12 or more hours. CRRT is used for people with acute kidney dysfunction who are often unable to tolerate haemodialysis and rapid fluid removal if their cardiovascular status is unstable (e.g. due to trauma, major surgery, heart failure, septicaemia), as it allows more gradual fluid and solute removal. Excess water and solutes such as electrolytes, urea, creatinine, uric acid and glucose are removed, and fluid may be replaced with normal saline or a balanced electrolyte solution as needed.

CRRT is a slower process than maintenance haemodialysis and helps maintain haemodynamic stability and avoid complications associated with rapid changes in extracellular fluid composition. Continuous therapies include continuous venovenous haemofiltration (CVVH), continuous venovenous haemodialysis (CVVHD), continuous venovenous haemodiafiltration (CVVHDF) and slow continuous ultrafiltration (SCUF). Intermittent therapies gaining popularity include sustained low-efficiency dialysis (SLED) and intermittent haemodiafiltration (IHD). See Table 27.9.

Collaborative care

A number of considerations affect the choice of long-term kidney replacement therapy. Haemodialysis and peritoneal dialysis each have advantages and disadvantages. Establishing vascular access for haemodialysis may take several months; therefore, planning ahead to develop the access before dialysis is necessary can ease the transition to dialysis (Morton et al., 2009). Established access

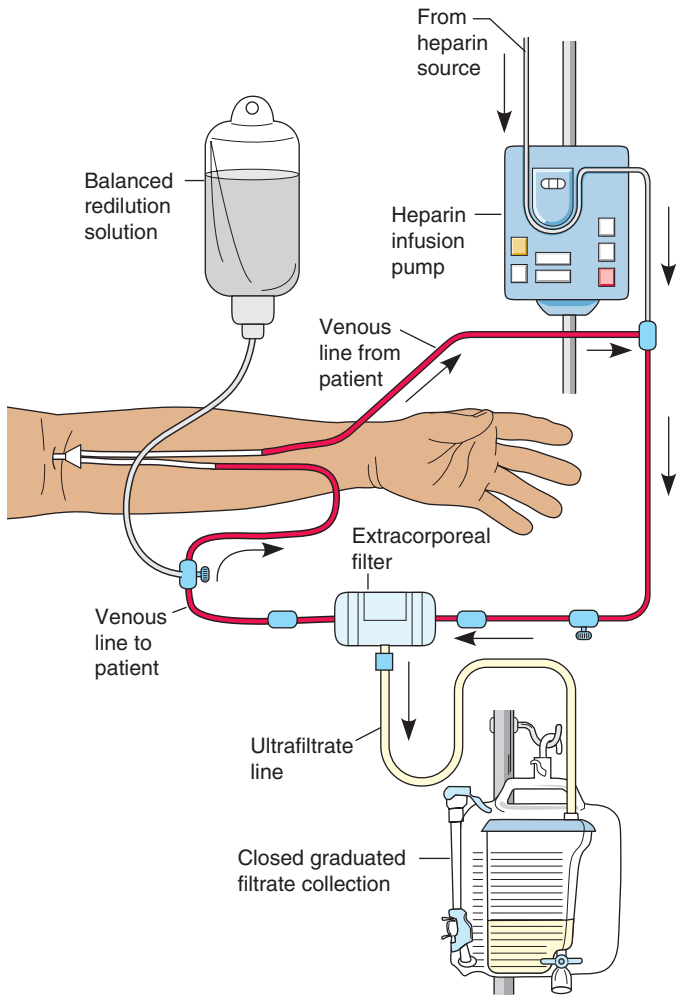

FIGURE 27.11 ■ Continuous renal replacement therapy

is not a consideration for peritoneal dialysis. The peritoneal catheter can be placed and treatment initiated as soon as it is indicated. When dialysis treatments will be performed at home, initiating instruction before it is required can result in more effective learning. If a family member or other care partner can serve as a dialysis helper, training begins prior to the onset of uraemia.

If transplantation is considered, tissue typing and identification of potential living related donors can be done prior to the onset of ESKD. To make an informed decision, both the person and the potential donor need to understand the risks, benefits and options available. If the decision for transplant is made early, dialysis can potentially be avoided. The person's age, concurrent health problems, donor availability and personal preference influence the choice of KRT.

KIDNEY TRANSPLANTATION

The first kidney transplant was performed in 1954 in Seattle, in the US; the donor and recipient were identical twins. Not long after, the first kidney transplants in Australia were performed in Melbourne and Adelaide. Unfortunately, kidney transplantation as a treatment for ESKD is limited primarily by the

NURSING CARE OF THE PERSON undergoing peritoneal dialysis

CONTINUOUS CARE

- Document vital signs including temperature, orthostatic blood pressures (lying, sitting and standing), pulse, respirations and lung sounds. *Data help assess fluid volume status and tolerance of the dialysis procedure. Hypertension, abnormal heart or lung sounds, or dyspnoea may indicate excess fluid volume. Poor respiratory function may affect the ability to tolerate peritoneal dialysis. Temperature measurement is vital because infection is the most common complication of peritoneal dialysis.*
- Assess weight and effluent drain volume between exchanges. *Weight is an accurate indicator of fluid volume status and allows assessment of ultrafiltration achieved from each exchange.*
- Monitor urea, serum electrolyte and creatinine levels. *These values are used to assess the effectiveness of dialysis.*
- Encourage healthy eating while assisting the person to maintain fluid and dietary restrictions as ordered. *Healthy eating while maintaining fluid and diet restrictions helps nutritional status and reduces hypervolaemia.*
- Warm the prescribed dialysate solution to body temperature (approx. 37°C) using a warm designated heating pad on low setting. *Dialysate is warmed to prevent hypothermia.*
- Explain all procedures and expected sensations. *Knowledge helps reduce anxiety and elicit cooperation.*
- Use strict aseptic technique during the exchange procedure and when caring for the Tenckhoff catheter. *Peritonitis is a common complication of peritoneal dialysis; sterile technique reduces the risk.*
- Add prescribed medications to the dialysate as required; prime the tubing with solution and connect it to the peritoneal catheter, avoiding kinks. *This allows dialysate to flow freely into the abdominal cavity and prevents leaking or contamination.*
- Instil dialysate into the abdominal cavity over a period of approximately 10 minutes. Clamp tubing and allow the dialysate to remain in the abdomen for the prescribed dwell time. Keep drainage tubing clamped at all times during instillation and dwell time. *Dialysate should flow freely into the abdomen if the peritoneal catheter is patent.*
- During instillation and dwell time, observe closely for signs of respiratory distress, such as dyspnoea, tachypnoea or crackles. Place in Fowler's or semi-Fowler's position and slow the rate of instillation slightly to relieve respiratory distress if it develops. *Respiratory compromise may result from overly rapid filling or overfilling of the abdomen or from a diaphragmatic defect that allows fluid to enter the thoracic cavity.*
- After prescribed dwell time, open drainage tubing clamps and allow dialysate to drain. Note the clarity, colour and odour of returned dialysate. *Cloudy dialysate may indicate an infection.*
- Accurately record amount and type of dialysate instilled (including any added medications), dwell time and amount and character of the drainage. *When more dialysate drains than has been instilled, excess fluid has been lost (output), the positive net difference between dialysate infused and effluent returned is termed the 'ultrafiltration volume'. If less dialysate is returned than has been instilled, a fluid gain has occurred (intake) and is referred to as 'fluid retained'.*
- Troubleshoot for possible problems during dialysis:
  a. Slow dialysate instillation. Increase the height of the dialysate bag and reposition the person. Check tubing and catheter for kinks. Check exit site dressing for wetness, indicating leakage around the catheter. *Slow dialysate flow may be related to a partially obstructed tube or catheter.*
  b. Excess dwell time. *Prolonged dwell time may lead to water depletion or hyperglycaemia.*
  c. Poor dialysate drainage. Lower the drainage container, reposition, check for tubing kinks. Check abdominal dressing. *Tubing or catheter obstruction can also interfere with dialysate drainage.*
- Time meals to correspond with dialysis drain. *Scheduling meals while the abdomen is empty of dialysate enhances intake and reduces nausea.*

TABLE 27.9 Continuous renal replacement therapies

TYPE	INDICATIONS	DESCRIPTION
Slow continuous utrafiltration (SCUF)	Remove mainly fluid	Blood circulates through dialyser and fluid is removed through negative pressure.
Continuous venovenous haemofiltration (CVVH)	Remove fluid and some solutes	Blood circulates through a haemofilter, then returns to person; ultrafiltrate collects in a drainage bag through convection.
Continuous arteriovenous haemodialysis (CVVHD)	Remove fluid and waste products	Venous blood circulates through a haemofilter surrounded by dialysate, then returns to the person through a double-lumen venous catheter; ultrafiltrate collects in a drainage bag following diffusion and osmosis.
Continuous venovenous haemodialysis (CVVHDF)	Remove fluid and waste products	Venous blood circulates through a haemofilter surrounded by dialysate, then returns to the person through a double-lumen venous catheter; ultrafiltrate collects in a drainage bag. Sterile dialysate is infused and removed through convection and diffusion.

availability of organs. In Australia, at the beginning of 2014 a total of 1056 people were on the transplant waiting list (ANZDATA Registry, 2015).

Kidney transplantation has become the treatment of choice for people with ESKD because it improves both survival and quality of life. In Australia, a person who has received a transplant has a far higher survival rate than those on dialysis (ANZDATA Registry, 2015). The person with a kidney transplant is no longer attached to a dialysis catheter, machine or centre. Dietary and fluid restrictions are reduced and the body image is more 'whole'. Importantly, medication and lifestyle regimes still have to be adhered to (Anderson et al., 2012).

Transplanted kidneys are obtained from living donors and cadaver donors. In Australia in 2013, 29% of transplanted kidneys came from living donors, most of whom were related to the recipient (ANZDATA Registry, 2015). Living donor transplants have been falling as a proportion of all transplants since 2008 (ANZDATA Registry, 2015). With both cadaver and living donor transplants, a close match between blood and tissue type is desired. Human leucocyte antigens (HLAs) are compared between the donor and recipient, with six antigens in common being considered to be a 'perfect' match. Close tissue matching may account for the better outcomes with living donors. Pre-emptive transplants (prior to commencement of dialysis) have maintained stable in Australia over the past 5 years with 38% of all living donors pre-emptive (ANZDATA Registry, 2015).

People with normal kidneys who are in good physical health may donate a kidney. Pre-donation counselling is vital because a nephrectomy (removal of the kidney) is major surgery and involves a small risk. If the transplant fails, the psychological impact on the donor can be significant.

Cadaver kidneys are obtained from people who meet the criteria for brain death and who are generally free of systemic disease, malignancy or infection. Kidneys are removed after brain death has been determined and are preserved by hypothermia or a technique called continuous hypothermic pulsatile perfusion. A kidney preserved by hypothermia is transplanted within 24 to 48 hours. Continuous pulsatile perfusion allows up to 3 days before transplantation. The system used to allocate cadaver kidneys for transplantation is outlined in Box 27.5.

In the surgical operation, the donor kidney is placed in the lower abdominal cavity of the recipient and the renal artery, vein and ureter are anastomosed (see Figure 27.12). The renal artery of the donor kidney is connected to the hypogastric artery and the renal vein to the iliac vein. The ureter is connected to one of the recipient's ureters or directly to the bladder, using a tunnel technique to prevent reflux.

Nursing care for the person receiving a kidney transplant is outlined in the box below.

BOX 27.5 How cadaver kidneys are allocated for transplant in Australia

The scarcity of organs for transplant raises questions about how cadaver kidneys are allocated. Past inequities in the allocation process (e.g. more men than women, more Caucasians than people of colour, more rich than poor and more young than old) led to the development of the United Network for Organ Sharing (UNOS) in 1986. UNOS developed policies for organ distribution, including kidneys, hearts, livers and other transplanted organs. The Transplantation Society of Australia and New Zealand (TSANZ) has developed Australian processes based on UNOS principles.

In Australia, the allocation of kidneys from a deceased donor to people on the waiting list is determined by a computer program called the National Organ Matching System (NOMS) which is administered by the Australian Red Cross. Mostly, only people who have commenced dialysis will be eligible to be listed on the waiting list. The main criteria that are used by NOMS to decide who will receive the kidneys are:

- the blood group (most kidneys go to somebody who is the same blood group as the donor)
- how long the person has been on dialysis
- the tissue typing or 'matching' with the donor
- whether the person has a lot of antibodies against other people's tissue types
- whether the person is a child; children get priority (Transplant Society of Australia and New Zealand (TSANZ), 2009).

NOMS runs a national matching program, which looks at all the people that are waiting in Australia to identify people who have antibodies against other people's tissue types. This is important because these people need a very well-matched kidney. It is much harder to find a suitable kidney for them than for people who do not have these antibodies. If somebody with a lot of these antibodies comes up as a very close match, the kidney can be sent to them from anywhere in Australia. This scheme covers people who have high levels of antibodies and only 0, 1 or 2 mismatches with the donor. It also allocates kidneys to people who have a perfect match with the donor, even if they have no antibodies. The exchange program also allows for kidneys to be sent from one state/territory to another to maintain a balance between the jurisdictions, so that an excess of kidneys does not move out of any one state/territory (TSANZ, 2009).

About 20% (1 in 5) of all kidneys are transferred according to this exchange program. The remaining 80% (4 in 5) kidneys are transplanted in the same state/territory where they were donated. NOMS calculates who should receive the kidneys in each state/territory, according to the jurisdiction's allocation formula. Each state/territory transplant service uses a slightly different formula to take into account differences in the number of people waiting for a transplant and other factors (TSANZ, 2009).

As long as the demand for kidneys exceeds the supply of donor organs, it is likely that controversy will exist regarding their allocation. Nurses can help by informing the public about organ donation and the allocation system and encouraging donation.

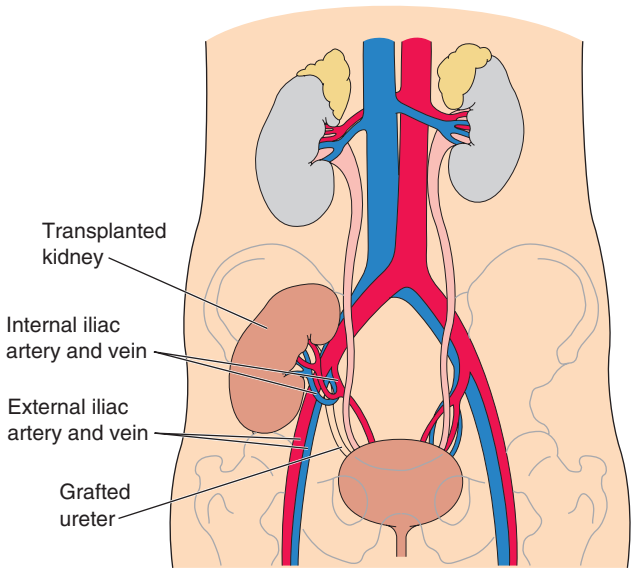

FIGURE 27.12 ■ Placement of a transplanted kidney in the iliac fossa with anastomosis to the hypogastric artery, iliac vein and bladder

The grafted kidney may stimulate an immune response to reject the transplanted kidney. Immunosuppressive drugs, such as tacrolimus, sirolimus, cyclosporin, azathioprine or mycophenolate mofetil, are commonly used to minimise the immune response. These drugs suppress a portion of the immune system and the inflammatory response, increasing the risk of infections and cancers with long-term therapy. The nursing implications of immunosuppressive therapy are outlined in Chapter 12.

During the period between 1990 and 2005 in Australia there was a sharp increase in the use of tacrolimus, mycophenolates and anti-CD25 antibodies (Chang et al., 2008). Glucocorticoids such as prednisone and methylprednisolone are used for both maintenance immunosuppression and to treat acute rejection episodes. Side effects of long-term corticosteroid use include impaired wound healing, emotional disturbances, osteoporosis and Cushingoid effects on glucose, protein and fat metabolism.

Azathioprine inhibits both cellular and humoral immunity. Because this drug is rapidly metabolised by the liver, the dose may not need to be altered in the presence of CKD. Bone marrow suppression, abnormalities of liver function and alopecia are the primary significant adverse effects for azathioprine. The action of mycophenolate mofetil is similar to that of azathioprine. Its advantages are minimal bone marrow suppression and increased potency in preventing or reversing rejection of the transplanted organ (Fauci et al., 2008). Sirolimus is not nephrotoxic and inhibits the response to interleukin-2 (IL-2), blocking activation of T and B cells.

Cyclosporin primarily affects cellular immunity, the T helper cells in particular. Among its many adverse effects, which include hepatotoxicity and hirsutism, nephrotoxicity is a primary concern for the kidney transplant recipient.

Even with immunosuppressive therapy, the transplanted kidney can be rejected at any time. Either acute or chronic rejection may develop. *Acute rejection* develops within months of the transplant. It is caused by a cellular immune response with T-lymphocyte proliferation (Porth & Matfin, 2009). Few manifestations may be apparent other than a rise in serum creatinine and possible oliguria. *Chronic rejection*, which may develop months to years following the transplant, is a major cause of graft loss. Both humoral and cellular immune responses are involved in chronic rejection. It does not respond to increased immunosuppression. The presenting manifestations of chronic rejection—progressive uraemia, proteinuria and hypertension—are those of progressive CKD.

Hypertension is a complication of kidney transplant, resulting from graft rejection, renal artery stenosis or renal vasoconstriction. People may develop glomerular lesions and manifestations of nephrosis. Hypertension and altered blood lipids (increased LDLs and decreased HDLs) increase the risk of death from myocardial infarction and stroke following transplant (Fauci et al., 2008).

Long-term immunosuppression has adverse effects. Infection is a continuing threat. Bacterial and viral infections may develop, as well as fungal infections of the blood, lungs and CNS. Tumours are also common, with carcinoma in situ of the cervix, lymphomas and skin cancers most prevalent. The risk of congenital anomalies is increased in infants whose mothers have undergone immunosuppressive therapy. Corticosteroid use may lead to bone problems, gastrointestinal disorders such as peptic ulcer disease and cataract formation.

Nursing care

Assessment

Both subjective and objective data are used to assess the person with CKD leading to ESKD:

- *Health history:* complaints of anorexia, nausea, weight gain or oedema; current treatment (if any), including type and frequency of dialysis or previous kidney transplant; chronic diseases such as diabetes, heart failure or kidney disease.
- *Physical examination:* mental status; vital signs, including temperature, heart and lung sounds, and peripheral pulses; urine output (if any); weight; skin colour, moisture, condition; presence of oedema (periorbital or dependent); bowel sounds; presence and location of an arteriovenous fistula or graft or peritoneal catheter.

Nursing diagnosis and interventions

Whether the person with ESKD is facing long-term dialysis, kidney transplantation or supportive care, a number of nursing care needs can be identified. This section focuses on nursing care related to impaired kidney function, nutritional deficits due to dietary restrictions and nausea, increased risk of

NURSING CARE OF THE PERSON receiving a kidney transplant

PREOPERATIVE CARE

- Provide routine preoperative care as outlined in Chapter 3.
- Assess knowledge and feelings about the procedure, answering questions and clarifying information as needed. Listen and address concerns about surgery, the source of the donor organ and possible complications. *Addressing concerns and reducing preoperative anxiety improve postoperative recovery.*
- Continue dialysis as ordered. *Intermittent or continuous renal replacement therapy may be necessary to manage fluid and electrolyte balance and prevent uraemia prior to surgery.*
- Administer immunosuppressive drugs as ordered before surgery. *Immunosuppression is initiated before transplantation to prevent immediate graft rejection.*

POSTOPERATIVE CARE

- Provide routine postoperative care as outlined in Chapter 3
- Maintain urinary catheter patency and a closed system. *Catheter patency is vital to keep the bladder decompressed and prevent pressure on suture lines. A closed drainage system minimises the risk of urinary tract infection.*
- Measure urine output every 30 to 60 minutes initially. Careful assessment of urine output helps determine fluid balance and transplant function. *Acute tubular necrosis is a common early complication, usually due to tissue ischaemia during the period between removal of the kidney from the donor and transplantation. Oliguria is an early sign.*
- Monitor vital signs and haemodynamic pressures closely. *Diuresis may occur immediately, resulting in hypervolaemia, low cardiac output and impaired perfusion of the transplanted kidney.*
- Maintain fluid replacement, generally calculated to replace urine output over the previous 30 or 60 minutes. *Fluid replacement is vital to maintain vascular volume and tissue perfusion.*
- Administer diuretics as ordered. *Loop and/or osmotic diuretics may be used to promote postoperative diuresis.*
- Remove the catheter within 2 to 3 days or as ordered. Encourage to void every 1 to 2 hours and assess frequently for signs of urinary retention following catheter removal. *The bladder may have atrophied prior to surgery, reducing its capacity. Urinary retention places stress on suture lines and increases the risk of infection.*
- Monitor serum electrolytes and renal function tests. *These tests are used to monitor graft function and fluid and electrolyte status. Electrolyte imbalances may develop as the transplanted kidney begins to function and diuresis occurs. Elevated serum creatinine and urea levels may be early signs of rejection or graft failure.*
- Monitor for possible complications:
  a. *Haemorrhage* from an arterial or venous anastomosis can be either acute or insidious. Indicators include swelling at the operative site, increased abdominal girth and signs of shock, including changes in vital signs and level of consciousness. *Haemorrhage is a surgical emergency, requiring prompt recognition and treatment to preserve the graft.*
  b. *Ureteral anastomosis failure* causes urine leakage into the peritoneal cavity. It may be marked by decreased urine output with abdominal swelling and tenderness. *Failure of the ureteral anastomosis requires surgical intervention.*
  c. *Renal artery thrombosis* is characterised by an abrupt onset of hypertension and reduced GFR. *Renal artery thrombosis can result in transplant failure.*
  d. *Infection* due to immunosuppression is an immediate and continuing risk. The inflammatory response is blunted and infection may not significantly elevate the temperature. Monitor for signs such as change in level of consciousness, cloudy or malodorous urine, or purulent drainage from the incision. *Prevention and prompt treatment of infections is particularly important in the immunosuppressed person.*
- Include the following in pre-discharge teaching for the person and family:
  a. The use and effects of prescribed medications, including antihypertensive medications, immunosuppressive agents, prophylactic antibiotics and others as ordered.
  b. Monitoring vital signs (including temperature) and weight.
  c. Manifestations of organ rejection, such as swelling and tenderness over the graft site, fever, joint aching, weight gain and decreased urinary output. Stress the importance of promptly reporting signs and symptoms to the person's nephrologist.
  d. Ordered or recommended dietary restrictions such as restricted carbohydrate and sodium intake and increased protein intake. Encourage good nutritional habits.
  e. Measures to prevent infection, such as avoiding crowds and obviously ill individuals.

  The person and family will manage care after discharge and therefore need a good understanding of what to expect, how to monitor graft status and measures to reduce the adverse effects of medications.
- Provide psychological support, address concerns and provide information as needed. The person has often been managing a chronic disease independently and is used to having a degree of control. *Providing information and allowing the person to retain control relieves anxiety and improves recovery.*

infection and changes in body image. Also see the nursing care plan below for nursing care of the person with ESKD.

Ineffective kidney perfusion

Capillaries are an integral part of the nephron. As nephrons are destroyed, kidney perfusion progressively declines. As kidney perfusion and nephron function fall, the kidney is less able to maintain fluid and electrolyte balance and eliminate waste products from the body.

- Monitor intake and output, vital signs including orthostatic blood pressures and weight. *These provide important data to identify changes in fluid volume.*

- Restrict fluids as ordered. *As kidney function declines, the ability to eliminate excess fluid is impaired.*

CONSIDERATION FOR PRACTICE

Weight changes are a more accurate indicator of fluid volume status in the oliguric or anuric person than intake and output measurements.

- Monitor respiratory status, including lung sounds as indicated. *Fluid volume overload may lead to heart failure and possible pulmonary oedema.*
- Monitor urea, serum creatinine, pH, electrolytes and FBC. Report significant changes. As kidney function declines, urea and serum creatinine increase. *Metabolic acidosis develops as the kidney is unable to eliminate hydrogen ions and conserve bicarbonate. Hyponatraemia, hyperkalaemia, hyperphosphataemia and hypocalcaemia are associated with kidney failure. The RBC count and haemoglobin decline due to deficient erythropoietin to stimulate cell production in the bone marrow. An acute fall in haemoglobin may also indicate GI bleeding, a risk in people with ESKD.*
- Report manifestations of electrolyte imbalances, such as cardiac arrhythmias and other ECG changes, muscle tremors and possible tetany and Kussmaul's respirations. *Manifestations of electrolyte imbalance may indicate the need for intervention.*

CONSIDERATION FOR PRACTICE

Monitor clarity of dialysate return. Dialysate should return clear in the person undergoing peritoneal dialysis. Cloudy dialysate may indicate peritonitis, the most common complication of peritoneal dialysis, and should be reported and cultured.

- Administer medications to treat electrolyte imbalances as ordered. *Medications may be prescribed to help maintain electrolyte and acid–base balance and prevent adverse effects of imbalances.*
- Administer antihypertensive medications as ordered. *Hypertension management is an important factor in slowing the progression of CKD.*
- Time activities and procedures to allow rest periods. *Anaemia associated with CKD may cause significant fatigue and activity intolerance.*

Imbalanced nutrition: less than body requirements

Anorexia, nausea and vomiting are common manifestations of ESKD and uraemia. The person often has a metallic taste and bad breath, which also diminish appetite. A diet restricted in protein and sodium will compound these problems. Food intake may be insufficient to meet metabolic needs. Catabolism, the breakdown of body proteins to meet energy needs, exacerbates uraemia.

- Monitor food and nutrient intake as well as episodes of vomiting. *Careful monitoring helps determine the adequacy of intake.*
- Weigh daily before breakfast. This provides the most accurate measurement. *Remember that a gain of 1 kg or more over a 24-hour period is more likely to reflect fluid retention than a gain in body mass.*
- Administer anti-emetic agents 30 to 60 minutes before eating. *Anti-emetics reduce nausea and the risk of vomiting with food intake.*
- Assist with mouth care prior to meals and at bedtime. *Mouth care improves taste, stimulates the appetite and maintains the integrity of oral mucous membranes.*
- Serve small meals and provide between-meal snacks. *Small meals are less likely to prompt nausea and help improve food intake*.
- Arrange for a dietary consultation. Provide preferred foods to the extent possible and involve the person in planning daily menus. Encourage family members to bring food as dietary restrictions allow. *Providing preferred foods within restrictions promotes intake.*
- Monitor nutritional status by tracking weight, laboratory values such as serum albumin, and urea and anthropometric measurements (see Chapters 20 and 21). *Indicators of impaired nutrition develop gradually and may be subtle. Careful assessment is important.*

Risk of infection

People with end-stage kidney disease have altered immune systems and leucocyte function and have increasing susceptibility to infection. Invasive devices required for haemodialysis or peritoneal dialysis add to this risk. The person who has had a kidney transplant remains on immunosuppressive therapy for life, further depressing the immune system and increasing the risk of infection.

- Use standard precautions and good handwashing technique at all times. Handwashing is a primary means of preventing the transfer of organisms. *People who are on haemodialysis have an increased risk of vancomycin-resistant* Enterococcus *(VRE), methicillin-resistant* Staphylococcus aureus *(MRSA), hepatitis B, hepatitis C and HIV infection.*
- Monitor temperature and vital signs at least every 4 hours. *A low-grade fever or increased pulse rate may indicate an infection in the immunosuppressed person.*
- Monitor WBC count and differential. *Increased WBCs may indicate a bacterial infection; decreased WBCs may indicate a viral infection. A shift in the differential showing more immature WBCs (bands) in circulation is another indicator of infection.*

CONSIDERATION FOR PRACTICE

Use strict aseptic technique when managing ports, catheters and incisions, to reduce the risk of introducing infectious organisms when immune responses are impaired.

- Culture peritoneal dialysis fluid and other drainage as indicated. *Culture is done to verify the presence of pathogens and actively treat early signs of peritonitis.*
- Provide good respiratory hygiene, including position changes, coughing and deep breathing. *These measures improve clearance of respiratory secretions, reducing the risk of infection.*

NURSING CARE PLAN A person with end-stage kidney disease

Walter Cohen, 45 years old, is the librarian at a local university. He has had type 1 diabetes since the age of 20 and was diagnosed with diabetic nephropathy 10 years ago. Despite blood pressure control, ACE inhibitor medications and frequent blood glucose monitoring with insulin coverage, he developed overt proteinuria 5 years ago and has now progressed to end-stage kidney disease. He is admitted to the nephrology ward and will undertake haemodialysis while waiting for a Tenckhoff catheter to be inserted to do CAPD. Mr Cohen's desire to continue working is the primary factor in his choice of CAPD over haemodialysis.

ASSESSMENT

Richard Gray, Mr Cohen's nurse, obtains a nursing assessment. Mr Cohen states that his diabetes has always been difficult to control. He has had numerous hypoglycaemic episodes and has been hospitalised 'four or five times' for ketoacidosis. Recently he has developed symptoms of peripheral neuropathy and increasing retinopathy. He attributed his lack of appetite, nausea, vomiting and fatigue over the past month to 'a touch of the flu'. His weight remained stable, so he did not worry about not eating much.

Physical assessment findings include T 36.5°C, P 96, R 20 and BP 178/100. His skin is cool and dry, with minor excoriations on forearms and lower legs. His breath has a strong offensive odour. Scattered fine rales noted in bilateral lung bases. He has bilateral pitting oedema of lower extremities to just below the knees; fingers and hands also oedematous. Abdominal assessment essentially normal, with hypoactive bowel sounds. Urinalysis shows a specific gravity of 1.011, gross proteinuria and multiple cell casts. FBC results: RBC 2.9 million/mm^3; haemoglobin 9.4 g/dL. Blood chemistry abnormalities include urea 32 mmol/L; creatinine 621 µmol/L; eGFR 9 mL/min; sodium 125 mmol/L; potassium 6.2 mmol/L; albumin 31 g/L; calcium 2.3 mmol/L; phosphate 3.5 mmol/L. A temporary jugular central venous dialysis catheter will be inserted for haemodialysis the next day, followed by a Tenckhoff catheter insertion later in the week.

DIAGNOSES

- *Excess fluid volume* related to failure of kidneys to eliminate excess body fluid.
- *Imbalanced nutrition: less than body requirements* related to effects of uraemia.
- *Impaired skin integrity* of lower extremities related to dry skin and itching.
- *Risk of infection* related to invasive catheters and impaired immune function.

PLANNING

- Plan fluid balance to a restriction of 750 mL per day.
- Plan a nutrition and fluid education program.
- Plan skin care program.
- Plan peritoneal exit site and catheter care education.

Expected outcomes

- Adhere to the prescribed fluid restriction of 750 mL per day.
- Demonstrate reduced extracellular fluid volume by weight loss, decreased peripheral oedema, clear lung sounds and normal heart sounds.
- Consume and retain 100% of prescribed diet, including snacks.
- Demonstrate healing of lower extremity skin lesions.
- Remain free of infection.
- Demonstrate appropriate peritoneal exit site and catheter care.

IMPLEMENTATION

- Space person's fluid intake. For example, 400 mL from 0700 to 1500, 200 mL from 1500 to 2300, and 100 mL from 2300 to 0700.
- Encourage and provide mouth care at least every 4 hours and before every meal.
- Weigh daily before breakfast; monitor vital signs every 4 hours.
- Document intake and output accurately.
- Arrange dietary consultation for menu planning.
- If required, administer prescribed anti-emetic 1 hour before meals.
- Monitor food intake, noting percentage and types of food consumed.
- Clean lesions on lower extremities every 8 hours and assess healing.
- If possible, begin to teach CAPD procedure and peritoneal exit site care.
- Assist to identify strengths and needs in health regimen management.

EVALUATION

Mr Cohen was hospitalised for 2 weeks, undergoing four haemodialysis sessions to reduce uraemic symptoms. An arteriovenous fistula was created in his left arm in case he should need haemodialysis in the future. He begins peritoneal dialysis the second week and by discharge he is able to manage the catheter care and dialysis runs with the help of his wife. His heart and lung sounds are normal and he has minimal peripheral oedema on discharge. The excoriations on his legs have healed. His temperature is normal and no evidence of infection is noted. Mr Cohen remains anorexic and slightly nauseated, but is eating most of his prescribed diet and snacks. He has lost 5 kg with excess fluid removal by dialysis, but his weight remains stable during the second week. Mr Cohen and his wife have been introduced to another person who has been on CAPD for several years and promises to help them with problem solving.

CRITICAL THINKING IN THE NURSING PROCESS

1. How does diabetes mellitus damage the kidneys and lead to ESKD? Why is this more significant for a person with type 1 diabetes than for someone with type 2 diabetes (see Chapter 19)?
2. Why do high levels of urea in the blood often cause changes in cognition and mental status? What manifestations of encephalopathy would you expect to see?
3. How might Mr Cohen's insulin dosage and diet need to be changed with the institution of peritoneal dialysis? Why?
4. Develop a care plan for the nursing diagnosis *Disturbed body image*.

REFLECTION ON THE NURSING PROCESS

1. What impact does Mr Cohen's cognitive status have on his ability to contribute to a planned education program?
2. How has the nursing process influenced Mr Cohen's nutrition status?

CONSIDERATION FOR PRACTICE

Monitor carefully for desired and adverse effects of all medications. Impaired kidney function affects drug elimination and increases the risk of toxic effects.

- Restrict visits from people who may be infective. Teach the person and family about the risk of infection and measures to reduce the spread of infection. *The person's resistance to infection is impaired, necessitating extra caution in preventing unnecessary exposures.*

Disturbed body image

Chronic disease and impaired kidney function can affect the person's body image. Haemodialysis requires an arteriovenous fistula or shunt; a permanent peritoneal catheter is required for peritoneal dialysis. While kidney transplant can restore an image of wholeness, a visible scar remains and the organ may be perceived as 'foreign'.

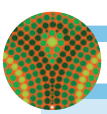
- Involve the person in care, including meal planning, dialysis, and catheter, port or incision care, to the extent possible. *Involvement improves acceptance and stimulates discussion about the effect of the disease and treatment measures on the person's life.*
- Encourage expression of feelings and concerns, accepting perceptions and feelings without criticism. *Self-expression enhances the person's self-worth and acceptance.* See the 'Translation to practice' box below.
- Include the person in decision making and encourage self-care. *Increased autonomy enhances the person's sense of control, independence and self-worth.*
- Support positive gains, but do not support denial. *The person may have difficulty accepting the kidney failure, but adaptation to the loss is important.*
- Help the person develop and achieve realistic goals. *Realistic goals allow the person to see progress.*
- Provide positive reinforcement and feedback. *These measures support growth and adaptation.*
- Reinforce effective coping strategies. *Reinforcement helps the person develop positive versus negative strategies for coping.*
- Facilitate contact with a support group, such as Kidney Health Australia or other community members. *The person benefits by providing and receiving support in a group of people going through similar circumstances.*
- Refer for mental health counselling as indicated or desired. *Counselling can help the person develop effective coping and adaptation strategies.*

Emerging nursing roles

Nurses have undertaken various roles in caring for people with kidney disease. Traditionally, these have involved renal ward care, haemodialysis care, peritoneal dialysis care and transplant care. Various specialty nursing roles have emerged to address the many areas that the person with ESKD has to address that have included vascular access, anaemia and transplant liaison (Schoch et al., 2014). These roles can be undertaken at an advanced practice nurse or nurse practitioner level (Bonner & Douglas, 2011).

The vascular access nurse, also known as renal access coordinator, has become a vital member of the renal team and can increase the proportion of people starting dialysis therapy with an AVF (Polkinghorne, Seneviratne & Kerr, 2009). The role includes organising timely surgical referral for AVF or AVG creation for haemodialysis or Tenchkoff insertion for peritoneal dialysis (Schoch et al., 2014). The vascular access nurse can also coordinate renal access surgical lists, access surveillance and vascular access education. Primarily the nurse provides a fluent communication channel between the renal services department, vascular surgery, allied health and other relevant units within the healthcare system.

The renal anaemia nurse, also known as the renal anaemia coordinator, provides specialised anaemia-related support for people living with CKD and ESKD. This support includes education for people with kidney disease, monitoring and



TRANSLATION TO PRACTICE Evidence-based practice: minimising hypotension during dialysis

Australian researchers explored the effects of pre-emptively pausing fluid removal to minimise dialysis hypotension (Bradshaw et al., 2011). Given that a sudden drop in blood pressure occurs in between 15% and 55% of all treatments, this is the most common serious side effect seen in haemodialysis. In an interventional pre- and post-test study involving 864 individual dialysis treatments, fluid removal was paused for a minimum of 10 minutes if the following criteria were met: (1) mean arterial pressure was less than or equal to 70 mmHg, or (2) the mean arterial pressure dropped by 30 mmHg or more. The results demonstrated that a pre-emptive nursing intervention decreased the odds of an intradialytic episode by 61% (Bradshaw et al., 2011).

IMPLICATIONS FOR NURSING

Pre-emptively pausing fluid removal according to specific mean arterial pressure parameters is a method to decrease intradialytic hypotensive episodes. This may be particularly useful for dialysis units without biofeedback or profiling machine technology.

CRITICAL THINKING IN PERSON-CENTRED CARE

1. Identify blood pressure assessment that is required throughout the dialysis treatment tools.
2. Identify a contextually appropriate intervention based on evidence to minimise hypotension.
3. Develop a teaching plan for people receiving dialysis, families and significant others to help them develop strategies to identify the early signs of hypotension.

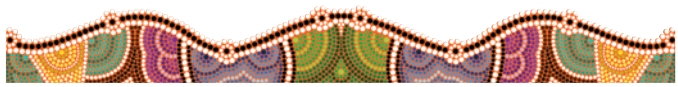
management of renal anaemia, administration of IV iron and blood transfusions, liaison with physicians, GPs and community nursing support, and education for nurses and other health professionals (Lee, 2009).

The transplant liaison nurse coordinates the evaluation and preparation of the person who has identified the request for a kidney transplant. Evaluation for kidney transplantation involves complete physical assessment to determine that the person is suitable to undergo a surgical procedure and to identify potential issues that will need to be managed post transplant (Wilden, 2008). Cardiovascular evaluation is especially important, as cardiovascular disease is the leading cause of death post transplant of people with functioning renal grafts (Siddiqu, Sundaram & Danovitch, 2005). It is also during the workup that contraindications to transplantation, such as malignancy, are identified. Preparation involves focused education, as the person's understanding, willingness and ability to manage their own care throughout the entire transplant process will have a major impact on the success and outcome of their transplant. Preparation also involves blood group typing and tissue typing. The transplant liaison nurse plays a pivotal role in encouraging the person to engage in healthy behaviours. Encouraging the person to be infection-free, adherent to medication and maintain a healthy body mass index is important to prevent post-transplant complications.

Community-based care

CKD and ESKD are long-term conditions that require self-management. No matter what treatment option is chosen (haemodialysis, peritoneal dialysis, kidney transplantation, supportive care), day-to-day management falls to the person and family. Teaching for home care includes the following topics:

- Nature of the kidney disease and kidney failure, including expected progression and effects.
- Monitoring weight, vital signs and temperature.
- Prescribed dietary and fluid restrictions. (Involve the person, a dietitian and the family member usually responsible for cooking. Include strategies to manage nausea and relieve thirst within allowed fluid limits.)
- How to assess and protect a fistula or graft for haemodialysis (or the extremity to be used if one is anticipated).
- Tenckhoff catheter care and the procedure for peritoneal dialysis as indicated. (Include a family member or significant other, in case the person is unable to perform the procedure independently at some time.)
- Following kidney transplant, prescribed medications, adverse effects and their management, infection prevention, graft protection and manifestations of organ rejection.
- Refer to a dietitian for diet planning and counselling. If home haemodialysis is planned, refer the designated dialysis helper for formal training. Kidney Health Australia can provide support and educational materials for the person with ESKD (visit www.kidney.org.au). Local and state trained representatives of these organisations can provide additional support.



CHAPTER HIGHLIGHTS

- Glomerulonephritis, inflammation of the glomerulus of the kidney, leads to loss of proteins and blood cells in the urine, a decrease in the glomerular filtration rate and severe oedema.
- The renal and cardiovascular systems are closely interrelated. Vascular disorders, such as hypertension, renal artery stenosis or obstruction of the renal artery or vein, can have serious consequences in terms of kidney function.
- Acute kidney injury is a frequent complication of critical illnesses, typically occurring in people with no prior history of kidney disorders. Ischaemic and nephrotoxic damage to the kidney are the most common precipitating factors for AKI.
- Chronic kidney disease is the end-stage of numerous systemic and kidney disorders, such as diabetes mellitus, systemic lupus erythematosus and chronic glomerulonephritis.
- When the kidneys are no longer able to maintain homeostasis, kidney replacement therapies are necessary to eliminate metabolic waste products and sustain life. Dialysis and kidney transplant are the primary kidney replacement therapies used.
- Home dialysis therapy is the preferred treatment for people with ESKD.

CONCEPT CHECK

1 The physician orders digoxin 0.125 mg 3 times per week for an 82-year-old person with heart failure. The nurse should:

1. question the order because older people frequently require larger doses of the drug due to impaired ability of the kidneys to concentrate urine
2. administer the drug as ordered, monitoring the person for manifestations of toxicity
3. assess the person's urine specific gravity and pH before administering the drug at this dose
4. use 0.25 mg digoxin tablets, cutting the tablet in half to save money for the person

2 A person newly diagnosed with polycystic kidney disease asks if there is anything his children need to know about their risk of getting the disorder. The appropriate response by the nurse is:

1. because the condition was just diagnosed, it is due to a new genetic mutation and there is no risk of passing the condition on to his children
2. when his children prepare to marry, they and their potential partners should undergo genetic testing to determine if their children will be at risk
3. the adult form of this disorder is transmitted as a dominant gene; each child has a 50% risk of having inherited the defective gene

4 his children would have developed symptoms of the disorder in utero or shortly after birth if they had inherited the defective gene

3 In obtaining a nursing history from a 22-year-old person admitted with a diagnosis of acute glomerulonephritis, the nurse specifically asks the person about a recent history of which of the following?
1 urinary tract infection
2 strep throat
3 x-ray using contrast media
4 illicit drug use

4 The nurse evaluates his teaching for a person with acute glomerulonephritis as effective when the person:
1 chooses soy or animal proteins for allowed grams of protein in diet
2 states the need to remain on bed rest until his urine returns to clear yellow
3 demonstrates care for the vascular shunt or peritoneal catheter
4 limits fluid intake to less than 1500 mL per day

5 Appropriate postoperative nursing interventions for the person who has had a partial or total nephrectomy include:
1 connecting all catheters and drains to a single collection device
2 routine irrigation of all catheters with sterile normal saline
3 administering cough suppressant medication as needed
4 labelling and securing all catheters, tubes and drains

6 Important nursing interventions to prevent acute kidney dysfunction in the critically ill person include:
1 maintaining fluid volume and cardiac output
2 avoiding all potentially nephrotoxic drugs
3 administering antihypertensive drugs
4 assessing for a history of diabetes or systemic lupus erythematosus

7 The nurse evaluates their teaching as effective when the person recovering from acute kidney dysfunction states that he will:
1 limit his fluid intake to 1500 mL or less per day
2 consume only vegetable proteins
3 avoid taking drugs that may be nephrotoxic
4 self-catheterise for residual urine at least once a week

8 The nurse caring for a person preparing to undergo haemodialysis includes which of the following in the plan of care? (Select all that apply.)
1 Obtain weight and orthostatic vital signs.
2 Assess blood pressure of extremity where fistula has been created.
3 Monitor serum creatinine, urea and haemoglobin levels.
4 Determine urine specific gravity and pH.
5 Restrict fluid and protein intake.

9 An appropriate goal of nursing care for a person with end-stage kidney disease is the person will be able to:
1 identify a live-in caregiver
2 state the advantages and disadvantages of haemodialysis, peritoneal dialysis and kidney transplant as kidney replacement therapies
3 demonstrate the ability to independently perform haemodialysis in the home
4 relate the hospice philosophy and identify indicators of the need for hospice care

10 Following a kidney transplant, the nurse notes that the person's urine is cloudy. The most appropriate response by the nurse is to:
1 record the finding
2 increase the intravenous flow rate
3 irrigate the urinary catheter
4 notify the physician

UNIT 7 BUILDING CLINICAL COMPETENCE

Responses to altered urinary elimination

CLINICAL SCENARIO

You have been assigned to work with the following four people for the 0700 shift on a renal medical–surgical unit. Significant data obtained during report are as follows:

- Phillip Connor is a 45 year old who was admitted 2 days ago after a fall from a ute. He experienced a bruised right kidney and numerous ecchymotic areas on his right side from the fall. His vital signs are T 37.2°C, P 98, R 28, BP 110/68. He is complaining of abdominal pain and difficulty urinating.
- Agnes Gibson is an 84 year old who was admitted 2 hours ago with manifestations of urinary incontinence, anorexia, confusion and lethargy. Her vital signs on admission were T 36.1°C, P 88, R 20, BP 148/90. The physician ordered trimethoprim-sulfamethoxazole (Bactrim) to be started as soon as possible.
- Joseph Rouse is a 45 year old who is to undergo surgery for removal of uric acid stones after having a failed lithotripsy. His vital signs are T 37.5°C, P 94, R 24, BP 112/68. His skin is pale, cool and clammy. He is complaining of nausea, severe left-sided flank pain with spasms and light headedness.
- Angela Baldwin is a 34 year old who has a medical history of systemic lupus erythematosus (SLE). She was admitted with complaints of left flank pain and generalised oedema. Urinalysis results indicate haematuria and proteinuria. Vital signs are T 37.8°C, P 88, R 26, BP 144/90. She is admitted for aggressive immunosuppressive therapy.

Critical thinking questions

1 In what order would you visit these people after report?

1. _____
2. _____
3. _____
4. _____

2 What top two priority nursing diagnoses would you choose for each of the people presented above? Can you explain, if asked, the rationale for your choices?

	Priority Nursing Diagnosis #1	Priority Nursing Diagnosis #2
Phillip Connor		
Agnes Gibson		
Joseph Rouse		
Angela Baldwin		

3 The physician ordered trimethoprim-sulfamethoxazole (Bactrim) for Agnes Gibson's uncomplicated cystitis. Mrs Gibson understands the length of antibiotic therapy when she verbalises which statement?

1. 'I will need to complete the full course of Bactrim.'
2. 'I can be discharged after 5 days of antibiotics.'
3. 'I need to stay in the hospital for 1 week to finish the antibiotics.'
4. 'I can stay in the hospital for 5 days of antibiotics and take 5 days of antibiotics at home.'

4 The physician orders phenazopyridine (Pyridium) for relief of pain and burning with cystitis. Which does the nurse teach the person about the use of this medication?

1. Take the medication with antacids to prevent stomach upset.
2. Drink less fluid to allow the drug to concentrate in the bladder.
3. Wear a sanitary pad to protect your clothing from stains while taking this drug.
4. Stop taking the drug if nausea and diarrhoea occur.

5 The person diagnosed with uric acid stones is ordered to follow a diet low in purines. Which is the meal plan lowest in purines?

1. liver with onions and potatoes
2. chicken burger with chips
3. spaghetti with bolognese sauce
4. macaroni and cheese with stewed tomatoes

6 When assessing a person with glomerulonephritis, which manifestations are indicative of an early disease process?

1. pyuria, leucocytosis and hyperthermia
2. haematuria, proteinuria and hypertension
3. dysuria, hyperglycaemia and hypertension
4. oliguria, flank pain and hypotension

7 Which are risk factors of urinary tract infections? (Select all that apply.)

1. circumcision in males
2. decreased cervicovaginal antibodies
3. sexual intercourse in women
4. short urethra in men
5. ageing in men
6. urinary catheterisation

8 Which is the most accurate indicator of fluid volume status in the oliguric or anuric person?

1. intake and output
2. weight changes
3. restricted fluids
4. urea and creatinine levels

9 The most reliable diagnostic procedure to determine glomerular disorders is which diagnostic test?

1. kidney scan
2. antistreptolysin O titre
3. kidney biopsy
4. blood urea nitrogen

10 A female postoperative person is complaining of inability to void. A bladder ultrasound indicates that there is a significant amount of urine in the bladder. Which interventions does the nurse perform?

1. Insert a urinary catheter and completely drain the bladder at once.
2. Insert a urinary catheter and drain urine in 500 mL increments.

3. Ambulate person to the bathroom to try to void and run water in the sink.
4. Give the person a glass of water to drink to encourage voiding.

11 Which nursing actions are instituted for the person with kidney trauma?

1. Monitor level of consciousness and urine output.
2. Monitor vital signs for hypotension and bradycardia.
3. Observe for hypertension and check urine for haematuria.
4. Observe urine for oliguria and proteinuria.

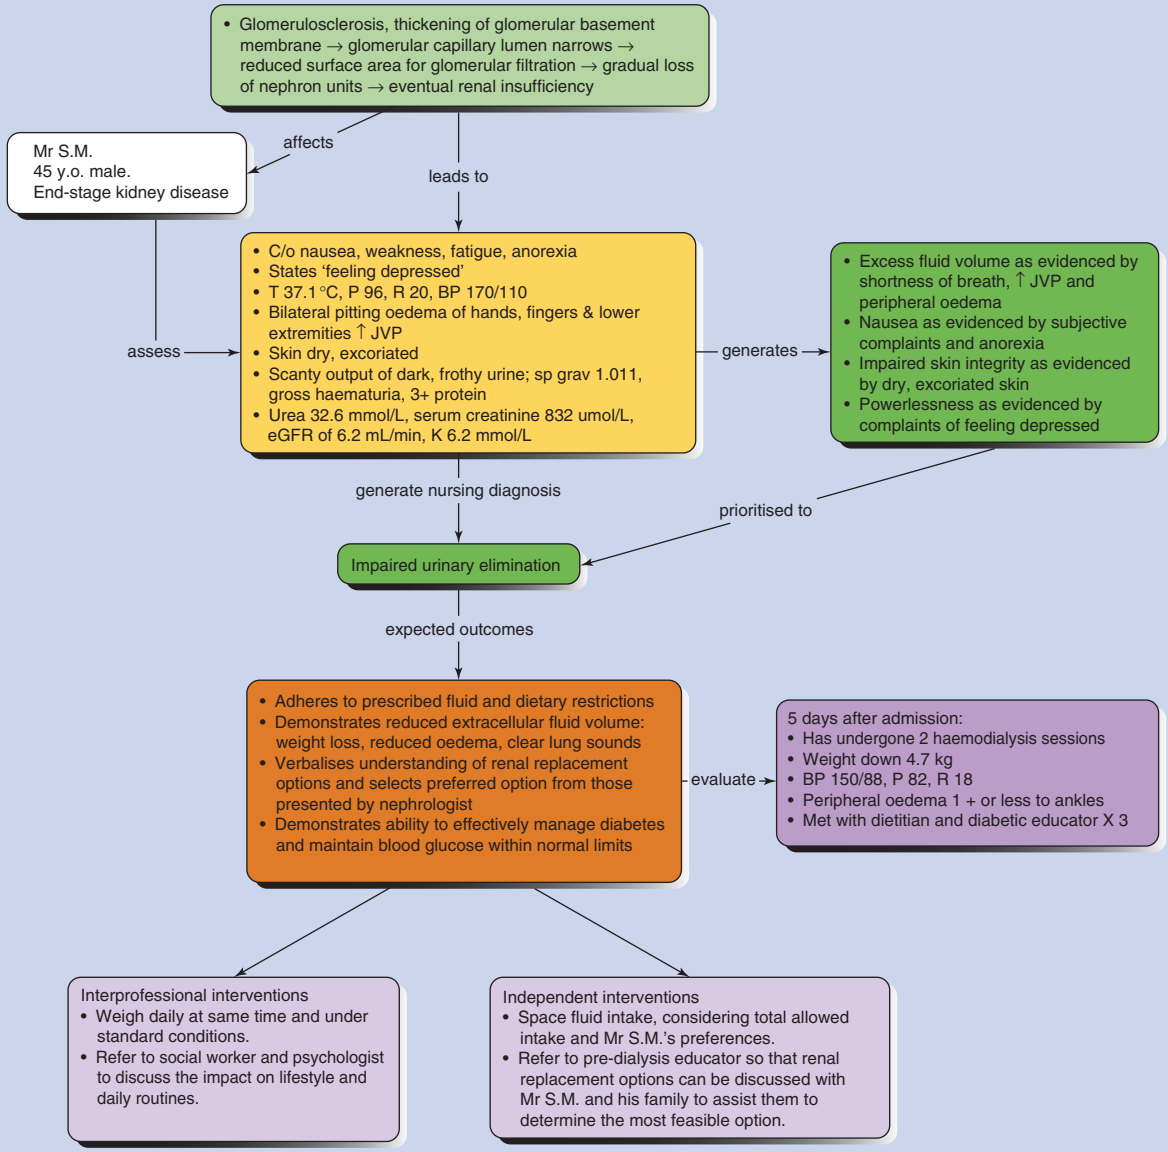
12 After a person has returned from surgery, the nurse needs to report which urinary output?

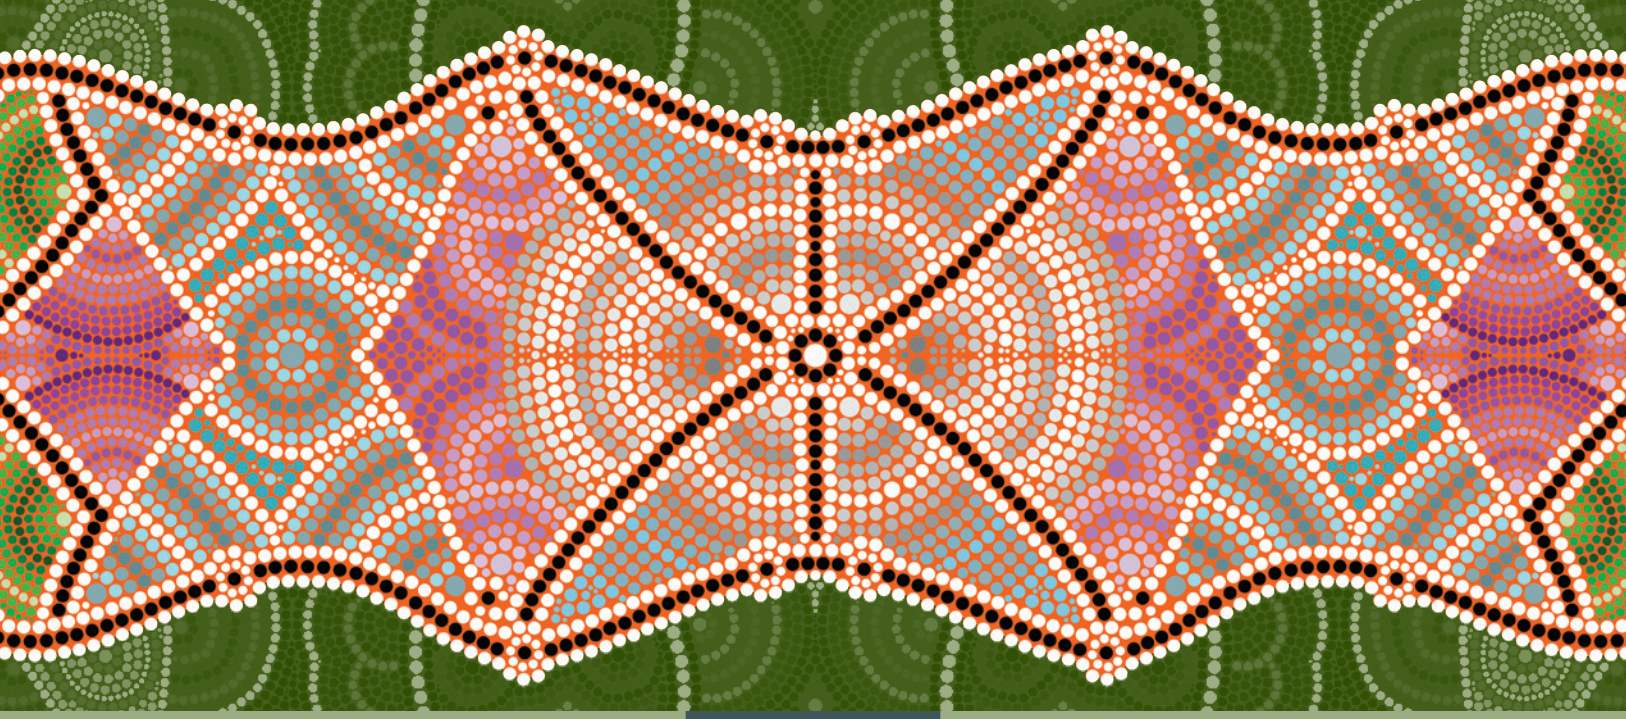
1. 20 mL per hour
2. 40 mL per hour
3. 300 mL per 8 hours
4. 400 mL per 8 hours

CASE STUDY

Steven McEvoy is a 45-year-old Indigenous male who has been a truck driver for the past 20 years. Increasing shortness of breath has prompted him to attend the ED. He is admitted to the hospital with a further history of nausea for several weeks, weakness, fatigue and loss of appetite. He has been feeling very depressed. He has a past medical history of type 1 diabetes mellitus, hypertension and diabetic nephropathy. On admission, his vital signs are T 37.1°C, P 96, R 20, BP 170/110. He has bilateral pitting oedema of the lower extremities. His fingers and hands are also oedematous. He complains of dry and itching skin. His urine is dark, frothy and scanty. A specimen is collected for a urinalysis and blood is taken and sent to the laboratory. Results returned with the urinalysis showing a specific gravity of 1.011, gross haematuria and 3+ protein. His blood work reveals a urea of 32.6 mmol/L, creatinine of 832 µmol/L and eGFR of 6.2 mL/min. Based on his past medical history of diabetes, hypertension and diabetic nephropathy and the current findings, a medical diagnosis of end-stage kidney disease is established.

Based on Mr McEvoy's assessment and past medical history, the nursing diagnosis of *Impaired urinary elimination* is identified as one of the high priorities for planning nursing care.





UNIT 8

RESPONSES TO ALTERED CARDIOVASCULAR FUNCTION

CHAPTER 28

A PERSON-CENTRED APPROACH TO ASSESSING THE CARDIOVASCULAR AND LYMPHATIC SYSTEMS

PENNY PALIADELIS

KEY TERMS

LEARNING OUTCOMES

- Describe the anatomy and physiology of the cardiovascular and lymphatic systems.
- Examine investigations and observations important for assessing a person's cardiovascular and lymphatic system function.
- Accurately interpret normal and aberrant data gained from assessment of a person's cardiovascular and lymphatic system.
- Discuss manifestations of impaired cardiovascular and lymphatic systems.

CLINICAL COMPETENCIES

- Assess an ECG strip and identify normal cardiac function and abnormal rhythm.
- Conduct and document a health history for people having or at risk of alterations in the structure and function of the cardiovascular, haematological or lymphatic systems.
- Conduct and document a physical assessment of cardiovascular, haematological and lymphatic status.
- Monitor the results of diagnostic tests and report abnormal findings.

EQUIPMENT NEEDED

- Stethoscope with diaphragm and bell
- Blood pressure cuff
- Tape measure
- Metric ruler
- Doppler ultrasound device (if needed) and transducer gel

The cardiovascular system is comprised of the heart (the system's pump), the peripheral vascular system (a network of arteries, veins and capillaries) and the haematological system (blood and blood components). The lymphatic system (the lymph, lymph nodes and spleen) is a special vascular system that helps maintain sufficient blood volume in the cardiovascular system by picking up excess tissue fluid and returning it to the bloodstream. The heart, a muscular pump, beats an average of 70 times per minute, or once every 0.86 seconds, every minute of a person's life. This continuous pumping moves blood through the body, nourishing tissue cells and removing wastes. Deficits in the structure or function of the heart affect all body tissues. Changes in cardiac rate, rhythm or output may limit almost all human functions, including self-care, mobility, and the ability to maintain tissue perfusion, fluid volume status, respirations and comfort. Cardiac changes may also affect self-concept, sexuality and role performance.

STRUCTURE AND FUNCTION OF THE CARDIOVASCULAR SYSTEM

The heart is a hollow, cone-shaped organ approximately the size of an adult's fist, weighing less than 500 grams. It is located in the mediastinum of the thoracic cavity, between the vertebral column and the sternum and is flanked laterally by the lungs. Two-thirds of the heart mass lies to the left of the sternum; the upper base lies beneath the second rib, and the pointed apex is approximate with the fifth intercostal space, midpoint to the clavicle (see Figure 28.1).

The heart is covered by the pericardium, a double layer of fibroserous membrane (see Figure 28.2). The pericardium encases the heart and anchors it to surrounding structures, forming the pericardial sac. The snug fit of the pericardium prevents the heart from overfilling with blood. The outermost layer is the parietal pericardium, and the visceral pericardium (or epicardium) adheres to the heart surface. The small space between the visceral and parietal layers of the pericardium is called the pericardial cavity. A serous lubricating fluid produced in this space cushions the heart as it beats.

The heart wall consists of three layers of tissue: the epicardium, the myocardium and the endocardium (see Figure 28.2). The epicardium covers the entire heart and great vessels and then folds over to form the parietal layer that lines the pericardium and adheres to the heart surface. The myocardium, which is the middle layer of the heart wall, consists of specialised cardiac muscle cells (myofibrils) that provide the bulk of contractile heart muscle. The endocardium, which is the innermost layer, is a thin membrane composed of three layers; the innermost layer is made up of smooth endothelial cells that line the inside of the heart's chambers, the great vessels and the valves.

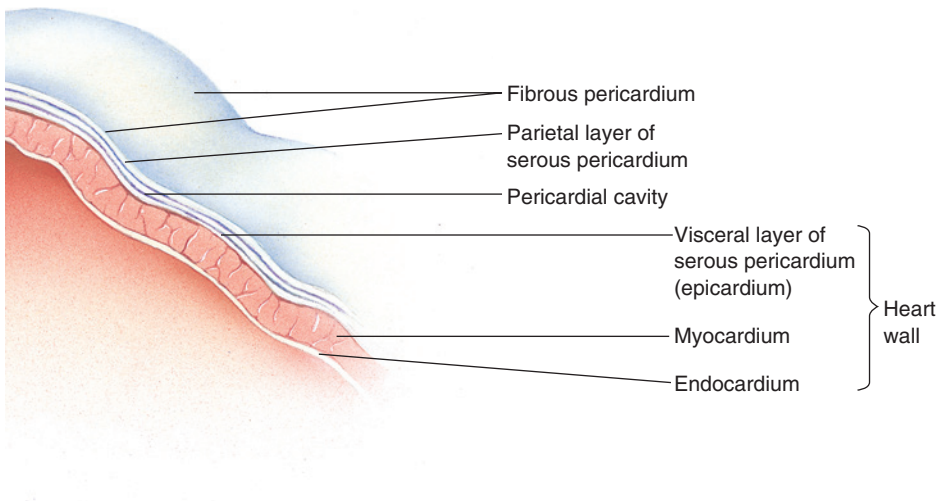

FIGURE 28.2 ■ Coverings and layers of the heart

Chambers and valves of the heart

The heart has four hollow chambers, two upper atria and two lower ventricles. They are separated longitudinally by the interventricular septum (see Figure 28.3).

The right atrium receives oxygen-poor blood from the veins of the body. (Note that the terms 'deoxygenated' and 'oxygen-poor' are often used interchangeably; however, 'oxygen-poor' is more technically correct. Haemoglobin will never become fully devoid of all oxygen—i.e. 'deoxygenated'—even at the tissues.) The superior vena cava returns blood from the body area above the diaphragm, the inferior vena cava returns blood from the body below the diaphragm, and the coronary sinus drains blood from the heart. The left atrium receives freshly oxygenated blood from the lungs through the pulmonary veins.

The right ventricle receives oxygen-poor blood from the right atrium and pumps it through the pulmonary artery to

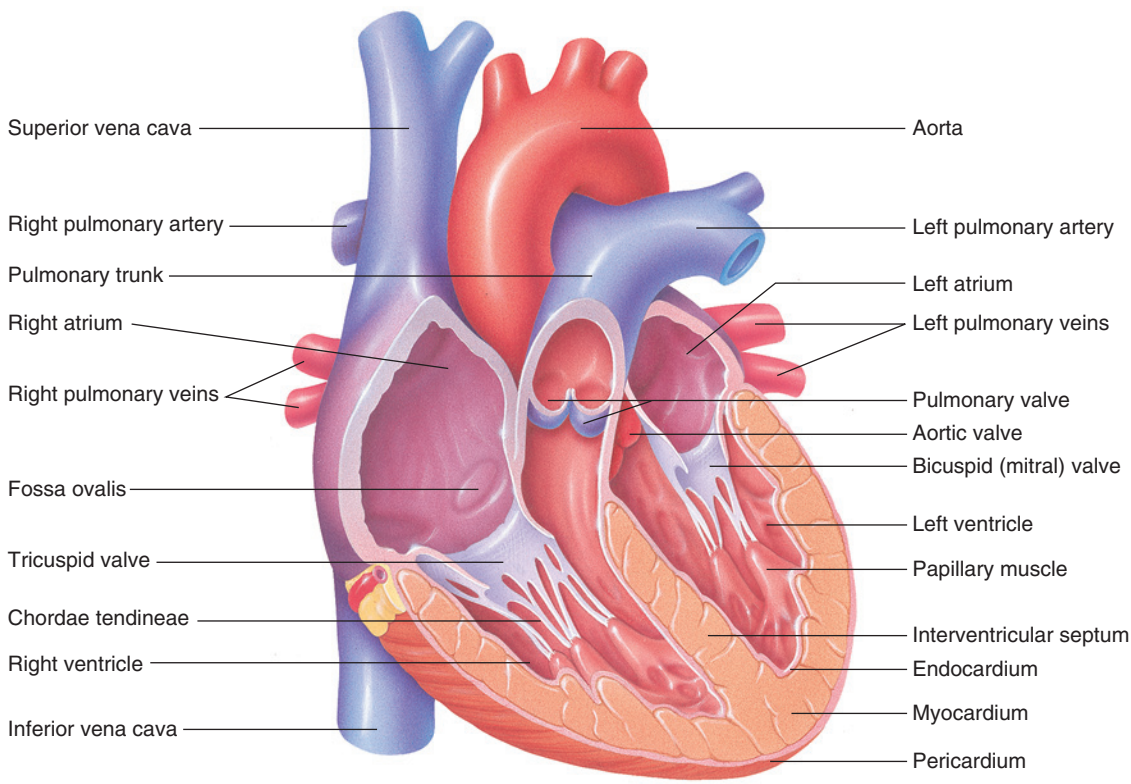

FIGURE 28.3 ■ The internal anatomy of the heart, frontal section

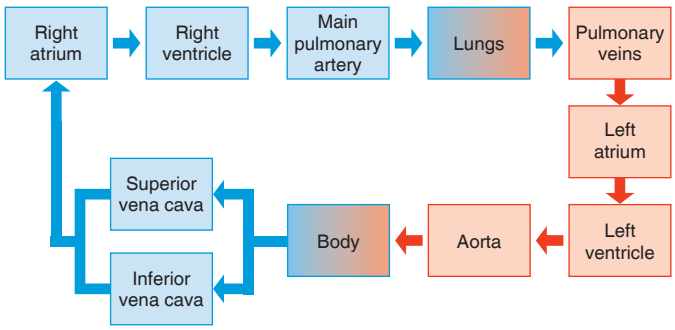

FIGURE 28.4 ■ Blood flow around the systemic circuit

the pulmonary capillary bed for oxygenation. The newly oxygenated blood then travels through the pulmonary veins to the left atrium. Blood enters the left atrium and crosses the mitral (bicuspid) valve into the left ventricle. Blood is then pumped out of the aorta to the arterial circulation (see Figure 28.4).

The chambers of the heart are separated by valves that allow unidirectional blood flow to the next chamber or great vessel. The atria are separated from the ventricles by the two atrioventricular (AV) valves; the tricuspid valve is on the right side and the bicuspid (or mitral) valve is on the left. The flaps of each of these valves are anchored to the papillary muscles of the ventricles by the chordae tendineae. These structures control the movement of the AV valves to prevent backflow of blood. The ventricles are connected to their great vessels by the semilunar valves. On the right, the pulmonary (pulmonic) valve joins the right ventricle with the pulmonary artery. On the left, the aortic valve joins the left ventricle to the aorta (see Figure 28.5).

Closure of the AV valves at the onset of contraction (systole) produces the first heart sound, or S_1 (characterised by the syllable 'lub'); closure of the semilunar valves at the onset of relaxation (diastole) produces the second heart sound, or S_2 (characterised by the syllable 'dub').

Systemic, pulmonary and coronary circulation

Because each side of the heart both receives and ejects blood, the heart is often described as a double pump. Blood enters the right atrium and moves to the pulmonary bed at almost the exact same time that blood is entering the left atrium. The circulatory system has two parts: the pulmonary circulation (moving blood through the capillary bed surrounding the lungs to link with the gas exchange system of the lungs) and the systemic circulation, which supplies blood to all other body tissues. In addition, the heart muscle itself is supplied with blood via the coronary circulation.

Systemic circulation

The systemic circulation consists of the left side of the heart, the aorta and its branches, the capillaries that supply the brain and peripheral tissues, the systemic venous system and the vena cavae. The systemic system, which must move blood to peripheral areas of the body, is a high-pressure system.

Pulmonary circulation

The pulmonary circulation consists of the right side of the heart, the pulmonary artery, the pulmonary capillaries and the pulmonary veins. Because it is located in the thorax near the heart, the pulmonary circulation is a low-pressure system. Pulmonary circulation begins with the right side of the heart. Oxygen-poor blood from the venous system enters the right atrium through two large veins, the superior and inferior venae cavae, and is transported to the lungs via the pulmonary artery and its branches (see Figure 28.6). After oxygen and carbon dioxide are exchanged in the pulmonary capillaries, oxygen-rich blood returns to the left atrium through several pulmonary veins. Blood is then pumped out of the left ventricle through the aorta and its major branches to supply all body tissues. This second circuit of blood flow is called the systemic circulation.

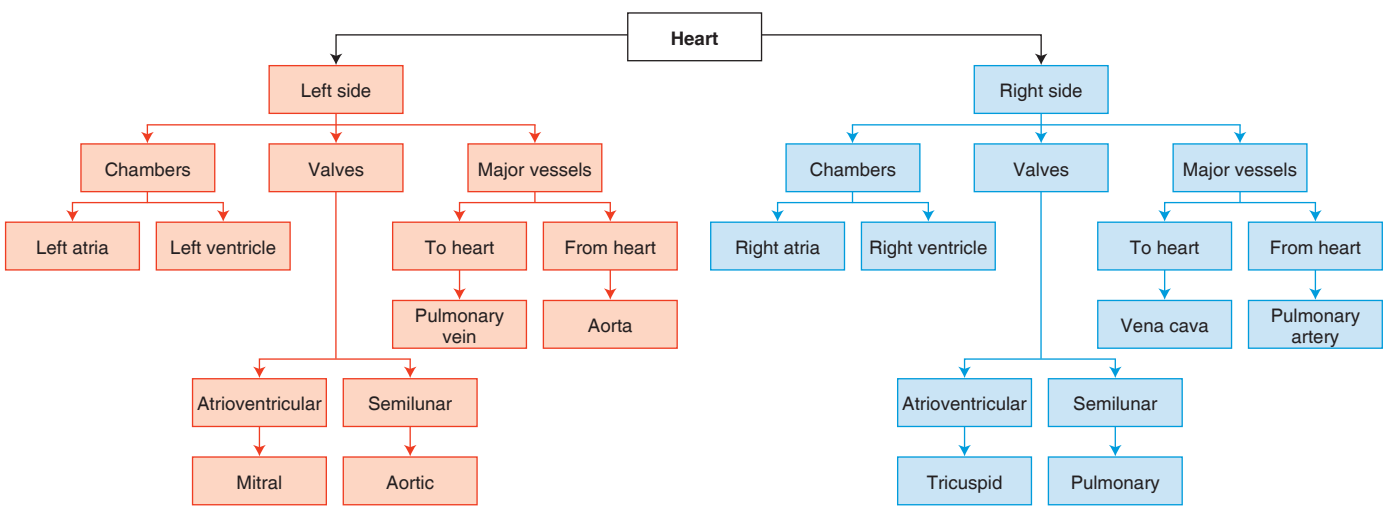

FIGURE 28.5 ■ Summary of key components of the heart

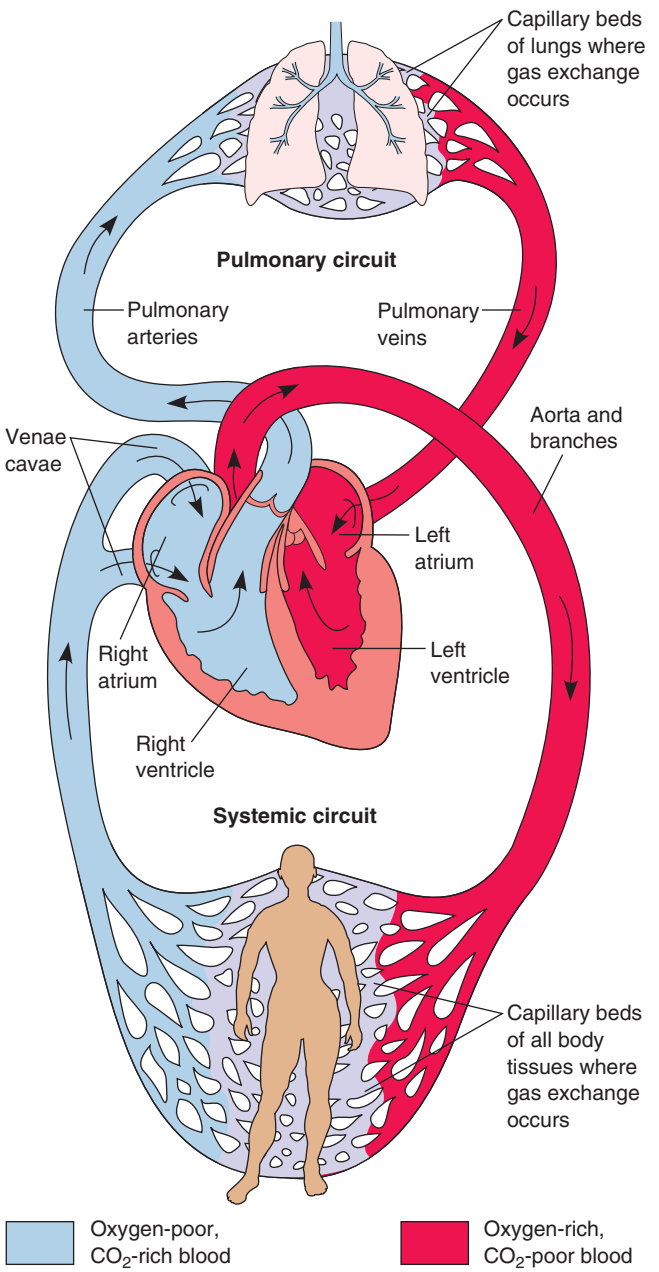

FIGURE 28.6 ■ Pulmonary and systemic circulation

Coronary circulation

The heart muscle itself is supplied by its own network of vessels through the coronary circulation. The left and right coronary arteries originate at the base of the aorta and branch out to encircle the myocardium (see Figure 28.7A), supplying blood, oxygen and nutrients to the myocardium. The left main coronary artery divides to form the anterior descending and circumflex arteries. The anterior descending artery supplies the anterior interventricular septum and the left ventricle. The circumflex branch supplies the left lateral wall of the left ventricle. The right coronary artery supplies the right ventricle and forms the posterior descending artery. The posterior descending artery supplies the posterior portion of the heart. While ventricular contraction delivers blood through the pulmonary circulation and the systemic circulation, it is during ventricular relaxation that the coronary arteries fill with oxygen-rich blood. After the blood perfuses the heart muscle, the cardiac veins drain the blood into the coronary sinus, which empties into the right atrium of the heart (see Figure 28.7B).

Blood flow through the coronary arteries is regulated by several factors. Aortic pressure is the primary factor. Other factors include the heart rate (most flow occurs during diastole, when the muscle is relaxed), metabolic activity of the heart and blood vessel tone (constriction).

The cardiac cycle and cardiac output

The contraction and relaxation of the heart constitutes one heartbeat and is called the cardiac cycle (see Figure 28.8). Ventricular filling is followed by ventricular systole, a phase during which the ventricles contract and eject blood into the pulmonary and systemic circuits. Systole is followed by a relaxation phase known as diastole, during which the ventricles refill, the atria contract and the myocardium is perfused. Normally, the complete cardiac cycle occurs about 70 to 80 times per minute, measured as the heart rate (HR).

During diastole the volume in the ventricles is increased to about 120 mL (the end-diastolic volume), and at the end of systole about 40 mL of blood remains in the ventricles (the end-systolic volume). The difference between the end-diastolic volume and the end-systolic volume is called the **stroke volume (SV)** (see Figure 28.9). Stroke volume ranges from 60 to 100 mL/beat and averages about 80 mL/beat in an adult. The **cardiac output (CO)** is the amount of blood pumped by the ventricles into the pulmonary and systemic circulations in 1 minute. Multiplying the stroke volume (SV) by the heart rate (HR) determines the cardiac output: CO = SV × HR. The **ejection fraction** is the stroke volume divided by the end-diastolic volume and represents the fraction or percentage of the diastolic volume that is ejected from the heart during systole (Mohrman & Heller, 2010). For example, an end-diastolic volume of 120 mL divided by a stroke volume of 80 mL equals an ejection fraction of 66% (see Figure 28.9). The normal ejection fraction ranges from 50% to 70%.

The average person's cardiac output ranges from 4 to 8 L/min. Cardiac output is an indicator of how well the heart is functioning as a pump. If the heart cannot pump effectively, cardiac output and tissue perfusion are decreased. Body tissues that do not receive enough blood and oxygen (carried in the blood on haemoglobin) become **ischaemic** (deprived of oxygen). If the tissues do not receive enough blood flow to maintain the functions of the cells, the cells die. (Cellular death results in necrosis or infarction.)

Activity level, metabolic rate, physiological and psychological stress responses, age and body size all influence cardiac output. In addition, cardiac output is determined by the interaction of four main factors: heart rate, preload, afterload and contractility. Changes in each of these variables influence cardiac output intrinsically and each can also be manipulated to affect cardiac output. The heart's ability to respond to the body's changing need for cardiac output is called **cardiac reserve**.

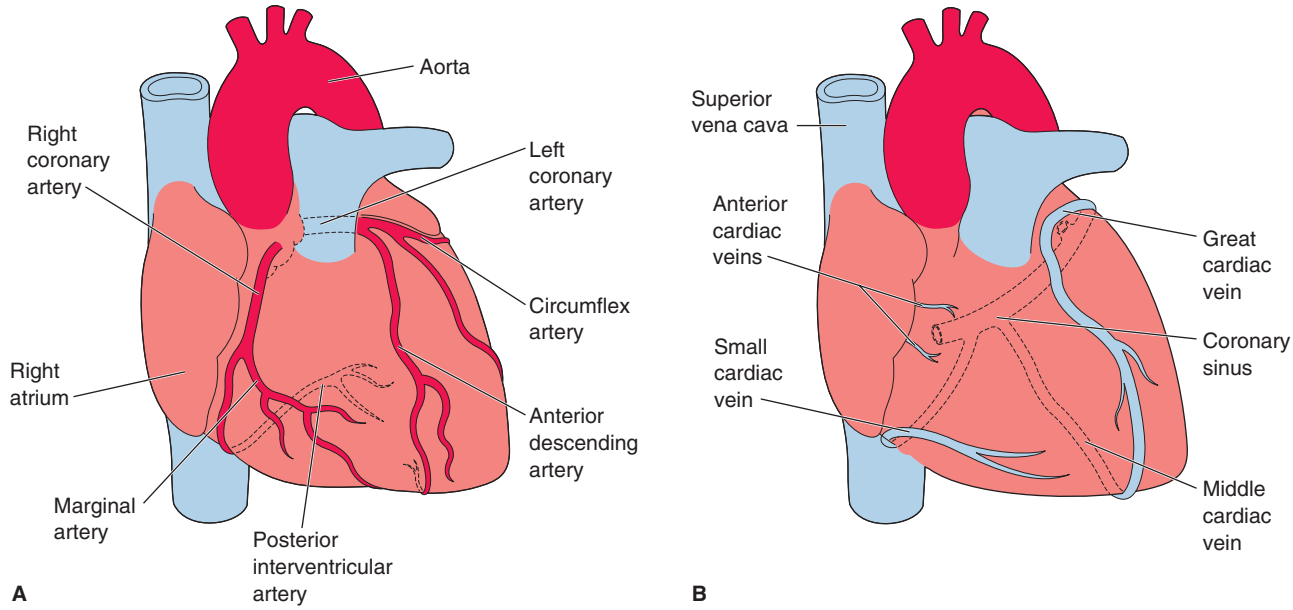

FIGURE 28.7 ■ Coronary circulation. *A*, Coronary arteries; *B*, coronary veins

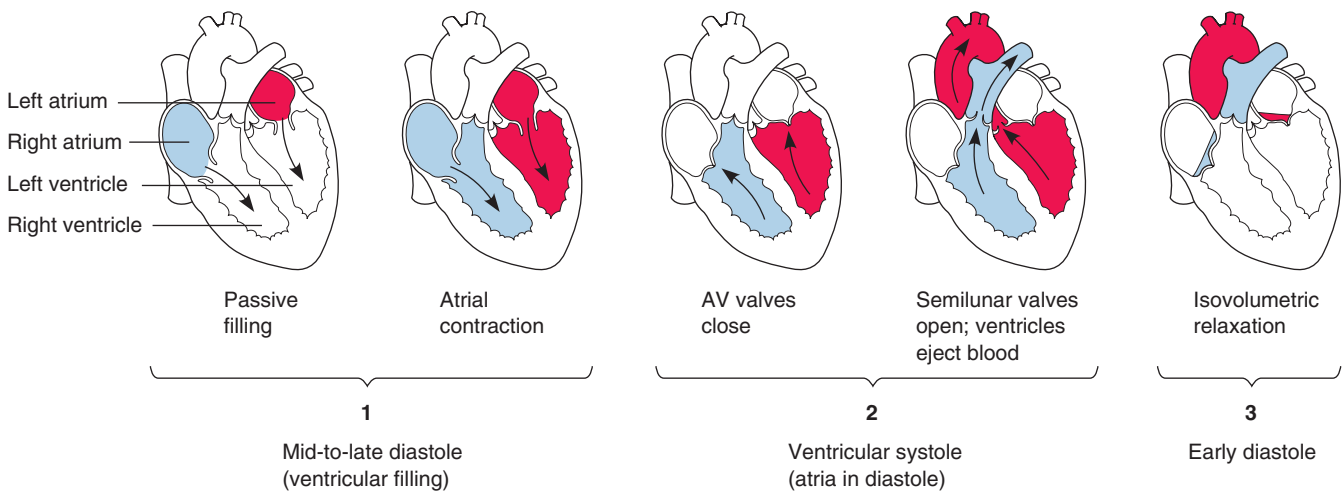

FIGURE 28.8 ■ The cardiac cycle has three events: (1) ventricular filling in mid-to-late diastole, (2) ventricular systole, and (3) isovolumetric relaxation in early diastole

Heart rate

Heart rate is affected by both direct and indirect autonomic nervous system stimulation. Direct stimulation is accomplished through the innervation of the heart muscle by sympathetic and parasympathetic nerves. The sympathetic nervous system increases the heart rate, whereas the parasympathetic vagal tone slows the heart rate. Reflex regulation of the heart rate in response to systemic blood pressure also occurs through activation of sensory receptors known as baroreceptors or pressure receptors located in the carotid sinus, aortic arch, venae cavae and pulmonary veins.

If heart rate increases, cardiac output increases (up to a point) even if there is no change in stroke volume. However, rapid heart rates decrease the amount of time available for ventricular filling during diastole. Cardiac output then falls because decreased filling time decreases stroke volume. Coronary artery perfusion also decreases because the coronary arteries fill primarily during diastole. Cardiac output decreases during bradycardia if stroke volume stays the same because the number of cardiac cycles is decreased.

Contractility

Contractility is the inherent capability of the cardiac muscle fibres to shorten. Poor contractility of the heart muscle reduces the forward flow of blood from the heart, increases the ventricular pressures from accumulation of blood volume and reduces cardiac output. Increased contractility may stress the heart.

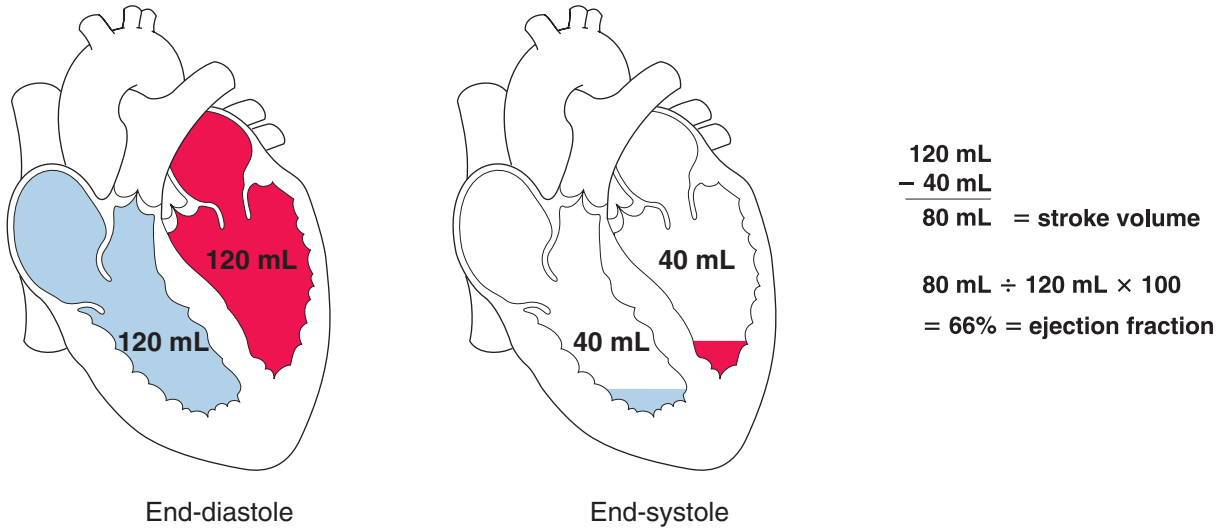

FIGURE 28.9 ■ Stroke volume is end-diastole volume minus end-systole volume; ejection fraction is stroke volume divided by end-diastole volume, expressed as a percentage

Preload

Preload is the amount of cardiac muscle fibre tension or stretch that exists at the end of diastole, just before contraction of the ventricles. Preload is influenced by venous return and the compliance of the ventricles. It is related to the total volume of blood in the ventricles: the greater the volume, the greater the stretch of the cardiac muscle fibres and the greater the force with which the fibres contract to accomplish emptying. This principle is called Starling's law of the heart.

This mechanism has a physiological limit. Just as continuous overstretching of a rubber band causes the band to relax and lose its ability to recoil, overstretching of the cardiac muscle fibres eventually results in ineffective contraction. Disorders such as kidney disease and congestive heart failure result in sodium and water retention and increased preload. Vasoconstriction also increases venous return and preload.

Too little circulating blood volume results in a decreased venous return and therefore a decreased preload. A decreased preload reduces stroke volume and thus cardiac output. Decreased preload may result from haemorrhage or maldistribution of blood volume, as occurs in 'third spacing' (see Chapter 9).

Afterload

Afterload is the force the ventricles must overcome to eject their blood volume. It is the pressure in the arterial system ahead of the ventricles. The right ventricle must generate enough tension to open the pulmonary valve and eject its volume into the low-pressure pulmonary arteries. Right ventricle afterload is measured as peripheral vascular resistance (PVR). The left ventricle, in contrast, ejects its load by overcoming the pressure behind the aortic valve. Afterload of the left ventricle is measured as systemic vascular resistance (SVR). Arterial pressures are much higher than pulmonary pressures; thus, the left ventricle has to work much harder than the right ventricle.

Alterations in vascular tone affect afterload and ventricular work. As the pulmonary or arterial blood pressure increases (e.g. through vasoconstriction), PVR and/or SVR increases and the work of the ventricles increases. As workload increases, consumption of myocardial oxygen also increases. A compromised heart cannot effectively meet this increased oxygen demand and a vicious cycle ensues. By contrast, a very low afterload decreases the forward flow of blood into the systemic circulation and the coronary arteries.

Clinical indicators of cardiac output

For many people who are critically ill, invasive haemodynamic monitoring catheters are used to measure cardiac output in quantifiable numbers. However, advanced technology is not the only way to identify and assess compromised blood flow. Because cardiac output perfuses the body's tissues, clinical indicators of low cardiac output may be manifested by changes in organ function that result from compromised blood flow. For example, a decrease in blood flow to the brain presents as a change in level of consciousness. Other manifestations of decreased cardiac output are discussed in Chapters 9 and 29.

Cardiac index (CI) is the cardiac output adjusted for the person's body size, also called the person's body surface area (BSA). Because it takes into account the person's BSA, the cardiac index provides more meaningful data about the heart's ability to perfuse the tissues and therefore is a more accurate indicator of the effectiveness of the circulation.

BSA is stated in square metres (m^2), and cardiac index is calculated as CO divided by BSA. Cardiac measurements are considered adequate when they fall within the range of 2.5 to 4.2 L/min/m^2. For example, two people are determined to have a cardiac output of 4 L/min. This parameter is within normal limits. However, one person is 157 cm tall and weighs 54.5 kg, with a BSA of 1.54 m^2. This person's cardiac index is 4 ÷ 1.54, or 2.6 L/min/m^2. The second person is 188 cm tall and weighs 81.7 kg, with a BSA of 2.52 m^2. This person's cardiac index is 4 ÷ 2.52, or 1.6 L/min/m^2.

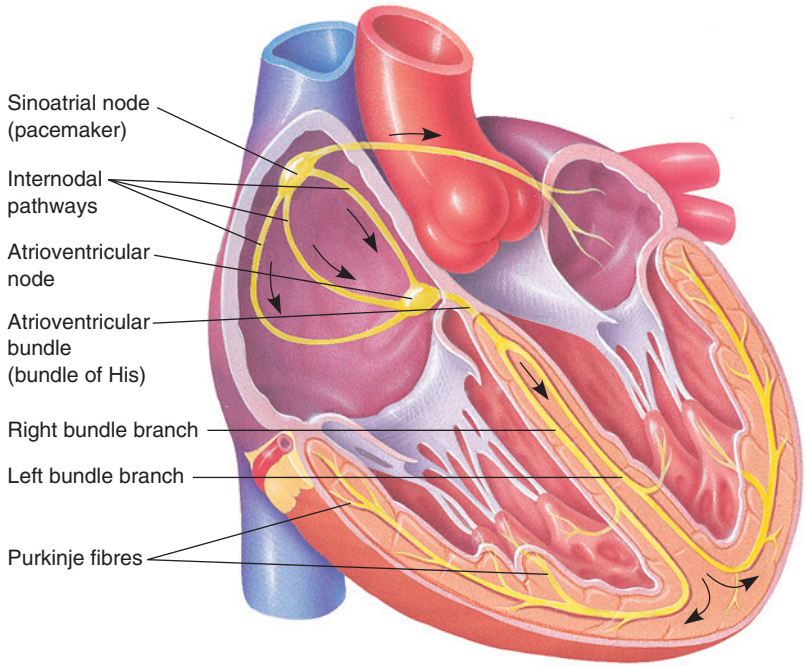

FIGURE 28.10 ■ The intrinsic conduction system of the heart

The cardiac index results show that the same cardiac output of 4 L/min is adequate for the first person but grossly inadequate for the second person.

The conduction system of the heart

The cardiac cycle is perpetuated by a complex electrical circuit commonly known as the intrinsic conduction system of the heart. Cardiac muscle cells possess an inherent characteristic of self-excitation, which enables them to initiate and transmit impulses independent of a stimulus. However, specialised areas of myocardial cells typically exert a controlling influence in this electrical pathway.

One of these specialised areas is the sinoatrial (SA) node, located at the junction of the superior vena cava and right atrium (see Figure 28.10). The SA node acts as the normal 'pacemaker' of the heart, usually generating an impulse 60 to 100 times per minute. This impulse travels across the atria via internodal pathways to the atrioventricular (AV) node, in the floor of the interatrial septum. The very small junctional fibres of the AV node slow the impulse, slightly delaying its transmission to the ventricles. It then passes through the bundle of His at the atrioventricular junction and continues down the interventricular septum through the right and left bundle branches and out to the Purkinje fibres in the ventricular muscle walls (Mohrman & Heller, 2010).

THE PERIPHERAL VASCULAR SYSTEM

The two main components of the peripheral vascular system are the arterial network and the venous network. The arterial network begins with the major arteries that branch from the aorta. The major arteries of the systemic circulation are illustrated in Figure 28.11. These major arteries branch into successively smaller arteries, which in turn subdivide into the smallest of the arterial vessels, called *arterioles*. The smallest arterioles feed into beds of hair-like capillaries in the body's organs and tissues.

In the capillary beds, oxygen and nutrients are exchanged for metabolic wastes, and deoxygenated blood begins its journey back to the heart through venules, the smallest vessels of the venous network. Venules join the smallest of veins, which in turn join larger and larger veins. The blood transported by the veins empties into the superior and inferior venae cavae entering the right side of the heart. The major veins of the systemic circulation are shown in Figure 28.12.

Structure of blood vessels

The structure of blood vessels reflects their different functions within the circulatory system (see Figure 28.13). Except for the tiniest vessels, blood vessel walls have three layers: the tunica intima, the tunica media and the tunica adventitia. The tunica intima, the innermost layer, is made of simple squamous epithelium (the endothelium); this provides a slick surface to facilitate the flow of blood. In arteries the middle layer, or tunica media, is made of smooth muscle and is thicker than the tunica media of veins. This makes arteries more elastic than veins and allows the arteries to alternately expand and recoil as the heart contracts and relaxes with each beat, producing a pressure wave, which can be felt as a **pulse** over an artery. The smaller arterioles are less elastic than arteries but contain more smooth muscle, which promotes their constriction (narrowing) and dilation (widening). In fact, arterioles exert the major control over arterial blood pressure. The tunica adventitia, or outermost layer, is made of

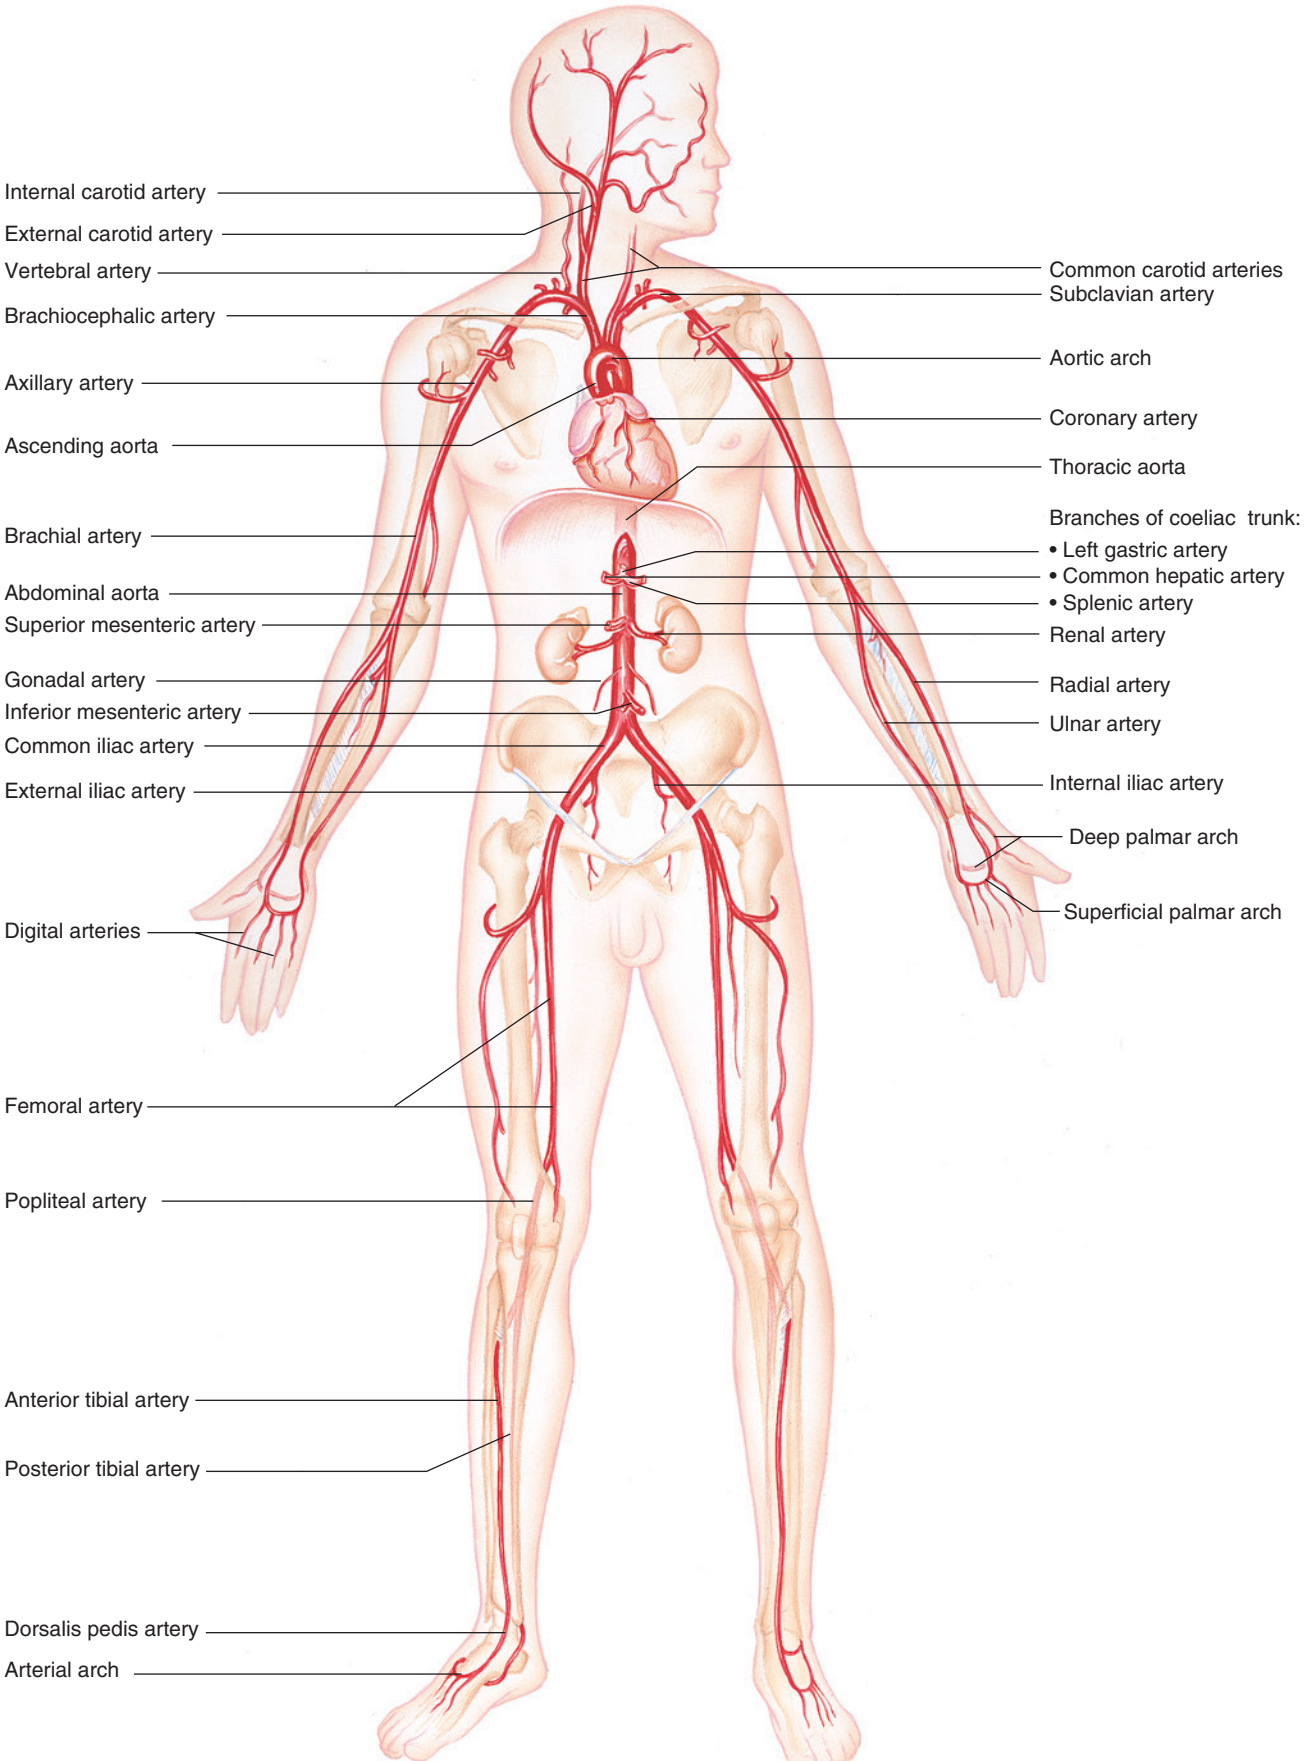

FIGURE 28.11 ■ Major arteries of the systemic circulation

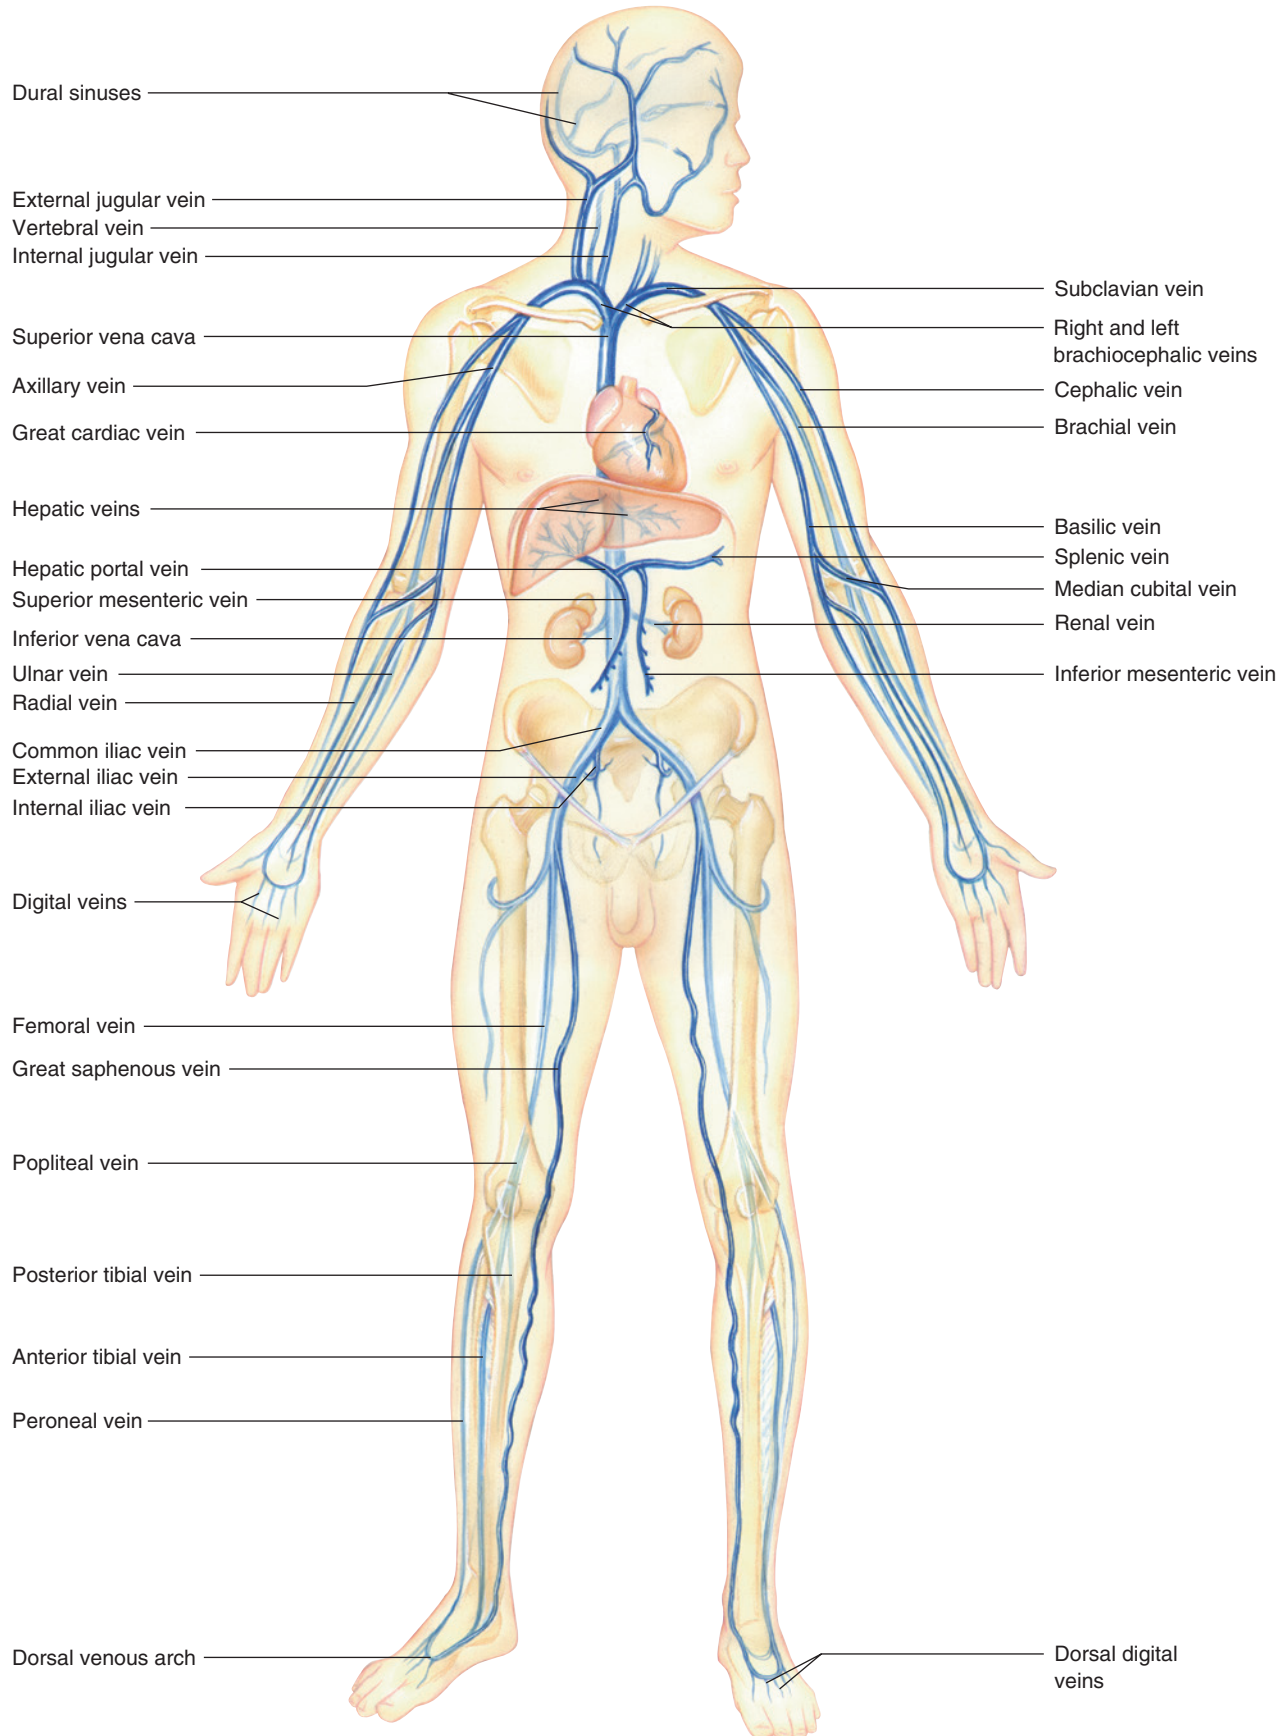

FIGURE 28.12 ■ Major veins of the systemic circulation

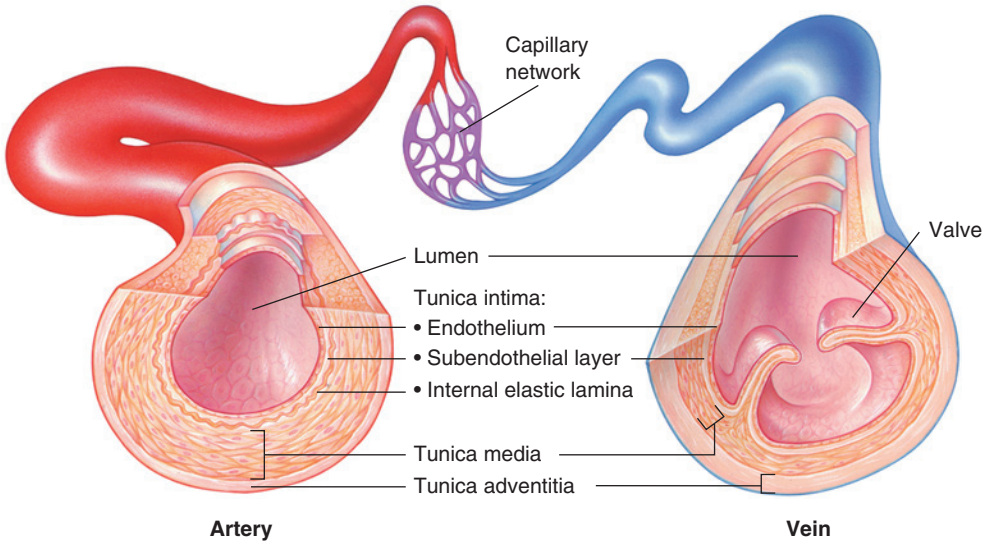

FIGURE 28.13 ■ Structure of arteries, veins and capillaries. Capillaries are composed of only a fine tunica intima. Notice that the tunica media is thicker in arteries than in veins

connective tissue and serves to protect and anchor the vessel. Veins have a thicker tunica adventitia than do arteries.

Blood in the veins travels at a much lower pressure than blood in the arteries. Veins have thinner walls, a larger lumen and greater capacity, and many are supplied with valves that help blood flow against gravity back to the heart. The 'milking' action of skeletal muscle contraction (called the muscular pump) also supports venous return. When skeletal muscles contract against veins, the valves proximal to the contraction open and blood is propelled towards the heart. The abdominal and thoracic pressure changes that occur with breathing (called the respiratory pump) also propel blood towards the heart.

The tiny capillaries that connect the arterioles and venules contain only one thin layer of tunica intima, which is permeable to the gases and molecules exchanged between blood and tissue cells. Capillaries typically are found in interwoven networks. They filter and shunt blood from precapillary arterioles to postcapillary venules.

Physiology of arterial circulation

The factors that affect arterial circulation are blood flow, peripheral vascular resistance and blood pressure. **Blood flow** refers to the volume of blood transported in a vessel, in an organ or throughout the entire circulation over a given period of time. It is commonly expressed as litres or millilitres per minute or cubic centimetres per second.

Peripheral vascular resistance (PVR) refers to the opposing forces or impedance to blood flow as the arterial channels become more and more distant from the heart. Peripheral vascular resistance is determined by three factors:

1. *Blood viscosity:* the greater the viscosity, or thickness, of the blood, the greater its resistance to moving and flowing.
2. *Length of the vessel:* the longer the vessel, the greater the resistance to blood flow.
3. *Diameter of the vessel:* the smaller the diameter of a vessel, the greater the friction against the walls of the vessel and, thus, the greater the impedance to blood flow.

Blood pressure is the force exerted against the walls of the arteries by the blood as it is pumped from the heart. It is most accurately referred to as **mean arterial pressure (MAP)**. The highest pressure exerted against the arterial walls at the peak of ventricular contraction (systole) is called the systolic blood pressure. The lowest pressure exerted during ventricular relaxation (diastole) is the diastolic blood pressure.

Mean arterial blood pressure is regulated mainly by cardiac output (CO) and peripheral vascular resistance (PVR), as represented in this formula: MAP = CO × PVR. For clinical use, the MAP may be estimated by calculating the diastolic blood pressure plus one-third of the pulse pressure (the difference between the systolic and diastolic blood pressure).

Factors influencing arterial blood pressure

Blood flow, peripheral vascular resistance and blood pressure, which influence arterial circulation, are in turn influenced by various factors, as follows:

- The sympathetic and parasympathetic nervous systems are the primary mechanisms that regulate blood pressure. Stimulation of the sympathetic nervous system exerts a major effect on peripheral resistance by causing vasoconstriction of the arterioles, thereby increasing blood pressure. Parasympathetic stimulation causes vasodilation of the arterioles, lowering blood pressure.
- Baroreceptors and chemoreceptors in the aortic arch, carotid sinus and other large vessels are sensitive to pressure and chemical changes and cause reflex sympathetic stimulation, resulting in vasoconstriction, increased heart rate and increased blood pressure.
- The kidneys help maintain blood pressure by excreting or conserving sodium and water. When blood pressure

decreases, the kidneys initiate the renin–angiotensin mechanism. This stimulates vasoconstriction, resulting in the release of the hormone aldosterone from the adrenal cortex, increasing sodium ion reabsorption and water retention. In addition, pituitary release of antidiuretic hormone (ADH) promotes renal reabsorption of water. The net result is an increase in blood volume and a consequent increase in cardiac output and blood pressure.

- Temperatures may also affect peripheral resistance: cold causes vasoconstriction, whereas warmth produces vasodilation. Many chemicals, hormones and drugs influence blood pressure by affecting CO and/or PVR. For example, epinephrine causes vasoconstriction and increased heart rate; prostaglandins dilate blood vessel diameter (by relaxing vascular smooth muscle); endothelin, a chemical released by the inner lining of vessels, is a potent vasoconstrictor; nicotine causes vasoconstriction; and alcohol and histamine cause vasodilation.
- Dietary factors, such as intake of salt, saturated fats and cholesterol, elevate blood pressure by affecting blood volume and vessel diameter.
- Race, gender, age, weight, time of day, position, exercise and emotional state may also affect blood pressure. These factors influence the arterial pressure. Systemic venous pressure, though it is much lower, is also influenced by such factors as blood volume, venous tone and right atrial pressure.

STRUCTURE AND FUNCTION OF BLOOD

Blood is an exchange medium between the external environment and the body's cells. Blood consists of plasma, solutes (e.g. proteins, electrolytes and organic constituents), red blood cells, white blood cells and platelets (which are fragments of cells). The haematopoietic (blood-forming) system includes the bone marrow (myeloid) tissues, where blood cells form, and the lymphoid tissues of the lymph nodes, where white blood cells mature and circulate. All blood cells originate from cells in the bone marrow called **stem cells** or *haemocytoblasts*. The origin of the cellular components of blood is illustrated in Figure 28.14.

Regulatory mechanisms cause stem cells to differentiate into families of parent cells, each of which gives rise to one of the formed elements of the blood (red blood cells, platelets and white blood cells). The functions of blood include transporting oxygen, nutrients, hormones and metabolic wastes; protecting against invasion of pathogens; maintaining blood coagulation; and regulating fluids, electrolytes, acids, bases and body temperature.

Red blood cells

Red blood cells (RBCs, erythrocytes) and the haemoglobin molecules they contain are required to transport oxygen to body tissues. Haemoglobin also binds with some carbon dioxide, carrying it to the lungs for excretion. Abnormal numbers of RBCs, changes in their size and shape, or altered haemoglobin content or structure can adversely affect health. Anaemia, the most common RBC disorder, is an abnormally low RBC count or reduced haemoglobin content. Polycythaemia is an abnormally high RBC count.

The red blood cell is shaped like a biconcave disk (see Figure 28.15). This unique shape increases the surface area of the cell and allows the cell to pass through very small capillaries without disrupting the cell membrane. RBCs are the most common type of blood cell.

Haemoglobin is the oxygen-carrying protein within RBCs. It consists of the haem molecule and globin, a protein molecule. Globin is made of four polypeptide chains—two alpha chains and two beta chains (see Figure 28.16). Each of the four polypeptide chains contains a haem unit containing an iron atom. The iron atom binds reversibly with oxygen, allowing it to transport oxygen as *oxyhaemoglobin* to the cells. Haemoglobin is synthesised within the RBCs. The rate of synthesis depends on the availability of iron (Bullock & Hales, 2012).

Normal adult laboratory values for red blood cells are defined and identified in Table 28.1. The size, colour and shape of stained RBCs also may be analysed. RBCs may be normocytic (normal size), smaller than normal (microcytic) or larger than normal (macrocytic). Their colour may be normal (normochromic) or diminished (hypochromic).

Red blood cell production and regulation

In adults, RBC production (**erythropoiesis**) (see Figure 28.17) begins in red bone marrow of the vertebrae, sternum, ribs and pelvis, and is completed in the blood or spleen. Erythroblasts begin forming haemoglobin while they are in the bone marrow, a process that continues throughout the RBC lifespan. Erythroblasts differentiate into *normoblasts*. As these slightly smaller cells mature, their nucleus and most organelles are ejected, eventually causing normoblasts to collapse inward and assume the characteristic biconcave shape of RBCs. The cells enter the circulation as *reticulocytes*, which fully mature in about 48 hours. The complete sequence from stem cell to RBC takes 3 to 5 days.

The stimulus for RBC production is tissue hypoxia. The hormone erythropoietin is released by the kidneys in response to hypoxia. It stimulates the bone marrow to produce RBCs. However, the process of RBC production takes about 5 days to maximise. During periods of increased RBC production, the percentage of reticulocytes (immature RBCs) in the blood exceeds that of mature cells.

Red blood cell destruction

RBCs have a life span of about 120 days. Old or damaged RBCs are lysed (destroyed) by phagocytes in the spleen, liver, bone marrow and lymph nodes. The process of RBC destruction is called **haemolysis**. Phagocytes save and reuse amino acids and iron from haem units in the lysed RBCs. Most of the haem unit is converted to bilirubin, an orange-yellow pigment that is removed from the blood by the liver and excreted in the bile. During disease processes causing increased haemolysis or impaired liver function, bilirubin accumulates in the serum, causing a yellowish appearance of the skin and sclera (jaundice).

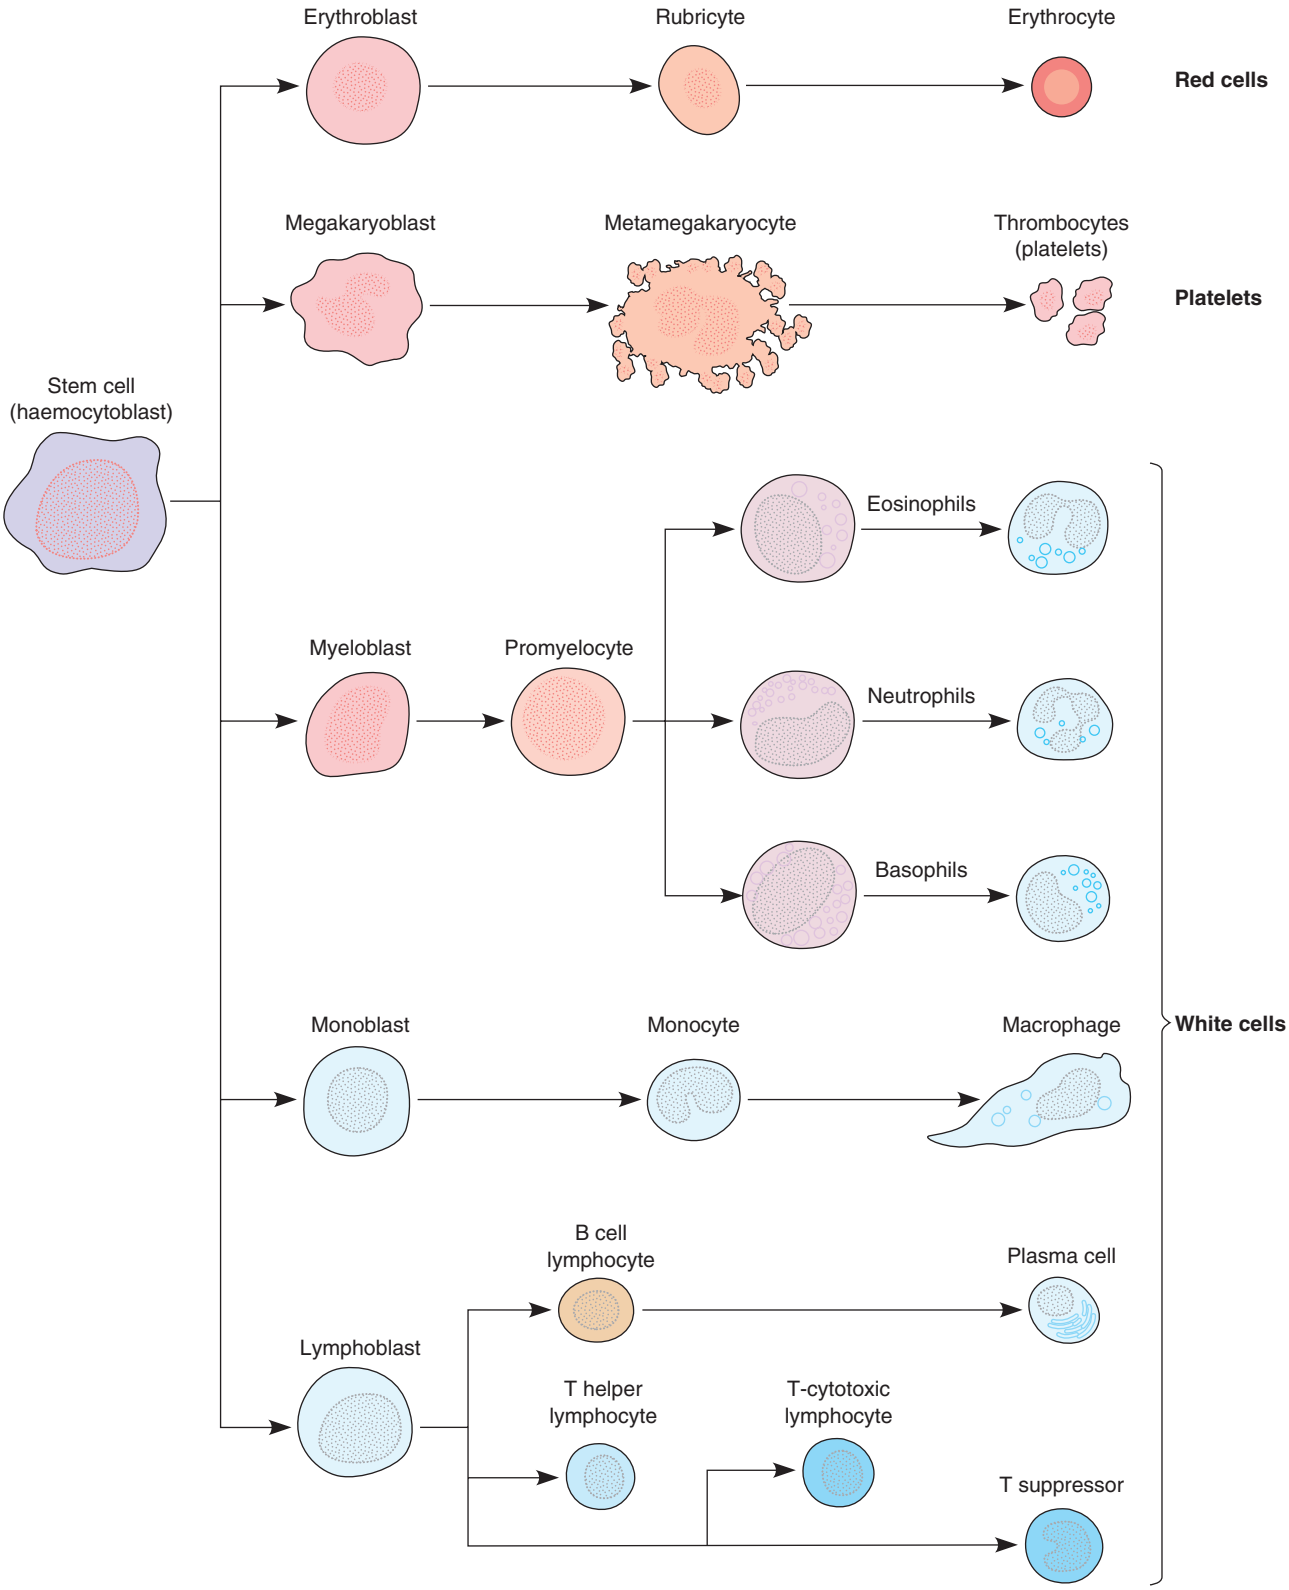

FIGURE 28.14 ■ Blood cell formation from stem cells. Regulatory factors control the differentiation of stem cells into blasts. Each of the five kinds of blasts is committed to producing one type of mature blood cell. Erythroblasts, for example, can differentiate only into RBCs; megakaryoblasts can differentiate only into platelets

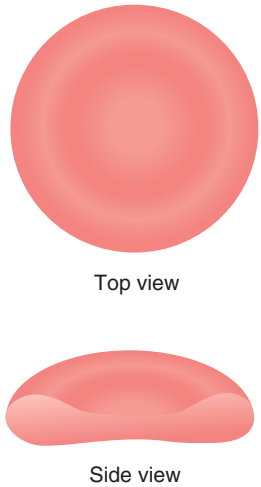

FIGURE 28.15 ■ Top and side view of a red blood cell (erythrocyte). Note the distinctive biconcave shape

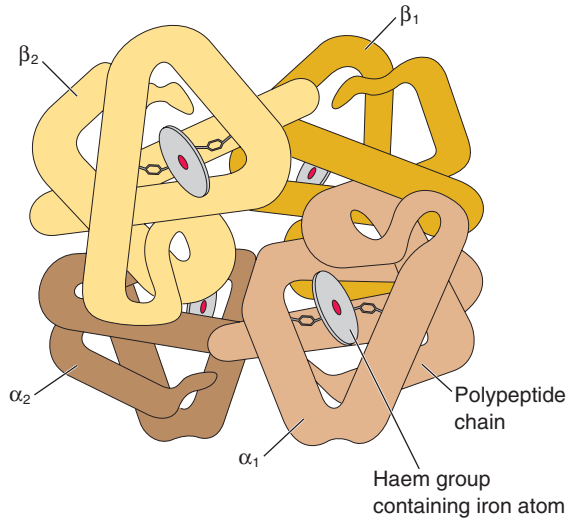

FIGURE 28.16 ■ The haemoglobin molecule includes globin (a protein) and haem, which contains iron. Globin is made of four subunits, two alpha and two beta polypeptide chains. A haem disk containing an iron atom (red dot) nests within the folds of each protein subunit. The iron atoms combine reversibly with oxygen, transporting it to the cells

TABLE 28.1 Full blood count (FBC)

COMPONENT	PURPOSE	NORMAL VALUES
Haemoglobin (Hb)	Measures the capacity of the haemoglobin to carry gases	Women: 12–17.5 g/dL Men: 13.6–17.5 g/dL
Haematocrit (HCT)	The haematocrit represents the percentage of whole blood volume composed of erythrocytes	Women: 35–45% Men: 39–49%
Total RBC count	Counts number of circulating RBCs	Women: 4–5 × 10^6 /μL Men: 4.5–6 × 10^6 /μL
Red cell indices:		
MCV	Determines relative size of MCV (mean corpuscular volume)	76–96 fL
MCH	Mean corpuscular haemoglobin	27–33 pg
MCHC	Evaluates RBC saturation with Hb (MCHC = mean corpuscular haemoglobin concentration)	32–36%
WBC count (leucocytes)	Measures total number of leucocytes (total count) and whether each kind of WBC is present in proper proportion (differential)	Total WBC count: 4300–10 800/ μL (4.3–10.8 × 10^9 /L) WBC differential: Neutrophils: 50–70% Eosinophils: 2–4% Basophils: 0–2% Lymphocytes: 20–40% Monocytes: 4–8%
Platelets	Measures number of platelets available to maintain clotting functions	150 000–400 000 /μL (150–400 × 10^9/L)

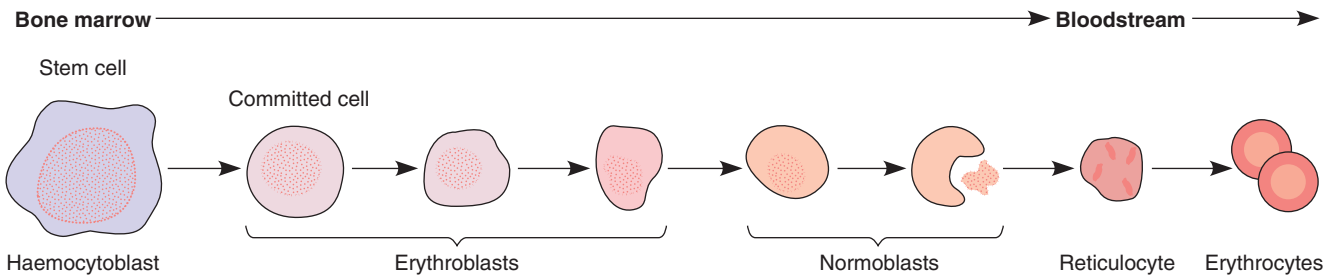

FIGURE 28.17 ■ Erythropoiesis. RBCs begin as erythroblasts within the bone marrow, maturing into normoblasts, which eventually eject their nucleus and organelles to become reticulocytes. Reticulocytes mature within the blood or spleen to become erythrocytes

White blood cells

White blood cells (WBCs, leucocytes) are a part of the body's defence against microorganisms. On average, there are 5000 to 10 000 WBCs per microlitre of blood, accounting for about 1% of total blood volume. **Leucocytosis** is a higher than normal WBC count; **leucopenia** is a WBC count that is lower than normal.

WBCs originate from haemopoietic stem cells in the bone marrow. These stem cells differentiate into the various types of white blood cells (see Figure 28.14).

The two basic types of WBCs are granular leucocytes (or granulocytes) and non-granular leucocytes. Granulocytes have horseshoe-shaped nuclei and contain large granules in the cytoplasm. Stimulated by granulocyte-macrophage colony-stimulating factor (GM-CSF) and granulocyte colony-stimulating factor (G-CSF), granulocytes mature fully in the bone marrow before being released into the bloodstream. The three types of granulocytes are as follows:

- Neutrophils (also called *polymorphonuclear (PMN)* or segmented (*segs*) leucocytes) comprise 60–70% of the total circulating WBCs. Their nuclei are divided into three to five lobes. Neutrophils are active phagocytes, the first cells to arrive at a site of injury. Their numbers increase during inflammation. Immature forms of neutrophils (bands) are released during inflammation or infections and are referred to as having a shift to the left (so named because immature cell frequencies appear on the left side of the graph) on a differential blood count. Neutrophils have a lifespan of only about 10 hours and are constantly being replaced.
- Eosinophils comprise 1–3% of circulating WBCs, but are found in large numbers in the mucosa of the intestines and lungs. Their numbers increase during allergic reactions and parasitic infestations.
- Basophils, which comprise less than 1% of the WBC count, contain histamine, heparin and other inflammatory mediators. Basophils increase in number during allergic and inflammatory reactions.

Non-granular WBCs (agranulocytes) include the monocytes and lymphocytes. They enter the bloodstream before final maturation.

- Monocytes are the largest of the WBCs. They comprise approximately 3–8% of the total WBC count. Monocytes contain powerful bactericidal substances and proteolytic enzymes. They are phagocytic cells that mature into macrophages. Macrophages dispose of foreign and waste material, especially in inflammation. They are an active part of the immune response.
- Lymphocytes comprise 20–30% of the WBC count. Lymphocytes mature in lymphoid tissue into B cells and T cells. B cells are involved in the humoral immune response and antibody formation, whereas T cells take part in the cell-mediated immunity process (see Chapter 12). Plasma cells (which arise from B cells) are lymphoid cells found in bone marrow and connective tissue; they also are involved in immune reactions.

Platelets

Platelets (thrombocytes) are cell fragments that have no nucleus and cannot replicate. They are metabolically active, however, producing ATP and releasing mediators required for clotting. Platelets are formed in the bone marrow as pinched-off portions of large megakaryocytes (see Figure 28.14). Platelet production is controlled by *thrombopoietin*, a protein produced by the liver, kidney, smooth muscle and bone marrow. The number of circulating platelets controls thrombopoietin release. Once released from the bone marrow, platelets remain in the spleen for about 8 hours before entering the circulation. Platelets live up to 10 days in circulation. There are about 250 000 to 400 000 platelets in each microlitre of blood. An excess of platelets is *thrombocytosis*. A deficit of platelets is *thrombocytopenia*.

Haemostasis

Platelet and coagulation disorders affect haemostasis, the control of bleeding. Haemostasis is a series of complex interactions between platelets and clotting mechanisms that maintains a relatively steady state of blood volume, blood pressure and blood flow through injured vessels. The five stages of haemostasis are (1) vessel spasm, (2) formation of the platelet plug, (3) development of an insoluble fibrin clot, (4) clot retraction, and (5) clot dissolution.

Vessel spasm

When a blood vessel is damaged, thromboxane A_2 (TXA_2) is released from platelets and cells, causing *vessel spasm*. This spasm constricts the damaged vessel for about 1 minute, reducing blood flow.

Formation of the platelet plug

Platelets attracted to the damaged vessel wall change from smooth disks to spiny spheres. Receptors on the activated platelets bind with *von Willebrand's factor*, a protein molecule and exposed collagen fibres at the site of injury to form the platelet plug (see Figure 28.18). The platelets release adenosine diphosphate (ADP) and TXA_2 to activate nearby platelets, adhering them to the developing plug. Activation of the clotting pathway on the platelet surface converts fibrinogen to fibrin. Fibrin, in turn, forms a meshwork that binds the platelets and other blood cells to form a stable plug (see Figure 28.19).

Development of the fibrin clot

The process of coagulation creates a meshwork of fibrin strands that cements the blood components to form an insoluble clot. Coagulation requires many interactive reactions and two clotting pathways (see Figure 28.20). The slower intrinsic pathway is activated when blood contacts collagen in the injured vessel wall; the faster extrinsic pathway is activated when blood is exposed to tissues. The final outcome of both pathways is fibrin clot formation. Each procoagulation substance is activated in sequence; the activation of one coagulation factor activates another in turn. Table 28.2 lists known factors, their origin and their function or pathway. A deficiency of one or

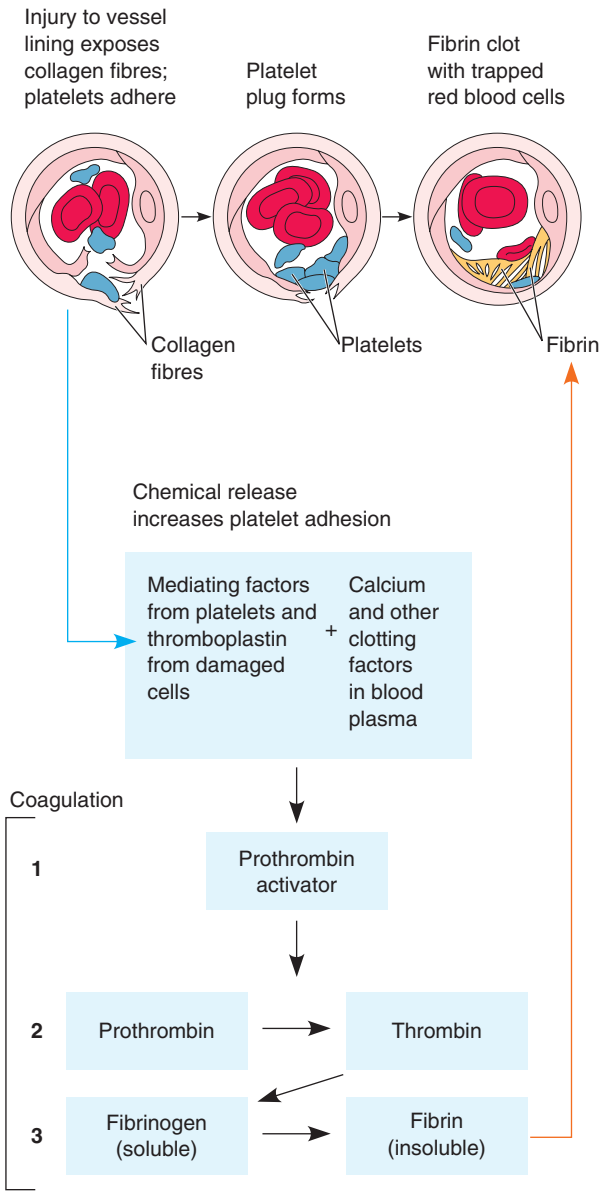

FIGURE 28.18 ■ Platelet plug formation and blood clotting. The flow diagram summarises the events leading to fibrin clot formation

more factors or inappropriate inactivation of any factor alters normal coagulation.

Clot retraction

After the clot is stabilised (within about 30 minutes), trapped platelets contract, much like muscle cells. Platelet contraction squeezes the fibrin strands, pulling the broken portions of the ruptured blood vessel closer together. Growth factors released by the platelets stimulate cell division and tissue repair of the damaged vessel.

Clot dissolution

Fibrinolysis, the process of clot dissolution, begins shortly after the clot has formed, restoring blood flow and promoting tissue repair. Like coagulation, fibrinolysis requires a sequence of interactions between activator and inhibitor substances. Plasminogen, an enzyme that promotes fibrinolysis, is converted into plasmin, its active form, by chemical mediators released from vessel walls and the liver. Plasmin dissolves the clot's fibrin strands and certain coagulation factors. Stimuli such as exercise, fever and vasoactive drugs promote plasminogen activator release. The liver and endothelium also produce fibrinolytic inhibitors.

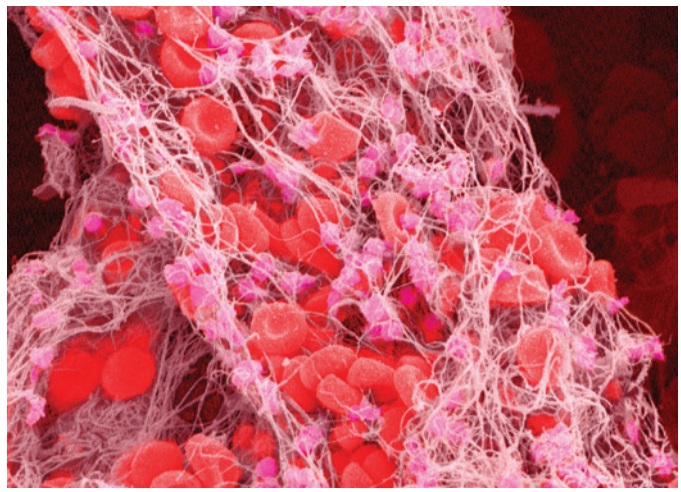

FIGURE 28.19 ■ Scanning electron micrograph of an RBC trapped in a fibrin mesh

Source: Micro Discovery/Corbis.

STRUCTURE AND FUNCTION OF THE LYMPHATIC SYSTEM

The structures of the lymphatic system include the lymphatic vessels and several lymphoid organs (see Figure 28.21). The organs of the lymphatic system are the lymph nodes, the spleen, the thymus, the tonsils and the Peyer's patches of the small intestine. Lymph nodes are small aggregates of specialised cells that assist the immune system by removing foreign material, infectious organisms and tumour cells from lymph. Lymph nodes are distributed along the lymphatic vessels, forming clusters in certain body regions, such as the neck, axilla and groin (see Figure 28.21). The spleen, the largest lymphoid organ, is in the upper left quadrant of the abdomen under the thorax. The main function of the spleen is to filter the blood by breaking down old red blood cells and storing or releasing to the liver their by-products (such as iron). The spleen also synthesises lymphocytes, stores platelets for blood clotting and serves as a reservoir of blood. The thymus gland is in the lower throat and is most active in childhood, producing hormones (such as thymosin) that facilitate the immune action of lymphocytes. The tonsils of the pharynx and Peyer's patches of the small intestine are lymphoid organs that protect the upper respiratory and digestive tracts from foreign pathogens.

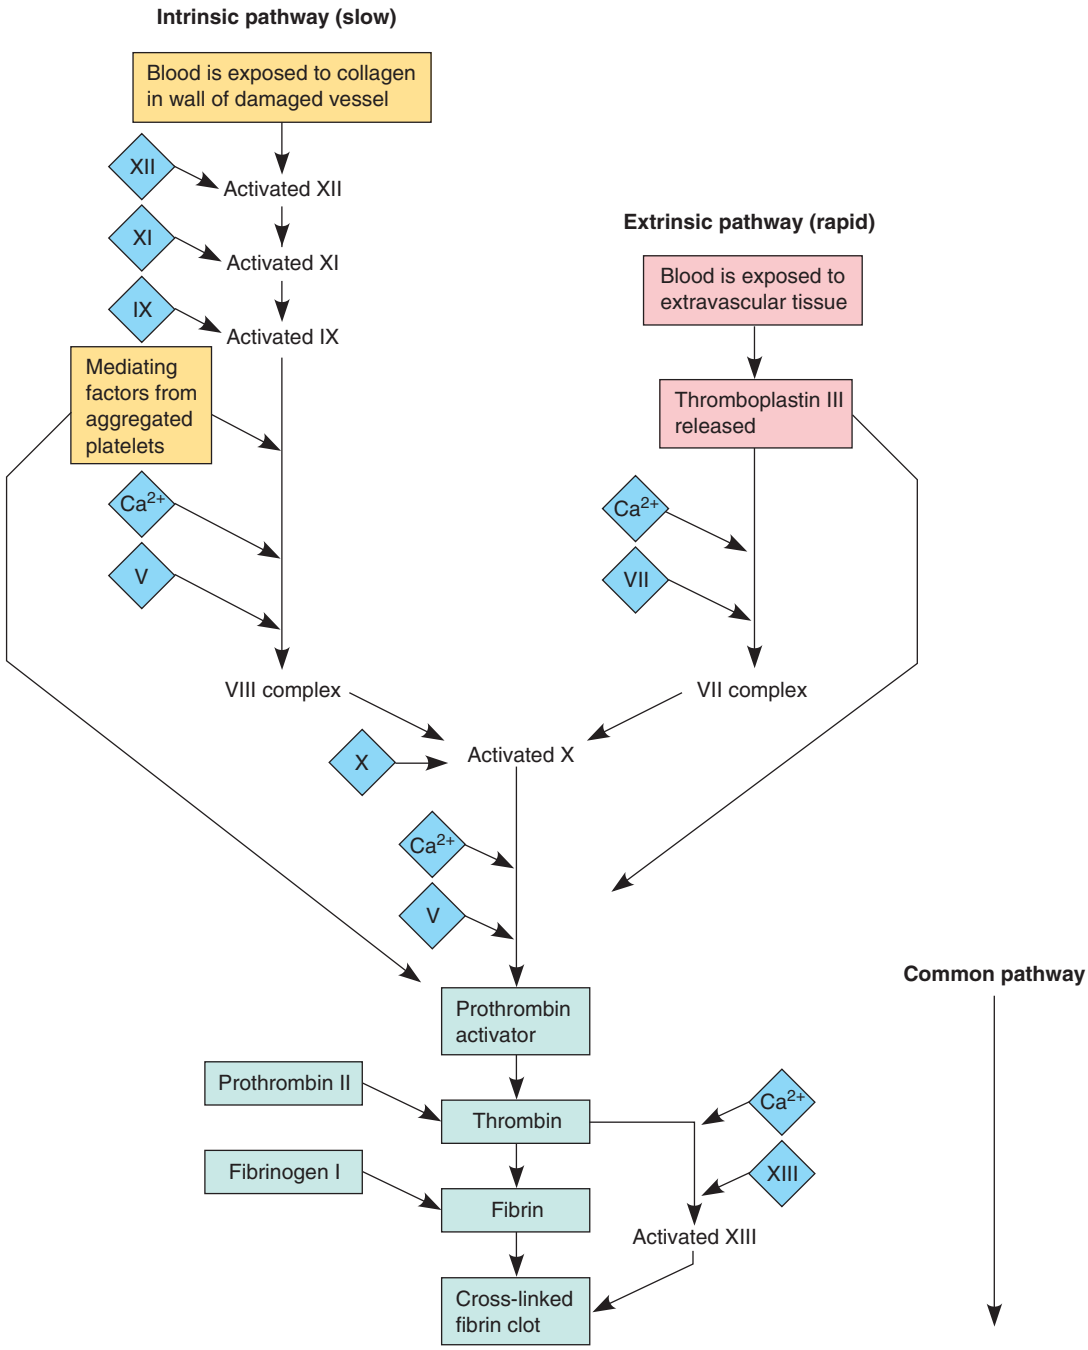

FIGURE 28.20 ■ Clot formation. Both the slower intrinsic pathway and the more rapid extrinsic pathway activate factor X. Factor X then combines with other factors to form prothrombin activator. Prothrombin activator transforms prothrombin into thrombin, which then transforms fibrinogen into long fibrin strands. Thrombin also activates factor XIII, which draws the fibrin strands together into a dense meshwork. The complete process of clot formation occurs within 3 to 6 minutes after blood vessel damage

The lymphatic vessels, or lymphatics, form a network around the arterial and venous channels and interweave at the capillary beds. They collect and drain excess tissue fluid, called *lymph*, that 'leaks' from the cardiovascular system and accumulates at the venous end of the capillary bed. The lymphatics return this fluid to the heart through a one-way system of lymphatic venules and veins that eventually drain into the right lymphatic duct and left thoracic duct, both of which empty into their respective subclavian veins. Lymphatics are a low-pressure system without a pump; their fluid transport depends on the rhythmic contraction of their smooth muscle and the muscular and respiratory pumps that assist venous circulation.

TABLE 28.2 Blood coagulation factors

FACTOR	NAME	FUNCTION OR PATHWAY
I	Fibrinogen	Converted to fibrin strands
II	Prothrombin	Converted to thrombin
III	Thromboplastin	Catalyses conversion of thrombin
IV	Calcium ions	Needed for all steps of coagulation
V	Proaccelerin	Extrinsic/intrinsic pathways
VI	Derived from proaccelerin	A hypothetical agent said to be derived from proaccelerin
VII	Serum prothrombin conversion accelerator	Extrinsic pathway
VIII	Antihaemophilic factor	Intrinsic pathway
IX	Plasma prothrombin component	Intrinsic pathway
X	Stuart factor	Extrinsic/intrinsic pathways
XI	Plasma prothrombin antecedent	Intrinsic pathway
XII	Hageman factor	Intrinsic pathway
XIII	Fibrin stabilising factor	Cross-links fibrin strands to form insoluble clot

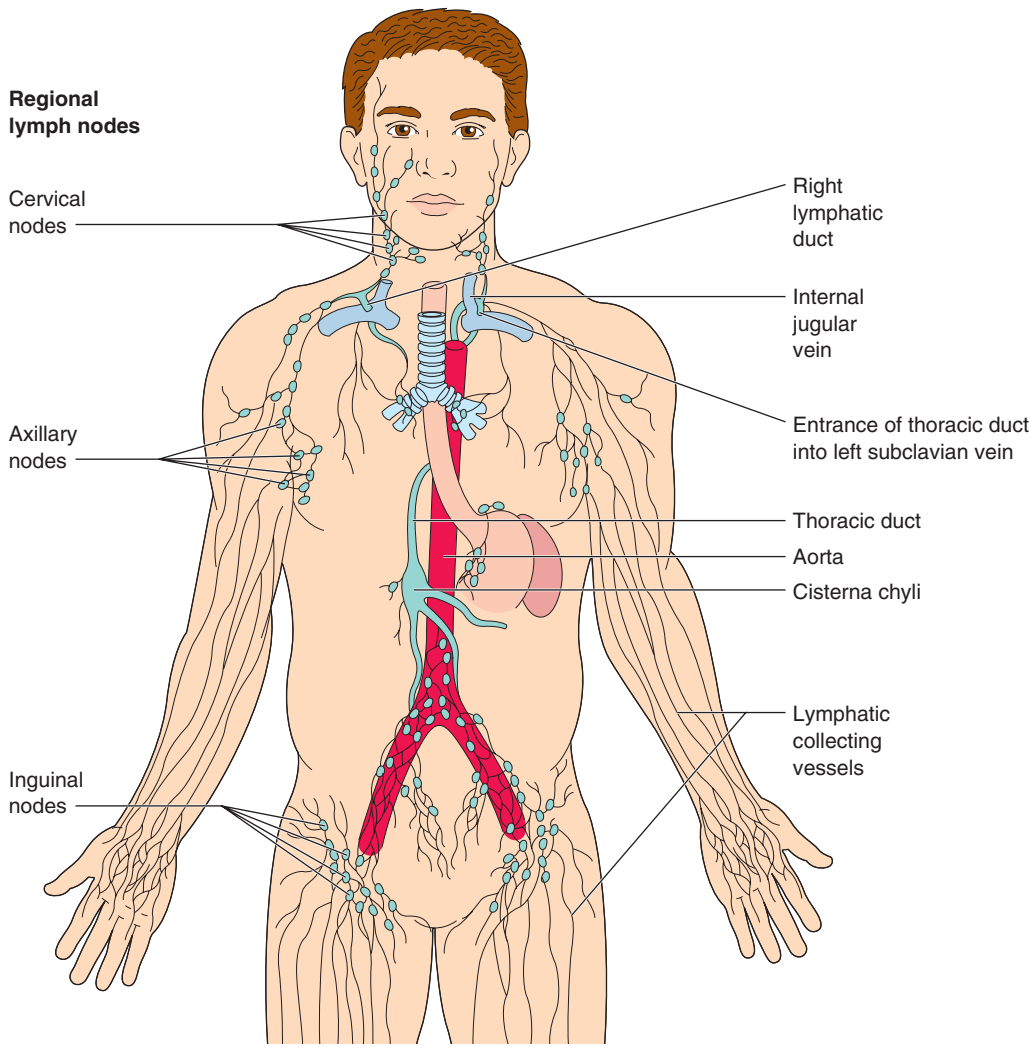

FIGURE 28.21 ■ The lymphatic system

HEALTH ASSESSMENT AND DOCUMENTATION

Cardiovascular, haematological and lymphatic function is assessed by findings from a health assessment interview to collect subjective data, a physical assessment to collect objective data and diagnostic tests. Consideration of all the data which contributes to understanding a person's absolute cardiovascular disease risk (CVD) should be considered. The National Vascular Disease Prevention Alliance has produced comprehensive guidelines to assist clinicians with assessment of CVD risk. Sample documentation of an assessment of cardiovascular function is included in the boxes below.

Health assessment interview

A health assessment interview to determine problems with the structure and functions of the cardiovascular and/or lymphatic systems may be conducted during a health screening, may focus on a chief complaint (such as chest pain, fatigue and bleeding) or may be part of a total health assessment.

If the person has a problem with cardiovascular or lymphatic function, analyse its onset, characteristics, course, severity, precipitating and relieving factors, and any associated symptoms, noting the timing and circumstances. For example, ask the person:

- What is the location of the chest pain you experienced? Did it move up to your jaw or into your left arm?
- Describe the type of activity that brings on your chest pain.
- Have you noticed any changes in your energy level?
- Have you felt light-headed during the times your heart is racing?
- Have you noticed any glands that are sore and swollen? What do you think causes this?

The interview begins by exploring the person's chief complaint (e.g. chest pain, palpitations or fatigue). Describe the person's chest or leg pain in terms of location, quality or character, timing, setting or precipitating factors, severity, aggravating and relieving factors, and associated symptoms (see Table 28.3).

Explore the person's history for heart disorders such as angina, heart attack, congestive heart failure (CHF), hypertension (HTN) and valvular disease. Ask the person about previous heart surgery or illnesses, such as rheumatic fever, scarlet fever or recurrent streptococcal throat infections. Also ask about the presence and treatment of other chronic illnesses such as diabetes mellitus, bleeding disorders or endocrine disorders. Review the person's family history for coronary artery disease (CAD), HTN, stroke, hyperlipidaemia, diabetes, congenital heart disease or sudden death.

Ask the person about past or present occurrence of various cardiac symptoms, such as chest pain, shortness of breath, difficulty breathing, cough, palpitations, fatigue, light headedness or dizziness, fainting, heart **murmur**, blood clots or swelling. Because cardiac function affects all other body systems, a full history may need to explore other related systems, such as respiratory function and/or peripheral vascular function.

Review the person's personal habits and nutritional history, including body weight; eating patterns; dietary intake of fats, salt, fluids; dietary restrictions; hypersensitivities or intolerances to food or medication; and the use of caffeine and alcohol. If the person uses tobacco/nicotine products, ask about type

SAMPLE DOCUMENTATION
Assessment of altered cardiac function

28/2/2016 Nursing entry 1000 hrs	56-year-old male admitted to a coronary care unit from ED to rule out myocardial infarction. He states he has pain in the middle of his chest that is 'like a heavy pressure'; 6 on a 10-point scale. Skin cool, slightly moist. BP 190/94 right arm and 186/92 left arm (both reclining). Apical pulse 92, regular and strong. No pulse deficit. Respirations 28. Apical impulse non-palpable, no visible heaves or thrusts. S_1 and S_2 auscultated without murmurs or clicks. S_4 noted. ——————————— RN Peres (S PERES RN)

SAMPLE DOCUMENTATION
Assessment of the peripheral vascular system

28/2/2016 Nursing entry 1100hrs	Mr Alex Fraser is a 57 year old with medical history of type 1 diabetes for 15 years. Mr Fraser states he has smoked cigars for 20 years (1/day), but 'knows he shouldn't'. And that he 'can't walk more than 20 steps without pain in his legs and sometimes has pain in his feet at night'. Mr Fraser also admits to not adhering to a regular regimen of BGLs TDS and takes his insulin when he remembers to. As Mr Fraser is a rural fencing contractor, his symptoms are preventing him from carrying out his work. Pulses in lower extremities (dorsalis pedis, posterior tibial and popliteal): regular but weak. No bruits auscultated over femoral arteries. When legs elevated and then lowered, the skin was pale on elevation and dusky red when dependent in the sitting position with lower legs dangling. Skin on both lower extremities from knees to toes is cool, shiny and hairless. Capillary refill of toenails (which are thickened) on great toe is 6 seconds bilaterally. No ankle or tibial oedema. assessed.——————————— ——————————— ——————————— RN Peres (S PERES RN)

LINKS TO NATIONAL PATIENT SAFETY STANDARDS

NSQHS Standard 9:
Recognising and Responding to Clinical Deterioration in Acute Health Care

'The intention of this standard is to ensure a patient's deterioration is recognised promptly, and appropriate action is taken.' (ACSQHC, 2011, p. 60)

Implementing this standard is achieved by the establishment of systems to assist with recognition, initiating appropriate responses and ensuring meaningful and appropriate communication between all individuals involved in a person's care (including patients, families and carers).

Comprehensive and ongoing assessment of a person's cardiovascular system function should be undertaken and documented as frequently as clinically necessary to facilitate rapid, responsive action in the event of a person's deterioration.

Source: © Australian Commission on Safety and Quality in Health Care.

TABLE 28.3 Assessing chest pain (OLDCART)

CHARACTERISTIC	EXAMPLES
Onset	Onset: Sudden or gradual?
	Awake, at rest, sleep interrupted?
	With activity? With eating, exertion, exercise, elimination, emotional upset?
Location	Where is the pain?
	(Substernal, precordial, jaw, back)
	Is the pain localised or diffuse?
Duration	How many minutes does the pain last?
Characteristics	Pressure; tightness; stabbing; crushing, burning or aching quality; heaviness; dullness; 'heartburn' or indigestion
	Can range from 0 (no pain) to 10 (worst pain ever felt)
	Is the pain continuous or periodic?
	Is it worse with a deep breath?
	Is it worse with temperature change?
Associated symptoms	Fatigue, shortness of breath, palpitations, nausea and vomiting, sweating, anxiety, light headedness or dizziness
Relieving factors	What has been done to try to relieve the pain? Medication (glyceryl trinitrate (GTN), antacid), repositioning, rest; there may be no relieving factors
Treatment	What can be done further to relieve the pain? Rest; position; oxygen; medication (GTN, morphine)

(cigarettes, patches, pipe, cigars, snuff), duration, amount and efforts to quit. If the person uses street drugs, ask about type, method of intake (e.g. inhaled or injected), duration of use and efforts to quit. Include questions about the person's activity level and tolerance, recreational activities and relaxation habits. Assess the person's sleep patterns for interruptions in sleep due to dyspnoea, cough, discomfort, urination or stress. Ask how many pillows the person uses when sleeping.

Also consider psychosocial factors that may affect the person's stress level:

- What is the person's marital status, family composition and role within the family?
- Have there been any changes?
- What is the person's occupation, level of education and socioeconomic level?
- Are resources for support available?
- What is the person's emotional disposition and personality type?
- How does the person perceive their state of health or illness, and how able is the person to comply with treatment?

See the 'Functional health pattern interview' box below for a list of interview questions categorised by functional health patterns.

Diagnostic tests of the cardiovascular and lymphatic systems

The results of diagnostic tests of cardiovascular and lymphatic function are used to support the diagnosis of a specific disease, to provide information to identify or modify the appropriate medications or therapy used to treat the disease and to help nurses monitor the person's responses to treatment and nursing care interventions. Diagnostic tests to assess the structures and functions of the heart are described below and summarised in the following bulleted list. More information is included in the discussion of specific disorders in Chapters 29 and 30.

- The primary test used to identify the risk of coronary artery disease or to monitor treatment for alterations in lipid levels is a measurement of lipid components of cholesterol, triglycerides and lipoproteins in the blood.
- Non-invasive tests of cardiac structure and function include a chest x-ray and stress/exercise tests. The treadmill test is the most basic exercise test, with diagnostic ability to measure cardiac perfusion enhanced by administering IV radioisotopes during the test. A treadmill exercise test is often combined

FUNCTIONAL HEALTH PATTERN INTERVIEW Cardiovascular, haematological and lymphatic systems

FUNCTIONAL HEALTH PATTERN	INTERVIEW QUESTIONS AND LEADING STATEMENTS
Health perception–Health management	■ Have you ever had any problems with your heart, such as angina (pain), heart attack or disease of the valves? If so, describe. What was used to treat these problems? ■ Describe any problems you have had with bleeding, bruising, swollen glands and circulation (e.g. heart disease, hardening of the arteries, high blood pressure, stroke, clots, high cholesterol). ■ Have you been diagnosed with high blood pressure? If so, how is it treated? ■ Have you had your cholesterol checked recently? What is it? If you have high cholesterol, how is it treated? ■ Have you ever been diagnosed with a health problem involving the blood, heart, blood vessels or lymph glands? If so, what were they and how were they treated? ■ Is there a family history of bleeding, cancer or anaemia? Explain. ■ What medications, vitamins, dietary supplements, complementary theories or over-the-counter drugs do you take now? ■ Do you, or have you ever, smoked? If so, what, for how long and how many a day?
Nutritional–Metabolic	■ Describe your usual intake of food and fluids in a 24-hour period. ■ Do you drink coffee, tea, cola or other caffeinated drinks? If so, how much? ■ Do you drink alcohol? If so, what type, how much and how often? ■ Describe how much salt you use on your food. ■ Describe what type of fatty foods you eat. How often? ■ Have you had a recent weight gain or loss? Explain. ■ Have you noticed any change in the colour, temperature or appearance of the skin on your arms, hands, legs or feet? If so, what were they? ■ Have you noticed any glands that are sore and swollen? What do you think causes this? ■ Have you noticed an increase in the time it takes your blood to clot if you cut yourself or how easily you bruise? ■ Have you noticed loss of hair, bulging veins, sores that will not heal on your legs or thicker toenails? Have you ever worn support stockings? ■ Do your feet ever swell or your shoes feel tight? If so, when does this happen and what do you do to decrease the swelling?
Elimination	■ Has a health problem interfered with your usual bowel and bladder movements? Explain. ■ Have your bowel movements been a dark black colour?
Activity–Exercise	■ Has there been any change in your ability, energy or strength to perform your usual activities (such as bathing, housework, gardening, shopping)? If so, explain. ■ Describe your activities in a typical day. ■ Do you exercise regularly? Describe what you do when you exercise. ■ Have your activities or exercise abilities changed? If so, explain. ■ Do you notice shortness of breath with certain activities? If so, what are they? How long does this last? What do you do to breathe better? ■ Do you have leg pain when you walk? If so, where is it located? How far do you walk before you have pain? Describe the pain. What do you do to relieve it? ■ Do you ever have to stop and rest while doing daily activities? Explain. ■ Do you feel tired even after sleep and rest? Describe the feeling.

FUNCTIONAL HEALTH PATTERN	INTERVIEW QUESTIONS AND LEADING STATEMENTS
Sleep–Rest	■ How much rest and sleep do you get each day? ■ Does your health problem interfere with your ability to sleep and rest? Explain. ■ Do leg cramps ever wake you at night? If so, describe the pain and what you do to relieve it. ■ Have you experienced any numbness or tingling, dizziness or light headedness, or palpitations? Describe if so. ■ Do you ever feel short of breath while you are resting or sleeping? Does this wake you up if so? Explain.
Cognitive–Perceptual	■ Describe any chest pain you have experienced. When did it occur? Where was it located? On a scale of 0 to 10, with 10 being the worst pain you have ever had, rate the pain and describe it (for example, burning, crushing, stabbing, squeezing, heavy, tight). ■ Did you have any other symptoms with the pain, such as nausea or vomiting, sweating, racing heart, pale skin, palpitations? ■ What made the pain worse? What did you do to try to relieve the pain? Did that work? ■ Do you have any of these sensations in your legs or feet: pain, cramps, burning, numbness, tingling? ■ If you have these sensations, when do they occur, how long do they last and what do you do to relieve them?
Self-perception–Self-concept	■ How does having this health problem make you feel about yourself?
Role–Relationships	■ How has having this health problem affected your relationships with others? ■ Has having this health problem interfered with your ability to work? Explain. ■ Does your work environment bring you into contact with any chemicals? Describe them.
Sexuality–Reproductive	■ Has this condition interfered with your usual sexual activity? ■ Have you ever had chest pain during sexual activity? What do you do for it? ■ *For women:* Have you noticed any changes in your menstrual cycle? (*For older women:* Have you gone through menopause?) If so, describe them.
Coping–Stress–Tolerance	■ Has having this condition created stress for you? ■ Have you experienced any kind of stress that makes the condition worse? Explain. ■ Describe what you do when you feel stressed.
Value–Belief	■ Describe how specific relationships or activities help you cope with this problem. ■ Describe specific cultural beliefs or practices that affect how you care for and feel about this problem. ■ Are there any specific treatments (such as blood transfusions) that you would not use to treat this problem?

with other tests to evaluate cardiac function under stress. The exercise thallium or technetium test is probably the most useful non-invasive test to monitor and diagnose CAD.

- Abnormal areas of the heart may be identified and evaluated by an MRI to locate areas of myocardial infarction, a CT scan to quantify calcium deposits in coronary arteries, or a positron emission tomography (PET) test to evaluate myocardial perfusion and myocardial metabolic function.
- Echocardiograms (ECGs) are conducted in conjunction with Dopplers and colour flow imaging to produce audio and graphical data about the motion, wall thickness and chamber size of the heart, and of the blood flow and velocity.
- A transoesophageal echocardiogram (TOE) allows visualisation of structures adjacent to the oesophagus to visualise cardiac and extracardiac structures, including mitral valve and aortic valve pathology, left atrium intracardiac thrombosis, acute dissection of the aorta, endocarditis, and ventricular function during and after surgery.
- A cardiac catheterisation with coronary angiography may be performed to identify CAD or cardiac valvular disease,

to determine pulmonary artery or heart chamber pressures, to obtain a myocardial biopsy, to evaluate artificial valves, or to perform angioplasty or stent of an area of CAD.

- Pericardiocentesis is a procedure done to remove fluid from the pericardial sac for diagnostic or therapeutic purposes. It may also be an emergency procedure to treat cardiac tamponade.
- A physical assessment of the lymphatic system includes specific problems such as lymph node enlargement or swollen glands, as well as other more general complaints about infection or impaired immunity.

Regardless of the type of diagnostic test, the nurse is responsible for explaining the procedure and any special preparation needed, for assessing for medication use that may affect the outcome of the tests, for supporting the person during the examination as necessary, for documenting the procedures as appropriate and for monitoring the results of the tests.

DIAGNOSTIC TESTS Cardiac disorders

NAME OF TEST Lipids

PURPOSE AND DESCRIPTION Blood lipids are cholesterol, triglycerides, and phospholipids. They circulate bound to proteins, and so are known as lipoproteins. Lipids are measured to evaluate risk of CAD and to monitor effectiveness of anti-cholesterol medications.

Normal values:
Cholesterol: 140–200 mg/dL
Triglycerides: 40–190 mg/dL
HDL: Men = 537–70 mg/dL
Women = 540–88 mg/dL
LDL: < 130 mg/dL
(*Note:* Normal values may vary by laboratory.)

RELATED NURSING CARE Cholesterol levels alone may be measured at any time of the day, regardless of food or fluid intake. When measuring triglycerides and lipoproteins (HDL and LDL), fasting for 12 hours (except for water) with no alcohol intake for 24 hours prior to the test is recommended.

NAME OF TEST Electrocardiogram (ECG)

PURPOSE AND DESCRIPTION See Boxes 28.1 and 28.2.

RELATED NURSING CARE No special preparation is needed.

NAME OF TEST Chest x-ray

PURPOSE AND DESCRIPTION An x-ray of the thorax can illustrate the contours, placement and chambers of the heart. It may be done to identify heart displacement or hypertrophy, or fluid in the pericardial sac.

RELATED NURSING CARE No special preparation is needed.

NAME OF TEST Stress/exercise tests

- Treadmill test

PURPOSE AND DESCRIPTION Stress testing is based on the theory that CAD results in depression of the ST segment with exercise. Depression of the ST segment and depression or inversion of the T wave indicates myocardial ischaemia. When the person is walking on a treadmill machine, the work rate of the heart is changed every 3 minutes for 15 minutes by increasing the speed and degree of incline by 3% each time. People exercise until they are fatigued, develop symptoms or reach their maximum predicted heart rate.

RELATED NURSING CARE *For all stress/exercise tests:* Ask the person to wear comfortable shoes, and to avoid food, fluids and smoking for 2 to 3 hours before the test. Assess for events that contraindicate the tests: recent myocardial infarction; severe, unstable angina; controlled arrhythmias; congestive heart failure or recent pulmonary embolism.

NAME OF TEST Thallium/technetium stress test (Myocardial perfusion scan, Cardiac blood pool imaging)

PURPOSE AND DESCRIPTION *Thallium stress test:* Thallium-201, a radioisotope that accumulates in myocardial cells, is used during the stress test to evaluate myocardial perfusion. Second scans are done 2 to 3 hours later when the heart is at rest; this is to differentiate between an ischaemic area and an infarcted or scarred area of myocardium.

Exercise technetium perfusion test: Technetium-99m-laced compounds are administered and a scan is done to evaluate cardiac perfusion, wall motion and ejection fraction. This is probably the most useful non-invasive test to diagnose and monitor CAD.

RELATED NURSING CARE Assess medications; those that affect the blood pressure or heart rate should be discontinued for 24 to 36 hours prior to the test (unless the test is being done to monitor the effectiveness of the medications).

NAME OF TEST Nuclear persantin (dipyridamole) stress test (Myocardial perfusion scan)

PURPOSE AND DESCRIPTION This test is used when the person is not physically able to walk on the treadmill. Persantin, given IV, dilates the coronary arteries and increases myocardial blood flow. Coronary arteries that are narrowed from CAD cannot dilate to increase myocardial perfusion.

RELATED NURSING CARE Person is nil by mouth (NBM) after midnight except for water. Food, fluids and drugs that contain caffeine should be avoided for 24 hours prior to the test, as should decaffeinated fluids. Some drugs, such as theophylline preparations, are discontinued for 36 hours prior to the test.

DIAGNOSTIC TESTS Cardiac disorders (continued)

NAME OF TEST Nuclear dobutamine stress test

PURPOSE AND DESCRIPTION Dobutamine is an adrenergic drug that increases myocardial contractility, heart rate and systolic blood pressure, which increases coronary oxygen consumption and thus increases coronary blood flow.

RELATED NURSING CARE Person is NBM after midnight except for water. Discontinue beta-blockers, calcium channel blockers and ACE inhibitors for 36 hours prior to the test. Do not administer nitrates for 6 hours prior to the test.

NAME OF TEST Magnetic resonance imaging (MRI)

PURPOSE AND DESCRIPTION An MRI may be used to identify and locate areas of myocardial infarction.

RELATED NURSING CARE Assess for any metallic implants (such as pacemaker, body piercing or artificial joint), which would contraindicate the test.

NAME OF TEST Computed tomography (CT) scan

PURPOSE AND DESCRIPTION A CT scan may be conducted to quantify calcium deposits in coronary arteries.

RELATED NURSING CARE Assess for allergy to iodine or seafood if contrast medium is to be administered.

NAME OF TEST Cardiolite—technetium-99m sestamibi (Myocardial perfusion scan)

PURPOSE AND DESCRIPTION Used to evaluate blood flow in different parts of the heart. Cardiolite (technetium-99m sestamibi) is injected IV. In a dipyridamole cardiolite scan, dipyridamole (Persantin) is injected to increase blood flow to coronary arteries. These scans may be done in conjunction with a treadmill test.

RELATED NURSING CARE As for stress/exercise tests, above. Instruct the person to avoid intake of caffeine for 12 hours before having a test with dipyridamole cardiolite.

NAME OF TEST Positron emission tomography (PET)

PURPOSE AND DESCRIPTION Two scans are performed following injection of radionuclides, and the resulting images compared for myocardial perfusion and myocardial metabolic function. A stress test (treadmill) may be a part of the test. If the myocardium is ischaemic or damaged, the images will be different. Normally, the images will be the same.

RELATED NURSING CARE Assess person's blood glucose: for accurate metabolic activity images, the blood glucose level must be between 60 and 140 mg/dL. If exercise is included in the test, the person will need to be NBM and avoid smoking and caffeine for 24 hours prior to the test.

NAME OF TEST Blood pool imaging

PURPOSE AND DESCRIPTION Following intravenous injection of technetium-99m pertechnetate, sequential evaluation of the heart can be performed for several hours. Useful for evaluation of cardiac status following myocardial infarction and congestive heart failure and assessing effectiveness of cardiac medications. Can be done at the person's bedside.

RELATED NURSING CARE No special preparation is needed. Following the procedure, explain that the dose if very low and the biological elimination of the technetium-99m is virtually complete by 6 hours. It is best to refrain from breastfeeding during this time.

NAME OF TEST Echocardiogram

- M-mode
- Two-dimensional (2-D)
- Cardiac Doppler
- Colour Doppler
- Stress echocardiogram

PURPOSE AND DESCRIPTION Echocardiograms use a transducer to record waves that are bounced off the heart, and to record the direction and flow of blood through the heart in audio and graphical data. An *M-mode (motion-mode) echocardiogram* records the motion, wall thickness and chamber size of the heart. A *2-D echocardiogram* provides a cross-sectional view of the heart. *Colour flow imaging* combines 2-D echocardiography and Doppler technology to evaluate the speed and direction of blood flow through the heart, which can identify pathology such as leaky valves. *Stress echocardiography* combines a treadmill test with ultrasound images to evaluate segmental function and wall motion. If the person is not physically able to exercise, IV dobutamine may be administered and ultrasound images taken.

RELATED NURSING CARE No special preparation is needed; see related nursing care for the person having a treadmill test for a stress echocardiogram.

NAME OF TEST Transoesophageal echocardiography (TOE)

PURPOSE AND DESCRIPTION Allows visualisation of adjacent cardiac and extracardiac structures to identify or monitor mitral and aortic valve pathology, left atrium intracardiac thrombus, acute dissection of the aorta, endocarditis, perioperative left ventricular function and intracardiac repairs during surgery. A transducer (probe) attached to an endoscope is inserted into the oesophagus and images are taken. Concurrent IV contrast medium, Doppler ultrasound and colour flow imaging may be used.

(continued)

DIAGNOSTIC TESTS Cardiac disorders (continued)

RELATED NURSING CARE A light sedative is often used and a local anaesthetic is applied to the oropharynx. It is important to ensure airway patency during this time. If constrast medium is to be administered, assess for allergy to iodine or seafood.

Following the procedure, explain that it may be difficult to swallow for a few hours and may be uncomfortable to swallow for a few days.

NAME OF TEST Cardiac catheterisation (Coronary angiography, Coronary arteriography)

PURPOSE AND DESCRIPTION A cardiac catheterisation may be performed to identify CAD or cardiac valvular disease, to determine pulmonary artery or heart chamber pressures, to obtain a myocardial biopsy, to evaluate artificial valves, or to perform angioplasty or stent an area of CAD. The test is performed by inserting a long catheter into a vein or artery (depending on whether the right side or the left side of the heart is being examined) in the arm or leg. Using fluoroscopy, the catheter is then threaded to the heart chambers or coronary arteries, or both. Contrast dye is injected and heart structures are visualised and heart activity is filmed. The test is done for diagnosis and before heart surgery.

Right cardiac catheterisation: The catheter is inserted into the femoral vein or antecubital vein and then threaded through the inferior vena cava into the right atrium to the pulmonary artery. Pressures are measured at each site, and blood samples can be obtained for the right side of the heart. The functions of the tricuspid and pulmonary valves can be observed.

Left cardiac catheterisation: The catheter is inserted into the brachial or femoral artery and advanced retrograde through the aorta to the coronary arteries and/or left ventricle. The patency of the coronary arteries and/or functions of the aortic and mitral valves and left ventricle can be observed.

RELATED NURSING CARE See 'Nursing care' box following.

NAME OF TEST Pericardiocentesis

PURPOSE AND DESCRIPTION This procedure is performed to remove fluid from the pericardial sac for diagnostic or therapeutic purposes. It may also be done as an emergency procedure for the person with cardiac tamponade (which may result in death). A large-gauge (16 to 18) needle is inserted to the left of the xiphoid process into the pericardial sac and excess fluid is withdrawn (see Figure 28.22). The needle is attached to an ECG lead to help determine if the needle is touching the epicardial surface, thus preventing piercing of the myocardium.

RELATED NURSING CARE See 'Nursing care' box following.

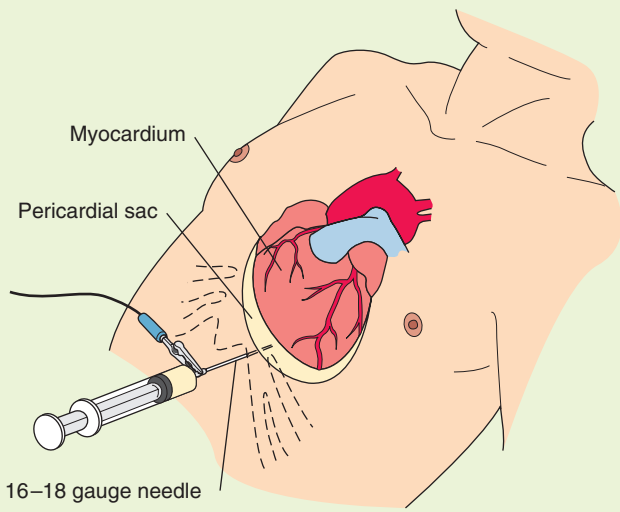

FIGURE 28.22 ■ Pericardiocentesis

BOX 28.1 Electrocardiogram

The *electrocardiogram (ECG)* is a graphical record of the heart's electrical activity. Electrodes applied to the body surface are used to obtain a graphical representation of cardiac electrical activity. These electrodes detect the magnitude and direction of electrical currents produced in the heart. They attach to the electrocardiograph by an insulated wire called a *lead*. The electrocardiograph converts the electrical impulses it receives into a series of waveforms that represent cardiac depolarisation and repolarisation. Placement of electrodes on different parts of the body allows different views of this electrical activity, much like turning the head while holding a camera provides different views of the scenery. ECG waveforms and patterns are examined to detect arrhythmias as well as myocardial damage, the effects of drugs and electrolyte imbalances.

ECG waveforms reflect the direction of electrical flow in relation to a positive electrode. Current flowing towards the positive electrode produces an upward (positive) waveform;

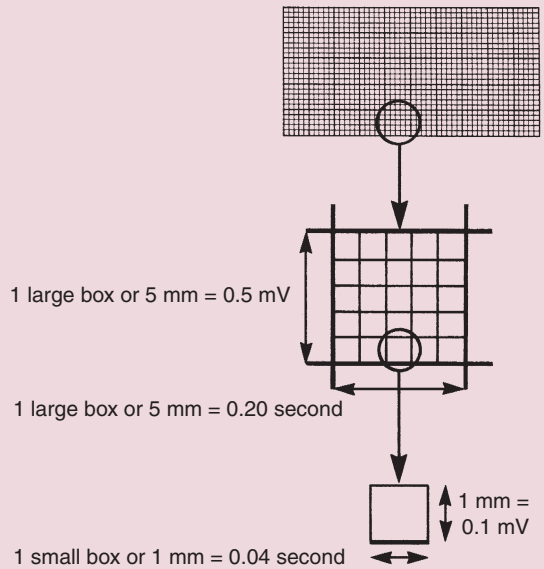
BOX 28.1 Electrocardiogram (continued)

current flowing away from the positive electrode produces a downward (negative) waveform. Current flowing perpendicular to the positive pole produces a biphasic (both positive and negative) waveform. Absence of electrical activity is represented by a straight line called the *isoelectric line*.

ECG waveforms are recorded by a heated stylus on heat-sensitive paper. The paper is marked at standard intervals that represent time and voltage or amplitude (see Figure 1). Each small box is 1 mm^2. The recording speed of the standard ECG is 25 mm/second, so each small box represents 0.04 second. Five small boxes horizontally and vertically make one large box, equivalent to 0.20 second. Five large boxes represent 1 full second. Measured vertically, each small box represents 0.1 mV.

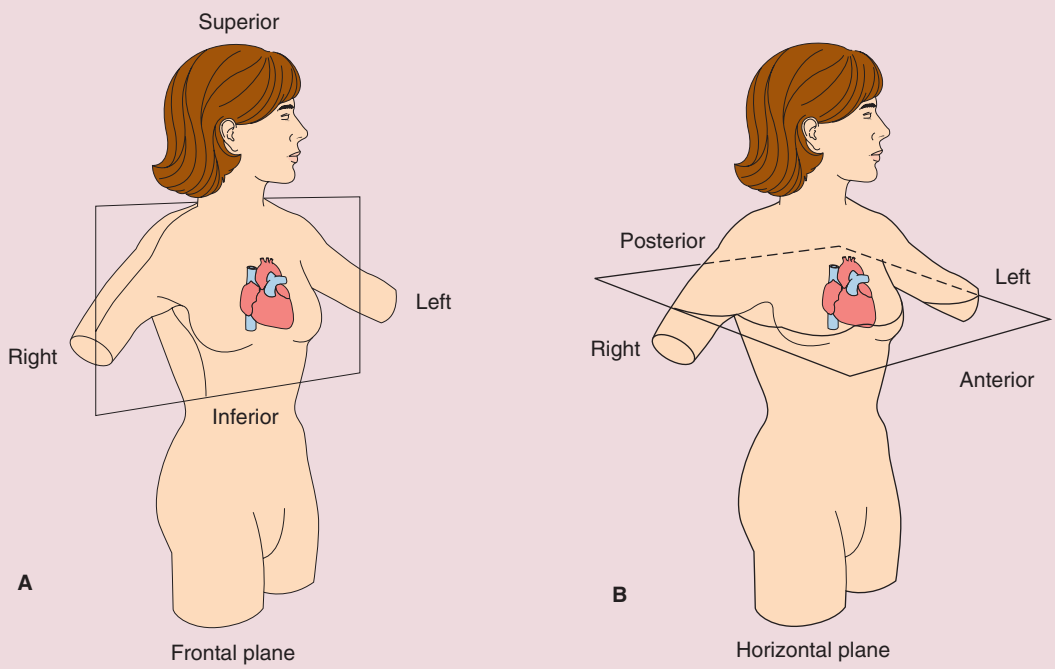
Both bipolar and unipolar leads are used in recording the ECG. A bipolar lead uses two electrodes of opposite polarity (negative and positive). In a *unipolar* lead, one positive electrode and a negative reference point at the centre of the heart are used. The electrical potential between the two monitoring points is graphically recorded as the ECG waveform.

The heart can be viewed from both the frontal plane and the horizontal plane (see Figure 2). Each plane provides a unique perspective of the heart muscle. The frontal plane is an imaginary cut through the body that views the heart from top to bottom (superior–inferior) and side to side (right–left). This perspective of the heart is analogous to a paper doll cut-out. It provides information about the inferior and lateral walls of the heart. The horizontal plane is a cross-sectional view of the heart from front to back (anterior–posterior) and side to side (right–left). Information regarding the anterior, septal and lateral walls of the heart, as well as the posterior wall, is obtained from this view.



(1) Time and voltage measurements on ECG paper at a recording speed of 25 mm/second

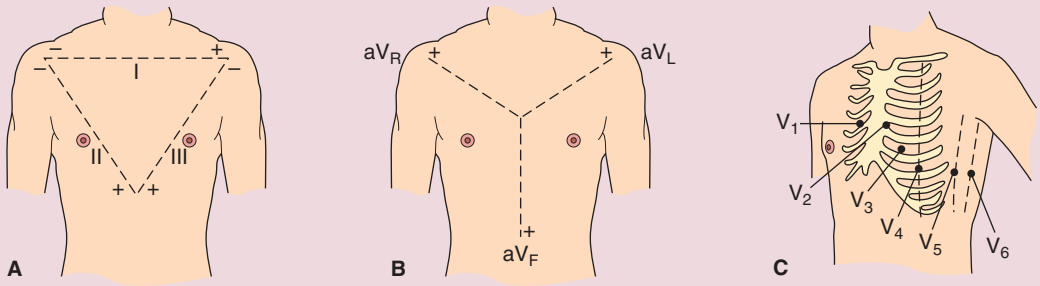
A standard 12-lead ECG provides a simultaneous recording of six limb leads and six precordial leads (see Figure 3). The limb leads provide information about the heart in the frontal plane and include three bipolar leads (I, II, III) and three unipolar leads (aV_R, aV_L and aV_F). The bipolar limb leads measure electrical activity between a negative lead on one extremity and a positive lead on another. The unipolar limb leads (called augmented leads) measure the electrical activity



(2) Planes of the heart. *A*, Frontal plane, *B*, Horizontal plane

(continued)

BOX 28.1 Electrocardiogram (continued)



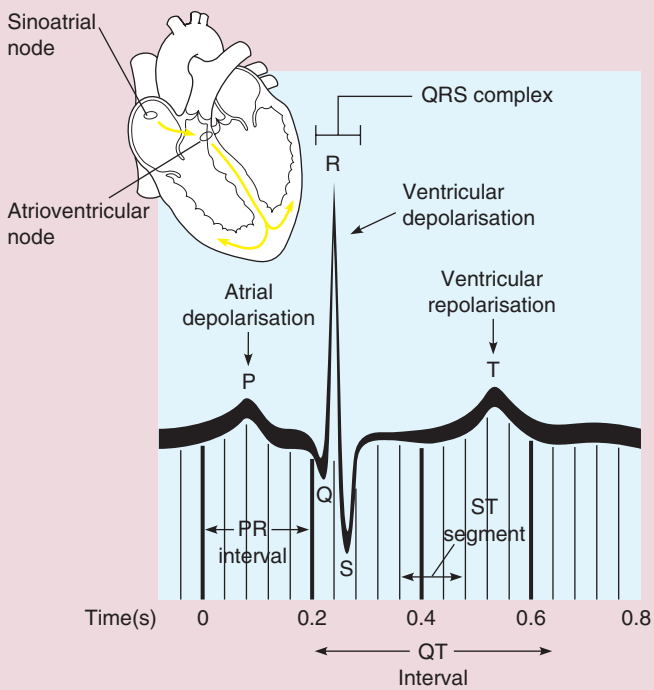
(3) Leads of the 12-lead ECG. *A*, Bipolar limb leads I, II, III; *B*, Unipolar limb leads aV_R, aV_L, aV_F; *C*, Unipolar precordial leads V_1 to V_6

between a single positive electrode on a limb (right arm (R), left arm (L) or left leg (F for foot)) and the centre of the heart.

The *precordial leads*, also known as chest leads or V leads, view the heart in the horizontal plane. They include six unipolar leads (V_1, V_2, V_3, V_4, V_5 and V_6), which measure electrical activity between the centre of the heart and a positive electrode on the chest wall.

The cardiac cycle is depicted as a series of waveforms, the P, Q, R, S and T waves (see Figure 4).

- The *P wave* represents atrial depolarisation and contraction. The impulse is from the sinoatrial (or sinus) node. The P wave precedes the QRS complex and is normally smooth, round and upright. P waves may be absent when the sinoatrial node is not acting as the pacemaker. Atrial repolarisation occurs during ventricular depolarisation and usually is not seen on the ECG.
- The *PR interval* represents the time required for the sinus impulse to travel to the atrioventricular node and into the Purkinje fibres. This interval is measured from beginning of P wave to beginning of QRS complex. If no Q wave is seen, the beginning of the R wave is used. The PR interval is normally 0.12 to 0.20 second. (Up to 0.24 second is considered normal in adults over age 65.) PR intervals greater than 0.20 second indicate a delay in conduction from the sinoatrial node to the ventricles.
- The *QRS complex* represents ventricular depolarisation and contraction. The QRS complex includes three separate waves: the Q wave is the first negative deflection, the R wave is the positive or upright deflection, and the S wave is the first negative deflection after the R wave. Not all QRS complexes have all three waves; nonetheless, the complex is called a QRS complex. The normal duration of a QRS complex is from 0.06 to 0.10 second. QRS complexes greater than 0.10 second indicate delays in transmitting the impulse through the ventricular conduction system.
- The *ST segment* signifies the beginning of ventricular repolarisation. The ST segment, the period from the end of the QRS complex to the beginning of the T wave, should be isoelectric. An abnormal ST segment is displaced (elevated or depressed) from the isoelectric line.
- The *T wave* represents ventricular repolarisation. It normally has a smooth, rounded shape that is usually less than 10 mm tall. It usually points in the same direction as the QRS complex. Abnormalities of the T wave may indicate myocardial ischaemia or injury or electrolyte imbalances.
- The *QT interval* is measured from the beginning of the QRS complex to the end of the T wave. It represents the total time of ventricular depolarisation and repolarisation. Its duration varies with gender, age and heart rate; usually, it is 0.32 to 0.44 second long. Prolonged QT intervals indicate a prolonged relative refractory period and a greater risk of arrhythmias. Shortened QT intervals may result from medications or electrolyte imbalances.
- The *U wave* is not normally seen. It is thought to signify repolarisation of the terminal Purkinje fibres. If present, the U wave follows the same direction as the T wave. It is most commonly seen in hypokalaemia.



(4) Normal ECG waveform and intervals

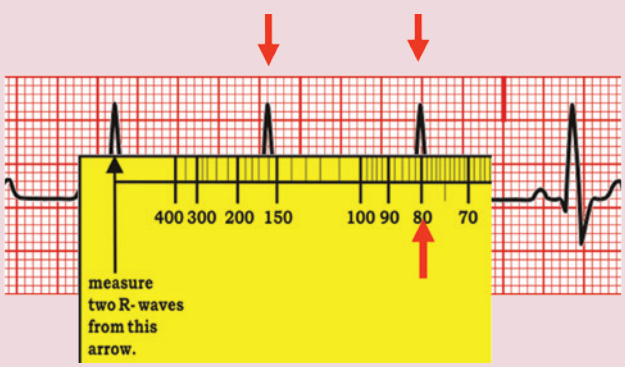
BOX 28.2 Interpreting an ECG

Interpreting an ECG strip to determine the cardiac rhythm is a skill that takes practice to learn and master. Many methods are used to analyse ECGs. It is important to use a consistent method for ECG analysis. Identifying and interpreting complex arrhythmias requires advanced skills and knowledge obtained through further training. One method follows.

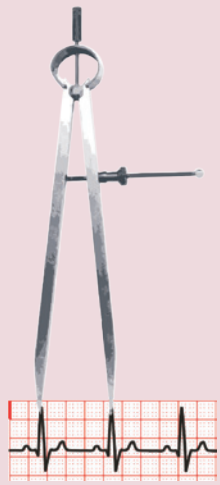
- **Step 1: Determine rate**. Assess heart rate. Use P waves to determine the atrial rate and R waves for the ventricular rate. Several approaches can be used to determine the heart rate.
  - Count the number of complexes in a 6-second rhythm strip (the top margin of ECG paper is marked at 3-second intervals) and multiply by 10. This provides an estimate of the rate and is particularly valuable if rhythms are irregular.
  - Count the number of large boxes between two consecutive complexes and divide 300 (the number of large boxes in 1 minute) by this number. For example, there are 6 large boxes between two R waves; 300 divided by 6 equals a ventricular rate of 50 bpm. Memorise the following sequence for rapid rate determination: 300, 150, 100, 75, 60, 50, 43. One large box between complexes equals a rate of 300; two, a rate of 150; three, a rate of 100; and so on.
  - Count the number of small boxes between two consecutive complexes and divide 1500 (the number of small boxes in 1 minute) by this number. For example, there are 19 small boxes between two R waves; 1500 divided by 19 equals a ventricular rate of 79 bpm. This is the most precise measurement of heart rate.
  - Use a commercially available rate ruler, following strictly the instructions on the device (see Figure 1).
- **Step 2: Determine regularity**. Regularity is the consistency with which the P waves or QRS complexes occur. In a regular rhythm, all waves occur at a consistent rate. Rhythm regularity is determined by measuring the interval between consecutive waves. Place one point of an ECG calliper (a measuring device) on the peak of the P wave (for atrial rhythm) or the R wave (for ventricular rhythm). Adjust the other point to the peak of the next wave, P to P or R to R (see Figure 2). Keeping the callipers set at this distance, evaluate intervals between consecutive waves. The rhythm is *regular* if all calliper points fall on succeeding wave peaks. Alternately, use a strip of blank paper on top of the ECG strip, marking the peaks of two or three consecutive waves. Then move the paper along the strip to consecutive waves. Wave peaks that vary by more than one to three small boxes (depending on the rate) are *irregular*. Irregular rhythms may be *irregularly irregular* (if the intervals have no pattern) or *regularly irregular* (if a consistent pattern to the irregularity can be identified).
- **Step 3: Assess P wave**. The presence or absence of P waves helps determine the origin of the rhythm. All the P waves should be alike in size and shape (*morphology*). If P waves are not seen or they differ in shape, the rhythm may not originate in the sinoatrial node.
- **Step 4: Assess P to QRS relationship**. Determine the relationship between P waves and QRS complexes. There should be one and only one P wave for every QRS complex, because the normal stimulus for ventricular contraction originates in the sinoatrial node.
- **Step 5: Determine interval durations**. To evaluate impulse transmission through the cardiac conduction system, measure the PR interval, QRS duration and QT interval. To measure, count the number of small boxes from the beginning of the interval to the end and multiply by 0.04 second. Then determine whether the interval duration is within its normal limits. For example, the PR interval is 3.5 small boxes wide, or 0.14 second. This is within the normal limits of 0.12 to 0.20 second. This interval should be consistent, not varying from beat to beat. A PR interval greater than 0.20 second or one that varies from beat to beat is abnormal.

  The QRS complex duration is normally between 0.06 and 0.10 second. A QRS complex greater than 0.12 second indicates delayed ventricular conduction.

  The QT interval is normally 0.32 to 0.44 second. It varies inversely with the heart rate: the faster the heart rate, the shorter the QT interval. As a general rule, the QT interval should be no more than half the previous R–R interval. A prolonged QT interval indicates a prolonged relative refractory period of the heart.
- **Step 6: Identify abnormalities**. Note the presence and frequency of ectopic (extra) beats, deviation of the ST segment above or below the baseline, and abnormalities in waveform shape and duration.



(1) Example of commercially available rate rule



(2) Use of callipers to determine rate

NURSING CARE OF THE PERSON having cardiac catheterisation

BEFORE THE PROCEDURE

- Explain the procedure to the person.
- No food or fluids are allowed for 6 to 8 hours before the test.
- Assess for allergies to seafood, iodine or iodine contrast dyes (if previous tests have been done). If an allergic response to the dye is possible, antihistamines (such as Benadryl) or steroids may be administered the evening before and the morning of the test.
- Assess for use of aspirin or NSAIDs (risk of bleeding), sildenafil (Viagra; risk of heart problems) or history of kidney disease (dye used may be toxic to the kidneys).
- Discontinue oral anticoagulant medications. Heparin may be ordered to prevent thrombi.
- An IV (with isotonic crystalloid solution) is started at a 'to-keep-vein-open' (TKVO) rate (in case intravenous access is needed for emergency drugs).
- Establish baseline of peripheral pulses.
- Take and record baseline vital signs.

PROCEDURE

- The person is positioned on a padded table that tilts. A local anaesthetic is used at the site of catheter insertion. ECG leads are applied and vital signs are monitored during the procedure. The person lies supine and is asked to cough and deep breathe frequently. The procedure takes ½ to 3 hours.
- Tell the person that a hot, flushing sensation may be felt for a minute or two when the dye is injected.

AFTER THE PROCEDURE

- Monitor vital signs every 15 minutes for the first hour and then every 30 minutes until stable. Assess cardiac rhythm and rate for alterations. Assess peripheral pulses distal to the insertion site.
- Assess the person for chest heaviness, shortness of breath, and abdominal or groin pain.
- Monitor catheter insertion site for bleeding or haematoma.
- Administer pain medications as prescribed.
- Instruct the person to remain on bed rest for 6 to 12 hours (or as ordered). If a collagen-like plug was inserted after removal of the catheter, only a 2- to 3-hour bed rest is necessary.
- Encourage oral fluids unless contraindicated (i.e. if the person has congestive heart failure).

NURSING CARE OF THE PERSON having pericardiocentesis

BEFORE THE PROCEDURE

- Gather all supplies:
  a. Pericardiocentesis tray
  b. ECG machine and electrode patches
  c. Emergency cart with defibrillator
  d. Dressing
  e. Culture bottles (if indicated).
- Reinforce teaching and answer questions about the procedure or associated care. Provide emotional support.
- Ensure that informed consent has been obtained.
- Provide for privacy.
- Obtain and document baseline vital signs.
- Connect the person to a cardiac monitor; obtain a baseline rhythm strip for comparison during and after the procedure.
- Connect the precordial ECG lead of the hub of the aspiration needle using an alligator clamp.

DURING THE PROCEDURE

- Follow standard precautions.
- Position seated at a 45- to 60-degree angle. Place a dry towel under the rib cage to catch blood or fluid leakage.
- Observe the ST segment for elevation and the ECG monitor for signs of myocardial irritability (PVCs) during the procedure. These indicate that the needle is touching the myocardium and should be withdrawn slightly.
- Notify the physician of changes in cardiac rhythm, blood pressure, heart rate, level of consciousness and urine output. These may indicate cardiac complications.
- Monitor central venous pressure (CVP) and blood pressure closely. As the effusion is relieved, CVP will decrease and BP will increase.

AFTER THE PROCEDURE

- Document the procedure and the person's response to and tolerance of the procedure.
- Continue to monitor vital signs and cardiac rhythm every 15 minutes during the first hour, every 30 minutes during the next hour, and every hour for the next 24 hours.
- Record the amount of fluid removed as output on the intake and output record.
- If indicated, send a sample of aspirated fluid for culture and sensitivity and laboratory analysis.
- Assess heart and breath sounds.

DIAGNOSTIC TESTS Haematological, peripheral vascular and lymphatic disorders

NAME OF TEST Full blood count (FBC)

PURPOSE AND DESCRIPTION This is a blood test involving several measurements of blood components. See Table 28.1.

RELATED NURSING CARE No special preparation is needed.

NAME OF TEST Erythrocyte sedimentation rate (ESR)

PURPOSE AND DESCRIPTION This blood test is done as a measure of inflammation and is increased in many illnesses, including cancer, heart disease and kidney disease. This test is performed to detect and monitor inflammation in both acute and chronic medical conditions. The findings are used to assist in identifying the cause of inflammation, infections, cancers and autoimmune diseases. It is a non-specific test; therefore, it is typically used in conjunction with other tests, such as FBC, to determine a specific cause of ill health.

Normal values:
Women: 1–12 mm in 1 hour; men: 1–14 mm in 1 hour; pregnant women: > 30 mm in the first hour (due to elevated levels of plasma globulins and fibrinogen)—therefore, ESR cannot be used as an inflammatory marker in pregnancy.

RELATED NURSING CARE No special preparation is needed.

NAME OF TEST Bone marrow biopsy

PURPOSE AND DESCRIPTION Conducted to evaluate blood-forming tissue; to diagnose multiple myeloma, leukaemia and some lymphomas; and to assess effectiveness of therapy for leukaemia. Bone marrow is removed from a site such as the posterior iliac crest with needle aspiration.

RELATED NURSING CARE See 'Nursing care' box below.

NAME OF TEST Magnetic resonance angiography (MRA)

PURPOSE AND DESCRIPTION Used to visualise vascular occlusive disease and aneurysms of the abdominal aorta. The procedure is done by using a non-iodine-based contrast medium injected IV.

RELATED NURSING CARE Assess for any metallic implants, such as a pacemaker or body piercings. (If present, test will not be performed.)

NAME OF TEST Magnetic resonance imaging (MRI)

PURPOSE AND DESCRIPTION A radiological study used to visualise liver, spleen and lymph nodes. Does not require injection of contrast medium.

RELATED NURSING CARE Assess for any metallic implants, such as a pacemaker or body piercings. (If present, the test will not be performed.)

NAME OF TEST Computed tomography (CT) scan

PURPOSE AND DESCRIPTION A radiological study used to evaluate the lymph nodes. Contrast medium may be used when assessing the nodes of the abdomen.

RELATED NURSING CARE Assess for allergy to iodine (such as shellfish) if contrast medium is to be administered.

NAME OF TEST Liver and/or spleen scan

PURPOSE AND DESCRIPTION A radiological study used to assess the liver and/or spleen. A radioisotope is injected IV prior to the scan.

RELATED NURSING CARE Assess for allergy to iodine (such as shellfish).

NAME OF TEST Lymphangiography (lymphangiogram)

PURPOSE AND DESCRIPTION This is an x-ray examination of the lymphatic vessels and lymph nodes, used to assess metastasis of the lymph nodes, to identify malignant lymphoma and to identify the cause of lymphoedema. An iodine contrast substance is injected at various sites and fluoroscopy is used to visualise lymphatic filling.

RELATED NURSING CARE Ask the person about allergies to seafood, iodine or contrast medium used in a previous x-ray test. Tell the person that the blue contrast dye discolours the urine and possibly the skin for a few days.

(continued)

DIAGNOSTIC TESTS Haematological, peripheral vascular and lymphatic disorders (continued)

NAME OF TEST Lymph node biopsy

PURPOSE AND DESCRIPTION Done to obtain tissue for histological examination for diagnosis and treatment. May be open (performed in the operating room) or closed (needle) by needle aspiration of tissue from a lymph node.

RELATED NURSING CARE Use sterile technique when changing dressings.

Disorders of the arteries and veins are diagnosed by various non-invasive examinations, including transoeosophageal echocardiography (TOE), ultrasound and Doppler studies. A magnetic resonance angiography (MRA) may be done to visualise vascular occlusive disease and abdominal aorta aneurysms.

Tests of the lymphatic system, including a lymphangiogram and a lymph node biopsy, may be done to identify malignancies, assess metastasis of cancer to lymph nodes, identify the causes of lymphoedema and obtain tissue for diagnosis and treatment.

NURSING CARE OF THE PERSON having bone marrow studies

Bone marrow specimens are obtained by either aspiration or biopsy. The preferred site for bone marrow aspiration is the posterior iliac crest; the anterior iliac crest or the sternum may also be used. The procedure is performed by inserting a needle into the bone and drawing out a sample of the blood in the marrow. A bone marrow biopsy is performed by making a small incision over the bone and screwing a core biopsy instrument into the bone to obtain a specimen. Bone marrow studies are used to diagnose leukaemias, metastatic cancer, lymphoma, aplastic anaemia and Hodgkin's disease.

PREPARATION OF THE PERSON

- Explain the purpose and procedure of the test.
- Ensure presence of a signed consent for the procedure.
- Offer sedation (neuroleptic or tranquillising) and/or pain relief before the procedure to alleviate discomfort.
- Record vital signs.
- Ask the person to void.
- Support person into the supine position if the specimen will be obtained from the sternum or anterior iliac crest; prone position if the posterior iliac crest will be used.
- Assist the person to remain still during the procedure.

AFTER THE PROCEDURE

- Apply pressure to the puncture site for 5 to 10 minutes.
- Assess vital signs and compare results with pre-procedure readings.
- Apply a dressing to the puncture site and monitor for bleeding and infection for 24 hours.

HEALTH EDUCATION FOR THE PERSON AND FAMILY

- The procedure (either aspiration or biopsy) takes about 20 minutes.
- A sedative may be given prior to the procedure.
- It is important the person remains very still during the procedure to prevent accidental injury.
- Although the area will be anaesthetised with a local anaesthetic, insertion of the needle will be painful for a short time. Taking deep breaths may make this part of the procedure less painful for the person. (In certain circumstances, such as with confused or paediatric patients, sedation or a short-acting general anaesthetic may be used to prevent excessive movement during the procedure.)
- The aspiration site may ache for 1 or 2 days.
- Ask the person to report any unusual bleeding immediately.

Physical assessment

Physical assessment of cardiovascular and lymphatic function may be performed either as part of a total assessment or alone for people with suspected or known problems with cardiovascular or lymphatic function. Assess the heart through inspection, palpation and auscultation over the precordium (the area of the chest wall overlying the heart). Normal age-related findings for the older person are summarised in Table 28.4.

The techniques used to assess these systems include inspection of the skin for such changes as oedema, ulcerations or alterations in colour and temperature; auscultation of blood pressure; and palpation of the major pulse points of the body (see Figure 28.23) and lymph nodes. The person may be assessed in the supine, sitting and standing positions. Normal age-related findings for the older adult are summarised in Table 28.5.

Before beginning the assessment, collect all required equipment and explain the techniques to the person to decrease anxiety. A quiet environment is essential to hear and assess heart sounds accurately.

The person may sit or lie in the supine position. Movements over the precordium may be more easily seen with tangential lighting (in which the light is directed at a right angle to the area being observed, producing shadows). Assess the following types of movements:

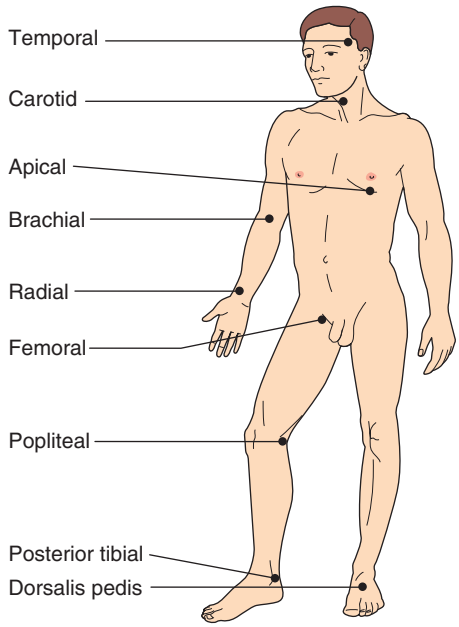


FIGURE 28.23 ■ Body sites at which peripheral pulses are most easily palpated

- The **apical impulse** is a normal, visible pulsation in the area of the midclavicular line in the left fifth intercostal space. It can be seen on inspection in about half of the adult population. (The apical impulse was previously called the point of maximal impulse (PMI), but this term is no longer used because a maximal impulse may occur in other areas of the precordium as a result of abnormal conditions.)
- Retraction is a pulling in of the tissue of the precordium; a slight retraction just medial to the midclavicular line at the area of the apical impulse is normal and is more likely to be visible in people who are thin.
- Pulsations (other than the normal apical pulsations), which may be called heaves or lifts, are considered abnormal. They may occur as the result of an enlarged ventricle.

Genetic considerations

When conducting a health assessment interview and a physical assessment, it is important for the nurse to consider genetic influences on the health of the person. During the health assessment interview, ask about family members with health problems affecting cardiovascular and lymphatic function, or about a family history of high cholesterol levels or early-onset

TABLE 28.4 Age-related changes in the heart

AGE-RELATED CHANGE	SIGNIFICANCE
Myocardium: ↓ efficiency and contractibility. Sinoatrial node: ↑ in thickness of shell surrounding the node and a ↓ in the number of pacemaker cells.	■ Decreased cardiac output when under physiological stress with resulting tachycardia that lasts longer. The person may require rest time between physical activities.
Left ventricle: slight hypertrophy, prolonged isometric contraction phase and relaxation time; ↑ time for diastolic filling and systolic emptying cycle.	■ Stroke volume may increase to compensate for tachycardia, leading to increased blood pressure.
Valves and blood vessels: aorta is elongated and dilated, valves are thicker and more rigid, and resistance to peripheral blood flow increases by 1% per year.	■ Blood pressure increases to compensate for increased peripheral resistance and decreased cardiac output.

TABLE 28.5 Age-related changes in the haematological, peripheral vascular and lymphatic systems

AGE-RELATED CHANGE	SIGNIFICANCE
Bone marrow: ↓ ability of bone marrow to respond to need for increased RBCs, WBCs and platelets.	■ Anaemia may result.
Blood vessels: ■ *Tunica intima:* fibrosis, calcium and lipid accumulation, cellular proliferation.	■ As a result of age-related changes, the systolic blood pressure rises. Decreased arterial elasticity results in vascular changes in the heart, kidneys and pituitary gland. Decreased baroreceptor function results in postural hypotension. Vessels in the head, neck and extremities are more prominent.
■ *Tunica media:* thins, elastin fibres calcify; increase in calcium results in stiffening. Baroreceptor function is impaired and peripheral resistance increases.	■ Inefficient vasoconstriction, decreased cardiac output and reduced muscle mass and subcutaneous tissue lead to a reduced ability to respond to cold temperatures. ■ With a decrease in blood pressure and changes in blood vessel walls, tissue perfusion may be inadequate, leading to oedema, inflammation, pressure ulcers and changes in effects of medications.
■ *Tunica adventitia:* no change.	
Immune system: ■ Impaired function of B and T lymphocytes. ■ Decreased production of antibodies. ■ Unable to distinguish 'self' from 'non-self'. ■ Phagocytic immune response delayed.	■ Increased risk of infection, with decreased manifestations of an actual infection. ■ Increased incidence of cancers. ■ Altered response to antigens (such as Mantoux tuberculin test). ■ May have reactivation of tuberculosis.

coronary artery disease. Ensure that the person considers both alive and deceased relatives in their family history. In addition, ask about a family history of high blood pressure, haemophilia, chronic myeloid leukaemia, porphyria and/or atherosclerosis. Depending on the racial and ethnic background of the person, ask about any family members with sickle cell anaemia or thalassaemia. During the physical assessment, assess for any manifestations that might indicate a genetic disorder (see the 'Genetic considerations' box below). If data are found to indicate genetic risk factors or alterations, ask about genetic testing and refer for appropriate genetic counselling and evaluation. Chapter 7 provides further information about genetics in medical–surgical nursing.

GENETIC CONSIDERATIONS Cardiovascular, haematological and lymphatic system disorders

Cardiovascular disorders

- Familial hypercholesterolaemia is a single gene disorder that results in atherosclerosis and CAD, which may occur at an earlier age than in the general population (i.e. before age 55 in men and age 65 in women). However, increased cholesterol levels may also be inherited and are a risk factor for CAD in both men and women.
- Marfan's syndrome is an autosomal dominant inherited disorder that affects the skeleton, the eyes and the cardiovascular system. The cardiovascular effects are a dilatation of the proximal aorta and aortic dissection associated with degeneration of the elastic fibres in the tunica media of the aorta. There may also be thoracic aortic aneurysms.
- Supraventricular aortic stenosis (SVAS) is a genetic vascular disorder resulting in an hourglass-shaped stenosis of the ascending aorta. It may also affect other major arteries, including the pulmonary, carotid, cerebral, renal and coronary arteries.
- Hypertropic cardiomyopathy, a disease of sarcomere proteins, has a genetic transmission.
- Williams syndrome is a rare genetic disorder characterised by characteristic 'elfin-like' features and heart and blood vessel problems (as well as other physical problems).
- Long QT syndrome (LQTS) is an inherited genetic disorder that results from structural abnormalities of the potassium channels in the heart, leading to arrhythmias. This can result in unconsciousness and may cause sudden cardiac death in teenagers and young adults when exposed to stressors ranging from stressors to loud sounds.

Haematological, peripheral vascular and lymphatic disorders

- There is a genetic link in 30–40% of people with primary hypertension.
- Sickle cell anaemia is an inherited genetic disorder seen in people of Mediterranean, Caribbean, Central and South American, Arab or East Indian ancestry. As Australia is an increasingly multicultural society, healthcare professionals need to be aware of its existence among people with these racial backgrounds.
- Gaucher disease, more common in descendants of Eastern European Jewish people, is an inherited illness caused by a gene mutation. The gene is responsible for an enzyme that breaks down a specific fat. When the fat is not broken down, it accumulates in the liver, spleen and bone marrow, causing pain, fatigue, jaundice, bone damage, anaemia and even death.
- Haemophilia A is a hereditary blood disorder, primarily affecting males, characterised by a deficiency of the blood clotting factor named factor VIII. Abnormal bleeding results.
- Chronic myeloid leukaemia (CML), a cancer of blood cells, is characterised by replacement of bone marrow with malignant, leukaemic cells. Leukaemic cells also circulate in the blood, causing enlargement of the spleen, liver and other organs. This leukaemia is the result of a chromosomal abnormality called the Philadelphia chromosome.
- Porphyria is a group of genetic blood diseases in which haem production is disrupted. When haem production is disrupted, porphyrins (a part of haem) are overproduced and cause illnesses; they also give urine a reddish-purple colour.
- Thalassaemia, an inherited disease of faulty haemoglobin synthesis, is more often found in descendants of people living near the Mediterranean Sea, Africa, the Middle East and Asia. It comprises a group of disorders that range from very mild blood abnormalities to severe or fatal anaemia.
- Atherosclerosis is characterised by narrowing of arteries by cholesterol-rich plaques of immune system cells. Risk factors may be genetic and/or environmental. Although it may affect people at any age, it usually does not cause health problems until people are in their forties and fifties.

INTERPRETATION OF NORMAL AND ABERRANT DATA OBTAINED FROM CARDIOVASCULAR AND LYMPHATIC SYSTEM ASSESSMENT

CARDIAC ASSESSMENTS

Technique/normal findings	Abnormal findings
Apical impulse assessment	
First using the palmar surface and then repeating with finger pads, palpate the precordium for symmetry of movement and the apical impulse for location, size, amplitude and duration. The sequence for palpation is shown in Figure 28.24. To locate the apical impulse, ask the person to assume a left lateral recumbent position. Simultaneous palpation of the carotid pulse may also be helpful. *The apical impulse is not palpable in all people. The apical impulse may be palpated in the mitral area and has only a brief small amplitude.*	■ An enlarged or displaced heart is associated with an apical impulse lateral to the midclavicular line (MCL) or below the fifth left intercostal space (ICS). ■ Increased size, amplitude and duration of the apical impulse are associated with left ventricular volume overload (increased afterload) in conditions such as hypertension (HTN) and aortic stenosis, and with pressure overload (increased preload) in conditions such as aortic or mitral regurgitation. ■ Increased amplitude alone may occur with hyperkinetic states, such as anxiety, hyperthyroidism and anaemia. ■ Decreased amplitude is associated with a dilated heart in cardiomyopathy. ■ Displacement alone may also occur with dextrocardia, diaphragmatic hernia, gastric distension or chronic lung disease. ■ A **thrill** (a palpable vibration over the precordium or an artery) may accompany severe valve stenosis. ■ A marked increase in amplitude of the apical impulse at the right ventricular area occurs with right ventricular volume overload in atrial septal defect. ■ An increase in amplitude and duration occurs with right ventricular pressure overload in pulmonic stenosis and pulmonary hypertension. A lift or heave may also be seen in these conditions (and in chronic lung disease). ■ A palpable thrill in this area occurs with ventricular septal defect.
Palpate the subxiphoid area with the index and middle finger. *No pulsations or vibrations should be palpated.*	■ Right ventricular enlargement may produce a downward pulsation against the fingertips. ■ An accentuated pulsation at the pulmonary area may be present in hyperkinetic states. ■ A prominent pulsation reflects increased flow or dilation of the pulmonary artery. ■ A thrill may be associated with aortic or pulmonary stenosis, aortic stenosis, pulmonary HTN or atrial septal defect. ■ Increased pulsation at the aortic area may suggest aortic aneurysm. ■ A palpable second heart sound (S_2) may be noted with systemic HTN.
Cardiac rate and rhythm assessment	
Auscultate heart rate. *The heart rate should be 60 to 100 beats per minute with regular rhythm.*	■ A heart rate exceeding 100 beats per minute (beats/min) is tachycardia. A heart rate less than 60 beats/min is bradycardia.
Simultaneously palpate the radial pulse while listening to the apical pulse. *The radial and apical pulses should be equal.*	■ If the radial pulse falls behind the apical rate, the person has a pulse deficit, indicating weak, ineffective contractions of the left ventricle.

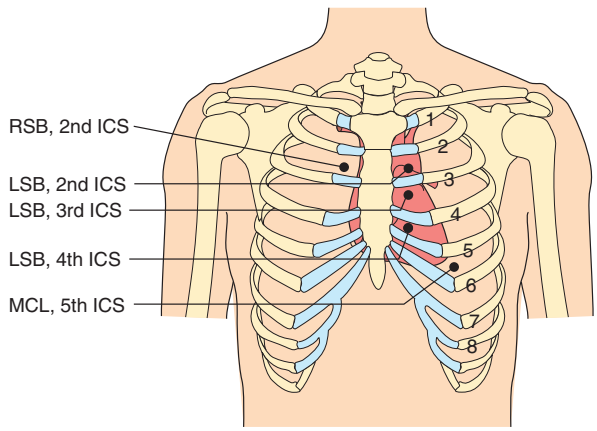

FIGURE 28.24 ■ Areas for inspection and palpation of the precordium, indicating the sequence for palpation (ICS = intercostal space; LSB = left sternal border; MCL = midclavicular line; RSB = right sternal border)

CARDIAC ASSESSMENTS (continued)

Technique/normal findings	Abnormal findings
Auscultate heart rhythm. *The heart rhythm should be regular.*	■ **Arrhythmias** (abnormal heart rate or rhythm) may be regular or irregular in rhythm; their rates may be slow or fast. Irregular rhythms may occur in a pattern (e.g. an early beat every second beat, called bigeminy), sporadically or with frequency and disorganisation (e.g. atrial fibrillation). A pattern of gradual increase and decrease in heart rate that is within the normal heart rate and that correlates with inspiration and expiration is called sinus arrhythmia.
Heart sounds assessment	
See guidelines for cardiac auscultation in Box 28.3.	
Identify S_1 (first heart sound) and note its intensity. At each auscultatory area, listen for several cardiac cycles. See Figure 28.25 for auscultation areas. *S_1 is loudest at the apex of the heart.*	■ An accentuated S_1 occurs with tachycardia, states in which cardiac output is high (fever, anxiety, exercise, anaemia, hyperthyroidism), complete heart block and mitral stenosis. ■ A diminished S_1 occurs with first-degree heart block, mitral regurgitation, CHF, CAD and pulmonary or systemic HTN. The intensity is also decreased with obesity, emphysema and pericardial effusion. Varying intensity of S_1 occurs with complete heart block and grossly irregular rhythms.
Listen for splitting of S_1. *Splitting of S_1 may occur during inspiration.*	■ Abnormal splitting of S_1 may be heard with right bundle branch block and premature ventricular contractions.
Identify S_2 (second heart sound) and note its intensity. *S_2 immediately follows S_1 and is loudest at the base of the heart.*	■ An accentuated S_2 may be heard with HTN, exercise, excitement, and conditions of pulmonary HTN such as CHF and cor pulmonale. ■ A diminished S_2 occurs with aortic stenosis, a fall in systolic blood pressure (shock) and increased anteroposterior chest diameter.
Listen for splitting of S_2. *No splitting of S_2 should be heard.*	■ Wide splitting of S_2 is associated with delayed emptying of the right ventricle, resulting in delayed pulmonary valve closure (e.g. mitral regurgitation, pulmonary stenosis and right bundle branch block).

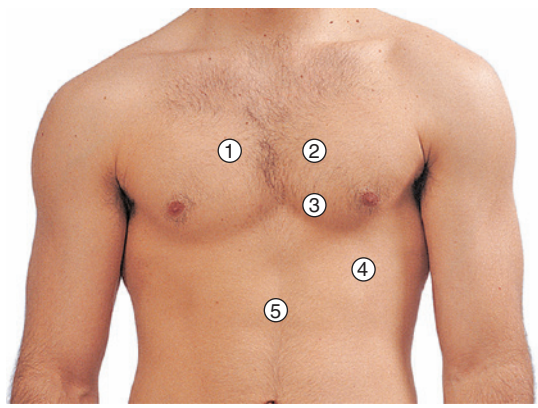

FIGURE 28.25 ■ Areas for auscultation of the heart

BOX 28.3 Guidelines for cardiac auscultation

1. Locate the major auscultatory areas on the precordium.
2. Choose a sequence of listening. Either begin from the apex and move upward along the sternal border to the base, or begin at the base and move downward to the apex.
3. Listen first with the person in the sitting or supine position. Then ask the person to lie on the left side and focus on the apex. Lastly, ask the person to sit up and lean forward. These position changes bring the heart closer to the chest wall and enhance auscultation. Carry out the following steps when the person assumes each of these positions:
   a. First, auscultate each area with the diaphragm of the stethoscope to listen for high-pitched sounds: S_1, S_2, murmurs, pericardial friction rubs.
   b. Next, auscultate each area with the bell of the stethoscope to listen for lower-pitched sounds: S_3, S_4, murmurs.
   c. Listen for the effect of respirations on each sound; while the person is sitting up and leaning forward, ask the person to exhale and hold the breath while you listen to heart sounds.

Technique/normal findings	Abnormal findings
	■ Fixed splitting occurs when right ventricular output is greater than left ventricular output and pulmonary valve closure is delayed (e.g. with atrial septal defect and right ventricular failure). ■ Paradoxical splitting occurs when closure of the aortic valve is delayed (e.g. left bundle branch block).
Identify extra heart sounds in systole. *Extra heart sounds are not present in systole.*	■ Ejection sounds (or clicks) result from the opening of deformed semilunar valves (e.g. aortic and pulmonary stenosis). ■ A midsystolic click is heard with mitral valve prolapse (MVP).
Identify the presence of extra heart sounds in diastole. *Extra heart sounds are not present in diastole.*	■ An opening snap results from the opening sound of a stenotic mitral valve. ■ A pathological S_3 (a third heart sound that immediately follows S_2, called a ventricular gallop) results from myocardial failure and ventricular volume overload (e.g. CHF, mitral or tricuspid regurgitation). ■ An S_4 (a fourth heart sound that immediately precedes S_1, called an atrial gallop) results from increased resistance to ventricular filling after atrial contraction (e.g. HTN, CAD, aortic stenosis and cardiomyopathy). ■ A combined S_3 and S_4 is called a summation gallop and occurs with severe CHF.
Identify extra heart sounds in both systole and diastole. *No extra heart sounds should be heard during systole and diastole.*	■ A pericardial friction rub results from inflammation of the pericardial sac, as with pericarditis.
Murmur assessment	
Identify any murmurs. Note location, timing, presence during systole or diastole, and intensity. Use the following scale to grade murmurs: I = Barely heard II = Quietly heard III = Clearly heard IV = Loud V = Very loud VI = Loudest; may be heard with stethoscope off the chest. A thrill may accompany murmurs of grade IV to grade VI. Note pitch (low, medium, high) and quality (harsh, blowing or musical). Note pattern/shape, crescendo, decrescendo and radiation/transmission (to axilla, neck). *No murmurs should be heard.*	■ Midsystolic murmurs are heard with semilunar valve disease (e.g. aortic and pulmonary stenosis) and with hypertrophic cardiomyopathy. ■ Pansystolic (holosystolic) murmurs are heard with AV valve disease (e.g. mitral and tricuspid regurgitation, ventricular septal defect). ■ A late systolic murmur is heard with MVP. ■ Early diastolic murmurs occur with regurgitant flow across incompetent semilunar valves (e.g. aortic regurgitation). ■ Mid-diastolic and presystolic murmurs, such as with mitral stenosis, occur with turbulent flow across the AV valves. ■ Continuous murmurs throughout systole and all or part of diastole occur with patent ductus arteriosus.
Blood pressure and pulse pressure assessment	
See Box 28.4 for blood pressure measurement guidelines.	
Auscultate blood pressure in each arm with the person seated. *The normal blood pressure is considered to be < 120/< 80, with readings of 120–139/80–89 diagnosed as prehypertension.*	■ Consistent BP readings over 140/90 in adults under age 40 are considered hypertension. ■ BP under 90/60 is considered hypotension. ■ An auscultatory gap—a temporary disappearance of sound between the systolic and diastolic BP—may be a normal variation or it may be associated with systolic HTN or a drop in diastolic BP due to aortic stenosis. ■ **Korotkoff's sounds** (see Box 28.4) may be heard down to zero with cardiac valve replacements, hyperkinetic states, thyrotoxicosis and severe anaemia, as well as after vigorous exercise. ■ The sounds of aortic regurgitation may obscure the diastolic BP. ■ A difference of over 10 mmHg between arms suggests arterial compression on the side of the lower reading, aortic dissection or coarctation of the aorta.

BOX 28.4 Guidelines for blood pressure assessment

Review of Korotkoff's sounds

The first sound heard is the systolic pressure; at least two consecutive sounds should be clear. If the sound disappears and then is heard again 10 to 15 mmHg later, an auscultatory gap is present; this may be a normal variant or it may be associated with hypertension. The first diastolic sound is heard as a muffling of the Korotkoff's sound and is considered the best approximation of the true diastolic pressure. The second diastolic sound is the level at which sounds are no longer heard.

The Heart Foundation of Australia's (2015) guidelines for assessing blood pressure include the following key issues.

Technique reminders

- Choose a cuff of an appropriate size: the cuff should snugly cover two-thirds of the upper arm and the bladder should completely encircle the arm. The bladder should be centred over the brachial artery, with the lower edge 2 to 3 cm above the antecubital space.
- The person's arm should be slightly flexed and supported (on a table or by the examiner) at heart level.
- To determine how high to inflate the cuff, palpate the brachial pulse and inflate the cuff to the point on the manometer at which the pulse is no longer felt; then, add 30 mmHg to this reading and use the sum as the target for inflation. Wait 15 seconds before reinflating the cuff to auscultate the BP.
- To recheck a BP, wait at least 30 seconds before attempting another inflation.
- Always inflate the cuff completely, then deflate it. Once deflation begins, allow it to continue; do not try to reinflate the cuff if the first systolic sound is not heard or if the cuff inadvertently deflates.
- The bell of the stethoscope more effectively transmits the low-pitched sounds of BP.

Sources of error

- Falsely high readings can occur if the cuff is too small or too loose, or if the person supports their own arm.
- Falsely low readings can occur if a standard cuff is used on a person with thin arms.
- Inadequate inflation may result in underestimation of the systolic pressure or overestimation of the diastolic pressure if an auscultatory gap is present.
- Rapid deflation and repeated or slow inflations (causing venous congestion) can lead to underestimation of the systolic BP and overestimation of the diastolic BP.

Factors altering blood pressure

- A change from the horizontal to upright position causes a slight decrease (5 to 10 mmHg) in systolic BP; the diastolic BP remains unchanged or rises slightly.
- BP taken in the arm is lower when the person is standing.
- If the BP is taken with the person in the lateral recumbent position, a lower BP reading may be obtained in both arms; this is especially apparent in the right arm with the person in the left lateral position.
- Factors that increase BP include exercise, caffeine, cold environment, eating a large meal, painful stimuli and emotions.
- Factors that lower BP include sleep (by 20 mmHg) and very fast, slow or irregular heart rates.
- BP tends to be higher in people who are taller or heavier.

Alternative methods of blood pressure measurement

- The palpatory method may be necessary if severe hypotension is present and the BP is inaudible. Palpate the brachial pulse and inflate the cuff 30 mmHg above the point where the pulse disappears; deflate the cuff and note the point on the manometer where the pulse becomes palpable again. Record this as the palpatory systolic BP.
- Leg BP measurement may be needed when there is injury of the arms or to rule out coarctation of the aorta or aortic insufficiency when arm diastolic BP is over 90 mmHg. Place the person in the prone or supine position with the leg slightly flexed. Place a large leg cuff on the thigh with the bladder centred over the popliteal artery. Place the bell of the stethoscope over the popliteal space. Normal leg systolic BP is higher than arm BP; diastolic BP should be equal to or lower than arm BP. Abnormally low leg BP occurs with aortic insufficiency and coarctation of the aorta.

Technique/normal findings	Abnormal findings
Auscultate blood pressure in each arm with the person standing. If orthostatic changes occur, measure the BP with the person supine, legs dangling, and again with the person standing, 1 to 3 minutes apart. *A decrease of systolic BP is expected, but should be < 10 mmHg; diastolic BP should not drop on standing.*	■ A decrease in systolic BP of over 10 to 15 mmHg and a drop in diastolic BP on standing is called **orthostatic hypotension**. Causes include antihypertensive medications, volume depletion, peripheral vascular disease, prolonged bed rest and ageing.

CONSIDERATION FOR PRACTICE

If unable to auscultate blood pressure or palpate pulses, a Doppler ultrasound device may be used to evaluate blood flow. Apply a five-cent-piece amount of gel over the blood vessel to be assessed and lightly place the probe over the gel. Listen for a whooshing (artery) or rushing (vein) sound.

Technique/normal findings	Abnormal findings
Observe the pulse pressure. The **pulse pressure** is the difference between the systolic and diastolic BP. For example, if the BP is 140/80, the pulse pressure is 60. *A normal pulse pressure is one-third the systolic measurement.*	■ A widened pulse pressure with an elevated systolic BP occurs with exercise, arteriosclerosis, severe anaemia, thyrotoxicosis and increased intracranial pressure. ■ A narrowed pulse pressure with a decreased systolic BP occurs with shock, cardiac failure and pulmonary embolus.
Skin assessment	
Inspect the colour of the skin. *The skin colour should be appropriate to the person's age and race.*	■ Pallor reflects constriction of peripheral blood flow (e.g. due to syncope or shock) or decreased circulating oxyhaemoglobin (e.g. due to haemorrhage or anaemia). ■ Central cyanosis of the lips, earlobes, oral mucosa and tongue suggests chronic cardiopulmonary disease. (See Box 28.5 for abnormal findings associated with peripheral vascular and lymphatic assessment.)
Inspect the skin of the extremities and over the regional lymph nodes, noting any oedema, erythema, red streaks or skin lesions. *There should be no oedema, redness or lesions over the regional lymph nodes.*	■ Lymphangitis (inflammation of a lymphatic vessel) may produce a red streak with induration (hardness) following the course of the lymphatic collecting duct; infected skin lesions may be present, particularly between the digits. ■ **Lymphoedema** (swelling due to lymphatic obstruction) occurs with congenital lymphatic anomaly (Milroy's disease) or with trauma to the regional lymphatic ducts from surgery or metastasis (e.g. arm lymphoedema after radical mastectomy with axillary node removal). ■ Oedema of lymphatic origin is usually not pitting and the skin may be thickened; one example is the taut swelling of the face and body that occurs with myxoedema, associated with hypothyroidism.

BOX 28.5 Abnormal findings associated with peripheral vascular and lymphatic assessment

- *Pallor* is an absence of colour of the skin. The degree of pallor depends on the person's normal skin colour and health status. Dark skin may appear ashen or have a yellowish tinge.
- *Cyanosis* is a bluish discolouration of the skin and mucous membranes in people with light skin. In people with dark skin, cyanosis may be difficult to observe. Inspect the nail beds and conjunctiva.
- *Oedema* is an abnormal accumulation of fluid in the interstitial spaces of body tissues. It is often most apparent in the lower extremities.
- *Varicose veins* are tortuous and dilated veins that have incompetent valves. The saphenous veins of the legs are most commonly affected.
- *Enlarged lymph nodes* result from infection or malignancy.
- *Atrophic changes* are changes in size or activity of body tissues as the result of pathology or injury. Decreased blood flow and oxygenation of the lower extremities often cause atrophic changes of loss of hair, thickened toenails, changes in pigmentation and ulcerations.
- *Gangrene* is the necrosis (or death) of tissue, most often the result of loss of blood supply and infection. Gangrene often begins in the most distal of the tissues of the extremities.
- *Pressure ulcers*, also called decubitus ulcers or bed sores, are the result of ischaemia and hypoxia of tissue following prolonged pressure. These ulcers often are located over bony prominences. If untreated, the tissue changes proceed from red skin to deep, crater-like ulcers.

Artery and vein assessment

Palpate the temporal arteries. *There should be no redness, swelling, nodules or variations in pulse amplitude.*

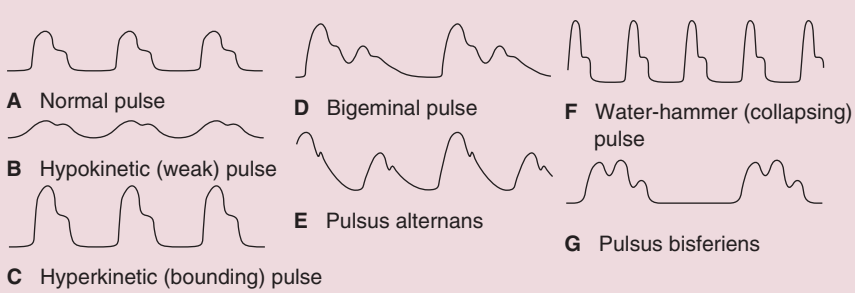
■ Redness, swelling, nodularity and variations in pulse amplitude may occur with temporal arteritis.

Inspect and palpate the carotid arteries. Note symmetry, the pulse rate, rhythm, volume and amplitude. Note any variation with respiration. Describe all pulses as increased, normal, diminished or absent. Scales ranging from 0 to 4+ are sometimes used as follows:

0 = Absent
1+ = Diminished
2+ = Normal
3+ = Increased
4+ = Bounding

Pulse waveforms are showne in Box 28.6.

BOX 28.6 Types of pulse patterns



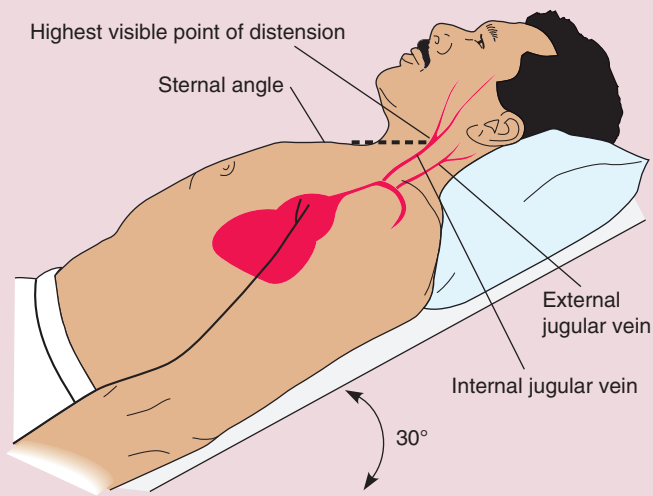
CARDIAC ASSESSMENTS (continued)

Technique/normal findings	Abnormal findings
Remember that carotid pulses should never be assessed simultaneously as this can cause vagal stimulation and potentially result in decreased cerebral perfusion. *The carotid pulses should be bilaterally equal in rate, rhythm, volume and amplitude.*	■ A unilateral pulsating bulge is seen with a tortuous or kinked carotid artery. ■ Alterations in pulse rate or rhythm are due to cardiac arrhythmias. ■ An absent pulse indicates arterial occlusion. ■ A hypokinetic (weak) pulse is associated with decreased stroke volume (see Box 28.6B). This may be due to congestive heart failure (CHF), aortic stenosis or hypovolaemia; to increased peripheral resistance, which may result from cold temperatures; or to arterial narrowing, commonly found with atherosclerosis. ■ A hyperkinetic (bounding) pulse occurs with increased stroke volume and/or decreased peripheral resistance (see Box 28.6C). This may result from states in which cardiac output is high or from aortic regurgitation. It also may occur with anaemia, hyperthyroidism, bradycardia or reduced compliance, as with atherosclerosis. ■ A bigeminal pulse is marked by decreased amplitude of every second beat (see Box 28.6D). This may be due to premature contractions (usually ventricular). ■ Pulsus alternans is a regular pulse with alternating strong and weak beats (see Box 28.6E). This may be due to left ventricular failure and severe HTN.
Auscultate the carotid arteries, using the bell of the stethoscope. *No bruits should be heard.*	■ A murmuring or blowing sound heard over stenosed peripheral vessels is known as a *bruit*. A bruit heard over the middle to upper carotid artery suggests atherosclerosis.
Inspect and palpate the internal and external jugular veins for venous pressure. *See Box 28.7 for guidelines for assessing jugular venous pressure (JVP).*	■ An increase in jugular venous pressure (JVP) over 3 cm and located above the sternal angle reflects increased right atrial pressure. This occurs with right ventricular failure or, less commonly, with constrictive pericarditis, tricuspid stenosis and superior venae cavae obstruction.
If venous pressure is elevated, assess the hepatojugular reflex. (Compress the liver in the right upper abdominal quadrant with the palm of the hand for 30 to 60 seconds while observing the jugular veins.)	■ A decrease in venous pressure reflects reduced left ventricular output or blood volume. ■ Unilateral neck vein distension suggests local compression or anatomic anomaly. ■ A rise in the column of neck vein distension over 1 cm with liver compression indicates right heart failure.
Upper extremity assessment	
Inspect and palpate the arms and hands, noting size and symmetry, skin colour and temperature. *Arms and hands should be symmetrical in size and shape, warm and of appropriate skin colour.*	■ Unilateral swelling with venous prominence occurs with venous obstruction. ■ Extreme localised pallor of the fingers is seen with Raynaud's disease. ■ Cyanosis of the nail beds reflects chronic cardiopulmonary disease. ■ Cold temperature of the hands and fingers occurs with vasoconstriction.
Palpate the nail beds for capillary refill. (Apply pressure to the person's fingertips. Watch for blanching of the nail beds. Release the pressure. Note the time it takes for capillary refill, indicated by the return of pink colour on release of the pressure.) *Capillary refill should be less than 2 seconds (i.e. immediate).*	■ Capillary refill that takes more than 2 seconds reflects circulatory compromise, such as hypovolaemia or anaemia.
Assess venous pattern and pressure. (Elevate one of the person's arms over the head for a few seconds. Slowly lower the arm. Observe the filling of the person's hand veins.) *Hand veins should fill equally and immediately.*	■ Distension of hand veins at elevations over 9 cm above heart level reflects an increase in systemic venous pressure
Palpate the radial and brachial pulses. Note rate, rhythm, volume amplitude, symmetry, variations with respiration. (See Box 28.6 for pulse patterns.) *Radial and brachial pulses should have equal and normal rate, be strong and not vary with respirations.*	■ Alterations in pulse rate or rhythm are due to cardiac arrhythmias (such as atrial fibrillation, atrial flutter and premature ventricular contractions). A pulse rate over 100 bpm is tachycardia; a pulse rate below 60 bpm is bradycardia. ■ A pulse deficit (slower radial rate than apical rate) occurs with arrhythmias and CHF.

BOX 28.7 Assessing jugular venous pressure

When a person with normal venous pressure lies in the supine position, full neck veins are normally visible, but as the head of the bed is elevated, the pulsations disappear. In the person with greatly elevated venous pressure, visible pulsations of the jugular vein are present even in the upright position. To conduct the inspection:

1. Remove clothing from the person's neck and chest. Elevate the head of the bed 30 to 45 degrees (semi-Fowler's position) and turn the person's head to the opposite side. As jugular venous pressure is the measurement of pressure in the right atrium, it is best to examine the right jugular vein. This is because it has a more direct anatomical path to the right atrium.
2. Make sure the neck and the upper thorax are exposed. Avoid neck flexion or hyperextension which may cause the jugular vein to become kinked or stretched, and thus cause compression pulsations.
3. Assess venous pressure by measuring the vertical distance between the angle of St Louis and the highest visible level of pulsation in the internal jugular vein. Using two rulers, line up the bottom edge with the top of the area of pulsation in the jugular vein. Then align another ruler perpendicular to the first at the level of the sternal angle. In centimetres, measure the distance between the second ruler and the sternal angle.
4. Repeat this technique on the other side. Bilateral pressures higher than 2.5 cm are considered elevated and are a sign of right-sided heart failure. One-sided pressure elevation can be a sign of obstruction.
5. If jugular distension is present, assess the JVP by measuring from the highest point of visible distension to the sternal angle (the point at which the clavicles meet) on both sides of the neck (see the accompanying figure). Bilateral measurements above 3 cm are considered elevated and indicate increased venous pressure; distension on only one side may indicate obstruction



Assessment of the highest point of jugular vein distension

Technique/normal findings	Abnormal findings
Colour should return within 3 to 5 seconds in both the ulnar and the radial arteries. See Box 28.8 for the Allen test.	■ Irregularities of rhythm produce early beats and pauses (skipped beats) in the pulse, which may be regular in pattern, sporadic or grossly irregular. ■ Diminished or absent radial pulses may be due to thromboangiitis obliterans (Buerger's disease) or acute arterial occlusion. ■ A weak and thready pulse, often with tachycardia, reflects decreased cardiac output. ■ A bounding pulse occurs with hyperkinetic states and atherosclerosis. ■ Unequal pulses between extremities suggest arterial narrowing or obstruction on one side. ■ In sinus arrhythmia (a normal variant, especially in young adults), the pulse rate increases with inspiration and decreases with expiration. ■ The normal ulnar artery may or may not have a palpable pulse. ■ Persistent pallor with the Allen test suggests ulnar artery occlusion.

BOX 28.8 Allen test

If arterial insufficiency is suspected, palpate the ulnar pulse and perform the Allen test:

- Have the person make a tight fist.
- Compress both the radial and ulnar arteries.
- Have the person open the hand to a slightly flexed position.
- Observe for pallor and manifestations of pain.
- Release the ulnar artery and observe for the return of pink colour within 3 to 5 seconds.
- Repeat the procedure on the radial artery.

Technique/normal findings	Abnormal findings
Lower extremity assessment	
Inspect and palpate each leg, noting size, shape and symmetry; arterial pattern; skin colour, temperature and texture; hair pattern; pigmentation; rashes; ulcers, sensation; and capillary refill. *Legs should be symmetrical in size and shape, arterial pattern, appropriate colour, warm, without lesions. Capillary refill on toenails should be immediate.*	■ Chronic arterial insufficiency may be due to arteriosclerosis or autonomic dysfunction, or to acute occlusion resulting from thrombosis, embolus or aneurysm. ■ Signs of arterial disruption include pallor, dependent rubor (dusky redness); cool to cold temperature; and atrophic changes, such as hair loss with shiny and smooth texture, thickened nails, sensory loss, slow capillary refill and muscle atrophy. ■ Ulcers with symmetric margins, a deep base, black or necrotic tissue, and absence of bleeding may occur at pressure points on or between the toes, on the heel, on the lateral malleolar or tibial area, over the metatarsal heads or along the side or sole of the foot. ■ Gangrene due to complete arterial occlusion presents as black, dry, hard skin; pregangrenous colour changes include deep cyanosis and purple-black discolouration.
With the person supine, assess the venous pattern of the legs. Repeat with the person standing. *Venous pattern on both legs should be symmetrical and there should be no oedema, cyanosis or lesions.*	■ Signs of venous insufficiency include swelling, thickened skin, cyanosis, stasis dermatitis (brown pigmentation, erythema and scaling) and superficial ankle ulcers located predominantly at the medial malleolus with uneven margins, ruddy granulation tissue and bleeding. ■ Varicose veins appear as dilated, tortuous and thickened veins, which are more prominent in a dependent position.
Palpate the femoral, popliteal, posterior tibial and dorsalis pedis pulses for volume, amplitude and symmetry (see Figure 28.23). *All lower extremity pulses should be strong and equal in amplitude.*	■ Diminished or absent leg pulses suggest partial or complete arterial occlusion of the proximal vessel and are often due to arteriosclerosis obliterans. ■ Increased and widened femoral and popliteal pulsations suggest aneurysm. ■ Absence of a posterior tibial pulse with signs and symptoms of arterial insufficiency is usually due to acute occlusion by thrombosis or embolus. ■ Diminished or absent pedal pulses are often due to popliteal occlusion associated with diabetes mellitus.
If pulses are diminished, observe for postural colour changes. Elevate both legs 60 degrees and observe the colour of the soles of the feet. Have the person sit and dangle the legs; note the return of colour to the feet.	■ Extensive pallor on elevation is suggestive of arterial insufficiency. ■ Rubor (dusky redness) of the toes and feet along with delayed venous return (over 45 seconds) suggests arterial insufficiency.
If arterial insufficiency is suspected, auscultate the femoral arteries. *No bruits should be heard.*	■ Femoral bruits suggest arterial narrowing due to arteriosclerosis.
Inspect and gently palpate the calves. *There should be no redness or swelling, heat or pain in the calves of the legs.*	■ Redness, warmth, swelling, tenderness and cords along a superficial vein suggest thrombophlebitis or deep venous thrombosis.

Inspect and palpate for oedema. Use your thumb to compress the dorsum of the person's foot, around the ankles and along the tibia (see Figure 28.26A). *A depression in the skin that does not immediately refill is called pitting oedema. Normally, there is no oedema.*	■ Oedema can be graded on a scale from 1+ to 4+ (Figure 28.26B):
	  ■ 1+ (–2 mm depression)—No visible change in the leg; slight pitting
	  ■ 2+ (–4 mm depression)—No marked change in the shape of the leg; pitting slightly deeper
	  ■ 3+ (–6 mm depression)—Leg visibly swollen; pitting deep
	  ■ 4+ (–8 mm depression)—Leg very swollen; pitting very deep
	■ Oedema may be caused by disease of the cardiovascular system such as CHF; by renal, hepatic or lymphatic problems; or by infection.
	■ Venous distension suggests venous insufficiency or incompetence.

Technique/normal findings **Abnormal findings**

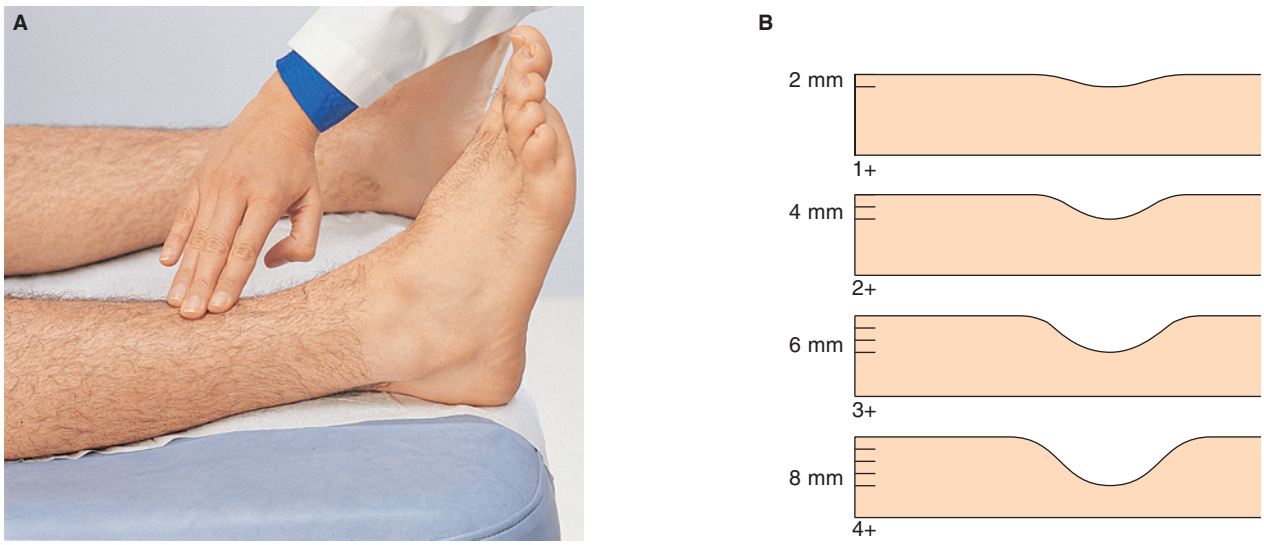


FIGURE 28.26 ■ Evaluation of oedema. *A*, Palpating for oedema over the tibia. *B*, Four-point scale for grading oedema

Abdominal assessment

Inspect and palpate the abdominal aorta. Note size, width and any visible pulsations or bulging. *Abdominal aorta should be of appropriate size without visible pulsations or bulging.*

- A pulsating mass in the upper abdomen suggests an aortic aneurysm, particularly in the older adult.
- An aorta greater than 2.5 to 3 cm in width reflects pathological dilation, most likely due to arteriosclerosis.

Auscultate the epigastrium and each abdominal quadrant, using the bell of the stethoscope (see Figure 28.27). *No bruits should be heard over the abdominal aorta.*

- Abdominal bruits reflect turbulent blood flow associated with partial arterial occlusion.
- A bruit heard over the aorta suggests an aneurysm.
- A bruit heard over the epigastrium and radiating laterally, especially with HTN, suggests renal artery stenosis.
- Bruits heard in the lower abdominal quadrants suggest partial occlusion of the iliac arteries.

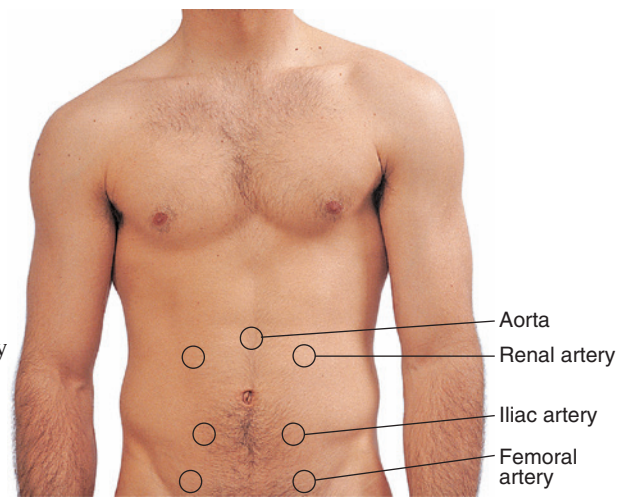

FIGURE 28.27 ■ Auscultation sites of the abdominal aorta and its branches

Lymph node assessment

Palpate the regional lymph nodes of the head and neck, axillae, arms and groin. Use firm, circular movements of the finger pads and note size, shape, symmetry, consistency, delineation, mobility, tenderness, sensation and condition of overlying skin. *Nodes should not be enlarged or painful.*

- **Lymphadenopathy** refers to the enlargement of lymph nodes (over 1 cm) with or without tenderness. It may be caused by inflammation, infection or malignancy of the nodes or the regions drained by the nodes.
- Lymph node enlargement with tenderness suggests inflammation (*lymphadenitis*). With bacterial infection, the nodes may be warm and matted with localised swelling.
- Malignant or metastatic nodes may be hard, indicating lymphoma; rubbery, indicating Hodgkin's disease; or fixed to adjacent structures. Usually they are not tender.
- Ear infections and scalp and facial lesions, such as acne, may cause enlargement of the pre-auricular and cervical nodes.

CARDIAC ASSESSMENTS (continued)

Technique/normal findings	Abnormal findings
	■ Anterior cervical nodes are enlarged and infected with streptococcal pharyngitis and mononucleosis. ■ Lymphadenitis of the cervical and submandibular nodes occurs with herpes simplex lesions. ■ Enlargement of supraclavicular nodes, especially the left, is highly suggestive of metastatic disease from abdominal and thoracic cancer. ■ Axillary lymphadenopathy is associated with breast cancer. ■ Lesions of the genitals may produce enlargement of the inguinal nodes. ■ Persistent generalised lymphadenopathy is associated with acquired immune deficiency syndrome (AIDS) and AIDS-related complex.
Spleen assessment	
Palpate for the spleen, in the upper left quadrant of the abdomen. *The spleen is normally not palpable.*	■ A palpable spleen in the left upper abdominal quadrant of an adult may indicate abnormal enlargement (splenomegaly) and may be associated with cancer, blood dyscrasias and viral infection, such as mononucleosis.
Percuss for splenic dullness in the lowest left intercostal space (ICS) at the anterior axillary line or in the ninth to tenth ICS at the midaxillary line (see Figure 28.28). *Normally, tympany is heard.*	■ A dull percussion note in the lowest left ICS at the anterior axillary line or below the tenth rib at the midaxillary line suggests splenic enlargement.

FIGURE 28.28 ■ Percussing the spleen

TRANSLATION TO PRACTICE

Evidence-based practice: core components of cardiovascular disease secondary prevention and cardiac rehabilitation 2014

Appropriate assessment and short-term monitoring are pivotal components to decrease morbidity and mortality rates of individuals experiencing cardiovascular disease. An article by Woodruffe et al. (2015) reported on the convening of a nationally represented, expert panel to review research evidence to guide practice in cardiovascular health care. Five core components were identified and recommended as necessary for secondary prevention and cardiac rehabilitation:

1. equity and access to services
2. assessment and short-term monitoring
3. recovery and longer-term maintenance
4. lifestyle/behavioural modification and medication adherence
5. evaluation and quality improvement (Woodruffe et al., 2015).

IMPLICATIONS FOR NURSING

This article highlights evidence-based recommendations essential for improving healthcare provision for users of cardiovascular health services. The core components are explained and advice regarding data collection, key performance indicators and methods to promote change are described. Specific considerations warranting attention are also emphasised for Aboriginal and Torres Strait Islander peoples.

CRITICAL THINKING IN PERSON-CENTRED CARE

1 How does appropriate, individualised assessment of people with cardiovascular disease decrease mortality and morbidity?

2 Consider all the data that should be collected when assessing an individual with cardiovascular disease. What assessment data are critical and what other data may influence outcomes for individuals experiencing cardiovascular disease?

3 How could information in this review improve your practice when caring for individuals experiencing cardiovascular disease?

CONCEPT CHECK

1 The amount of blood pumped by the ventricles in 1 minute is known as:
1 heart rate
2 ventricular contraction
3 stroke volume
4 cardiac output

2 During what part of the cardiac cycle is the myocardium perfused?
1 prior to atrial filling
2 prior to ventricular relaxation
3 during diastole
4 during pulmonary perfusion

3 What physiological process is responsible for the electrical impulse that stimulates myocardial contraction?
1 action potential
2 cardiac reserve
3 cardiac potential
4 ventricular contraction

4 The intensity of chest pain may be assessed by asking which question?
1 'Did the pain move into your left arm?'
2 'Was your pain relieved by resting or worse when you were busy?'
3 'On a scale of 0 (no pain) to 10 (worst pain), what number was your pain?'
4 'Was the pain a pressure, a burning or a tightness?'

5 At what anatomical location would you assess the apical impulse?
1 left midclavicular, fifth intercostal space
2 left substernal, sixth intercostal space
3 right midaxillary, second intercostal space
4 right nipple line, any intercostal space

6 A person's heart rate is 50. You would document this as:
1 tachycardia
2 bradycardia
3 hypertension
4 hypotension

7 A person has a very low RBC count. What subjective manifestation would you expect to find during a health history?
1 sore throat
2 chest pain
3 fatigue
4 nausea

8 A person has a low platelet count. What would you likely find on physical assessment?
1 enlarged lymph nodes
2 excessive bruising
3 varicose veins
4 changes in pulse pressure

9 An older person is severely dehydrated and, as a result, has increased blood viscosity. How will this affect the peripheral vascular resistance (PVR)?
1 increased PVR
2 decreased PVR
3 no change
4 depends on gender

10 When auscultating the abdominal aorta, you hear a murmuring or blowing sound. You would document this sound as a:
1 hypokinetic pulse
2 bigeminal pulse
3 bruit
4 arrhythmia

11 Swelling of a body part as a result of lymphatic obstruction is labelled:
1 lymphoedema
2 lymphadenopathy
3 atrophic change
4 central cyanosis

12 You are assessing a man who has severe leg pain. The leg is cool and cyanotic. You are unable to palpate a femoral pulse. What would be your priority intervention based on these assessments?
1 Document your findings.
2 Ask the family about this problem.
3 Teach the man relaxation techniques.
4 Notify the medical officer immediately.

CHAPTER 29

NURSING CARE OF PEOPLE WITH CORONARY HEART DISEASE

MAJELLA HALES

LEARNING OUTCOMES

- Discuss how alterations to myocardial perfusion contribute to the development of a person's heart disease.
- Relate interprofessional care principles for a person with angina to the course and manifestations of the condition.
- Summarise the course, management and outcomes when caring for a person with acute coronary syndrome.
- Compare and contrast the potential complications for a person experiencing an acute myocardial infarction.
- Differentiate between various cardiac arrhythmia in the context of influence on lifestyle and management principles.
- Discuss the interprofessional care and implications for a person with sudden cardiac death.

CLINICAL COMPETENCIES

- Assess functional health status of the person with coronary heart disease and/or an arrhythmia, including the impact of the disorder on the person's ability to perform activities of daily living and usual tasks.
- Apply knowledge of the normal anatomy and physiology of the heart to improve care of the person with coronary heart disease.
- Monitor the person with coronary heart disease or arrhythmias for expected and unexpected manifestations, reporting and recording findings as indicated.
- Interpret assessment data, determine priorities of care and develop and implement individualised nursing interventions for the person with coronary heart disease and arrhythmias.
- Administer medications and treatments to the person with coronary heart disease and arrhythmias safely and knowledgeably.
- Integrate multidisciplinary care into nursing care planning and implementation for the person with coronary heart disease and arrhythmias.
- Provide appropriate teaching for prevention, health promotion and self-care related to coronary heart disease and arrhythmias.
- Evaluate the effectiveness of nursing interventions, revising or modifying the plan of care as needed to promote, maintain or restore functional health for the person with coronary heart disease or arrhythmias.

KEY TERMS

Irrespective of the underlying cause, impaired cardiac function affects the person's ability to participate in exercise and activities of daily living. When the functioning of other systems becomes affected by problems such as impaired blood flow to the myocardium, changes in the conduction of electrical impulses through the heart or structural changes in the heart itself, it becomes unable to pump enough blood to meet the body's demand for oxygen and nutrients. Death may result.

Cardiovascular disease (CVD) is a generic term for disorders of the heart and blood vessels. CVD is the leading cause of death and disability in many developed countries and affects over 3.7 million Australians. In Australia, CVD kills one person every 12 minutes and represented 26% of all deaths in 2010. Nationally, almost $7.7 billion is spent on CVD annually, representing 10.4% of the total allocated health expenditure (Australian Institute of Health and Welfare (AIHW), 2014). Indigenous Australians are twice as likely to die from CVD (AIHW, 2014).

Coronary heart disease (CHD) refers more specifically to an ischaemic pathology related to disease of the blood vessels, causing myocardial oxygenation issues. Angina and myocardial infarction are the two main clinical forms of this disease. Cardiovascular disease is a National Health Priority and through increased funding, research and public education campaigns, deaths from CHD have reduced by 73% since 1980 (AIHW, 2014). Although obesity is still a major concern, education involving the reduction of fat intake, increasing exercise and lowering cholesterol levels have made Australians more aware of risk factors associated with CHD.

This chapter focuses on disorders of myocardial blood flow (coronary heart disease) and cardiac rhythm. Disorders of cardiac structure and function are discussed in Chapter 30. Review the normal anatomy and physiology and nursing assessment of the heart in Chapter 28 before proceeding with this chapter.

FAST FACTS

- Heart disease accounts for over 21 500 deaths annually in Australia.
- 15% of Australians aged over 70 have CHD.
- Aboriginal and Torres Strait Islander people are twice as likely as non-Indigenous Australians to experience CHD.

Source: AIHW (2014).

DISORDERS OF MYOCARDIAL PERFUSION

THE PERSON WITH CORONARY HEART DISEASE

Coronary heart disease or *coronary artery disease (CAD)* is caused by impaired blood flow to the myocardium. Accumulation of atherosclerotic plaque in the coronary arteries is the usual cause. Coronary heart disease may be asymptomatic or may lead to angina pectoris, acute coronary syndrome, myocardial infarction (MI), arrhythmias, heart failure and even sudden death.

Incidence and prevalence

Many risk factors for CHD can be controlled through lifestyle modification. In fact, with increased public awareness of risk factors related to CHD, mortality rates have declined by over 40% since the 1970s. Nevertheless, CHD remains a major public health problem. Nurses are in a prime position to encourage and support positive lifestyle changes by teaching and promoting healthy living practices.

Both men and women are affected by CHD in women, however, the onset is about 10 years later because of the heart-protective effects of oestrogen. After menopause, women's risk is equal to that of men.

Physiology review

The two main coronary arteries, the left and the right, supply blood, oxygen and nutrients to the myocardium. They originate in the root of the aorta, just outside the aortic valve. The *left main coronary artery* divides to form the anterior descending and circumflex arteries. The *anterior descending* artery supplies the anterior interventricular septum and the left ventricle, including the apex of the heart. The *circumflex* branch supplies the lateral wall of the left ventricle. The *right coronary artery* supplies the right ventricle and forms the posterior descending artery. The *posterior descending artery* supplies the posterior portion of the heart (see Figure 28.7).

Blood flow through the coronary arteries is regulated by several factors. Aortic pressure is the primary factor. Other factors include the heart rate (most flow occurs during diastole, when the muscle is relaxed), metabolic activity of the heart, blood vessel tone (constriction) and collateral circulation. Although there are no connections between the large coronary arteries, small arteries are joined by **collateral vessels**. If large vessels are gradually occluded, the collateral vessels enlarge, providing alternative routes for blood flow.

Pathophysiology

Coronary atherosclerosis is the most common cause of reduced coronary blood flow.

Atherosclerosis

Atherosclerosis is a progressive disease characterised by *atheroma* (plaque) formation, which affects the intimal and medial layers of large and midsize arteries. See 'Pathophysiology illustrated: coronary heart disease' below.

Atherosclerosis is initiated by unknown precipitating factors that cause lipoproteins and fibrous tissue to accumulate in the arterial wall. Although the precise mechanisms are

unknown, endothelial dysfunction, abnormal lipid metabolism and injury to or inflammation of endothelial cells lining the artery appear to be key to its development.

Endothelial dysfunction is mediated by various factors including endothelial tone and vascular remodelling. An imbalance of endothelial-derived relaxing factors (EDRFs) and endothelial-derived constricting factors (EDCFs) results in augmented constriction intake (Bleakley et al., 2015). This continued workload results in arterial hypertrophy within the media and perpetuates local hypertension, increasing shear stress and contributing to further endothelial damage and remodelling.

In the bloodstream, lipids are transported attached to proteins called apoproteins. High levels of certain *lipoproteins*, a type of apoprotein, increase the risk of atherosclerosis. *Low-density lipoproteins*, which are high in cholesterol, carry cholesterol to peripheral tissues where some of it is released to be taken up and incorporated into cells for use in producing energy. *Very-low-density lipoproteins*, large molecules primarily composed of triglycerides and cholesterol, carry triglycerides to muscle and fat cells. When the triglycerides are released into these tissues, the remainder of the molecule is a low-density lipoprotein. *High-density lipoproteins*, in contrast, attract cholesterol, returning it from peripheral tissues to the liver (Bullock & Hales, 2012).

Hyperlipidaemia itself may damage arterial endothelium. Endothelial damage promotes platelet adhesion and aggregation and attracts leucocytes to the area. At the site of injury, *atherogenic* (atherosclerosis-promoting) lipoproteins collect in the intimal lining of the artery. These lipoproteins appear to actually bind with the extracellular portion of the vessel endothelium. Macrophages migrate to the injured site as part of the inflammatory process. Contact with platelets, cholesterol and other blood components stimulates smooth muscle cells and connective tissue within the vessel wall to proliferate abnormally. Although blood flow is not affected at this stage, this early lesion appears as a yellowish fatty streak on the inner lining of the artery. Fibrous plaque develops as smooth muscle cells enlarge, collagen fibres proliferate and blood lipids accumulate. The lesion protrudes into the arterial lumen and is fixed to the inner wall of the intima. It may invade the muscular media layer of the vessel as well. The developing plaque not only gradually occludes the vessel lumen but also impairs the vessel's ability to dilate in response to increased oxygen demands. Fibrous plaque lesions often develop at arterial bifurcations or curves or in areas of narrowing. As the plaque expands, it can produce severe stenosis or total occlusion of the artery.

The final stage of the process is the development of *atheromas*, complex lesions consisting of lipids, fibrous tissue, collagen, calcium, cellular debris and capillaries. These calcified lesions can ulcerate or rupture, stimulating thrombosis. The vessel lumen may be rapidly occluded by the thrombus or it may embolise to occlude a distal vessel.

Plaque formation may be *eccentric*, located in a specific, asymmetric region of the vessel wall, or *concentric*, involving the entire vessel circumference. Manifestations of the process usually do not appear until about 75% of the arterial lumen has been occluded.

Atherosclerosis tends to develop where arteries bifurcate or branch which encourages atheroma-prone conditions such as high shear forces, less ordered endothelial cell alignment and inferior shear-resistant endothelial cell morphology, ultimately promoting a pro-inflammatory microenvironment (Tabas, García-Cardeña & Owens, 2015). Certain vessels have a higher likelihood of being affected, including the coronary arteries (the left anterior descending artery, in particular), the renal arteries, the bifurcation of the carotid arteries and branching sections of peripheral arteries. In addition to obstructing or occluding blood flow, atherosclerosis weakens arterial walls and is a major cause of aneurysm in vessels such as the aorta and iliac arteries.

Myocardial ischaemia

Myocardial cells become ischaemic when the oxygen supply is inadequate to meet metabolic demands. The critical factors in meeting metabolic demands of cardiac cells are coronary perfusion and myocardial workload. Coronary perfusion can be affected by several different mechanisms:

- One or more vessels may be partially occluded by large, stable areas of plaque.
- Platelets can aggregate in narrowed vessels, forming a thrombus.
- Normal or already narrowed vessels may spasm.
- A drop in blood pressure may lead to inadequate flow through coronary vessels.
- Normal autoregulatory mechanisms that increase flow to working muscles may fail.

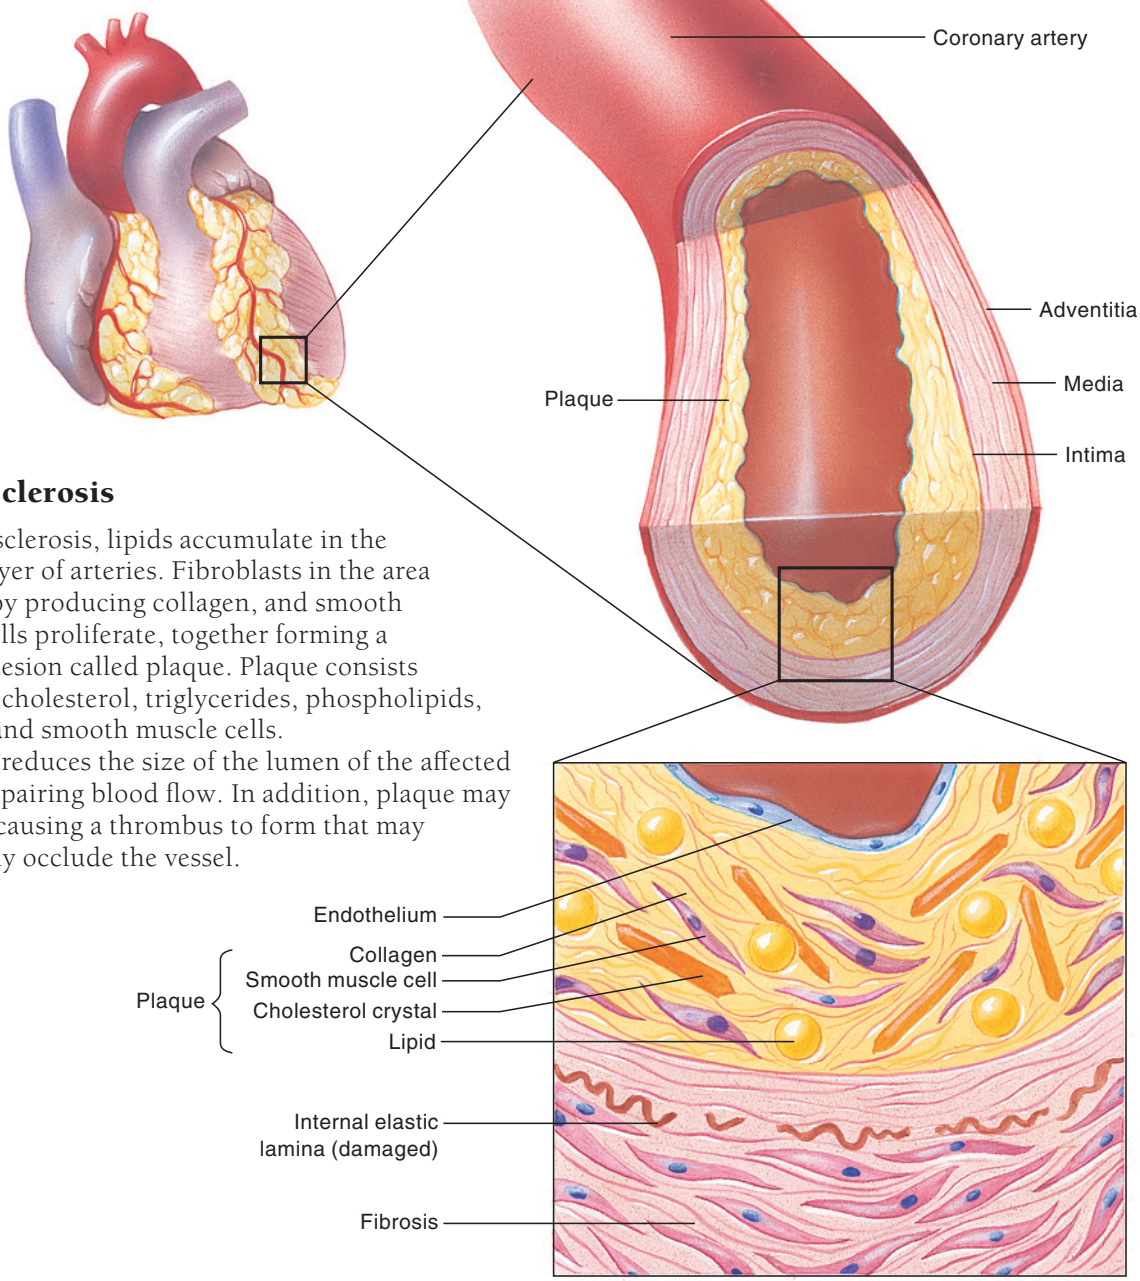
Workload is affected by the heart rate, myocardial contractility, preload (the amount of blood in the ventricles just prior to systole) and afterload (the peripheral pressure that must be overcome to move blood out of the heart into the circulation). The oxygen content of the blood and haematocrit are contributing factors to myocardial ischaemia. Table 29.1 lists factors that may lead to myocardial ischaemia.

TABLE 29.1 Factors contributing to myocardial ischaemia

CORONARY PERFUSION	MYOCARDIAL WORKLOAD	BLOOD OXYGEN CONTENT
• Atherosclerosis • Thrombosis • Vasospasm • Poor perfusion pressure	• Rapid heart rate • Increased preload, afterload or contractility • Increased metabolic demands (e.g. hyperthyroidism)	• Reduced atmospheric oxygen pressure • Impaired gas exchange • Low red blood cells and haemoglobin content

Coronary heart disease

Coronary heart disease usually is due to *atherosclerosis*, occlusion of the coronary arteries by fibrous, fatty plaque. Coronary heart disease is manifested by *angina pectoris, acute coronary syndrome* and/or *myocardial infarction*. Risk factors for coronary heart disease include age (over 50 years), heredity, smoking, obesity, high serum cholesterol levels, hypertension and diabetes mellitus. Other factors, such as diet and lack of exercise, also contribute to the risk of CHD.



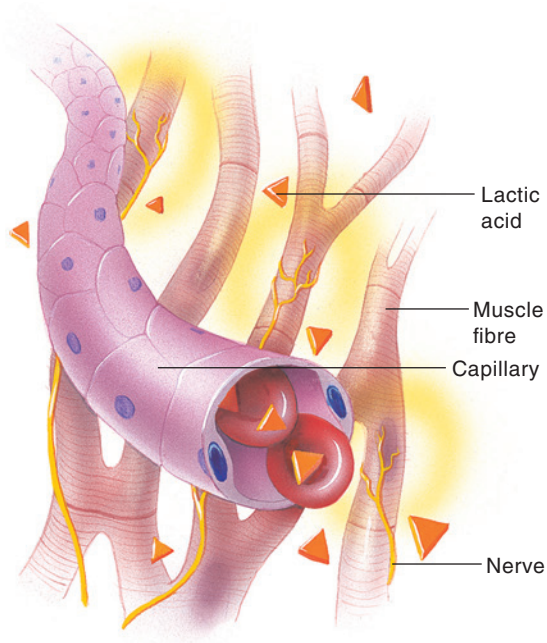
Atherosclerosis

In atherosclerosis, lipids accumulate in the intimal layer of arteries. Fibroblasts in the area respond by producing collagen, and smooth muscle cells proliferate, together forming a complex lesion called plaque. Plaque consists mostly of cholesterol, triglycerides, phospholipids, collagen and smooth muscle cells.

Plaque reduces the size of the lumen of the affected artery, impairing blood flow. In addition, plaque may ulcerate, causing a thrombus to form that may completely occlude the vessel.

Angina pectoris

Angina is characterised by episodes of chest pain, usually precipitated by exercise and relieved by rest. When myocardial oxygen needs are greater than partially occluded vessels can supply, myocardial cells become ischaemic and shift to anaerobic metabolism. Anaerobic metabolism produces lactic acid that stimulates nerve endings in the muscle, causing pain. The pain subsides when the oxygen supply again meets myocardial demand.



Myocardial infarction

Myocardial infarction occurs when complete obstruction of a coronary artery interrupts blood supply to an area of myocardium. Affected tissue becomes ischaemic and eventually dies (infarcts) if the blood supply is not restored. The necrotic area is bordered by an area of injured or damaged tissue, which is in turn surrounded by an area of ischaemic tissue.

As myocardial cells die, they lyse and release various cardiac isoenzymes into the circulation. Elevated serum levels of creatine kinase (CK) and cardiac-specific troponins are specific indicators of myocardial infarction.

Myocardial cells have limited supplies of adenosine triphosphate (ATP) for energy storage. When myocardial workload increases or the supply of blood and oxygen falls, cellular ATP stores are quickly depleted, affecting their contractility. Cellular metabolism switches from an efficient aerobic process to anaerobic metabolism. Lactic acid accumulates and cells are damaged. If blood flow is restored within 20 minutes, aerobic metabolism and contractility are restored and cellular repair begins (Bullock & Hales, 2012). Continued ischaemia results in cell necrosis and death (infarction).

Coronary heart disease is generally divided into two categories: chronic ischaemic heart disease and acute coronary syndromes. *Chronic ischaemic heart disease* includes stable and unstable angina pectoris and silent myocardial ischaemia. In women, angina is the most common presenting symptom of CHD. *Acute coronary syndromes* range from unstable angina to myocardial infarction (Coven, 2015). Acute coronary syndromes and myocardial infarction are the most common presenting symptoms of CHD in men. These disorders are discussed in the following sections of this chapter.

Risk factors

The causes of atherosclerosis are not known, but certain risk factors have been linked with the development of atherosclerotic plaques. The Framingham Heart Study (FHS) provided vital research into the relationship between risk factors and the development of heart disease (see the 'Translation to practice' box below). Research into CHD is ongoing, looking at causative factors, manifestations and protective measures for many populations. Risk factors for CHD are frequently classified as *non-modifiable*, factors that cannot be changed, and *modifiable*, those factors that can be changed (see Table 29.2).

Non-modifiable risk factors

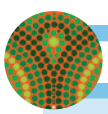
Age is a non-modifiable risk factor. In Australia, approximately 6.7% of all male deaths and 2.7% of all female deaths attributable to CHD occur in individuals under 55. By contrast, over 68% of all male deaths and 87% of all female deaths can be attributable to CHD in individuals 75 years or older (Nichols et al., 2014). *Genetic factors* and *gender* also are non-modifiable risk factors for CHD. A family history of CHD is considered a strong risk factor of the development of coronary artery disease. Men are affected by CHD at an earlier age than women, yet women are still at risk of CHD despite the perception otherwise. In a recent study by Cainzos-Achirica and Blaha (2015), a discordance in CHD risk perception existed in over 60% of the female study cohort. Results such as these reinforce the need for better CHD information campaigns encompassing factors such as risk, prevention and identification.

Modifiable risk factors

Modifiable risk factors include lifestyle factors and pathological conditions that predispose the person to developing CHD. Disease conditions that contribute to CHD include hypertension, diabetes mellitus and hyperlipidaemia. Although these conditions are not a matter of choice, they are modifiable risk factors that can often be controlled through medication, weight control, diet and exercise.

Behavioural or lifestyle factors can be controlled or completely eliminated. Lifestyle changes require significant commitment by the person; ongoing support from the healthcare team is vital for success.

HYPERTENSION *Hypertension* is consistent blood pressure readings greater than 140 mmHg systolic or 90 mmHg



TRANSLATION TO PRACTICE Evidence-based practice: Framingham Heart Study

The Framingham Heart Study (FHS) is an ongoing, significant clinical research study that has provided data about cardiovascular disease for over 60 years. The study was initiated in 1948 with an original study group of 5209 participants in the town of Framingham, Massachusetts, in the United States (Framingham Heart Study, 2015). Every 2 years, this original group is evaluated for cardiovascular 'events' via their medical history, physical findings and diagnostic testing. Children and grandchildren of the original group have also been studied as part of the Framingham Offspring Study. It was in reports of the Framingham study that the term 'risk factor' first appeared.

IMPLICATIONS FOR NURSING

Data collected from the Framingham Heart Study and the Framingham Offspring Study provide a rich database from which to develop evidence-based approaches for people with heart disease. A major application of these research findings to practice is in primary preventive education—for example, through community cardiovascular health programs. Although research shows that increased public awareness of cardiovascular risk factors has lowered morbidity and mortality from heart disease, it remains a leading cause of premature death in Australia. For cardiovascular disease to be reduced on a large scale, education about the effects of lifestyle on the cardiovascular system must begin in the early school years and be reinforced throughout the formative years where healthy choices can become habit.

A second application of these findings is in interprofessional treatment. Nurses should keep up to date on the latest strategies for medical treatment so that they can provide accurate rationales to individuals and formulate effective nursing care plans that complement medical management strategies. The result is better communication, a sense of collegiality and teamwork, and positive health outcomes.

CRITICAL THINKING IN PERSON-CENTRED CARE

1. What kinds of strategies can be used in primary school settings to teach cardiovascular health in a fun, informative manner?
2. Which healthcare providers should be included in a multidisciplinary effort to encourage individuals to modify their lifestyles?
3. What lifestyle changes does one need to make to role model healthy living for optimal cardiovascular health?

TABLE 29.2 Risk factors for coronary heart disease

NON-MODIFIABLE	MODIFIABLE	PATHOPHYSIOLOGICAL
Age	Cigarette smoking	Hyperlipidaemia
Men ≥ 45 years	Obesity	Elevated LDL cholesterol
Women ≥ 55 years	Sedentary behaviour	Elevated triglycerides
Gender	Low fruit and vegetable intake	Low HDL cholesterol
Heredity	Excessive alcohol intake	Hypertension
	Women only: use of oral contraceptives, hormone replacement therapy	Diabetes mellitus
		Kidney disease
		Women only: premature menopause
		Emerging risk factors:
		Elevated homocysteine levels
		Thrombogenic factors
		Inflammatory factors
		Impaired fasting glucose

diastolic. Hypertension affects approximately 30% of Australians. Indigenous Australians experience higher rates of hypertension than non-Indigenous Australians. Aboriginal and Torres Strait Islander people develop hypertension earlier (Australian Bureau of Statistics (ABS), 2014). Hypertension damages arterial endothelium. Inflammatory responses stimulate the development of atherosclerotic plaque. Individuals can reduce hypertension through lifestyle changes.

DIABETES *Diabetes mellitus* contributes to CHD in several ways. Diabetes is associated with several risk factors, including hyperlipidaemia, a higher incidence of hypertension and obesity. In addition, diabetes affects vascular endothelium, which contributes to the development of atherosclerosis. Hyperglycaemia and hyperinsulinaemia, altered platelet function, elevated fibrinogen levels and inflammation also are thought to play a role in the development of atherosclerosis in people with diabetes.

ABNORMAL BLOOD LIPIDS *Hyperlipidaemia* is an abnormally high level of blood lipids and lipoproteins. Lipoproteins carry cholesterol in the blood. Low-density lipoproteins (LDLs) are the primary carriers of cholesterol. High levels of LDL promote atherosclerosis because LDLs deposit cholesterol on artery walls. By contrast, high-density lipoproteins (HDLs) help clear cholesterol from the arteries by transporting it to the liver for excretion. HDL levels above 0.4 mmol/L have a protective effect, reducing the risk of CHD; by contrast, HDL levels lower than 0.4 mmol/L are associated with an increased risk of CHD. Triglycerides are compounds of fatty acids bound to glycerol. They are used for fat storage by the body and are carried on very low-density lipoprotein (VLDL) molecules. Elevated triglycerides also contribute to the risk of CHD. Table 29.3 lists the aims for lipid lowering therapy as recommended by National Vascular Disease Prevention Alliance.

CIGARETTE SMOKING *Cigarette smoking* is an independent risk factor for CHD. The effects of nicotine and other toxins from cigarette smoke negatively affect the cardiovascular system. Individuals who smoke are significantly more at risk of developing CHD than non-smokers (Mons et al., 2015). Research suggests that stopping smoking by the age of 30 removes almost all mortality risks associated with smoking (National Drug Strategy (NDS), 2012) Cigarette smoking promotes CHD in several ways. The carbon monoxide damages vascular endothelium, promoting cholesterol deposition. Nicotine stimulates catecholamine release and increases blood pressure, heart rate and myocardial oxygen demand. Nicotine also causes arterial vasoconstriction, which reduces tissue perfusion. Nicotine also reduces HDL levels, increases platelet aggregation and increases the risk of thrombus formation.

TABLE 29.3 Serum cholesterol and triglyceride targets

Total cholesterol	< 4 mmol/L
High-density lipoprotein cholesterol (HDL-C)	≥ 1 mmol/L
Low-density lipoprotein cholesterol (LDL-C)	< 2 mmol/L
Non-high-density lipoprotein cholesterol (Non-HDL-C)	< 2.5 mmol/L
Triglycerides (TG)	< 2 mmol/L

Source: National Vascular Disease Prevention Alliance (NVDPA) (2012).

FAST FACTS

- Cigarette smoking is the leading independent risk factor for coronary heart disease and a primary target of risk factor management.

OBESITY *Obesity* (excess adipose tissue) is generally defined as a body mass index (BMI) of 30 kg/m^2 or greater. Obese people have higher rates of hypertension, diabetes and hyperlipidaemia. In the Framingham Study (FHS, 2015),

obese men over age 50 had twice the incidence of CHD and acute myocardial infarction (MI) of those who were within 10% of their ideal weight. Central obesity, or intra-abdominal fat, is associated with an increased risk of CHD. The best indicator of central obesity is the waist circumference. A waist-to-hip ratio of greater than 0.8 (women) or 0.9 (men) increases the risk of CHD.

PHYSICAL INACTIVITY *Physical inactivity* is associated with a higher risk of CHD. Research data indicate that people who maintain a regular program of physical activity are less prone to developing CHD than sedentary people. Cardiovascular benefits of exercise include increased availability of oxygen to the heart muscle, decreased oxygen demand and cardiac workload, and increased myocardial function and electrical stability. Other positive effects of regular physical activity include decreased blood pressure and blood lipids, and a decrease in insulin resistance, platelet aggregation and weight (Rahmati-Najarkolaei et al., 2015).

DIET *Diet* is a risk factor for CHD, independent of fat and cholesterol intake. Diets high in fruits, vegetables, whole grains and unsaturated fatty acids appear to have a protective effect. The underlying factors are not clear, but probably relate to nutrients such as antioxidants, folic acid, other B vitamins, omega-3 fatty acids and other unidentified micronutrients (Cespedes & Hu, 2015; Reidlinger et al., 2015).

Emerging risk factors

Recent research demonstrates a link between *elevated serum homocysteine levels* and CHD. Until menopause, women have lower homocysteine levels than men, which may partially explain their lower risk of CHD. Increased homocysteine levels negatively correlate with serum folate and dietary folate intake. Increasing folate intake can reduce homocysteine levels. However, currently, studies do not show benefits of folic acid supplementation. As an alternative, a balanced diet including two serves of fruit and five serves of vegetables a day is recommended to provide adequate vitamin and nutrient supply.

Based on evidence that aspirin and antiplatelet therapies reduce the risk of MI, *clot-promoting factors* are identified as CHD risk factors. *Inflammation* has also recently been identified as a risk factor. Inflammatory processes may increase the development of atherosclerotic plaque (Bullock & Hales, 2012). Inflammation also promotes clot formation at the site of ruptured plaque.

Metabolic syndrome

Metabolic syndrome, a group of metabolic risk factors occurring in an individual, is a strong risk factor for CHD (see Box 29.1). Metabolic syndrome has emerged as a risk factor for premature CHD that is equal to cigarette smoking. Three underlying causes of metabolic syndrome have been identified: overweight/obesity, physical inactivity and genetic factors. It is closely associated with *insulin resistance*, where tissue responds poorly to insulin signalling. Both genetic and acquired factors play a role in insulin resistance, including the presence of abdominal obesity, physical inactivity, and dietary and lifestyle choices.

BOX 29.1 Characteristics of the metabolic syndrome

- Abdominal obesity
- Abnormal blood lipids (low HDL, high triglycerides)
- Hypertension
- Elevated fasting blood glucose
- Clotting tendency
- Inflammatory factors

Risk factors unique to women

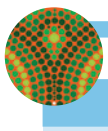
Risk factors unique to women include *premature menopause*, *oral contraceptive use* and *hormone replacement therapy (HRT)*. At menopause, serum HDL levels drop and LDL levels rise, increasing the risk of CHD (see the 'Translation to practice' box below. Early menopause (natural or surgically induced) increases the risk of CHD and MI. Women who have bilateral oophorectomy before age 35 without hormone replacement are eight times more likely to have an MI than women experiencing natural menopause. Oestrogen replacement therapy reduces the risk of CHD and MI in these women. Oral contraceptives with unopposed oestrogen (oestrogen without progestogen), by contrast, increase the risk of MI, particularly in women who also smoke. This increased risk is due to the tendency of oral contraceptives to promote clotting and their effects on blood pressure, serum lipids and glucose tolerance (Fallah et al., 2012; Andersson et al., 2012).

FAST FACTS

- Risk factors for coronary heart disease are those factors that promote atherosclerosis and plaque development.
- Angina pectoris, acute coronary syndromes and myocardial infarction are the manifestations of myocardial ischaemia and coronary heart disease due to atherosclerosis.
- Atherosclerosis also is the primary underlying cause of stroke and peripheral vascular disease; therefore, the risk factors for atherosclerosis are also the risk factors for coronary heart disease, including angina, acute coronary syndromes and myocardial infarction.

Risk factors unique to indigenous Australians

Some significant cardiovascular risk factors include obesity, diabetes, smoking, inactivity and chronic kidney disease. Indigenous Australians experience CVD-related risk factors more than non-Indigenous Australians. Prevalence of type 2 diabetes is three times greater and chronic kidney disease is four times greater in Indigenous Australians than in non-Indigenous Australian populations (AIHW, 2015c). There are stark demographic differences between Indigenous and non-Indigenous Australians (see Table 29.4 and the 'Focus on cultural diversity' box below).



TRANSLATIONTO PRACTICE Evidence-based practice: HRT and cardiovascular disease prevention in postmenopausal women

Numerous research projects have attempted to ascertain the benefit of hormone replacement therapy in the prevention of cardiovascular disease in postmenopausal women. In a recent Cochrane review by Boardman et al. (2015), 19 trials with a combined total of over 40 000 women found strong evidence to suggest that HRT is of little benefit in the context of preventing cardiovascular disease events. Furthermore, HRT demonstrated an increase in the risk of stroke and thromboembolic events.

IMPLICATIONS FOR NURSING

Nurses often are in the position of advising women about menopause, its manifestations and hormone replacement therapy. While HRT does reduce unpleasant menopausal effects such as night sweats and hot flushes, and it reduces the risk of osteoporosis and subsequent fractures, it carries associated risks. Advise each woman about the risks and benefits of HRT, clearly presenting the evidence. Encourage measures such as weight-bearing exercise, calcium supplements and a diet high in fibre to reduce the risks for osteoporosis, fracture and colorectal cancer. Ultimately, each woman will make her own decision about postmenopausal HRT.

CRITICAL THINKING IN PERSON-CENTRED CARE

1. What are some common effects of menopause and how does HRT influence these effects?
2. What are the risks and benefits of HRT consumption in women after menopause?
3. What factors might you suggest an individual consider when deciding whether to use HRT for menopausal manifestations?

TABLE 29.4 Comparison of demographic characteristics between Indigenous and non-Indigenous Australians

	INDIGENOUS AUSTRALIANS	NON-INDIGENOUS AUSTRALIANS
Percentage of population	3%	75%
Current smokers—% of population (15 years and above)	44%	17%
Median age	22 years old	38 years old
Life expectancy (years)	Male—69, Female—74	Male—84, Female—87
Obesity	1.6% higher	
Hypertension	1.5% higher	
CVD-related deaths	25%	12%

INTERPROFESSIONAL CARE

Care of people with coronary heart disease focuses on aggressive risk factor management to slow the atherosclerotic process and maintain myocardial perfusion. Until manifestations of chronic or acute ischaemia are experienced, the diagnosis often is presumptive, based on history and the presence of risk factors.

Diagnosis

Laboratory testing is used to assess for risk factors such as an abnormal blood lipid profile (elevated triglyceride and LDL levels and decreased HDL levels).

- *Total serum cholesterol* is elevated in hyperlipidaemia. A *lipid profile* includes triglyceride (TG), HDL and LDL levels. Calculations are made of the ratio of HDL to total cholesterol. The ratio should be at least 1:5, with 1:3 being the ideal ratio. Elevated lipid levels are associated with an increased risk of atherosclerosis. In people with a strong family history of premature CHD or familial hypercholesterolaemia, *lipoprotein (a)* (Lp(a)) may also be measured. Elevated levels of Lp(a) may independently increase the risk of CHD. Other subsets of blood lipids may also be measured in selected individuals. See the 'Diagnostic tests' boxes in Chapter 28 for nursing care related to lipid profile studies.

Diagnostic tests to identify subclinical (asymptomatic) CHD may be indicated when multiple risk factors are present.

- *C-reactive protein* is a serum protein associated with inflammatory processes. Recent evidence suggests that elevated blood levels of this protein may be predictive of CHD.
- *The ankle–brachial blood pressure index (ABI)* is an inexpensive, non-invasive test for peripheral vascular disease that may be predictive of CHD. The systolic blood pressure in the brachial, posterior tibial and dorsalis pedis arteries is measured by Doppler. An ABI of < 0.9 in either leg indicates the presence of peripheral arterial disease and a significant risk of CHD.
- *Exercise ECG testing* may be performed. ECGs are used to assess the response to increased cardiac workload induced by exercise. The test is considered 'positive' for CHD if myocardial ischaemia is detected on the ECG (depression of

FOCUS ON CULTURAL DIVERSITY Aboriginal and Torres Strait Islander people

Cardiovascular mortality in Aboriginal and Torres Strait Islander people is double that of non-Indigenous Australians and constitutes a significant health burden on Indigenous Australians. Myocardial infarctions account for almost 66% of cardiovascular-related deaths in males and almost 50% of cardiovascular-related deaths in females. All cardiovascular disease-associated risk factors are higher in Aboriginal and Torres Strait Islander Australians than they are for non-Indigenous Australians.

Ethnicity has a strong role in the development of cardiovascular disease. People from some countries experience fewer risk factors by virtue of their diet and genetics. Table 29.5 compares selected risk factors associated with CVD for non-Indigenous Australians against those in some other countries.

Implications for nursing

Australia is a multicultural country and an understanding of how ethnicity may increase or decrease an individual's risk factors for coronary artery disease is important in not only the assessment of an individual presenting with symptoms of cardiovascular dysfunction, providing holistic care and administering medications, but also in individualised planning of education sessions.

Critical thinking in person-centred care

1. It is well established that an individual's diet will influence cardiovascular risk factors. Choose four different cultures/ethnicities commonly found in Australia. Research a typical diet of these four different cultures.
2. Of the four cultures/ethnicities that you've chosen, predict how the diets might influence cardiovascular risk factors. Pay particular attention to fat, cholesterol and triglycerides.
3. Genetics can play an influence on the pharmacology of antihyperlipidaemic agents. Research the influence of genetics/ethnicity on lipid-lowering medications. Relate this to the answers you have given for question 2.

TABLE 29.5 Comparison of risk factors for CVD related to ethnicity

ETHNICITY (PEOPLE FROM)	RISK FACTOR COMPARED TO NON-INDIGENOUS AUSTRALIANS							
	HTN	Smoking	ETOH	Obesity	Physical inactivity	LDLs	HDLs	TG
New Zealand	↓	↑	↑	↑	↑	↑		
South Asia	↓				↑	↑		≅
China	↓	↑						≅
Middle East	↓	↑		↑	↑		↑	
UK and Ireland	↓	↑	↑		↑			
Greece	↓	↑		↑			↓	
Italy	↓		↑				↓	

↓ = lower risk; ↑ = higher risk; ≅ = approximately equal risk; HTN = hypertension; ETOH = drinks excessive alcohol; LDLs = low-density lipoproteins; HDLs = high-density lipoproteins; TG = triglycerides

Sources: Data compiled from various resources, including Foulds, Bredin & Warburton (2012); and Dassanayake et al. (2011).

the ST segment by greater than 3 mm) (see Figure 29.1 below), the person develops chest pain or the test is stopped due to excess fatigue, arrhythmias or other symptoms before the predicted maximal heart rate is achieved.

- *Electron beam computed tomography (EBCT)* creates a three-dimensional image of the heart and coronary arteries that can reveal plaque and other abnormalities. This non-invasive test requires no special preparation and can identify individuals at risk of developing myocardial ischaemia.
- *Myocardial perfusion imaging* (scintigraphy), see the section on angina that follows, may be used to evaluate myocardial blood flow and perfusion, both at rest and during stress testing (exercise or mental stress). These diagnostic tests are further explained in Chapter 28 and the section on angina. Perfusion imaging studies are costly and therefore are not recommended for routine CHD risk assessment.

Risk factor management

Conservative management of CHD focuses on risk factor modification, including smoking, diet, exercise and management of contributing conditions.

SMOKING Individuals who smoke have 20 times more angina attacks and are up to four times more at risk of dying from coronary artery disease than non-smokers (Australian National Preventive Health Agency, 2012). Smoking cessation reduces the risk of CHD within months after quitting and improves cardiovascular status (Zwar et al., 2011). In addition, stopping smoking improves HDL levels, lowers LDL levels and reduces blood viscosity. All smokers are advised to quit. Health promotion activities focus on preventing children, teenagers and adults from starting to smoke. Specific attention should also be paid to pregnant women in order to assist them to quit smoking.

DIET Dietary recommendations for cardiovascular health should include strategies to lower LDL levels and the need to reduce saturated fat and cholesterol intake. Most fats are a mixture of saturated and unsaturated fatty acids. The highest proportions of saturated fat are found in whole-milk products, red meats and coconut oil. Non-fat dairy products, fish and poultry as primary protein sources are recommended. Solidified vegetable fats (e.g. margarine, shortening) contain *trans* fatty acids, which behave more like saturated fats. Soft margarines and vegetable oil spreads contain low levels of trans fatty acids and should be used instead of butter, margarine and shortening. Monounsaturated fats, found in olive, canola and peanut oils, actually lower LDL and cholesterol levels. Certain cold-water fish, such as tuna, salmon and mackerel, contain high levels of omega-3 fatty acids, which help raise HDL levels and decrease serum triglycerides, total serum cholesterol and blood pressure (State Government of Victoria, 2015).

In addition, increased intake of soluble fibre (found in oats, psyllium, pectin-rich fruit and beans) and insoluble fibre (found in whole grains, vegetables and fruit) is recommended. Folic acid and vitamins B_6 and B_{12} affect homocysteine metabolism, reducing serum levels. Leafy green vegetables (e.g. spinach and broccoli) and legumes (e.g. black-eyed peas, dried beans and lentils) are rich sources of folate. Meat, fish and poultry are rich in vitamins B_6 and B_{12}. Vitamin B_6 also is found in soy products; B_{12} is in fortified cereals. Increased intake of antioxidant nutrients (vitamin E, in particular) and foods rich in antioxidants (fruits and vegetables) appear to increase HDL levels and have a protective effect on CHD (State Government of Victoria, 2015).

In middle-aged and older adults, low levels of alcohol consumption (½ standard drink a day) may reduce the risk of CHD. Consumption of no more than two drinks per day for men or one drink per day for women is recommended. People who do not drink alcohol, however, should not be encouraged to start consuming it as a heart-protective measure as any benefit from alcohol consumption can be gained more readily from healthy diet and exercise (National Health and Medical Research Council (NHMRC), 2009).

People who are overweight or obese are encouraged to lose weight through a combination of reduced kilojoule intake (maintaining a nutritionally sound diet) and increased exercise. High-protein, high-fat weight-loss programs are not recommended for weight reduction.

EXERCISE Regular physical exercise reduces the risk of CHD in several ways. It lowers VLDL, LDL and triglyceride levels and raises HDL levels. Regular exercise reduces blood pressure and insulin resistance. National guidelines for physical activity for adults between 18 and 64 years of age have recently changed to accumulate between 150 and 300 minutes of moderate intensity or 75–150 minutes of intense physical intensity (or a combination) each week. Several themes are fostered in the new guidelines, including doing any physical activity is better than none, trying to be active most days and gradually building to the recommended amount (Department of Health, 2014).

HYPERTENSION Although hypertension often cannot be prevented or cured, it can be controlled. Hypertension control (maintaining a blood pressure lower than 140/90 mmHg) is vital to reduce its atherosclerosis-promoting effects and to reduce the workload of the heart. Management strategies include reducing sodium intake, increasing calcium intake, regular exercise, stress management and medications. Hypertension management is discussed in Chapter 31.

DIABETES Diabetes increases the risk of CHD by accelerating the atherosclerotic process. Weight loss (if appropriate), reduced fat intake and exercise are particularly important for the person with diabetes. Because hyperglycaemia also contributes to atherosclerosis, consistent blood glucose management is vital. See Chapter 19 for a detailed discussion of diabetes and blood glucose management.

Medications

Drug therapy to lower total serum cholesterol and LDL levels and to raise HDL levels is now an integral part of CHD management. It is used in conjunction with diet and other lifestyle changes and is based on the individual's overall risk of CHD.

Drugs used to treat hyperlipidaemia act specifically by lowering LDL levels and increasing HDLs. The goal of treatment is to achieve an LDL level of < 1.8 mmol/L and an HDL of > 1.0 mmol/L (NHFA/CSANZ, 2012). Medications to treat hyperlipidaemia are not inexpensive; the cost–benefit ratio needs to be considered because long-term treatment may be required. The four main classes of cholesterol-lowering drugs are statins, bile acid sequestrants, nicotinic acid and fibrates (see 'Medication administration' box).

People at high risk of MI are often started on prophylactic low-dose aspirin therapy. The usual dose is 100 mg/day. In women, the benefit of low-dose aspirin in reducing the risk of CHD is not clear prior to age 65. Aspirin is contraindicated for individuals who have a history of aspirin sensitivity, bleeding disorders or active peptic ulcer disease. Angiotensin-converting-enzyme (ACE) inhibitors or angiotensin receptor blockers also may be prescribed for high-risk individuals, including diabetics with other CHD risk factors (Bullock & Manias, 2013).

THE PERSON WITH ANGINA PECTORIS

Angina pectoris, or *angina*, is chest pain resulting from reduced coronary blood flow, which causes a temporary imbalance between myocardial blood supply and demand. The imbalance may be due to coronary heart disease, atherosclerosis or vessel constriction that impairs myocardial blood supply. Hypermetabolic conditions such as exercise, thyrotoxicosis, stimulant abuse (e.g. cocaine), hyperthyroidism and emotional stress can increase myocardial oxygen demand, precipitating angina. Anaemia, heart failure, ventricular hypertrophy or pulmonary diseases may affect blood and oxygen supplies as well, causing angina.

Pathophysiology

The imbalance between myocardial blood supply and demand causes temporary and reversible myocardial ischaemia. **Ischaemia**, deficient blood flow to tissue, may be caused by partial obstruction of a coronary artery, coronary artery spasm or a

MEDICATION ADMINISTRATION Cholesterol-lowering drugs

STATINS

Statins inhibit the enzyme HMG-CoA reductase in the liver, lowering LDL synthesis and serum levels. The statins are first-line treatment for elevated LDL, used in conjunction with diet and lifestyle changes. Although their side effects are minimal, they may cause increased serum liver enzyme levels and myopathy.

Nursing responsibilities

- Monitor serum cholesterol and liver enzyme levels before and during therapy. Report elevated liver enzyme levels.
- Assess for muscle pain and tenderness. Monitor creatine phosphokinase (CPK) level if present.
- If taking digoxin concurrently, monitor for and report digoxin toxicity.

Health education for the person and family

- Promptly report muscle pain, tenderness or weakness; skin rash or hives or changes in skin colour; abdominal pain, nausea or vomiting.
- Drugs should not be used when pregnant or if pregnancy is planned.
- Inform the medical officer if taking any other medications concurrently.

BILE ACID SEQUESTRANTS

Bile acid sequestrants lower LDL levels by binding bile acids in the intestine, reducing LDL reabsorption and cholesterol production in the liver. They are used in combination therapy regimens and for women who are considering pregnancy. Their primary disadvantages are inconvenience of administration due to bulk and gastrointestinal side effects such as constipation.

Nursing responsibilities

- Store in a tightly closed container.

Health education for the person and family

- Promptly report constipation, severe gastric distress with nausea and vomiting, unexplained weight loss, black or bloody stools, or sudden back pain.
- Drinking ample amounts of fluid while taking these drugs reduces problems of constipation and bloating.
- Do not omit doses as this may affect the absorption of other drugs you are taking.

NICOTINIC ACID

Nicotinic acid in both prescription and non-prescription forms lowers total and LDL cholesterol and triglyceride levels. The crystalline form and the extended-release tablet also raise HDL levels. Because the doses required to achieve significant cholesterol-lowering effects are associated with multiple side effects, nicotinic acid generally is used in combination therapy, particularly with statins.

Nursing responsibilities

- Give oral preparations with meals and accompanied by a cold beverage to minimise GI effects.
- Administer with caution to individuals with active liver disease, peptic ulcer disease, gout or type 2 diabetes.
- Monitor blood glucose, uric acid levels and liver function tests during treatment.

Health education for the person and family

- Flushing of face, neck and ears may occur within 2 hours following dose; these effects generally subside as treatment continues. Alcohol use during nicotinic acid therapy may worsen this effect.
- Report weakness or dizziness with changes in posture (lying to sitting; sitting to standing). Change positions slowly to reduce the risk of injury.

FIBRIC ACID DERIVATIVES

The fibrates are used to lower serum triglyceride levels; they have only a slight to modest effect on LDL. They affect lipid regulation by blocking triglyceride synthesis. They are used to treat very high triglyceride levels and may be used in combination with statins.

Nursing responsibilities

- Monitor serum LDL and VLDL levels, electrolytes, glucose, liver enzymes, renal function tests and full blood count (FBC) during therapy. Report abnormal values.
- Up to 2 months of treatment may be required to achieve a therapeutic effect; rebound, with decreasing benefit, may occur in the second or third month of treatment.

Health education for the person and family

- Take with meals if the drug causes gastric distress.
- Promptly report flu-like symptoms (fatigue, muscle aching, soreness or weakness).
- Drug should not be used in pregnancy. Use reliable birth control measures while taking this drug.
- Consultation with a medical officer is required before stopping this drug and before taking any over-the-counter preparations.

thrombus. Obstruction of a coronary artery deprives cells in the region of the heart normally supplied by that vessel of oxygen and nutrients needed for metabolic processes. Cellular processes are compromised as ATP stores are depleted. Reduced oxygen causes cells to switch from aerobic metabolism to anaerobic metabolism. Anaerobic metabolism causes lactic acid to build up in the cells. It also affects cell membrane permeability, releasing substances such as histamine, kinins and specific enzymes that stimulate terminal nerve fibres in the cardiac muscle and send pain impulses to the central nervous system. The pain radiates to the upper body because the heart shares the same dermatome as this region. Return of adequate circulation provides the nutrients needed by cells and clears the waste products. More than 30 minutes of ischaemia irreversibly damages myocardial cells (necrosis).

Three types of angina have been identified:

1. *Stable angina* is the most common and predictable form of angina. It occurs with a predictable amount of activity or stress and is a common manifestation of CHD. Stable angina usually occurs when the work of the heart is increased by physical exertion, exposure to cold or by stress. Stable angina is relieved by rest and nitrates.

2. *Prinzmetal's (variant) angina* is atypical angina that occurs unpredictably (unrelated to activity) and often at night. It is caused by coronary artery spasm with or without an atherosclerotic lesion. The exact mechanism of coronary artery spasm is unknown. It may result from hyperactive sympathetic nervous system responses, altered calcium flow in smooth muscle or reduced prostaglandins that promote vasodilation.
3. *Unstable angina* occurs with increasing frequency, severity and duration. Pain is unpredictable and occurs with decreasing levels of activity or stress and may occur at rest. People with unstable angina are at risk of myocardial infarction. Unstable angina is discussed further in the section on acute coronary syndromes that follows.

Silent myocardial ischaemia, or asymptomatic ischaemia, is thought to be common in people with CHD, especially with the co-morbidity diabetes mellitus. Silent ischaemia may occur with either activity or mental stress. Mental stress increases the heart rate and blood pressure, increasing myocardial oxygen demand (Bullock & Hales, 2012). Like symptomatic angina, silent myocardial ischaemia is associated with an increased chance of myocardial infarction and death.

FAST FACTS

- Stable angina occurs with a predictable amount of activity or stress.
- Unstable angina occurs with increasing frequency and severity; it may occur at times unrelated to activity or stress.
- Prinzmetal's angina is the only type of angina not necessarily related to coronary heart disease and atherosclerosis; it develops due to coronary artery spasm.

Course and manifestations

The cardinal manifestation of angina is chest pain. The pain typically is precipitated by an identifiable event, such as physical activity, strong emotion, stress, eating a heavy meal or exposure to cold. The classic sequence of angina is activity–pain, rest–relief. The person may describe the pain as a tight, squeezing, heavy pressure or constricting sensation. It characteristically begins beneath the sternum and may radiate to the jaw, neck, shoulder or arm. Less characteristically, the pain may be felt in the jaw, epigastric region or back. Anginal pain usually occurs in a crescendo–decrescendo pattern (increasing to a peak, then gradually decreasing) and typically lasts 2 to 5 minutes. It generally is relieved by rest. Additional manifestations of angina include dyspnoea, pallor, tachycardia, and great anxiety and fear.

Women frequently present with atypical symptoms of angina, including indigestion or nausea, vomiting and upper back pain. The manifestations of angina are summarised in the accompanying box.

The severity of angina can be graded by the degree to which it limits the individual's activities. Class I angina does not occur with ordinary physical activities. It is prompted by strenuous, rapid or prolonged physical exertion. Class II angina may develop with rapid or prolonged walking or stair climbing, whereas class III angina significantly limits ordinary physical activities. The person with class IV angina may have angina at rest, as well as with any physical activity (Alaeddini, 2014).

MANIFESTATIONS Angina

- *Chest pain:* substernal or precordial (across the chest wall); may radiate to neck, arms, shoulders or jaw.
- *Quality:* tight, squeezing, constricting or heavy sensation; may also be described as burning, aching, choking, dull or constant.
- *Associated manifestations:* dyspnoea, pallor, tachycardia, anxiety and fear.
- *Atypical manifestations:* indigestion, nausea, vomiting, upper back pain.
- *Precipitating factors:* exercise or activity, strong emotion, stress, cold, heavy meal.
- *Relieving factors:* rest, position change; glyceryl trinitrate.

INTERPROFESSIONAL CARE

The management of stable angina focuses on maintaining coronary blood flow and cardiac function. Stable angina often can be managed by medical therapy. Measures to restore coronary blood flow are discussed in the section on acute coronary syndrome. As for CHD, risk factor management is a vital component of care for the person with angina (see the preceding section of this chapter).

Diagnosis

The diagnosis of angina is based on past medical history and family history, a comprehensive description of the chest pain and physical assessment findings. Laboratory tests may confirm the presence of risk factors, such as an abnormal blood lipid profile and elevated blood glucose. Diagnostic tests provide information about overall cardiac function.

Common diagnostic tests to assess for coronary heart disease and angina include electrocardiography, stress testing, nuclear medicine studies, echocardiography (ultrasound) and coronary angiography.

ELECTROCARDIOGRAPHY A resting ECG may be normal, may show non-specific changes in the ST segment and T wave, or may show evidence of previous myocardial infarction. Characteristic ECG changes are seen during anginal episodes. During periods of ischaemia, the ST segment is depressed or downsloping and the T wave may flatten or invert (see Figure 29.1). These changes reverse when ischaemia is relieved. For more details about the ECG, its waveforms and its uses, see Chapter 28.

STRESS ELECTROCARDIOGRAPHY Stress electrocardiography (exercise stress test) uses ECGs to monitor the cardiac response to an increased workload during progressive exercise.

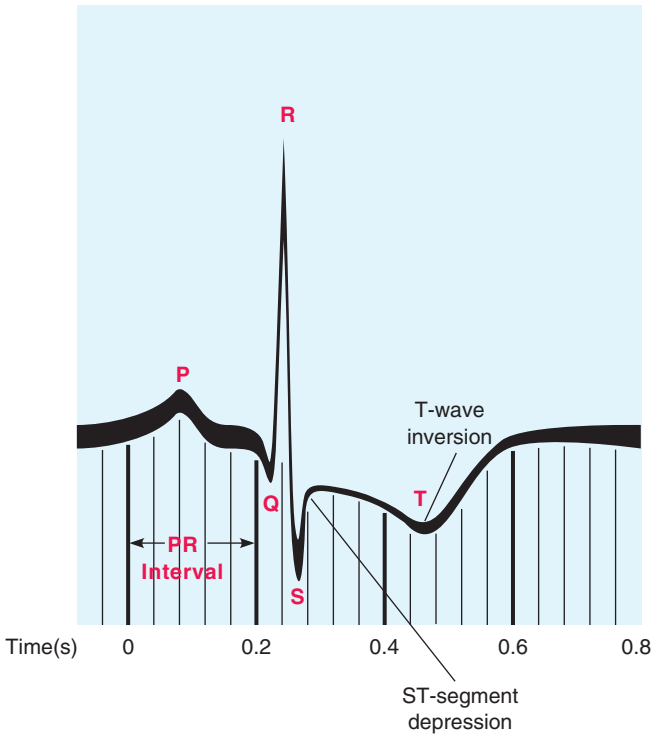

FIGURE 29.1 ■ ECG changes during an episode of angina. Note characteristic T-wave inversion and ST-segment depression of myocardial ischaemia

See the 'Diagnostic tests' box in the previous chapter for more information about exercise stress tests.

RADIONUCLIDE TESTING Radionuclide testing is a safe, non-invasive technique to evaluate myocardial perfusion and left ventricular function. The amount of radioisotope injected is very small; no special radiation precautions are required during or after the scan. Thallium-201 or a technetium-based radio compound is injected intravenously and the heart is scanned with a radiation detector. Ischaemic or infarcted cells of the myocardium do not take up the substance normally, appearing as a 'cold spot' on the scan. If the ischaemia is transient, these spots gradually fill in, indicating the reversibility of the process. With severe ischaemia or a myocardial infarction, these areas may remain devoid of radioactivity.

Left ventricular function can also be evaluated. Whereas the ejection fraction or portion of blood ejected from the left ventricle during systole normally increases during exercise, it may actually decrease in coronary heart disease and stress-induced ischaemia.

Radionuclide testing may be combined with pharmacological stress testing for individuals who are physically unable to exercise or to detect subclinical myocardial ischaemia. A vasodilator is injected to induce the same ischaemic changes that occur with exercise in the diseased heart. Coronary arteries unaffected by atherosclerosis dilate in response to the drugs, increasing blood flow to already well-perfused tissue. This reduces flow to ischaemic muscle, called *myocardial steal syndrome*.

ECHOCARDIOGRAPHY *Echocardiography* is a non-invasive test that uses ultrasound to evaluate cardiac structure and function. It may be done at rest, during supine exercise or immediately following upright exercise to evaluate movement of the myocardial wall and assess for possible ischaemia or infarction.

Transoesophageal echocardiography (TOE) uses ultrasound to identify abnormal blood flow patterns as well as cardiac structures. In TOE, the probe is on the tip of an endoscope inserted into the oesophagus, positioning it close to the posterior heart (especially the left atrium and the aorta). It avoids interference by breasts, ribs or lungs.

See the 'Diagnostic tests' box in Chapter 28 for more information about nursing care of the person undergoing these tests.

CORONARY ANGIOGRAPHY *Coronary angiography* is the gold standard for evaluating the coronary arteries. Guided by fluoroscopy, a catheter introduced into the femoral or brachial artery is threaded into the coronary artery. Dye is injected into each coronary opening, allowing visualisation of the main coronary branches and any abnormalities, such as stenosis or obstruction. Narrowing of the vessel lumen by more than 50% is considered significant; most lesions that cause symptoms involve more than 70% narrowing. Vessel obstructions are noted on a coronary artery 'map' that provides a guide for tracking disease progression and for elective treatment with angioplasty or cardiac surgery. See the 'Diagnostic tests' box in Chapter 28 for the nursing care of the person undergoing coronary angiography. See the 'Translation to practice' box below regarding recent research related to angiography alternatives.

Medications

Drugs may be used for both acute and long-term relief of angina. The goal of drug treatment is to reduce oxygen demand and increase oxygen supply to the myocardium. Three main classes of drugs are used to treat angina: nitrates, beta-blockers and calcium channel blockers.

NITRATES Nitrates, including glyceryl trinitrate (GTN) and longer-acting nitrate preparations, are used to treat acute anginal attacks and prevent angina.

Sublingual glyceryl trinitrate (Anginine) is the drug of choice to treat acute angina. It acts within 1 to 2 minutes, decreasing myocardial work and oxygen demand through venous and arterial dilation, which in turn reduces preload and afterload. It may also improve myocardial oxygen supply by dilating collateral blood vessels and reducing stenosis. Rapid-acting glyceryl trinitrate is also available as a buccal spray in a metered system. For some individuals, this may be easier to handle than small glyceryl trinitrate tablets. The spray also stores longer, reducing the need to discard and repurchase fresh medication every 3 months.

CONSIDERATION FOR PRACTICE

Sublingual glyceryl trinitrate tablets and glyceryl trinitrate spray are the only medications appropriate to treat an acute anginal attack.

TRANSLATION TO PRACTICE Possible non-invasive alternative to angiography to determine the presence of coronary artery disease

A group based at the Monash Centre of Cardiovascular Research Education in Therapeutics is investigating whether measurement of 5-minute heart rate variability can assist with risk stratification in people with cardiovascular disease. In a prospective observational study of over 450 people, it was determined that low heart rate variability is a strong predictor of coronary artery disease in people with sinus rhythm (Kotecha et al., 2012).

IMPLICATIONS FOR NURSING

Nurses are often required to care for individuals following coronary angiography, which is an invasive procedure used to quantify the presence of cardiovascular disease. This research may have identified a simple, non-invasive method of risk stratification that may be plausible for use in determining management or drug therapies.

CRITICAL THINKING IN PERSON-CENTRED CARE

1. What are the risks and benefits associated with reliance on heart rate variability as opposed to the current gold standard for determining coronary artery disease (angiography)?
2. How will this potential change in method of cardiac investigation impact on provision of care, nursing workload and education of individuals with CVD?

Longer-acting glyceryl trinitrate preparations (oral tablets, ointment or transdermal patches) are used to prevent attacks of angina, not to treat an acute attack. The primary problem with long-term nitrate use is the development of *tolerance*, a decreasing effect from the same dose of medication. Tolerance can be limited by a dosing schedule that allows a nitrate-free period of at least 8 to 10 hours daily. This is usually scheduled at night, when angina is less likely to occur.

Headache is a common side effect of nitrates and may limit their usefulness. Nausea, dizziness and hypotension are also common effects of therapy.

BETA-BLOCKERS Beta-blockers, including propranolol, metoprolol and atenolol, are considered first-line drugs to treat stable angina. They block the cardiac-stimulating effects of noradrenaline and adrenaline, preventing anginal attacks by reducing heart rate, myocardial contractility and blood pressure, thus reducing myocardial oxygen demand. Beta-blockers may be used alone or with other medications to prevent angina.

Beta-blockers are contraindicated for people with asthma or severe COPD (see Chapter 36) because they may cause severe bronchospasm. They are not used in people with significant bradycardia or atrioventricular (AV) conduction blocks and are used cautiously in heart failure. Beta-blockers are not used to treat Prinzmetal's angina because they may make it worse.

CALCIUM CHANNEL BLOCKERS Calcium channel blockers reduce myocardial oxygen demand and increase myocardial blood and oxygen supply. These drugs, which include verapamil, diltiazem and nifedipine, lower blood pressure, reduce myocardial contractility and, in some cases, lower the heart rate, decreasing myocardial oxygen demand. They are also potent coronary vasodilators, effectively increasing oxygen supply. Like beta-blockers, calcium channel blockers act too slowly to effectively treat an acute attack of angina; they are used for long-term prophylaxis. Because they may actually increase ischaemia and mortality in people with heart failure or left ventricular dysfunction, these drugs are not usually prescribed in the initial treatment of angina. They are used cautiously in individuals with arrhythmias, heart failure or hypotension.

The nursing implications of antianginal medications are summarised in the 'Medication administration' box below.

ASPIRIN The person with angina, particularly unstable angina, is at risk of myocardial infarction because of significant narrowing of the coronary arteries. Low-dose aspirin (100 mg/day) is often prescribed to reduce the risk of platelet aggregation and thrombus formation.

Nursing care

The focus of nursing care for the person with angina is similar to the interprofessional care focus: to reduce myocardial oxygen demand and improve the oxygen supply. Angina usually is treated in community settings; the primary nursing focus is education.

Health promotion

In addition to health promotion measures identified for CHD, emphasise the importance of active CHD risk factor management to slow progression of the disease. Encourage the person to stop smoking. Discuss the use of cholesterol-lowering drug therapy with people who have hypercholesterolaemia. Encourage regular aerobic exercise and a diet based on the National Heart Foundation guidelines.

Assessment

Focused assessment data for the person with angina include the following:

- *Health history:* chest pain—Onset, Location, Duration, Characteristics, Aggravating symptoms, methods to Relieve the pain, current Treatment (OLDCART); history of other cardiovascular disorders, peripheral vascular disease or stroke; current medications and treatment; usual diet, exercise and alcohol intake patterns; smoking history; use of other recreational drugs.
- *Physical assessment:* vital signs and heart sounds; strength and equality of peripheral pulses; skin colour and

MEDICATION ADMINISTRATION Antianginal medications

ORGANIC NITRATES

Nitrates dilate both arterial and venous vessels, depending on the dose. Coronary artery vasodilation increases myocardial oxygen supply. Venous dilation allows peripheral blood pooling, reducing venous return, preload and cardiac work. Arterial dilation reduces vascular resistance and afterload, also reducing cardiac work. Sublingual glyceryl trinitrate (GTN) is used to treat and prevent acute anginal attacks (when taken prophylactically before activity). Nitrates are administered sublingually by buccal spray, or intravenously for immediate effect; or orally or topically for sustained effect.

Nursing responsibilities

- Dilute intravenous glyceryl trinitrate before infusing; use only glass bottles for the mixture. Glyceryl trinitrate will adsorb onto many infusion lines and PVC bags, affecting the amount of drug that is delivered. Special GTN infusion tubing must be used.
- Wear gloves when opening ampoule and drawing up glyceryl trinitrate infusions to prevent inadvertent administration to self by absorbing through the skin.
- Remove glyceryl trinitrate patches daily (or when required) reducing tolerance by providing GTN-free time.

Health education for the person and family

- Use only the sublingual, buccal and spray forms of nitrates to treat acute angina.
- If the first nitrate dose does not relieve angina within 5 minutes, take a second dose. After 5 more minutes, you may take a third dose if needed. If the pain is unrelieved, seek medical assistance immediately.
- Advise the person to carry a supply of glyceryl trinitrate tablets with them. Dissolve sublingual glyceryl trinitrate tablets under the tongue or between the upper lip and gum. Do not eat, drink or smoke until the tablet is completely dissolved.
- Keep sublingual tablets in their original amber glass bottle to protect them from heat, light and moisture. Replacement should occur every 3 months after opening the supply (tablets). Spray can be kept for a year.
- Burning or tingling sensation may be felt under the tongue and the individual may develop a transient headache on taking the drug. These effects are expected; the headache will diminish over time.
- Use caution when standing from a sitting position; glyceryl trinitrate may cause light headedness.
- Rotate the application sites of the transdermal patches. Apply to a hairless area so that the drug can reach the skin. Remove the patch at bedtime daily (or as ordered). Apply a fresh dose in the morning (or as ordered).
- If using a long-acting nitrate, a supply of immediate-acting nitrates should be kept to treat acute angina.

BETA-BLOCKERS

Beta-blockers decrease cardiac workload by blocking beta receptors on the heart muscle, thus decreasing heart rate, contractility, myocardial oxygen consumption and blood pressure. Beta-blockers also reduce *reflex tachycardia* (an increased heart rate in response to stimuli such as increased sympathetic nervous system activity or vasodilation), which may develop with other antianginal drugs. Beta-blockers are frequently prescribed as antianginal and antihypertensive agents. Some examples include metoprolol and carvedilol.

Nursing responsibilities

- Document heart rate and blood pressure before administering the medication. Withhold drug if the heart rate is below 50 bpm or the blood pressure is below prescribed limits. Notify the doctor.
- Assess for and report possible contraindications to therapy, including heart failure, bradycardia, AV block, asthma or chronic obstructive pulmonary disease (COPD).
- Concurrent use of beta-blockers and calcium channel blockers increases the risk of heart failure; notify the doctor if these drugs are prescribed together.
- Do not abruptly discontinue these drugs after long-term therapy, as this can increase heart rate, contractility and blood pressure, and cause fatal arrhythmia, myocardial infarction or stroke.

Health education for the person and family

- Beta-blockers help prevent angina but will not relieve an acute attack. Keep a supply of fast-acting nitrates on hand for acute anginal attacks.
- Do not suddenly stop taking this medication. Discuss discontinuing medication with medical officers.
- Take pulse before administration. Do not take the drug and contact the doctor if the heart rate is below 50 bpm. Check blood pressure frequently.
- Report a slow or irregular pulse, swelling or weight gain, or difficulty breathing.

CALCIUM CHANNEL BLOCKERS

Calcium channel blockers are used to control angina, hypertension and arrhythmias. By blocking the entry of calcium into cells, these drugs reduce contractility, slow the heart rate and conduction, and cause vasodilation. Calcium channel blockers increase myocardial oxygen supply by dilating the coronary arteries; they decrease the workload of the heart by lowering vascular resistance and oxygen demand. Calcium channel blockers are often prescribed for people with coronary artery spasm (Prinzmetal's angina). Some examples include verapamil and nifedipine.

Nursing responsibilities

- Do not mix verapamil in any solution containing sodium bicarbonate. Administer IV push verapamil over 2 to 3 minutes.
- Document blood pressure and heart rate before administering the drug. Withhold the drug if the heart rate is below 50 bpm. Notify the doctor.
- The nifedipine capsule may be punctured and administered by extracting the liquid with a syringe and squirting the dose under the person's tongue. (Discard the needle first!)

MEDICATION ADMINISTRATION Antianginal medications (continued)

- Use caution when giving a calcium channel blocker with other cardiac depressants, such as beta-blockers. Concomitant administration with nitrates may cause excessive vasodilation.
- Manifestations of toxicity include nausea, generalised weakness, signs of decreased cardiac output, hypotension, bradycardia and AV block. Report these findings immediately. Maintain intravenous access and slowly administer intravenous calcium chloride. Do not infuse large volumes of fluid to treat hypotension as heart failure may result.

Health education for the person and family

- Take pulse before taking the drug. Do not take the drug and notify doctor if the heart rate drops below 50 bpm.
- Keep a fresh supply of immediate-acting nitrate available to treat acute anginal attacks. Calcium channel blockers will not work fast enough to relieve an acute attack.

temperature (central and peripheral); physical appearance during pain episode (e.g. shortness of breath, apparent anxiety, colour, diaphoresis).

Nursing diagnoses and interventions

High-priority nursing problems for individuals with angina include ineffective cardiac tissue perfusion and management of the prescribed therapeutic regimen.

Ineffective tissue perfusion: cardiac

The pain of angina results from impaired blood flow and oxygen supply to the myocardium. Nursing interventions can both prevent ischaemia and shorten the duration of pain.

- Keep prescribed glyceryl trinitrate tablets (or spray) at the person's side so that this can be taken at the onset of pain. Anginal pain indicates *myocardial ischaemia. Glyceryl trinitrate causes vasodilation improving myocardial oxygen supply, relieving ischaemia and pain.*
- Start oxygen at 4 to 6 L/min per nasal prongs or as prescribed. *Supplemental oxygen reduces myocardial hypoxia by increasing oxygen supply.*
- Plan activities to allow rest between them. *Activity increases myocardial oxygen demand and may precipitate angina. Spacing activities reduces the risk of exceeding myocardial oxygen supply.*
- Teach about prescribed medications to maintain myocardial perfusion and reduce cardiac work. Emphasise that beta-blockers, calcium channel blockers and long-acting nitrates are used to *prevent* anginal attacks, not to *treat* an acute attack. *It is important for the person to understand the purpose and use of prescribed drugs to maintain optimal myocardial perfusion.*
- Instruct to take sublingual glyceryl trinitrate before engaging in activities that precipitate angina (e.g. climbing stairs, sexual intercourse). *This prophylactic dose of glyceryl trinitrate helps maintain cardiac perfusion (by improving myocardial oxygen supply) when increased work (myocardial oxygen demand) is anticipated; this reduces ischaemia and chest pain.*
- Encourage the person to implement and maintain a progressive exercise program under the supervision of the primary care provider or a cardiac rehabilitation professional. *Exercise slows the atherosclerotic process and helps develop collateral circulation to the heart muscle.*
- Refer individual to a smoking cessation program as indicated. *Nicotine causes vasoconstriction, increases the heart rate, decreases myocardial perfusion and increases cardiac workload.*

Risk of ineffective therapeutic regimen management

Denial may be strong in the person with angina pectoris. Because many people think of the heart as the locus of life itself, problems such as angina remind people of their mortality, an uncomfortable fact. Denial may lead to 'forgetting' to take prescribed medications or to attempting activities that will precipitate angina. Some people, by contrast, may become 'cardiac cripples', afraid to engage in activities because of anticipated chest pain. Their inactivity may actually hasten the atherosclerotic process and inhibit collateral circulation development, worsening angina.

- Assess knowledge and understanding of angina. *Assessment allows tailoring of teaching and interventions to the needs of the person.*
- Teach the individual about angina and atherosclerosis, building on current knowledge base. *This can help the person understand that angina is a manageable disease and that pain can usually be controlled and the disease progress slowed.*
- Provide written and verbal instructions about prescribed medications and their use. *Written instructions reinforce teaching and are available to the person for future reference.*
- Stress the importance of taking chest pains seriously while maintaining a positive attitude. *Although it is vital to recognise the significance of chest pain and deal with it appropriately, it is also important to maintain a positive outlook.*
- Refer to a cardiac rehabilitation program or other organised activities and support groups for individuals with coronary heart disease. *Programs such as these help the person develop risk factor management strategies, maintain a program of supervised activity and gain coping skills.*

Community-based care

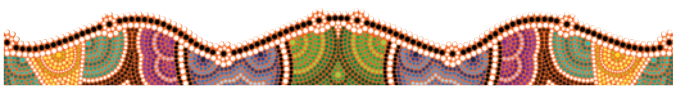
Many people with stable angina manage their pain effectively, continuing to live active and productive lives. To promote

effective management of this disorder, include the following topics in teaching for home care:

- coronary heart disease and the processes that cause chest pain, including the relationship between the pain and reduced blood flow to the heart muscle
- use and effects (desired and adverse) of prescribed medications; importance of not discontinuing medications abruptly
- glyceryl trinitrate use for acute angina: always carry tablets; use prophylactically before activities that often cause chest pain; take tablet at first indication of pain rather than waiting to see if the pain develops; seek immediate medical assistance if three glyceryl trinitrate tablets over 15 minutes do not relieve the pain
- the importance of calling 000 or going to the emergency department immediately for unrelieved chest pain
- appropriate storage of glyceryl trinitrate: this unstable compound needs to be stored in a cool, dry, dark place; no more than a 3-month supply should be kept on hand.

For the person who has undergone cardiac surgery, also include the following:

- respiratory care, activity and pain management
- the importance of actively participating in rehabilitation
- manifestations of infection or other potential complications and their management.



THE PERSON WITH ACUTE CORONARY SYNDROME

Acute coronary syndrome (ACS) is a condition of unstable cardiac ischaemia. ACS includes unstable angina and acute myocardial ischaemia with or without significant injury of myocardial tissue. Although the term ACS may, in some cases, be applied to acute myocardial infarction (AMI) (myocardial tissue death), myocardial infarction is discussed separately in the next section of this chapter.

FAST FACTS

- Acute coronary syndrome (severe cardiac ischaemia), a common cause of hospital admission, includes unstable angina and acute myocardial infarction.
- Unstable angina is characterised by injury to myocardial cells. With prompt restoration of blood flow, muscle tissue recovers.
- Myocardial infarction is characterised by necrosis and death of myocardial cells; scar tissue forms and functional muscle is lost.

Pathophysiology

ACS is a dynamic state in which coronary blood flow is acutely reduced, but not fully occluded. Myocardial cells are injured by the acute ischaemia that results. Most people affected by ACS have significant stenosis of one or more coronary arteries.

ACS is precipitated by any number of pathophysiological causes, including partial occlusion and clot formation of myocardial blood vessels, an oxygen demand versus supply issue or acute changes in the patency of critical myocardial vessels (Coven, 2015). Changes in haemodynamic factors such as increased heart rate, blood flow and blood pressure occur in response to a surge of sympathetic nervous system (SNS) activity. Increased SNS activity also is thought to contribute to the higher incidence of plaque rupture (van Rosendael, de Graaf & Scholte, 2015).

When atherosclerotic plaque ruptures or erodes, the exposed lipid core of the plaque stimulates platelet aggregation and the extrinsic clotting pathway. Thrombin is generated and fibrin is deposited, forming a clot that severely impairs or obstructs blood flow to tissue distal to the area of plaque rupture. As a result, these cells become ischaemic.

Injured myocardial cells contract less effectively, potentially reducing cardiac output if a large area of myocardium is affected. Lactic acid released from ischaemic cells stimulates pain receptors, causing chest pain. Ischaemia and injury affect electrical impulse conduction, producing inversion of the T wave and possibly elevation of the ST segment on the ECG.

Manifestations

The cardinal manifestation of ACS is chest pain, usually substernal or epigastric. The pain often radiates to the neck, left shoulder and/or left arm. The pain may occur at rest and typically lasts longer than 10 to 20 minutes. In ACS, the chest pain is more severe and prolonged than that previously experienced by the individual. It may be a new onset of pain or may represent a pattern of increasing frequency and severity of anginal pain. Dyspnoea, diaphoresis, pallor and cool skin may be present. Tachycardia and hypotension may occur. The person may be nauseated or feel light headed.

INTERPROFESSIONAL CARE

The person with ACS generally presents at the emergency department or doctor's office with complaints of severe chest pain. The pain may be unrelieved by glyceryl trinitrate or may be more severe and of longer duration than previous anginal episodes. The ECG is used in conjunction with blood levels of cardiac markers to differentiate between unstable angina and acute myocardial infarction. People with unstable angina generally are admitted to the acute care unit on bed rest with cardiac monitoring for 12 to 24 hours. Coronary revascularisation procedures may be performed within 48 hours if significant CHD is identified.

Diagnosis

The ECG and serum cardiac markers are the primary tests used to establish the diagnosis of ACS. Serum cardiac markers, proteins released from injured and necrotic heart muscle, can be measured. (See the following section on acute myocardial infarction and Table 29.6 for more information about serum cardiac markers.)

- Cardiac muscle troponins, *cardiac-specific troponin T* (cT_nT) and *cardiac-specific troponin I* (cT_nI), are sensitive indicators of myocardial damage. Troponins may be elevated in

TABLE 29.6 Serum cardiac markers

MARKER	NORMAL LEVEL	PRIMARY TISSUE LOCATION	SIGNIFICANCE OF ELEVATION	CHANGES OCCURRING WITH MI		
				APPEARS	PEAKS	DURATION
CK (CPK)	< 270 U/L	Cardiac muscle, skeletal muscle, brain	Injury to muscle cells	3 to 6 hours	12 to 24 hours	24 to 48 hours
CK-MB	< 10 U/L	Cardiac muscle	MI, cardiac ischaemia, myocarditis, cardiac contusion, defibrillation	4 to 8 hours	18 to 24 hours	72 hours
cT_nT	< 0.1 µg/L	Cardiac and skeletal muscle	Acute MI, unstable angina	2 to 4 hours	24 to 36 hours	10 to 14 days
cT_nI	0.4 µg/L (ACS) > 01.5 µg/L (AMI)	Cardiac muscle	Acute MI, unstable angina	2 to 4 hours	24 to 36 hours	7 to 10 days

ACS or may be within normal limits if chest pain is due to unstable angina.

- Creatine kinase (CK) and CK-MB (specific to myocardial muscle) levels are likely to be within normal limits or demonstrate transient elevation, returning to normal levels within 12 to 24 hours.

The ECG, particularly when done during the acute episode of chest pain, is a valuable diagnostic tool for ACS. ST-segment changes (elevation or depression) during chest pain that resolve when the pain abates usually indicate acute myocardial ischaemia and severe underlying CHD.

Medications

Medications include drugs to reduce myocardial ischaemia and to reduce the risk of blood clotting. Thrombolytic drugs (i.e. drugs that break down the fibrin in blood clots) may be given prior to or on admission to the emergency department. These drugs restore blood flow to ischaemic cardiac muscle and can prevent permanent damage. See the section on myocardial infarction for more information about thrombolytic drugs and their nursing implications.

Nitrates and beta-blockers are used to restore blood flow to the ischaemic myocardium and reduce the workload of the heart. Glyceryl trinitrate is given by sublingual tablet or buccal spray. If chest pain is unrelieved after three doses 5 minutes apart, an intravenous glyceryl trinitrate infusion is initiated. The infusion may be continued until the chest pain is relieved or for 12 to 24 hours. Topical or oral nitrates are then initiated. Beta-adrenergic blockers are initially given intravenously, followed by oral beta-blockers. See the 'Medication administration' box above for the nursing implications of these drugs.

Aspirin, other antiplatelet drugs and heparin are given to inhibit blood clotting and reduce the risk of thrombus formation. Aspirin and clopidogrel are given to people with ACS who do not have an excessive bleeding risk. Aspirin and clopidogrel suppress platelet aggregation, interrupting the process of forming a stable blood clot. Both increase the risk of serious haemorrhage; for most people, however, the benefit outweighs the risk. Intravenous antiplatelet drugs such as abciximab, eptifibatide or tirofiban may be used when an invasive coronary revascularisation procedure is anticipated in the immediate or near future. Nursing implications for the antiplatelet drugs are outlined in the 'Medication administration' box below.

Revascularisation procedures

Several procedures may be used to restore blood flow and oxygen to ischaemic tissue. Non-surgical techniques include transluminal coronary angioplasty, laser angioplasty, coronary atherectomy and intracoronary stents. Coronary artery bypass grafting (CABG) is a surgical procedure that may be used.

PERCUTANEOUS TRANSLUMINAL CORONARY REVASCULARISATION

Percutaneous transluminal coronary revascularisation (PTCA) procedures are used to restore blood flow to the ischaemic myocardium in the person with CHD. There are over 37 600 percutaneous coronary interventions a year performed in Australia (AIHW, 2015b). PTCA is used to treat the person with:

- moderately severe, chronic stable angina unrelieved by medical therapy
- unstable angina
- acute myocardial infarction
- significant stenosis of the left anterior descending coronary artery
- stenosis of a coronary artery bypass graft.

PTCA procedures are similar to the procedure used for coronary angiography. A catheter introduced into the arterial circulation is guided into the opening of the narrowed coronary artery. A flexible guide wire is inserted through the catheter lumen into the affected vessel. The guide wire is then used to thread an angioplasty balloon, arterial stent or other therapeutic device into the narrowed segment of the artery (see Figure 29.2). The procedure is performed in the cardiac catheterisation laboratory using local anaesthesia. The hospital stay is short (1 to 2 days), minimising costs.

Intracoronary stents are metallic scaffolds used to maintain an open arterial lumen. Stents are now used in the majority of all PTCA procedures. Some stents are drug-eluting and release chemicals known to reduce restenosis (Shurmur, 2014). The stent is placed over a balloon catheter, guided into position and expanded

MEDICATION ADMINISTRATION Antiplatelet drugs

ORAL ANTIPLATELET DRUGS

Antiplatelet drugs suppress platelet aggregation in arteries, preventing the development of an arterial thrombus. Aspirin and clopidogrel block different platelet activation pathways to inhibit platelet aggregation and clot formation. The dose of aspirin given to achieve antiplatelet effects is low, 100 mg/day.

Nursing responsibilities

- Inquire about a history of intracranial haemorrhage, upper gastrointestinal bleeding, peptic ulcer disease or known bleeding tendency.
- Observe for and report increased bruising, petechiae, purpura, apparent or occult bleeding (e.g. melaena, haematemesis).
- Do not administer concurrently with warfarin.

Health education for the person and family

- Take as directed. Take aspirin with food or milk; clopidogrel may be taken at any time of day.
- Do not use non-steroidal anti-inflammatory drugs (NSAIDs) or other over-the-counter drugs that may contain aspirin or an NSAID unless prescribed by the doctor.
- Check with your doctor before taking any herbal remedies such as evening primrose oil, feverfew, garlic, ginkgo biloba or grapeseed extract while taking these medications.
- Report unusual bruising or excessive bleeding.
- Inform all care providers (including dental professionals) of use of these drugs.

INTRAVENOUS ANTIPLATELET DRUGS

The intravenously administered antiplatelet drugs, abciximab, epifibatide and tirofiban, block the final common pathway of platelet activation and thus are more effective. However, the risk of bleeding is greater than with the orally administered antiplatelet drugs.

Nursing responsibilities

- Determine history of bleeding disorders, intracranial haemorrhage, recent trauma or surgery.
- Inquire about recent use of oral antiplatelet or anticoagulant drugs.
- Monitor FBC, including haemoglobin, haematocrit and platelet count; clotting studies, including prothrombin time (PT), International Normalized Ratio (INR), activated partial thromboplastin time (aPTT); vital signs; and ECG during therapy.
- Maintain a separate intravenous line for blood draws and administration of other drugs during infusion.
- Closely observe for and immediately report anaphylaxis or bleeding uncontrolled by pressure. Keep resuscitation equipment readily available.
- Maintain bed rest during infusion.

Health education for the person and family

- This drug is given to reduce the risk of clotting and myocardial infarction. It helps maintain blood flow through the affected vessel following angioplasty and stent placement.
- Immediately report any chest tightness, difficulty breathing, shortness of breath or itching that develops during the infusion.
- The risk of bleeding should return to normal within about 2 days following the infusion.
- Immediately report any unusual bruising or bleeding.

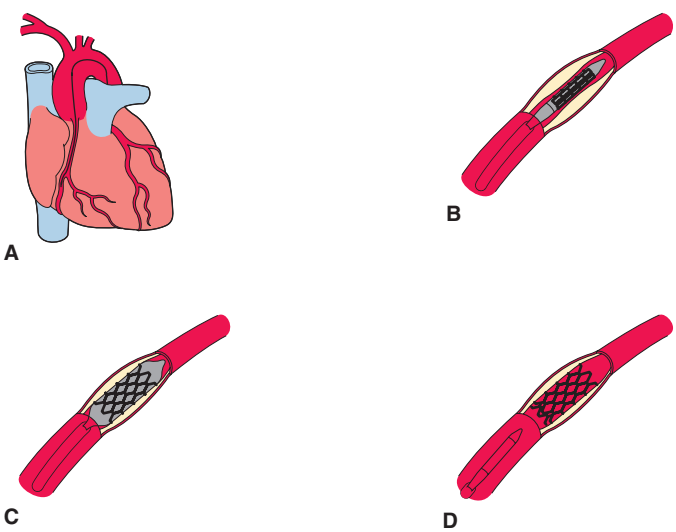


FIGURE 29.2 ■ Percutaneous coronary revascularisation. *A*, The balloon catheter with the stent is threaded into the affected coronary artery. *B*, *C*, The stent is positioned across the blockage and expanded. *D*, The balloon is deflated and removed, leaving the stent in place

as the balloon is inflated. It then remains in the artery as a prop after the balloon is removed. Endothelial cells will completely line the inner wall of the stent to produce a smooth inner lining. Antiplatelet medications (aspirin and ticlopidine) are given following stent insertion to reduce the risk of thrombus formation at the site.

In contrast to stent procedures, which enlarge the artery by displacing plaque, atherectomy procedures remove plaque from the identified lesion. The directional atherectomy catheter shaves the plaque off vessel walls using a rotary cutting head, retaining the fragments in its housing and removing them from the vessel. Rotational atherectomy catheters pulverise plaque into particles small enough to pass through the coronary microcirculation. Laser atherectomy devices use laser energy to remove plaque.

Complications following PTCA procedures include haematoma at the catheter insertion site, pseudoaneurysm, embolism, hypersensitivity to contrast dye, arrhythmias, bleeding and vessel perforation. Other complications include restenosis or reocclusion of the treated vessel.

Nursing care of the person undergoing PTCA is outlined in the box below.

CORONARY ARTERY BYPASS GRAFTING Surgery for coronary heart disease involves using a section of a vein or an

NURSING CARE OF THE PERSON having PTCA

BEFORE THE PROCEDURE

- Assess knowledge of the procedure and expectations of treatment. *This allows information to be tailored to the person's needs and provides an opportunity to clarify misconceptions.*
- Describe the cardiac catheterisation laboratory and the planned PTCA procedure, including:
  - preoperative preparation (see Chapter 3)
  - planned anaesthesia or sedation to be used
  - drugs that may be given during the procedure, such as anticoagulants to reduce the risk of thrombus formation; intravenous glyceryl trinitrate; and a calcium channel blocker to dilate coronary arteries and prevent anginal pain.
- Discuss possible sensations during the procedure, including flushing or warmth and a metallic taste in the mouth as the contrast dye is injected, and a feeling of pressure or chest pain during balloon inflation. *Advanced preparation for expected sensations reduces anxiety and improves outcomes.*
- Perform a comprehensive assessment, including hydration status (skin and mucous membrane moisture, turgor) and peripheral circulation (colour, warmth, sensation, pulses and capillary refill).

AFTER THE PROCEDURE

- Complete a head-to-toe assessment. Note any complaints of chest pain or evidence of decreased cardiac output or myocardial infarction. *Assessment provides a baseline for subsequent assessments and allows early identification of possible complications.*
- Monitor vital signs and cardiac rhythm continuously. Treat arrhythmias as ordered. Obtain a 12-lead ECG if signs of ischaemia develop and notify doctor. *Vital signs reflect cardiac output. Arrhythmias may develop with reperfusion of the ischaemic myocardium. ECG changes may indicate infarction or restenosis of the affected vessel.*
- Maintain intravenous glyceryl trinitrate infusion. Administer anticoagulant and antiplatelet medications, nitrates and calcium channel blockers as ordered. *These drugs decrease oxygen demand and increase oxygen supply by dilating the coronary arteries and systemic vasculature. They also reduce the risk of thrombus formation.*
- Monitor for and treat or report chest pain as indicated. *Chest pain may indicate ischaemia and possible myocardial infarction.*
- Maintain bed rest as ordered with the head of the bed at 30 degrees or less. Prevent flexion of the leg on the affected side. Following sheath removal, follow protocol for pressure dressing or device or sandbag placement. *A large puncture wound occurs at the insertion site. Immobilisation allows the wound to seal; a pressure dressing helps prevent bleeding.*
- Monitor distal pulses, colour, movement, sensation and temperature of the affected leg and insertion site every 15 minutes for the first hour, every 30 minutes for the next hour, every hour for the next 8 hours, then every 4 hours. A clot may form at the site, reducing perfusion of the affected leg. The site and dressing are monitored for excessive bleeding, haematoma formation or pseudoaneurysm. *Pseudoaneurysm occurs as a result of inadequate haemostasis after catheter removal.*
- Monitor intake and output, serum electrolytes, urea, creatinine, full blood count (FBC), activated partial thromboplastin time (aPTT) and cardiac enzymes. Report abnormal results to the medical officer. *Contrast dye causes osmotic diuresis and may cause kidney damage or a hypersensitivity reaction. Electrolyte imbalances increase the risk of arrhythmias. Cardiac enzymes are monitored for indications of possible myocardial damage during the procedure. The aPTT monitors the effectiveness of heparin therapy.*
- Monitor for bradycardia, light headedness, hypotension, diaphoresis and loss of consciousness during sheath removal. Keep atropine at bedside during sheath removal. Bradycardia and signs of decreased cardiac output may occur during sheath removal because of a vasovagal reaction. *Atropine decreases vagal tone and increases heart rate.*

artery to create a connection (or bypass) between the aorta and the coronary artery beyond the obstruction (see Figure 29.3). This then allows blood to perfuse the ischaemic portion of the heart. The internal mammary artery in the chest and the saphenous vein from the leg are the vessels most commonly used for CABG.

Bypass grafts are safe and effective. Angina is totally relieved or significantly reduced in 90% of people who undergo complete revascularisation. While anginal pain may recur within 3 years, it rarely is as severe as before surgery. Coronary artery bypass graft has a positive effect on mortality in many cases. It is recommended for people who have multiple vessel disease and impaired left ventricular function or diabetes, and for people who have significant obstruction of the left main coronary artery (Kalyanasundaram, 2014).

A median sternotomy commonly is used to access the heart. The heart is usually stopped during surgery. The *cardiopulmonary bypass (CPB) pump* is used to maintain perfusion to the rest of the organs during open-heart surgery. Venous blood is removed from the body through a cannula placed in the right atrium or the superior and inferior venae cavae. Blood then circulates through the CPB pump, where it is oxygenated, its temperature is regulated and it is filtered. Oxygenated blood is returned to the body through a cannula in the ascending aorta (see Figure 29.4). Cardiopulmonary bypass enables surgeons to operate on a still heart and a relatively bloodless field. Hypothermia can be maintained to reduce the metabolic rate and decrease oxygen demand during surgery.

Newer techniques have been developed that allow surgeons to perform CABG without cardioplegia (stopping the heart) and CPB. Off-pump coronary artery bypass (OPCAB) allows use of a smaller incision for access. Although cardiopulmonary bypass is employed for the majority of coronary artery bypass procedures, OPCAB is a promising alternative. OPCABs reduce mortality and morbidity rates and result in faster recovery for

the person undergoing OPCAB as compared to CABG with cardiopulmonary bypass (Kalyanasundaram, 2014).

Even more recently, a technique known as robotic CABG has emerged. The surgeon uses a computer to manipulate robotic arms to undertake surgery on anterior vessels in a more endoscopic approach (Kalyanasundaram, 2014). Early evidence is suggesting that this intervention may become a valuable and less traumatic option for selected individuals.

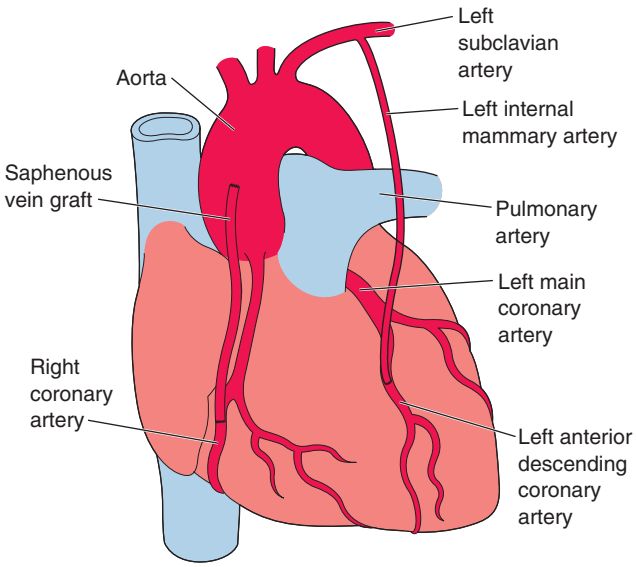

FIGURE 29.3 ■ Coronary artery bypass grafting using the internal mammary artery and a saphenous vein graft

When the saphenous vein is used, it is excised from its normal attachments in the leg and flushed with a cold heparinised saline solution. It is then reversed so that its valves do not interfere with blood flow. When appropriate, a laparoscopic approach may be used to remove the vein. The vein is *anastomosed* (grafted) to the aorta and the coronary artery, distal to the occlusion (see Figure 29.3). This provides a bridge or conduit for blood flow past the obstruction. If the internal mammary artery (IMA) is used, its distal end is excised and anastomosed to the coronary artery distal to the obstruction. The IMA often is used to revascularise the left coronary artery because of the greater oxygen demand of the left ventricle.

Once grafting is completed, cardiopulmonary bypass is discontinued and the person is rewarmed. Rewarming stimulates the heart to resume beating. Temporary pacing wires are sutured in place and passed through the chest wall in case temporary pacing is necessary. Chest tubes are placed in the pleural space and mediastinum to drain blood and re-establish negative pressure in the thoracic cavity, and to and drain bleeding as a result of the operation. The sternum is closed using heavy wires and bone wax, the skin is closed with sutures or staples, and sterile dressings are applied over sternal and leg incisions.

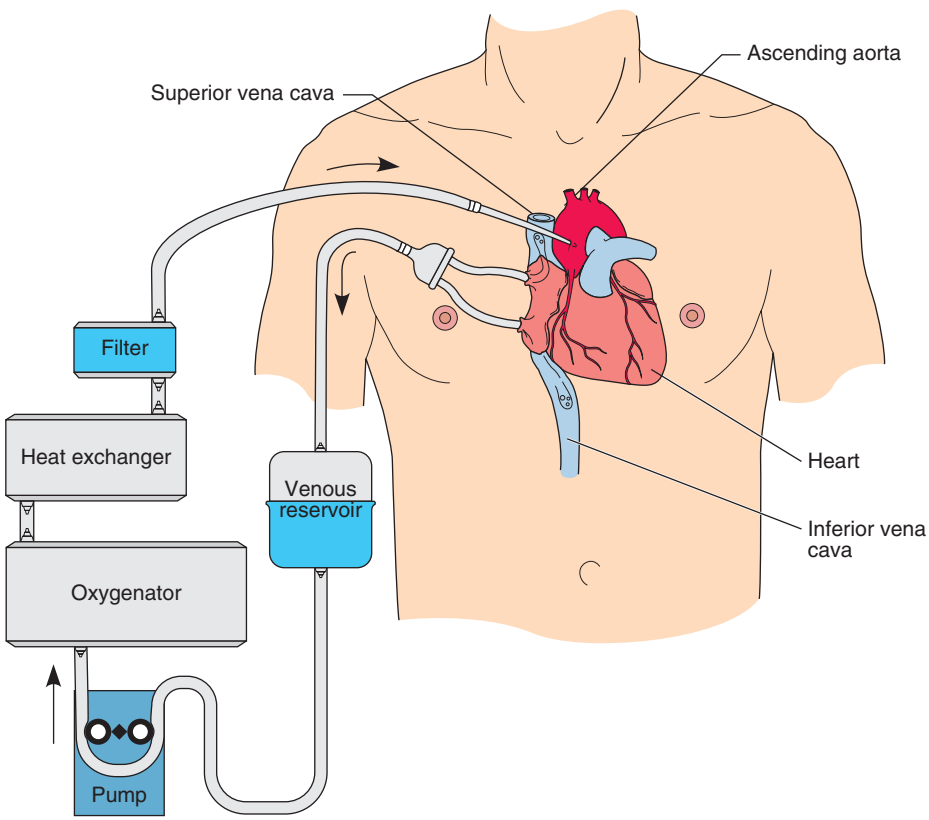

FIGURE 29.4 ■ A diagrammatic representation of cardiopulmonary bypass. A cannula in the superior and inferior venae cavae removes venous blood, which is then pumped through an oxygenator and heat exchanger. After filtering, oxygenated blood is returned to the ascending aorta

Pre- and postoperative nursing care and teaching for the person having a coronary artery bypass graft or other open-heart surgery are outlined in the following 'Nursing care' box.

MINIMALLY INVASIVE CORONARY ARTERY SURGERY

Minimally invasive coronary artery surgery is a potential future alternative to CABG. Two approaches may be used. *Port-access coronary artery bypass* uses several small holes, or 'ports', in the chest wall to access vessels for connection to the CPB pump and the surgical site. Alternatively, the femoral artery and femoral vein may be used for CPB. CPB is avoided altogether using the *minimally invasive direct coronary artery bypass (MIDCAB)* approach. With MIDCAB, a small surgical incision and several chest wall ports are used to graft a chest wall artery to the affected coronary vessel while the heart continues to beat. Beta-blockers are often used to reduce the heart rate to reduce movement in the surgical site.

TRANSMYOCARDIAL LASER REVASCULARISATION

A new development in myocardial revascularisation techniques is called *transmyocardial laser revascularisation (TMLR)*. In this procedure, a laser is used to drill tiny holes into the myocardial muscle itself to provide collateral blood flow to ischaemic muscle. Individuals whose coronary artery obstructions are too diffuse to bypass are candidates for this new surgical treatment.

NURSING CARE OF THE PERSON having coronary artery bypass grafts

PREOPERATIVE CARE

- Provide routine preoperative care and teaching as outlined in Chapter 3.
- Verify presence of laboratory and diagnostic test results in the chart, including FBC, coagulation profile, urinalysis, chest x-ray and coronary angiogram. *These baseline data are important for comparison of postoperative results and values.*
- Type and crossmatch four or more units of blood as ordered. *Blood is made available for use during and after surgery as needed.*
- Provide the person and their family with specific teaching related to procedure and postoperative care. Include the following topics:
  - cardiac recovery unit; sensory stimuli, personnel; noise and alarms; visiting policies
  - tubes, drains and general appearance
  - monitoring equipment, including cardiac and haemodynamic monitoring systems
  - respiratory support: ventilator, endotracheal tube, suctioning; communication while intubated
  - incisions and dressings
  - pain management.

  Preoperative teaching reduces anxiety and prepares the person and family for the postoperative environment and expected sensations.

POSTOPERATIVE CARE

- Provide routine postoperative care as outlined in Chapter 3. In addition to the care needs of all individuals having major surgery, the person having cardiac surgery has specific care needs related to open-heart and thoracic surgery. These are outlined under the nursing diagnoses identified below.

Decreased cardiac output

Cardiac output may be compromised postoperatively due to bleeding and fluid loss; depression of myocardial function by drugs, hypothermia and surgical manipulation; arrhythmias; increased vascular resistance; and a potential complication, *cardiac tamponade*, compression of the heart due to collected blood or fluid in the pericardium.

- Monitor vital signs, oxygen saturation and haemodynamic parameters every 15 minutes. Note trends and report significant changes to the doctor. *Initial hypothermia and bradycardia are expected; the heart rate should return to the normal range with rewarming. The blood pressure may fall during rewarming as peripheral vasodilation occurs. Hypotension and tachycardia, however, may indicate low cardiac output. Pulmonary artery pressure (PAP), pulmonary artery wedge pressure (PAWP), cardiac output and oxygen saturation are often monitored to evaluate fluid volume, cardiac function and gas exchange.* Haemodynamic monitoring is further discussed in Chapter 30.
- Auscultate heart and breath sounds on admission and at least every 4 hours. *A ventricular gallop, or S_3, is an early sign of heart failure; an S_4 may indicate decreased ventricular compliance. Muffled heart sounds may be an early indication of cardiac tamponade. Adventitious breath sounds (wheezes or rales—crackles) may be a manifestation of heart failure or respiratory compromise.*
- Assess skin colour and temperature, peripheral pulses and level of consciousness with vital signs. *Pale, mottled or cyanotic colouring, cool and clammy skin, and diminished pulse amplitude are indicators of decreased cardiac output.*
- Continuously monitor and document cardiac rhythm. *Arrhythmias are common and may interfere with cardiac filling and contractility, decreasing the cardiac output.*
- Measure intake and output hourly. Report urine output less than 30 mL/h for 2 consecutive hours. *Intake and output measurements help evaluate fluid volume status. A fall in urine output may be an early indicator of decreased cardiac output.*
- Record chest tube output hourly. *Chest tube drainage greater than 70 mL/h or that is warm, bright red and free flowing indicates haemorrhage and may necessitate a return to surgery. A sudden drop in chest tube output may indicate impending cardiac tamponade.* Monitoring for the presence of pulsus paradoxis and pulsus alternans should occur.
- Monitor haemoglobin, haematocrit and serum electrolytes. *A drop in haemoglobin and haematocrit may indicate haemorrhage that is not otherwise obvious. Electrolyte imbalances—potassium, calcium and magnesium, in particular—affect cardiac rhythm and contractility.*
- Administer intravenous fluids, fluid boluses and blood transfusions as ordered. *Fluid and blood replacement helps ensure adequate blood volume and oxygen-carrying capacity.*

(continued)

NURSING CARE OF THE PERSON having coronary artery bypass grafts (continued)

- Administer medications as ordered. *Medications ordered in the early postoperative period to maintain the cardiac output include inotropic drugs (e.g. dopamine, dobutamine) to increase the force of myocardial contractions; vasodilators (e.g. nitroprusside or glyceryl trinitrate) to decrease vascular resistance and afterload; and antiarrhythmic agents to correct arrhythmias that affect cardiac output.*
- Keep a temporary pacemaker at the bedside; initiate pacing as indicated. *Temporary pacing may be needed to maintain the cardiac output with bradyarrhythmias, such as high-level AV blocks.*

CONSIDERATION FOR PRACTICE

Assess for signs of cardiac tamponade: increased heart rate, decreased BP, decreased urine output, increased central venous pressure, a sudden decrease in chest tube output, muffled/distant heart sounds and diminished peripheral pulses. Notify medical officer immediately. Cardiac tamponade is a life-threatening complication that may develop postoperatively. Cardiac tamponade interferes with ventricular filling and contraction, decreasing cardiac output. Untreated, cardiac tamponade leads to cardiogenic shock and possible cardiac arrest.

Hypothermia

Hypothermia is maintained during cardiac surgery to reduce the metabolic rate and protect vital organs from ischaemic damage. Although rewarming is instituted on completion of the surgery, the person often remains hypothermic on admission to cardiac recovery. Gradual rewarming is necessary to prevent profound and rapid peripheral vasodilation and hypotension.

- Monitor core body temperature for the first 8 hours following surgery. Often temperature probes will be put in beside the nasogastric tubes. *Oral temperature measurements are not reliable indicators of core body temperature during this period. Tympanic temperature monitoring is indicated.*
- Institute rewarming measures (e.g. warmed intravenous solutions or blood transfusion, warm blankets, warm inspired gases, radiant heat lamps) as needed to maintain a temperature above 36°C. Administer pethidine to relieve shivering (as ordered). *Low body temperature may cause shivering, increasing oxygen demand. Hypothermia also increases the risk of hypoxia, metabolic acidosis, vasoconstriction and increased cardiac work, altered clotting and arrhythmias. If shivering cannot be controlled with narcotic agents, paralysing agents may be needed if the individual's haemodynamic stability is compromised. This intervention is not desirable, but is occasionally necessary.*

Acute pain

Following a CABG, pain is experienced due to both the thoracic incision and removal of the saphenous vein from the leg. Dissection of the internal mammary artery (usually the left IMA) from the chest wall also causes chest pain on the affected side. Chest tube sites are also uncomfortable. The leg from which the saphenous vein graft was obtained may be more painful than the chest incision.

- Frequently assess for pain, including its location and character. Document its intensity using a standard pain scale. Assess for verbal and non-verbal indicators of pain. Validate pain cues with the individual. *Pain is subjective and differs among individuals. Incisional pain is expected; however, anginal pain also may develop. It is important to differentiate the type of pain.*
- Administer analgesics on a scheduled basis, by patient-controlled analgesia (PCA), or by continuous infusion for the first 24 to 48 hours. *Research demonstrates that adequate pain management in the immediate postoperative period reduces complications from sympathetic stimulation and allows faster recovery. Pain causes muscle tension and vasoconstriction, impairing circulation and tissue perfusion, slowing wound healing and increasing cardiac work.*
- Premedicate 30 minutes before activities or planned procedures. *Premedication and the subsequent reduction of pain improve the person's participation and cooperation with care.*

CONSIDERATION FOR PRACTICE

Promptly report anginal or cardiac pain. Cardiac pain may indicate a perioperative or postoperative myocardial infarction.

Ineffective airway clearance/Impaired gas exchange

Atelectasis due to impaired ventilation and airway clearance is a common pulmonary complication of cardiac surgery. Gas exchange may also be affected by blood loss and decreased oxygen-carrying capacity following surgery. Phrenic nerve paralysis is a potential complication of cardiac surgery which may also contribute to impaired ventilation and gas exchange.

- Evaluate respiratory rate, depth, effort, symmetry of chest expansion and breath sounds frequently. *Pain, anxiety, excess fluid volume, surgical injury, narcotics and anaesthesia, and altered homeostasis can affect respiratory rate, depth and effort postoperatively. Decreased chest expansion or asymmetrical movement may indicate impaired ventilation of one lung and needs further evaluation.*
- Note endotracheal tube (ETT) placement on chest x-ray. Mark tube position and secure in place. *The chest x-ray documents correct ETT placement above the carina (bifurcation to the right and left mainstem bronchus). Marking its appropriate placement allows evaluation of potential tube movement. Secure the tube firmly in place to prevent slippage or inadvertent removal.*
- Maintain ventilator settings as ordered. Monitor arterial blood gases (ABGs) as ordered. *Mechanical ventilation promotes optimal lung expansion and oxygenation postoperatively. ABGs are used to evaluate oxygenation and acid–base balance.*
- Suction as needed. *Suctioning is performed only as indicated to clear airway secretions.*
- Prepare for ventilator weaning and extubation, as appropriate. *The individual is removed from the ventilator and*

NURSING CARE OF THE PERSON having coronary artery bypass grafts (continued)

extubated as soon as possible to reduce complications associated with mechanical ventilation and intubation.

- After extubation, teach use of the incentive spirometer and encourage use every 2 hours. Encourage deep breathing; advise against vigorous coughing. Teach use of a 'cough pillow' to splint chest incision and decrease pain. Assist in frequent pressure area care and encourage movement. *Deep breathing, controlled coughing and position changes improve ventilation and airway clearance and help prevent complications. Vigorous coughing may excessively increase intrathoracic pressure and cause sternal instability.*

Risk of infection

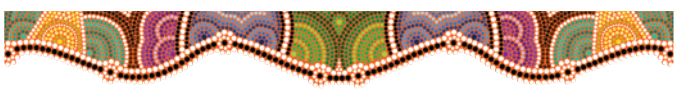
Following an open chest procedure, a sternal infection may develop that can progress to involve the mediastinum. Incisions for removal of the saphenous vein also may become infected. People with IMA grafts who are diabetic, older or malnourished are at high risk: harvesting of IMA disrupts blood supply to the sternum, and these individuals have impaired immune responses and healing.

- Assess sternal incision and leg wounds every shift. Document redness, warmth, swelling and/or drainage from the site. Note wound approximation. *These assessments provide indicators of inflammation and healing.*
- Depending on the type of dressing applied in theatre, it might be necessary to maintain a sterile dressing for the first 48 hours and then leave the incision open to air. Use Steri-Strips® as needed to maintain approximation of the wound edges. Alternatively, an occlusive dressing may be left in situ longer. *Care to reduce the risk of wound infection is paramount.*
- Report signs of wound infection: a swollen, erythematous area that is hot and painful to the touch; drainage from the wound; impaired healing or healed areas that reopen. *Evidence of infection or impaired healing requires further evaluation and treatment. Individuals with a subclinical infection will often report greater pain from the surgical wound.*
- Culture wound drainage as indicated. *Identifying the infective organism facilitates appropriate antibiotic therapy.*
- Collaborate with the dietitian to promote nutrition and fluid intake. *Good nutritional status is vital to healing and immune function.*

Disturbed thought processes

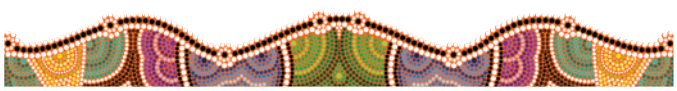
Many factors affect neuropsychological function after CABG, including the length of cardiopulmonary bypass, age, presurgery organic brain dysfunction, severity of illness and decreased cardiac output. Sensory overload and deprivation, sleep disruption and numerous drugs also affect thinking and mental clarity.

- Frequently reorient during initial recovery period. State that surgery is over and that the person is in the recovery area. *Frequent reorientation provides emotional support and reality checks.*
- Explain all procedures before performing them. Speak in a clear, calm voice. Encourage questions and give honest answers. *These measures provide information, decrease anxiety and establish trust.*
- Secure all intravenous lines and invasive catheters/tubes (e.g. ETT, urinary catheter, nasogastric tube). *Disoriented individuals may tug or pull at invasive equipment, disrupting them and increasing the risk of injury.*
- Note verbal responses to questions. Correct misconceptions immediately. *False beliefs or confused impressions regarding care may result in further confusion or acceptance of necessary care.*
- Orientate the individual to person, place and time (PPT). *This reduces confusion and assists the person to participate more in recovery.*
- Involve family members in providing reorientation. Place familiar objects and photographs within view. Encourage family presence. *The family provides reassurance and contact with the familiar, assisting with orientation.*
- Promote participation in their own care and decision making as appropriate. *This allows the person to maintain a degree of power and control, and enables the individual to take an active role in recovery.*
- Report signs of hallucinations, delusions, depression or agitation. *These may indicate progressive deterioration of mental status.*
- Administer sedatives cautiously. *Mild sedation may help prevent injury. Some sedatives may, however, have adverse effects, increasing confusion and disorientation.*
- Re-evaluate neurological status every shift. *These data allow evaluation of the effect of interventions.*



Nursing care

Health promotion, assessment, nursing diagnoses and interventions for the person with ACS are similar to those identified for people with angina and with acute myocardial infarction. See the preceding and subsequent sections of this chapter for specific nursing care activities, as well as the nursing care plan that follows.



THE PERSON WITH ACUTE MYOCARDIAL INFARCTION

An **acute myocardial infarction (AMI)**—necrosis (death) of myocardial cells—is a life-threatening event. If circulation to the affected myocardium is not promptly restored, loss of functional myocardium affects the heart's ability to maintain an effective cardiac output. This may ultimately lead to cardiogenic shock and death.

Many deaths from MI occur during the first few hours after symptoms begin. Heightening public awareness of the manifestations of MI, the importance of seeking immediate medical assistance and training in cardiopulmonary resuscitation (CPR) techniques are vital to decrease deaths due to MI.

NURSING CARE PLAN A person having coronary artery bypass surgery

Six weeks ago, John Clements, aged 50, was discharged from the hospital after emergency triple bypass surgery. Despite having emergency surgery, his postoperative recovery was uneventful and he was discharged 6 days after admission. He returns to the clinic for a postoperative stress test and to discuss his cardiac rehabilitation program.

ASSESSMENT

Mr Clements's medical history reveals significant CHD, an anterior wall myocardial infarction that led to his emergency triple bypass, and hyperlipidaemia. Current medications include diltiazem, isosorbide mononitrate, aspirin and a glyceryl nitrate patch. The ECG reveals sinus rhythm with some ST segment and T wave flattening, resting heart rate 68 and blood pressure 136/84.

Mr Clements has a strong family history of CHD. He does not smoke and uses alcohol occasionally in social situations. He enjoys takeaway fried chicken and watching television. Mr Clements states his only regular exercise used to be an evening of dancing with his wife and friends about once a month, 'But I get short of breath walking around the block now, so I guess I can't go dancing anymore!'

Mr Clements owns his own contracting business and states that he typically works about 50 to 60 hours per week. He doesn't know what the cardiac rehabilitation program is supposed to do for him. 'I have got to get back to work! You just can't sit around in my business—you have to make sure that the work is getting done on time and you have to check on supplies and equipment and the like. But I feel like a weakling—I need to get my energy back!'

DIAGNOSIS

- *Activity intolerance* related to general weakness and fatigue and manifested by inability to perform activities.
- *Ineffective role performance* related to health crisis manifested by inability to return to work.

PLANNING

- Define the purpose and components of a cardiac rehabilitation program.
- Enrol in 'cardiac rehabilitation' classes, including cardiac anatomy, physiology and coronary heart disease; exercise and activity prescriptions; lifestyle modifications, including diet counselling and stress management; emotional reactions to CAD; sexual activity; use of cardiac medications; and self-responsibility for health.
- Plan an exercise program based on stress test results, physical examination and interview.
- Encourage to schedule rest periods before and after activity/exercise.
- Review signs and symptoms of overexertion.
- Provide information about community resources for emotional and educational support.
- Assist to identify strategies for dealing with concerns about his business role.

Expected outcomes

- Verbalise an understanding of the definition and components of his structured cardiac rehabilitation program.
- Verbalise a desire to make lifestyle changes.
- Identify resources available in the community to assist with lifestyle changes.

IMPLEMENTATION

- Participate in his activity program without suffering any complications.
- Verbalise an increase in energy after 6 weeks on the program.
- Accept the reality of the temporary change in his usual work responsibilities.

EVALUATION

Mr Clements decides to 'give the rehab program a try'. Together, the cardiac rehabilitation team work with him to plan an individualised exercise/activity program. A dietitian provides dietary counselling. Stress management strategies are emphasised. Mr Clements is able to list manifestations of overexertion and states that he realises the need for gradual activity progression.

After 6 weeks, Mr Clements has reported a significant increase in energy and strength. 'I am feeling much stronger and have been sleeping better. Mary and I are taking evening walks around the neighbourhood. My chest soreness is also gone.' He has completed the 12-week cardiac rehabilitation program and another stress test indicates that his cardiac function is adequate. Mr Clements has joined the local National Heart Foundation 'Just Walk It' group and states that he is now incorporating 'heart-healthy' considerations into his daily routines.

CRITICAL THINKING IN THE NURSING PROCESS

1. Develop a personalised risk factor reduction plan for Mr Clements.
2. How might denial affect Mr Clements's ability to (a) accept the need for cardiac rehabilitation, (b) comply with the proposed lifestyle changes, and (c) make permanent adjustments to his daily life?
3. How does spousal support influence an individual's engagement with and adherence to a structured cardiac rehabilitation program?
4. Mr Clements tells you that since the surgery, his wife has been afraid that sexual activity will induce another heart attack. How would you respond to these concerns?

CRITICAL THINKING IN PERSON-CENTRED CARE

1. Given the significance of cardiovascular function on exercise tolerance, is there a risk that Mr Clements may further damage his myocardium if demand outweighs supply? If so, what are the risks and how can they be avoided?
2. Outline what you have learned from this case study that you will apply to your clinical practice.

Myocardial infarction rarely occurs in people without pre-existing coronary heart disease. While no specific cause has been identified, the risk factors for MI are those for coronary heart disease: age, gender, heredity, race, smoking, obesity, hyperlipidaemia, hypertension, diabetes, sedentary lifestyle, diet and others. See the previous section of this chapter on coronary heart disease for further discussion of these risk factors.

Pathophysiology

Atherosclerotic plaque may form stable or unstable lesions. *Stable* lesions progress by gradually occluding the vessel lumen, whereas *unstable* (or *complicated*) lesions are prone to rupture and thrombus formation (Bullock & Hales, 2012). Stable lesions often cause angina (discussed previously); unstable lesions often lead to acute coronary syndromes or acute ischaemic heart diseases. Acute coronary syndromes include unstable angina, myocardial infarction and sudden cardiac death.

Myocardial infarction occurs when blood flow to a portion of cardiac muscle is completely blocked, resulting in prolonged tissue ischaemia and irreversible cell damage. Coronary occlusion is usually caused by ulceration or rupture of a complicated atherosclerotic lesion. When an atherosclerotic lesion ruptures or ulcerates, substances are released that stimulate platelet aggregation, thrombin generation and local vasomotor tone. As a result, the vessel constricts and a thrombus (clot) forms, occluding the vessel and interrupting blood flow to the myocardium distal to the obstruction.

Cellular injury occurs when the cells are denied adequate oxygen and nutrients. When ischaemia is prolonged, lasting more than 20 to 45 minutes, irreversible hypoxaemic damage causes cellular death and tissue necrosis. Oxygen, glycogen and ATP stores of ischaemic cells are rapidly depleted. Cellular metabolism shifts to an anaerobic process, producing hydrogen ions and lactic acid. Cellular acidosis increases cells' vulnerability to further damage. Intracellular enzymes are released through damaged cell membranes into interstitial spaces.

Cellular acidosis, electrolyte imbalances and hormones released in response to cellular ischaemia affect impulse conduction and myocardial contractility. The risk of arrhythmias increases and myocardial contractility decreases, reducing stroke volume, cardiac output, blood pressure and tissue perfusion.

The subendocardium suffers the initial damage, within 20 minutes of injury, because this area is the most susceptible to changes in coronary blood flow. If blood flow is restored at this point, the infarction is limited to subendocardial tissue (a *subendocardial* or *non-Q-wave infarction*). The damage progresses to the epicardium within 1 to 6 hours. When all layers of the myocardium are affected, it is known as a *transmural infarction*. A significant Q wave develops with a transmural infarction, so this may also be called a *Q-wave MI*. Complications such as heart failure are more frequently associated with Q-wave MIs; however, individuals with non-Q-wave MIs frequently experience recurrent ischaemia or subsequent MI within weeks or months of the event (Zafari, 2015).

The necrotic, infarcted tissue is surrounded by regions of injured and ischaemic tissues. Tissue in this ischaemic area is potentially viable; restoration of blood flow minimises the amount of tissue lost. This surrounding tissue also undergoes metabolic changes. It may be *stunned*, its contractility impaired for hours to days following reperfusion, or *hibernating*, a process that protects myocytes until perfusion is restored. *Myocardial remodelling* also may occur, with cellular hypertrophy and loss of contractility in regions distant from the infarction. Rapid restoration of blood flow limits these changes (Bullock & Hales, 2012).

When a larger artery is compromised, *collateral vessels* connecting smaller arteries in the coronary system dilate to maintain blood flow to the cardiac muscle. The degree of collateral circulation helps determine the extent of myocardial damage from ischaemia. Acute occlusion of a coronary artery without any collateral flow results in massive tissue damage and possible death. Progressive narrowing of the larger coronary arteries allows collateral vessels to develop and enlarge, meeting the demand for blood flow. Good collateral circulation can limit the size of an MI.

Myocardial infarctions are described by the damaged area of the heart. The coronary artery that is occluded determines the area of damage. Myocardial infarction usually affects the left ventricle because it is the major 'workhorse' of the heart; its muscle mass is greater, as are its oxygen demands. Occlusion of the left anterior descending (LAD) artery affects blood flow to the anterior wall of the left ventricle (an *anterior MI*) and part of the interventricular septum. Occlusion of the left circumflex artery (LCA) causes a lateral MI. *Right ventricular, inferior* and *posterior infarcts* involve occlusions of the right coronary artery (RCA) and posterior descending artery (PDA). Occlusion of the left main coronary artery is the most devastating, causing ischaemia of the entire left ventricle and a grave prognosis. Identifying the infarct site helps predict possible complications and determine appropriate therapy.

Cocaine-induced MI

Acute myocardial infarction may develop due to cocaine intoxication. Cocaine increases sympathetic nervous system activity by both increasing the release of catecholamines from central and peripheral stores and interfering with the reuptake of catecholamines. This increased catecholamine concentration stimulates the heart rate and increases its contractility, increases the automaticity of cardiac tissues and the risk of arrhythmias, and causes vasoconstriction and hypertension. The person with cocaine-induced MI may present with an altered level of consciousness, confusion and restlessness, seizure activity, tachycardia, hypotension, increased respiratory rate and respiratory crackles.

Manifestations

Pain is a classic manifestation of myocardial infarction. Chest pain due to MI is more severe than anginal pain. However, it is not the intensity of the chest pain that distinguishes MI from angina or acute coronary syndrome, but its duration and its continuous nature. The onset of pain is sudden and usually is not associated with activity. In fact, most MIs occur in the early morning. People with a history of angina may have more frequent anginal attacks in the days or weeks prior to an MI (unstable angina or ACS). Chest pain may be described as crushing and severe; as a pressure, heavy or squeezing sensation; or as chest tightness or burning. The pain often begins in the centre of the chest (*substernal*) and may radiate to the shoulders, neck, jaw or arms. It lasts more than 15 to 20 minutes and is not relieved by rest or glyceryl trinitrate.

Women and older adults often experience atypical chest pain, presenting with complaints of indigestion, heartburn, nausea and vomiting (see the box below). The greater diversity

MEETING INDIVIDUALISED NEEDS Recognising acute myocardial infarction in women and older adults

Women and older adults often present with atypical manifestations of MI. However, heart disease is the number one cause of death in both groups, making early recognition and aggressive treatment vital.

Women are more likely than men to have a 'silent' or unrecognised heart attack or to present in cardiac arrest or with cardiogenic shock. Women often experience epigastric pain and nausea, causing them to blame their discomfort on heartburn. Shortness of breath is common, as is fatigue and weakness of the shoulders and upper arms.

Older people often seek treatment for vague complaints of difficulty breathing, confusion, fainting, dizziness, abdominal pain or cough. They often attribute their symptoms to a stroke. The prevalence of silent ischaemia is greater in older adults.

Stress the importance of seeking medical help promptly for atypical manifestations of MI. Prompt diagnosis and intervention reduces the mortality and morbidity of MI in women and older adults, just as it does in men. Despite this fact, both women and older adults are more likely to delay seeking treatment and are less likely to be accurately diagnosed and aggressively treated for CHD. Women are almost three times more likely to die from heart disease than from breast cancer (National Heart Foundation, 2015).

of clinical manifestations experienced by women having a cardiovascular event decreases the likelihood of healthcare professionals recognising an event, and also reduces the likelihood of the woman seeking assistance (Lichtman et al., 2015).

Compensatory mechanisms cause many of the other symptoms of MI. Sympathetic nervous system stimulation causes anxiety, tachycardia and vasoconstriction. This results in cool, clammy, mottled skin. Pain and blood chemistry changes stimulate the respiratory centre, causing tachypnoea. The person often has a sense of impending doom and death. Tissue necrosis causes an inflammatory reaction that increases the white blood cell count and elevates the temperature. Serum cardiac enzyme levels rise as enzymes are released from necrotic myocytes.

Other manifestations may vary, depending on the location and amount of infarcted tissue. Hypertension, hypotension or signs of heart failure may develop. Vagal stimulation may cause nausea and vomiting, bradycardia and hypotension. Hiccupping may develop due to diaphragmatic irritation. If a large vessel is occluded, the first sign of MI may be sudden death. Typical manifestations of MI are listed in the box below.

Complications

The risk of complications associated with myocardial infarction is related to the size and location of the MI.

MANIFESTATIONS Acute myocardial infarction

- Chest pain: substernal or precordial (across the entire chest wall); may radiate to neck, jaw, shoulder(s) or left arm
- Tachycardia, tachypnoea
- Dyspnoea, shortness of breath
- Nausea and vomiting
- Anxiety, sense of impending doom
- Diaphoresis
- Cool, mottled skin; diminished peripheral pulses
- Hypotension or hypertension
- Palpitations, arrhythmias
- Signs of left heart failure
- Decreased level of consciousness

Arrhythmias

Arrhythmias, disturbances or irregularities of heart rhythm, are the most frequent complication of MI. Arrhythmias are discussed in detail in the next section of this chapter.

Infarcted tissue is *arrhythmogenic*; that is, it affects the generation and conduction of electrical impulses in the heart, increasing the risk of arrhythmias. Premature ventricular contractions (PVCs) are common following an MI, and may be predictive of more dangerous arrhythmias such as ventricular tachycardia or ventricular fibrillation (Zafari, 2015). The risk of ventricular fibrillation is greatest the first hour after MI; it is a frequent cause of sudden cardiac death associated with acute MI. Its incidence declines with time. If the infarct affects a conduction pathway, electrical conduction may be affected. Any degree of AV block may occur following MI, especially when the anterior wall is infarcted. First-degree and Mobitz I (Wenckebach) blocks are most common, although complete heart block may develop. Bradyarrhythmias (abnormal slow rhythms) also may develop, particularly when the inferior wall of the ventricle is affected.

Pump failure

Myocardial infarction reduces myocardial contractility, ventricular wall motion and compliance. Impaired contractility and filling may produce heart failure. The risk of heart failure is greatest when large portions of the left ventricle are infarcted. Heart failure may be more severe with an anterior infarction. Loss of 20–30% of the left ventricular muscle mass may cause manifestations of left-sided heart failure, including dyspnoea, fatigue, weakness and respiratory crackles on auscultation. Inferior or right ventricular MI may lead to right-sided heart failure with manifestations such as neck vein distension and peripheral oedema. Haemodynamic monitoring is often initiated for people with evidence of heart failure. Heart failure and its manifestations are discussed in greater depth in Chapter 30.

CARDIOGENIC SHOCK *Cardiogenic shock*, impaired tissue perfusion due to pump failure, results when functioning myocardial muscle mass decreases by more than 40%. The heart is unable to pump enough blood to meet the needs of the

body and maintain organ function. Low cardiac output due to cardiogenic shock also impairs perfusion of the coronary arteries and myocardium, further increasing tissue damage. Mortality from cardiogenic shock is greater than 70%, although this can be reduced by prompt intervention with revascularisation procedures (Ren, 2014). See Chapter 10 for a more extensive discussion of cardiogenic shock.

Infarct extension

Approximately 10% of people experience extension or reinfarction in the area of the original infarction during the first 10 to 14 days after an MI. *Extension* of the MI is characterised by increased myocardial necrosis from continued blood flow impairment and ongoing injury. *Expansion* of the MI is described as a permanent expansion of the infarcted area from thinning and dilation of the muscle. Infarct extension and expansion may cause manifestations such as continuing chest pain, haemodynamic compromise and worsening heart failure.

Structural defects

Necrotic muscle is replaced by scar tissue that is thinner than the ventricular muscle mass. This can lead to such complications as ventricular aneurysm, rupture of the interventricular septum or papillary muscle, and myocardial rupture. A *ventricular aneurysm* is a weakening and bulging of the ventricular wall. It may develop when a large section of the ventricle is replaced by scar tissue. Because it does not contract during systole, stroke volume decreases. Blood may pool within the aneurysm, causing clots to form. Ischaemia of the papillary muscle or chordae tendineae may cause structural damage leading to papillary muscle dysfunction or rupture. This affects AV valve function (usually the mitral valve), causing *regurgitation*, backflow of blood into the atria during systole. The interventricular septum may perforate or rupture due to ischaemia and infarction. Myocardial rupture is a risk between days 4 and 7 after MI, when the injured tissue is soft and weak. This potential complication of MI is often fatal.

Pericarditis

Tissue necrosis prompts an inflammatory response. *Pericarditis*, inflammation of the pericardial tissue surrounding the heart, may complicate AMI, usually within 2 to 3 days. Pericarditis causes chest pain that may be aching or sharp and stabbing, aggravated by movement or deep breathing. A *pericardial friction rub* may be heard on auscultation of heart sounds.

Dressler's syndrome, thought to be a hypersensitivity response to necrotic tissue or an autoimmune disorder, may develop days to weeks after AMI. It is a symptom complex characterised by fever, chest pain and dyspnoea. Dressler's syndrome may spontaneously resolve or recur over several months, causing significant discomfort and distress.

FAST FACTS

- Arrhythmias are the most common complication of AMI.
- Heart failure also is a common complication or consequence of myocardial infarction, developing due to loss of functional muscle tissue.

INTERPROFESSIONAL CARE

Immediate treatment goals for the person with an MI are to:

- relieve chest pain
- reduce the extent of myocardial damage
- maintain cardiovascular stability
- decrease cardiac workload
- prevent complications.

Slowing the process of coronary heart disease and reducing the risk of future MI is a major long-term management goal for the person.

Rapid assessment and early diagnosis is important in treating AMI. 'Time is muscle' is a medical truism for the person with AMI. The evolution of an AMI is dynamic: the quicker the artery is reopened (medically, surgically or spontaneously), the more myocardium can be salvaged. Survival and long-term outcomes following AMI are improved by rapidly restoring blood flow to the 'stunned' myocardium surrounding the infarcted tissue, reducing myocardial oxygen demand and limiting the accumulation of toxic by-products of necrosis and reperfusion (Herrmann, Kaski & Lerman, 2012).

The major problem interfering with timely reperfusion is delay in seeking medical care following the onset of symptoms. Up to 44% of people with symptoms of chest discomfort or pain wait more than 4 hours before seeking treatment. Many factors are cited as reasons for treatment delay, including advanced age, the perception of the seriousness of symptoms, denial, access to medical care, the availability of an emergency response system and in-hospital delays. Immediate evaluation of the person presenting with manifestations of myocardial infarction is essential to early diagnosis and treatment.

Diagnosis

Diagnostic testing is used to establish the diagnosis of AMI.

- *Serum cardiac markers* are proteins released from necrotic heart muscle. The proteins most specific for diagnosis of MI are the cardiac-specific troponins and creatine kinase (CK or creatine phosphokinase, CPK) (see Table 29.6).
- *Creatine kinase* is an important enzyme for cellular function, found principally in cardiac and skeletal muscle and the brain. CK levels rise rapidly with damage to these tissues, appearing in the serum 4 to 6 hours after AMI, peaking within 12 to 24 hours, and then declining over the next 48 to 72 hours. The CK level correlates with the size of the infarction; the greater the amount of infarcted tissue, the higher the serum CK level.
- *CK-MB* (also called MB-bands) is a subset of CK specific to cardiac muscle. This isoenzyme of CK is considered the most sensitive indicator of MI. Elevated CK alone is not specific for MI; elevated CK-MB greater than 5% is considered a positive indicator of MI. CK-MB levels do not normally rise with chest pain from angina or causes other than MI.
- Cardiac muscle troponins, *cardiac-specific troponin T* (cT_nT) and *cardiac-specific troponin I* (cT_nI), are proteins released during myocardial infarction that are sensitive indicators of myocardial damage. These proteins are part of the actin–myosin unit in cardiac muscle and normally are not detectable in the

blood. With necrosis of cardiac muscle, troponins are released and blood levels rise. The specificity of cT_nT and cT_nI to cardiac muscle necrosis makes these markers particularly useful when skeletal muscle trauma contributes to elevated CK levels (e.g. when CPR has been performed or traumatic injury occurred at the time of the MI). They are sensitive enough to detect very small infarctions that do not cause significant CK elevation. Both cT_nT and cT_nI remain in the blood for 10 to 14 days after an MI, making them useful to diagnose MI when medical treatment is delayed.

Serum levels of cardiac markers are ordered on admission and for 3 succeeding days. Serial blood levels help establish the diagnosis and determine the extent of myocardial damage.

Other laboratory tests may include the following:

- *Myoglobin* is one of the first cardiac markers to be detectable in the blood after an MI. It is released within 2–4 hours of symptom onset. Its lack of specificity to cardiac muscle and rapid excretion (blood levels return to normal within 24–36 hours) limit its use, however (Schreiber, 2011).
- *Full blood count (FBC)* shows an elevated white blood cell (WBC) count due to inflammation of the injured myocardium. The erythrocyte sedimentation rate (ESR) also rises because of inflammation, although ESR is a non-specific marker of inflammation.
- *Arterial blood gases (ABGs)* may be ordered to assess blood oxygen levels and acid–base balance.

Electrocardiography, echocardiography and myocardial nuclear scans are the most common diagnostic tests performed when AMI is suspected. With the exception of the ECG, the timing of these tests depends on the individual's immediate condition. Haemodynamic monitoring may be initiated in the unstable person following MI.

- The *electrocardiogram* reflects changes in conduction due to myocardial ischaemia and necrosis. Classic ECG changes seen in AMI include T-wave inversion, ST-segment elevation and formation of a Q wave. Ischaemic changes in the heart are seen as depression of the ST segment or inversion of the T wave (see Figure 29.1). With myocardial injury, elevation of the ST segment occurs (see Figure 29.5A). Significant Q-wave development (see Figure 29.5B) indicates a transmural or full-thickness infarction. Myocardial damage can be localised using the 12-lead ECG. See Chapter 28 for more information about ECGs.
- *Echocardiography* is done to evaluate cardiac wall motion and left ventricular function. Stunned and infarcted tissue does not contract as effectively (if at all) as healthy myocardium.
- *Radionuclide imaging* may be done to evaluate myocardial perfusion. These studies cannot differentiate between an acute MI and old scar tissue, but do help identify the specific area of myocardial ischaemia and damage.
- *Haemodynamic monitoring* may be initiated when AMI significantly affects cardiac output and haemodynamic status. These invasive procedures are described in Chapter 30.

Medications

Aspirin, a platelet inhibitor, is now considered an essential part of treating AMI. A 300 mg aspirin tablet is given by emergency personnel, with the instruction that it is to be chewed (for buccal absorption). This initial dose is followed by a daily oral dose of 100 mg of aspirin.

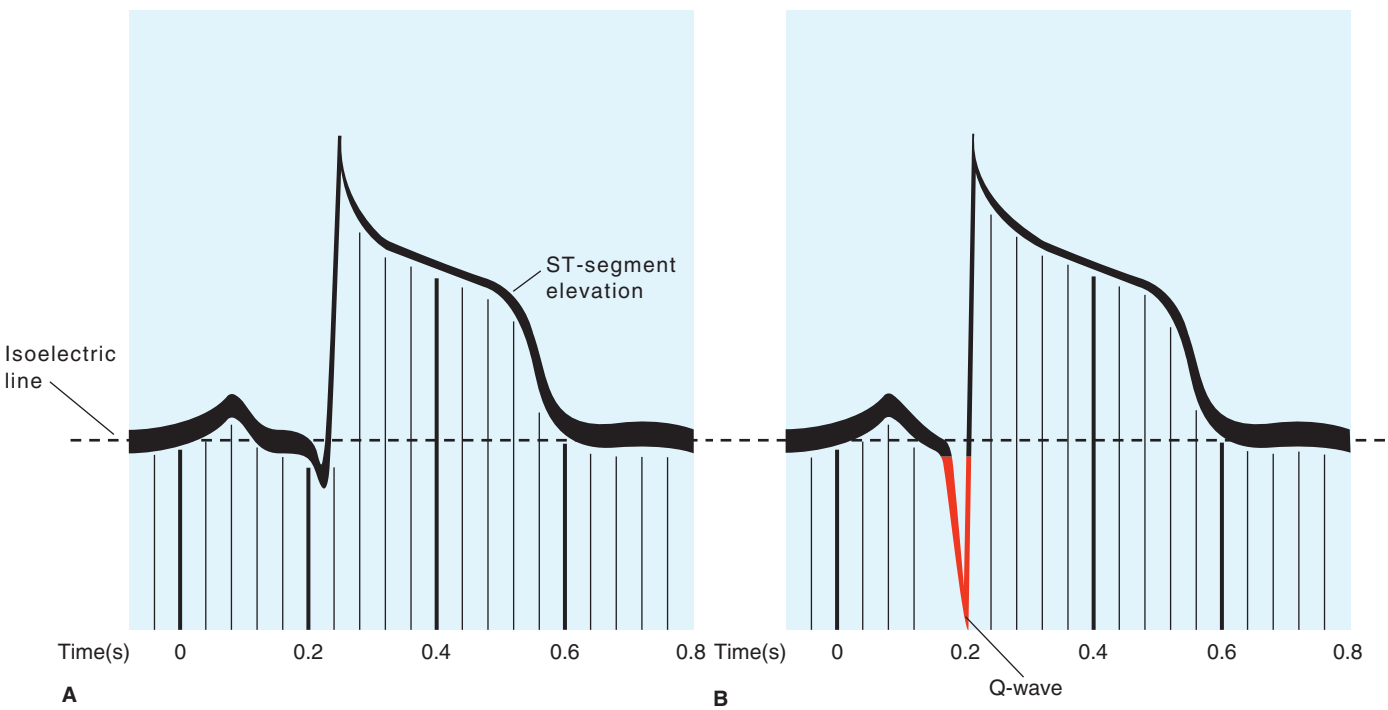


FIGURE 29.5 ■ ECG changes characteristic of MI. *A*, ST-segment elevation characteristic of myocardial injury. *B*, Clinically significant Q-wave characteristic of a transmural infarction

Thrombolytic agents, analgesics and antiarrhythmic agents are among the principal classes of drugs used in treating AMI.

ANALGESIA Pain relief is vital in managing the care of a person with AMI. Pain stimulates the sympathetic nervous system, increasing the heart rate and blood pressure and, in turn, myocardial workload. Sublingual glyceryl trinitrate may be given (up to three 0.4 mg doses at 5-minute intervals). Intravenous glyceryl trinitrate may be continued for the first 24 to 48 hours to reduce myocardial work. In addition to pain relief, glyceryl trinitrate decreases myocardial oxygen demand and may increase the supply of oxygen to the myocardium. Glyceryl trinitrate is a peripheral and arterial vasodilator that reduces afterload. It dilates coronary arteries and collateral channels in the heart, increasing coronary blood flow to save myocardial tissue at risk. Nitrates may, however, cause reflex tachycardia or excessive hypotension, so close monitoring is necessary during administration. It also is important to ask the person about use of sildenafil (Viagra) within the previous 24 hours before administering glyceryl trinitrate, as the combination can precipitate a significant drop in blood pressure. See the 'Medication administration' box on page 996 for the nursing implications of glyceryl trinitrate and other drugs given to reduce myocardial work following AMI.

Morphine sulfate is the drug of choice for pain unrelieved by glyceryl trinitrate and for sedation. Following an initial intravenous dose of 4 to 8 mg, small doses (2 to 4 mg) may be repeated intravenously every 5 minutes until pain is relieved. It is important to assess frequently for pain relief and possible adverse effects of analgesia, such as excessive sedation. Pain unrelieved by expected or usual doses should be reported to the doctor as it may indicate a complication such as extension of the infarct. See Chapter 8 for more details about morphine administration. Anxiolytic agents such as diazepam may also be administered to promote rest.

THROMBOLYTIC THERAPY Thrombolytic agents, drugs that dissolve or break up blood clots, are first-line drugs used to treat acute MI when access to a cardiac catheterisation lab for revascularisation procedures is not immediately available. Thrombolytic drugs activate the thrombolytic system to *lyse* or destroy the clot, restoring blood flow to the obstructed artery. Early thrombolytic administration (within the first 3 hours of MI onset) limits infarct size, reduces heart damage and improves outcomes. Activation of the thrombolytic system can cause multiple complications; approximately 0.5–5% of people receiving thrombolytic drugs experience serious bleeding complications. Not every person is a candidate for thrombolytic therapy; for example, it is contraindicated in people with known bleeding disorders, history of cerebrovascular disease, uncontrolled hypertension, pregnancy or recent trauma or surgery of the head or spine (Australian Resuscitation Council (ARC), 2011).

Several thrombolytic agents are commonly used today. Little difference in effectiveness has been demonstrated between these; there are, however, big differences in cost. Streptokinase, a biological agent derived from group C *Streptococcus* organisms, is the least expensive of the drugs. Its primary drawback is the risk of a severe hypersensitivity reaction, including anaphylaxis. Streptokinase is administered by intravenous infusion. Anisoylated plasminogen streptokinase activator complex (APSAC) is a related drug that can be administered by bolus over 2 to 5 minutes. It has many of the same effects as streptokinase, but is considerably more expensive. Tissue plasminogen activator (t-PA), tenecteplase (TNK) and reteplase (rPA) are more effective in re-establishing myocardial perfusion, especially when the pain developed more than 3 hours previously. These drugs, however, are the most expensive. Nursing care of the person receiving a thrombolytic agent is outlined in the following box.

ANTIARRHYTHMICS Arrhythmias are a common complication of AMI, particularly in the first 12 to 24 hours. Antiarrhythmic medications are used as needed to treat arrhythmias. They also may be given prophylactically to prevent arrhythmias. Ventricular arrhythmias are treated with a class I or class III antiarrhythmic drug (see the 'Medication administration' box on page 1029). Symptomatic bradycardia (bradycardia with associated hypotension and other signs of low cardiac output) is treated with intravenous atropine, 0.5 to 1 mg. Intravenous verapamil or the short-acting beta-blocker esmolol may be ordered to treat atrial fibrillation or other supraventricular tachyarrhythmias.

OTHER MEDICATIONS Beta-blockers such as propranolol, atenolol and metoprolol limit infarct size and decrease the incidence of serious ventricular arrhythmias in AMI. They may also reduce the risk of papillary muscle rupture. These drugs decrease the heart rate, reducing cardiac work and myocardial oxygen demand. Initial doses are given intravenously. Oral beta-blocker therapy is continued to reduce the risk of reinfarction and death related to cardiovascular causes (Bullock & Manias, 2013; Coven, 2015).

ACE inhibitors also reduce mortality associated with AMI. These drugs reduce ventricular remodelling following an MI, reducing the risk of subsequent heart failure. They also may reduce the risk of reinfarction (Bullock & Manias, 2013; Coven, 2015).

Anticoagulants and antiplatelet medications often are prescribed to maintain coronary artery patency following thrombolysis or a revascularisation procedure. Abciximab reduces platelet aggregation and the risk of reocclusion following angioplasty. It also improves vessel opening with thrombolytic therapy, permitting lower doses of thrombolytic drugs. Standard or low-molecular-weight heparin preparations often are given to person with AMI. Heparin helps establish and maintain patency of the affected coronary artery. It also is used, along with long-term warfarin, to prevent systemic or pulmonary embolism in people with significant left ventricular impairment or atrial fibrillation following AMI. See the 'Medication administration' box on page 1000 for the nursing implications of antiplatelet drugs and Chapter 32 for more information about anticoagulant therapy.

Individuals with pump failure and hypotension may receive intravenous dopamine, a vasopressor. At low doses

NURSING CARE OF THE PERSON receiving thrombolytic therapy

PRE-INFUSION CARE

- Obtain nursing history and perform a physical assessment. *Information obtained from the history and physical exam helps determine whether thrombolytic therapy is appropriate. The goal is to initiate thrombolytic therapy within 30 minutes of arrival.*
- Evaluate for contraindications to thrombolytic therapy: recent surgery or trauma (including prolonged CPR), bleeding disorders or active bleeding, cerebral vascular accident, neurosurgery within the last 2 months, gastrointestinal ulcers, diabetic haemorrhagic retinopathy and uncontrolled hypertension. *Thrombolytic agents dissolve clots and therefore may precipitate intracranial, internal or peripheral bleeding.*
- Inform the person of the purpose of the therapy. Discuss the risk of bleeding and the need to keep the extremity immobile during and after the infusion. *Minimal movement of the extremity is necessary to prevent bleeding from the infusion site.*

DURING THE INFUSION

- Assess and record vital signs and the infusion site for haematoma or bleeding every 15 minutes for the first hour, every 30 minutes for the next 2 hours and then hourly until the intravenous catheter is discontinued. Assess pulses, colour, sensation and temperature of both extremities with each vital sign check. *Vital signs and the site are frequently assessed to detect possible complications.*
- Remind the person to keep the extremity still and straight. Do not elevate head of bed above 15 degrees. *Extremity immobilisation helps prevent infusion site trauma and bleeding. Hypotension may develop; keeping the bed flat helps maintain cerebral perfusion.*
- Maintain continuous cardiac monitoring during the infusion. Keep antiarrhythmic drugs and the emergency trolley readily available for treatment of significant arrhythmias. *Ventricular arrhythmias commonly occur with reperfusion of the ischaemic myocardium.*

POST-INFUSION CARE

- Assess vital signs, distal pulses and infusion site frequently as needed. *The person remains at high risk of bleeding following thrombolytic therapy.*
- Evaluate response to therapy: normalisation of ST segment, relief of chest pain, reperfusion arrhythmias, early peaking of the CK and CK-MB. *These are signs that the clot has been dissolved and the myocardium is being reperfused.*
- Maintain bed rest for 6 hours. Keep the head of the bed at or below 15 degrees. Reinforce the need to keep the extremity straight and immobile. Avoid any injections for 24 hours after catheter removal. *Precautions such as these are important to prevent bleeding.*
- Assess puncture sites for bleeding. On catheter removal hold direct pressure over the site for at least 30 minutes. Apply a pressure dressing to any venous or arterial sites as needed. Perform routine care in a gentle manner to avoid bruising or injury. *Thrombolytic therapy disrupts normal coagulation. Peripheral bleeding may occur at puncture sites and there may not be sufficient fibrin to form a clot. Direct or indirect pressure may be needed to control the bleeding.*
- Assess body fluids, including urine, vomit and faeces, for evidence of bleeding; frequently assess for changes in level of consciousness and manifestations of increased intracranial pressure, which may indicate intracranial bleeding. Assess surgical sites for bleeding. Monitor haemoglobin and haematocrit levels, prothrombin time (PT) and activated partial thromboplastin time (aPTT). *These provide additional means of assessing for bleeding.*
- Administer platelet-modifying drugs (e.g. aspirin, dipyridamole) as ordered. *Platelet inhibitors decrease platelet aggregation and adhesion and are used to prevent reocclusion of the artery.*
- Report manifestations of reocclusion, including changes in the ST segment, chest pain or arrhythmias. *Early recognition of reocclusion is vital to save myocardial tissue.*

(less than 5 mg/kg/min), it improves blood flow to the kidneys, preventing renal ischaemia and possible acute kidney injury (see Chapter 27). With increasing doses, dopamine increases myocardial contractility and causes vasoconstriction, improving blood pressure and cardiac output.

Antihyperlipidaemic agents are used for the person with hyperlipidaemia. A stool softener such as docusate sodium is prescribed to maintain normal bowel function and reduce straining.

Treatments

The individual with a suspected or confirmed MI is monitored continuously. Care is provided in the intensive coronary care unit for the first 24 to 48 hours, after which time less intensive monitoring (e.g. telemetry) may be required. At least one intravenous line is established to allow rapid administration of emergency medications.

Bed rest is prescribed for the first 12 hours to reduce the cardiac workload. The bedside commode generally is allowed; studies have shown this to be less stressful than using a bedpan. If the person's condition is stable, sitting in a chair at the bedside is permitted after 12 hours. Activities are gradually increased as tolerated. A quiet, calm environment with limited outside stimuli is preferred. Visitors are limited to promote rest. Oxygen is administered by nasal prongs at 2 to 5 L/min to improve oxygenation of the myocardium and other tissues.

A liquid diet may be prescribed for the first 4 to 12 hours to reduce gastric distension and myocardial work. Following that, a low-fat, low-cholesterol, reduced-sodium diet is allowed. Sodium restrictions may be lifted after 2 to 3 days if no evidence of heart failure is present. Small, frequent feedings are often recommended. Drinks containing caffeine, and very hot and cold foods, may also be limited.

Revascularisation procedures

Many people with AMI are treated with immediate or early coronary revascularisation such as angioplasty and stent placement. Percutaneous transluminal coronary revascularisation (PCTA) may follow thrombolytic therapy or be used in place of thrombolytic therapy to restore blood flow to ischaemic myocardium. When compared with thrombolytic therapy, prompt PTCA reduces hospital mortality (Kalyanasundaram, 2014). In some cases, coronary artery bypass grafting (CABG) surgery may be performed. The choice of procedure depends on the person's age and immediate condition, the time elapsed from the onset of manifestations and the extent of myocardial disease and damage. These procedures and related nursing care are covered in more depth in the preceding section on acute coronary syndrome.

Other invasive procedures

For individuals with large MIs and evidence of pump failure, invasive devices may be used to temporarily take over the function of the heart, allowing the injured myocardium to heal. The intra-aortic balloon pump is widely used to augment cardiac output. Ventricular assist devices are indicated for people requiring more or longer-term artificial support than the intra-aortic balloon pump provides.

INTRA-AORTIC BALLOON PUMP The *intra-aortic balloon pump (IABP)*, also called intra-aortic balloon counterpulsation, is a mechanical circulatory support device that may be used after cardiac surgery or to treat cardiogenic shock following AMI. The IABP temporarily supports cardiac function, allowing the heart gradually to recover by decreasing myocardial workload and oxygen demand and increasing perfusion of the coronary arteries.

A catheter with a 30 to 40 mL balloon is introduced into the aorta, usually via the femoral artery. The balloon catheter is connected to a console that regulates the inflation and deflation of the balloon. The IABP catheter inflates during diastole, increasing perfusion of the coronary and renal arteries, and deflates just prior to systole, decreasing afterload and cardiac workload (see Figure 29.6). The inflation–deflation sequence is triggered by the ECG pattern. During the most acute period, the balloon inflates and deflates with each heartbeat (1:1 ratio), providing maximal assistance to the heart. As the person's condition improves, the IABP is weaned to inflate–deflate at varying intervals (e.g. 1:2, 1:4, 1:8). This provides a continually decreasing amount of support as the heart muscle recovers. When mechanical assistance is no longer required, the IABP catheter is removed.

VENTRICULAR ASSIST DEVICES Use of *ventricular assist devices (VADs)* to aid the failing heart is becoming more common with advances in technology. Whereas the IABP can supplement cardiac output by approximately 10–15%, the VAD temporarily takes partial or complete control of cardiac function, depending on the type of device used. VADs may be used as temporary or complete assist in AMI and cardiogenic shock when there is a chance for recovery of normal heart function after a period of cardiac rest. The device also may be used as a bridge in heart transplant. Nursing care for the person with a VAD is supportive and includes assessing haemodynamic status and for complications associated with the device. People with VADs *in situ* are at considerable risk of infection; strict aseptic technique is used with all invasive catheters and dressing changes. Pneumonia also is a risk due to immobility and ventilatory support. Mechanical failure of the VAD is a life-threatening event that requires immediate intervention (Kirkpatrick et al., 2015).

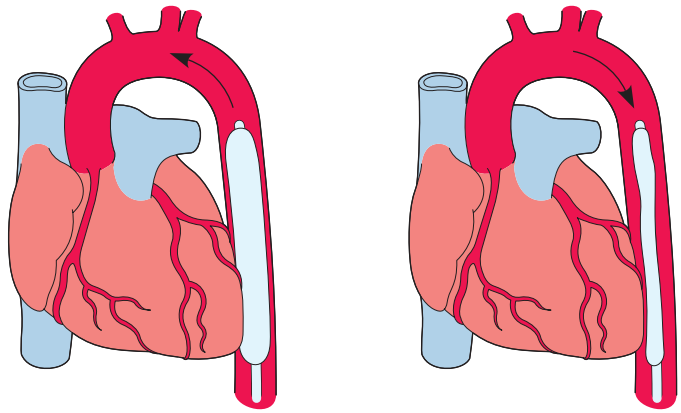

FIGURE 29.6 ■ The intra-aortic balloon pump. *A*, When inflated during diastole, the balloon supports cerebral, renal and coronary artery perfusion. *B*, The balloon deflates during systole, so cardiac output is unimpeded

Cardiac rehabilitation

Cardiac rehabilitation is a long-term program of medical evaluation, exercise, risk factor modification, education and counselling designed to limit the physical and psychological effects of cardiac illness and improve the person's quality of life. Cardiac rehabilitation begins with admission for a cardiac event such as AMI or a revascularisation procedure. Phase 1 of the program is the inpatient phase. A thorough assessment of the person's history, current status, risk factors and motivation is obtained. During this phase, activity progresses from bed rest to independent performance of activities of daily living (ADLs) and ambulation within the facility. Both subjective and objective responses to increasing activity levels are evaluated. Excess fatigue, shortness of breath, chest pain, tachypnoea, tachycardia or cool, clammy skin indicates activity intolerance. Phase 2, immediate outpatient cardiac rehabilitation, begins within 3 weeks of the cardiac event. The goals for the outpatient program are to increase activity level, participation and capacity; improve psychosocial status and treat anxiety or depression; and provide education and support for risk factor reduction. Continuation programs, phase 3 of cardiac rehabilitation, are directed at providing a transition to independent exercise and exercise maintenance. During this final phase, the person may 'check in' every 3 months to evaluate risk factors, quality of life and exercise habits.

Nursing care

Nursing care of the person with an acute myocardial infarction focuses on reducing cardiac work, identifying and treating complications in a timely manner, and preparing the person for rehabilitation. See the following nursing care plan for a person with an AMI.

Health promotion

Health promotion activities to prevent AMI are those outlined for coronary heart disease and angina in previous sections of this chapter. In addition, discuss risk factor management, use of prescribed medications and cardiac rehabilitation to reduce the risk of complications or future infarctions.

Assessment

Nursing assessment for the person with AMI must be both timely and ongoing. Assessment data related to AMI include the following:

- *Health history:* complaints of chest pain, including its location, intensity, character, radiation and timing; associated symptoms such as nausea, heartburn, shortness of breath and anxiety; treatment measures taken since onset of pain; past medical history, especially cardiac related; chronic diseases; current medications and any known allergies to medications; smoking history and use of recreational drugs and alcohol.
- *Physical examination:* general appearance, including obvious signs of distress; vital signs; peripheral pulses; skin colour, temperature, moisture; level of consciousness; heart and breath sounds; cardiac rhythm (on bedside monitor); bowel sounds, abdominal tenderness.

Nursing diagnoses and interventions

Priorities of nursing care include relieving chest pain, reducing cardiac work and promoting oxygenation. Psychosocial support is especially important because an acute myocardial infarction can be devastating, bringing the person face to face with their own mortality for the first time.

Acute pain

Chest pain occurs when the oxygen supply to the heart muscle does not meet the demand. Myocardial ischaemia and infarction causes pain, as does reperfusion of an ischaemic area following thrombolytic therapy or emergent PTCA. Pain stimulates the sympathetic nervous system, increasing cardiac work. Pain relief is a priority of care for the person with AMI.

- Assess for verbal and non-verbal signs of pain. Document characteristics and the intensity of the pain, using a standard pain scale. Verify non-verbal indicators of pain with the person. Frequent, careful pain assessment allows early intervention to reduce the risk of further damage. *Pain is a subjective experience; its expression may vary with location and intensity, previous experiences and cultural and social background. Pain scales provide an objective tool for measuring pain and a way to assess pain relief or reduction.*
- Administer oxygen at 2 to 5 L/min per nasal prongs. *Supplemental oxygen increases oxygen supply to the myocardium, decreasing ischaemia and pain.*
- Promote physical and psychological rest. Provide information and emotional support. *Rest decreases cardiac workload and sympathetic nervous system stimulation, promoting comfort. Information and emotional support help decrease anxiety and provide psychological rest.*
- Titrate intravenous glyceryl trinitrate as ordered to relieve chest pain, maintaining a systolic blood pressure greater than 100 mmHg. *Glyceryl trinitrate decreases chest pain by dilating peripheral vessels, reducing cardiac work and dilating coronary vessels, including collateral circulation, improving blood flow to ischaemic tissue.*

CONSIDERATION FOR PRACTICE

Intravenous glyceryl trinitate (GTN) causes peripheral vasodilation, which may lead to hypotension, reduced coronary blood flow and tachycardia. Reduce the GTN flow rate and notify the medical officer if this occurs.

- Administer 2 to 4 mg morphine by intravenous push for chest pain as needed. *Morphine is an effective narcotic analgesic for chest pain. It acts as a venodilator and decreases the respiratory rate, anxiety and the perception of pain. The resulting reduction in preload and sympathetic nervous system stimulation reduces cardiac work and oxygen consumption.*

CONSIDERATION FOR PRACTICE

Reassess for relief of chest pain. The goal of care is to achieve absolute pain relief, not simply a reduction in pain to a 'manageable' level. Any chest pain of cardiac origin indicates myocardial ischaemia.

Ineffective tissue perfusion

Cardiac muscle damage affects compliance, contractility and cardiac output. The extent of the effect on tissue perfusion depends on the location and amount of damage. Anterior wall infarcts have a greater effect on cardiac output than do right ventricular infarcts. Infarcted muscle also increases the risk of cardiac arrhythmias, which can also affect the delivery of blood and oxygen to the tissues.

- Assess and document vital signs. Report increases in heart rate and changes in rhythm, blood pressure and respiratory rate. *Decreased cardiac output activates compensatory mechanisms that may cause tachycardia and vasoconstriction, increasing cardiac work.*
- Assess for changes in level of consciousness (LOC); decreased urine output; moist, cool, pale, mottled or cyanotic skin; dusky or cyanotic mucous membranes and nail beds; diminished to absent peripheral pulses; delayed capillary refill. *These are manifestations of impaired tissue*

perfusion. A change in LOC is often the first manifestation of altered perfusion because brain tissue and cerebral function depend on a continuous supply of oxygen.

- Auscultate heart and breath sounds. Note abnormal heart sounds (e.g. an S_3 or S_4 gallop or a murmur) or adventitious lung sounds. *Abnormal heart sounds or adventitious lung sounds may indicate impaired cardiac filling or output, increasing the risk of decreased tissue perfusion.*
- Monitor ECG rhythm continuously. *Arrhythmias can further impair cardiac output and tissue perfusion.*

CONSIDERATION FOR PRACTICE

Obtain a 12-lead ECG to assess complaints of chest pain. Report marked changes to the doctor. Continued or unrelieved chest pain may indicate further myocardial ischaemia and extension of the infarct; an ECG during episodes of chest pain provides a valuable diagnostic tool to assess myocardial perfusion. A repeat ECG on subsidence of pain is also very valuable.

- Monitor oxygen saturation levels. Administer oxygen as ordered. Obtain and assess ABGs as indicated. *Oxygen saturation is an indicator of gas exchange, tissue perfusion and the effectiveness of oxygen administration. ABGs provide a more precise measurement of blood oxygen levels and allow assessment of acid–base balance.*
- Administer antiarrhythmic medications as needed. *Arrhythmias affect tissue perfusion by altering cardiac output.*
- Obtain serial CK, isoenzyme and troponin levels as ordered. *Levels of cardiac markers—CK isoenzymes, in particular—correlate with the extent of myocardial damage.*
- Plan for invasive haemodynamic monitoring. *Haemodynamic monitoring facilitates AMI management and treatment evaluation by providing a means of assessing pressures in the systemic and pulmonary arteries, the relationship between oxygen supply and demand, cardiac output and cardiac index.*

CONSIDERATION FOR PRACTICE

Continuously evaluate the response to interventions such as thrombolytic therapy, drugs to improve cardiac output and tissue perfusion, and drugs to reduce cardiac work. Adverse effects of therapy may reduce the effectiveness of treatment. Bleeding due to thrombolytic therapy may affect vascular volume and cardiac output; reperfusion arrhythmias also may affect cardiac output. Drugs used to improve cardiac output may also increase cardiac work, whereas those given to reduce cardiac work may significantly affect contractility and cardiac output.

Ineffective coping

Coping mechanisms help a person deal with a life-threatening event or with acute changes in health. However, certain coping mechanisms may be detrimental to restoring health, particularly if the person relies on them for a prolonged period. Denial, for example, is a common coping mechanism among people following an MI. In the initial stages, denial can reduce anxiety. Continued denial, however, can interfere with learning and compliance with treatment.

- Establish an environment of caring and trust. Encourage the person to express feelings. *Establishing a trusting relationship provides a safe environment for the person to discuss feelings of helplessness, powerlessness, anxiety and hopelessness. The nurse may then be able to provide additional resources to meet the person's needs.*
- Accept denial as a coping mechanism, but do not reinforce it. *Denial may initially help by diminishing the psychological threat to health, decreasing anxiety. However, its prolonged use can interfere with acceptance of reality and cooperation, possibly delaying treatment and hindering recovery.*
- Note aggressive behaviours, hostility or anger. *Document any failure to comply with treatments. These signs can indicate anxiety and denial.*
- Help the person identify positive coping skills used in the past (e.g. problem-solving skills, verbalisation of feelings, asking for help, prayer). *Reinforce use of positive coping behaviours. Coping behaviours that have been successful in the past can help the person deal with the current situation. These familiar methods can decrease feelings of powerlessness.*
- Provide opportunities for the person to make decisions about the plan of care, as far as possible. *This promotes self-confidence and independence. Participating in care planning gives the person a sense of control and the opportunity to use positive coping skills.*
- Provide privacy for the person and significant other to share their questions and concerns. *Privacy provides an opportunity for the person and their partner to share their feelings and fears, offer support and encouragement to one another, relieve anxiety and establish effective coping methods.*

Fear

The fear of death and disability can be a paralysing emotion that adversely affects the person's recovery from acute myocardial infarction.

- Identify the person's level of fear, noting verbal and non-verbal signs. This information enables the nurse to plan appropriate interventions. *Individuals may not voice concerns; attention to non-verbal indicators is important. Controlling fear helps decrease sympathetic nervous system responses and catecholamine release that may increase feelings of fear and anxiety.*
- Acknowledge the person's perception of the situation. Allow individuals to verbalise concerns. *A sudden change in health status causes anxiety and fear of the unknown. Verbalising these fears may help the person cope with change and allow the healthcare team to provide information and correct misconceptions.*

- Encourage questions and provide consistent, factual answers. Repeat information as needed. *Accurate and consistent information can reduce fear. Honest explanations help strengthen the patient–nurse relationship and help the person develop realistic expectations. Anxiety and fear decrease the ability to concentrate and retain information; therefore, information may need to be repeated.*
- Encourage self-care. Allow the individual to make decisions regarding the plan of care. *This promotes personal responsibility for health and allows some control over the situation. The person's confidence increases as their dependence decreases.*
- Administer anxiolytic medications as ordered. *These medications promote rest and relaxation and decrease feelings of anxiety, which may act as barriers to health restoration.*
- Teach non-pharmacological methods of stress reduction (e.g. relaxation techniques, mental imagery, music therapy, breathing exercises, meditation, massage). *Stress management techniques can help reduce tension and anxiety, provide a sense of control and enhance coping skills.*

NURSING CARE PLAN A person with acute myocardial infarction

Betty Williams, a 62-year-old office worker, is admitted to the emergency department with complaints of severe substernal chest pain. Mrs Williams states that the pain began after lunch, about 4 hours ago. She initially attributed the pain to indigestion. She described the pain, which now radiates to her jaw and left arm, as 'really severe heartburn'. It is accompanied by a 'choking feeling', severe shortness of breath and diaphoresis. The pain is unrelieved by rest, antacids or three sublingual glyceryl trinitrate tablets (0.4 mg).

Oxygen is started per nasal prongs at 5 L/min. Central and peripheral intravenous lines are inserted. A 12-lead ECG and the following labwork are obtained: cardiac troponins, CK and CK isoenzymes, ABGs, FBC and a chemistry panel. Morphine relieves Mrs Williams's pain.

Mrs Williams's medical history includes type 2 diabetes, angina and hypertension. She has a 45-year history of cigarette smoking, averaging 1.5 to 2 packets per day. Family history reveals that Mrs Williams's father died at age 42 of AMI and her paternal grandfather died at age 65 of AMI. Mrs Williams is taking the following medications: tolbutamide, hydrochlorothiazide and isosorbide mononitrate.

Based on ECG changes and cardiac markers, an acute anterior MI is diagnosed. Mrs Williams has no contraindications to thrombolytic therapy and is deemed a good candidate. Intravenous alteplase (t-PA) is given by bolus followed by intravenous infusions of alteplase and heparin. She is transferred to the coronary care unit (CCU).

ASSESSMENT

Mrs Williams is alert and oriented to person, place and time. Vital signs are T 37.5°C, P 118, R 24 with adequate depth and BP 172/92. Auscultation reveals an S_4 and fine crackles in the bases of both lungs. The ECG shows sinus tachycardia with occasional premature ventricular contractions (PVCs). Her skin is cool and slightly diaphoretic. Capillary refill is less than 3 seconds and peripheral pulses are strong and equal. Her nail beds are pink.

A triple-lumen central line is in place. Glyceryl trinitrate is infusing at 200 µg/min in the distal lumen; the alteplase infusion is in the middle lumen; and a heparin infusion is in the proximal lumen. The peripheral intravenous line has a saline lock. Mrs Williams states, 'The pain is better since the nurse in the ER gave me a shot. But it has been coming and going. I would rate it a 4 right now, but it was terrible before. The doctor told me that this drug I'm getting will quickly open up the artery that is blocked. I hope it works! Do many people get this drug?'

DIAGNOSIS

- *Acute pain* related to ischaemic myocardial tissue.
- *Anxiety* and *fear* related to change in health status.
- *Ineffective protection* related to the risk of bleeding secondary to thrombolytic therapy.
- *Risk of decreased cardiac output* related to altered cardiac rate and rhythm.

PLANNING

The following interventions are planned during the immediate phase of Mrs Williams's hospitalisation.

- Instruct her to report all chest pain. Monitor and evaluate pain using a scale of 0 to 10. Titrate intravenous glyceryl trinitrate infusion for chest pain; stop infusion if systolic BP is below 100 mmHg. Administer 2 to 4 mg of morphine intravenously for chest pain unrelieved by glyceryl trinitrate infusion.
- Encourage verbalisation of fears and concerns. Respond honestly and correct misconceptions about the disease, therapeutic interventions or prognosis.
- Assess knowledge of CHD. Explain the purpose of thrombolytic therapy to dissolve the fresh clot and reperfuse the heart muscle, limiting heart damage.
- Explain the need for frequent monitoring of vital signs and potential bleeding.
- Assess for manifestations of internal or intracranial bleeding: complaints of back or abdominal pain, headache, decreased level of consciousness, dizziness, bloody secretions or excretions, or pallor. Test all stools, urine and vomit for occult blood. Notify doctor immediately of any abnormal findings.

Expected outcomes

- Rate chest pain as 0 on a pain scale of 0 to 10.
- Verbalise reduced anxiety and fear.
- Demonstrate no signs of internal or external bleeding.
- Maintain an adequate cardiac output during and following reperfusion therapy.

IMPLEMENTATION

- Monitor for signs of reperfusion: decreased chest pain, return of ST segment to baseline, reperfusion arrhythmias (e.g. PVCs, bradycardia and heart block).
- Continuously monitor ECG for changes in cardiac rate, rhythm and conduction. Assess vital signs.
- Treat dangerous arrhythmias or other cardiac events per protocol. Notify the medical officer.
- Discuss continuing cardiac care and rehabilitation.

NURSING CARE PLAN A person with acute myocardial infarction (continued)

EVALUATION

The initial morphine dose reduces Mrs Williams's chest pain from a rating of 8 to 4. The glyceryl trinitrate infusion and thrombolytic therapy further reduce her pain to 2. The glyceryl trinitrate infusion is gradually discontinued after 24 hours. As her pain subsides, Mrs Williams states that she feels 'much better now that the pain is gone. I was afraid it would just get worse'. She verbalises an understanding of thrombolytic therapy to limit myocardial damage. No indication of bleeding problems are noted. Reperfusion is indicated by relief of chest pain, return of the ST segment to baseline on the ECG, early peaking of CK levels and increased frequency of PVCs but no significant arrhythmias. Mrs Williams remains in the CCU for 36 hours until she is transferred to the cardiac medical ward.

CRITICAL THINKING IN THE NURSING PROCESS

1 How would the initial plan of care have changed if Mrs Williams was not a candidate for thrombolytic therapy?
2 Two days after her initial therapy, Mrs Williams complains of palpitations. You notice frequent PVCs on the ECG monitor. What do you do?
3 What health promotion topics would you teach Mrs Williams before discharge?
4 Mrs Williams states, 'I've been smoking for 45 years and I'm not going to stop now! Besides, it calms me down when I'm anxious.' How would you respond to this statement?

RFLECTION ON THE NURSING PROCESS

1 Outline what you have learned from this case study that you will apply to your future practice.
2 Cardiovascular disease in women presents many challenges for assessment and diagnosis, resulting in higher mortality and morbidity statistics. Explore the factors that complicate the identification of cardiovascular disease in women. How will this information modify your practice when next assessing a woman presenting with chest pain?

Community-based care

Cardiac rehabilitation begins with admission to the healthcare facility and continues through the inpatient stay and after discharge into the rehabilitative period. The emphasis is on realistic application of information to maintain lifestyle changes.

Assessing readiness to learn is an important first step in preparing for home care. The person in strong denial may not identify any relevance to the information being taught. Evaluate ability to learn, assessing physiological and psychological health, beliefs regarding personal responsibility for health and expectations of the healthcare system. Also assess developmental level, ability to perform psychomotor skills, cognitive function, learning disabilities, existing knowledge base and the influence of previous learning experiences. Provide written material to supplement teaching and encourage questions.

Include the following topics in teaching for home care:

- the normal anatomy and physiology of the heart and the specific area of heart damage
- the process of CHD and implications of MI
- purposes and side effects of prescribed medications
- the importance of complying with the medical regimen and cardiac rehabilitation program and of keeping follow-up appointments
- information about community resources such as the National Heart Foundation.

After discharge, follow up by telephone within 1 week and periodically thereafter during the recovery period. Provide telephone numbers of resource personnel who are available to respond to questions and concerns after discharge. Research demonstrates the value of motivational and social support in adopting healthier behaviours after AMI (see the following 'Translation to practice' box).

Because the person who has had an MI is at high risk of sudden cardiac death, encourage family members to learn CPR and provide information about community resources for CPR training.

CARDIAC RHYTHM DISORDERS

Heart muscle contracts in response to electrical stimulation. In the normal heart, electrical stimulation produces a synchronised, rhythmic heart muscle contraction that propels blood into the vascular system. Changes in cardiac rhythm affect this synchronised activity and the heart's ability to effectively pump blood to body tissues.

THE PERSON WITH A CARDIAC ARRHYTHMIA

A cardiac arrhythmia is a disturbance or irregularity in the electrical system of the heart. Cardiac arrhythmias may be benign or have lethal consequences. Prompt recognition of a lethal arrhythmia and quick action can be lifesaving.

Arrhythmias develop for many reasons. Not all are pathological; some alterations in cardiac rhythm occur in response to events such as exercise or fear. For example, a rapid heart rate due to exercise, fever or excitement is a normal response to the body's demand for oxygen or to stimulation of the sympathetic nervous system. Slow heart rates also may be normal. Athletic heart syndrome, which results from long-term training on the heart muscle, allows the heart to beat more slowly and forcefully while maintaining cardiac output and tissue perfusion. Many athletes have a heart rate of less than 60 beats per minute (beats/min or bpm). Ageing affects cardiac rhythm as well (see the following 'Nursing care of the older adult' box).

TRANSLATION TO PRACTICE Evidence-based practice: the prevalence and pathophysiology of MINOCA

Most people who experience a myocardial infarction have angiographically recordable atherosclerotic disease. However, there are a small number of individuals who are diagnosed with an MI yet, strangely, demonstrate no evidence of obstructive atherosclerotic lesion. Consequently, a new diagnosis is emerging from the literature: myocardial infarction with non-obstructive coronary arteries (MINOCA).

In a systematic review by Pasupathy et al. (2015), a meta-analysis of 28 publications revealed that the prevalence of MINOCA is approximately 6%, with 60% of the individuals being male. However, when compared to myocardial infarction with associated coronary artery obstruction, the profile tended to favour younger females with less likelihood of having hyperlidipaemia. The mortality of the MINOCA group after 1 year was also lower.

IMPLICATIONS FOR NURSING

When working with younger females or individuals with no distinct hyperlipidaemia, the risk for developing non-obstructive coronary artery disease resulting in myocardial ischaemia or infarction should not be ignored. Education promoting healthy lifestyle choices, including nutrition and activity levels, remains paramount in the prevention of CHD.

CRITICAL THINKING IN PERSON-CENTRED CARE

1. Which clinical manifestations might a person experiencing a myocardial infarction experience?
2. How might a woman's description of clinical manifestations differ from a man's when experiencing a myocardial infarction?
3. Which assessments would you undertake and what data might you collect from a person you suspect is experiencing an MI?
4. How will the findings of this meta-analysis influence your clinical practice?

Source: Based on Pasupathy, S. et al. (2015). Systematic review of patients presenting with suspected myocardial infarction and nonobstructive coronary arteries. *Circulation*, *131*(10), 861–70. Doi: 10.1161/circulationaha.114.011201.

NURSING CARE OF THE OLDER ADULT Cardiac arrhythmias

Ageing affects the heart and the cardiac conduction system, increasing the incidence of arrhythmias and conduction defects. Older adults may experience arrhythmias even when no evidence of heart disease is found.

Older adults have a higher incidence of both ventricular and supraventricular arrhythmias without detrimental effects than younger people. Ectopic beats, including short runs of ventricular tachycardia, occur more commonly during exercise in older adults. These arrhythmias do not affect cardiac morbidity or mortality. Fibrosis of the bundle branches can lead to atrioventricular blocks; a prolonged PR interval is common in people over the age of 65. Older adults also have a higher incidence of diseases that may affect heart rhythm. An older adult person with hyperthyroidism, for example, may present with atrial fibrillation, syncope and confusion instead of the usual manifestations of goitre, tremor and exophthalmos.

ASSESSING FOR HOME CARE

Assessing older adults for problems related to cardiac arrhythmias focuses on the effect of the arrhythmia on functional health status.

- Ask about a history of cardiovascular disease and current medications.
- Inquire about symptoms such as episodes of presyncope, syncope, palpitations, chest pain or dyspnoea.
- Ask about relationship of symptoms such as palpitations to intake of certain foods and caffeine-containing beverages.
- Evaluate for other contributing factors such as smoking or alcohol intake.
- Inquire about a history of falls, particularly those occurring without apparent reason.

HEALTH EDUCATION FOR THE PERSON AND FAMILY

Teach measures to reduce the risk of cardiac arrhythmias and potential adverse consequences of arrhythmias.

- Emphasise the importance of taking medications as prescribed. Discuss possible effects of over-the-counter medications on the heart.
- Encourage reducing or eliminating caffeine intake. Caffeine increases the risk of ectopic beats and rapid heart rates.
- Encourage participation in a smoking cessation program and reduction or elimination of alcohol intake if appropriate.
- Encourage engaging in regular exercise. Discuss the beneficial effects of exercise in maintaining muscle mass, including cardiac muscle and cardiovascular health.
- Instruct the individual to contact the primary healthcare provider for evaluation of symptoms such as dizziness, fainting, frequent palpitations, dyspnoea, unexplained falls or chest pain.

Regardless of cause, an arrhythmia can significantly affect cardiac performance, depending on heart muscle health. The person's response to the arrhythmia is key to determining the urgency and type of treatment needed.

Physiology review

The unique properties of cardiac cells allow effective heart function. Four properties are electrical; the fifth is cardiac muscle's mechanical response to electrical stimulation.

1. *Automaticity* is the ability of pacemaker cells to spontaneously initiate an electrical impulse (action potential). The sinoatrial (SA) node is the dominant pacemaker, generating impulses at 60 to 100 times a minute. Myocardial muscle cells do not possess this ability.
2. *Excitability* is the ability of myocardial cells to respond to stimuli generated by pacemaker cells.
3. *Conductivity* is the ability to transmit an impulse from cell to cell. When one cell is stimulated, the impulse rapidly spreads throughout the heart muscle.
4. *Refractoriness* is the inability of cardiac cells to respond to additional stimuli immediately following depolarisation. In the absolute refractory period, depolarisation will not occur in response to any stimulus. A stronger than normal stimulus is required to initiate depolarisation during the relative refractory period. This is followed by the supernormal period, during which a mild stimulus will cause depolarisation.
5. *Contractility* is the ability of myocardial fibres to shorten in response to a stimulus. Heart muscle responds in an all-or-nothing manner: stimulation of one muscle fibre causes the entire muscle mass to contract to its fullest extent as one unit.

Electrical activity of the heart is normally controlled by the cardiac conduction. The SA node, the primary pacemaker of the heart, usually generates impulses at a regular rate of 60 to 100 bpm. The impulse spreads through the atria, is briefly delayed at the AV node, then spreads through conduction pathways of the ventricles and to ventricular muscle. The AV nodal delay allows the atria to contract, delivering an extra bolus of blood to the ventricles before they contract (the atrial kick). The AV node also controls the number of impulses that reach the ventricles, preventing extremely rapid heart rates.

Pathophysiology

Arrhythmias arise through disruption of the very properties that stimulate and control the heartbeat: automaticity, excitability, conductivity and refractoriness.

Arrhythmias due to altered impulse formation include changes in rate and rhythm and the development of ectopic beats. This category includes *tachyarrhythmias* (rapid heart rates), *bradyarrhythmias* (slow heart rates) and ectopic rhythms. These arrhythmias result from a change in the automaticity of cardiac cells. The rate of impulse formation may abnormally increase or decrease. Aberrant (abnormal) impulses may originate outside normal conduction pathways, causing **ectopic beats**. Ectopic beats interrupt the normal conduction sequence and may not initiate a normal muscle contraction. Depending on the site and timing of abnormal impulses, they may have little effect on the person or pose a significant threat.

Ischaemia, injury and infarction of myocardial tissue affect its excitability and ability to conduct and respond to an electrical stimulus. Conduction abnormalities cause varying degrees of **heart block**, a block in the normal conduction pathways. Myocardial injury or infarction can obstruct or delay impulse conduction. Bundle branch blocks are common in acute myocardial infarction.

The *re-entry phenomenon*, a phenomenon of normal and slow conduction, is a major cause of tachyarrhythmias. A stimulus such as an ectopic beat triggers the re-entry phenomenon. The impulse is delayed in one area of the heart (e.g. an area of ischaemia or injury) but conducted normally through the rest. Muscle that has been depolarised by the normally conducted impulse is repolarised by the time the impulse travelling through the area of slow conduction reaches it, thus initiating another cycle of depolarisation (Grossman & Mattson, 2013). The result is an arrhythmia that propagates itself.

Several forms of re-entry may occur. The impulse may travel through a set pathway to re-enter repolarised tissue. Many atrial arrhythmias follow this pattern, including atrial flutter. In functional re-entry, local differences in the conduction of an impulse interrupt the normal wave of depolarisation, sending it back upon itself in a spiral pattern and setting up a permanent rotation. This type of pattern suppresses normal pacemaker activity and can lead to atrial fibrillation (Grossman & Mattson, 2013).

Cardiac rhythms are classified according to the site of impulse formation or the site and degree of conduction block. Supraventricular rhythms arise above the ventricles. These rhythms usually produce a QRS complex within the normal range. Sinus rhythms, atrial rhythms and junctional (arising from the AV junction) rhythms are all supraventricular rhythms. Ventricular rhythms originate in the ventricles and may prove fatal if left untreated. AV conduction blocks result from a defect in impulse transmission from the atria to the ventricles. The major normal and abnormal cardiac rhythms are summarised in Table 29.7.

FAST FACTS

- The normal sinus rhythm is 60 to 100 bpm. Each complex includes a P wave, QRS and T wave.
- Supraventricular arrhythmias arise in the sinus node or the atria. A P wave may be present; the QRS appears normal and a T wave may be seen.
- Junctional arrhythmias arise in tissue just above or just below the AV node. The P wave may be inverted and may precede, follow or be buried in the QRS complex. The QRS usually appears normal and is followed by a T wave.
- Ventricular arrhythmias arise in ventricular myocardium. They do not reset the SA node or activate the atria. QRS complexes are wide and bizarre.

Supraventricular rhythms

NORMAL SINUS RHYTHM **Normal sinus rhythm (NSR)** is the normal heart rhythm, in which impulses originate in the SA (sinus) node and travel through all normal conduction pathways without delay. All waveforms are of normal configuration, look alike and have consistent (fixed) durations. The rate is between 60 and 100 bpm.

TABLE 29.7 Characteristics of selected cardiac rhythms and arrhythmias

RHYTHM/ECG APPEARANCE	ECG CHARACTERISTICS	MANAGEMENT
Supraventricular rhythms		
Normal sinus rhythm (NSR) 	Rate: 60 to 100 beats/min Rhythm: regular P:QRS: 1:1 PR interval: 0.12 to 0.20 sec QRS complex: 0.6 to 0.10 sec	None; normal heart rhythm.
Sinus arrhythmia 	Rate: 60 to 100 beats/min Rhythm: irregular, varying with respirations P:QRS: 1:1 PR interval: 0.12 to 0.20 sec QRS complex: 0.6 to 0.10 sec	Generally none; considered a normal rhythm in the very young and very old.
Sinus tachycardia 	Rate: 101 to 150 beats/min Rhythm: regular P:QRS: 1:1 (With very fast rates, P wave may be hidden in preceding T wave) PR interval: 0.12 to 0.20 sec QRS complex: 0.6 to 0.10 sec	Treated only if symptomatic or person is at risk for myocardial damage. Treat underlying cause (e.g. hypovolaemia, fever, pain). Beta-blockers or verapamil may be used.
Sinus bradycardia 	Rate: < 60 beats/min Rhythm: regular P:QRS: 1:1 PR interval: 0.12 to 0.20 sec QRS complex: 0.6 to 0.10 sec	Treated only if symptomatic. Intravenous atropine or isoprenaline, and/or pacemaker therapy may be used.
Premature atrial contractions (PACs) 	Rate: variable Rhythm: irregular, with normal rhythm interrupted by early beats arising in the atria P:QRS: 1:1 PR interval: 0.12 to 0.20 sec, but may be prolonged QRS complex: 0.6 to 0.10 sec	Usually require no treatment. Advise to reduce alcohol and caffeine intake, to reduce stress and to stop smoking. Beta-blocker may be prescribed.
Paroxysmal supraventricular tachycardia (PSVT) 	Rate: 100 to 280 beats/min (usually 150 to 200 beats/min) Rhythm: regular P:QRS: P waves often not identifiable PR interval: not measured QRS complex: 0.6 to 0.10 sec	Treat if symptomatic. Treatment may include vagal manoeuvres (Valsalva, carotid sinus massage); oxygen therapy; adenosine or a beta-blocker; temporary pacing or synchronised cardioversion.

TABLE 29.7 Characteristics of selected cardiac rhythms and arrhythmias (continued)

RHYTHM/ECG APPEARANCE	ECG CHARACTERISTICS	MANAGEMENT
Atrial flutter 	Rate: atrial 240 to 360 beats/min, ventricular rate depends on degree of AV block and usually is < 150 beats/min Rhythm: atrial regular; ventricular usually regular P:QRS: 2:1, 4:1, 6:1; may vary PR interval: not measured QRS complex: 0.6 to 0.10 sec	Synchronised cardioversion; medications to slow ventricular response such as a beta-blocker or calcium channel blocker, followed by a class I antiarrhythmic agent or amiodarone.
Atrial fibrillation 	Rate: atrial 300 to 600 beats/min (too rapid to count); ventricular 100 to 180 beats/min in untreated people Rhythm: irregularly irregular P:QRS: variable PR interval: not measured QRS complex: 0.06 to 0.10 sec	Synchronised cardioversion; medications to reduce ventricular response rate: metaprolol, diltiazem or digoxin; anticoagulant therapy to reduce risk of clot formation and stroke.
Junctional escape rhythm 	Rate: 40 to 60 beats/min; junctional tachycardia 60 to 140 beats/min Rhythm: regular P:QRS: P waves may be absent, inverted and immediately preceding or succeeding QRS complex or hidden in QRS complex PR interval: < 0.10 sec QRS complex: 0.06 to 0.10 sec	Treat cause if symptomatic.
Ventricular rhythms		
Premature ventricular contractions (PVCs) 	Rate: variable Rhythm: irregular, with PVC interrupting underlying rhythm and followed by a compensatory pause P:QRS: No P wave noted before PVC PR interval: absent with PVC QRS complex: wide (> 0.12 sec) and bizarre in appearance; differs from normal QRS complex	Treat if symptomatic or in presence of severe heart disease. Advise against stimulant use (caffeine, nicotine). Beta-blockers or class I or III antiarrhythmic agents (see the box on page 1029) may be used in people with severe heart disease who are symptomatic.
Ventricular tachycardia (VT, V tach) 	Rate: 100 to 250 beats/min Rhythm: regular P:QRS: P waves usually not identifiable PR interval: not measured QRS complex: 0.12 sec or greater; bizarre shape	Treat if VT is sustained, symptomatic or associated with organic heart disease. Treatment includes DC cardioversion or intravenous procainamide, lignocaine or a class III antiarrhythmic agent if haemodynamic instability accompanies. Surgical ablation or pacing with an implanted cardioverter-defibrillator (ICD) for repeated episodes.

(continued)

TABLE 29.7 Characteristics of selected cardiac rhythms and arrhythmias (continued)

RHYTHM/ECG APPEARANCE	ECG CHARACTERISTICS	MANAGEMENT
Ventricular fibrillation (VF, V fib) 	Rate: no real rate to count Rhythm: grossly irregular P:QRS: no identifiable P waves PR interval: none QRS: bizarre, varying in shape and direction	Immediate cardioversion/ defibrillation.
Atrioventricular conduction blocks		
First-degree AV block 	Rate: usually 60 to 100 beats/min Rhythm: regular P:QRS: 1:1 PR interval: > 0.21 sec QRS complex: 0.06 to 0.10 sec	None required.
Second-degree AV block, type I (Mobitz I, Wenckebach) 	Rate: 60 to 100 beats/min Rhythm: atrial regular; ventricular irregular P:QRS: 1:1 until P wave blocked with no subsequent QRS complex PR interval: progressively lengthens in a regular pattern QRS complex: 0.06 to 0.10 sec; sudden absence of QRS complex	Monitoring and observation; rarely progresses to a higher degree of block or requires treatment.
Second-degree AV block, type II (Mobitz II) 	Rate: atrial 60 to 100 beats/min; ventricular < 60 beats/min Rhythm: atrial regular; ventricular irregular P:QRS: typically 2:1, may vary PR interval: constant PR interval for each conducted QRS complex QRS complex: 0.06 to 0.10 sec	Atropine or isoprenaline; pacemaker therapy.
Third-degree AV block (complete heart block) 	Rate: atrial 60 to 100 beats/min; ventricular 15 to 60 beats/min Rhythm: atrial regular; ventricular regular P:QRS: no relationship P waves and QRS complexes; independent rhythms PR interval: not measured QRS complex: 0.06 to 0.10 sec if junctional escape rhythm; > 0.12 sec if ventricular escape rhythm	Immediate pacemaker therapy.

SINUS NODE ARRHYTHMIAS *Sinus node arrhythmias* may occur as a normal compensatory response (e.g. to exercise) or because of altered automaticity. In these rhythms, as in NSR, the initiating impulse is from the sinus node. They differ from NSR in the rate or regularity of the rhythm. Sinus arrhythmias include sinus arrhythmia, sinus tachycardia and sinus bradycardia.

Sinus arrhythmia *Sinus arrhythmia* is a sinus rhythm in which the rate varies with respirations, causing an irregular rhythm. The rate increases during inspiration and decreases with expiration. Sinus arrhythmia is common in the very young and the very old. It can be caused by an increase in vagal tone, by digoxin toxicity or by morphine administration.

Sinus tachycardia *Sinus tachycardia* has all of the characteristics of NSR, except that the rate is greater than 100 bpm. Tachycardia arises from enhanced automaticity in response to changes in the internal environment. Sympathetic nervous system stimulation or blocked vagal (parasympathetic) activity increases the heart rate. Tachycardia is a normal response to any condition or event that increases the body's demand for oxygen and nutrients, such as exercise or hypoxia. If the person on bed rest or someone who has done little to increase oxygen demand has tachycardia, this is an ominous sign. Sinus tachycardia may be an early sign of cardiac dysfunction, such as heart failure. Tachycardia is detrimental in the person with cardiac disease because it increases oxygen demand and decreases oxygen supply (because of decreased diastole reducing coronary artery filling time).

Common causes of sinus tachycardia include exercise, excitement, anxiety, pain, fever, hypoxia, hypovolaemia, anaemia, hyperthyroidism, myocardial infarction, heart failure, cardiogenic shock, pulmonary embolism, caffeine intake and certain drugs, such as atropine, adrenaline or isoprenaline.

Manifestations of sinus tachycardia include a rapid pulse rate. The person may complain of feeling that the heart is 'racing', shortness of breath and dizziness. In the presence of heart disease, sinus tachycardia may precipitate chest pain.

Sinus bradycardia *Sinus bradycardia* has all of the characteristics of NSR, but the rate is less than 60 bpm. Sinus bradycardia may result from increased vagal (parasympathetic) activity or from depressed automaticity due to injury or ischaemia to the sinus node. Sinus bradycardia may be normal (e.g. in the person with athletic heart syndrome). The heart rate also normally slows during sleep because the parasympathetic nervous system is dominant at this time. Other causes of sinus bradycardia include pain, increased intracranial pressure, sinus node disease, AMI (especially with inferior wall damage), hypothermia, acidosis and certain drugs.

Sinus bradycardia may be asymptomatic; it is important to assess the person before treating the rhythm. Manifestations of decreased cardiac output, such as decreased level of consciousness, syncope (faintness) or hypotension, indicate a need for intervention.

Sick sinus syndrome *Sick sinus syndrome (SSS)* results from sinus node disease or dysfunction that causes problems with impulse formation, transmission and conduction. Sick sinus syndrome is often found in older adults. It may be caused by direct injury to sinus tissue, fibrosis of conduction fibres associated with ageing and such drugs as digoxin, beta-blockers and calcium channel blockers.

ECG characteristics of SSS include sinus bradycardia, sinus arrhythmia, sinus pauses or arrest, and atrial tachyarrhythmias such as atrial fibrillation, atrial flutter or atrial tachycardia. Bradycardia–tachycardia syndrome, characterised either by paroxysmal (abrupt onset and termination) atrial tachycardia followed by prolonged sinus pauses or alternating periods of bradycardia and tachycardia, also may indicate sinus node dysfunction.

Manifestations of sinus node dysfunction often are intermittent, related to a drop in cardiac output caused by the irregular rhythm. Fatigue, dizziness, light headedness and syncope are common. The heart rate may not increase in response to stressors such as exercise or fever.

SUPRAVENTRICULAR ARRHYTHMIAS When an action potential originates in atrial tissue outside the sinus node, the resulting rhythm is classified as a *supraventricular rhythm*. In these arrhythmias, an ectopic pacemaker takes over or overrides the SA node. They may also occur when the SA node fails; an *escape rhythm* develops as a fail-safe mechanism to maintain the heart rate. The most common supraventricular arrhythmias are premature atrial contractions, paroxysmal supraventricular tachycardia, atrial flutter and atrial fibrillation. These rhythms may be paroxysmal; that is, occur in bursts with an abrupt beginning and end.

Premature atrial contractions *A premature atrial contraction (PAC)* is an ectopic atrial beat that occurs earlier than the next expected sinus beat. PACs can arise anywhere in the atria. They are usually asymptomatic and benign, but they may initiate paroxysmal supraventricular tachycardia in susceptible individuals. PACs are common in older adults, often occurring without an obvious cause. Strong emotions, excessive alcohol intake, tobacco and stimulants such as caffeine can precipitate PACs. They also may be associated with myocardial infarction, heart failure and other cardiac disorders, hypoxaemia, pulmonary embolism, digoxin toxicity and electrolyte or acid–base imbalances. In people with underlying heart disease, PACs may precede a more serious arrhythmia.

The ECG tracing shows interruption of the underlying rhythm by a premature complex that looks similar to the underlying beats. The ectopic impulse of the PAC is usually conducted normally, leading to depolarisation of cardiac muscle and a normal QRS complex. Because the impulse arises above the ventricles, it follows normal conduction pathways through the ventricles. The QRS complex is narrow or matches those of the underlying rhythm. The shape of the P wave of a PAC differs from normal P waves because its impulse arises outside the sinus node. A *non-compensatory pause* usually follows, as the PAC resets the SA node rhythm. Occasionally, the ectopic impulse may not be conducted through the heart, resulting in a lone P wave without a QRS or a non-conducted PAC.

PACs cause few manifestations. If frequent, they may cause palpitations or a fluttering sensation in the chest. Early beats may be noted on auscultating or palpating the pulse.

Paroxysmal supraventricular tachycardia *Paroxysmal supraventricular tachycardia (PSVT)* is tachycardia of sudden onset and termination. PSVT is usually initiated by a re-entry loop in or around the AV node; that is, an impulse re-enters the same section of tissue over and over, causing repeated depolarisations.

PSVT occurs more frequently in women. Sympathetic nervous system stimulation and stressors such as fever, sepsis and hyperthyroidism may precipitate PSVT. It also may be associated with heart diseases such as CHD, myocardial infarction, rheumatic heart disease, myocarditis or acute pericarditis. Abnormal conduction pathways associated with Wolff–Parkinson–White (WPW) syndrome may account for PSVT.

PSVT affects ventricular filling and cardiac output and decreases coronary artery perfusion. Its manifestations include complaints of palpitations and a 'racing' heart, anxiety, dizziness, dyspnoea, anginal pain, diaphoresis, extreme fatigue and polyuria. (Urine output may reach up to 3 L in the first few hours after PSVT onset.)

Atrial flutter *Atrial flutter* is a rapid and regular atrial rhythm thought to result from an intra-atrial re-entry mechanism. Causes include sympathetic nervous system stimulation due to anxiety or caffeine and alcohol intake; thyrotoxicosis; coronary heart disease or myocardial infarction; pulmonary embolism; and abnormal conduction syndromes, such as WPW syndrome. Older people with rheumatic heart disease and/or valvular disease are especially vulnerable.

Two types of atrial flutter have been identified. Type I atrial flutter has an atrial rate of 240 to 340 bpm. It develops due to a re-entry mechanism in the right atrium. The mechanism leading to type II atrial flutter has not been identified. In this type of flutter, the atrial rate is faster, to 350 bpm.

People with atrial flutter may complain of palpitations or a fluttering sensation in the chest or throat. If the ventricular rate is rapid, manifestations of decreased cardiac output, such as decreased level of consciousness, hypotension, decreased urinary output and cool, clammy skin, may be noted. The atrial kick (additional ventricular filling with atrial contraction) is lost because of inadequate atrial filling.

ECG characteristics include a 'sawtooth' or 'picket fence' appearance of P waves, which are labelled flutter (F) waves. The atrial rate is rapid, often around 300 bpm. As a protective mechanism, many impulses are blocked at the AV node and the ventricular rate is rarely greater than 150 to 170 bpm. Usually, atrial impulses are evenly conducted through the AV node; for example, two impulses to one QRS complex (2:1), four impulses to one QRS complex (4:1) or six impulses to one QRS complex (6:1). A constant conduction ratio results in a regular ventricular rhythm; the ventricular rhythm is irregular if the conduction ratio varies. The ventricular rate usually ranges from 150 to 170 bpm in 2:1 conduction and from 60 to 75 bpm for lower conduction ratios. The T wave is usually hidden by overriding F waves; some F waves may be hidden in the QRS complex.

Atrial fibrillation *Atrial fibrillation* is a common arrhythmia characterised by disorganised atrial activity without discrete atrial contractions. Multiple small re-entry circuits develop in the atria. Atrial cells cannot repolarise in time to respond to the next stimulus (Grossman & Mattson, 2013). Extremely rapid atrial impulses bombard the AV node, resulting in an irregularly irregular ventricular response which may be rapid > 100 bpm or slow < 60 bpm. Atrial fibrillation may occur suddenly and recur or it may persist as a chronic arrhythmia. Atrial fibrillation is commonly associated with heart failure, rheumatic heart disease, coronary heart disease, hypertension and hyperthyroidism.

Manifestations of atrial fibrillation are dependent on the ventricular rate. With rapid ventricular response rates, manifestations of decreased cardiac output such as hypotension, dyspnoea, fatigue and angina may develop. People with extensive heart disease may develop syncope or heart failure. Peripheral pulses are irregular and of variable amplitude (strength).

The specific ECG characteristics of atrial fibrillation include an irregularly irregular rhythm and the absence of identifiable P waves. The atrial rate is so rapid that it is not measurable. The ventricular rate varies.

Atrial fibrillation increases the risk of formation of thromboemboli. Organ infarction may occur as a result; the incidence of stroke is high.

Junctional arrhythmias

Rhythms that originate in AV nodal tissue are termed *junctional*. The AV junction includes the AV node and the bundle of His, which branches into the right and left bundle branches. An impulse arising from the AV junction may occur in response to failure of higher pacemakers, as in a *junctional escape rhythm,* or may result from an abnormal mechanism, such as altered automaticity. An impulse arising from the AV junction may or may not be conducted back up to the atria. This conduction against the normal flow or pattern is called *retrograde conduction*. The resulting atrial wave, called a P wave, may be found before, during or after the QRS complex, depending on the speed of conduction. The P wave is inverted in some ECG leads because the impulse moves from the AV node up to the atria, instead of from the SA node down towards the AV node. In addition, the PR interval is shorter than normal (less than 0.12 sec). The QRS complex is typically narrow.

A junctional rhythm may be due to drug toxicity (e.g. digoxin, beta-blockers or calcium channel blockers) or other causes such as hypoxaemia, hyperkalaemia, increased vagal tone or damage to the AV node, myocardial infarction and heart failure. Loss of synchronised atrial contraction and the atrial kick may affect cardiac output, leading to manifestations of decreased cardiac output and impaired myocardial tissue perfusion. Heart failure may develop.

Premature junctional contractions (PJCs) occur before the next expected beat of the underlying rhythm. Isolated PJCs

may occur in healthy people and are insignificant. *Junctional tachycardia* is a junctional rhythm with a rate greater than 60 bpm. It is caused by increased automaticity of AV nodal tissue. The ventricular rate is usually less than 140 bpm. Both rhythms are most commonly associated with digoxin toxicity, hypoxia, ischaemia or electrolyte imbalances.

Ventricular arrhythmias

Ventricular arrhythmias originate in the ventricles. Because the ventricles pump blood into the pulmonary and systemic vasculature, any disruption of their rhythm can affect cardiac output and tissue perfusion. A wide and bizarre QRS complex (greater than 0.12 sec) is a characteristic feature of ventricular arrhythmias. This occurs because ventricular ectopic impulses begin and travel outside normal conduction pathways. Other characteristics include no relationship of the QRS complex to a P wave, increased amplitude of the QRS complex, an abnormal ST segment and a T wave deflected in the opposite direction from the QRS complex.

PREMATURE VENTRICULAR CONTRACTIONS *Premature ventricular contractions (PVCs)* are ectopic ventricular beats that occur before the next expected beat of the underlying rhythm. They usually do not reset the atrial rhythm and are followed by a full compensatory pause. PVCs often have no significance in people without heart disease. Frequent, recurrent or multifocal PVCs may be associated with an increased risk of lethal arrhythmias. PVCs result from either enhanced automaticity or a re-entry phenomenon. They may be triggered by anxiety or stress; tobacco, alcohol or caffeine use; hypoxia, acidosis and electrolyte imbalances; sympathomimetic drugs; coronary heart disease; heart failure; mechanical stimulation of the heart (e.g. the insertion of a cardiac catheter); or reperfusion after thrombolytic therapy. The incidence and significance of PVCs is greatest after myocardial infarction.

PVCs may be isolated or occur in a specific pattern. Two PVCs in a row are called a *couplet* or *paired* PVCs. Three consecutive PVCs (a *triplet* or *salvo*) is a short run of ventricular tachycardia. *Ventricular bigeminy* is characterised by a PVC following each normal beat; a PVC noted every third beat is called *ventricular trigeminy*. When the ventricular impulse arises from one ectopic site, all PVCs look the same (*monomorphic*) and are called *unifocal* PVCs. *Multifocal* PVCs arise from different ectopic sites and appear different from one another on the ECG (*polymorphic*).

The frequency and patterns of PVCs can be indicative of myocardial irritability and the risk of a lethal arrhythmia. The following are considered warning signs in the person with acute heart disease (e.g. an acute MI):

- PVCs that develop within the first 4 hours of an MI
- frequent PVCs (six or more per minute)
- couplets or triplets
- multifocal PVCs
- R-on-T phenomenon (PVCs or ventricular pacing falling on the T wave).

In people without heart disease, isolated PVCs usually are insignificant and do not require treatment. Individuals may complain of feeling that their hearts 'skip a beat' or of palpitations. In person with pre-existing heart disease, PVCs may indicate a drug toxicity or an increased risk of lethal arrhythmias and cardiac arrest. The risk is greatest following acute MI.

VENTRICULAR TACHYCARDIA *Ventricular tachycardia (VT, V tach)* is a rapid ventricular rhythm defined as three or more consecutive PVCs. Ventricular tachycardia may occur in short bursts or 'runs', or may persist for more than 30 seconds (sustained ventricular tachycardia). The rate is greater than 100 bpm and the rhythm is usually regular. Re-entry is the usual electrophysiological mechanism responsible for VT. Myocardial ischaemia and infarction are the most common predisposing factors for VT. It also is associated with cardiac structural disorders such as valvular disease, rheumatic heart disease or cardiomyopathy. It may occur in the absence of heart disease and with anorexia nervosa, metabolic disorders and drug toxicity.

Non-sustained VT may occur paroxysmally and convert back to an effective rhythm spontaneously. The person may experience a fluttering sensation in the chest or complain of palpitations and brief shortness of breath. People in sustained VT generally develop signs and symptoms of decreased cardiac output and haemodynamic instability, including severe hypotension, a weak or non-palpable pulse, and loss of consciousness. Allowed to continue, VT can deteriorate into ventricular fibrillation. Sustained ventricular tachycardia is a medical emergency that requires immediate intervention, particularly in people with cardiac disease.

Torsades de pointes is a type of ventricular tachycardia associated with *long QT syndrome*, a prolongation of the QT interval. Long QT syndrome may be genetic or acquired, occurring secondarily to electrolyte disruptions, myocardial infarction, cocaine use, liquid protein diets, medications or other conditions. In torsades de pointes, the QRS complexes vary in size, shape and amplitude (see Figure 29.7). Individuals with torsades de pointes may have multiple bursts or episodes of ventricular tachycardia or may develop ventricular fibrillation and sudden cardiac death (Dave, 2014).

VENTRICULAR FIBRILLATION *Ventricular fibrillation (VF, V fib)* is extremely rapid, chaotic ventricular depolarisation causing the ventricles to quiver and cease contracting; the heart

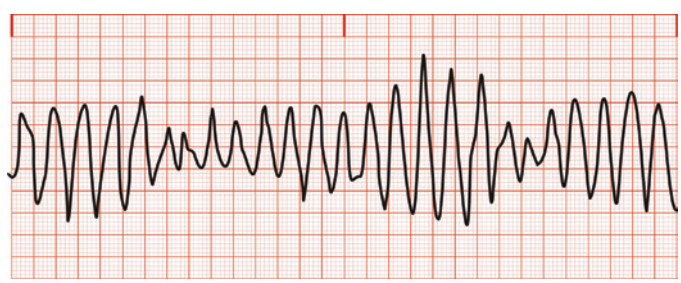

FIGURE 29.7 ■ Torsades de pointes. Note the wide and bizarre QRS complexes of varying size, shape (morphology) and amplitude

does not pump. This is known as **cardiac arrest**; it is a medical emergency requiring immediate intervention with cardiopulmonary resuscitation (CPR). VF is the most common initial rhythm and is found in 60–80% of all cardiac arrests. Survival rates are poor; however, strong predictors of a favourable outcome are the return of spontaneous circulation within 20 minutes and being less than 60 years of age (Wibrandt et al., 2015).

Ventricular fibrillation is usually triggered by severe myocardial ischaemia or infarction. It is the terminal event in many disease processes or traumatic conditions. Ventricular fibrillation may be precipitated by a single PVC or may follow VT. Other causes of VF include digoxin toxicity, reperfusion therapy, antiarrhythmic drugs, hypokalaemia and hyperkalaemia, hypothermia, metabolic acidosis, mechanical stimulation (as with the insertion of cardiac catheters or pacing wires) and electric shock.

Clinically, loss of ventricular contractions results in absence of a palpable or audible pulse. The person loses consciousness and stops breathing as perfusion ceases. The ECG shows grossly irregular, bizarre complexes with no discernible rate or rhythm.

Atrioventricular conduction blocks

Conduction defects that delay or block transmission of the sinus impulse through the AV node are called *atrioventricular conduction blocks*. Impaired conduction may result from tissue injury or disease, increased vagal (parasympathetic) tone, drug effects or a congenital defect. AV conduction blocks vary in severity from benign to severe.

FAST FACTS

- First-degree AV block = delayed conduction through the AV node and a long PR interval.
- Second-degree AV block = complete blockage of *some* impulses through the AV node; some P waves are not followed by a QRS complex.
- Third-degree AV block = complete blockage of *all* impulses through the AV node; no relationship between P waves and QRS complexes.

FIRST-DEGREE AV BLOCK *First-degree AV block* is a benign conduction delay that generally poses no threat, has no symptoms and requires no treatment. Impulse conduction through the AV node is slowed, but all atrial impulses are conducted to the ventricles. It may result from injury or infarct of the AV node, other cardiac diseases or drug effects. The ECG shows all characteristics of NSR, except the PR interval is greater than 0.20 second.

SECOND-DEGREE AV BLOCK *Second-degree AV block* is characterised by failure to conduct one or more impulses from the atria to the ventricles. Two patterns of second-degree AV block are seen, identified as type I and type II.

Second-degree AV block—type I *Type I second-degree AV block (Mobitz type I* or *Wenckebach phenomenon)* is characterised by a repeating pattern of increasing AV conduction delays until an impulse fails to conduct to the ventricles. On the ECG, PR intervals progressively lengthen until one QRS complex is not conducted or dropped. The ventricular rate remains adequate to maintain cardiac output and the person usually is asymptomatic. Mobitz type I AV block usually is transient, associated with acute MI or drug intoxication (e.g. digoxin, beta-blockers or calcium channel blockers). It rarely progresses to complete heart block.

Second-degree AV block—type II *Type II second-degree AV block (Mobitz type II)* involves intermittent failure of the AV node to conduct an impulse to the ventricles without preceding delays in conduction. The PR interval remains constant, but not all P waves are followed by QRS complexes (e.g. there may be two P waves for every QRS). Conduction through the His–Purkinje system usually is delayed as well, causing a widened QRS complex. Mobitz type II block is frequently associated with acute anterior wall MI and a high rate of mortality (Grossman & Mattson, 2013). Manifestations of Mobitz type II block depend on the ventricular rate. Pacemaker therapy may be required to maintain the cardiac output.

THIRD-DEGREE AV BLOCK *Third-degree AV block (complete heart block)* occurs when atrial impulses are completely blocked at the AV node and fail to reach the ventricles. As a result, the atria and ventricles are controlled by different and independent pacemakers, with separate rates and rhythms. The ventricular impulse arises from either junctional fibres (with a rate of 40 to 60 bpm) or a ventricular pacemaker at a rate of less than 40 bpm. The width of the QRS complex depends on the location of the escape pacemaker. The QRS is wide and the rate is slow when the rhythm arises distal to the bundle of His.

Third-degree block is frequently associated with an inferior or anteroseptal myocardial infarction. Other causes include congenital conditions, acute or degenerative cardiac disease or damage, drug effects and electrolyte imbalances. The slow escape rhythm significantly affects cardiac output, causing manifestations such as syncope (known as a *Stokes–Adams attack*), dizziness, fatigue, exercise intolerance and heart failure. Third-degree AV block is life threatening and requires immediate intervention to maintain adequate cardiac output.

AV DISSOCIATION Complete dissociation of atrial and ventricular rhythms can occur in conditions other than third-degree AV block. The two primary factors leading to AV dissociation are severe sinus bradycardia and a lower pacemaker (junctional or ventricular) that competes with or exceeds the normal sinus rhythm. AV dissociation may result from acute myocardial ischaemia or infarction, cardiac surgery or drug effects. The ECG shows separate and competing atrial (P waves) and ventricular (QRS complexes) rhythms.

Intraventricular conduction blocks

Once the impulse enters the ventricles, its conduction through the right and left bundle branches may be impaired (*bundle branch block*). As a result, the impulse is conducted more slowly than normal through the ventricles. On the ECG, the QRS complex is prolonged. Its appearance varies, depending on the affected bundle (right or left). Typically, no clinical

manifestations are associated with bundle branch block unless it occurs in conjunction with an AV block.

INTERPROFESSIONAL CARE

Cardiac arrhythmias may be either benign or critical: recognising lethal arrhythmias is a matter of life and death. Major goals of care include identifying the arrhythmia, evaluating its effect on physical and psychosocial wellbeing and treating underlying causes. This may involve correcting fluid and electrolyte or acid–base imbalances; treating hypoxia, pain or anxiety; administering antiarrhythmic medications; or mechanical and surgical interventions.

Diagnosis

Diagnostic tests for arrhythmias include the electrocardiogram, cardiac monitoring and electrophysiology studies. Laboratory tests such as serum electrolytes, drug levels and ABGs may be done to help identify the cause of the arrhythmia.

ELECTROCARDIOGRAM The 12-lead ECG may be required to accurately diagnose an arrhythmia. It also provides information about underlying disease processes, such as myocardial infarction or other cardiac disease. The ECG may also be used to monitor the effects of treatment. See Chapter 28 for more information about the 12-lead ECG.

CARDIAC MONITORING Cardiac monitoring allows continuous observation of the cardiac rhythm. It is used in many different circumstances (see Box 29.2). Different types of ECG monitoring are employed for different situations.

Continuous cardiac monitoring Continuous monitoring of the cardiac rhythm is provided by bedside and central monitoring stations. Electrodes placed on the person's chest attach to cables connected to a monitor. The heart rate and rhythm is displayed on a bedside monitor connected to a central monitoring station. The central station allows simultaneous monitoring of many individuals within a nursing unit. Alarms on both bedside and central monitors warn of potential problems such as very rapid or very slow heart rates. Alarm limits are preset by the nurse for the individual. Procedure 29.1 describes how to place a person on cardiac monitoring.

Telemetry may be used in acute care settings when the person is ambulatory. Chest electrodes are connected to a portable transmitter worn around the neck or waist; the ECG is transmitted electronically to a central monitoring station for continuous monitoring.

Holter monitoring Individuals often complain of palpitations or other heart symptoms but are asymptomatic during evaluation in a hospital or community-based setting. Ambulatory or Holter monitoring may be used to identify intermittent arrhythmias, to detect silent ischaemia, to monitor the effects of treatment and to assess pacemaker or automatic cardioverter-defibrillator function. Electrodes are applied and the leads attached to a portable telemetry monitor that records and stores all electrical activity. Individuals are instructed to leave the electrode pads in place during monitoring, record any cardiac symptoms or events in a journal (such as chest pain, palpitations, syncope) and are told when to return to the clinic. After the prescribed period, usually 48 to 72 hours, the person returns and the monitor is removed. Diary entries are compared to the recorded heart rhythms to identify the effects of arrhythmias.

ELECTROPHYSIOLOGY STUDIES *Diagnostic cardiac electrophysiology (EP) procedures* are used to identify arrhythmias and their causes. EP studies are used to analyse components of the conduction system, identify sites of ectopic stimulation and evaluate the effectiveness of treatment. EP procedures can be used both for diagnosis and as a therapeutic intervention.

In the electrophysiology laboratory, electrode catheters are guided by fluoroscopy into the heart through the femoral or brachial vein. The timing and sequence of electrical activation during normal and abnormal (aberrant) rhythms is observed and measured. Electrical stimulation may be used to induce arrhythmias similar to the person's clinical arrhythmia (Greenberg, 2015). Following diagnosis, an EP procedure may be used to treat the arrhythmia—for example, by overdrive pacing (stimulating the person's heart rate to a rate faster than that of the tachyarrhythmia) to break the arrhythmia's cycle or to perform ablative therapy to destroy the ectopic site. See the section on cardiac mapping and catheter ablation for further information.

Nursing care for the individual undergoing an EP procedure is similar to that for a percutaneous coronary revascularisation (see 'Nursing care of the person having PTCA' on page 1001). The procedure and expected sensations are explained. The person remains awake during the procedure; anxiolytic medications or sedatives are given to reduce apprehension. Intravenous heparin may be given during the procedure to reduce the risk of thromboembolism.

BOX 29.2 Indications for cardiac monitoring

- Perioperative monitoring of heart rate and rhythm
- Detecting and identifying arrhythmias
- Monitoring the effects of cardiac and non-cardiac diseases on the heart
- Monitoring people with potentially life-threatening conditions:
  a. Major trauma (especially cardiac trauma)
  b. Dissecting aneurysm
  c. Acute myocardial infarction
  d. Heart failure
  e. Shock
  f. Other emergency conditions
- Evaluating responses to procedures and interventions:
  a. Drug therapies
  b. Diagnostic procedures
  c. Ablative techniques
  d. Angioplasty or cardiac catheterisation
  e. Cardiac surgery
  f. Pacemaker function
  g. Automatic implantable cardioverter-defibrillator function

PROCEDURE 29.1 Initiating cardiac monitoring

GATHER SUPPLIES

- Bedside monitor and cable or telemetry unit with fresh battery
- Electrodes—self-adherent, pre-gelled, disposable
- Lead wires
- Washcloth, soap and towel
- Alcohol prep pads
- Dry gauze pads or ECG prep pads

BEFORE THE PROCEDURE

Explain the reason for ECG monitoring. Reassure person that changes in heart rhythm can be noted and immediately treated if necessary. Explain that loose or disconnected lead wires, poor electrode contact, excessive movement, electrical interference or equipment malfunction may trigger alarms and alert the staff, allowing correction of the problem. Reassure that movement is allowed, within activity restrictions, while on the monitor. Explain skin preparation procedure. Provide for privacy and drape appropriately.

PROCEDURE

1. Follow standard precautions.
2. Check equipment for damage (i.e. fraying, bent or broken wires). Connect lead wires to cable and secure connections.
3. Select electrode sites on the chest wall, avoiding areas of excessive movement, joints, skin creases, scar tissue or other lesions.
4. Clean sites with soap and water and dry thoroughly. Alcohol may be used to remove skin oils; allow the skin to dry for 60 seconds after use.
5. Gently rub the site with a dry gauze pad or ECG prep pad to remove dead skin cells, debris and residue.
6. Open the electrode package; peel the backing from the electrode and check to ensure that the centre of the pad is moist with conductive gel.
7. Apply electrode pads, pressing firmly to ensure contact.
8. Attach leads and position cable with sufficient slack for comfort. Place the telemetry unit (if used) in gown pouch or pocket.
9. Assess ECG tracing on the monitor, adjusting settings as needed.
10. Set monitor alarm limits typically at 20 bpm higher and lower than the person's baseline rate. Turn alarms on and leave on at all times. Assess immediately if an alarm is triggered.
11. Time and date pads with every change.

AFTER THE PROCEDURE

Monitor periodically for comfort. Assess electrode and lead wire connections as needed. Remove and apply new pads every 24 to 48 hours or whenever the pad becomes dislodged or non-adherent. Clean gel residue from previous site and document skin condition under the pads. Choose an alternative site if the skin appears irritated or blistered. Document ECG strips according to unit policy and/or doctor's order, as well as when the cardiac rhythm or the person's condition changes (especially with complaints of chest pain, decreased level of consciousness or changes in vital signs). Note the date, time, personal identification, monitor lead, duration of PR and QT intervals, and rhythm interpretation on each ECG strip.

Complications of EP procedures are infrequent, but include fatal ventricular fibrillation, cardiac perforation and major venous thrombosis (Greenberg, 2015). Careful post-procedure monitoring is vital.

Medications

The goal of drug therapy is to suppress arrhythmia formation. No drug has been found to be completely safe and effective. Antiarrhythmic drugs are primarily used for acute treatment of arrhythmias, although they may also be used to manage chronic conditions. The overall goal of therapy is to maintain an effective cardiac output by stabilising cardiac rhythm.

It is important to remember that virtually all antiarrhythmic drugs also have proarrhythmic effects; that is, they can worsen existing arrhythmias and precipitate new ones. Because of this tendency, the higher mortality rates demonstrated in people receiving antiarrhythmic medications, and the increasing safety and availability of interventional techniques, antiarrhythmic medications are used sparingly.

Most antiarrhythmic drugs are classified by their effects on the cardiac action potential. Most are class I drugs or fast sodium channel blockers. By blocking sodium channels, these drugs slow impulse conduction in the atria and ventricles. This class is further divided into subclasses A, B and C. Class II drugs are beta-blockers, which decrease SA node automaticity, AV conduction velocity and myocardial contractility. Class III agents block potassium channels, delaying repolarisation and prolonging the relative refractory period. Class IV drugs are calcium channel blockers. Their effect is similar to that of beta-blockers. Adenosine and digoxin do not fit within the major classes. Both drugs reduce SA node automaticity and slow AV conduction. Magnesium also falls outside the major classes, but is used to treat arrhythmias. The 'Medication administration' box below identifies common antiarrhythmic drugs within each class and the nursing implications in caring for people receiving these drugs.

Drugs that affect the autonomic nervous system may also be used to treat arrhythmias. Sympathomimetics, such as adrenaline, stimulate the heart, increasing both heart rate and contractility. Anticholinergic agents such as atropine are used to decrease vagal tone and increase the heart rate. Magnesium sulfate is an unclassified drug that has been shown to be safe and effective in the treatment of ventricular tachycardias.

MEDICATION ADMINISTRATION Antiarrhythmic drugs

CLASS I DRUGS: SODIUM CHANNEL BLOCKERS

Class IA

Class IA drugs decrease the flow of sodium into the cell and prolong the action potential. This decreases automaticity, slows the rate of impulse conduction and prolongs refractoriness. They are used to treat both supraventricular and ventricular tachycardias.

Class IB

Class IB, or lignocaine-like, drugs decrease the refractory period but have little effect on automaticity. Drugs in this class are used primarily to treat ventricular arrhythmias, including PVCs and ventricular tachycardia.

Class IC

Class IC drugs slow impulse conduction velocity but have little effect on refractoriness. They are used to reduce or eliminate tachyarrhythmias associated with re-entry. Their significant proarrhythmic effects limit their usefulness, but they may be used to treat supraventricular tachycardia.

CLASS II DRUGS: BETA-BLOCKERS

Class II drugs are beta-blockers that decrease automaticity and conduction through the AV node. They also reduce the heart rate and myocardial contractility. They are used to treat supraventricular tachycardia and to slow the ventricular response rate to atrial fibrillation. These drugs may cause bronchospasm and are contraindicated for people with asthma, chronic obstructive pulmonary disease (COPD) or other restrictive or obstructive lung diseases.

CLASS III DRUGS: POTASSIUM CHANNEL BLOCKERS

Class III drugs block potassium channels, prolonging repolarisation and the refractory period. Drugs in this class are used primarily to treat ventricular tachycardia and ventricular fibrillation. Amiodarone may also be used for supraventricular tachycardias.

CLASS IV DRUGS: CALCIUM CHANNEL BLOCKERS

Calcium channel blockers decrease automaticity and AV nodal conduction. They are used to manage supraventricular tachycardias. Like the beta-blockers, calcium channel blockers reduce myocardial contractility.

OTHER DRUGS

Adenosine and digoxin decrease conduction through the AV node and are used to treat supraventricular tachycardias.

Nursing responsibilities

- Obtain baseline data, including vital signs, cardiac rhythm (including rate, PR and QT intervals, and QRS duration) and physical assessment (especially cardiac, neurological and respiratory status).
- Assess medication regimen to identify drugs that may interfere with antiarrhythmic therapy.
- Monitor ECG to evaluate the effectiveness of therapy and to assess for possible arrhythmias precipitated by treatment.
- Immediately report manifestations of drug toxicity:
  - Procainamide—signs of heart failure; conduction delays or ventricular arrhythmias; skin rash, myalgias or arthralgias, flu-like symptoms.
  - Lignocaine—changes in neurological status, such as agitation, confusion, dizziness, nervousness.
  - Amiodarone—pulmonary fibrosis (increasing dyspnoea, cough, hepatic dysfunction—changes in liver function tests, jaundice); vision changes, photosensitivity.
  - Digoxin—anorexia, nausea, vomiting; blurred or double vision; yellow–green halos; new-onset arrhythmias.
- Use an infusion pump to administer intravenous infusions. Monitor the dose and assess its appropriateness (in mg/min or µg/kg/min).

Health education for the person and family

- Take the drug exactly as prescribed. Do not skip or double doses. Check with the medical officer regarding instructions for a missed dose.
- Pulse rates should be taken and recorded daily before rising. The record should be brought to all appointments with healthcare professionals.
- Report irregular pulse rates or rhythms, dizziness, eye pain, changes in vision, skin rashes or colour changes, wheezing or other respiratory problems, or changes in behaviour to the medical officer.

Countershock

Countershock is used to interrupt cardiac rhythms that compromise cardiac output and the person's welfare. Delivery of a direct current charge depolarises all cardiac cells at the same time. This simultaneous depolarisation may stop a tachyarrhythmia and allow the sinus node to recover control of impulse formation. There are two types of countershock: synchronised cardioversion and defibrillation.

SYNCHRONISED CARDIOVERSION

Synchronised cardioversion delivers direct electrical current synchronised with the person's heart rhythm. Synchronisation of the shock with the QRS complex prevents ventricular fibrillation by avoiding current delivery during the vulnerable period of repolarisation. Cardioversion is usually done as an elective procedure to treat supraventricular tachycardia, atrial fibrillation, atrial flutter or haemodynamically stable ventricular tachycardia.

The nurse assists with cardioversion by preparing the individual before the procedure; obtaining any laboratory tests ordered; obtaining and documenting ECG strips prior to, during and after treatment; setting up the equipment; and monitoring the person's response. Procedure 29.2 describes synchronised cardioversion.

Peoples in atrial fibrillation are at high risk of thromboembolism following cardioversion. Loss of atrial contractions with atrial fibrillation leads to blood pooling in the atria, increasing the risk of clot formation. When the atria begin to contract following successful cardioversion, clots may be dislodged, embolising to the pulmonary or systemic circulation. If possible, anticoagulants are given for several weeks before cardioversion is attempted.

PROCEDURE 29.2 Elective synchronised cardioversion

GATHER SUPPLIES

- Cardioverter-defibrillator with ECG cable and monitor
- Conductive gel pads or paste
- Dry gauze pads
- Emergency drug kit and resuscitation equipment
- IV supplies (catheter, solution, administration set)

BEFORE THE PROCEDURE

Explain the purpose of the procedure (to restore an effective cardiac rhythm). Describe the procedure in simple, non-threatening terms. Advise that some discomfort may be felt with each countershock, but a light anaesthetic will be given to minimise discomfort. Witness the signature on the procedure consent form. Document pre-procedure rhythm on an ECG strip. Ensure a patent intravenous access site for emergency drug administration. Keep nil by mouth (NBM) as specified prior to the procedure. Assess acid–base and electrolyte levels (especially potassium, magnesium and calcium) and drug levels if appropriate. Report abnormalities to the doctor prior to the procedure. Document vital signs, level of consciousness and peripheral pulses. Remove any medication patches from the chest and all metallic objects. Assist where necessary with the airway and medications for level of consciousness. Ensure privacy and position the person supine.

PROCEDURE

1. Use standard precautions.
2. Turn on the cardioverter-defibrillator and ECG monitor.
3. Connect the person's ECG cable to the cardioverter. Select a lead with prominent R waves for monitoring (generally lead II).
4. Set cardioverter to 'synchronise' mode. Observe the ECG waveform on the monitor for indications of synchronisation, such as a flashing bold line or a blip. Many units also display the message 'synchronised mode' on the monitor.
5. Place conductive pads on the chest below the right clavicle to the right of the sternum and in the midaxillary line on the left.
6. Turn on the ECG recording strip for a continuous printout during the procedure.
7. Turn oxygen off and remove it.
8. The paddles should be firmly applied to the chest over the conductive pads by the medical officer or the nurse qualified in advanced cardiac life support (ACLS).
9. Charge the paddles to the prescribed energy dose. The machine will beep to indicate that the selected energy level has been reached and that the paddles are ready for discharge.
10. Ensure that no one is touching the person or the bed prior to discharge of the electrical shock. There may be a slight delay in shock delivery as the machine synchronises with the R wave.
11. Assess person's status and ECG rhythm. Assure a patent airway and the presence of a pulse.
12. The procedure may be repeated if unsuccessful. The energy level may be increased with each attempt.
13. Remove conductive pads. Ensure that the skin is clean and dry.

AFTER THE PROCEDURE

Assess the individual for return of consciousness from sedative or cardioversion. Evaluate neurological, cardiovascular and respiratory status. Assess for possible complications, including emboli (especially cerebral), respiratory depression and arrhythmias. Document postcardioversion rhythm strip. Assess skin for burns. Document the procedure and the person's response in the medical record.

DEFIBRILLATION Unlike carefully synchronised cardioversion, *defibrillation* is an emergency procedure that delivers direct current without regard to the cardiac cycle. Ventricular fibrillation is immediately treated as soon as the arrhythmia is recognised. Early defibrillation has been shown to improve survival in people experiencing VF.

Defibrillation can be delivered by external or internal paddles or pads. Conductive gel pads or paste is applied and external paddles or pads are placed on the chest wall at the apex and base of the heart (see Figure 29.8). Internal paddles are applied directly on the heart and may be used in surgery, the emergency department or critical care. Internal defibrillation is done only by a doctor; external defibrillation may be performed by any healthcare provider who has been trained in the procedure. Automatic external defibrillators (AEDs) are available on most hospital units to allow early defibrillation for cardiac arrest (see Procedure 29.3).

FIGURE 29.8 ■ Placement of pads for defibrillation

Source: Floyd Jackson/Pearson Education.

PROCEDURE 29.3 Emergency external defibrillation

GATHER SUPPLIES

- Automatic external defibrillator or defibrillator with ECG cable and monitor
- Conductive gel pads or paste
- Dry gauze pads
- Emergency medications and emergency trolley with pacemaker, airway management equipment and oxygen supplies

BEFORE THE PROCEDURE

Verify the lethal arrhythmia, such as pulseless VT, VF or asystole. Initiate the cardiac arrest (code) procedure and obtain the defibrillator. If one is not immediately available, begin CPR until the emergency cart and defibrillator are brought to the bedside. Place person in supine position on a firm surface.

PROCEDURE

1. Turn on the defibrillator. Set it in *defibrillation* mode.
2. Turn ECG recording on for a continuous printout of events during the procedure.
3. Set the energy level and charge the paddles. Monophasic—360 J for all shocks. Biphasic—200 J for all shocks.
4. Place conductive pads on the chest.
5. Position the paddles, holding them firmly on the chest wall.
6. Ensure that no one is touching the person or the bed. State, 'All clear.'
7. Depress the button on each paddle simultaneously to discharge the energy.
8. Immediately resume CPR.
9. Evaluate cardiac rhythm and for a pulse after approximately 2 minutes.
10. Implement ACLS protocols.

AFTER THE PROCEDURE

If the arrhythmia is successfully converted, evaluate and support neurological, cardiovascular and respiratory status. Monitor and titrate any intravenous infusions as ordered. Maintain ventilatory support as needed. Evaluate skin for burns. Obtain blood for laboratory analysis as ordered. Monitor vital signs and ECG continuously. Transfer to the critical care unit as indicated. Provide support and information to the individual and their family.

Pacemaker therapy

A **pacemaker** is a pulse generator used to provide an electrical stimulus to the heart when the heart fails to generate or conduct its own at a rate that maintains the cardiac output. The pulse generator is connected to *leads* (insulated wires) passed intravenously into the heart or sutured directly to the epicardium. The leads sense intrinsic electrical activity of the heart and provide an electrical stimulus to the heart when necessary (pacing).

Pacemakers are used to treat both acute and chronic conduction defects such as third-degree AV block. They also may be used to treat bradyarrhythmias and tachyarrhythmias.

Temporary pacemakers use an external pulse generator (see Figure 29.9) attached to a lead threaded intravenously into the right ventricle, to temporary pacing wires implanted during cardiac surgery or to external conductive pads placed on the chest wall for emergency pacing.

Permanent pacemakers use an internal pulse generator placed in a subcutaneous pocket in the subclavian space or abdominal wall. The generator connects to leads sewn directly onto the heart (*epicardial*) or passed transvenously into the heart (*endocardial*). Epicardial pacemakers (see Figure 29.10) require surgical exposure of the heart. Leads may be placed during cardiac surgery or using a small subxiphoid incision to expose the heart. Transvenous pacemaker leads are positioned in the right heart via the cephalic, subclavian or jugular vein (see Figure 29.11). Local anaesthesia can be used for permanent pacemaker insertion.

Pacemakers are programmed to stimulate the atria or the ventricles (*single-chamber pacing*) or both (*dual-chamber pacing*). Table 29.8 defines terms used to describe pacemaker modes and functions. The most commonly used pacemakers either: (1) sense activity in and pace the ventricles only; or (2) sense activity in and pace both the atria and the ventricles. Dual-chamber or *atrioventricular sequential pacing* stimulates both chambers of the heart in sequence. AV pacing imitates the normal sequence of atrial contraction followed by ventricular contraction, improving cardiac output.

Pacing is detected on the ECG strip by the presence of pacing artefacts (see Figure 29.12). A sharp spike is noted before the P wave with atrial pacing and before the QRS complex with ventricular pacing. Pacing spikes are seen before both the P wave and QRS complex in AV sequential pacing. Capture is noted if there is a contraction of the chamber immediately following the pacer spike. Problems in sensing, pacing and capture are noted in Table 29.9.

Care of the person with a temporary or permanent pacemaker focuses on monitoring for pacemaker malfunctioning, maintaining safety (see Box 29.3) and preventing infection and postoperative complications. Nursing care for the person having a pacemaker implant is outlined in the following box.

Implantable cardioverter-defibrillator

The true incidence of sudden cardiac death in Australia and New Zealand is unknown. The implantable cardioverter-defibrillator (ICD) detects life-threatening changes in the cardiac rhythm and automatically delivers an electric shock to convert the arrhythmia back into a normal rhythm. ICDs are used for sudden death survivors, people with recurrent

TABLE 29.8 Terms used to describe pacemaker functions

TERM	DEFINITION
Asynchronous pacing	A setting that results in delivery of a pacing stimulus at a set rate regardless of intrinsic cardiac activity.
Base rate	The rate at which the unit paces when no intrinsic cardiac activity is detected.
Capture	The ability of the stimulus to generate depolarisation through the myocardium.
Demand pacing	A setting that results in delivery of a pacing stimulus only when the intrinsic rate falls below the unit's base rate.
Dual-chamber pacing	The pacing of both atria and ventricles; mode most often used in permanent implanted pacing devices.
Lead	An insulated wire that is capable of sensing intrinsic cardiac activity and delivering a pacing stimulus.
Output	The electrical stimulus delivered by the unit.
Pacing spike	A vertical line occurring on the ECG with every pacemaker stimulus.
Sensing	The unit's ability to sense and respond to intrinsic cardiac activity.
Single-chamber pacing	The pacing of only atria or ventricles; mode most often used in the context of temporary pacing activities.

C

FIGURE 29.12 ■ Pacing artefacts. *A*, Atrial pacing and ventricular sensing. Note the pacer spike preceding the P wave. *B*, Ventricular demand pacing. Note the absence of pacer spikes when the person's natural rhythm predominates. *C*, Atrioventricular pacing. Note the pacer spikes preceding both P waves and QRS complexes

ventricular tachycardia and individuals with demonstrated risk factors for sudden death. ICDs can deliver a shock as needed, provide pacing on demand and can store ECG records of tachycardic episodes (Beyerbach, 2014).

A pulse generator connected to lead electrodes for rhythm detection and current delivery is implanted in the left pectoral region. The lead is threaded transvenously to the apex of the right ventricle. The ICD is programmed to sense a change in heart rate or rhythm. When it detects a potentially lethal rhythm, it shocks the heart to convert the rhythm. The device can be programmed or reprogrammed at the bedside as necessary. The ICD may be tested prior to discharge.

Local or general anaesthesia is used and the individual may be discharged within 24 hours. The lithium-powered battery must be surgically replaced every 5 years. Complications and nursing care are similar to that for an individual having a permanent pacemaker implant.

The person may briefly lose consciousness before the device discharges, typically regaining consciousness quickly after the episode. Some people report significant discomfort with ICD discharge (like a 'blow to the chest'). A person in direct contact with the individual when the device discharges may experience a tingling sensation.

BOX 29.3 Safety for the person with a temporary pacemaker

- Ensure that all electrical equipment in use has a grounded plug; do not use adapters or extension cords.
- Encourage the use of battery-powered equipment (e.g. electric razor).
- Remove any damaged electrical equipment from the unit, including equipment that:
  a. has been abused (e.g. has been dropped or in which liquid has been spilled)
  b. has given anyone a shock
  c. has damaged electrical cords or plugs
  d. has other evidence of impaired function, such as a hot smell during use, or control knobs that are loose or do not consistently produce the expected response.
- Wear gloves when handling the pacemaker electrodes or wires (to prevent microshock).
- Insulate pacemaker terminals and pacing wires with non-conductive, moisture-proof material (e.g. a rubber glove).
- Test the pacemaker battery prior to use.
- Keep a spare pacemaker, cable, batteries and battery tester available at all times.
- Immediately report any apparent deviation from expected pacemaker function.

Cardiac mapping and catheter ablation

Cardiac mapping and catheter ablation are used to locate and destroy an ectopic focus. These diagnostic and therapeutic measures use electrophysiology techniques and can be performed in the cardiac catheterisation laboratory. *Cardiac mapping* is used to identify the site of earliest impulse formation in the atria or the ventricles. Intracardiac and extracardiac catheter electrodes and computer technology are used to pinpoint the ectopic site on a map of the heart. These same catheters can be used to deliver the ablative intervention.

Ablation destroys, removes or isolates an ectopic focus. In most instances, radio-frequency energy produced by high-frequency alternating current is used to create heat as it passes through tissue. Catheter ablation is used to treat supraventricular tachycardias, atrial fibrillation and flutter, and, in some cases, paroxysmal ventricular tachycardia.

Anticoagulant therapy may be started after catheter ablation to reduce the risk of clot formation at the ablation site.

Other therapies

In addition to medications and interventional techniques, other measures may be used to treat selected arrhythmias. Vagal manoeuvres that stimulate the parasympathetic nervous system may be used to slow the heart rate in supraventricular

TABLE 29.9 Selected pacing problems

PROBLEM	POSSIBLE CAUSE	RESOLUTION
Failure to capture  Occurs when there is no atrial (or ventricular complex—whichever is appropriate) following the pacing spike. The pacing unit has delivered an impulse but the target myocardium did not achieve depolarisation.	The output mA* is set too low on the pacing unit.	Support HR & BP†. Increase the mA* on the unit until capture is obtained.
	The tip may have migrated or is not well enough in contact with the target myocardium.	Support HR & BP†. Reposition the individual lying on the other side (sometimes this will facilitate capture again). Observe for other signs that the tip may have migrated (i.e. hiccupping—the tip may have migrated to the diaphragm).
	The lead may have fractured.	Support HR & BP†. Change pacing leads.
	The threshold in the target myocardium may have increased due to chemical or metabolic changes making the cells less responsive to the mA* set.	Support HR & BP†. Increase the mA* on the unit until capture is obtained. Change the polarity of the pacing wires in the pacing box (place the negative where the positive had been and the positive where the negative wire had been).
	The pacemaker unit's battery may be low.	Change pacing box to programmed replacement unit and then replace batteries in old unit ready for use.
Failure to sense (undersensing)  Occurs when the pacing unit does not detect the intrinsic/native event (P wave or QRS complex) and delivers an impulse. If the pacing unit delivers an impulse onto the myocardium during repolarisation it can cause fibrillation in the target tissue (i.e. if it occurs during atrial repolarisation it can cause atrial fibrillation and if it occurs during ventricular repolarisation it can cause ventricular fibrillation).	The person's intrinsic/native myocardial voltage is low. The sensitivity is set too low (mV‡ is set too high) on the pacing unit.	Increase the sensitivity of the pacing unit (decrease mV‡) until sensing is identified.
	A wire or lead may be dislodged, loose or fractured, or the pacemaker may be malfunctioning.	Check all connections and change pacing leads. Try another pacing unit.
	The pacemaker unit's battery may be low.	Change pacing box to programmed replacement unit and then replace batteries in old unit ready for use.
	The person may be experiencing an electrolyte imbalance.	Check the person's electrolytes.
Failure to pace (oversensing)  Occurs when the pacing unit does not deliver an impulse even though the person's intrinsic/native rhythm is inadequate.	The sensitivity is set too high (mV‡ is set too low) on the pacing unit.	Support HR & BP†. Decrease the sensitivity of the pacing unit (increase mV‡) until appropriate sensing is identified.
	A wire or lead may be dislodged, loose or fractured, or the pacemaker may be malfunctioning.	Support HR & BP†. Check all connections and change pacing leads. Try another pacing unit.
	The pacemaker unit's battery may be low.	Support HR & BP†. Change pacing box to programmed replacement unit and then replace batteries in old unit ready for use.
	The person may be experiencing some cellular or electrolyte issues.	Support HR & BP†. Change the polarity of the pacing wires in the pacing box. Check the person's electrolytes.

* mA = milliamperes. † Support HR & BP (i.e. support the person's heart rate and blood pressure by other means where possible). ‡ mV = millivolts.

NURSING CARE OF THE PERSON having a permanent pacemaker implant

PREOPERATIVE CARE

- Provide routine preoperative care and teaching as outlined in Chapter 3.
- Assess knowledge and understanding of the procedure, clarifying and expanding on existing knowledge as needed. *Clarifying knowledge, providing information and conveying emotional support reduces anxiety and fear and allows the individual to develop a realistic outlook regarding pacer therapy.*
- Place ECG monitor electrodes away from potential incision sites. *This helps preserve skin integrity*.
- Teach range-of-motion (ROM) exercises for the affected side. *ROM exercises of the affected arm and shoulder prevent stiffness and impaired function following pacemaker insertion.*

POSTOPERATIVE CARE

- Provide postoperative monitoring, analgesia and care as outlined in Chapter 3.
- Obtain a chest x-ray as ordered. *A postoperative chest x-ray is used to identify lead location and detect possible complications, such as pneumothorax or pleural effusion.*
- Position for comfort. Minimise movement of the affected arm and shoulder during the initial postoperative period. *Restricting movement minimises discomfort on the operative side and allows the leads to become anchored, reducing the risk of dislodging.*
- Assist with gentle ROM exercises at least three times daily, beginning 24 hours after pacemaker implantation. *ROM exercises help restore normal shoulder movement and prevent contractures on the affected side.*
- Monitor pacemaker function with cardiac monitoring or intermittent ECGs. Report pacemaker problems to the doctor:
  - Failure to pace. *This may indicate battery depletion, damage or dislodgement of pacer wires or inappropriate sensing.*
  - Failure to capture (the pacemaker stimulus is not followed by ventricular depolarisation). The electrical output of the pacemaker may not be adequate or the lead may be dislodged.
  - Improper sensing (the pacemaker is firing or not firing, regardless of the intrinsic rate). *This increases the risk of decreased cardiac output and arrhythmias*.
  - Runaway pacemaker (a pacemaker firing at a rapid rate). *This may be due to generator malfunction or problems with sensing.*
  - Hiccups. A lead positioned near the phrenic nerve or diaphragm can stimulate it, causing hiccups. *Hiccups may occur in extremely thin individuals or may indicate a medical emergency with perforation of the right ventricle by the pacing electrode tip.*
- Assess for arrhythmias and treat as indicated. *Until the catheter is 'seated' or adheres to the myocardium, its movement may cause myocardial irritability and arrhythmias. Fibrotic tissue develops within 2 to 3 days.*
- Document the date of pacemaker insertion, the model and type, and settings. *This information is important for future reference.*
- Immediately report signs of potential complications, including myocardial perforation, cardiac tamponade, pneumothorax or haemothorax, emboli, skin breakdown, bleeding, infection, endocarditis or poor wound healing. (See Chapter 30 for more information about cardiac tamponade and endocarditis, and Chapter 35 for pneumothorax and haemothorax.) *Early identification of complications allows for aggressive intervention.*
- Provide a pacemaker identification card, including the manufacturer's name, model number, mode of operation, rate parameters and expected battery life. *This card provides a reference for the individual and future healthcare providers.*

HEALTH EDUCATION FOR THE PERSON AND FAMILY

Provide appropriate teaching for the person and their family about:

- Placement of the pacemaker generator and leads in relation to the heart.
- How the pacemaker works and the rate at which it is set.
- Battery replacement. Most pacemaker batteries last 6 to 12 years. Replacement requires an outpatient surgery to open the subcutaneous pocket and replace the battery.
- How to take and record the pulse rate. Instruct to assess pulse daily before arising and notify the doctor if 5 or more bpm slower than the preset pacemaker rate.
- Incision care and signs of infection. Bruising may be present following surgery.
- Signs of pacemaker malfunction to report, including dizziness, fainting, fatigue, weakness, chest pain or palpitations.
- Activity restrictions as ordered. This usually is limited to contact sports (which may damage the generator) and avoiding heavy lifting for 2 months after surgery.
- Resuming sexual activity as recommended by the medical officer. Avoid positions that cause pressure on the site.
- Avoiding tight-fitting clothing over the pacemaker site to reduce irritation and avoid skin breakdown.
- Carrying the pacemaker identification card at all times and wearing a MedicAlert® bracelet or tag.
- Notifying all care providers of the pacemaker.
- Not holding or using certain electrical devices over the pacemaker site, including household appliances or tools, garage door openers, antitheft devices or burglar alarms. Pacemaker will set off airport security detectors; notify security officials of its presence.
- Maintaining follow-up care with the doctor as recommended.

tachycardias. These manoeuvres include *carotid sinus massage* and the *Valsalva manoeuvre*. Carotid sinus massage is performed only by a medical officer during continuous cardiac monitoring. Excessive slowing of the heart rate may result. The Valsalva manoeuvre—forced exhalation against a closed glottis (e.g. bearing down)—increases intrathoracic pressure and vagal tone, slowing the pulse rate.

Nursing care

Caring for the person with cardiac arrhythmias requires the ability to recognise, identify and, in some cases, promptly treat the arrhythmia. The urgency of intervention is determined by the effects of the arrhythmia on the individual. Nursing care focuses on maintaining cardiac output, monitoring the response to therapy and teaching. See also the following nursing care plan for a person with superventricular tachycardia.

Health promotion

Health promotion measures to prevent coronary heart disease also reduce the risk of arrhythmias. In most cases, arrhythmias develop as a result of ischaemic or structural changes in the heart, rather than in isolation. Advise people who are at risk or who complain of occasional palpitations or 'flutters' in their chest to reduce their intake of caffeine and other sympathetic nervous system stimulants, such as excess chocolate.

Assessment

Assessment is vital before treating any suspected arrhythmia. What appears to be ventricular tachycardia on the monitor may be the individual scratching or brushing their teeth. Apparent asystole on the monitor may be due to a loose electrode patch. Similarly, a heart rate of 52 bpm may not affect the overall cardiac output in some individuals. Review Chapter 28 for complete assessment of the person with a cardiac problem.

- *Health history:* complaints of palpitations (ask for further definition of palpitations), 'fluttering' sensations or a sensation of the heart racing; episodes of dizziness, light headedness or syncope (fainting); timing (duration, time of day); correlation with food or beverage intake, activity; presence of chest pain, shortness of breath or other associated symptoms; history of heart or endocrine disease (such as hyperthyroidism); current medications.
- *Physical examination:* LOC; vital signs, including apical pulse for a full minute; regularity and amplitude of peripheral pulses; colour; presence of dyspnoea, adventitious lung sounds; ECG rhythm analysis; oxygen saturation levels.

Nursing diagnoses and interventions

The effect of the arrhythmia on cardiac output is the priority of nursing care. Other potential nursing diagnoses related to arrhythmias may include *Ineffective tissue perfusion, Activity intolerance*, and *Fear* or *Anxiety*.

Decreased cardiac output

Arrhythmias can affect cardiac output. Bradycardias decrease cardiac output if the stroke volume does not increase to compensate for the slow heart rate. Tachycardia reduces diastolic filling time, affecting stroke volume and coronary artery perfusion. Loss of the atrial kick in junctional rhythms, atrial fibrillation and AV blocks also decreases ventricular filling and cardiac output. In ventricular fibrillation, loss of ventricular contractions causes cardiac arrest and no cardiac output.

- Assess for decreased cardiac output: decreased LOC; tachycardia; tachypnoea; hypotension; low oxygen saturation; diaphoresis; low urine output; cool, clammy, mottled skin; pallor or cyanosis; diminished peripheral pulses. Initial signs of decreased cardiac output may be subtle, such as decreased LOC. *Early recognition of the arrhythmia's effect on cardiac output facilitates appropriate treatment and may prevent further adverse effects.*

CONSIDERATION FOR PRACTICE

Before treating any arrhythmia, assess the individual, not just the monitor! Loose electrode pads, disconnected leads or cables, and muscle movement can simulate critical arrhythmias. The person's condition is the best indicator of the need for treatment.

- Monitor ECG; obtain a rhythm strip and 'post event' ECG strip every shift and when rhythm changes occur. *Documenting cardiac rhythm provides a record of disease progression and treatment effectiveness.*
- Assess for underlying causes of arrhythmias, such as hypovolaemia, hypoxia, anaemia, vagal stimulation or medications. *Sinus tachycardia often develops in response to tissue hypoxia. Vagal stimulation (such as the Valsalva manoeuvre) can precipitate bradycardia.*
- Assess serum electrolytes (especially potassium, calcium and magnesium) and digoxin and antiarrhythmic drug levels as indicated. Report abnormal values. *Electrolyte imbalances affect cardiac depolarisation and repolarisation and may cause arrhythmias. Toxic levels of digoxin and antiarrhythmic drugs can precipitate further arrhythmias. Impaired renal or hepatic function increases the risk of toxicity, as does ageing.*

CONSIDERATION FOR PRACTICE

Assess vital signs, ECG and oxygen saturation every 5 to 15 minutes during acute arrhythmic episodes and during antiarrhythmic drug infusions. These data provide a record of cardiac output during the arrhythmia. Antiarrhythmic drugs can adversely affect heart rate, rhythm and blood pressure, further decreasing cardiac output.

- Be prepared to administer antiarrhythmic medications as indicated. Implement advanced cardiac life support (ACLS) protocols as needed. *Emergency drugs should be readily available, especially on units with individuals at high risk of a life-threatening cardiac event.* See Table 29.7 and the 'Medication administration: antiarrhythmic drugs' box on page 1029 for drugs used to treat common arrhythmias that may affect cardiac output.
- If appropriate, instruct to perform the Valsalva manoeuvre (bear down as if straining or coughing) for supraventricular tachycardia or ventricular tachycardia without angina.

NURSING CARE PLAN A person with supraventricular tachycardia

Sandra Banks, a 53-year-old woman from the Torres Strait Islands, is admitted to the cardiac unit with complaints of palpitations, light headedness and dyspnoea. Her history reveals rheumatic fever at age 12 with subsequent rheumatic heart disease and mitral stenosis. An intravenous line is in place and she is receiving oxygen.

ASSESSMENT

Ms Banks is moderately anxious. Her ECG shows supraventricular tachycardia (SVT) with a rate of 154. Vital signs: T 37.1°C, R 26, BP 95/60. Peripheral pulses weak but equal, mucous membranes pale pink, skin cool and dry. Fine crackles noted in both lung bases. A loud S_3 gallop and a diastolic murmur are noted. Ms Banks is still complaining of palpitations and states that she 'feels so nervous and weak and dizzy'. Adenosine was trialled with no effect followed by an order for verapamil 2.5 mg IV. Preparations for synchronised cardioversion may need to be organised if the drug therapy does not control the ventricular rate.

DIAGNOSES

- *Decreased cardiac output* related to inadequate ventricular filling associated with rapid tachycardia.
- *Ineffective tissue perfusion: cerebral/cardiopulmonary/peripheral* related to decreased cardiac output.
- *Anxiety* related to unknown outcome of altered health state.

PLANNING

- Prepare propofol infusion (or intraprocedure medications as ordered).
- Document pretreatment vital signs, level of consciousness and peripheral pulses.
- Place emergency trolley with drugs and airway management supplies in person's area.

Expected outcomes

- Maintain adequate cardiac output and tissue perfusion.
- Demonstrate a ventricular rate within normal limits and stable vital signs.
- Verbalise reduced anxiety.
- Verbalise an understanding of the rationale for the treatment measures to control the heart rate.

IMPLEMENTATION

- Assist with cardioversion as indicated.
- Document procedure and postcardioversion rhythm and response to intervention.
- Provide oxygen per nasal prongs at 4 L/min.
- Explain the importance of rapidly reducing the heart rate. Explain the cardioversion procedure and encourage questions.
- Encourage verbalisation of fears and concerns. Answer questions honestly, correcting misconceptions about the disease process, treatment or prognosis.

EVALUATION

- Assess LOC, level of sedation, cardiovascular and respiratory status and skin condition following cardioversion.
- Continuously monitor ECG for rate, rhythm and conduction. Assess vital signs and associated symptoms with changes in ECG. Report findings to medical officer.

Intravenous verapamil lowers Ms Banks's heart rate to 138 for a short time, after which it increases to 164 with BP of 82/64. Her cardiologist, Dr Mullins, performs carotid sinus massage. The ventricular rate slows to 126 for 2 minutes, revealing atrial flutter waves, and then returns to a rate of 150. Dr Mullins explains the treatment options, including synchronised cardioversion.

Ms Banks is lightly sedated and synchronised cardioversion is performed. One countershock converts Ms Banks to regular sinus rhythm at 96 bpm with BP 112/60.

Ms Banks is sleepy from the sedation but recovers without incident. She states that she feels 'much better', and her vital signs return to her normal levels. She remains in NSR with a rate of 86 to 92 for the remainder of her hospital stay. Dr Mullins places Ms Banks on frusemide to treat manifestations of mild heart failure.

CRITICAL THINKING IN THE NURSING PROCESS

1. What is the scientific basis for using carotid massage to treat supraventricular tachycardias? Was this an appropriate manoeuvre in the case of Ms Banks?
2. What other treatment options might the doctor have used to treat Ms Banks's supraventricular tachycardia if she had been asymptomatic with stable vital signs?
3. Why might the adenosine failed? What critical interventions are required to increase the likelihood of success with this drug? (Hint: related to drug half life.)
4. Develop a teaching plan for Ms Banks related to her prescription for frusemide.

REFLECTION ON THE NURSING PROCESS

1. What is the likelihood of Ms Banks experiencing SVT again? What education is required for an individual who presents with SVT?
2. Outline what you have learned from this case study that you will apply to your future practice.

Vagal manoeuvres stimulate the parasympathetic system and may terminate some arrhythmias. The Valsalva manoeuvre is contraindicated if chest pain occurs with the arrhythmia.

- Prepare to assist with cardioversion. Prepare the individual per orders or hospital protocol (see Procedure 29.2). Explain the procedure to reduce anxiety. Have emergency equipment readily available. *Elective or emergency cardioversion is a treatment of choice for certain arrhythmias.*

CONSIDERATION FOR PRACTICE

On recognising ventricular fibrillation and cardiac arrest, begin emergency basic life support procedures. Call for help. Initiate advanced cardiac life support (ACLS) protocols if it is within your scope and training to do so. Assist with resuscitation measures as directed. Cardiac output ceases with ventricular fibrillation. Immediate or early defibrillation has been shown to have the greatest impact on survival following cardiac arrest.

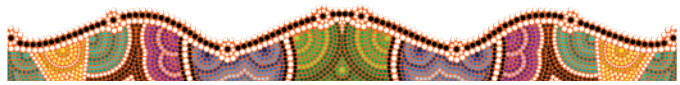
- After cardiac arrest, transfer to critical care. Perform and document head-to-toe assessment; obtain laboratory tests, 12-lead ECG and chest X-ray as ordered; monitor and maintain oxygenation and intravenous infusions; and monitor vital signs and cardiac rhythm. *The period following resuscitation is critical, necessitating careful monitoring. Post-arrest assessment allows comparison of the individual's condition with pre-arrest status and may identify CPR-related injuries. Correcting electrolyte disturbances, hypoxia and acid–base imbalances is important to prevent further arrhythmias and potential adverse effects on cardiac output. Intravenous access is crucial to maintain drug infusions. Haemodynamic monitoring may be instituted. The 12-lead ECG documents myocardial status and the chest x-ray provides information about pulmonary status and possible thoracic injury due to CPR.*
- Notify the family of significant changes in the person's condition, providing up-to-date information. Prepare family members prior to visits by explaining interventions (such as invasive tubes, a ventilator or additional equipment) implemented since the last visit. *Concern for the family and significant others is part of holistic nursing. Researchers studying the needs of families have found that one of the most important needs was information about their loved one's condition. Individuals and their families need and appreciate honest communication and compassionate care. Preparing the family for critical changes in the person's condition and plan of care helps them to cope with a situational crisis.*

Community-based care

Arrhythmias have a significant physical and psychological impact on the person and all their family members. Many of these individuals and their families are under a great deal of stress from frequent hospitalisations, experimentation with therapies, frustration and the fear of sudden cardiac death. A major teaching effort focuses on coping strategies and lifestyle changes as well as specific management of prescribed therapies. Include the following topics as appropriate when teaching the person and their family for home care:

- function, maintenance, precautions and signs of malfunction or complications of any implanted device such as a pacemaker or ICD
- monitoring pulse rate and rhythm
- activity or dietary restrictions, and any potential effects of the arrhythmia or its treatment on lifestyle
- medication management to reduce the risk of arrhythmias, including the desired and potential adverse effects of antiarrhythmic drugs
- specific instructions related to planned diagnostic tests or procedures
- the importance of follow-up visits with the cardiologist
- the importance of obtaining CPR training for the individual and their family members.

In addition, discuss fears related to treatment or implanted devices, such as that of shocking a significant other during close contact or sexual activity. Explain that if a shock occurs, the partner may feel a slight buzz or tingling but should not be harmed. Refer to and encourage the person and their family to attend a peer support group for the specific condition.



THE PERSON WITH SUDDEN CARDIAC DEATH

Sudden cardiac death (SCD) is defined as unexpected death occurring within 1 hour of the onset of cardiovascular symptoms. The presence of left ventricular dysfunction caused by any condition is the greatest predictor of SCD and usually results from ventricular fibrillation or pulseless ventricular tachycardia (Sovari, 2014). These rhythms are within the group of rhythms that cannot sustain life and can be called a cardiac arrest. *Cardiac arrest* is the sudden collapse, loss of consciousness and cessation of effective circulation that precedes biological death. Worldwide fewer than 6% of out-of-hospital cardiac arrest victims survive.

Almost 50% of all deaths due to coronary heart disease are attributed to SCD. A significant per cent of sudden cardiac deaths can be attributed to CHD. Other cardiac pathologies such as cardiomyopathy and valvular disorders also may lead to SCD. Non-cardiac causes of sudden death include electrocution, pulmonary embolism and rapid blood loss from a ruptured aortic aneurysm.

Ventricular fibrillation is the most common arrhythmia associated with sudden cardiac death, accounting for the majority of cardiac arrests. Sustained severe bradyarrhythmias, *asystole* or cardiac standstill, and pulseless electrical activity (organised cardiac electrical activity without a mechanical response) are responsible for most of the remaining SCDs. Selected cardiac and non-cardiac causes of sudden cardiac death are listed in Box 29.4.

Risk factors for SCD are those associated with coronary heart disease (see the first section of this chapter). Advancing age and male gender are powerful risk factors. After age 65, the gap between male and female incidence of SCD narrows. Individuals with arrhythmias such as recurrent ventricular tachycardia (VT) may have a higher risk of SCD. Women with acute myocardial infarction, however, are more likely to present with cardiac arrest and cardiogenic shock than with ventricular tachycardia. Recent Australian statistics demonstrate that in the first decade of the 21st century, even though deaths from cardiovascular diseases have decreased for both men and women, overall there are still more women dying of cardiac arrest and CVD than men (ABS, 2015).

Pathophysiology

Evidence of coronary heart disease with significant atherosclerosis and narrowing of two or more major coronary arteries is found in the majority of SCD victims. An acute change in cardiovascular status precedes cardiac arrest by up to 1 hour; however, often the onset is instantaneous or abrupt. An

BOX 29.4 Selected causes of sudden cardiac death

Cardiac causes

- Coronary heart disease
- Reperfusion following ischaemia
- Myocardial hypertrophy
- Cardiomyopathy
- Inflammatory myocardial disorders
- Valve disorders
- Primary electrical disorders
- Dissecting or ruptured aortic or ventricular aneurysm
- Cardiac drug toxicity

Non-cardiac causes

- Pulmonary embolism
- Cerebral haemorrhage
- Autonomic dysfunction
- Choking
- Electrical shock
- Electrolyte and acid–base imbalances

imbalance in electrolytes, or autonomic tone, irregular cellular activity, or functional blockages within the conduction system, may contribute to the development of ventricular tachycardiac or ventricular fibrillation (Sovari, 2014).

Various other factors can also contribute to the development of lethal arrhythmia, including abnormalities of myocardial structure or function. Structural abnormalities include infarction, hypertrophy and myopathy. Functional deviations are caused by such factors as ischaemia followed by reperfusion, altered homeostasis, pathological hormone interactions, and toxic effects. The interactions of the two cause myocardial instability and may precipitate fatal arrhythmias.

Manifestations

Sudden cardiac death may be preceded by typical manifestations of acute coronary syndrome or myocardial infarction, including severe chest pain, dyspnoea or orthopnoea, and palpitations or light headedness. The event itself is abrupt, with complete loss of consciousness and death within minutes. If ventricular tachycardia precedes cardiac arrest, consciousness and mentation may be impaired prior to collapse and loss of consciousness.

INTERPROFESSIONAL CARE

The goal of care is to restore cardiac output and tissue perfusion. Treatment measures are initiated as soon as clinical cardiac arrest is verified by the absence of respirations and carotid or femoral pulses. Basic life support and ACLS measures must be instituted within 2 to 4 minutes of cardiac arrest to prevent permanent neurological damage and ischaemic injury to other organs.

Providers trained in use of the *automated external defibrillator (AED)* should immediately defibrillate the person in ventricular fibrillation. Self-adhesive conductive pads attached to connecting cables are positioned on the chest (see Figure 29.13). The Australian Resuscitation Council supports the use of public access defibrillation in association with emergency services and locally provided training.

Cardiopulmonary resuscitation is a mechanical attempt to maintain tissue perfusion and oxygenation using oral resuscitation and external cardiac compressions. All healthcare providers need to be proficient in CPR. The technique should be performed according to the Australian Resuscitation Council's most recent procedures. Healthcare personnel need to be familiar with these protocols and maintain up-to-date knowledge and skills, as the techniques and theory do change.

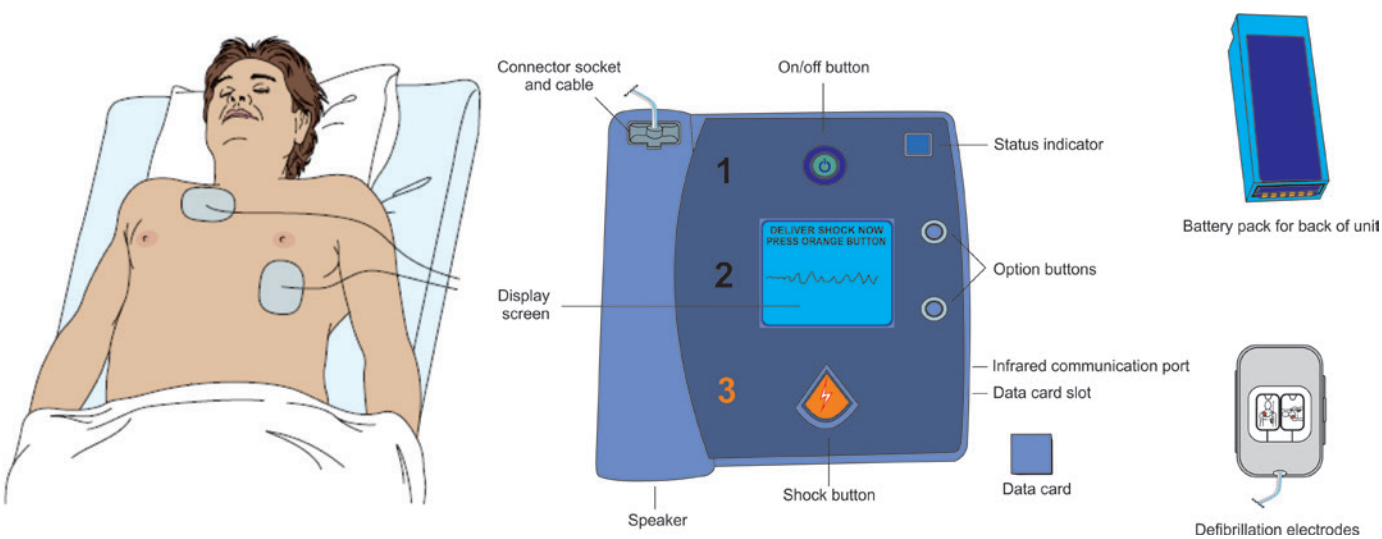


FIGURE 29.13 ■ Schematic of an automated external defibrillator (AED) attached to an individual

Nursing care

Nursing care of the person experiencing sudden cardiac death requires prompt recognition of the event and immediate initiation of basic lifesaving (BLS) and advanced lifesaving (ALS) protocols. As noted before, fast and effective cardiac compressions and early defibrillation of unstable VT and VF are the most important keys to survival of cardiac arrest victims. Important concepts of emergency cardiac care are:

- Treat the person, not the monitor. If a bizarre rhythm is displayed on the monitor, it is important to determine if this is artefact, clinical deterioration or emergency. It is critical to look at the individual. If they are talking, well perfused and in no apparent discomfort, there may be other explanations for what is occurring on the monitor. Recognise signs and symptoms of cardiac compromise early.
- Activate the emergency medical services system (i.e. call a 'code', call 000 or 112 from a mobile phone—even if it has no credit).
- Begin and continue basic cardiac life support principles throughout the resuscitation effort.
- Continually assess the effectiveness of emergency interventions.
- Defibrillate ventricular fibrillation (VF) and pulseless ventricular tachycardia (VT) as soon as possible.
- Initiate advanced cardiac life support protocols early if within scope of practice.

The family should not be forgotten during resuscitation. If the family is present, a staff member needs to support significant others and offer a private room in which to await the outcome. If the family is not present, they should be notified that their family member is not doing well and asked to come to the hospital as soon as possible. The outcome should be presented in a careful manner to prevent the family from racing to the hospital, possibly precipitating an automobile crash. Pastoral care or the family's choice of spiritual support is offered to help during this difficult time. Attendance of family members during resuscitation efforts is controversial and depends on institutional protocols and family desires.

After successful resuscitation, the nurse provides care specific to the individual's underlying disease processes and needs. Intravenous infusions such as lignocaine, bretylium or dopamine may be ordered to prevent further arrhythmias and maintain haemodynamic stability.

If the person does not survive the arrest, the nurse provides postmortem care and emotional and spiritual support to the family.

Nursing diagnoses to consider for the person experiencing SCD include the following:

- *Ineffective tissue perfusion: cerebral* related to ineffective cardiac output.
- *Impaired spontaneous ventilation* related to cardiac arrest.
- *Spiritual distress* related to unexplained sudden cardiac death.
- *Disturbed thought processes* related to compromised cerebral circulation.
- *Fear* related to risk of future episodes of sudden cardiac death.

The risk of a future episode of sudden cardiac death requires careful and effective teaching for home care prior to discharge. Discuss the following topics with the person and family:

- risk factor reduction for coronary heart disease
- planned diagnostic studies to identify the cause of SCD and possible interventions
- the risks and benefits of an ICD if appropriate
- the importance of carrying a card at all times listing all current medications and the healthcare provider
- early manifestations or warning signs of cardiac arrest
- the importance of CPR training and maintaining proficiency in performing CPR. (Provide referral to local CPR training providers.)

Nurses can affect death rates from cardiac arrest through community teaching as well. Survival rates from sudden cardiac death improve in communities in which a significant portion of the population is trained in CPR and early response by emergency services is stressed. Work with community groups and individuals can help create a population of people able to perform effective CPR.

CHAPTER HIGHLIGHTS

- Atherosclerosis is the primary underlying process in coronary heart disease, and impaired perfusion of myocardial tissue.
- The risk factors for coronary heart disease are those for atherosclerosis: age, gender and genetic factors; hypertension, diabetes, abnormal blood lipids; cigarette smoking, obesity, physical inactivity and diet; and emerging risk factors such as the metabolic syndrome and homocysteine levels.
- Smoking cessation, exercise, diet modification, weight loss, medications to achieve desired blood lipid values and effective hypertension and diabetes management are the primary treatment measures for coronary heart disease.
- Atherosclerosis of coronary vessels impairs the supply of blood, oxygen and nutrients to the myocardium. Myocardial ischaemia results in the manifestations of coronary heart disease: angina pectoris, acute coronary syndrome and myocardial infarction.
- Stable angina develops with a predictable amount of activity or stress and typically follows an activity–pain, rest–relief pattern. Stable angina often can be managed effectively by medications and risk factor modification. The nursing focus is on education.

- Acute coronary syndrome or unstable angina is characterised by increasingly severe chest pain that occurs unpredictably. Acute coronary syndrome often requires aggressive interventions such as percutaneous coronary revascularisation or coronary artery bypass surgery.
- Myocardial infarction, necrosis of myocardial tissue, results from complete blockage of a coronary artery, usually due to atherosclerotic plaque rupture and thrombus formation. Prompt restoration of blood flow through a revascularisation procedure or administration of a thrombolytic drug to dissolve the blood clot is necessary to preserve functional muscle tissue.
- The nursing focus for individuals with acute coronary syndrome and myocardial infarction is on reducing myocardial work through measures such as pain relief and activity limitation, promoting blood flow and oxygenation through medication and oxygen administration and positioning, and early recognition and treatment of complications.
- Cardiac arrhythmias may arise anywhere in conductive tissue of the myocardium. Arrhythmias may be either benign or fatal, depending on their effect on cardiac output.
- Tachycardias increase the workload of the heart and may interfere with cardiac output if ventricular filling is impaired by the rapid rate.
- Bradycardias can affect cardiac output when the rate is too slow to meet the metabolic needs of the body.
- Atrial fibrillation is a common arrhythmia that can lead to formation of blood clots within the heart and subsequent stroke if these clots lodge in cerebral blood vessels.
- Frequent ventricular arrhythmias may indicate an increased risk of ventricular fibrillation and cardiac arrest.
- AV conduction blocks interfere with conduction of the sinus or atrial impulse through the AV node and to the ventricles.
- Although many antiarrhythmic medications are available, all increase the risk of arrhythmia development, so they are used sparingly.
- The nurse's role in caring for a person with cardiac arrhythmias focuses on prompt identification of the rhythm disruption, assessment of its effect on the person, administration of medications and other treatment measures, and institution of life support procedures as indicated.

CONCEPT CHECK

1 The nurse evaluates her teaching as effective when an individual identifies which of the following modifiable risk factors for coronary heart disease (CHD) as contributing to the greatest extent?
1 obesity
2 diet
3 smoking
4 stress

2 When teaching an individual about simvastatin, the nurse instructs the person to:
1 promptly report muscle pain or tenderness to the doctor
2 consume a diet that includes no more than 20% of kilojoules from saturated fat
3 abstain from alcohol use while taking this drug
4 take the drug with meals to minimise gastric distress

3 When assessing a person with stable angina, the nurse would expect to find:
1 persistent ECG changes
2 correlation between activity level and pain
3 increasing nocturnal pain
4 evidence of impaired cardiac output such as weak peripheral pulses

4 The nurse caring for a person with acute coronary syndrome identifies which of the following nursing diagnoses to be of highest priority?
1 *Anxiety* related to unknown outcome of disorder.
2 *Ineffective health maintenance* related to lack of knowledge about coronary heart disease.
3 *Decreased cardiac output* related to myocardial ischaemia.
4 *Ineffective tissue perfusion: cardiopulmonary* related to underlying coronary heart disease.

5 The nurse caring for a person returning from a coronary angioplasty with stent placement plans which of the following interventions?
1 securing chest tubes to bedding
2 maintaining leg extension on the affected side
3 discontinuing intravenous lines when taking oral fluids
4 treating chest pain with intravenous morphine as needed

6 In planning care for the person with acute myocardial infarction (AMI), the nurse identifies the highest priority goal of care as:
1 stable ECG rhythm
2 ability to verbalise causes and effects of CHD
3 compliance with prescribed bed rest
4 relief of pain

7 Which of the following nursing diagnoses is of highest priority for the person undergoing thrombolytic therapy?
1 *Ineffective protection.*
2 *Ineffective health maintenance.*
3 *Risk of powerlessness.*
4 *Anxiety.*

8 In reviewing laboratory results for a person admitted with acute chest pain, the nurse is most concerned about which of the following?
1 haematocrit 35%
2 AST 65 U/L
3 CK 320 U/L
4 aPTT 35 seconds

9 The nurse recognises second-degree AV block, type II (Mobitz II) and intervenes appropriately when he:
1 records the finding in the chart
2 prepares for temporary pacemaker insertion
3 administers a class IB antiarrhythmic drug
4 places the person in Fowler's position

10 On identifying sinus bradycardia at a rate of 45 bpm, the nurse should:
1 assess mental status and blood pressure
2 assess peripheral pulses on all four extremities
3 determine if an apical–radial pulse deficit is present
4 prepare to administer intravenous atropine

CHAPTER 30

NURSING CARE OF PEOPLE WITH CARDIAC DISORDERS

MAJELLA HALES

KEY TERMS

LEARNING OUTCOMES

- Relate the interprofessional care requirements for a person with heart failure to the pathophysiology of the condition.
- Explain the risk factors, course and interventions required to competently care for a person with pulmonary oedema.
- Differentiate between the various inflammatory and infective conditions resulting in a person's cardiac disorder.
- Compare and contrast the course and management principles for individuals experiencing various cardiomyopathies.

CLINICAL COMPETENCIES

- Apply knowledge of normal cardiac anatomy and physiology and assessment techniques in caring for the person with cardiac disorders.
- Assess functional health status of individuals with cardiac disorders, documenting and reporting deviations to expected findings.
- Plan, prioritise and provide evidence-based, individualised care for the person with cardiac disorders.
- Administer prescribed medications and treatments to individuals with cardiac disorders.
- Actively participate in planning and coordinating interprofessional care for the person with cardiac disorders.
- Provide appropriate teaching and community-based care for people with cardiac disorders and their families.
- Evaluate the effectiveness of nursing care, revising the plan of care as needed to promote, maintain or restore functional health status of individuals with cardiac disorders.

Cardiac disorders affect the structure and/or function of the heart. These disorders interfere with the heart's primary purpose: to pump enough blood to meet the body's demand for oxygen and nutrients. Disruptions in cardiac function affect the performance of other organs and tissues, potentially leading to organ system failure and death.

Heart failure is the most common cardiac disorder. Pulmonary oedema is also discussed in this chapter. The inclusion and organisation of the inflammatory and infective cardiac disorders proves difficult as there is usually an intimate relationship between these conditions, either as a cause or effect. As such, although conditions such as rheumatic heart disease, the various carditises and cardiomyopathy are often related, they are treated as separate entities in this chapter in order to facilitate sufficient coverage of content.

Before continuing with this chapter, please review the heart's anatomy and physiology, nursing assessment and diagnostic tests in Chapter 28.

HEART FAILURE

Heart failure is a complex syndrome caused by conditions that impair the ejection of oxygen- and nutrient-rich blood from the ventricles. The failure to pump sufficient blood into the systemic circulation results in an inability to meet the body's metabolic demands (Bullock & Hales, 2012). It is often a long-term effect of coronary heart disease (CHD) and myocardial infarction (MI) when left ventricular damage is extensive enough to impair cardiac output (see Chapter 29). Other diseases of the heart also may cause heart failure, including structural and inflammatory disorders. In normal hearts, failure can result from excessive demands placed on the heart. Heart failure may be acute or chronic.

THE PERSON WITH HEART FAILURE

When the heart cannot effectively fill or contract with adequate strength to meet the needs of the body, cardiac output falls and decreased tissue perfusion develops. Initially, compensatory mechanisms are activated to offset reduced cardiac output and restore tissue perfusion. The heart failure will often result in vascular congestion resulting in oedema in either the lungs or the periphery, and is therefore commonly called *congestive heart failure (CHF)*. As the compensatory mechanisms are exhausted, morbidity and mortality risks increase.

Reduced cardiac function may occur due to *impaired myocardial contraction*, from CHD, myocardial ischaemia or infarction, or from a primary cardiac muscle disorder such as cardiomyopathy or myocarditis. Structural cardiac disorders, such as valve disorders or congenital heart defects, and hypertension also can lead to heart failure when the heart muscle is damaged by the long-standing *excessive workload* associated with these conditions. Individuals without a primary abnormality of myocardial function may present with manifestations of heart failure due to *acute excess demands* placed on the myocardium, such as volume overload, hyperthyroidism and massive pulmonary embolus (see Table 30.1). Hypertension and coronary heart disease are the leading causes of heart failure in Australia.

Incidence, prevalence and risk factors

In Australia in 2014, 0.8% of male and 1.1% of female deaths resulted from heart failure. It has dropped to the 11th leading cause of death in males but remains the 8th leading cause of death in females (Australian Bureau of Statistics (ABS), 2015; Australian Institute of Health and Welfare (AIHW), 2014a). Some explanation of the gender disparity in the statistics may be related to greater life expectancy in women, as a significant percentage of heart-failure-related deaths occur in older women (see the 'Nursing care of the older adult' box below). In 2012–2013, 10.1% and 12.1% of all cardiovascular-related hospitalisations were as a result of heart failure for males and females respectively (AIHW, 2015).

Prevalence of heart failure in Aboriginal and Torres Strait Islander Australians is reportedly 1.7 times higher than in non-Indigenous Australians (AIHW, 2011). In a study by McGrady et al. (2012) risk factors for heart failure in Aboriginal and Torres Strait Islander Australians included a BMI > 30 kg/m^2, hypertension, diabetes mellitus, coronary artery disease, history of rheumatic fever or rheumatic heart disease, and asymptomatic left ventricular dysfunction (see the 'Focus on cultural diversity' box below).

The prognosis for an individual with heart failure depends on its underlying cause and how effectively precipitating factors can be treated.

In Aboriginal and Torres Strait Islander Australians, rheumatic heart disease (RHD) plays a significant role in mortality, more than in most other developed countries. Rheumatic heart disease

TABLE 30.1 Selected causes of heart failure

IMPAIRED MYOCARDIAL FUNCTION	INCREASED CARDIAC WORKLOAD	ACUTE NON-CARDIAC CONDITIONS
• Coronary heart disease	• Hypertension	• Volume overload
• Cardiomyopathies	• Valve disorders	• Hyperthyroidism
• Rheumatic fever	• Anaemias	• Fever, infection
• Infective endocarditis	• Congenital heart defects	• Massive pulmonary embolus

NURSING CARE OF THE OLDER ADULT with heart failure

Ageing affects cardiac function. Diastolic filling is impaired by decreased ventricular compliance. With ageing, the heart is less responsive to sympathetic nervous system stimulation. As a result, maximal heart rate, cardiac reserve and exercise tolerance are reduced. Concurrent health problems such as arthritis that affect stamina or mobility often contribute to a more sedentary lifestyle, further decreasing the heart's ability to respond to increased stress.

ASSESSING FOR HOME CARE

The older adult with heart failure may not be dyspnoeic, instead presenting with weakness and fatigue, somnolence, confusion, disorientation or worsening dementia. Dependent oedema and respiratory crackles may or may not indicate heart failure in older adults.

Assess the diet of the older adult. Decreased taste may lead to increased use of salt to bring out food flavours. Limited mobility or visual acuity may cause the older adult to rely on prepared foods that are high in sodium, such as canned soups and frozen meals. Discuss normal daily activities and assess sleep and rest patterns. It is also important to assess the environment for:

- safe roads or neighbourhoods for walking
- access to pharmacy, medical care and assistive services
- a cardiac rehabilitation program or structured exercise programs designed for older adults.

HEALTH EDUCATION FOR THE PERSON AND FAMILY

Teaching for the older adult with heart failure focuses on maintaining function and promptly identifying and treating episodes of heart failure. Teach individuals how to adapt to changes in cardiovascular function associated with ageing, such as:

- allowing longer warm-up and cool-down periods during exercise
- engaging in regular exercise such as walking five or more times a week
- resting with feet elevated (e.g. in a recliner) when fatigued
- maintaining adequate fluid intake
- preventing infection through pneumococcal and influenza immunisations.

FOCUS ON CULTURAL DIVERSITY

Heart failure in the Aboriginal and Torres Strait Islander Australian populations

- Aboriginal and Torres Strait Islander Australians are 1.7 times more likely to experience CHF than non-Indigenous Australians.
- Manifestations of heart failure develop at an earlier age.
- The disease progresses more rapidly.
- More hospital visits are attributed to heart failure.
- The mortality rate is higher than in non-Indigenous Australians.

Heart failure in overseas-born individuals living in Australia

- In proportion to percentage of population, hospital admission rates of Australian residents born in Italy, Poland and Greece are higher than for Australian-born individuals.
- Hospital admission rates of Australian residents born in most other countries are lower than those of Australian-born individuals in proportion to percentage of population.

RHD in the Aboriginal and Torres Strait Islander Australian population

- Aboriginal and Torres Strait Islander Australians are 25 times more likely to develop RHD than non-Indigenous Australians.
- Aboriginal and Torres Strait Islander women are almost twice as likely to develop RHD than Aboriginal and Torres Strait Islander men.

prevalence in Aboriginal and Torres Strait Islander Australians is 26 times higher than in non-Indigenous Australians (AIHW, 2013).

Physiology review

The mechanical pumping action of cardiac muscle propels the blood it receives to the pulmonary and systemic vascular systems for reoxygenation and delivery to the tissues. *Cardiac output (CO)* is the amount of blood pumped from the ventricles in 1 minute. Cardiac output is used to assess cardiac performance, especially left ventricular function. Effective cardiac output depends on adequate functional muscle mass and the ability of the ventricles to work together. Cardiac output normally is regulated by the oxygen needs of the body: as oxygen use increases, cardiac output increases to maintain cellular function. *Cardiac reserve* is the ability of the heart to increase CO to meet metabolic demand. Ventricular damage reduces the cardiac reserve.

Cardiac output is a product of heart rate and stroke volume. *Heart rate (HR)* affects cardiac output by controlling the number of ventricular contractions per minute. It is influenced by the autonomic nervous system, catecholamines and thyroid hormones. Activation of a stress response (e.g. hypovolaemia or fear) stimulates the sympathetic nervous system, increasing heart rate and contractility. Elevated heart rates increase cardiac output. However, very rapid heart rates shorten ventricular filling time (diastole), reducing stroke volume and cardiac output. On the other hand, a slow heart rate reduces cardiac output simply because of fewer cardiac cycles.

Stroke volume, the volume of blood ejected with each heartbeat, is determined by preload, afterload and myocardial contractility. *Preload* is the volume of blood in the ventricles at end diastole (just prior to contraction). The blood in the ventricles exerts pressure on the ventricle walls, stretching muscle fibres.

BOX 30.1 Explaining physiological terms using practical examples

The concepts of preload, the Frank–Starling mechanism, compliance and afterload can be difficult to understand and to explain to people. Use common analogies to make these concepts easier to understand.

- *Preload:* Think about a new rubber band. The further a rubber band is stretched, the greater the force with which it snaps back.
- *Frank–Starling mechanism:* When a rubber band is repeatedly stretched beyond its limit, it loses some elasticity and fails to return to its original shape and size.
- *Compliance:* A new balloon is not very compliant—it takes a lot of work (force) to inflate it. As the balloon is repeatedly inflated and stretched, it becomes more compliant, expanding easily with less force.
- *Afterload:* When a hose is crimped or plugged, more force is required to eject a stream of water out its end.

The greater the blood volume, the greater the force with which the ventricle contracts to expel the blood. End-diastolic volume depends on the amount of blood returning to the ventricles (*venous return*) and the distensibility or stiffness of the ventricles (*compliance*). See Box 30.1.

Afterload is the force needed to eject blood into the circulation. This force must be great enough to overcome arterial pressures within the pulmonary and systemic vascular systems. Increased systemic vascular resistance (e.g. hypertension) increases afterload, impairing stroke volume and increasing myocardial work.

Contractility is the natural ability of cardiac muscle fibres to shorten during systole. Contractility is necessary to overcome arterial pressures and eject blood during systole. Impaired contractility affects cardiac output by reducing stroke volume. The *ejection fraction (EF)* is the percentage of blood in the ventricle that is ejected during systole. A normal ejection fraction is approximately 60%.

Pathophysiology

When the heart begins to fail, mechanisms are activated to compensate for the impaired function and to maintain the cardiac output. The primary compensatory mechanisms are (1) the Frank–Starling mechanism, (2) neuroendocrine responses including activation of the sympathetic nervous system and the renin–angiotensin system, and (3) myocardial hypertrophy. These mechanisms and their effects are summarised in Table 30.2.

Decreased cardiac output initially stimulates aortic baroreceptors, which in turn stimulate the sympathetic nervous system (SNS). SNS stimulation produces both cardiac and vascular responses through the release of noradrenaline. Noradrenaline increases heart rate and contractility by stimulating cardiac beta-receptors. Cardiac output improves as both heart rate and stroke volume increase. Noradrenaline also causes arterial and venous vasoconstriction, increasing venous return to the heart. Increased venous return increases ventricular filling and myocardial stretch, increasing the force of contraction (the Frank–Starling

TABLE 30.2 Compensatory mechanisms activated in heart failure

MECHANISM	PHYSIOLOGY	EFFECT	COMPLICATIONS
Frank–Starling mechanism	The greater the stretch of cardiac muscle fibres, the greater the force of contraction.	• ↑ contractile force leading to ↑ CO	• ↑ myocardial oxygen demand • Limited by overstretching
Neuroendocrine response	↓ CO stimulates the sympathetic nervous system and catecholamine release.	• ↑ HR, BP and contractility • ↑ vascular resistance • ↑ venous return	• ↑ vascular resistance • Tachycardia with ↓ filling time and ↓ CO • ↑ myocardial workload and oxygen demand
	↓ CO and ↓ renal perfusion stimulate renin–angiotensin system. Angiotensin stimulates aldosterone release from adrenal cortex.	• Vasoconstriction and ↑ BP	• Fluid retention • Pulmonary congestion • ↑ preload and afterload
	ADH is released from posterior pituitary. Atrial natriuretic peptide and brain natriuretic peptide are released.	• ↓ sodium excretion • ↓ diuresis • ↑ vascular volume	• Fluid retention • Pulmonary congestion • ↑ myocardial workload
	Blood flow is redistributed to vital organs (heart and brain).	• Vasodilation some locations • Vasoconstriction other locations • ↓ perfusion of other organ systems • ↓ perfusion of skin and muscles	• Renal vasoconstriction and ↓ renal perfusion • Renal failure • Anaerobic metabolism and lactic acidosis • ↑ preload and afterload
Ventricular hypertrophy	↑ cardiac workload causes myocardial muscle to hypertrophy and ventricles to dilate.	• ↑ contractile force to maintain CO	• ↑ myocardial oxygen demand • Myocyte enlargement

mechanism). An ineffective contraction results from overstretching the muscle fibres past their physiological limit.

Blood flow is redistributed to the brain and the heart to maintain perfusion of these vital organs. Decreased renal perfusion causes renin to be released from the kidneys. Activation of the renin–angiotensin system produces additional vasoconstriction and stimulates the adrenal cortex to produce aldosterone and the posterior pituitary to release antidiuretic hormone (ADH). Aldosterone stimulates sodium reabsorption in renal tubules, promoting water retention. ADH acts on the distal tubule to inhibit water excretion and also causes vasoconstriction. The effect of these hormones is significant vasoconstriction and salt and water retention, with a resulting increase in vascular volume. Increased ventricular filling increases the force of contraction, improving cardiac output. The effects of the renin–angiotensin–aldosterone system and ADH release are counterbalanced to a certain extent by two additional hormones. The increased vascular volume and venous return prompted by vasoconstriction and sodium and water retention increase the volume and pressures in the heart. Stimulation of stretch receptors in the atria and ventricles lead to the release of *atrial natriuretic peptide (ANP)* and *brain natriuretic peptide (BNP)* from stores in the atria (ANP and BNP) and ventricles (BNP). These hormones promote sodium and water excretion and inhibit the release of noradrenaline, renin and ADH, with resulting vasodilation. Although beneficial, the effects of these hormones are too weak to completely counteract the vasoconstriction and sodium and water retention that occurs in heart failure.

Ventricular remodelling occurs as the chambers and myocardium adapt to fluid volume and pressure increases. The chambers dilate to accommodate excess fluid resulting from increased vascular volume and incomplete emptying. Initially, this additional stretch causes more effective contractions. *Ventricular hypertrophy* occurs as existing cardiac muscle cells enlarge, increasing their contractile elements (actin and myosin) and force of contraction.

Although these responses may help in the short-term regulation of cardiac output, it is now recognised that they hasten the deterioration of cardiac function. The onset of heart failure is indicated by *decompensation*, the loss of effective compensation. Heart failure progresses due to the very mechanisms that initially maintained circulatory stability.

The rapid heart rate shortens diastolic filling time, compromises coronary artery perfusion and increases myocardial oxygen demand. Resulting ischaemia further impairs cardiac output. Beta-receptors in the heart become less sensitive to continued SNS stimulation, decreasing heart rate and contractility. As the beta-receptors become less sensitive, noradrenaline stores in the cardiac muscle become depleted. In contrast, alpha-receptors on peripheral blood vessels become increasingly sensitive to persistent stimulation, promoting vasoconstriction and increasing afterload and cardiac work.

Initially, ventricular hypertrophy and dilation increase cardiac output, but chronic distension causes the ventricular wall to eventually thin and degenerate. The purpose of hypertrophy is therefore defeated. In addition, chronic overloading of the dilated ventricle eventually stretches the fibres beyond the optimal point for effective contraction. The ventricles continue to dilate to accommodate the excess fluid, but the heart loses the ability to contract forcefully. The heart muscle may eventually become so large that the coronary blood supply is inadequate, causing ischaemia.

Chronic distension exhausts stores of ANP and BNP. The effects of noradrenaline, renin and ADH prevail and the renin–angiotensin pathway is continually stimulated. This mechanism ultimately raises the haemodynamic stress on the heart by increasing both preload and afterload. As heart function deteriorates, less blood is delivered to the tissues and to the heart itself. Ischaemia and necrosis of the myocardium further weaken the already failing heart and the cycle repeats.

In normal hearts, the cardiac reserve allows the heart to adjust its output to meet metabolic needs of the body, increasing the cardiac output by up to five times the basal level during exercise. People with heart failure have minimal to no cardiac reserve. At rest, they may be unaffected; however, any stressor (e.g. exercise, illness) tips the balance between oxygen demand and oxygen supply. Manifestations of activity intolerance when the person is at rest indicate a critical level of cardiac decompensation.

Classifications and manifestations of heart failure

Heart failure is commonly classified in several different ways, depending on the underlying pathology. Classifications include systolic versus diastolic failure, left-sided versus right-sided failure, high-output versus low-output failure, and acute versus chronic failure.

FAST FACTS

Terms used to describe or classify heart failure:

- systolic or diastolic failure
- left ventricular (or sided) or right ventricular (or sided) failure
- low-output or high-output failure
- acute or chronic failure
- forward or backward effects.

Systolic versus diastolic failure

Systolic failure occurs when the ventricle fails to contract adequately to eject a sufficient blood volume into the arterial system. Systolic function is affected by loss of myocardial cells due to ischaemia and infarction, cardiomyopathy or inflammation. The manifestations of systolic failure are those of decreased cardiac output: weakness, fatigue and decreased exercise tolerance.

Diastolic failure results when the heart cannot completely relax in diastole, disrupting normal filling. Passive diastolic filling decreases, increasing the importance of atrial contraction to preload. Diastolic dysfunction results from decreased ventricular compliance due to hypertrophic and cellular changes and impaired relaxation of the heart muscle. Its manifestations result from increased pressure and congestion behind the ventricle: shortness of breath, tachypnoea and respiratory crackles if the left ventricle is affected; distended neck veins, liver enlargement, anorexia and

nausea if the right ventricle is affected. Many individuals have components of both systolic and diastolic failure.

Left-sided versus right-sided failure

Depending on the pathophysiology involved, either the left or the right ventricle may be primarily affected. In chronic heart failure, however, both ventricles typically are impaired to some degree. Coronary heart disease and hypertension are common causes of *left-sided heart failure*, whereas *right-sided heart failure* often is caused by conditions that increase blood pressure in the pulmonary vasculature, such as acute or chronic pulmonary disease. Left-sided heart failure also can lead to right-sided failure as pressures in the pulmonary vascular system increase with congestion behind the failing left ventricle.

As left ventricular function fails, cardiac output falls. Pressures in the left ventricle and atrium increase as the amount of blood remaining in the ventricle after systole increases. These increased pressures impair filling, causing congestion and increased pressures in the pulmonary vascular system. Increased pressures in this normally low-pressure system increase fluid movement from the blood vessels into interstitial tissues and the alveoli (see Figure 30.1).

The manifestations of left-sided heart failure result from pulmonary congestion (*backward effects*) and decreased cardiac output (*forward effects*). Fatigue and activity intolerance are common early manifestations. Dizziness and syncope also may result from decreased cardiac output. Pulmonary congestion causes dyspnoea and cough. The person may develop orthopnoea (difficulty breathing while lying down), prompting use of two or three pillows or a recliner for sleeping. Cyanosis from impaired gas exchange may be noted. On auscultation of the lungs, inspiratory crackles (rales) and wheezes may be heard in lung bases. An S_3 gallop may be present, reflecting the heart's attempts to fill an already distended ventricle.

In right-sided heart failure, increased pressures in the pulmonary vasculature or right ventricular muscle damage impair the right ventricle's ability to pump blood into the pulmonary circulation. The right ventricle and atrium become distended and blood accumulates in the systemic venous system. Increased venous pressures cause abdominal organs to become congested and peripheral tissue oedema to develop (see Figure 30.2).

Dependent tissues tend to be affected because of the effects of gravity; oedema develops in the feet and legs or, if the person is bedridden, in the sacrum. Congestion of gastrointestinal tract

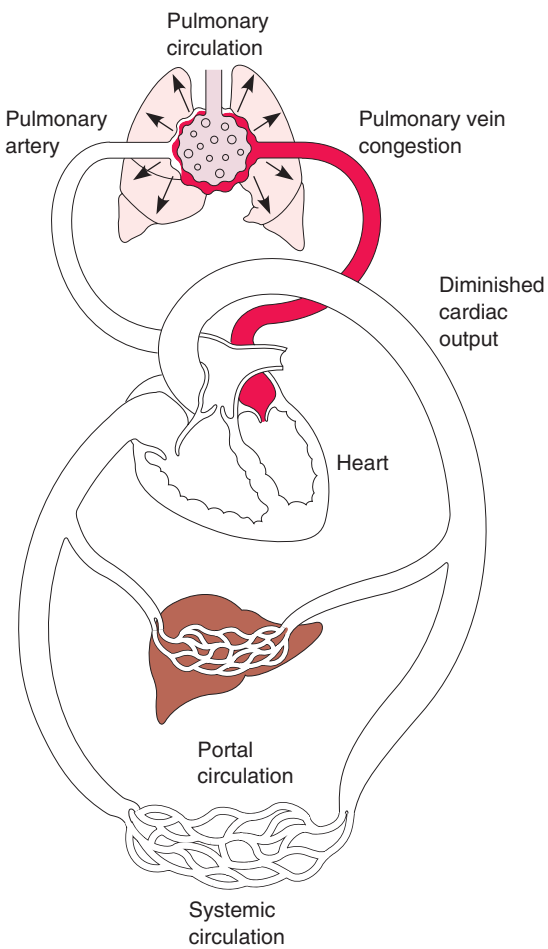

FIGURE 30.1 ■ The haemodynamic effects of left-sided heart failure

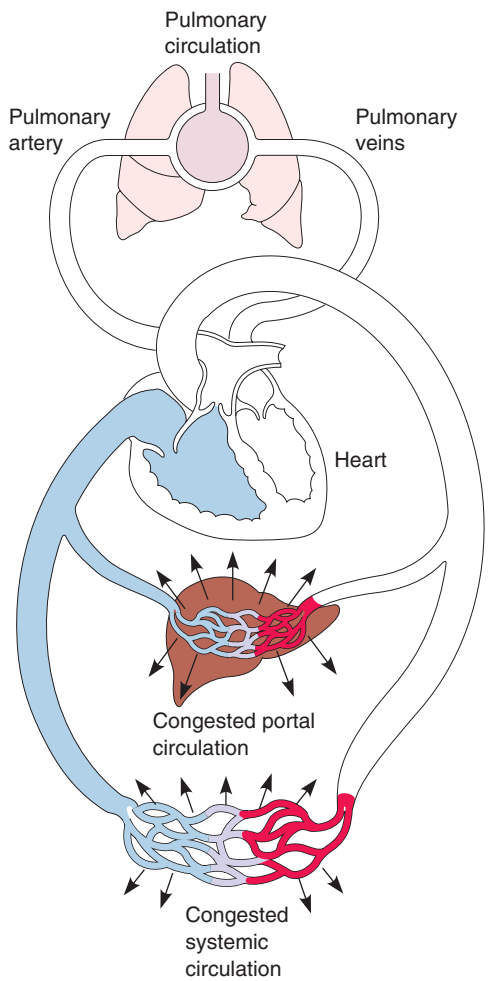

FIGURE 30.2 ■ The haemodynamic effects of right-sided heart failure

vessels causes anorexia and nausea. Right upper quadrant pain may result from liver engorgement. Neck veins distend and become visible even when the person is upright, due to increased venous pressure.

Low-output versus high-output failure

People with heart failure due to coronary heart disease, hypertension, cardiomyopathy and other primary cardiac disorders develop *low-output failure* and manifestations such as those previously described. Individuals in hypermetabolic states (e.g. hyperthyroidism, infection, anaemia or pregnancy) require increased cardiac output to maintain blood flow and oxygen to the tissues. If the increased blood flow cannot meet the oxygen demands of the tissues, compensatory mechanisms are activated to further increase cardiac output, which in turn further increases oxygen demand. Thus, even though cardiac output is high, the heart is unable to meet increased oxygen demands. This condition is known as *high-output failure*.

Acute versus chronic failure

Acute failure is the abrupt onset of a myocardial injury (such as a massive MI) resulting in suddenly decreased cardiac function and signs of decreased cardiac output. *Chronic failure* is a progressive deterioration of the heart muscle due to cardiomyopathies, valvular disease or CHD.

Other manifestations

In addition to the previous manifestations for the various classifications of heart failure, other signs and symptoms commonly are seen.

A fall in cardiac output activates mechanisms that cause increased salt and water retention. This causes weight gain and further increases pressures in the capillaries, resulting in oedema. *Nocturia*, voiding more than one time at night, develops as oedema fluid from dependent tissues is reabsorbed while the person is supine. **Paroxysmal nocturnal dyspnoea (PND)** may develop. PND is a frightening condition in which the person awakens at night acutely short of breath. PND occurs when fluid that has accumulated in the tissues during the day is reabsorbed into the circulation at night, causing fluid overload and pulmonary congestion. Severe heart failure with little or no cardiac reserve may cause dyspnoea at rest, as well as with activity. Both an S_3 and an S_4 gallop may be heard on auscultation.

See below for the multisystem effects of heart failure.

Complications

The compensatory mechanisms initiated in heart failure can lead to complications in other body systems. Congestive hepatomegaly and splenomegaly caused by engorgement of the portal venous system result in increased abdominal pressure, ascites and gastrointestinal problems. With prolonged right-sided heart failure, liver function may be impaired. Myocardial distension can precipitate arrhythmias, further impairing cardiac output. Pleural effusions and other pulmonary problems may develop. Major complications of severe heart failure are cardiogenic shock (described in Chapter 10) and acute pulmonary oedema, a medical emergency described in the next section of this chapter.

INTERPROFESSIONAL CARE

The main goals for care of heart failure are to slow its progression, reduce cardiac workload, improve cardiac function and control fluid retention. Treatment strategies are based on the evolution and progression of heart failure. The National Heart Foundation of Australia and the Cardiac Society of Australia and New Zealand (NHF Australia, 2011) produce guidelines for the prevention, detection and management of chronic heart failure. These guidelines are a comprehensive set of recommendations regarding the diagnosis and management of individuals with heart failure. A comprehensive online resource has also been developed for clinicians encompassing all aspects of heart failure assessment and management (National Heart Foundation of Australia, n.d.).

In Australia, symptom classification is still achieved using the New York Heart Association (NYHA) grading of symptoms in chronic heart failure (see Table 30.3).

Diagnosis

Diagnosis of heart failure is based on the history, physical examination and diagnostic findings. The National Heart Foundation of Australia recommends an echocardiogram, electrocardiogram, chest x-ray, full blood count (FBC), plasma, urea, creatinine and electrolytes in all individuals suspected of heart failure (NHF Australia, 2011) (see Table 30.4).

The arterial blood pressure reflects the cardiac output and resistance to blood flow created by the elastic arterial walls (*systemic vascular resistance, SVR*). Cardiac output is determined by the blood volume and the ability of the ventricles to fill and effectively pump that blood. Systemic vascular resistance is primarily determined by vessel diameter and distensibility (compliance). Factors such as SNS input, circulating hormones (e.g. adrenaline, noradrenaline, ANP and vasopressin) and the renin–angiotensin system affect SVR.

TABLE 30.3 NYHA grading of symptoms in chronic heart failure

NYHA Class I	No limitations. Ordinary physical activity does not cause undue fatigue, dyspnoea or palpitations (asymptomatic LV dysfunction).
NYHA Class II	Slight limitation of physical activity. Ordinary physical activity results in fatigue, palpitation, dyspnoea or angina pectoris (mild CHF).
NYHA Class III	Marked limitation of physical activity. Less than ordinary physical activity leads to symptoms (moderate CHF).
NYHA Class IV	Unable to carry on any physical activity without discomfort. Symptoms of CHF present at rest (severe CHF).

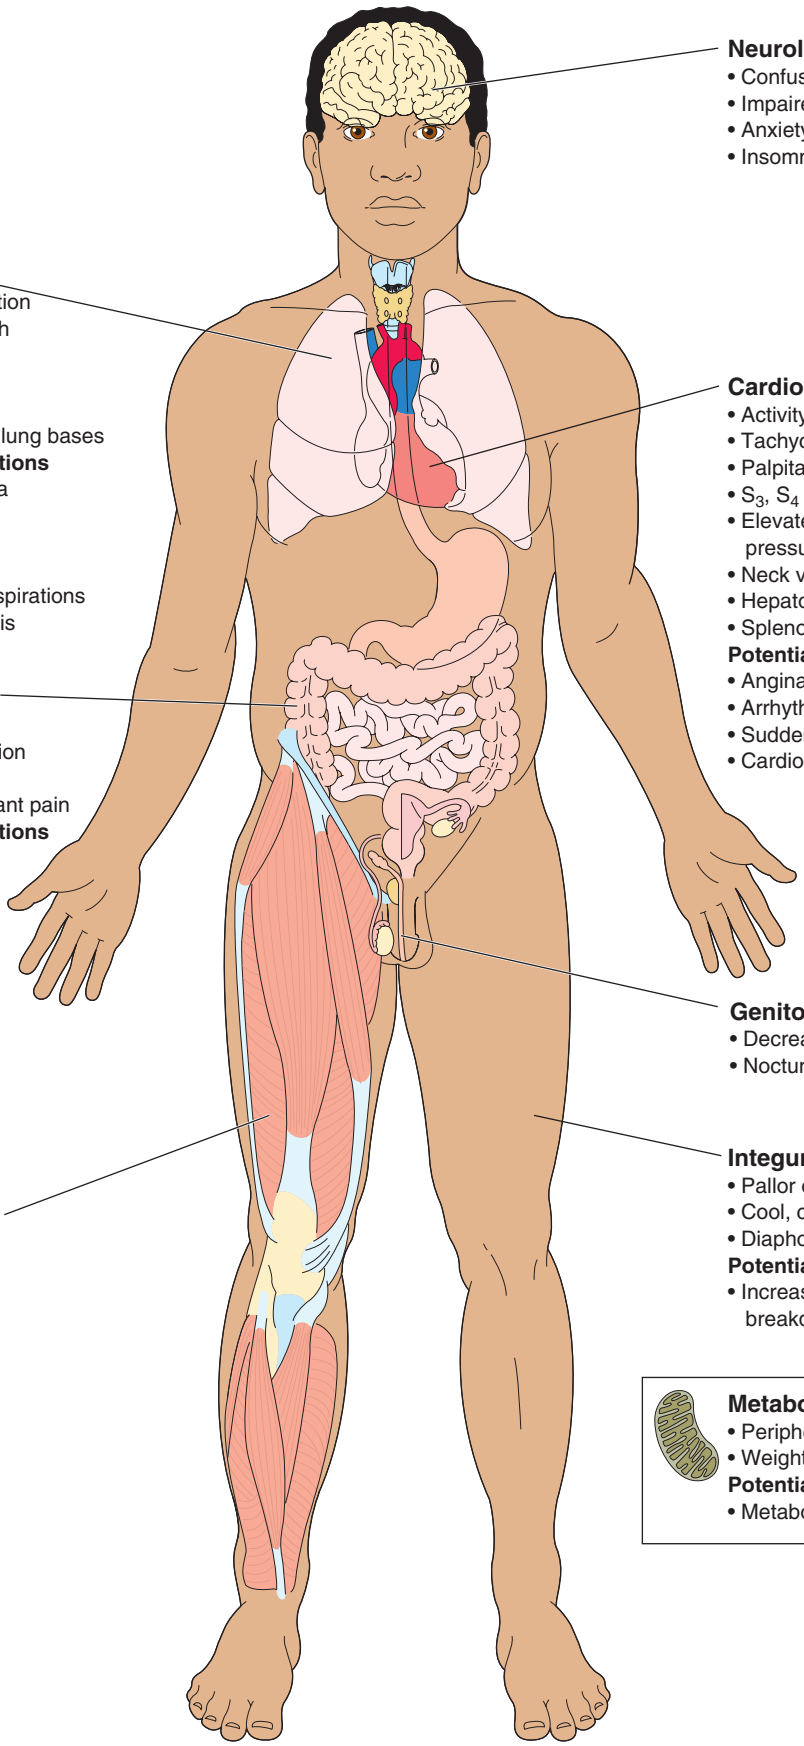
MULTISYSTEM EFFECTS OF HEART FAILURE



Neurological
- Confusion
- Impaired memory
- Anxiety, restlessness
- Insomnia

Respiratory
- Dyspnoea on exertion
- Shortness of breath
- Tachypnoea
- Orthopnoea
- Dry cough
- Crackles (rales) in lung bases

Potential complications
- Pulmonary oedema
- Pneumonia
- Cardiac asthma
- Pleural effusion
- Cheyne-Stokes respirations
- Respiratory acidosis

Cardiovascular
- Activity intolerance
- Tachycardia
- Palpitations
- S_3, S_4 heart sounds
- Elevated central venous pressure
- Neck vein distension
- Hepatojugular reflux
- Splenomegaly

Potential complications
- Angina
- Arrhythmias
- Sudden cardiac death
- Cardiogenic shock

Gastrointestinal
- Anorexia, nausea
- Abdominal distension
- Liver enlargement
- Right upper quadrant pain

Potential complications
- Malnutrition
- Ascites
- Liver dysfunction

Genitourinary
- Decreased urine output
- Nocturia

Integumentary
- Pallor or cyanosis
- Cool, clammy skin
- Diaphoresis

Potential complications
- Increased risk for tissue breakdown

Musculoskeletal
- Fatigue
- Weakness

Metabolic processes
- Peripheral oedema
- Weight gain

Potential complication
- Metabolic acidosis

TABLE 30.4 Tests indicated for individuals suspected of heart failure

Blood glucose	Metabolic disorders not only increase the risk of cardiovascular disease but complicate its course and management.
BNP and NT-pro BNP	Natriuretic peptides released by the atria may detect deterioration in pump function as increases in these values correlate with worsening heart failure.
Chest x-ray (CXR)	Assesses structure; some inferences regarding function may be made.
Echocardiogram (ECHO)	Assesses structure and function of the myocardium.
Electrocardiogram (ECG)	May demonstrate possible contributing factor or resulting consequence (arrhythmia or chamber enlargement).
Full blood count (FBC)	May detect anaemia.
Urea and electrolytes (U&Es)	Urea and creatinine are markers of renal function and can suggest renal failure or cause of fluid retention. Electrolyte measures may detect fluid and electrolyte imbalances.
Liver function tests (LFTs)	May detect alterations in liver function which can demonstrate possible cause or effect.
Arterial blood gases (ABGs)	May detect hypoxia as a cause or consequence of heart failure.
Myocardial perfusion scans (MPS or sestamibi)	May detect changes in ventricular wall function, such as wall motion or perfusion anomalies, as causes or consequences of heart failure.
Coronary angiogram	May quantify vessel occlusion as a cause of heart failure.

The systolic blood pressure, normally about 120 mmHg in healthy adults, reflects the pressure generated during ventricular systole. During diastole, elastic arterial walls keep a minimum pressure within the vessel (diastolic blood pressure) to maintain blood flow through the capillary beds. The average diastolic pressure in a healthy adult is 80 mmHg. The mean arterial pressure (MAP) is the average pressure in the arterial circulation throughout the cardiac cycle. It reflects the driving pressure or perfusion pressure, an indicator of tissue perfusion. The formula MAP = CO × SVR is often used to show the relationships between factors determining the blood pressure. Mean arterial pressure can be calculated by adding two times the diastolic blood pressure to the systolic blood pressure and dividing by 3 (MAP = [(2 × diastolic) + systolic]/3). For example, a blood pressure of 120/80 results in a MAP of 93. Mean arterial pressures of 70 to 90 mmHg are desirable. Perfusion to vital organs is severely jeopardised at MAPs of 50 or less; MAPs greater than 105 mmHg may indicate hypertension or vasoconstriction.

Medications

People with heart failure often receive multiple medications to reduce cardiac work and improve cardiac function. The main drug classes used to treat heart failure are the angiotensin-converting-enzyme (ACE) inhibitors, angiotensin II receptor blockers (ARBs), beta-blockers, diuretics, inotropic medications (including digoxin, sympathomimetic agents and phosphodiesterase inhibitors), direct vasodilators and antiarrhythmic drugs. Nursing implications for ACE inhibitors and ARBs, diuretics and inotropic medications are found in the 'Medication administration' box below.

Surgery

Nursing care of the person who has had a heart transplant (see Figure 30.3) is similar to care for a person who has had cardiac surgery (see box on the nursing care of person having a coronary artery bypass in Chapter 29). Bleeding is a major concern in the early postoperative period. Chest tube drainage is frequently monitored (initially every 15 minutes), as are the cardiac output, pulmonary artery pressures and CVP. Cardiac tamponade (compression of the heart) can develop, presenting as either a sudden event or a gradual process. Chest tubes are gently milked (not stripped) as needed to maintain patency.

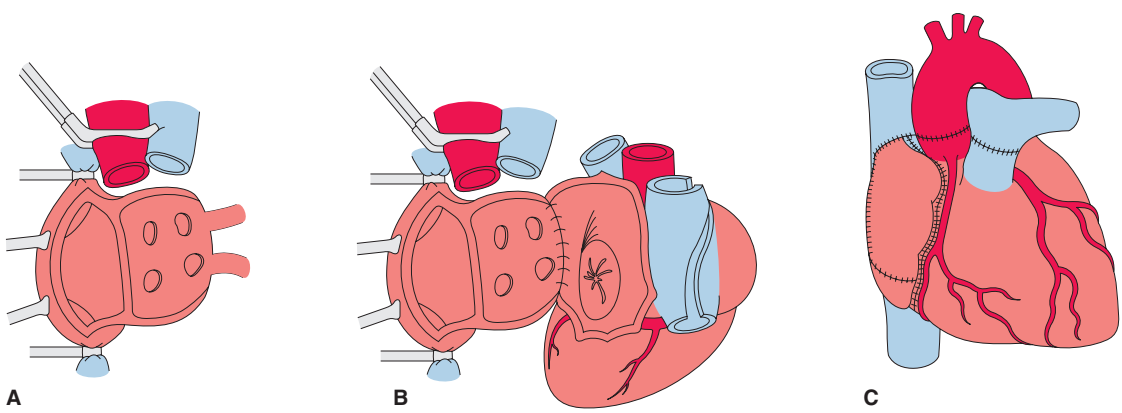


FIGURE 30.3 ■ Cardiac transplantation. *A*, The person's heart is removed, leaving the posterior walls of the atria intact. The donor heart is anastomosed to the atria, *B*, and the great vessels, *C*

MEDICATION ADMINISTRATION Heart failure

ACE INHIBITORS AND ARBs

Angiotensin-converting-enzyme inhibitors (ACE inhibitors) and angiotensin II receptor blockers (ARBs) prevent acute coronary events and reduce mortality in heart failure. ACE inhibitors interfere with production of angiotensin II, resulting in vasodilation and reduced circulating blood volume, ultimately reducing blood pressure. In heart failure, ACE inhibitors reduce afterload, improve cardiac output and increase renal perfusion. They also reduce pulmonary congestion and peripheral oedema. ACE inhibitors suppress myocyte growth and reduce ventricular remodelling in heart failure. While the pharmacological effect of ARBs is similar, they block the action of angiotensin II at the receptor rather than interfering with its production. This mechanism of action results in fewer side effects as ACE is also required in the lungs to break down the substances responsible for increasing airway hyperreactivity, tachykinins and bradykinins.

Nursing responsibilities

- Do not administer these drugs to women in the second and third trimesters of pregnancy.
- Carefully monitor individuals who are volume depleted or who have impaired renal function.
- Use an infusion pump when administering ACE inhibitors intravenously.
- Monitor blood pressure closely for 2 hours following first dose and as indicated thereafter.
- Monitor serum potassium levels; ACE inhibitors can cause hyperkalaemia. (This is less of a concern with ARBs.)
- Monitor white blood cell (WBC) count for potential neutropenia. Report to the doctor.

Health education for the person and family

- Take the drug at the same time every day to ensure a stable blood level.
- Monitor blood pressure and weight weekly. Report significant changes to the doctor.
- Avoid making sudden position changes; for example, rise from bed slowly. Lie down if feeling dizzy or light headed, particularly after the first dose.
- Report any signs of easy bruising and bleeding, sore throat or fever, oedema or skin rash. Immediately report swelling of the face, lips or eyelids, and itching or breathing problems.
- A persistent, dry cough may develop if taking an ACE inhibitor. Contact the doctor if this becomes a problem.

DIURETICS

Diuretics act on different portions of the kidney tubule to inhibit the reabsorption of sodium and water and promote their excretion. With the exception of the potassium-sparing diuretics—spironolactone and amiloride—diuretics also promote potassium excretion, increasing the risk of hypokalaemia. Spironolactone, an aldosterone receptor blocker, reduces symptoms and slows progression of heart failure. Aldosterone receptors in the heart and blood vessels promote myocardial remodelling and fibrosis, activate the sympathetic nervous system and promote vascular fibrosis (which decreases compliance) and baroreceptor dysfunction.

Nursing responsibilities

- Obtain baseline weight and vital signs.
- Monitor blood pressure, intake and output, weight, skin turgor and oedema as indicators of fluid volume status.
- Assess for volume depletion, particularly with loop diuretics (frusemide and ethacrynic acid—ethacrynic acid is primarily restricted to people who are either allergic to, or refractory to, frusemide or bumetanide): dizziness, orthostatic hypotension, tachycardia, muscle cramping.
- Report abnormal serum electrolyte levels to the doctor. Replace electrolytes as indicated.
- Do not administer potassium replacements to individuals receiving a potassium-sparing diuretic.
- Evaluate renal function by assessing urine output and serum urea and creatinine.
- Administer intravenous frusemide slowly, no faster than 20 mg/minute. Evaluate for signs of ototoxicity. Do not administer this drug or ethacrynic acid concurrently with aminoglycoside antibiotics (e.g. gentamicin), which are also ototoxic.

Health education for the person and family

- Drink at least 6 to 8 glasses of water per day.
- Take your diuretic at times that will be the least disruptive to your lifestyle, usually in the morning and early afternoon if a second dose is ordered. Take with meals to decrease gastric upset.
- Monitor your blood pressure, pulse and weight weekly. Report significant weight changes to your doctor.
- Report any of the following to your doctor: severe abdominal pain, jaundice, dark urine, abnormal bleeding or bruising, flu-like symptoms, signs of hypokalaemia, hyponatraemia and dehydration (thirst, salt craving, dizziness, weakness, rapid pulse). See Chapter 9 for manifestations of electrolyte imbalances.
- Avoid sudden position changes. They may cause dizziness, light headedness or feelings of faintness.
- Unless taking a potassium-sparing diuretic, integrate foods rich in potassium into your diet (see Chapter 9). Limit sodium use.

POSITIVE INOTROPIC AGENTS

Digoxin glycosides

Digoxin (Lanoxin)

Digoxin improves myocardial contractility by interfering with ATPase in the myocardial cell membrane and increasing the amount of calcium available for contraction. The increased force of contraction causes the heart to empty more completely, increasing stroke volume and cardiac output. Improved cardiac output improves renal perfusion, decreasing renin secretion. This decreases preload and afterload, reducing cardiac work. Digoxin also has electrophysiological effects, slowing conduction through the AV node decreasing heart rate and reducing oxygen consumption.

Nursing responsibilities

- Assess apical pulse before administering. Withhold digoxin and notify the doctor if heart rate is below 60 bpm

(continued)

MEDICATION ADMINISTRATION Heart failure (continued)

and/or manifestations of decreased cardiac output are noted. Record apical rate on medication record.
- Evaluate electrocardiogram (ECG) for scooped (spoon-shaped) ST segment, AV block, bradycardia and other arrhythmias (especially PVCs and atrial tachycardias).
- Report manifestations of digoxin toxicity: anorexia, nausea, vomiting, abdominal pain, weakness, vision changes (diplopia, blurred vision, yellow-green or white halos seen around objects) and new-onset arrhythmias.
- Assess potassium, magnesium, calcium and serum digoxin levels before giving digoxin. Hypokalaemia can precipitate toxicity even when the serum digoxin level is in the 'normal' range.
- Monitor individuals with renal insufficiency or renal failure and older adults carefully for digoxin toxicity.
- Prepare to administer digoxin immune Fab (Digibind) for digoxin toxicity.

Health education for the person and family

- Take pulse daily before taking the digoxin. Do not take the digoxin if the pulse is below 60 bpm or if weak, fatigued, light headed, dizzy, short of breath or having chest pain. Notify the doctor immediately.
- Contact the doctor if any manifestations of digoxin toxicity occur: palpitations, weakness, loss of appetite, nausea, vomiting, abdominal pain, blurred or coloured vision, double vision.
- Avoid using antacids and laxatives; they decrease digoxin absorption.
- Notify the doctor immediately if any manifestations of potassium deficiency occur: weakness, lethargy, thirst, depression, muscle cramps or vomiting.
- Incorporate foods high in potassium into your diet: fresh orange or tomato juice, bananas, raisins, dates, figs, prunes, apricots, spinach, cauliflower and potatoes.

SYMPATHOMIMETIC AGENTS

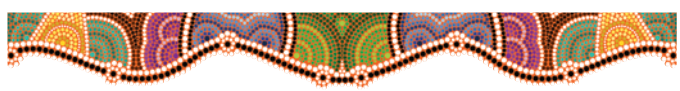
Sympathomimetic agents stimulate the heart, improving the force of contraction. Dobutamine is preferred in managing heart failure because it does not increase the heart rate as much as dopamine and it has a mild vasodilatory effect. These drugs are given by intravenous infusion and may be titrated to obtain their optimal effects.

Atrial arrhythmias are relatively common following cardiac transplant. Temporary pacing wires are placed during surgery as the conduction system may be disrupted by surgical manipulation or postoperative swelling. Hypothermia is induced during surgery; postoperatively, the person is gradually rewarmed over a 1- to 2-hour period. Prevention of rapid rewarming and shivering are important to maintain haemodynamic stability and reduce oxygen consumption. Cardiac function is impaired in up to 50% of transplanted hearts during the early postoperative period. Inotropic agents such as low-dose dopamine or dobutamine may be required to support cardiac function and circulation.

Infection and rejection are major postoperative concerns; these are the chief causes of mortality in people who have had a heart transplant. Rejection may develop immediately after transplant (rarely) or within weeks to months or even years after the transplant. Acute rejection usually presents within weeks of the transplant, developing when the transplanted organ is recognised by the immune system as foreign. Lymphocytes infiltrate the organ and myocardial cell necrosis can be detected on biopsy. Acute rejection often can be treated using immunosuppressive drugs. These drugs also are given to prevent rejection of the transplanted organ, even when the tissue match is good (see Chapter 12). Although immunosuppressive medications help prevent organ rejection, they impair the person's defences against infection. Early postoperative infections commonly are bacterial or fungal (*Candida*). Multiple invasive lines, prolonged ventilator support and immunosuppressive therapy contribute to the transplant recipient's risk of infection. Nursing care directed at prevention of infection is vital and includes strict aseptic technique, early extubation to reduce the risk of ventilator-associated infections, limitation of individuals who may present an infection risk and early ambulation (Elliot, Aitken & Chaboyer, 2012).

The donor heart is denervated during the transplant procedure and therefore the person's heart rate is commonly between 90–100 bpm. This occurs because the slowing effects of the parasympathetic nervous system are lost. The endocrine system, position changes, exercise and certain drugs moderate heart rate following a heart transplant.

OTHER PROCEDURES A person with heart failure may benefit from coronary revascularisation, left ventricular aneurysmectomy or mitral valvuloplasty (NHF Australia, 2011). Other surgical procedures such as cardiomyoplasty and ventricular reduction surgery are not recommended because of unfavourable results.



Nursing care

Health promotion

Health promotion activities to reduce the risk and incidence of heart failure should be directed at the risk factors. Teach individuals about coronary heart disease, the primary underlying cause of heart failure. Discuss CHD risk factors and ways to reduce those risk factors (see Chapter 29).

Hypertension also is a major cause of heart failure. Routinely screen individuals for hypertension and refer them

to a medical officer as required. Discuss the importance of effectively managing hypertension to reduce the future risk of heart failure. Likewise, stress the relationship between effective diabetes management and reduced risk of heart failure.

Assessment

Obtain both subjective and objective data when assessing the person with heart failure:

- *Health history:* complaints of increasing dyspnoea, decreasing activity tolerance or paroxysmal nocturnal dyspnoea; number of pillows used for sleeping; recent weight gain; presence of a cough; chest or abdominal pain; anorexia or nausea; history of cardiac disease, previous episodes of heart failure; other risk factors such as hypertension or diabetes; current medications; usual diet and activity and recent changes.
- *Physical examination:* general appearance; ease of breathing, conversing, changing positions; apparent anxiety; vital signs including apical pulse; colour of skin and mucous membranes; neck vein distension, peripheral pulses, capillary refill, presence and degree of oedema; heart and breath sounds; abdominal contour, bowel sounds, tenderness; right upper abdominal tenderness, liver enlargement.
- *Diagnostic tests:* serum electrolyte, urea, creatinine and digoxin levels; arterial blood gas (ABG) results; ECG, echocardiogram and chest x-ray reports.

Nursing diagnosis and interventions

Heart failure impacts on quality of life and interferes with activities of daily living (ADLs). Reducing myocardial oxygen demand is a major nursing care goal for the individual in acute heart failure. This includes providing rest and undertaking the prescribed interventions to reduce cardiac work, improve contractility and manage symptoms. See also the accompanying nursing care plan for additional nursing diagnoses and interventions for the individual with heart failure.

- Auscultate the person's heart and breath sounds regularly. *S_1 and S_2 may be diminished if cardiac function is poor. A ventricular gallop (S_3) is an early sign of heart failure; atrial gallop (S_4) may also be present. Crackles are often heard in the lung bases; increasing crackles and dyspnoea indicate worsening failure.*

Decreased cardiac output

Pump failure results in decreased upstroke volume and tissue perfusion.

- Monitor the person's vital signs and oxygen saturation as indicated. *Decreased cardiac output stimulates the SNS to increase the heart rate in an attempt to restore CO. Tachycardia at rest is common. Diastolic blood pressure may initially be elevated because of vasoconstriction; in late stages, compensatory mechanisms fail and the person's BP will fall. Oxygen saturation levels provide a measure of gas exchange and tissue perfusion.*

CONSIDERATION FOR PRACTICE

Report manifestations of decreased cardiac output and tissue perfusion including changes in mentation, decreased urine output, cool, clammy skin, diminished pulses, pallor or cyanosis, and arrhythmias.

- Administer supplemental oxygen as needed. *This improves oxygenation of the blood, decreasing the effects of hypoxia and ischaemia.*
- Administer prescribed medications as ordered. *Drugs are used to decrease the cardiac workload and increase contractility.*
- Encourage rest, explaining the rationale. Elevate the head of the bed to reduce the work of breathing. Provide a bedside commode and assist with ADLs. Instruct the person to avoid the Valsalva manoeuvre and encourage the use of stool softeners to reduce strain. *These measures reduce cardiac workload.*

CONSIDERATION FOR PRACTICE

Encourage the person to rest and teach methods to decrease anxiety. Maintain a quiet environment and encourage expression of fears and feelings. Explain care measures and their purpose. Reducing anxiety diminishes the sympathetic nervous system effects, resulting in an improved balance between oxygen demand and supply.

Excess fluid volume

As cardiac output falls, compensatory mechanisms cause salt and water retention, increasing blood volume. This increased fluid volume places additional stress on the already failing ventricles, making them work harder to move the fluid load.

- Assess respiratory status and auscultate lung sounds at least every 4 hours. Notify the doctor of significant changes in condition. *Declining respiratory status indicates worsening left heart failure.*

CONSIDERATION FOR PRACTICE

Immediately notify the doctor if the person develops dyspnoea, tachypnoea, severe orthopnoea, a cough productive of large amounts of pink, frothy sputum, or an overwhelming sense of impending doom or panic. Acute pulmonary oedema is a medical emergency and can develop rapidly. Immediate intervention is required to preserve life.

- Monitor the person's intake and output. Notify the doctor if urine output is less than 30 mL/h. Weigh daily. *Careful monitoring of fluid volume is important during treatment of heart failure. Diuretics may reduce circulating volume, producing hypovolaemia despite persistent peripheral oedema. A fall in urine output may indicate significantly reduced cardiac output and renal ischaemia. Weight is an objective measure of fluid status: 1 L of fluid is equal to 1 kg of weight.*

NURSING CARE PLAN A person with heart failure

One year ago, Arthur Jackson, 67 years old, had a large anterior wall MI and underwent subsequent coronary artery bypass surgery. On discharge, he was started on a regimen of enalapril, digoxin, frusemide, warfarin and a potassium chloride supplement. He is now in the cardiac unit complaining of severe shortness of breath, haemoptysis and poor appetite for 1 week. He is diagnosed with acute heart failure.

ASSESSMENT

Mr Jackson refuses to settle in bed, preferring to sit in the bedside recliner in high-Fowler's position. He states, 'Lately, this is the only way I can breathe.' Mr Jackson states that he has not been able to work in his garden without getting short of breath. He complains of his shoes and belt being too tight.

Mr Jackson insists that he takes his medications regularly. He states that he normally works in his garden for light exercise. In his diet history, Mr Jackson admits fondness for bacon and takeaway food and sheepishly admits to snacking between meals 'even though I need to lose weight'.

Mr Jackson's vital signs are: BP 95/72 mmHg, HR 124 and irregular, R 28 and laboured, and T 36.5°C. The cardiac monitor shows atrial fibrillation. An S_3 is noted on auscultation; the cardiac impulse is left of the midclavicular line. He has crackles and diminished breath sounds in the bases of both lungs. Significant jugular venous distension, 3+ pitting oedema of feet and ankles and abdominal distension are noted. Liver size is within normal limits by percussion. His skin is cool and he is diaphoretic. Chest x-ray shows cardiomegaly and pulmonary infiltrates.

DIAGNOSES

- *Excess fluid volume* related to impaired cardiac pump and salt and water retention manifested by crackles and pitting oedema.
- *Risk of activity intolerance* related to impaired cardiac output manifested by inability to undertake activities of daily living.
- *Impaired health maintenance* related to lack of knowledge about diet restrictions manifested by frequent consumption of foods high in salt and fat.

PLANNING

- Hourly vital signs and haemodynamic pressure measurements.
- Monitor oxygen saturation continuously. Notify doctor if less than 94%.
- Administer and monitor effects of prescribed diuretics and vasodilators.
- Weigh daily; strict fluid balance monitoring.
- Enforce fluid restriction of 1500 mL/24 hours.
- Auscultate heart and breath sounds every 4 hours and as indicated.

Expected outcomes

- Demonstrate loss of excess fluid by weight loss and decreases in oedema, jugular venous distension and abdominal distension.
- Demonstrate improved activity tolerance.
- Verbalise understanding of diet restrictions.

IMPLEMENTATION

- Administer oxygen per nasal prongs at 2 L/min.
- High-Fowler's or position of comfort.
- Notify doctor of significant changes in laboratory values.
- Teach about all medications and how to take and record pulse. Provide information about anticoagulant therapy and signs of bleeding.
- Design an activity plan with Mr Jackson that incorporates preferred activities and scheduled rest periods.
- Instruct about sodium-restricted diet. Allow meal choices within allowed limits.
- Consult dietitian for planning and teaching Mr and Mrs Jackson about a low-sodium diet.

EVALUATION

Mr Jackson is discharged after 3 days in the cardiac unit. He has lost 3.5 kilograms during his stay and states it is much easier to breathe and his shoes fit better. He is able to sleep in semi-Fowler's position with only one pillow. His peripheral oedema has resolved. Mr and Mrs Jackson met with the dietitian, who helped them develop a realistic eating plan to limit sodium, sugar and fats. The dietitian also provided a list of high-sodium foods to avoid. The physiotherapist designed a progressive activity plan with Mr Jackson that he will continue at home. He remains in atrial fibrillation, a chronic condition. His knowledge of digoxin and warfarin has been assessed and reinforced. The nurse confirms that he is able to accurately check his pulse and can identify signs of digoxin toxicity and excessive bleeding.

CRITICAL THINKING IN THE NURSING PROCESS

1. Mr Jackson's medication regimen remains the same after discharge. What specific teaching does he need related to potential interactions of these drugs?
2. Mr Jackson exclaims, 'Talk to my wife about my medications—she's Tarzan and I'm Jane, now.' How would you respond?
3. Mr Jackson tells you, 'Sometimes I forget whether I have taken my aspirin, so I'll take another just to be sure. After all, they are only baby aspirin. One or two extra a day shouldn't hurt, right?' What is your response?
4. Mr Jackson is admitted to the neurology unit 6 months later with a cerebral vascular accident (CVA). What are the possible contributing factors of his stroke?

REFLECTION ON THE NURSING PROCESS

1. Outline what you have learned from this case study that you will apply to your future practice.
2. Given that Mr Jackson has a cerebrovascular accident 6 months later, explore the influence of cardiovascular conditions on the development of other co-morbidities and conditions. What other conditions/co-morbidities are common in individuals who present with an ischaemic heart disease? Why? What specifically can a nurse do to influence a person with ischaemic heart disease to reduce the risk of developing these common co-morbidities and conditions in the future?

- Record abdominal girth every shift. Note complaints of a loss of appetite, abdominal discomfort or nausea. *Venous congestion can lead to ascites and may affect gastrointestinal function and nutritional status.*
- Monitor and record the person's haemodynamic measurements. Report significant changes and negative trends. *Haemodynamic measurements provide a means of monitoring condition and response to treatment.*
- Restrict fluids as ordered. Offer appropriate choices of fluid type and timing of intake, scheduling most fluid intake during morning and afternoon hours. Offer ice chips and frequent mouth care. *Providing choices increases the person's sense of control. Ice chips and frequent mouth care relieve dry mouth and thirst and promote comfort.*

Activity intolerance

People with heart failure have insufficient cardiac reserve to meet increased oxygen demands. As the disease progresses and cardiac function is further compromised, activity intolerance increases. The low cardiac output and inability to participate in activities may hinder self-care.

- Organise nursing care to allow rest periods. Grouping activities together allows adequate time to 'recharge'. However, care must be taken to avoid overtaxing the individual during the grouped activities. *Frequently gauge the person's capacity to continue and adjust the plans as required.*

CONSIDERATION FOR PRACTICE

Monitor vital signs and cardiac rhythm during and after activities. Tachycardia, arrhythmias, increasing dyspnoea, changes in blood pressure, diaphoresis, pallor, complaints of chest pain, excessive fatigue or palpitations indicate activity intolerance. Instruct to rest if manifestations are noted. The failing heart is unable to increase cardiac output to meet increased oxygen demands associated with activity. Assessing response to activities helps evaluate cardiac function. Decreasing activity tolerance may signal deterioration of cardiac function, not overexertion.

- Assist with ADLs as needed. Encourage independence within prescribed limits. *Assisting with ADLs helps ensure that care needs are met while reducing cardiac workload. Involving the individual promotes a sense of control and reduces helplessness.*
- Plan and implement progressive activities. Use passive and active range-of-motion (ROM) exercises as appropriate. Consult with physical therapist on activity plan. *Progressive activity slowly increases exercise capacity by strengthening and improving cardiac function without strain. Activity also helps prevent skeletal muscle atrophy. ROM exercises prevent complications of immobility in severely compromised individuals.*
- Provide written and verbal information about activity after discharge. *Written information provides a reference for important information. Verbal information allows clarification and validation of the material.*

Deficient knowledge: low-sodium diet

Diet is an important part of long-term management of heart failure to manage fluid retention.

- Discuss the rationale for sodium restrictions. *Understanding fosters compliance with the prescribed diet.*
- Consult with dietitian to plan and teach a low-sodium and, if necessary for weight control, low-kilojoule diet. Provide a list of high-sodium, high-fat, high-cholesterol foods to avoid. Provide National Heart Foundation materials. *Dietary planning and teaching increase the individual's sense of control and participation in disease management. Food lists are useful memory aids.*
- Assist the person to construct a 2-day meal plan choosing foods low in sodium. *This allows learning assessment, clarification of misunderstandings and reinforcement of teaching.*
- Encourage small, frequent meals rather than three heavy meals per day. *Small, frequent meals provide continuing energy resources and decrease the work required to digest a large meal.*

CONSIDERATION FOR PRACTICE

Teach a person with cardiovascular pathology how to read food labels for nutritional information. Many processed foods contain 'hidden' sodium, which can be identified by careful label reading.

Community-based care

Heart failure is a chronic condition requiring active participation by the individual and family for effective management. In teaching for home care, include the following topics:

- the disease process and its effects on the individual's life
- warning signals of cardiac decompensation requiring treatment
- desired and adverse effects of prescribed drugs; monitoring for effects; importance of compliance with drug regimen to prevent acute and long-term complications of heart failure
- prescribed diet and sodium restriction; practical suggestions for reducing salt intake; recommend National Heart Foundation materials and recipes
- exercise recommendations to strengthen the heart muscle and improve aerobic capacity (see Box 30.2)
- the importance of keeping scheduled follow-up appointments to monitor disease progression and effects of therapy.

Provide referrals for home healthcare and household assistance (shopping, transportation, personal needs and housekeeping) as indicated. Referrals to community agencies, such as local cardiac rehabilitation programs, heart support groups or the National Heart Foundation, can provide the person and their family with additional materials and psychosocial support.

BOX 30.2 Home activity guidelines for the person with heart failure

- Perform as many activities as independently as possible.
- Space meals and activities.
  a. Eat six small meals a day.
  b. Allow time during the day for periods of rest and relaxation.
- Perform all activities at a comfortable pace.
  a. If tired during activity, stop and rest for 15 minutes.
  b. Resume activity only when capable.
- Stop any activity that causes chest pain, shortness of breath, dizziness, faintness, excessive weakness or sweating. Rest. Notify the doctor if activity tolerance changes and if symptoms continue after rest.
- Avoid straining. Do not lift heavy objects. Eat a high-fibre diet and drink plenty of water to prevent constipation. Use laxatives or stool softeners, as approved by the doctor, to avoid constipation and straining during bowel movements.
- Begin a graded exercise program. Walking is good exercise that does not require any special equipment (except a good pair of walking shoes). The amount and quality of exercise should be determined by the NYHA functional class symptoms (see Table 30.5). Exercise programs should be initiated by a medical officer and supervised by appropriately trained exercise prescription professionals taking into account the clinical status of the individual. Isometric activity is not recommended as it increases left ventricular afterload.

TABLE 30.5 NYHA functional class symptoms

NYHA Class I and II	Progress gradually to at least 30 minutes of physical activity (continuously or in 10-minute bouts) up to moderate intensity on most, if not all, days of the week.
NYHA Class III and IV	Short intervals of low-intensity activity, with frequent rest days.
NYHA Class IV	Gentle mobilisation as symptoms allow.

THE PERSON WITH PULMONARY OEDEMA

Pulmonary oedema is an abnormal accumulation of fluid in the interstitial tissue and alveoli of the lung. Both cardiac and non-cardiac disorders can cause pulmonary oedema. Cardiac causes include acute myocardial infarction, acute heart failure and valvular disease. *Cardiogenic pulmonary oedema*, the focus of this section, is a sign of severe cardiac decompensation. Non-cardiac causes of pulmonary oedema include primary pulmonary disorders, such as acute respiratory distress syndrome (ARDS), trauma, sepsis, drug overdose or neurological sequelae. Pulmonary oedema due to ARDS is discussed in Chapter 36.

Pulmonary oedema is a medical emergency: the person is literally drowning in the fluid in the alveolar and interstitial pulmonary spaces. Its onset may be acute or gradual, progressing to severe respiratory distress. Immediate treatment is necessary.

FAST FACTS

- Cardiogenic pulmonary oedema is a severe form of heart failure. Risk factors are those associated with heart failure and treatment focuses on maintaining oxygenation and improving cardiac function.
- Non-cardiogenic pulmonary oedema is a primary or secondary lung disorder. It usually occurs secondarily to a critical event such as major trauma, shock or disseminated intravascular coagulation (DIC). Treatment focuses on maintaining oxygenation and the primary, underlying disorder.

Pathophysiology

In cardiogenic pulmonary oedema, the contractility of the left ventricle is severely impaired. The ejection fraction falls because the ventricle is unable to eject the blood that enters it, causing a sharp rise in end-diastolic volume and pressure. Pulmonary hydrostatic pressures rise, ultimately exceeding the osmotic pressure of the blood. As a result, fluid leaking from the pulmonary capillaries congests interstitial tissues, decreasing lung compliance and interfering with gas exchange. As capillary and interstitial pressures increase further, the tight junctions of the alveolar walls are disrupted and the fluid enters the alveoli, along with large red blood cells (RBCs) and protein molecules. Ventilation and gas exchange are severely disrupted and hypoxia worsens.

Manifestations

The person with acute pulmonary oedema presents with classic manifestations (see box below). Dyspnoea and laboured respirations are acute and severe, accompanied by orthopnoea. Cyanosis is present and the skin is cool, clammy and diaphoretic. A productive cough with pink, frothy sputum develops due to fluid, RBCs and plasma proteins in the alveoli and airways. Crackles are heard throughout the lung fields on auscultation. As the condition worsens, lung sounds become harsher. The person often is restless and highly anxious, although severe hypoxia may cause confusion or lethargy.

As noted earlier, pulmonary oedema is a medical emergency. Without rapid and effective intervention, severe tissue hypoxia and acidosis will lead to organ system failure and death.

MANIFESTATIONS Acute pulmonary oedema

RESPIRATORY
- Tachypnoea
- Laboured respirations
- Dyspnoea
- Orthopnoea
- Paroxysmal nocturnal dyspnoea
- Cough productive of frothy, pink sputum
- Crackles, wheezes

CARDIOVASCULAR
- Tachycardia
- Hypotension
- Cyanosis
- Cool, clammy skin
- Hypoxaemia
- Ventricular gallop (S_3)

NEUROLOGICAL
- Restlessness
- Anxiety
- Sense of impending doom

INTERPROFESSIONAL CARE

Immediate treatment for acute pulmonary oedema focuses on restoring effective gas exchange and reducing fluid and pressure in the pulmonary vascular system. The individual is placed in an upright sitting position with the legs dangling to reduce venous return by trapping some excess fluid in the lower extremities. This position also facilitates breathing.

Diagnosis

Diagnostic testing is limited to assessment of the acute situation. *ABGs* are drawn to assess gas exchange and acid–base balance. Oxygen tension (PaO_2) is usually low. Initially, carbon dioxide levels ($PaCO_2$) may also be reduced because of rapid respirations. As the condition progresses, the $PaCO_2$ rises and respiratory acidosis develops (see Chapter 9). *Oxygen saturation* levels also are continuously monitored. The *chest x-ray* shows pulmonary vascular congestion and alveolar oedema. Provided the person's condition allows, *haemodynamic monitoring* is instituted. In cardiogenic pulmonary oedema, the pulmonary artery wedge pressure is elevated, usually over 25 mmHg. Cardiac output may be decreased.

Medications

Morphine is administered intravenously to relieve anxiety and improve the efficacy of breathing. It also is a vasodilator that reduces venous return and lowers left atrial pressure. Although morphine is very effective for individuals with cardiogenic pulmonary oedema, naloxone, its antidote, should be kept readily available in case respiratory depression occurs.

Oxygen is administered using a positive-pressure system that can achieve a 100% oxygen concentration. A continuous positive airway pressure (CPAP) mask system may be used or the person may be intubated and mechanical ventilation employed (see Chapter 36). Positive pressure increases alveolar pressures and gas exchange while decreasing fluid diffusion into the alveoli.

Potent loop diuretics such as frusemide are administered intravenously to promote rapid diuresis. Vasodilators such as intravenous glyceryl trinitrate may be given to improve cardiac output by reducing afterload. However, care must be taken to avoid profound hypotension. Positive inotropes may be administered to improve the myocardial contractility and cardiac output.

When the person's condition has stabilised, further diagnostic tests may be done to determine the underlying cause of pulmonary oedema and specific treatment measures directed at the cause instituted.

Nursing care

Nursing care of the person with acute pulmonary oedema focuses on relieving the pulmonary effects of the disorder. Interventions are directed towards improving oxygenation, reducing fluid volume and providing emotional support.

The nurse is often instrumental in recognising early manifestations of pulmonary oedema and initiating treatment. As with many critical conditions, emergent care is directed towards the ABCs: airway, breathing and circulation.

Nursing diagnoses and interventions

Promoting effective gas exchange and restoring an effective cardiac output are the priorities for nursing and interprofessional care of the person with cardiogenic pulmonary oedema. The experience of acute dyspnoea is terrifying for the individual; the nurse is instrumental in providing emotional support and reassurance.

Impaired gas exchange

Accumulated fluid in the alveoli and airways interferes with ventilation of the lungs. As a result, alveolar oxygen levels fall and carbon dioxide levels may rise. Reduced alveolar oxygen decreases diffusion of the gas into pulmonary capillaries. In addition, pulmonary oedema increases the distance over which gases must diffuse to cross the alveolar–capillary membrane, further reducing oxygen levels in the blood and oxygen delivery to the tissues.

- Ensure airway patency. *A patent airway is absolutely vital for pulmonary function, including ventilation and gas exchange.*

CONSIDERATION FOR PRACTICE

Assess the effectiveness of respiratory efforts and airway clearance. Pulmonary oedema increases the work of breathing. This increased effort can lead to fatigue and decreased respiratory effort.

- Assess respiratory status frequently, including rate, effort, use of accessory muscles, sputum characteristics, lung sounds and skin colour. *The status of a person in acute pulmonary oedema can change rapidly for the better or worse.*
- Place in high-Fowler's position with the legs dangling. *The upright position facilitates breathing and decreases venous return.*

- Administer oxygen as ordered by mask, CPAP mask or ventilator. *Supplemental oxygen promotes gas exchange; positive pressure increases the pressure within the alveoli, airways and thoracic cavity, decreasing venous return, pulmonary capillary pressure and fluid leak into the alveoli.*
- Encourage to cough up secretions; provide nasotracheal suctioning if necessary. *Coughing moves secretions from smaller airways into larger airways where they can be suctioned out or coughed up if necessary.*

CONSIDERATION FOR PRACTICE

Have emergency equipment readily available in case of respiratory arrest. Be prepared to assist with intubation and initiation of mechanical ventilation. Fatigue, impaired gas exchange and respiratory acidosis can lead to respiratory and cardiac arrest.

Decreased cardiac output

Cardiogenic pulmonary oedema usually is caused by either an acute decrease in myocardial contractility or increased workload that exceeds the ability of the left ventricle. The significant decrease in cardiac output increases pressure within the pulmonary vascular system and triggers compensatory mechanisms that increase the heart rate and blood volume. These compensatory mechanisms further increase the workload of the failing heart.

- Monitor vital signs, haemodynamic status and rhythm continuously. *Acute pulmonary oedema is a critical condition and cardiovascular status can change rapidly.*
- Assess heart sounds for possible S_3, S_4 or murmurs. *These abnormal heart sounds may be due to excess fluid.*
- Initiate an intravenous line for medication administration. Administer morphine, diuretics, vasodilators, bronchodilators and positive inotropic medications (e.g. digoxin, dopamine or dobutamine) as ordered. *These drugs reduce cardiac work and improve contractility.*
- Keep accurate intake and output records. Restrict fluids as ordered. *Fluids may be restricted to reduce vascular volume and cardiac work.*

Fear and anxiety

Acute pulmonary oedema is a very frightening experience for everyone (including the nurse).

- Provide emotional support for the person and their family members. *Fear and anxiety stimulate the sympathetic nervous system, which can lead to ineffective respiratory patterns and interfere with cooperation with care measures.*
- Explain all procedures and the reasons they are performed to the person and their family members. Keep information brief and to the point. Use short sentences and a reassuring tone. *Anxiety and fear interfere with the ability to assimilate information; brief, factual information and reassurance reduce anxiety and fear.*
- Maintain close contact and provide reassurance that recovery from acute pulmonary oedema is often as dramatic as its onset.

Answer questions and provide accurate information in a caring manner. *Knowledge reduces anxiety and psychological stress associated with this critical condition.*

CONSIDERATION FOR PRACTICE

Insert an indwelling catheter; record output hourly. Urine output of less than 30 mL/h indicates impaired renal perfusion due to severely impaired cardiac output and a risk of renal failure or other complications.

Community-based care

During the acute period, teaching is limited to immediate care measures. Once the acute episode of pulmonary oedema has resolved, teach the person and their family about its underlying cause and prevention of future episodes. If pulmonary oedema follows an acute MI, include information related to CHD and the acute AMI, as well as information related to heart failure. Review the teaching and home care needs for the person with these disorders.

THE PERSON WITH AN INFLAMMATORY OR INFECTIVE CONDITION OF THE HEART

Infective conditions include rheumatic heart disease and conditions that result in inflammation of any layer of the cardiac tissue. Manifestations of inflammatory heart disorders range from very mild to life threatening. This section discusses the causes and management of rheumatic heart disease, endocarditis, myocarditis and pericarditis.

THE PERSON WITH RHEUMATIC FEVER AND RHEUMATIC HEART DISEASE

Rheumatic fever is a systemic inflammatory disease caused by an abnormal immune response to pharyngeal infection by group A beta-haemolytic streptococci. Rheumatic fever usually is a self-limiting disorder, although it may become recurrent or chronic. The heart commonly is involved in the acute inflammatory process, and approximately 60% of people with rheumatic fever develop rheumatic heart disease (Wallace, 2014). Rheumatic heart disease frequently damages the heart valves and is a major cause of mitral and aortic valve disorders discussed in the next section of this chapter.

Incidence, prevalence and risk factors

In Australia, rheumatic fever is more common than in most other developed countries. As described earlier, rheumatic heart disease (RHD) remains a significant problem for northern and central Indigenous Australians, although RHD is relatively uncommon

in other Australian populations. Indigenous Australian females are 35 times and Indigenous males 30 times more likely to develop RHD than non-Indigenous Australians. The incidence of RHD is considered to be underreported as it is often difficult to diagnose (RHD Australia, 2012).

Rheumatic fever and rheumatic heart disease remain significant public health problems in many developing countries. Globally it is estimated that there are over 15.6 million people with rheumatic heart disease.

Risk factors for streptococcal infections of the pharynx include environmental and economic factors such as crowded living conditions, malnutrition, immunodeficiency and poor access to healthcare (RHD Australia, 2012).

Pathophysiology

The pathophysiology of rheumatic fever is not yet totally understood. It results from an abnormal immune response to M proteins on group A beta-haemolytic streptococcal bacteria. These antigens can bind to cells in the heart, muscles and brain. They also bind with receptors in synovial joints, provoking an autoimmune response (Wallace, 2014). The resulting immune response to the bacteria also leads to inflammation in tissues containing these M proteins. Inflammatory lesions develop in connective tissues on the heart, joints and skin. The antibodies may remain in the serum for up to 6 months following the initiating event. See Chapters 11 and 12 for more information about the immune system and inflammatory response.

FAST FACTS

- 98% of all cases of ARF recorded in the Northern Territory were experienced by Aboriginal and Torres Strait Islander people.
- Aboriginal and Torres Strait Islander people are 26 times more likely to develop RHD than non-Indigenous Australians.
- Aboriginal and Torres Strait Islander people are 6.7 times more likely to be hospitalised for ARF or RHD than non-Indigenous Australians.
- Aboriginal and Torres Strait Islander people are 1.75 times less likely to undergo a heart valve procedure for RHD than non-Indigenous Australians.
- Aboriginal and Torres Strait Islander people are 5 times more likely to die from RHD than non-Indigenous Australians.

Source: AIHW (2013).

Carditis, inflammation of the heart, develops in 30–60% of people with rheumatic fever. The inflammatory process usually involves all three layers of the heart—the pericardium, myocardium and endocardium. *Aschoff bodies*, localised areas of tissue necrosis surrounded by immune cells, develop in cardiac tissues. Pericardial and myocardial inflammation tends to be mild and self-limiting. Endocardial inflammation, however, causes swelling and erythema of valve structures and small vegetative lesions on valve leaflets. As the inflammatory process resolves, fibrous scarring occurs, causing deformity.

Rheumatic heart disease (RHD) is a slowly progressive valvular deformity that may follow acute or repeated attacks of rheumatic fever. Valve leaflets become rigid and deformed; commissures (openings) fuse and the chordae tendineae fibrose and shorten. This results in stenosis or regurgitation of the valve. In **stenosis**, a narrowed fused valve obstructs forward blood flow. **Regurgitation** occurs when the valve fails to close properly (an *incompetent* valve), allowing blood to flow back through it. Valves on the left side of the heart are usually affected; the mitral valve is most frequently involved.

Manifestations

Manifestations of acute rheumatic fever (ARF) typically follow the initial streptococcal infection by about 2 to 3 weeks. Fever and migratory joint pain are often initial manifestations. The knees, ankles, hips and elbows are common sites of swelling and inflammation. *Erythema marginatum* is a temporary non-pruritic skin rash characterised by red lesions with clear borders and blanched centres usually found on the trunk and proximal extremities. Neurological symptoms of rheumatic fever, although rare in adults, may range from irritability and an inability to concentrate to clumsiness and involuntary muscle spasms. See the 'Manifestations' box below.

Manifestations of carditis include chest pain, tachycardia, a pericardial friction rub or evidence of heart failure. On auscultation,

MANIFESTATIONS Acute rheumatic fever

CARDIAC
- Chest pain
- Friction rub
- Heart murmur

MUSCULOSKELETAL
- *Migratory polyarthritis*: redness, heat, swelling, pain and tenderness of more than one joint
- Usually affects large joints of extremities

SKIN
- *Erythema marginatum*: transitory pink, non-pruritic, macular lesions on trunk or inner aspect of upper arms or thighs
- *Subcutaneous nodules* over extensors of wrist, elbow, ankle and knee joints

NEUROLOGICAL
- *Sydenham's chorea:* irritability, behaviour changes; sudden, jerky, involuntary movements

BLOOD TESTS
- Serum antistreptolysin O (ASO) antibodies titres are measured to confirm the diagnosis. Serum ASO rises within 1–2 weeks of infection and reaches a maximum at about 3–6 weeks after infection.
- Serum antideoxyribonuclease B (anti-DNase B) antibodies are also commonly measured to increase the sensitivity of the testing. It is produced by all group A beta-haemolytic streptococci. Serum anti-DNase B peaks 4–8 weeks after infection, remains elevated for several months, and declines slowly.

TABLE 30.6 Major and minor manifestations of rheumatic fever

	HIGH-RISK GROUPS	ALL OTHER GROUPS
Major manifestations	Carditis (including subclinical evidence of rheumatic valve disease on echocardiogram) Polyarthritis, aseptic monoarthritis or polyarthralgia Chorea Erythema marginatum Subcutaneous nodules	Carditis (excluding subclinical evidence of rheumatic valvulitis on echocardiogram) Polyarthritis Chorea Erythema marginatum Subcutaneous nodules
Minor manifestations	Monoarthralgia Fever ESR ≥ 30 mm/h or CRP level ≥ 30 mg/L Prolonged PR interval on ECG	Fever Polyarthralgia or aseptic monoarthritis ESR ≥ 30 mm/h or CRP level ≥ 30 mg/L Prolonged PR interval on ECG

CRP = C-reactive protein, ECG = electrocardiogram, ESR = erythrocyte sedimentation rate.
Source: RHD Australia, National Heart Foundation of Australia and the Cardiac Society of Australia and New Zealand (2012). *Australian guideline for prevention, diagnosis and management of acute rheumatic fever and rheumatic heart disease* (2nd ed.). Retrieved from www.rhdaustralia.org.au/sites/default/files/guideline_0.pdf.

an S_3, S_4 or heart murmur may be heard. Cardiomegaly or pericardial effusion may develop. See Table 30.6 for other manifestations.

INTERPROFESSIONAL CARE

Management of the person with rheumatic heart disease focuses on eradicating the streptococcal infection and managing the manifestations of the disease. Carditis and resulting heart failure are treated with measures to reduce the inflammatory process and manage the heart failure. Activities are limited, but bed rest is not generally ordered.

Diagnosis

As Australia has a significant incidence of rheumatic heart disease, RHD Australia, the National Heart Foundation of Australia and the Cardiac Society of Australia and New Zealand (2012) have modified the two previously used tools (Jones criteria and the WHO criteria) to develop the 2012 Australian guidelines for the diagnosis of ARF. In addition to the history and physical examination, a number of laboratory and diagnostic tests may be ordered for the person with suspected rheumatic fever. For diagnosis guidelines, see Tables 30.7 and 30.8.

TABLE 30.7 Australian diagnostic criteria for acute rheumatic fever, 2012

MANIFESTATION	HIGH RISK	LOW RISK
Carditis	Major	Major
Subclinical carditis	Major	n/a
Prolonged PR interval	Minor	Minor
Polyarthritis	Major	Major
Polyarthralgia	Major	Minor
Aseptic monoarthritis	Major	Minor
Monoarthralgia	Major	n/a
Subcutaneous nodules	Major	Major
Sydenham's chorea	Major	Major
Erythema marginatum	Major	Major
Fever	Minor	Minor
Inflammatory	Minor	Minor
Evidence of recent streptococcal infection	Required	Required

Source: RHD Australia, National Heart Foundation of Australia and the Cardiac Society of Australia and New Zealand (2012). *Australian guideline for prevention, diagnosis and management of acute rheumatic fever and rheumatic heart disease* (2nd ed.). Retrieved from www.rhdaustralia.org.au/sites/default/files/guideline_0.pdf.

- *Full blood count (FBC)* and *erythrocyte sedimentation rate (ESR)* are indicators of the inflammatory process. The WBC count is elevated and the number of RBCs may be low due to the inflammatory inhibition of erythropoiesis. The ESR, a general indicator of inflammation, is elevated.

Medications

As soon as rheumatic fever is diagnosed, antibiotics are started to eliminate the streptococcal infection. Intramuscular benzathine penicillin G (BPG) is the antibiotic of choice to treat group A streptococci. A single dose of intramuscular BPG or a 10-day dose of oral penicillin V is administered. Erythromycin is used if the person is allergic to penicillin (RHD Australia, 2012).

Joint pain and fever are treated with salicylates (e.g. aspirin), ibuprofen or another non-steroidal anti-inflammatory drug (NSAID); corticosteroids may be used for severe pain due to inflammation. See Chapter 12 for information about the use of these anti-inflammatory medications.

Nursing care

Health promotion

Rheumatic fever is preventable. Prompt identification and treatment of a person's streptococcal throat infection helps to decrease spread of the pathogen and the risk of rheumatic fever. Characteristics of streptococcal pharyngitis include a sore throat,

TABLE 30.8 Diagnosis guidelines for rheumatic heart disease

	HIGH-RISK GROUPS	ALL OTHER GROUPS
Definite initial episode of ARF	2 major OR 1 major and 2 minor manifestations, PLUS evidence of a preceding group A streptococcal infection	As for high-risk groups
Definitive recurrent episode of ARF in a patient with known past ARF or RHD	2 major OR 1 major and 1 minor OR 3 minor manifestations, PLUS evidence of a preceding group A streptococcal infection	As for high-risk groups
Probable ARF (first episode or recurrence)	A clinical presentation that falls short by either one major or one minor manifestation, or the absence of streptococcal serology results, but one in which ARF is considered the most likely diagnosis. Such cases should be further categorised according to the level of confidence with which the diagnosis is made: • highly-suspected ARF • uncertain ARF	As for high-risk groups

Source: RHD Australia, National Heart Foundation of Australia and the Cardiac Society of Australia and New Zealand (2012). *Australian guideline for prevention, diagnosis and management of acute rheumatic fever and rheumatic heart disease* (2nd ed.). Retrieved from www.rhdaustralia.org.au/sites/default/files/guideline_0.pdf.

odynophagia, headache, fever, tonsillopharyngeal erythema, swollen uvula and lymphadenopathy. The importance of finishing the complete course of medication to eradicate the pathogen must be emphasised. As the route of choice of antibiotic administration is intramuscular, methods to reduce pain at the injection site should be implemented. Simple interventions include: choosing a 23-gauge needle; ensuring the alcowipe is dry before inserting the needle; applying pressure on site (with thumb) for 10 seconds before administration; injecting slowly (over > 2–3 minutes); and using distraction techniques to assist with reducing pain.

Assessment

Assess the person at risk of rheumatic fever (prolonged, untreated or recurrent pharyngitis) for possible manifestations.

- *Health history:* complaints of recent sore throat with fever, difficulty swallowing and general malaise; treatment measures; previous history of strep throat or rheumatic fever; history of heart murmur or other cardiac problems; current medications.
- *Physical examination:* vital signs, including temperature; skin colour, presence of rash on trunk or proximal extremities; mental status; evidence of inflamed joints; heart and lung sounds.
- *Diagnostic tests:* full blood count with differential, ESR, CRP results, throat culture, ECG and echocardiogram.

Nursing diagnoses and interventions

The nursing care focus for the person with RHD is on providing supportive care and preventing complications. Teaching to prevent recurrence of rheumatic fever is extremely important. *Pain* and *Activity intolerance* are priority nursing diagnoses for the person with rheumatic fever and RHD.

Acute pain

Joint and chest pain due to acute inflammation is common in rheumatic fever. Pain and inflammation may interfere with rest and healing.

- Administer anti-inflammatory drugs as ordered. Promptly report manifestations of aspirin toxicity, including tinnitus, vomiting and gastrointestinal bleeding. Give aspirin and other NSAIDs with food, milk or antacids to minimise gastric irritation. *Joint pain and fever may be treated with anti-inflammatory agents such as aspirin and NSAIDs. When used for its anti-inflammatory effect, aspirin doses may be high and it is given around the clock (e.g. every 4 hours). Steroids may be prescribed for severe carditis.*
- Provide warm compresses for local pain relief of acutely inflamed joints. *Warmth helps relieve pain associated with inflamed joints by reducing inflammation.*
- Auscultate heart sounds as indicated (every shift or each home visit). Notify the doctor if a pericardial friction rub or a new murmur develops. *A friction rub is produced as inflamed pericardial surfaces rub against each other. This also stimulates pain receptors and may increase discomfort.*

Activity intolerance

The person with acute carditis or RHD may develop heart failure if the heart is unable to supply enough oxygen to meet the body's demand. Manifestations of fatigue, weakness and dyspnoea on exertion may result.

- Explain the importance of activity limitations and reinforce teaching as needed. *Activities are limited during the acute phase of carditis to reduce the workload of the heart. Understanding the rationale improves cooperation with the limitations.*
- Encourage social and diversional activities such as visits with friends and family, reading, playing cards or board games, watching television and listening to music or talking books. *Diversional activities provide a focus for the person whose physical activities must be limited.*
- Encourage gradual increases in activity, monitoring for evidence of intolerance or heart failure. Consult a cardiac rehabilitation specialist to help design an activity progression schedule. *Gradual activity progression is encouraged as the person's condition improves. Activity tolerance is monitored and activities modified as needed.*

Community-based care

Most people with rheumatic fever and carditis do not require hospitalisation. Teaching for home care focuses on both acute care and preventing recurrences and further tissue damage. Include the following topics:

- the importance of completing the full course of antibiotic therapy and continuing antibiotic prophylaxis as prescribed. For the individual with chronic RHD, include the importance of antibiotic prophylaxis for invasive procedures (e.g. dental care, endoscopy or surgery) to prevent bacterial endocarditis. Pamphlets on endocarditis prevention are helpful reminders and are available from the National Heart Foundation
- preventive dental care and good oral hygiene to maintain oral health and prevent gingival infections, which can lead to recurrence of the disease
- early recognition of streptococcal sore throat and appropriate treatment for both the individual and their family members
- early manifestations of heart failure to report to the doctor
- prescribed medications, including their dosage, route, intended and potential adverse effects, and manifestations to report to the doctor
- dietary sodium restriction if ordered or recommended. A high-carbohydrate, high-protein diet may be recommended to facilitate healing and combat fatigue.

Refer for home health services or household assistance as indicated.

THE PERSON WITH INFECTIVE ENDOCARDITIS

Endocarditis, inflammation of the endocardium, can involve any portion of the endothelial lining of the heart. The valves usually are affected. Endocarditis is usually infectious in nature, characterised by colonisation or invasion of the endocardium and heart valves by a pathogen.

Incidence and risk factors

Endocarditis is relatively uncommon in Australia. In 2013, endocarditis was listed as the cause of death for only 349 people, which equates to 0.24% of all deaths that year (ABS, 2015), and incidence statistics are difficult to locate. Nevertheless, a little over 2000 people were admitted to hospital with a primary diagnosis of endocarditis in 2012–2013 (AIHW, 2015).

The greatest risk factor for endocarditis is previous heart damage. Lesions develop on deformed valves, on valve prostheses or in areas of tissue damage due to congenital deformities or ischaemic disease. The left side of the heart—the mitral valve, in particular—is usually affected. Intravenous drug use also is a significant risk factor. The right side of the heart usually is affected in these individuals. Other risk factors include invasive catheters (e.g. a central venous catheter, haemodynamic monitoring or an indwelling urinary catheter), dental procedures or poor dental health, and recent heart surgery.

FAST FACTS

- Subacute bacterial endocarditis develops more slowly and usually occurs in people with previous heart valve damage.
- Acute bacterial endocarditis has an abrupt onset and typically affects people with no previous history of heart problems.

Prosthetic valve endocarditis (PVE) may occur in individuals with a mechanical or tissue valve replacement. This infection may develop in the early postoperative period (within 2 months after surgery) or late. Prosthetic valve endocarditis accounts for 10–20% of endocarditis cases (O'Connor & Kiernan, 2015). Early PVE occurs within 60 days of valve implantation and is usually due to prosthetic valve contamination during surgery or perioperative bacteraemia. Its course often is rapid and mortality is high. Late-onset PVE occurring after 60 days following surgery more closely resembles subacute endocarditis.

Pathophysiology

Entry of pathogens into the bloodstream is required for infective endocarditis to develop. Bacteria may enter through oral lesions, during dental work or invasive procedures such as intravenous catheter insertion, surgery or urinary catheterisation; during intravenous drug use; or as a result of infectious processes such as urinary tract or upper respiratory infection.

The initial lesion is a sterile platelet–fibrin vegetation formed on damaged endothelium (see Figure 30.4). In acute infective endocarditis, these lesions develop on healthy valve structures, although the mechanism is unknown. In subacute endocarditis, they usually develop on already damaged valves or in endocardial tissue that has been damaged by abnormal pressures or blood flow within the heart.

Organisms that have invaded the blood colonise these vegetations. The vegetation enlarges as more platelets and fibrin are attracted to the site and cover the infecting organism. This covering 'protects' the bacteria from quick removal by immune defences such as phagocytosis by neutrophils, antibodies and

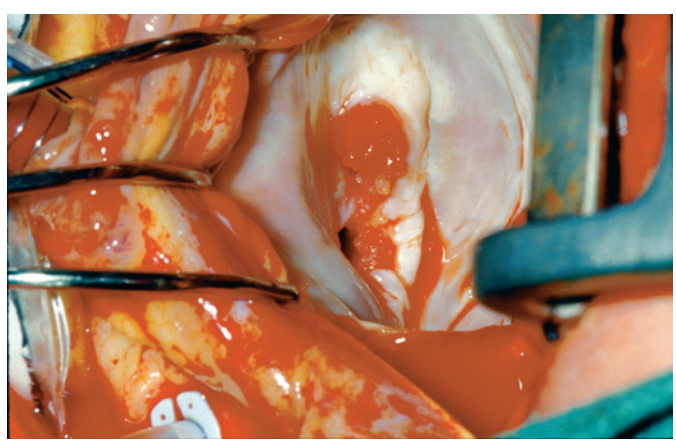

FIGURE 30.4 ■ A vegetative lesion of bacterial endocarditis

Source: M. English/Custom Medical Stock Photo, Inc.

complement. Vegetations may be singular or multiple. They expand while loosely attached to the edges of the valve. Friable vegetations can break or shear off, embolising and travelling through the bloodstream to other organ systems. When they lodge in small vessels, they may cause haemorrhages, infarcts or abscesses. Ultimately, the vegetations scar and deform the valves and cause turbulence of blood flowing through the heart. Heart valve function is affected, either obstructing forward blood flow or closing incompletely.

Endocarditis is classified by its acuity and disease course. *Acute infective endocarditis* (IE) has an abrupt onset and is a rapidly progressive, severe disease. Further classifications can be made as to whether the endocarditis has occurred on a person's native valve (NVE), on a prosthetic valve (PVE) or as a result of intravenous drug abuse (IVDA IE). Although almost any organism can cause infective endocarditis, virulent organisms such as *Staphylococcus aureus* cause a more abrupt onset and destructive course. *S. aureus* is commonly the infective organism in acute endocarditis. In contrast, *subacute infective endocarditis* has a more gradual onset, with predominant systemic manifestations. It is more likely to occur in people with pre-existing heart disease and is commonly caused by alpha-haemolytic streptococci or enterococci. In IVDA infective endocarditis, *S. aureus* is the most common organism with the majority of cases affecting the tricuspid valve (Brusch, 2014).

Manifestations

The manifestations of infective endocarditis often are non-specific (see the box below). A temperature above 39.4ºC and flu-like symptoms develop, accompanied by cough, shortness of breath and joint pain. The presentation of acute staphylococcal endocarditis is more severe, with a sudden onset, chills and a high fever. Heart murmurs are heard in 90% of individuals with infective endocarditis. An existing murmur may worsen or a new murmur may develop.

Splenomegaly is common in chronic disease. Peripheral manifestations of infective endocarditis result from microemboli or circulating immune complexes. These manifestations include:

- *Petechiae:* small, purplish-red haemorrhagic spots on the trunk, conjunctiva and mucous membranes.
- *Splinter haemorrhages:* haemorrhagic streaks under the fingernails or toenails.
- *Osler's nodes:* small, reddened, painful raised growths on finger and toe pads.
- *Janeway lesions:* small, non-tender, purplish-red macular lesions on the palms of the hands and soles of the feet.
- *Roth's spots:* small, whitish spots (cottonwool spots) seen on the retina.

Complications

Embolisation of vegetative fragments may affect any organ system, particularly the lungs, brain, kidneys and the skin and mucous membranes, with resulting organ infarction. Other common complications of infective endocarditis include heart failure, abscess and aneurysms due to infiltration of the arterial wall by organisms. Without treatment, endocarditis is almost universally fatal; fortunately, antibiotic therapy is usually effective to treat this disease.

MANIFESTATIONS Infective endocarditis

- Chills and fever
- General malaise, fatigue
- Arthralgias
- Cough, dyspnoea
- Heart murmur
- Anorexia, abdominal pain
- Petechiae, splinter haemorrhages
- Splenomegaly

INTERPROFESSIONAL CARE

Eradicating the infecting organism and minimising valve damage and other adverse consequences of infective endocarditis are the priorities of care.

Diagnosis

There are no definitive tests for infective endocarditis, but diagnostic tests help establish the diagnosis.

- *Blood cultures* usually are positive for bacteria or other pathogens. Blood cultures are considered positive when a typical infecting organism is identified from two or more separate blood cultures (drawn from different sites and/or at different times, e.g. 12-hour intervals).
- *Echocardiography* (either transthoracic or transoesophageal) to visualise vegetations can be diagnostic for infective endocarditis when combined with positive blood cultures. See Chapter 28 for more information about echocardiography.
- *Serological immune testing* for circulating antigens to typical infective organisms may be done.

Other diagnostic tests may include the FBC, ESR, serum creatinine, chest x-ray and an electrocardiogram.

Medications

Preventing endocarditis in individuals at high risk is important. Antibiotics are commonly prescribed for individuals with pre-existing valve damage or heart disease prior to high-risk procedures.

Antibiotic therapy effectively treats infective endocarditis in most cases. The goal of therapy is to eradicate the infecting organism from the blood and vegetative lesions in the heart. The fibrin covering that protects colonies of organisms from immune defences also protects them from antibiotic therapy. Therefore, an extended course of multiple intravenous antibiotics is required.

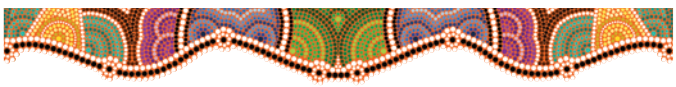
Following blood cultures, antibiotic therapy is initiated with drugs known to be effective against the most common infecting organisms: *Staphylococcus*, *Streptococcus* and *Enterococcus* species. The initial regimen will include an antibiotic to which the causative organism is sensitive. See Chapter 11 for the nursing implications for antibiotic therapy.

Surgery

Some individuals with infective endocarditis require surgery to:

- replace severely damaged valves
- remove large vegetations at risk of embolisation
- remove a valve that is a continuing source of infection that does not respond to antibiotic therapy.

The most common indication for surgery is valvular regurgitation that causes heart failure and does not respond to medical therapy. When the infection has not responded to antibiotic therapy within 7 to 10 days, the infected valve may be replaced to facilitate eradication of the organism. Individuals with fungal endocarditis usually require surgical intervention. More information on valve replacement surgery is provided in the section on valve disorders.



Nursing care

Health promotion

Prevention of endocarditis is vital in susceptible people. Education is a key part of prevention. Use every opportunity to educate individuals and the public about the risks of intravenous drug use, including endocarditis. Discuss preventive measures with all individuals with specific risk factors, such as a heart murmur or known heart disease.

Assessment

Assessment related to infective endocarditis includes identifying risk factors and manifestations of the disease.

- *Health history:* complaints of persistent flu-like symptoms, fatigue, shortness of breath and activity intolerance; history of recent dental work or other invasive procedures; known heart murmur, valve or other heart disorder; recent intravenous drug use.
- *Physical examination:* vital signs, including temperature; apical pulse and heart sounds; rate and ease of respirations, lung sounds; skin colour, temperature and presence of petechiae or splinter haemorrhages.
- *Diagnostic tests:* FBC and differential, ESR; blood culture and sensitivity results; echocardiogram reports.

Nursing diagnoses and interventions

Nursing care focuses on managing the manifestations of endocarditis, administering antibiotics and teaching the person and their family members about the disorder. In addition to the diagnoses identified below, nursing diagnoses and interventions for heart failure also may be appropriate for individuals with infective endocarditis.

Risk of imbalanced body temperature

Fever is common in individuals with infective endocarditis. It may be acutely elevated and accompanied by chills, particularly with acute infective endocarditis. The inflammatory process initiates a cycle of events that affects the regulation of temperature and causes discomfort.

- Record temperature every 2 to 4 hours. Report temperature above 38.5ºC. Assess for complaints of discomfort. *Fever is usually low grade (38ºC) in infective endocarditis; higher temperatures may cause discomfort. The temperature usually returns to normal within 1 week after initiation of antibiotic therapy. Continued fever may indicate a need to modify the treatment regimen.*
- Obtain blood cultures as ordered, before initial antibiotic dose. *Initial blood cultures are obtained before antibiotic therapy is started to obtain adequate organisms to culture and identify. Follow-up cultures are used to assess the effectiveness of therapy.*
- Provide anti-inflammatory or antipyretic agents as prescribed. *Fever may be treated with anti-inflammatory or antipyretic agents such as aspirin, ibuprofen or paracetamol.*
- Administer antibiotics as ordered; obtain peak and trough drug levels as indicated. Intravenous antibiotics are given to eradicate the pathogen. *Peak and trough levels are used to evaluate the dose effectiveness in maintaining a therapeutic blood level.*

Risk of ineffective tissue perfusion

Embolisation of vegetative lesions can threaten tissue and organ perfusion. Vegetations from the left heart may lodge in arterioles or capillaries of the brain, kidneys or peripheral tissues, causing infarction or abscess. A large embolism can cause manifestations of stroke or transient ischaemic attack, renal failure or tissue ischaemia. Emboli from the right side of the heart become entrapped in pulmonary vasculature, causing manifestations of pulmonary embolism.

- Assess for, document and report manifestations of decreased organ system perfusion:
  a. *Neurological:* changes in level of consciousness, numbness or tingling in extremities, hemiplegia, visual disturbances or manifestations of stroke.
  b. *Renal:* decreased urine output, haematuria, elevated urea or creatinine.
  c. *Pulmonary:* dyspnoea, haemoptysis, diminished breath sounds, restlessness, sudden chest or shoulder pain.
  d. *Cardiovascular:* chest pain radiating to jaw or arms, tachycardia, anxiety, tachypnoea, hypotension.

  All major organs and tissues and the microcirculation may be affected by emboli when vegetations break off due to turbulent blood flow. Emboli may cause manifestations of organ dysfunction. The most devastating effects of emboli are in the brain and the myocardium, with resulting infarctions. Intravenous drug users have a high risk of pulmonary emboli as a result of right-sided endocardial fragments.
- Assess and document skin colour and temperature, quality of peripheral pulses and capillary refill. *Peripheral emboli affect tissue perfusion, with a risk of tissue necrosis and possible extremity loss.*

Ineffective health maintenance

The person with endocarditis is often treated in the community. Teaching about disease management and prevention of possible recurrences of endocarditis is vital.

- Demonstrate intravenous catheter site care and intermittent antibiotic administration if the person and their family will manage therapy. Have the person and/or significant other redemonstrate appropriate techniques. *Intermittent antibiotic infusions may be managed by the person or family members, or the individual may go to an outpatient facility to receive the infusions. Appropriate site care is necessary to reduce the risk of trauma and infection.*
- Explain the actions, doses, administration and desired and adverse effects of prescribed drugs. Identify manifestations to be reported to the doctor. Provide practical information about measures to reduce the risk of superinfection (e.g. the concomitant use of antithrush preparations). *Careful compliance with prescribed drug therapy is vital to eradicate the infecting organism. Antibiotic therapy can, however, cause superinfections such as candidiasis due to elimination of normal body flora.*
- Teach the person about the function of heart valves and the effects of endocarditis on heart function. Include a simple definition of endocarditis and explain the risk of its recurrence. *Information helps the person and their family understand endocarditis, its treatment and its effects. Understanding increases compliance.*
- Describe the manifestations of heart failure to be reported to the doctor. *Evidence of heart failure may necessitate modification of the treatment regimen or replacement of infected valves.*
- Encourage good dental hygiene and mouth care and regular dental checkups. Teach the person how to prevent bleeding from the gums and avoid developing mouth ulcers (e.g. gentle tooth brushing, ensuring that dentures fit properly and avoiding toothpicks, dental floss and high-flow water devices). *The oropharynx harbours streptococci, which are common causes of endocarditis. Bleeding gums offer an opportunity for bacteria to enter the bloodstream.*
- Encourage the person to avoid people with upper respiratory infections. *Streptococci are normal pathogens in the upper respiratory tract; exposure to people with upper respiratory infections may increase the risk of infection.*
- If anticoagulant therapy is ordered, explain its actions, administration and major side effects. Identify manifestations of bleeding to be promptly reported to the doctor. *Individuals with valve disease or a prosthetic valve following infective endocarditis may require continued anticoagulant therapy to prevent thrombi and emboli. Knowledge is vital for appropriate management of anticoagulant therapy and prevention of complications.*

CONSIDERATION FOR PRACTICE

Stress the importance of notifying all care providers of valve disease, heart murmur or valve replacement before undergoing invasive procedures. Invasive procedures provide a portal of entry for bacteria. A history of valve disease increases the risk of the development or recurrence of endocarditis.

Community-based care

When preparing the person with infective endocarditis for home care, provide teaching as outlined for the nursing diagnosis of *Ineffective health maintenance*. In addition, discuss the following topics:

- Although serious and frightening, infective endocarditis can usually be treated effectively with intravenous antibiotics.
- The importance of promptly reporting any unusual manifestation, such as a change in vision, sudden pain or weakness, so that interventions to control complications can be promptly implemented.
- The rationale for all treatments and procedures.
- Preventing recurrences of infective endocarditis.
- The importance of maintaining contact with the doctor for follow-up care and monitoring for long-term effects such as progressive valve damage and dysfunction.
- If appropriate, explain the risks associated with intravenous drug use.

Provide educational materials on infective endocarditis from the National Heart Foundation. Refer as appropriate to home health or home intravenous therapy services. Refer the person and their family members or significant others as appropriate to a drug or substance abuse treatment program or facility. Provide follow-up care to ensure compliance with the referral and treatment plan.

THE PERSON WITH MYOCARDITIS

Myocarditis is inflammation of the heart muscle. It usually results from an infectious process, but also may occur as an immunological response or due to the effects of radiation, toxins or drugs.

Incidence and risk factors

Myocarditis may occur at any age and is more common in men than women. Factors that alter immune response (e.g. malnutrition, alcohol use, immunosuppressive drugs, exposure to radiation, stress and advanced age) increase the risk of myocarditis. It also is a common complication of rheumatic fever and pericarditis. Myocarditis can also be an adverse effect of a common antipsychotic, clozapine.

Pathophysiology

Myocardial cells are damaged by an inflammatory process that causes local or diffuse swelling and damage. Infectious

agents infiltrate interstitial tissues, forming abscesses. Autoimmune injury may occur when the immune system destroys not only the invading pathogen but also myocardial cells. The extent of damage to cardiac muscle ultimately determines the long-term outcome of the disease. Viral myocarditis usually is self-limiting; it may progress, however, to become chronic, leading to dilated cardiomyopathy. (See later in this chapter.) Severe myocarditis may lead to heart failure.

Manifestations

The manifestations of myocarditis depend on the degree of myocardial damage. The person may be asymptomatic. Non-specific manifestations of inflammation, such as fever, fatigue, general malaise, dyspnoea, palpitations and arthralgias, may be present. A non-specific febrile illness or upper respiratory infection often precedes the onset of myocarditis symptoms. Abnormal heart sounds such as muffled S_1, an S_3, murmur and pericardial friction rub may be heard. In some cases, manifestations of myocardial infarction, including chest pain, may occur.

INTERPROFESSIONAL CARE

Myocarditis treatment focuses on resolving the inflammatory process to prevent further damage to the myocardium.

Diagnosis

Diagnostic studies may be ordered to help diagnose myocarditis:

- *Electrocardiography* may show transient ST-segment and T-wave changes, as well as arrhythmias and possible heart block.
- *Cardiac markers*, such as creatinine kinase (CK), troponin T (cT_nT) and troponin I (cT_nI), may be elevated, indicating myocardial cell damage.
- *Endomyocardial biopsy* to examine myocardial cells is necessary to establish a definitive diagnosis; patchy cell necrosis and the inflammatory process can be identified.

Medications

If appropriate, antimicrobial therapy is used to eradicate the infecting organism. Antiviral therapy with interferon alpha may be instituted. Immunosuppressive therapy with corticosteroids or other immunosuppressive agents (see Chapter 12) may be used to minimise the inflammatory response. Heart failure is treated as needed, using ACE inhibitors and other cardiac drugs. Individuals with myocarditis often are particularly sensitive to the effects of digoxin, so it is used with caution. Other medications used in treating myocarditis include antiarrhythmic agents to control arrhythmias and anticoagulants to prevent emboli.

Bed rest and activity restrictions are ordered during the acute inflammatory process to reduce myocardial work and prevent myocardial damage. Activities may be limited for as long as 6 months to a year (Tang, 2014).

Nursing care

Nursing care is directed at decreasing myocardial work and maintaining cardiac output. Both physical and emotional rest are indicated because anxiety increases myocardial oxygen demand. Haemodynamic parameters and the ECG are monitored closely, especially during the acute phase of the illness. Activity tolerance, urine output and heart and breath sounds are frequently assessed for manifestations of heart failure. Consider the following nursing diagnoses for the person with myocarditis:

- *Risk of activity intolerance* related to impaired cardiac muscle function manifested by inability to undertake activities of daily living independently.
- *Risk of decreased cardiac output* related to myocardial inflammation manifested by hypotension, tachycardia, and shortness of breath.
- *Risk of fatigue* related to inflammation and impaired cardiac output manifested by inability to mobilise or perform self-care without resting frequently.
- *Risk of anxiety* related to possible long-term effects of the disorder manifested by verbal statements and behaviour consistent with anxiety.
- *Risk of excess fluid volume* related to compensatory mechanisms for decreased cardiac output manifested by orthopnoea, dyspnoea, oedema and weight gain.

Community-based care

Include the following topics when preparing the person with myocarditis for home care:

- activity restrictions and other prescribed measures to reduce cardiac workload
- early manifestations of heart failure to report to the doctor
- the importance of following the prescribed treatment regimen
- any recommended dietary modifications (such as a low-sodium diet for heart failure)
- prescribed medications, their purpose, doses and possible adverse effects
- the importance of adhering to the treatment plan and recommended follow-up appointments to reduce the risk of long-term consequences such as cardiomyopathy.

THE PERSON WITH PERICARDITIS

The pericardium is the outermost layer of the heart. It is a two-layered membranous sac with a thin layer of serous fluid (normally no more than 30 to 50 mL) separating the layers. It protects and cushions the heart and the great vessels, provides a barrier to infectious processes in adjacent structures, prevents displacement of the myocardium and blood vessels, and prevents sudden distension of the heart.

BOX 30.3 Selected causes of pericarditis

Infectious
- Viruses
- Bacteria
- Fungi
- Parasites

Non-infectious
- Myocardial and pericardial injury
- Uraemia
- Neoplasms
- Radiation
- Trauma or surgery
- Myxoedema
- Autoimmune disorders
- Rheumatic fever
- Connective tissue diseases
- Some drugs
- Post-cardiac injury

Pericarditis is the inflammation of the pericardium. Pericarditis may be a primary disorder or may develop secondarily to another cardiac or systemic disorder. Some possible causes of pericarditis are listed in Box 30.3. Viral infections are more common than bacterial and fungal pericarditis (Spangler, 2014). Other types of pericarditis can develop post myocardial infarction and post cardiotomy (following open-heart surgery).

Pathophysiology

Pericardial tissue damage triggers an inflammatory response. Inflammatory mediators released from the injured tissue cause vasodilation, hyperaemia and oedema. Capillary permeability increases, allowing plasma proteins, including fibrinogen, to escape into the pericardial space. White blood cells amass at the site of injury to destroy the causative agent. Exudate is formed, usually fibrinous or serofibrinous (a mixture of serous fluid and fibrinous exudate). In some cases, the exudate may contain red blood cells or, if infectious, purulent material. The inflammatory process may resolve without long-term effects or scar tissue and adhesions may form between the pericardial layers.

Fibrosis and scarring of the pericardium may restrict cardiac function. Pericardial effusions may develop as serous or purulent exudate (depending on the causative agent) collects in the pericardial sac. Pericardial effusion may be recurrent. Chronic inflammation causes the pericardium to become rigid.

Manifestations

Classic manifestations of acute pericarditis include chest pain, a pericardial friction rub and fever. Chest pain, the most common symptom, has an abrupt onset. It is caused by inflammation of nerve fibres in the lower parietal pericardium and pleura covering the diaphragm. The pain is usually sharp, may be steady or intermittent and may radiate to the back or neck. The pain can mimic myocardial ischaemia; careful assessment is important to rule out myocardial infarction. Pericardial pain is aggravated by respiratory movements (i.e. deep inspiration and/or coughing), changes in body position or swallowing. Sitting upright and leaning forward reduces the discomfort by moving the heart away from the diaphragmatic side of the lung pleura.

Although not always present, a pericardial friction rub is the characteristic sign of pericarditis. A pericardial friction rub is a leathery, grating sound produced by the inflamed pericardial layers rubbing against the chest wall or pleura. It is heard most clearly at the left lower sternal border with the person sitting up or leaning forward. The rub is usually heard on expiration and may be constant or intermittent.

The person may develop low-grade fever (below 38.4ºC) due to the inflammatory process. Dyspnoea and tachycardia are common.

Complications

Pericardial effusion, cardiac tamponade and constrictive pericarditis are possible complications of acute pericarditis.

Pericardial effusion

A *pericardial effusion* is an abnormal collection of fluid between the pericardial layers that threatens normal cardiac function. The fluid may consist of pus, blood, serum, lymph or a combination. The manifestations of a pericardial effusion depend on the rate at which the fluid collects. Although the pericardium normally contains about 30 to 50 mL of fluid, the sac can stretch to accommodate a gradual accumulation of fluid. Over time, the pericardial sac can accommodate up to 2 L of fluid without immediate adverse effects. Conversely, a rapid build-up of pericardial fluid (as little as 100 mL) does not allow the sac to stretch and can compress the heart, interfering with myocardial function. This compression of the heart is known as **cardiac tamponade**. Slowly developing pericardial effusion is often painless and has few manifestations. Heart sounds may be distant or muffled. The person may have a cough or mild dyspnoea.

Cardiac tamponade

Cardiac tamponade is a medical emergency that must be aggressively treated to preserve life. Cardiac tamponade may result from pericardial effusion, trauma, cardiac rupture or haemorrhage. Rapid collection of fluid in the pericardial sac interferes with ventricular filling and pumping, critically reducing cardiac output.

Classic manifestations of cardiac tamponade result from rising intracardiac pressures and decreased diastolic filling and cardiac output. A hallmark of cardiac tamponade is a paradoxical pulse, or *pulsus paradoxus*. A paradoxical pulse markedly decreases in amplitude during inspiration. Intrathoracic pressure normally drops during inspiration, enhancing venous return to the right heart. This draws more blood into the right side of the heart than the left, causing the interventricular septum to bulge slightly into the left ventricle. When ventricular filling is impaired by excess fluid in the pericardial sac, this bulging of the interventricular septum decreases cardiac output during inspiration (see Figure 30.5). On palpation of the carotid or femoral artery, the pulse is diminished or absent during inspiration. A drop in systolic blood pressure of more than 10 mmHg during inspiration also indicates pulsus paradoxus.

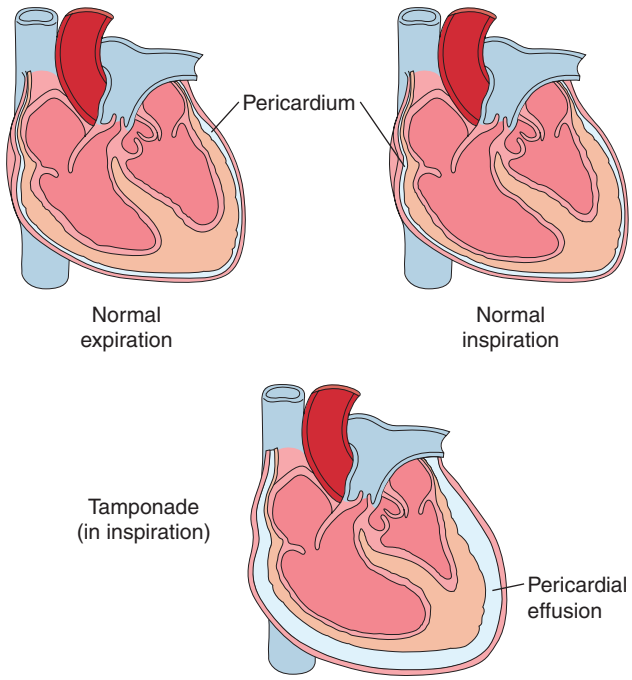


FIGURE 30.5 ■ Cardiac tamponade. Note increased volume in the right ventricle during inspiration in both the normal heart and the heart affected by a pericardial effusion. In tamponade, fluid in the pericardial sac and the distended right ventricle restrict filling of the left ventricle and, consequently, cardiac output

Other manifestations of cardiac tamponade include muffled heart sounds, dyspnoea and tachypnoea, tachycardia, a narrowed pulse pressure and distended neck veins (see the box below).

Chronic constrictive pericarditis

Chronic pericardial inflammation can lead to scar tissue formation between the pericardial layers. This scar tissue eventually contracts, restricting diastolic filling and elevating venous pressure. Constrictive pericarditis (see Figure 30.6) may follow viral infection, radiation therapy or heart surgery. Its manifestations include progressive dyspnoea, fatigue and weakness. Ascites is common; peripheral oedema may develop. Neck veins are distended and may be particularly noticeable during inspiration (*Kussmaul's sign*). This occurs because the right atrium is unable to dilate to accommodate increased venous return during inspiration.

MANIFESTATIONS Cardiac tamponade

- Paradoxical pulse
- Narrowed pulse pressure, hypotension
- Tachycardia
- Weak peripheral pulses
- Distant, muffled heart sounds
- Jugular venous distension
- High central venous pressure
- Decreased level of consciousness
- Low urine output
- Cool, mottled skin

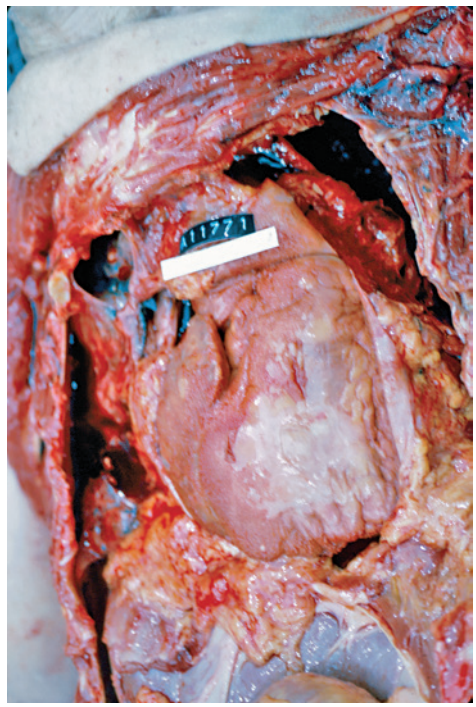

FIGURE 30.6 ■ Constrictive pericarditis

Source: Custom Medical Stock Photo, Inc.

INTERPROFESSIONAL CARE

Care for the person with pericarditis focuses on identifying its cause, if possible, reducing inflammation, relieving symptoms and preventing complications. The person is closely monitored for early manifestations of cardiac tamponade so that it can be treated promptly.

Diagnosis

There are no specific laboratory tests to diagnose pericarditis, but tests are often performed to differentiate pericarditis from myocardial infarction.

- *FBC* shows elevated WBCs and an ESR greater than 20 mm/h, indicating acute inflammation.
- *Cardiac enzymes* may be slightly elevated because the inflammatory process extends to involve the epicardial surface of the heart. Cardiac enzymes are typically much lower in pericarditis than in myocardial infarction.
- *Electrocardiography* shows typical changes associated with pericarditis, such as diffuse ST-segment elevation in all leads. This resolves more quickly than changes of acute MI and is not associated with the QRS-complex and T-wave changes typically seen in MI. With a large pericardial effusion, the QRS amplitude may be decreased. Atrial arrhythmias may occur in acute pericarditis.

- *Echocardiography* is used to assess heart motion, for pericardial effusion and the extent of restriction.
- *Haemodynamic monitoring* may be used in acute pericarditis or pericardial effusion to assess pressures and cardiac output. Elevated pulmonary artery pressures and venous pressures occur with impaired filling due to pericardial effusion or constrictive pericarditis.
- *Chest x-ray* may show cardiac enlargement if a pericardial effusion is present.
- *Computed tomography (CT) scan* or *magnetic resonance imaging (MRI)* may be used to identify pericardial effusion or constrictive pericarditis.

Medications

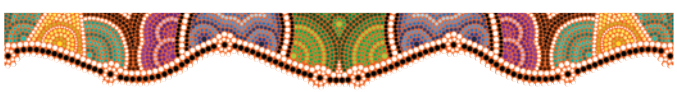
Drug treatment for pericarditis addresses its manifestations. Aspirin and paracetamol may be used to reduce fever. NSAIDs are used to reduce inflammation and promote comfort. In severe cases or with recurrent pericarditis, corticosteroids may be given to suppress the inflammatory response.

Pericardiocentesis

Pericardiocentesis may be done to remove fluid from the pericardial sac for diagnostic or therapeutic purposes. The doctor inserts a large (16- to 18-gauge) needle into the pericardial sac and withdraws excess fluid. The needle is attached to an ECG monitoring lead to help determine if the needle is touching the epicardial surface, which helps prevent piercing the myocardium. Pericardiocentesis may be an emergency procedure for the person with cardiac tamponade.

Surgery

For recurrent pericarditis or recurrent pericardial effusion, a rectangular piece of the pericardium, or 'window', may be excised to allow collected fluid to drain into the pleural space. Constrictive pericarditis may necessitate a partial or total *pericardiectomy*, removal of part or all of the pericardium, to relieve the ventricular compression and allow adequate filling.



Nursing care

Health promotion

While it may not yet be possible to identify many people at risk and to prevent acute pericarditis, early identification and treatment of the disorder can reduce the risk of complications. Promptly report a pericardial friction rub or other manifestations of pericarditis in individuals with recent acute AMI, cardiac surgery or systemic diseases associated with a risk of pericarditis.

Assessment

Assessment data to collect from the person with suspected pericarditis include:

- *Health history:* complaints of acute substernal or precordial chest pain, effect of movement and breathing on discomfort, pain radiation, associated symptoms; recent acute AMI, heart surgery or other cardiac disorder; current medications; chronic conditions such as renal failure or a connective tissue or autoimmune disorder.
- *Physical examination:* vital signs, including temperature, variation in systolic BP with respirations; strength of peripheral pulses, variations with respiratory movement; apical pulse, clarity, changes with respiratory movement, presence of a friction rub; neck vein distension; level of consciousness, skin colour and other indicators of cardiac output.
- *Diagnostic tests:* FBC and differential, ESR; cardiac enzyme levels; ECG and echocardiogram reports.

Nursing diagnoses and interventions

Nursing care for the person with pericarditis may occur in the acute or community setting. Closely observe for early manifestations of increasing effusion or cardiac tamponade. Priority nursing diagnoses relate to comfort, the risk of tamponade and effects of the acute inflammatory process.

Acute pain

Inflamed pericardial layers rubbing against each other and the lung pleura stimulate phrenic nerve pain fibres in the lower portion of the parietal pericardium. Pain is usually acute and may be severe until inflammation resolves.

- Assess chest pain using a standard pain scale and noting the quality and radiation of the pain. Note non-verbal cues of pain (grimacing, guarding behaviours) and validate with the person. *Careful assessment helps identify the cause of pain. The pain of pericarditis may radiate to the neck or back and is aggravated by movement, coughing or deep breathing. A pain scale allows evaluation of the effectiveness of interventions.*
- Auscultate heart sounds every 4 hours. *Presence of a pericardial friction rub often correlates with the location and severity of the pain.*
- Administer NSAIDs on a regular basis as prescribed with food. Document effectiveness. NSAIDs reduce fever, inflammation and pericardial pain. *They are most effective when administered around the clock on a consistent basis. Administering the medications with food helps decrease gastric distress.*
- Maintain a quiet, calm environment and position of comfort. Offer back rubs, heat/cold therapy, diversional activity and emotional support. *Supportive interventions enhance the effects of the medication, may decrease pain perception and convey a sense of caring.*

Ineffective breathing pattern

Respiratory movement intensifies pericardial pain. In an effort to decrease pain, the person often breathes shallowly, increasing the risk of pulmonary complications.

- Encourage deep breathing and use of the incentive spirometer. Provide pain medication before respiratory therapy, as needed. *Deep breathing and an incentive spirometer promote alveolar ventilation and prevent atelectasis. Administration of analgesia prior to respiratory treatments improves their effectiveness by decreasing guarding.*

- Administer oxygen as needed. *Supplementary oxygen promotes optimal gas exchange and tissue oxygenation.*
- Place the person in Fowler's or high-Fowler's position. Assist the person to a position of comfort. *Appropriate positioning reduces the work of breathing and decreases chest pain due to pericarditis.*

CONSIDERATION FOR PRACTICE

Document respiratory rate, effort and breath sounds every 2 to 4 hours. Report adventitious or diminished breath sounds. Shallow, guarded respirations may lead to increased respiratory rate and effort. Poor ventilation of peripheral alveoli may lead to congestion or atelectasis.

Risk of decreased cardiac output

The acute inflammatory process of pericarditis can lead to significant pericardial effusion and cardiac tamponade. This potentially fatal complication can also occur with chronic pericardial effusion if the amount of fluid exceeds the ability of the pericardial sac to expand. Constrictive pericarditis increases the risk of decreased cardiac output because of restricted cardiac filling.

- Document vital signs hourly during the acute inflammatory processes. *Frequent assessment allows early recognition of manifestations of decreased cardiac output, such as tachycardia, hypotension or changes in pulse pressure.*
- Report significant changes or trends in haemodynamic parameters and arrhythmias. *Compression of the heart interferes with venous return, increasing CVP and right atrial pressures; arrhythmias may also occur.*
- Promptly report other signs of decreased cardiac output: decreased level of consciousness; decreased urine output; cold, clammy, mottled skin; delayed capillary refill; and weak peripheral pulses. *These signs of decreased organ and tissue perfusion indicate a significant drop in cardiac output.*
- Maintain at least one patent intravenous access site. *The person in cardiac tamponade may require rapid intravenous fluid infusion to restore blood volume and administration of emergency drugs to support the circulation.*
- Prepare for emergency pericardiocentesis and/or surgery as necessary. Provide appropriate explanations and reassurance. Observe for adverse responses during pericardiocentesis. *Excess pericardial fluid must be rapidly evacuated to prevent further compromise of cardiac output and death. Emotional support and explanations reduce the person's and their family's anxiety and promote a caring atmosphere.*

Activity intolerance

In chronic constrictive pericarditis, pericardial adhesions and scarring restrict pericardial compliance, restricting heart filling and movement. Restricted filling and ineffective cardiac contraction decrease the cardiac output. The heart cannot compensate for increased metabolic demands by increasing cardiac output and cardiac reserve falls significantly.

- Work with the person and physiotherapist to develop a realistic, progressive activity plan. Monitor response. Encourage independence, but provide assistance as needed. *Involvement in their own planning increases the likelihood of success, as well as the person's self-esteem and sense of control. Promoting self-care provides additional control and independence and enhances self-image. Activity that significantly increases the heart rate (more than 20 bpm over resting) should be stopped and reassessed for intensity.*
- Plan interventions and care activities to allow uninterrupted rest and sleep. *This supports healing and restoration of physical and emotional health.*

Community-based care

Include the following topics when teaching the person and their family in preparation for home care:

- The importance of continuing anti-inflammatory medications as ordered. Advise to take NSAIDs with food, milk or antacids to minimise gastric distress and to notify the doctor if unable to tolerate the drug.
- Prescribed medications, including dose, desired and possible adverse effects, and interactions with other drugs or food.
- Monitoring weight twice weekly because NSAIDs may cause fluid retention.
- Maintaining fluid intake of at least 2500 mL/day to minimise the risk of renal toxicity due to NSAID use.
- Measures to maintain activity restriction if ordered. Activity will be gradually increased once the inflammatory process has resolved.

DISORDERS OF CARDIAC STRUCTURE

THE PERSON WITH VALVULAR HEART DISEASE

Proper heart valve function ensures one-way blood flow through the heart and vascular system. **Valvular heart disease** interferes with blood flow to and from the heart. Acquired valvular disorders can result from acute conditions, such as infective endocarditis, or from chronic conditions, such as rheumatic heart disease. Rheumatic heart disease is the most common cause of valvular disease (Papadakis, McPhee & Rabow, 2013). Acute myocardial infarction also can damage heart valves, causing tearing, ischaemia or damage to the papillary muscles that affects valve leaflet function. Congenital heart defects may affect the heart valves, often with no manifestations until adulthood.

Physiology review

The heart valves direct blood flow within and out of the heart. The valves are fibroelastic tissue supported by a ring of fibrous tissue (the annulus) that provides support.

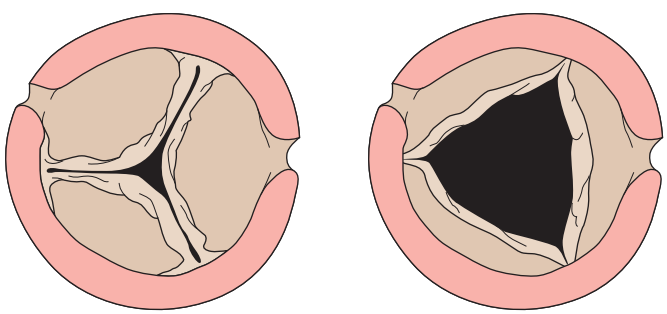
The AV valves, the **mitral** (or *bicuspid*) **valve** on the left and the **tricuspid valve** on the right, separate the atria from the ventricles. These valves normally are fully open during diastole, allowing blood to flow freely from the atria into the ventricles. Rising pressure within the ventricles at the onset of systole (contraction) closes the AV valves, creating the S_1 heart sound ('lub'). The leaflets of the AV valves are connected to ventricular papillary muscles by fibrous *chordae tendineae*. The chordae tendineae prevent the valve leaflets from bulging back into the atria during systole.

The semilunar valves, the **aortic** and **pulmonic valves**, separate the ventricles from the great vessels. They open during systole, allowing blood to flow out of the heart with ventricular contraction. As the ventricle relaxes and intraventricular pressure falls at the beginning of diastole, the higher pressure within the great vessels (the aorta and pulmonary artery) closes these valves, creating the S_2 heart sound ('dub').

Pathophysiology

Valvular heart disease occurs as two main types of disorders: stenosis and regurgitation. Stenosis occurs when valve leaflets fuse together and cannot fully open or close. The valve opening narrows and becomes rigid (see Figure 30.7A). Scarring of the valves from endocarditis or infarction and calcium deposits can lead to stenosis. Stenotic valves impede the forward flow of blood, decreasing cardiac output because of impaired ventricular filling or ejection, and stroke volume.

Regurgitant valves (also called *insufficient* or *incompetent* valves) do not close completely (see Figure 30.7B). Regurgitation can result from deformity or erosion of valve cusps caused by the vegetative lesions of bacterial endocarditis, by scarring or tearing from myocardial infarction, or by cardiac dilation. As the heart enlarges, the *valve annulus* (supporting ring of the valve) is stretched and the valve edges no longer meet to allow complete closure.



A Thickened and stenotic valve leaflets

B Retracted fibrosed valve openings

FIGURE 30.7 ■ Valvular heart disorders. *A*, Stenosis of a heart valve. *B*, An incompetent or regurgitant heart valve

Valvular disease causes haemodynamic changes both in front of and behind the affected valve. Blood volume and pressures are reduced in front of the valve. By contrast, volumes and pressures characteristically increase behind the diseased valve. These haemodynamic changes may lead to pulmonary complications, cardiac remodelling, hypertrophy or heart failure.

Stenosis increases the work of the chamber behind the affected valve as the heart attempts to move blood through the narrowed opening. Excess blood volume behind regurgitant valves causes dilation of the chamber. In mitral stenosis, for example, the left atrium hypertrophies to generate enough pressure to open and deliver its blood through the narrowed mitral valve. Not all of the blood is delivered before the valve closes, leaving blood to accumulate in the left atrium. This chamber dilates to accommodate the excess volume.

Eventually, cardiac output falls as compensatory mechanisms become less effective. The normal balance of oxygen supply and demand is upset and the heart begins to fail. Increased muscle mass and size increase myocardial oxygen consumption. The size and workload of the heart exceed its blood supply, causing ischaemia and chest pain. Eventually, necrosis occurs and functional muscle is lost. Contractile force, stroke volume and cardiac output decrease. High pressures on the left side of the heart are reflected backward into the pulmonary system, causing pulmonary oedema, pulmonary hypertension and, eventually, right ventricular failure.

Valvular disorders interfere with the smooth flow of blood through the heart. The flow becomes turbulent, causing a **murmur**, a characteristic manifestation of valvular disease. Table 30.9 describes the murmurs associated with various types of valvular disorders.

Blood forced through the narrowed opening of a stenotic valve or regurgitated from a higher pressure chamber through an incompetent valve creates a jet stream effect (much like water spurting out of a partially occluded hose opening). The physical force of this jet stream damages the endocardium of the receiving chamber, increasing the risk of infective endocarditis.

The higher pressures on the left side of the heart subject its valves (the mitral and aortic valves) to more stress and damage than those on the right side of the heart (the tricuspid and pulmonic). Pulmonic valve disease is the least common of the valvular disorders.

Mitral stenosis

Mitral stenosis narrows the mitral valve, obstructing blood flow from the left atrium into the left ventricle during diastole. It is usually caused by rheumatic heart disease or bacterial endocarditis; it rarely results from congenital defects. In Australia, the mean age for mitral stenosis is 33 years. However, in the Northern Territory, 30% of children aged 10–19 years with rheumatic heart disease have mitral stenosis (RHD Australia, 2012). Mitral stenosis is chronic and progressive.

In mitral valve stenosis, fibrous tissue replaces normal valve tissue, causing valve leaflets to stiffen and fuse. Resulting changes in blood flow through the valve lead to calcification of

TABLE 30.9 Heart murmur timing and characteristics

MURMUR	CARDIAC CYCLE TIMING	AUSCULTATION SITE	CONFIGURATION OF SOUND	CONTINUITY
Mitral stenosis	Diastole	Apical		Rumble that increases in sound towards the end, continuous
Mitral regurgitation	Systole	Apex		Holosystolic (occurs throughout systole), continuous
Aortic stenosis	Midsystolic	Right sternal border (RSB) 2nd intercostal space (ICS)		Crescendo–decrescendo, continuous
Aortic regurgitation	Diastole (early)	3rd ICS, left sternal border (LSB)		Decrescendo, continuous
Tricuspid stenosis	Diastole	Lower LSB		Rumble that increases in sound towards the end, continuous
Tricuspid regurgitation	Systole	4th ICS, LSB		Holosystolic, continuous

the valve leaflets. As calcium is deposited in and on the valve, the leaflets become more rigid and narrow the opening further (see Figure 30.8). As the valve leaflets become less mobile, the chordae tendineae fuse, thicken and shorten. Thromboemboli may form on the calcified leaflets.

The narrowed mitral opening impairs blood flow into the left ventricle, reducing end-diastolic volume and pressure, and decreasing stroke volume. The narrowed opening also forces the left atrium to generate higher pressure to deliver blood to the left ventricle. This leads to left atrial hypertrophy. The left atrium also dilates as obstructed blood flow increases its volume. As the resistance to blood flow increases, high atrial pressures are reflected back into the pulmonary vessels, increasing pulmonary pressures (see Figure 30.8). Pulmonary hypertension increases the workload of the right ventricle, causing it to dilate and hypertrophy. Eventually, heart failure occurs.

MANIFESTATIONS Mitral stenosis may be asymptomatic or cause severe impairment. Its manifestations depend on cardiac output and pulmonary vascular pressures. Dyspnoea on exertion is typically the earliest manifestation. Others include cough, haemoptysis, frequent pulmonary infections such as bronchitis and pneumonia, paroxysmal nocturnal dyspnoea, orthopnoea, weakness, fatigue and palpitations. As the stenosis worsens, manifestations of right heart failure, including jugular venous distension, hepatomegaly, ascites and peripheral oedema, develop. Crackles may be heard in the lung bases. In severe mitral stenosis, cyanosis of the face and extremities may be noted. Chest pain is rare but may occur.

On auscultation, a loud S_1, a split S_2 and a mitral opening snap may be heard. The opening snap reflects high left atrial pressure. The murmur of mitral stenosis occurs during diastole and is typically low pitched, rumbling, crescendo–decrescendo. It is heard best with the bell of the stethoscope in the apical region. It may be accompanied by a palpable thrill (vibration).

COMPLICATIONS Atrial arrhythmias, particularly atrial fibrillation, are common due to chronic atrial distension. Thrombi may form and subsequently embolise to the brain, coronary arteries, kidneys, spleen and extremities—potentially devastating complications.

Women with mitral stenosis may be asymptomatic until pregnancy. As the heart tries to compensate for increased circulating volume (30% more in pregnancy) by increasing cardiac output, left atrial pressures rise, tachycardia reduces ventricular filling, and stroke volume and pulmonary pressures increase. Sudden pulmonary oedema and heart failure may threaten the lives of the mother and foetus.

Mitral regurgitation

Mitral regurgitation or *insufficiency* allows blood to flow back into the left atrium during systole because the valve does not close fully. Rheumatic heart disease is a common cause of mitral regurgitation. Processes that dilate the mitral annulus or affect the supporting structures, papillary muscles or the chordae tendineae may cause mitral regurgitation (e.g. left ventricular hypertrophy and MI). Congenital defects also may cause mitral regurgitation.

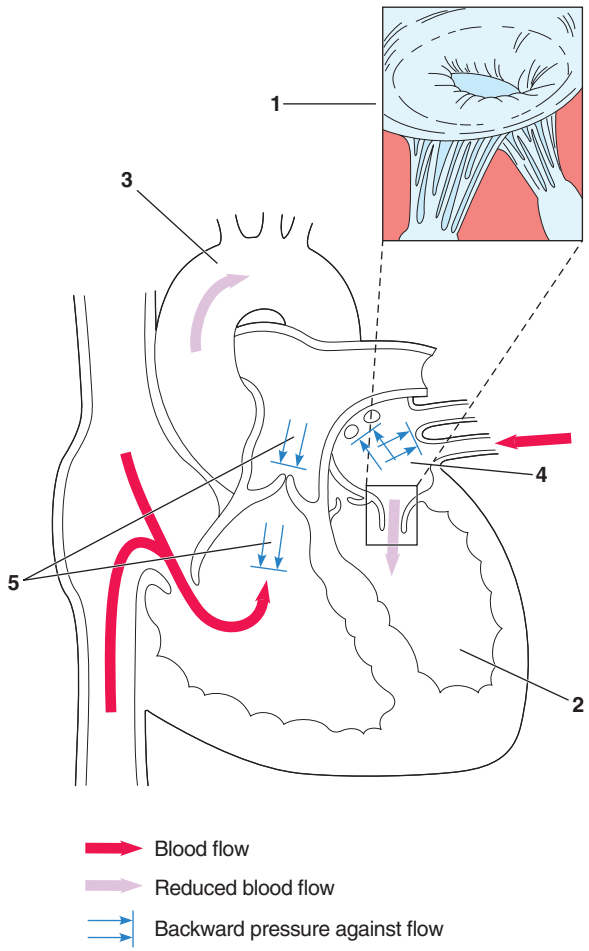


FIGURE 30.8 ■ Mitral stenosis. Narrowing of the mitral valve orifice (1) reduces blood volume to left ventricle (2) reducing cardiac output (3). Rising pressure in the left atrium (4) causes left atrial hypertrophy and pulmonary congestion. Increased pressure in pulmonary vessels (5) causes hypertrophy of the right ventricle and right atrium

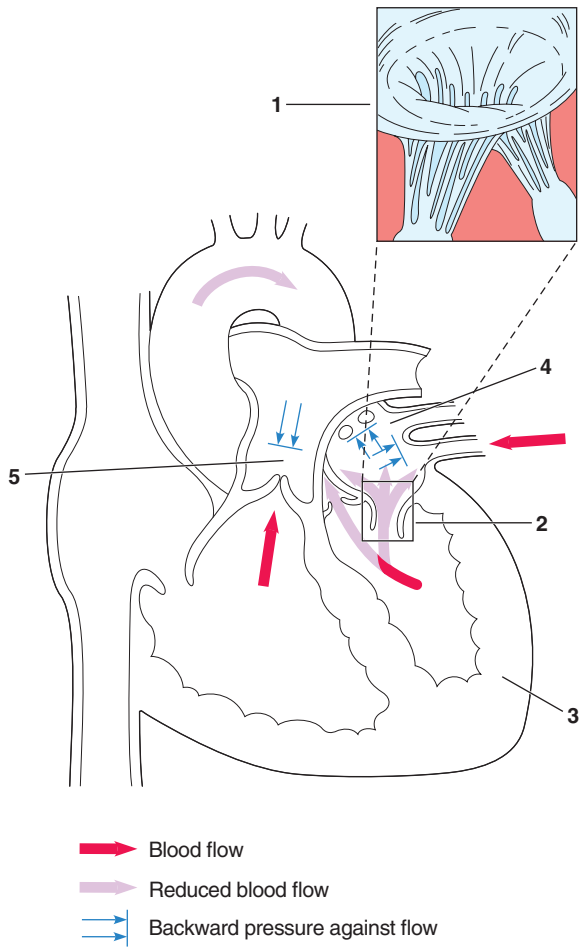

FIGURE 30.9 ■ Mitral regurgitation. The mitral valve closes incompletely (1), allowing blood to regurgitate during systole from the left ventricle to the left atrium (2). Cardiac output falls; to compensate, the left ventricle hypertrophies (3). Rising left atrial pressure (4) causes left atrial hypertrophy and pulmonary congestion. Elevated pulmonary artery pressure (5) causes slight enlargement of the right ventricle

In mitral regurgitation, blood flows into both the systemic circulation and back into the left atrium through the deformed valve during systole. This increases left atrial volume (see Figure 30.9). The left atrium dilates to accommodate its extra volume, pulling the posterior valve leaflet further away from the valve opening and worsening the defect. The left ventricle dilates to accommodate its increased preload and low cardiac output, further aggravating the problem.

MANIFESTATIONS Mitral regurgitation may be asymptomatic or cause symptoms such as fatigue, weakness, exertional dyspnoea and orthopnoea. In severe or acute regurgitation, manifestations of left-sided heart failure develop, including pulmonary congestion and oedema. High pulmonary pressures may lead to manifestations of right-sided heart failure.

The murmur of mitral regurgitation is usually loud, high pitched, rumbling and holosystolic (occurring throughout systole). It is often accompanied by a palpable thrill and is heard most clearly at the cardiac apex.

Mitral valve prolapse

Mitral valve prolapse (MVP) is a type of mitral insufficiency that occurs when one or both mitral valve cusps billow into the atrium during ventricular systole. Its cause often is unclear. However, it can also result from acute or chronic rheumatic damage, ischaemic heart disease or other cardiac disorders. It commonly affects people with inherited connective tissue disorders such as Marfan syndrome (see the 'Genetic considerations' box below).

Excess collagen tissue in the valve leaflets and elongated chordae tendineae impair closure of the mitral valve, allowing the leaflets to billow into the left atrium during systole. Some ventricular blood volume regurgitates into the left atrium (see Figure 30.10).

MANIFESTATIONS AND COMPLICATIONS Mitral valve prolapsed is usually asymptomatic. A midsystolic ejection click or murmur may be audible. A high-pitched late systolic

GENETIC CONSIDERATIONS
The person with Marfan syndrome

Marfan syndrome is a genetic (autosomal dominant) connective tissue disorder that affects the skeleton, eyes and cardiovascular system. Skeletal characteristics include a long, thin body, with long extremities and long, tapering fingers, sometimes called *arachnodactyly* (spider fingers). Joints are hyperextensible, and skeletal deformities such as kyphosis, scoliosis, pigeon chest or pectus excavatum are common (Papadakis et al., 2013). The potentially life-threatening cardiovascular effects of Marfan syndrome include mitral valve prolapse, progressive dilation of the aortic valve ring and weakness of arterial walls. People with Marfan syndrome frequently die young, between 30 and 40 years, often due to dissection and rupture of the aorta (Chen, 2014; Prashanth, 2014).

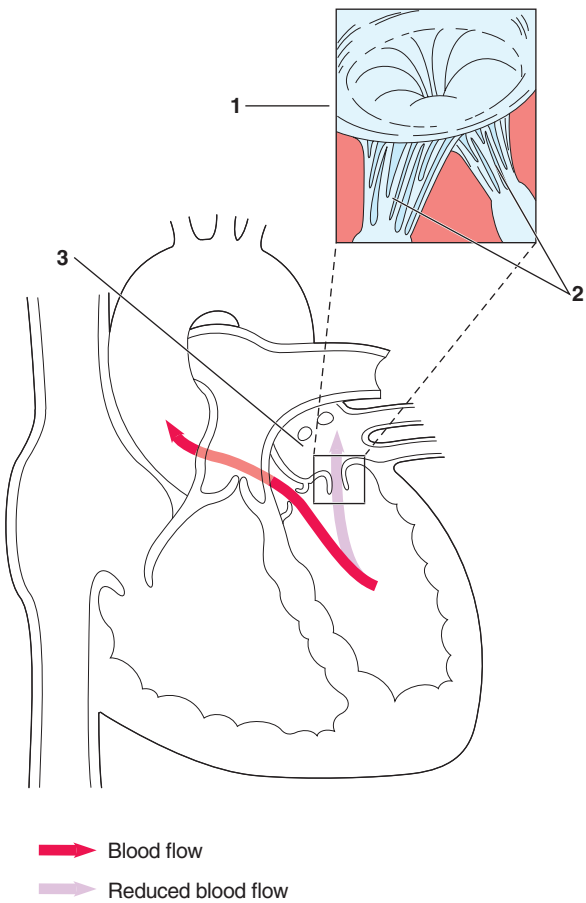

FIGURE 30.10 ■ Mitral valve prolapse. Excess tissue in the valve leaflets (1) and elongated chordae tendineae (2) impair mitral valve closure during systole. Some ventricular blood regurgitates into the left atrium (3)

murmur, sometimes described as a 'whoop' or 'honk', due to the regurgitation of blood through the valve, may develop in MVP. Atypical chest pain is the most common symptom of MVP. It may be left sided or substernal and is frequently related to fatigue, not exertion (Papadakis et al., 2013). Tachyarrhythmias may develop with MVP, causing palpitations, light headedness and syncope. Increased sympathetic nervous system tone may cause a sense of anxiety.

Mitral valve prolapse increases the risk of bacterial endocarditis. Progressive worsening of regurgitation can lead to heart failure. Thrombi may form on prolapsed valve leaflets; embolisation may cause transient ischaemic attacks (TIAs).

Aortic stenosis

Aortic stenosis obstructs blood flow from the left ventricle into the aorta during systole. Aortic stenosis may be idiopathic or due to a congenital defect, rheumatic damage or degenerative changes. When rheumatic heart disease is the cause, mitral valve deformity is also often present. RHD destroys aortic valve leaflets, with fibrosis and calcification causing rigidity and scarring. In the older adult, calcific aortic stenosis may result from degenerative changes associated with ageing. Constant wear and tear on this valve can lead to fibrosis and calcification. Idiopathic calcific stenosis generally is mild and does not impair cardiac output.

As aortic stenosis progresses, the valve annulus decreases in size, increasing the work of the left ventricle to eject its volume through the narrowed opening into the aorta. To compensate, the ventricle hypertrophies to maintain an adequate stroke volume and cardiac output (see Figure 30.11). Left ventricular compliance also decreases. The additional workload increases myocardial oxygen consumption, which can precipitate myocardial ischaemia. Coronary blood flow may also decrease in aortic stenosis. As left ventricular end-diastolic pressure increases because of reduced stroke volume, left atrial pressures increase. These pressures also affect the pulmonary vascular system; pulmonary vascular congestion and pulmonary oedema may result.

COURSE AND MANIFESTATIONS Aortic stenosis may be asymptomatic for many years. As the disease progresses and compensation fails, usually between age 50 and 70 years, obstructed cardiac output causes manifestations of left ventricular failure. Dyspnoea on exertion, angina pectoris and exertional syncope are classic manifestations of aortic stenosis. Pulse pressure, an indicator of stroke volume, narrows to 30 mmHg or less.

Aortic stenosis produces a harsh systolic murmur best heard in the second intercostal space to the right of the sternum. This crescendo–decrescendo murmur is produced by turbulence of blood entering the aorta through the stenotic valve. A palpable thrill is often felt. The murmur may radiate to the carotid arteries. Ventricular hypertrophy displaces the cardiac impulse to the left of the midclavicular line. As aortic stenosis progresses, S_3 and S_4 heart sounds may be heard, indicating heart failure and reduced left ventricular compliance.

As cardiac output falls, tissue perfusion decreases. Late in the disease, pulmonary hypertension and right ventricular failure develop. Untreated, symptomatic aortic stenosis has a poor prognosis as at 3 years after diagnosis only approximately 50% of people are still alive (Papadakis et al., 2013).

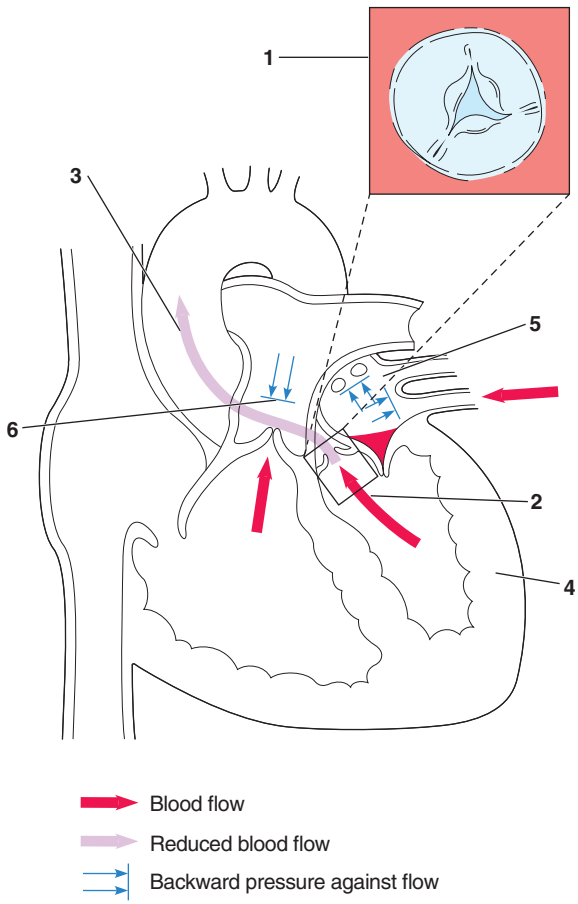

FIGURE 30.11 ■ Aortic stenosis. The narrowed aortic valve orifice (1) decreases the left ventricular ejection fraction during systole (2) and cardiac output (3). The left ventricle hypertrophies (4). Incomplete emptying of the left atrium (5) causes backward pressure through pulmonary veins and pulmonary hypertension. Elevated pulmonary artery pressure (6) causes right ventricular strain

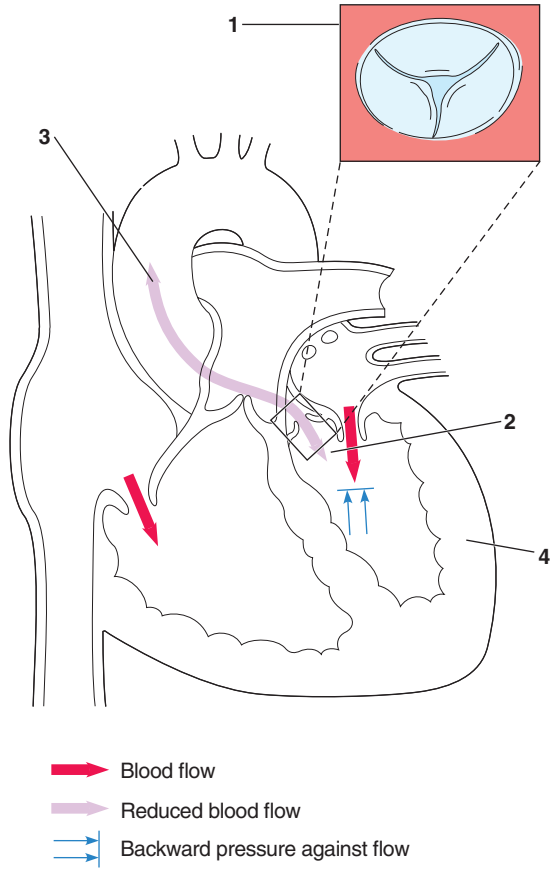

FIGURE 30.12 ■ Aortic regurgitation. The cusps of the aortic valve widen and fail to close during diastole (1). Blood regurgitates from the aorta into the left ventricle (2), increasing left ventricular volume and decreasing cardiac output (3). The left ventricle dilates and hypertrophies (4) in response to the increase in blood volume and workload

Aortic regurgitation

Aortic regurgitation, also called *aortic insufficiency*, allows blood to flow back into the left ventricle from the aorta during diastole. Most aortic regurgitation results from rheumatic heart disease. Other causes include congenital disorders, infective endocarditis, blunt chest trauma, aortic aneurysm, syphilis, Marfan syndrome and chronic hypertension.

In aortic regurgitation, thickened and contracted valve cusps, scarring, fibrosis and calcification impede complete valve closure. Chronic hypertension and aortic aneurysm may dilate and stretch the aortic valve opening, increasing the degree of regurgitation.

In aortic regurgitation, volume overload affects the left ventricle as blood from the aorta adds to blood received from the atrium during diastole. This increases diastolic left ventricular pressure. Increased preload causes more forceful contractions and a high stroke volume (see Figure 30.12). With time, muscle cells hypertrophy to compensate for increased cardiac work and afterload; eventually this hypertrophy compromises cardiac output and increases regurgitation.

High left-ventricular pressures increase left atrial workload and pressure. This pressure is transmitted to the pulmonary vessels, causing pulmonary congestion. The workload of the right ventricle increases as a result and right-sided heart failure may develop. Acute aortic regurgitation from traumatic injury or infective endocarditis causes a rapid decline in haemodynamic status from acute heart failure and pulmonary oedema, because compensatory mechanisms do not have time to develop.

MANIFESTATIONS Aortic regurgitation may be asymptomatic for many years, even when severe. The increased stroke volume may cause complaints of persistent palpitations, especially when recumbent. A throbbing pulse may be visible in arteries of the neck; the force of contraction may cause a characteristic head bob (Musset's sign) and shake the whole body. Other symptoms include dizziness and exercise intolerance.

Fatigue, exertional dyspnoea, orthopnoea and paroxysmal nocturnal dyspnoea are common in aortic regurgitation.

Anginal pain may result from excessive cardiac work and decreased coronary perfusion. Unlike CHD, angina often occurs at night and may not respond to conventional therapy.

The murmur of aortic regurgitation is heard during diastole as blood flows back into the left ventricle from the aorta. It is a 'blowing', high-pitched sound heard most clearly at the third left intercostal space. A palpable thrill and ventricular heave may be noted. An S_3 and S_4 may be heard as the heart fails and ventricular compliance diminishes. The apical impulse is displaced to the left.

High systolic and low diastolic pressures cause a widened pulse pressure. The arterial pressure waveform has a rapid upstroke and quickly collapsing downstroke, known as a *water-hammer pulse*. It is caused by the force of rapid and early delivery of the stroke volume into the aorta.

Tricuspid valve disorders

Tricuspid stenosis obstructs blood flow from the right atrium to the right ventricle. It usually results from rheumatic heart disease; mitral stenosis often occurs concurrently with tricuspid stenosis.

Fibrosed, retracted tricuspid valve cusps and fused leaflets narrow the valve orifice and prevent complete closure. Right ventricular filling is impaired during diastole, and during systole some blood regurgitates back into the right atrium. Pressure in the right atrium increases and enlarges in response to the increased pressure and workload. This increased right atrial pressure is reflected backward into the systemic circulation. Right ventricular stroke volume decreases, reducing the volume delivered to the pulmonary system and left heart. Stroke volume, cardiac output and tissue perfusion fall.

Manifestations of tricuspid stenosis relate to systemic congestion and right-sided heart failure. They include increased CVP, jugular venous distension, ascites, hepatomegaly and peripheral oedema. Low cardiac output causes fatigue and weakness. The low-pitched, rumbling diastolic murmur of tricuspid stenosis is most clearly heard in the fourth intercostal space at the left sternal border or over the xiphoid process.

Tricuspid regurgitation usually occurs secondarily to right ventricular dilation. Stretching distorts the valve and its supporting structures, preventing complete valve closure. Left ventricular failure is the usual cause of right ventricular overload; pulmonary hypertension is another cause. The valve may also be damaged by rheumatic heart disease, infective endocarditis, inferior MI, trauma or other conditions.

Tricuspid regurgitation allows blood to flow back into the right atrium during systole, increasing right atrial pressures. Increased right atrial pressure causes manifestations of right-sided heart failure, including systemic venous congestion and low cardiac output. Atrial fibrillation due to atrial distension is common.

Pulmonic valve disorders

Pulmonic stenosis obstructs blood flow from the right ventricle into the pulmonary system. It usually is a congenital disorder, although rheumatic heart disease or cancer also may cause pulmonic stenosis. Both the right atrium and ventricle hypertrophy to overcome high pressures. Right-sided heart failure occurs when the ventricle can no longer generate adequate pressure to force blood past the narrowed valve opening.

Pulmonic stenosis typically is asymptomatic unless severe. Dyspnoea on exertion and fatigue are early signs. As the condition progresses, right-sided heart failure develops, with peripheral oedema, ascites, hepatomegaly and increased venous pressures. Turbulent blood flow caused by the narrowed valve generates a harsh, systolic crescendo–decrescendo murmur heard in the pulmonic area, the second left intercostal space.

Pulmonic regurgitation is more common than pulmonary stenosis. It is a complication of pulmonary hypertension, which stretches and dilates the pulmonary orifice, causing incomplete valve closure. Infective endocarditis, pulmonary artery aneurysm and syphilis also may cause pulmonic regurgitation.

Incomplete valve closure allows blood to flow back into the right ventricle during diastole, decreasing blood flow to the pulmonary circuit increasing end-diastolic pressure. When the ventricle can no longer compensate for the increased volume, right-sided heart failure develops.

INTERPROFESSIONAL CARE

A heart murmur identified during routine physical examination often is the initial indication of valvular disease. If no symptoms are present, close observation for disease progression and prophylactic therapy to prevent infection of the diseased heart may be the only treatment. When medical management is no longer effective, surgery is considered.

Diagnosis

The following diagnostic tests help to identify and diagnose valvular disease. See Chapter 28 for more information about these tests and related nursing care.

- *Echocardiography* is used routinely to diagnose valvular disease. Thickened valve leaflets, vegetations or growths on valve leaflets, myocardial function and chamber size can be determined, and pressure gradients across valves and pulmonary artery pressures can be estimated. Either transthoracic or transoesophageal echocardiography may be used.
- *Chest x-ray* can identify cardiac hypertrophy, chamber and great vessel enlargement, and dilation of the pulmonary vasculature. Calcification of the valve leaflets and annular openings may also be visible.
- *Electrocardiography* can demonstrate atrial and ventricular hypertrophy, conduction defects and arrhythmias associated with valvular disease.
- *Cardiac catheterisation* may be used to assess contractility and to determine the pressure gradients across the heart valves, in the heart chambers and in the pulmonary system.

Medications

Heart failure resulting from valvular disease is treated with diuretics, ACE inhibitors, vasodilators and possibly digoxin. Digoxin increases the force of myocardial contraction to maintain cardiac output. Diuretics, ACE inhibitors and vasodilators reduce preload and afterload. (See the 'Medication administration' box on pages 1053–1054.)

In individuals with valvular disorders, atrial distension often causes atrial fibrillation. Digoxin or small doses of beta-blockers are given to slow the ventricular response. (See Chapter 29 for more information about atrial fibrillation and its treatment.) Anticoagulant therapy is added to prevent clot and embolus formation, a common complication of atrial fibrillation as blood pools in the non-contracting atria. Anticoagulant therapy also is required following insertion of a mechanical heart valve. See Chapter 31 for more information about anticoagulant therapy.

Valvular damage increases the risk of infective endocarditis as altered blood flow allows bacterial colonisation. Antibiotics are prescribed prophylactically prior to any dental work, invasive procedures or surgery to minimise the risk of bacteraemia (bacteria in the blood) and subsequent endocarditis.

Percutaneous balloon valvuloplasty

Percutaneous balloon valvuloplasty is an invasive procedure performed in the cardiac catheterisation laboratory. A balloon catheter similar to that used in coronary angioplasty procedures is inserted into the femoral vein or artery. Guided by fluoroscopy, the catheter is advanced into the heart and positioned with the balloon straddling the stenotic valve. The balloon is then inflated for approximately 90 seconds to divide the fused leaflets and enlarge the valve orifice (see Figure 30.13). Balloon valvuloplasty is the treatment of choice for symptomatic mitral valve stenosis. It is used to treat children and young adults with aortic stenosis. Nursing care of the individual with a balloon valvuloplasty is similar to that of the person having percutaneous coronary revascularisation (see Chapter 29).

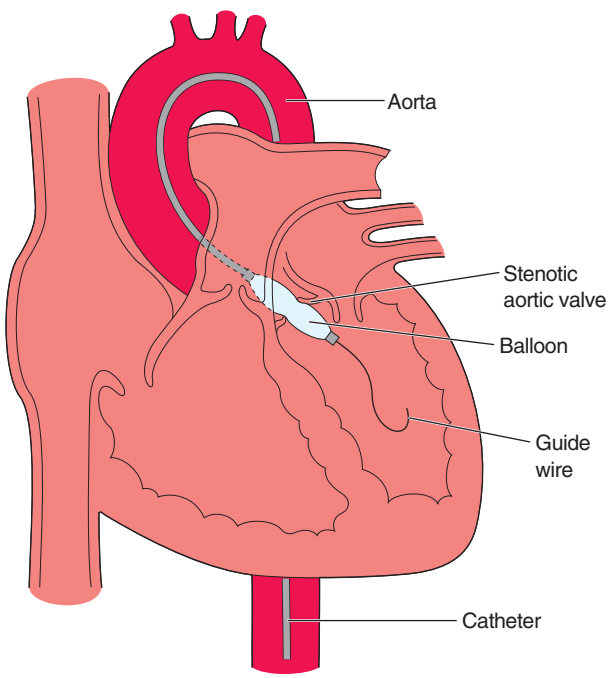

FIGURE 30.13 ■ Balloon valvuloplasty. The balloon catheter is guided into position straddling the stenosed valve. The balloon is then inflated to increase the size of the valve opening

Surgery

Surgery to repair or replace the diseased valve may be done to restore valve function, alleviate symptoms and prevent complications and death. The diseased valve is repaired when possible, because the risk of surgical mortality and complications is lower than with valve replacement.

RECONSTRUCTIVE SURGERY *Valvuloplasty* is a general term for reconstruction or repair of a heart valve. Methods include 'patching' the perforated portion of the leaflet, resecting excess tissue, debriding vegetations or calcification, and other techniques. Valvuloplasty may be used for stenotic or regurgitant mitral and tricuspid valves, mitral valve prolapse and aortic stenosis. Common valvuloplasty procedures include the following:

- *open commissurotomy*, surgical division of fused valve leaflets, is done to open stenotic valves
- *annuloplasty,* which repairs a narrowed or an enlarged or dilated valve annulus, the supporting ring of the valve.

VALVE REPLACEMENT Valve replacement is indicated when manifestations of valve dysfunction develop, preferably before left heart function is seriously impaired. In general, three factors determine the outcome of valve replacement surgery: (1) heart function at the time of surgery, (2) intraoperative and postoperative care, and (3) characteristics and durability of the replacement valve.

Many different prosthetic heart valves are available, including mechanical and biological tissue valves. Selection depends on numerous variables, including the valve haemodynamics, resistance to clot formation, ease of insertion, anatomical suitability and the person's acceptance of the procedure. The individual's age, underlying condition and contraindications to anticoagulation (such as a desire to become pregnant) also are considered in selecting the appropriate prosthesis. Table 30.10 lists the advantages and disadvantages of biological and mechanical valves.

Biological tissue valves may be *heterografts*, excised from a pig (see Figure 30.14A), or made of calf pericardium or *homografts* from a human (obtained from a cadaver or during heart transplant). Biological valves allow more normal blood flow and have a low risk of thrombus formation. As a result, long-term anticoagulation rarely is necessary. They are less durable, however, than mechanical valves.

Mechanical prosthetic valves have the major advantage of long-term durability. These valves are frequently used when life expectancy exceeds 10 years. Their major disadvantage is the need for lifetime anticoagulation to prevent the development of clots on the valve.

Most mechanical valves are either a tilting-disk (see Figure 30.14B) or a ball-and-cage design. Both biological and mechanical valves increase the risk of endocarditis, although its incidence is fairly low.

TABLE 30.10 Advantages and disadvantages of prosthetic heart valves

CATEGORY	TYPES	ADVANTAGES	DISADVANTAGES
Mechanical valves	Ball-and-cage Tilting disk	Long-term durability Good haemodynamics	Lifetime anticoagulation Audible click Risk of thromboembolism Infections are harder to treat
Biological tissue valves	Porcine heterograft Bovine heterograft Human aortic homograft	Low incidence of thromboembolism No long-term anticoagulation Good haemodynamics Quiet Infections are easier to treat	Prone to deterioration Frequent replacement is required

Nursing care

Health promotion

Preventing rheumatic heart disease is a key element in preventing heart valve disorders. Rheumatic heart disease is a consequence of rheumatic fever (see the previous section of this chapter), an immune process that may be a sequela to beta-haemolytic streptococcal infection of the pharynx (strep throat). Early treatment of strep throat prevents rheumatic fever. Teach individuals, families and communities about the importance of timely and effective treatment of strep throat. Emphasise the importance of completing the full prescription of antibiotics to prevent development of resistant bacteria. Prophylactic antibiotic therapy before invasive procedures to prevent infectious endocarditis is an important health promotion measure for individuals with pre-existing heart disease.

Assessment

Assessment data related to valvular heart disease include the following:

- *Health history:* complaints of decreasing exercise tolerance, dyspnoea on exertion, palpitations; history of frequent respiratory infections; previous history of rheumatic heart disease, endocarditis or a heart murmur.
- *Physical examination:* vital signs; skin colour and temperature, evidence of clubbing or peripheral oedema; neck vein distension; breath sounds; heart sounds and presence of S_3, S_4 or murmur; timing, grade and characteristics of any murmur; palpate for cardiac heave and thrills; abdominal contour, liver and spleen size.
- *Diagnostic tests:* echocardiogram and cardiac catheterisation reports; cardiac index and cardiac output.

Nursing diagnoses and interventions

Nursing priorities include maintaining cardiac output, managing manifestations of the disorder, teaching about the disease process and its management, and preventing complications.

Nursing care of the person undergoing valve surgery is similar to that of the person having other types of open-heart surgery, with increased attention to anticoagulation and preventing endocarditis.

Decreased cardiac output

Nearly all valve disorders affect ventricular filling and/or emptying, reducing cardiac output. Stenosis of the AV valves impairs ventricular filling and increases atrial pressures. Regurgitation of these valves reduces cardiac output as a portion of the blood in the ventricle regurgitates into the atria during systole. Stenosis of the semilunar valves obstructs ventricular outflow to the great vessels; regurgitation allows blood to flow back into the ventricles, creating higher filling pressures. When compensatory measures fail, heart failure develops.

- Monitor vital signs and haemodynamic parameters, reporting changes from the baseline. *A fall in systolic blood pressure and tachycardia may indicate decreased cardiac output.*

CONSIDERATION FOR PRACTICE

Promptly report changes in level of consciousness; distended neck veins; dyspnoea or respiratory crackles; urine output less than 30 mL/h (or 0.5 mL/h in children); cool, clammy or cyanotic skin; diminished peripheral pulses; or slow capillary refill. These findings indicate decreased cardiac output and impaired tissue and organ perfusion.

- Monitor intake and output; weigh daily. Report weight gain of 1.5 kg within 24 hours. *Fluid retention is a compensatory mechanism that occurs when cardiac output decreases; 1 kg of weight equals 1 L of fluid.*
- Restrict fluids as ordered. *Fluid intake may be restricted to reduce cardiac workload and pressures within the heart and pulmonary circuit.*
- Monitor oxygen saturation continuously and arterial blood gases as ordered. Report oxygen saturation less than 95% (or as specified) and abnormal ABG results. *Oxygen saturation levels and ABGs allow assessment of oxygenation.*
- Elevate the head of the bed. Administer supplemental oxygen as ordered. *These measures improve alveolar ventilation and oxygenation.*
- Provide for physical and emotional rest. *Physical and psychological rest decrease the cardiac workload.*
- Administer prescribed medications as ordered to reduce cardiac workload. *Diuretics, ACE inhibitors and direct vasodilators may be prescribed to reduce fluid volume and afterload, reducing cardiac work.*

Activity intolerance

Altered blood flow through the heart impairs delivery of oxygen and nutrients to the tissues. As the heart muscle fails and is unable to compensate for altered blood flow, tissue perfusion is further compromised. Dyspnoea on exertion is often an early symptom of valvular disease.

- Monitor vital signs before and during activities. *A change in heart rate of more than 20 bpm, a change of 20 mmHg or more in systolic BP and complaints of dyspnoea, excessive fatigue, chest pain, diaphoresis, dizziness or syncope may indicate activity intolerance.*
- Encourage self-care and gradually increasing activities as allowed and tolerated. Provide for rest periods, uninterrupted sleep and adequate nutritional intake. *Gradual progression of activities avoids excessive cardiac stress. Encouraging self-care increases the person's self-esteem and sense of power. Adequate rest and nutrition facilitate healing, decrease fatigue and increase energy reserves.*
- Provide assistance as needed. Suggest the person uses a shower chair, sitting while brushing hair or teeth, and other energy-saving measures. *Reducing energy expenditure helps maintain a balance of oxygen supply and demand.*
- Consult with cardiac rehabilitation nurse or physiotherapist for in-bed exercises and an activity plan. *In-bed exercises may help improve strength.*
- Discuss ways to conserve energy at home. *Information provides practical ways to deal with activity limitations and empowers the person to manage these limitations.*

Risk of infection

Damaged and deformed valve leaflets and turbulent blood flow through the heart significantly increase the risk of infective endocarditis. Invasive diagnostic and monitoring lines (e.g. cardiac catheterisation, haemodynamic monitoring) and disrupted skin with surgery also increase the risk of infection.

- Use aseptic technique for all invasive procedures. *Invasive procedures breach the body's protective mechanisms, potentially allowing bacteria to enter. Aseptic technique reduces this risk.*
- Assess wounds and catheter sites for redness, swelling, warmth, pain or evidence of drainage. *These signs of inflammation may signal infection.*
- Administer antibiotics as ordered. Ensure completion of the full course. *Antibiotics are used to prevent and treat infection. Completion of the full course of therapy prevents drug-resistant organisms from multiplying.*
- Monitor FBC and differential. Notify doctor of leucocytosis or leucopenia. *A high WBC count and increased percentage of immature WBCs (bands) may indicate bacterial infection; a low WBC count may indicate an impaired immune response and increased susceptibility to infection.*

Ineffective protection

Anticoagulant therapy commonly is prescribed for people with chronic atrial fibrillation, a history of emboli and following valve replacement surgery. Although chronic anticoagulant therapy decreases the risk of clots and emboli, it increases the risk of bleeding and haemorrhage.

- Test stools and vomitus for occult blood. *Bleeding due to excessive anticoagulation may not be apparent.*
- Instruct to avoid using aspirin or other NSAIDs. Encourage the person to read ingredient labels on over-the-counter drugs; many contain aspirin. *Aspirin and other NSAIDs*

interfere with clotting and may potentiate the effects of the anticoagulant therapy.
- Advise using a soft-bristled toothbrush, electric razor and gentle touch when cleaning fragile skin. *These measures decrease the risk of skin or gum trauma and bleeding.*

CONSIDERATION FOR PRACTICE

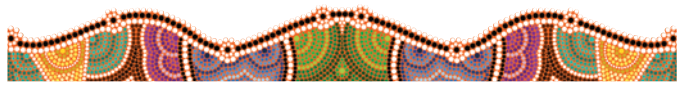
Monitor the International Normalized Ratio (INR) or prothrombin time (PT). For anticoagulation in people:
- with mechanical prosthetic heart valves: INR 2.5–3.5
- all other indications such as AF, DVT, PE: INR 2.0–3.0

Report an INR > 3.5 or a PT > 2.5 times the normal to the doctor. An excessively high INR or PT indicates excessive anticoagulation and an increased risk of bleeding.

Community-based care

For most individuals, valvular disease is a chronic condition. The person has the primary responsibility for managing effects of the disorder. To prepare the individual and their family for home care, discuss the following topics:
- management of symptoms, including any necessary activity restrictions or lifestyle changes
- the importance of adequate rest to prevent fatigue
- diet restrictions to reduce fluid retention and symptoms of heart failure
- information about prescribed medications, including purpose, desired and possible adverse effects, scheduling, and possible interactions with other drugs
- the importance of keeping follow-up appointments to monitor the disease and its treatment
- notifying all healthcare providers about valve disease or surgery to facilitate prescription of prophylactic antibiotics before invasive procedures or dental work
- reporting increasing severity of symptoms, especially of worsening heart failure or pulmonary oedema; signs of transient ischaemic attacks or other embolic events; evidence of bleeding, such as joint pain, easy bruising, black and tarry stools, bleeding gums or blood in the urine or sputum.

Provide referrals to community resources such as cardiac rehabilitation programs and community support services. Refer the person and their family (especially the primary food preparer) to a dietician or nutritionist for teaching and assistance with menu planning. See the accompanying nursing care plan for additional nursing care and teaching for an individual with mitral valve prolapse.



THE PERSON WITH CARDIOMYOPATHY

The **cardiomyopathies** are disorders that affect the heart muscle itself. They are a diverse group of disorders that affect both systolic and diastolic functions. Cardiomyopathies may be either primary or secondary in origin. Primary cardiomyopathies are idiopathic; their cause is unknown. Secondary cardiomyopathies occur as a result of other processes, such as ischaemia, infectious disease, exposure to toxins, connective tissue disorders, metabolic disorders or nutritional deficiencies. In many cases, the cause of cardiomyopathy is unknown. In 2013 in Australia, cardiomyopathy was listed as the cause of death in 993 people, which equates to 0.67% of all deaths (ABS, 2015).

Pathophysiology

The cardiomyopathies are categorised by their pathophysiology and presentation into three groups: dilated, hypertrophic

NURSING CARE PLAN A person with mitral valve prolapse

Julie Snow, a 22-year-old university student, sees the local medical officer for a physical examination after experiencing palpitations, fatigue and a headache during midterm examinations. Ms Snow stated, 'I'm scared that something is wrong with me.'

Over the past few months, Ms Snow has had occasional palpitations that she describes as 'feeling like my heart is doing flip-flops'. Rarely, these palpitations have been accompanied by a sharp, stabbing pain in her chest that lasts only a few seconds. She initially attributed her symptoms to stress, but she is increasingly concerned because the 'attacks' are becoming more frequent. Ms Snow states that she has 'always been healthy', does not smoke, uses alcohol socially and exercises, albeit intermittently. Ms Snow admits that she has been drinking a lot of coffee and cola and eating a lot of 'junk food' lately.

ASSESSMENT

Ms Snow's assessment revealed the following: height 168 cm, weight 63.6 kg, T 37°C, BP 118/64, P 82 and R 18. She was slightly anxious but in no acute distress. Systolic click and soft crescendo murmur grade II/VI was noted on auscultation. Apical impulse at fifth intercostal space left midclavicular line. Her lungs are clear to auscultation. A review of the remaining systems reveals no apparent abnormalities. An ECG shows sinus rhythm with occasional premature atrial contractions (PACs). Based on the admission history, manifestations and physical assessment, a mitral valve prolapse (MVP) is suspected.

DIAGNOSES

- *Anxiety* related to fear of heart disease and implications for lifestyle manifested by facial expressions and statements consistent with anxiety.
- *Feelings of powerlessness* related to unpredictability of symptoms manifested by anxiety.
- *Risk of infection* (endocarditis) related to altered valve function manifested by chest pain, cardiac dysfunction and fever.

NURSING CARE PLAN A person with mitral valve prolapse (continued)

PLANNING

- Consult with and refer the person to a cardiologist for continued monitoring and follow up.
- Discuss symptoms of progressive mitral regurgitation and the need to report these to the cardiologist.
- Discuss recommended follow-up care and its rationale.
- Discuss ways to decrease or relieve MVP symptoms.
- Acknowledge the risk of endocarditis and identify precautions to prevent it.
- Discuss the prognosis for MVP, emphasising that most people live normal lives using diet and lifestyle management.
- Discuss lifestyle changes to manage symptoms: aerobic exercise with warm-up and cool-down periods; maintaining adequate fluid intake, especially during hot weather or exercise; relaxation techniques (e.g. meditation, deep-breathing exercises, music therapy, yoga, guided imagery, heat therapy or progressive muscle relaxation) to perform daily; avoiding caffeine and crash diets; forming healthy eating habits.

Expected outcomes

- Verbalises an understanding of MVP and its management.
- Is able to identify signs of deterioration of the condition and the methods by which they will report it.
- Attends follow-up appointments.
- Verbalises methods to prevent endocarditis.
- Demonstrates hopes for future health and management.
- Undertakes lifestyle changes that result in weight loss, increased circulation and improved cardiovascular and muskuloskeletal condition.

IMPLEMENTATION

- Teach the person about MVP, including heart valve anatomy, physiology and function, common manifestations of MVP and treatment rationale.
- Provide opportunity for the person to verbalise feelings and share concerns about MVP. Encourage to attend an MVP support group meeting.
- Instruct the person to keep a weekly record of symptoms and their frequency for 1 month.
- Teach the person about infective endocarditis risk and discuss the protocol for prevention with prophylactic antibiotics with the doctor. Encourage notifying dentist and other healthcare providers of MVP before dental or any invasive procedure.

EVALUATION

After several educational sessions Ms Snow verbalises an understanding of MVP by explaining heart valve function, listing common manifestations of MVP and describing indications of deteriorating heart function. She states she will report these manifestations to her cardiologist if they occur. She is given a booklet on MVP for additional reading. She also verbalises understanding of the risk of endocarditis and states that she will notify her doctors of her MVP and the need for antibiotics before invasive procedures. Ms Snow is attending a monthly MVP support group (led by a cardiac rehabilitation nurse) and states, 'I am so glad to know I'm not alone! It really helps to know that others are living well with MVP.' Her weekly symptom log shows her symptoms are associated with late-night studying and drinking large amounts of coffee and cola. Ms Snow has moderated her caffeine intake and increased her fluids, relieving her symptoms. Ms Snow states that she realises that she has 'the ability to control my life through the choices I make'.

CRITICAL THINKING IN THE NURSING PROCESS

1. Develop an action plan for Ms Snow that outlines specific activities she can use to manage symptoms of MVP.
2. Why are people with symptomatic MVP encouraged to include regular exercise in their health habits?
3. How does the support of family, friends and other people with MVP assist individuals in managing their condition?
4. What manifestations would indicate a progressive worsening of Ms Snow's mitral regurgitation?

REFLECTION ON THE NURSING PROCESS

1. Outline what you have learned from this case study that you will apply to your future practice.
2. What techniques would assist you to facilitate communication about lifestyle change principles in an individual with mitral valve prolapse?

and restrictive. Table 30.11 compares the causes, pathophysiology, manifestations and management of the cardiomyopathies.

Dilated cardiomyopathy

Dilated cardiomyopathy is the most common type of cardiomyopathy.

The cause of dilated cardiomyopathy is unknown, although it appears to frequently result from toxins, metabolic conditions or infection. Reversible dilated cardiomyopathy may develop due to alcohol and cocaine abuse, chemotherapeutic drugs, pregnancy and systemic hypertension. In dilated cardiomyopathy, heart chambers dilate and ventricular contraction is impaired. Both end-diastolic and end-systolic volumes increase and the left ventricular ejection fraction is substantially reduced, decreasing cardiac output. Left ventricular dilation is prominent; left ventricular hypertrophy is usually minimal. The right ventricle may also be enlarged and extensive interstitial fibrosis (scarring) may be evident (Goswami, 2014).

MANIFESTATIONS AND COURSE Manifestations of dilated cardiomyopathy develop gradually. Heart failure often presents years after the onset of dilation and pump failure. Both right- and left-sided failure occur, with dyspnoea on exertion, orthopnoea, paroxysmal nocturnal dyspnoea, weakness, fatigue, peripheral oedema and ascites. Both S_3 and S_4 heart sounds are commonly heard, as well as an AV regurgitation murmur.

TABLE 30.11 Classifications of cardiomyopathy

	DILATED	HYPERTROPHIC	RESTRICTIVE
			Causes	Usually idiopathic; may be secondary to chronic alcoholism or myocarditis	Hereditary; may be secondary to chronic hypertension	Usually secondary to amyloidosis, radiation or myocardial fibrosis
Pathophysiology	Scarring and atrophy of myocardial cells Thickening of ventricular wall Dilation of heart chambers Impaired ventricular pumping Increased end-diastolic and end-systolic volumes Mural thrombi are common	Hypertrophy of ventricular muscle mass Small left ventricular volume Septal hypertrophy may obstruct left ventricular outflow Left atrial dilation	Excess rigidity of ventricular walls restricts filling Myocardial contractility remains relatively normal
Manifestations	Heart failure Cardiomegaly Arrhythmias S_3 and S_4 gallop; murmur of mitral regurgitation	Dyspnoea, anginal pain, syncope Left ventricular hypertrophy Arrhythmias Loud S_4 Sudden death	Dyspnoea, fatigue Right-sided heart failure Mild to moderate cardiomegaly S_3 and S_4 Mitral regurgitation murmur
Management	Management of heart failure Implantable cardioverter-defibrillator (ICD) as needed Cardiac transplantation	Beta-blockers Antiarrhythmic agents Calcium channel blockers ICD, dual-chamber pacing Surgical excision of part of the ventricular septum	Management of heart failure Exercise restriction

Arrhythmias are common, including supraventricular tachycardias, atrial fibrillation and complex ventricular tachycardias. Untreated arrhythmias and thromboembolism can lead to sudden death (Goswami, 2014).

The prognosis of dilated cardiomyopathy is grim; most individuals get progressively worse.

Hypertrophic cardiomyopathy

Hypertrophic cardiomyopathy is characterised by decreased compliance of the left ventricle and hypertrophy of the ventricular muscle mass. This impairs ventricular filling, leading to small end-diastolic volumes and low cardiac output. Several people with hypertrophic cardiomyopathy have a family history of the disease. It is genetically transmitted in an autosomal dominant pattern (Shah, 2014).

The pattern of left ventricular hypertrophy is unique in that the muscle may not hypertrophy 'equally'. In a majority of people, the interventricular septal mass, especially the upper portion, increases to a greater extent than the free wall of the ventricle. The enlarged upper septum narrows the passageway of blood into the aorta, impairing ventricular outflow. For this reason, this disorder is also known as *idiopathic hypertrophic subaortic stenosis (IHSS)* or *hypertrophic obstructive cardiomyopathy (HOCM)*.

MANIFESTATIONS AND COURSE Hypertrophic cardiomyopathy may be asymptomatic for many years. Symptoms typically occur when increased oxygen demand causes increased ventricular contractility. They may develop suddenly during or after physical activity; in children and young adults, sudden cardiac death may be the first sign of the disorder. Hypertrophic cardiomyopathy is the probable cause of death in young athletes who die suddenly.

The usual manifestations of hypertrophic cardiomyopathy are dyspnoea, angina and syncope. Angina may result

from ischaemia due to overgrowth of the ventricular muscle, coronary artery abnormalities or decreased coronary artery perfusion. Syncope may occur when the outflow tract obstruction severely decreases cardiac output and blood flow to the brain. Ventricular arrhythmias are common; atrial fibrillation also may develop. Other manifestations of hypertrophic cardiomyopathy include fatigue, dizziness and palpitations. A harsh, crescendo–decrescendo systolic murmur of variable intensity heard best at the lower left sternal border and apex is characteristic in hypertrophic cardiomyopathy. An S_4 may also be noted on auscultation.

Restrictive cardiomyopathy

The least common form of cardiomyopathy, *restrictive cardiomyopathy*, is characterised by rigid ventricular walls that impair diastolic filling. Causes of restrictive cardiomyopathy include myocardial fibrosis and infiltrative processes, such as amyloidosis. Fibrosis of the myocardium and endocardium causes excessive stiffness and rigidity of the ventricles. Decreased ventricular compliance impairs filling, with decreased ventricular size, elevated end-diastolic pressures and decreased cardiac output. Contractility is unaffected and the ejection fraction is normal.

MANIFESTATIONS AND COURSE The manifestations of restrictive cardiomyopathy are those of heart failure and decreased tissue perfusion. Dyspnoea on exertion and exercise intolerance are common. Jugular venous pressure is elevated and S_3 and S_4 are common. The prognosis for restrictive cardiomyopathy is poor. Many people die within 3 years as the systemic nature of the underlying disease process precludes effective treatment.

INTERPROFESSIONAL CARE

With the exception of treating an underlying cause, little can be done to treat either dilated or restrictive cardiomyopathies. For these disorders, treatment focuses on managing heart failure and treating arrhythmias. Refer to the section of this chapter on heart failure and Chapter 29 for specific treatment strategies. Treatment of hypertrophic cardiomyopathy focuses on reducing contractility and preventing sudden cardiac death. Strenuous physical exertion is restricted, because it may precipitate arrhythmias or sudden cardiac death. Dietary and sodium restrictions may help diminish the manifestations.

Diagnosis

Diagnosis begins with a history and physical assessment to rule out known causes of heart failure. Other tests may include the following:

- *Echocardiography* is done to assess chamber size and thickness, ventricular wall motion, valvular function and systolic and diastolic function of the heart.
- *Electrocardiography* and *ambulatory ECG monitoring* demonstrate cardiac enlargement and detect arrhythmias.
- *Chest x-ray* shows cardiomegaly, enlargement of the heart and any pulmonary congestion or oedema.
- *Haemodynamic studies* are used to assess cardiac output and pressures in the cardiac chambers and pulmonary vascular system.
- *Radionuclear scans* help identify changes in ventricular volume and mass, as well as perfusion deficits.
- *Cardiac catheterisation* and *coronary angiography* may be done to evaluate coronary perfusion, the cardiac chambers, valves and great vessels for function and structure, pressure relationships and cardiac output.
- *Myocardial biopsy* uses the transvenous route to obtain myocardial tissue for biopsy. The cells are examined for infiltration, fibrosis or inflammation.

Medications

The drug regimen used to treat heart failure also is used for dilated or restrictive cardiomyopathy. This includes ACE inhibitors, vasodilators and digoxin (see the earlier section of this chapter on medications for heart failure). Beta-blockers also may be used with caution in individuals with dilated cardiomyopathy. Anticoagulants are given to reduce the risk of thrombus formation and embolisation. Antiarrhythmic drugs are avoided if possible due to their tendency to precipitate further arrhythmias (Dumitru, 2015; Papadakis et al., 2013).

Beta-blockers are the drugs of choice to reduce anginal symptoms episodes associated with hypertrophic cardiomyopathy. The negative inotropic effects of beta-blockers and calcium channel blockers decrease the myocardial contractility, decreasing obstruction of the outflow tract. Beta-blockers also decrease heart rate and increase ventricular compliance, increasing diastolic filling time and cardiac output. Vasodilators, digoxin, nitrates and diuretics are contraindicated. Amiodarone may be used to treat ventricular arrhythmias (Dumitru, 2015; Papadakis et al., 2013).

Surgery

Without definitive treatment, individuals with cardiomyopathy develop end-stage heart failure. Cardiac transplant is the definitive treatment for dilated cardiomyopathy. Ventricular assist devices may be used to support cardiac output until a donor heart is available. Transplantation is not a viable option for restrictive cardiomyopathy because transplantation does not eliminate the underlying process causing infiltration or fibrosis and eventually the transplanted organ is affected as well. See the section on heart failure for more information about cardiac transplantation.

An implantable cardioverter-defibrillator (ICD) often is inserted to treat potentially lethal arrhythmias. A dual-chamber pacemaker also may be used to treat hypertrophic cardiomyopathy.

Nursing care

Nursing assessment and care for individuals with dilated and restrictive cardiomyopathy are similar to those for individuals with heart failure. Teaching about the disease process and its management is vital. Some degree of activity restriction is often

TRANSLATION TO PRACTICE

Outcomes and opportunities: a nurse-led model of chronic disease management in Australian general practice

A NURSE-LED MODEL OF CHRONIC DISEASE MANAGEMENT

In a study by Eley et al. (2012), mixed-method research trialled the feasibility of a new nurse-led model of disease management in people with chronic cardiovascular disease. Individuals were randomised to either a practice-nurse-managed group or general-practitioner-managed group. The results indicated no statistical difference between self-reported quality of life and perceptions of the models' acceptability over a 12-month period. At the conclusion of the study, all GPs elected to continue the practice-nurse-led model as they saw significant advantages.

IMPLICATIONS FOR NURSING

A practice nurse may be suitable to lead the routine community management of people with stable chronic cardiovascular disease. An appropriately designed and supported nurse-led model would provide appropriate and feasible primary health opportunity to individuals with chronic conditions. Other benefits of such a model could include an increase in nurses' scope of practice and also an economic benefit for the already overburdened health-care system.

CRITICAL THINKING IN PERSON-CENTRED CARE

1. In this study, the findings indicate that a practice nurse is capable of providing to people with cardiovascular conditions selected services that are sufficiently similar to those of GPs. Given your knowledge of what is required to assist an individual to maintain their cardiovascular health in the context of heart failure, what components would a nurse-led primary health model contain? Consider aspects of education, intervention and monitoring. Make a table outlining these three components with statements to justify each component identified.
2. How will the findings of this study impact on the scope of practice of a practice nurse? What further education requirements would be needed to adequately and safely support a practice-nurse-led model?

Source: D. Eley, E. Patterson, J. Young et al. (2012). Outcomes and opportunities: A nurse-led model of chronic disease management in Australian general practice. *Australian Journal of Primary Health*, 8 May (online).

necessary; assist to conserve energy while encouraging self-care. Support coping skills and adaptation to required lifestyle changes. Provide information and support for decision making about cardiac transplantation if that is an option. Discuss the toxic and vasodilator effects of alcohol and encourage abstinence. For nursing diagnoses and suggested interventions see the nursing care section for heart failure.

The person with hypertrophic cardiomyopathy requires care similar to that provided for myocardial ischaemia; nitrates and other vasodilators, however, are avoided. If surgery is performed, nursing care is similar to that for any person undergoing open-heart surgery. Discuss the genetic transmission of hypertrophic cardiomyopathy and suggest screening of close relatives (parents and siblings).

Provide pre- and postoperative care and teaching as appropriate for individuals undergoing invasive procedures or surgery for cardiomyopathy.

Nursing diagnoses that may be appropriate for people with cardiomyopathy include:

- *Risk of decreased cardiac output* related to impaired left ventricular filling, contractility or outflow obstruction.
- *Risk of fatigue* related to decreased cardiac output.
- *Risk of ineffective breathing pattern* related to heart failure.
- *Risk of fear* related to risk of sudden cardiac death.
- *Risk of ineffective role performance* related to decreasing cardiac function and activity restrictions.
- *Risk of anticipatory grieving* related to poor prognosis.

Community-based care

Cardiomyopathies are chronic, progressive disorders generally managed in home and community care settings unless surgery or transplant is planned or end-stage heart failure develops. When teaching the person and family for home care, include the following topics:

- activity restrictions and dietary changes to reduce manifestations and prevent complications
- prescribed drug regimen, its rationale, intended and possible adverse effects
- the disease process, its expected ultimate outcome and treatment options
- cardiac transplantation, including the procedure, the need for lifetime immunosuppression to prevent transplant rejection and the risks of postoperative infection and long-term immunosuppression
- symptoms to report to the doctor or for which immediate care is needed
- cardiopulmonary resuscitation procedures and available training sites.

Refer the person and their family for home and social services and counselling as indicated. Provide community resources such as support groups or the National Heart Foundation.

BOX 30.4 Comparison of Australian hospital separations for selected cardiovascular conditions, 2012–2013 by gender

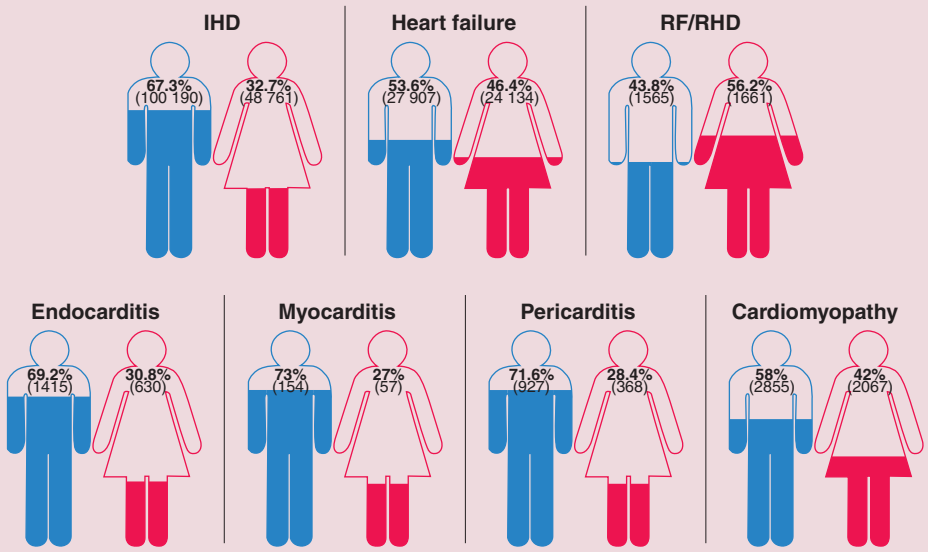


FIGURE 30.15 ■ Top value—percentage admitted with selected condition comparing gender; bracketed value—actual number admitted in 2012–2013 by gender.

IHD = ischaemia heart disease; RF = rheumatic fever; RHD = rheumatic heart disease.

CHAPTER HIGHLIGHTS

- All of the disorders discussed in this chapter can lead to heart failure, a condition in which the heart is unable to pump effectively to meet the body's needs for blood and oxygen to the tissues.
- Coronary heart disease (myocardial ischaemia) and cardiomyopathies are the leading causes of heart failure.
- When the heart starts to fail, compensatory mechanisms are activated to help maintain tissue perfusion. While these mechanisms, including increased contractile force, vasoconstriction, sodium and water retention and remodelling of the heart, effectively maintain cardiac output in the short term, in the long term they hasten deterioration of heart function.
- The goals of heart failure management are to reduce the workload of the heart and improve its function. Medical management includes administration of drugs such as ACE inhibitors, beta-blockers, diuretics and vasodilators to reduce the workload of the heart, and inotropic medications such as digoxin to improve the strength of cardiac muscle contraction.
- Nursing care of the person with heart failure is primarily supportive and educative, providing the individual and their family with necessary knowledge and resources to manage this chronic condition.
- Cardiogenic pulmonary oedema, a manifestation of severe cardiac decompensation, is a medical emergency, requiring immediate and effective treatment to preserve life. The nurse's role in managing pulmonary oedema focuses on supporting respiratory and cardiac function, administering prescribed medications and providing reassurance to the person and their family.
- Inflammatory and infectious processes, such as rheumatic fever, endocarditis, myocarditis and pericarditis, can affect any layer of the heart. While some processes, such as myocarditis and pericarditis, typically are mild and self-limiting, others can have long-term effects on cardiac structure and function.
- Processes such as rheumatic heart disease, endocarditis and congenital conditions can affect the structure and function of the heart valves, resulting in either stenosis (narrowing) of the valve and restricted flow through it, or regurgitation (backflow of blood through a valve that does not fully close). The mitral and aortic valves are commonly affected due to the higher pressures and increased workload of the left side of the heart.
- Valve disorders may be mild, producing a heart murmur but no functional impairment for the individual, or severe, causing symptoms of heart failure even at rest. Repair or replacement of the valve may ultimately be required.
- Cardiomyopathies affect the heart muscle and its ability to stretch during filling and to contract effectively. Dilated cardiomyopathy, the most common type, is progressive,

ultimately necessitating heart transplant. Hypertrophic cardiomyopathy affects both ventricular filling and outflow through the aortic valve. Surgical resection of excess tissue may relieve its manifestations.

CONCEPT CHECK

1 In reviewing the doctor's admitting notes for a person with heart failure, the nurse notes that the person has an ejection fraction of 25%. The nurse recognises this as meaning:
   1 ventricular function is severely impaired
   2 the amount of blood being ejected from the ventricles is within normal limits
   3 25% of the blood entering the ventricle remains in the ventricle after systole
   4 cardiac output is greater than normal, overtaxing the heart

2 In assessing a person admitted 24 hours previously with heart failure, the nurse notes that the person has lost 1 kg of weight, his heart rate is 88 (HR was 105 on admission) and he now has crackles in the bases of his lung fields only. The nurse correctly interprets these data as indicating:
   1 the person's condition is unchanged from admission
   2 a need for more aggressive treatment
   3 the treatment regimen is achieving the desired effect
   4 no further treatment is required at this time as the failure has resolved

3 The nurse assessing a person admitted with left ventricular failure would recognise which of the following findings as consistent with the diagnosis? (Select all that apply.)
   1 5 cm jugular vein distension at 30 degrees
   2 complaints of shortness of breath with minimal exertion
   3 substernal chest pain during exercise
   4 bilateral inspiratory crackles to midscapular
   5 fatigue

4 Morphine 2–5 mg IV as needed for pain and dyspnoea is ordered for a person in acute pulmonary oedema. The nurse appropriately:
   1 questions this order because no time intervals have been specified
   2 administers the drug as ordered, monitoring respiratory status
   3 withholds the drug until the person's respiratory status improves
   4 administers the drug only when the person complains of chest pain

5 An expected assessment finding in a person with mitral stenosis being admitted for a valve replacement would be:
   1 muffled heart sounds
   2 S_3 and S_4 heart sounds
   3 diastolic murmur heard at the apex
   4 cardiac heave

6 A person facing heart valve replacement asks the nurse which type of valve is the best, biological or mechanical. Which of the following would be an appropriate response?
   1 The need to take drugs to prevent rejection of biological tissue is a major consideration.
   2 Clotting is a risk with mechanical valves, necessitating anticoagulant drug therapy after insertion.
   3 Biological valves tend to be more durable than mechanical valves.
   4 Endocarditis is a risk following valve replacement; it is more easily treated with mechanical valves.

CHAPTER 31

NURSING CARE OF PEOPLE WITH VASCULAR AND LYMPHATIC DISORDERS

MAJELLA HALES

KEY TERMS

LEARNING OUTCOMES

- Discuss the course, implications and health management options for a person with a hypertensive condition.
- Differentiate between various types, implications and management options for an individual with an aneurysm.
- Relate the implications and interventions for a person with peripheral vascular disease to its pathophysiology.
- Compare and contrast the types of arterial occlusive conditions a person may develop.
- Discuss the risks, implications and health management options for a person who has developed a venous thrombosis.
- Differentiate between implications and management options for a person with venous insufficiency or varicose veins.
- Describe the aetiology, pathophysiology and manifestations of lymphadenopathy and lymphoedema.

CLINICAL COMPETENCIES

- Perform a comprehensive vascular assessment on people with vascular disorders, using data to select and prioritise appropriate nursing diagnoses, implementation of care and identify desired outcomes of care.
- Identify the effects on the functional health status of people with vascular disorders.
- Use research-informed practice and evidence-based plans to provide individualised care for people with vascular disorders.
- Collaborate with the interprofessional care team in planning and providing care for people with vascular disorders.
- Safely and knowledgeably administer medications and prescribed treatments for people with vascular disorders.
- Provide person and family teaching to promote, maintain and restore health in people with common vascular disorders.

The main processes that interfere with peripheral blood flow and that of lymphatic fluid include constriction, obstruction, inflammation and vasospasm. These conditions lead to disorders of blood pressure regulation, peripheral artery function, aortic structure, venous circulation and lymphatic circulation.

A holistic approach is important when caring for people with disorders of the vascular and lymphatic systems. The focus of care is on teaching long-term care measures, pain relief, improving peripheral blood and lymphatic circulation, preventing tissue damage and promoting healing. The prescribed treatment may have emotional, social and economic effects on the person and family.

Prevalence of cardiovascular conditions such as angina, myocardial infarction, stroke, heart failure, oedema and hypertension are so high that the Australian government considers them to be a National Health Priority. These conditions are not only causing a financial burden, but also a physical and emotional cost for many individuals. See Figure 31.1 for information regarding prevalence of common cardiovascular conditions.

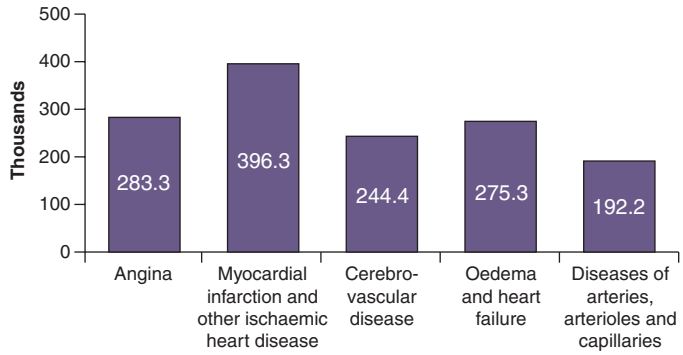

FIGURE 31.1 ■ Prevalence of heart, stroke and vascular conditions in Australia, 2011–2012

Source: Generated using data from Australian Bureau of Statistics (ABS) (2013b). *Australian Health Survey: First Results—Table 3: Long-term Conditions by Age then Sex*. (Cat. no. 4364.0.55.001.) DISORDERS OF BLOOD PRESSURE REGULATION

Blood flows through the circulatory system from areas of higher pressure to areas of lower pressure. The amount of pressure in any portion of the vascular system is affected by a number of factors, including blood volume, vascular resistance and cardiac output. The **blood pressure (BP)** is the tension or pressure exerted by blood against arterial walls. A certain amount of pressure within the system is necessary to maintain open vessels, capillary perfusion and oxygenation of all body tissues. Excess pressure, however, has harmful effects, increasing the workload of the heart, altering the structure of the vessels and affecting sensitive body tissues such as the kidneys, eyes and central nervous system (CNS).

This section focuses on **hypertension**, or excess pressure in the arterial portion of systemic circulation. Excessively low blood pressure, *hypotension*, is discussed in the shock section of Chapter 10. Altered pulmonary vascular pressures are discussed in Chapter 36.

Physiology review

Blood flow through the circulatory system requires *sufficient blood volume* to fill the blood vessels and *pressure differences* within the system that allow blood to move forward. The arterial, or supply, side of the circulation has relatively high pressures created by the thick elastic walls of the arteries and arterioles. The venous, or return, side of the system, on the other hand, is a low-pressure system of thin-walled, distensible veins. Blood flows through the capillaries linking these two systems from the higher-pressure arterial side to the lower-pressure venous side.

The arterial blood pressure is created by the ejection of blood from the heart during systole (*cardiac output*, or *CO*) and the tension or resistance to blood flow created by the elastic arterial walls (*systemic vascular resistance*, or *SVR*). The blood pressure rises as the heart contracts during systole, ejecting its blood. This pressure wave, or the **systolic blood pressure**, is felt as the peripheral pulse and heard as the Korotkoff's sounds during blood pressure measurement. In healthy adults the average systolic pressure is less than 120 mmHg. During diastole or cardiac relaxation and filling, elastic arterial walls maintain a minimum pressure, the **diastolic blood pressure**, to maintain blood flow through the capillary beds. The average diastolic pressure in a healthy adult is less than 80 mmHg. The difference between the systolic and diastolic pressure, normally about 40 mmHg, is known as the **pulse pressure**. The **mean arterial pressure (MAP)** is the average pressure in the arterial circulation throughout the cardiac cycle. It can be calculated using the formula (systolic BP + diastolic BP + diastolic BP)/3. Diastole counts twice as much as the systole because two-thirds of the cardiac cycle is spent in diastole.

CONSIDERATION FOR PRACTICE

- Cardiac output and systemic (or peripheral) vascular resistance are the primary factors that determine blood pressure.
- A decrease in cardiac output (e.g. due to haemorrhage) or decreased peripheral vascular resistance (e.g. systemic vasodilation) causes the blood pressure to fall.
- Increased cardiac output (e.g. during exercise) or increased peripheral vascular resistance (e.g. vasoconstriction due to drug administration) causes the blood pressure to rise.

Cardiac output is determined by the blood volume and the ability of the ventricles to fill and effectively pump that blood. A number of factors contribute to systemic vascular resistance, including vessel length, blood viscosity and vessel diameter

and distensibility (compliance). While vessel length and blood viscosity remain relatively constant, vessel diameter and compliance are subject to normal regulatory activities and disease.

The arterioles normally determine the SVR as their diameter changes in response to a variety of stimuli:

- *Sympathetic nervous system (SNS) stimulation*. Baroreceptors in the aortic arch and carotid sinus signal the SNS via the cardiovascular control centre in the medulla when the MAP changes. A drop in MAP stimulates the SNS, increasing the heart rate and cardiac output and constricting arterioles (except in skeletal muscle). As a result, BP rises. A rise in MAP has the opposite effect, decreasing the heart rate and cardiac output causing arteriolar vasodilation.
- *Circulating adrenaline and noradrenaline* from the adrenal cortex (e.g. the fight-or-flight response) have the same effect as SNS stimulation.
- *Renin–angiotensin–aldosterone system* responds to renal perfusion. A drop in renal perfusion stimulates renin release. Renin converts angiotensinogen to angiotensin I, which is subsequently converted to angiotensin II in the lungs by angiotensin-converting enzyme (ACE). Angiotensin II is a potent vasoconstrictor. It also promotes sodium and water retention both directly and by stimulating the adrenal medulla to release aldosterone. Both SVR and CO increase, resulting in a rise in BP.
- *Atrial natriuretic peptide (ANP)* and *brain natriuretic peptide (BNP)* are released from atrial cells in response to stretching by excess blood volume. These hormones promote vasodilation along with sodium and water excretion, resulting in lowering of BP.
- *Adrenomedullin* is a peptide synthesised and released by endothelial and smooth muscle cells in blood vessels. It is a potent vasodilator.
- *Vasopressin* or *antidiuretic hormone* (from the posterior pituitary gland) promotes water retention and vasoconstriction, resulting in a rise in BP.
- *Local factors* such as inflammatory mediators and various metabolites can promote vasodilation, causing changes in BP.

In addition to the preceding, the primary factor affecting vessel compliance is the extent of arteriosclerosis (hardening of the arteries) and atherosclerosis (plaque accumulation). Figure 31.2 summarises the interrelationships of major factors regulating blood pressure.

CONSIDERATION FOR PRACTICE

- Sympathetic nervous system stimulation, adrenaline and noradrenaline, and the hormones angiotensin II and vasopressin (antidiuretic hormone or ADH) are *vasoconstrictors*, increasing BP.
- Parasympathetic nervous system stimulation and the hormones ANP, BNP and adrenomedullin are *vasodilators*, decreasing BP.
- The hormones aldosterone and ADH promote sodium and water retention, increasing BP.

PRIMARY HYPERTENSION

Primary hypertension, also known as *essential hypertension*, is a persistently elevated systemic blood pressure. Hypertension is defined as systolic blood pressure of 140 mmHg or higher, or diastolic pressure of 90 mmHg or higher, based on the average of three or more readings taken on separate occasions (Australian Institute of Health and Welfare (AIHW), 2014a). People who are currently normotensive but are taking antihypertensive medication are also considered to have hypertension for the sake of statistics.

Hypertension is an important and very common public health issue. While it rarely causes symptoms or noticeably limits the person's functional health patterns, hypertension is a major risk factor for coronary heart disease, heart failure, stroke and kidney failure.

Despite steady improvement over the past three decades, cardiovascular disease remains one of the biggest causes of death in Australia and continues to generate a considerable burden on the population in terms of illness and disability. The treatment options for cardiovascular disease prolong life, but as individuals develop more risk factors such as hypertension, obesity and diabetes, the burden on the health dollar will only increase (Department of Health (DOH), 2015).

Incidence and risk factors

In Australia, almost 8500 people were admitted for primary hypertension in 2012–2013. Hypertension is the third most common chronic disease behind arthritis and back pain and has been diagnosed in 10.2% (2.2 million) of Australians (AIHW, 2014a). However, in the 2011–2012 *Australian Health Survey*, 32% of all adults who had their blood pressure measured were hypertensive, with a slightly higher incidence in males (34%) than females (29%) (ABS 2013a; AIHW 2014a). Nevertheless, interestingly, in the same period of time, 62% of all admissions to Australian hospitals with a primary diagnosis of hypertension were women (ABS, 2013b).

Prevalence of hypertension in Aboriginal and Torres Strait Islander people is also more complex than one would initially consider. Government statistics examining the prevalence of hypertension in Aboriginal and Torres Strait Islander people report a figure 1.2 times higher than in non-Indigenous Australians (ABS, 2014). When both cultures are analysed separately, a recently published research article suggested that Aboriginal people were twice as likely to develop hypertension than Torres Strait Islander people (Li & McDermott, 2015) (see the 'Focus on cultural diversity' box below). Another variable that appears important in determining the prevalence of hypertension in Australia is location and degree of remoteness. Australians living in rural and remote areas are 1.15 to 3 times more likely to develop hypertension (ABS, 2011; National Heart Foundation of Australia (NHF), 2010).

Hypertension and its consequences are not unique to Australia. The World Health Organization identified that 40% of adults have hypertension worldwide (WHO, 2013). However, prevalence differs between countries and within regions; for example, the Republic of Korea (13.2%) is reported to have the lowest prevalence and Estonia (38.3%) the highest (WHO, 2014). See Table 31.1 for prevalence of hypertension in the Western Pacific region.

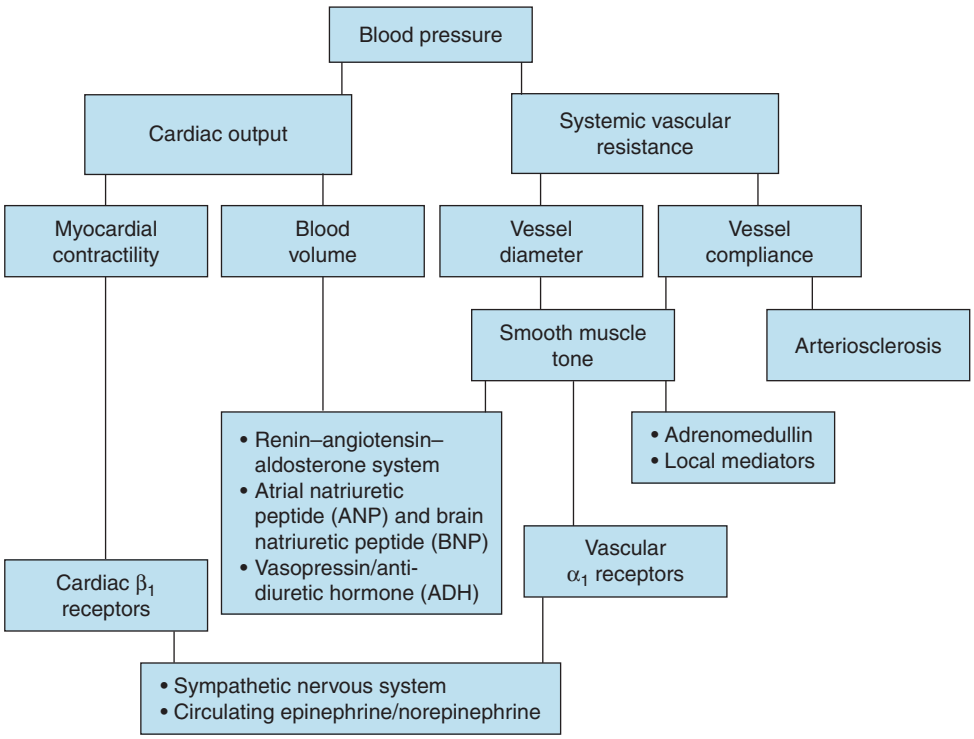

FIGURE 31.2 ■ Factors affecting blood pressure

TABLE 31.1 Age-standardised estimated prevalence of hypertension statistics for selected countries in the Pacific region

COUNTRY	ESTIMATED PREVALENCE REPORTED BY WHO
Australia	18.4%
New Zealand	19.1%
Solomon Islands	22.9%
Papua New Guinea	23.2%
Philippines	23.5%
Malaysia	24.5%
Cook Islands	25.3%
Fiji	25.5%
Nauru	25.9%
Mongolia	34.3%

Source: Generated using data from WHO (2014).

A number of risk factors have been identified for primary hypertension (see Box 31.1). Genetics play a role, as do environmental factors.

- *Family history*. Studies show a genetic link in about 31–68% of people with primary hypertension with over 40 potential loci identified for genes which may play a role in blood pressure regulation (Padmanabhan, Caulfield & Dominiczak, 2015). These include genes involved in the renin–angiotensin–aldosterone system, vascular tone, sodium transport, renal function, steroid synthesis, sympathetic nervous system function, endothelial function, obesity and insulin resistance (Padmanabhan, Newton-Cheh & Dominiczak, 2012).
- *Age*. The incidence of hypertension rises with increasing age. Ageing affects baroreceptors involved in blood pressure regulation as well as arterial compliance. As the arteries become less compliant, pressure within the vessels increases. This is often most apparent as a gradual increase in the systolic pressure with ageing.
- *Race*. The prevalence of hypertension in Aboriginal and Torres Strait Islander people is 25% compared to 20% for non-Indigenous Australians (NHF, 2014).

FOCUS ON CULTURAL DIVERSITY

- Aboriginal and Torres Strait Island people are 1.2 times more likely to develop hypertension than non-Indigenous Australians.
- Aboriginal Australians are twice as likely to develop hypertension than Torres Strait Islander Australians.
- The prevalence of hypertension in New Zealand in 2012–2013 was 15.9%, with Māori people 1.4 times and Pacific Island people 1.3 times more likely to have high blood pressure than non-Māori people.

Source: ABS (2014); Li & McDermott (2015); Ministry of Health (MOH) 2013).

BOX 31.1 Factors contributing to hypertension

Modifiable factors
- High sodium intake
- Low potassium, calcium and magnesium intake
- Obesity
- Excess alcohol consumption
- Insulin resistance

Non-modifiable factors
- Genetic factors
- Age
- Family history
- Race

- *Mineral intake*. High sodium intake often is associated with fluid retention. Hypertension related to sodium intake involves a number of different physiological mechanisms, including the renin–angiotensin–aldosterone system, nitric oxide, catecholamines, endothelin and atrial natriuretic peptide. Low potassium, calcium and magnesium intake can contribute to the development of hypertension, as it results in renin–angiotensin–aldosterone system activity (Adebamowo et al., 2015). The ratio of sodium to potassium intake appears to play a role, with a sodium-to-potassium ratio of < 1 being protective. Potassium promotes vasodilation by reducing responses to catecholamines and angiotensin II, modulating baroreflex sensitivity and reducing intracellular sodium. Magnesium has antihypertensive effects through numerous mechanisms including an increase in nitric-oxide-mediated vasodilation, reduction of noradrenaline and inhibition of platelet aggregation (Houston, 2014).
- *Obesity*. Central obesity (fat cell deposits in the abdomen), determined by an increased waist-to-hip ratio, has a stronger correlation with hypertension than body mass index or skinfold thickness. Weight reduction by as little as 4.5 kg reduces BP and/or prevents hypertension in a large proportion of overweight people (Iqubal et al., 2015). Weight loss of 10 kg can reduce systolic BP by 5–20 mmHg (Williams, 2015). Although a clear correlation exists between obesity and hypertension, the relationship may be one of common cause: genetic factors appear to play a role in the common triad of obesity, hypertension and insulin resistance. (See the 'Focus on cultural diversity' box below.)
- *Insulin resistance*. Insulin resistance with resulting hyperinsulinaemia is linked with hypertension by its effects of excess circulating insulin on the sympathetic nervous system, vascular smooth muscle, renal regulation of sodium and water and ion transport across cell membranes. Insulin resistance may be a genetic or an acquired trait. Although it is more commonly seen in obese individuals, insulin resistance also has been found in people of normal weight.
- *Excess alcohol consumption*. Regular consumption of three or more drinks a day increases the risk of hypertension. Decreasing or discontinuing alcohol consumption reduces the blood pressure, particularly systolic readings. Lifestyle factors associated with excessive alcohol intake (obesity and lack of exercise) may contribute to hypertension as well.
- *Stress*. Physical and emotional stress cause transient elevations of blood pressure, but the role of stress in primary hypertension is less clear. Blood pressure normally fluctuates throughout the day, increasing with activity, discomfort or emotional responses such as anger. Sympathetic nervous system hyperactivity, renin–angiotensin–aldosterone system activation and inflammation-mediated endovascular dysfunction have all been implicated (De Ciuceis et al., 2014).

FAST FACTS

- Major preventable risk factors for cardiovascular disease include tobacco smoking, hypertensive disease (high blood pressure), high blood cholesterol, inadequate physical activity, overweight and obesity, poor nutrition and diabetes.
- Data from the *Australian Health Disease Statistics* showed that prevalence of hypertensive disease increases with age, with less than 10% of those aged 25–34 years reporting the disease compared to almost 50% for those aged 75 years and over.
- The proportion of overweight and obese Australians is increasing. In 1995, 56.3% of people aged 18 years and over were classified as overweight or obese. This increased to 62.8% by 2012 (age adjusted).

Source: National Heart Foundation of Australia (2014). *Australian Heart Disease Statistics*. Retrieved from www.heartfoundation.org.au/SiteCollectionDocuments/HeartStats_2014_web.pdf.

Pathophysiology

Primary hypertension is thought to develop from complex interactions among factors that regulate cardiac output and systemic vascular resistance. These interactions may include:
- Excess sympathetic nervous system with overstimulation of α- and β-adrenergic receptors, resulting in vasoconstriction and increased cardiac output.
- Altered function of the renin–angiotensin–aldosterone system and its responsiveness to factors such as sodium intake and overall fluid volume. The renin–angiotensin–aldosterone system affects vasomotor tone and salt and water excretion. Chronically high levels of angiotensin II lead to arteriolar remodelling, which permanently increases SVR. In approximately 20% of people with primary hypertension, renin levels are lower than normal. Increased sodium intake increases the blood pressure in these people. Another 15% of people with hypertension

FOCUS ON CULTURAL DIVERSITY

Australia is rich with people who were born overseas, but choose to live here. See Figure 31.3 for comparisons between obesity values in Australians and other ethnic groups.

FIGURE 31.3 ■ Obesity prevalence (reported as a percentage) for people living in Australia by country of birth, 2012

Source: Generated using data from Australian Bureau of Statistics (2013c). *Australian Health Survey: Updated Results 2011–2012—Table 7: Body Mass Index by Selected Population Characteristics—Australia.* (Cat. no. 4364.0.55.001.) Retrieved from www.abs.gov.au/AUSSTATS/abs@.nsf/DetailsPage/4364.0.55.0032011-2012?OpenDocument. © Commonwealth of Australia.

have higher than normal plasma renin levels. For these people, salt intake has less of an effect on blood pressure (Kasper et al., 2015). Most people with hypertension have normal levels of renin activity.

- Other chemical mediators of vasomotor tone and blood volume, such as atrial natriuretic peptide, also play a role by affecting vasomotor tone and sodium and water excretion. Vascular endothelium itself produces hormones (*endothelins*) that also affect vasomotor tone. Endothelin-1 is a potent vasoconstrictor (Kasper et al., 2015).
- The interaction between insulin resistance, hyperinsulinaemia and endothelial function may be a primary cause of hypertension. Excess insulin has several effects that potentially contribute to hypertension: (1) sodium retention by the kidneys, (2) increased SNS activity, (3) hypertrophy of vascular smooth muscle, and (4) changes in ion transport across cell membranes (Kasper et al., 2015).

The result is sustained increases in blood volume and peripheral resistance. The cardiovascular system adapts to increased blood volume by increasing cardiac output. Autoregulatory mechanisms in the systemic arteries react to the increased volume, causing vasoconstriction. The increased systemic vascular resistance causes hypertension.

It appears unlikely that one single cause and pathological process will be found to account for essential hypertension. Increasingly, evidence points to hypertension as a diverse group of pathophysiological mechanisms resulting in the common manifestation of elevated blood pressure.

Manifestations

The early stages of primary hypertension typically are asymptomatic, marked only by elevated blood pressure. Blood pressure elevations are initially transient but eventually become permanent. When symptoms do appear, they are usually vague. Headache, usually in the back of the head and neck, may be present on awakening, subsiding during the day. See Box 31.2 for common errors that lead to the undertreatment of hypertension.

Other symptoms result from target-organ damage and may include nocturia, confusion, nausea and vomiting, and visual disturbances. Examination of the retina of the eye may reveal narrowed arterioles, haemorrhages, exudates and *papilloedema* (swelling of the optic nerve).

Complications

Sustained hypertension affects the cardiovascular, neurological and renal systems. The rate of atherosclerosis accelerates,

BOX 31.2 Common errors in assessing hypertension

The following errors can contribute to undertreatment of hypertension:

- Cuff placed over clothing
- Incorrect cuff size
- Worn cuff
- Inaccurate sphygmomanometer (e.g. not serviced regularly, not validated correctly)
- Arm elevated above heart
- Failure to check that both arms give comparable readings (e.g. at initial visit)
- Person not rested before measurement
- Person talking during measurement
- Failure to palpate radial pulse before auscultatory measurements (results in failure to detect auscultatory gap)
- Deflating the cuff too quickly (> 2–3 mmHg/beat, whether using a mercury or digital sphygmomanometer)
- Re-inflating the cuff to repeat measurement before it has fully deflated
- Rounding off actual reading by more than 2 mmHg when recording measurement
- Taking a single measurement.

Source: National Heart Foundation (2010). *Guide to management of hypertension 2008: Updated December 2010.* Retrieved from www.heartfoundation.org.au/SiteCollectionDocuments/HypertensionGuidelines2008to2010Update.pdf.

increasing the risk of coronary heart disease and stroke. The workload of the left ventricle increases, leading to ventricular hypertrophy, which then increases the risk of coronary heart disease, arrhythmias and heart failure. The diastolic blood pressure is a significant cardiovascular risk factor until age 50; the systolic pressure then becomes the more important factor contributing to cardiovascular risk. The National Heart Foundation (2010) recommends a cardiovascular risk assessment be performed by all Australians aged 45–74 who are not already known to be at high risk. Most deaths due to hypertension result from coronary heart disease and acute myocardial infarction or heart failure (Kasper et al., 2015).

Accelerated atherosclerosis associated with hypertension increases the risk of cerebral infarction (stroke). Increased pressure in the cerebral vessels can lead to development of microaneurysms and an increased risk of cerebral haemorrhage. *Hypertensive encephalopathy*, a syndrome characterised by extremely high blood pressure, altered level of consciousness, increased intracranial pressure, papilloedema and seizures, may develop. Its aetiology is unclear.

Hypertension also can lead to nephrosclerosis and renal insufficiency. Proteinuria and microscopic haematuria develop, as well as signs of chronic kidney failure. In 2013, after adjusting for differences in the age structure of the populations, Indigenous Australians were 3.3 times more likely than non-Indigenous Australians to have diabetes and more than 2.1 times as likely to have kidney disease. However, the gaps in remote areas were more remarkable, with Aboriginal and Torres Strait Australians being 5.4 times more likely to have diabetes and almost 4 times more likely to have kidney disease than non-Indigenous Australians.

INTERPROFESSIONAL CARE

Hypertension management focuses on reducing the blood pressure to less than 140 mmHg systolic and 90 mmHg diastolic. The ultimate goal of hypertension management is to reduce cardiovascular and renal morbidity and mortality. The risk of cardiovascular complications (coronary heart disease, heart failure, stroke) decreases when the average blood pressure is less than 140/90; when the person also has diabetes or renal disease, the treatment goal is a blood pressure of less than 130/80. The decision to intervene and the development of a comprehensive management plan (including lifestyle advice and drug treatment) should be based on a thorough clinical investigation to identify associated clinical conditions and/or end-organ damage and assessment of cardiovascular risk (NHF, 2010). Although there is no cure for hypertension, it can be controlled. Figure 31.4 shows the recommended algorithm for hypertension management.

Diagnosis

The person with hypertension is evaluated for the presence of identifiable causes of hypertension, cardiovascular risk factors and the presence or absence of target-organ damage (heart, brain, kidneys, peripheral vascular systems and retina of the eye). Before treatment is started, the following diagnostic tests are performed: electrocardiogram (ECG); urinalysis; blood glucose level; haematocrit; serum potassium, creatinine and calcium; and cholesterol and lipoprotein profile, including HDL, LDL and triglycerides.

Additional tests that may be done include urinary albumin excretion, evaluation of the glomerular filtration rate (such as the creatinine clearance) and tests for emerging cardiovascular risk factors such as C-reactive protein and homocystine levels.

Lifestyle modifications

Lifestyle modifications are recommended for all people whose blood pressure falls within the prehypertension range (120–139/80–89 mmHg) and everyone with intermittent or sustained hypertension. These modifications include weight loss, dietary changes, restricted alcohol use and cigarette smoking, increased physical activity and stress reduction (see Box 31.3).

DIET Dietary approaches to managing hypertension focus on reducing sodium intake, maintaining adequate potassium and calcium intakes, and reducing total and saturated fat intake. A mild to moderate sodium restriction (no added salt) lowers blood pressure and potentiates the effect of antihypertensive drugs for most people with hypertensive. A diet that focuses on whole foods rather than individual nutrients has proven to have beneficial effects in lowering blood pressure (see Box 31.4).

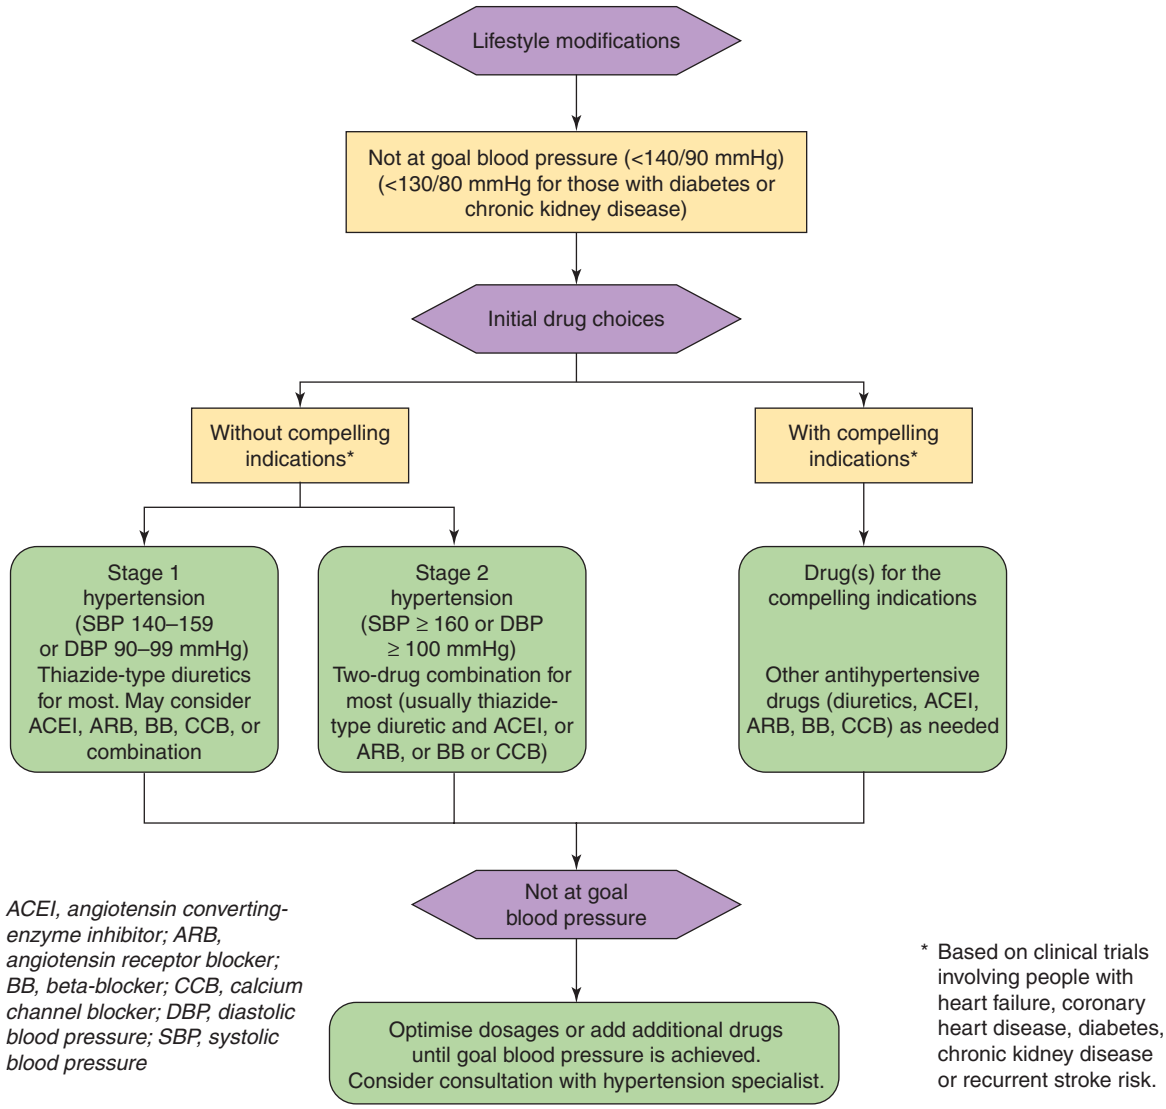

FIGURE 31.4 ■ Algorithm for treating hypertension

Source: Adapted from *The Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation and Treatment of High Blood Pressure* (2004). National Heart, Lung and Blood Institute, Bethesda, MD: National Institutes of Health.

It is rich in fruit and vegetables (up to 10 servings per day) and low in total and saturated fats.

Managing identifiable lifestyle risk factors is recommended for people with or without hypertension. Waist measurements of < 94 cm for men and < 80 cm for women along with a body mass index (BMI) of < 25 kg/m^2 should be encouraged. When recommending weight loss, advise on reducing kilojoule intake as well as increasing physical activity (NHF, 2010).

PHYSICAL ACTIVITY Regular exercise (such as walking, cycling, jogging or swimming) reduces blood pressure and contributes to weight loss, stress reduction and feelings of overall wellbeing. Advise all people to become physically active as part of a comprehensive plan to control hypertension, regardless of drug treatment. Aim for 30 minutes of moderate-intensity physical activity on most, if not all, days of the week (NHF, 2010).

ALCOHOL Moderate drinking may increase BP by 38–40 mmHg and binge drinking may increase the risk of hypertension. Reducing alcohol consumption can substantially lower BP in some people. Although alcohol withdrawal may increase blood pressure, this is usually temporary and diminishes as abstinence or restricted intake continues. Advise people with hypertension to limit their intake to a maximum of two standard drinks (a standard drink equals 10 g of alcohol) per day for men, and a maximum of one standard drink per day for women and lighter-weight men. Finally, people should be advised to observe at least two alcohol-free days per week.

SMOKING CESSATION Smoking cessation may not directly reduce BP, but it markedly reduces overall cardiovascular risk. The risk of myocardial infarction is two to six times higher, and the risk of stroke is three times higher, in people who smoke than in non-smokers. Advice from health professionals is effective in increasing quit rates. Even 3–5 minutes taken to

BOX 31.3 Lifestyle modifications for hypertension

The following guidelines need to take into account a person's cultural background and the resources available to them. Further, nurses need to assess a person's readiness for change and tailor recommendations accordingly.

Advise person to aim for healthy targets:

- At least 30 minutes of moderate-intensity physical activity on most, if not all, days of the week (daily total can be accumulated, e.g. three 10-minute sessions). Advise people of all ages to become more active.
- Smoking cessation. Refer the person to Quit Helpline. Consider recommending nicotine replacement therapy and/or prescribing oral therapy (bupropion or varenicline) in people who smoke more than 10 cigarettes per day and have no contraindications.
- Waist measurement < 94 cm for men and < 80 cm for women, and body mass index (BMI) < 25 kg/m^2. When recommending weight loss, advise the person on reducing kilojoule intake as well as increasing physical activity.
- Dietary salt restriction: ≤ 4 g/day (65 mmol/day sodium). Recommend low-salt and reduced-salt foods as part of a healthy eating pattern.
- Limited alcohol intake: maximum of two standard drinks per day for men or one standard drink per day for women.

Source: NHF (2010). *Guide to the management of hypertension 2008: Updated December 2010.* © National Heart Foundation of Australia.

BOX 31.4 Dietary recommendations

A healthy eating pattern includes mainly plant-based foods (e.g. fruit, vegetables, pulses); a wide selection of wholegrain foods; moderate amounts of low-fat or reduced-fat dairy products; moderate amounts of lean unprocessed meats, poultry and fish; and moderate amounts of polyunsaturated and monounsaturated fats (e.g. olive oil, canola oil, reduced-salt margarines).

Source: NHF (2010). *Guide to the management of hypertension 2008: Updated December 2010.* © National Heart Foundation of Australia.

encourage smokers to attempt to quit can increase success rates (NHF, 2010).

STRESS REDUCTION Stress stimulates the sympathetic nervous system, increasing vasoconstriction, systemic vascular resistance, cardiac output and blood pressure. Regular, moderate exercise is the treatment of choice for reducing stress in people with hypertension. Relaxation techniques such as biofeedback, therapeutic touch, yoga and meditation to relax both mind and body may also lower blood pressure, although their effect has not been proven in hypertension management (Oza & Garcellano, 2015).

Medications

Current pharmacological treatment of hypertension involves using one or more of the following drug classes: diuretics, beta-adrenergic blockers, centrally acting sympatholytics, vasodilators, ACE inhibitors, angiotensin II receptor blockers (ARBs) and calcium channel blockers. For most people, two or more antihypertensive drugs selected from different drug classes are necessary to achieve effective control. These drug classes have different sites of action (see Figure 31.5). See the 'Medication administration' box below.

DRUG CLASSES For all major antihypertensive drug classes, the beneficial effect is mainly due to BP lowering, irrespective of their mechanism of action. In uncomplicated hypertension, the following classes of antihypertensive agents are equally effective for first-line use, both in initial and maintenance therapy:

- ACE inhibitors (or angiotensin II receptor antagonists)
- calcium channel blockers
- low-dose thiazide diuretics (for people aged 65 years and older).

Thiazide diuretics have been associated with increased risk of new-onset diabetes and should be used with caution in people with glucose intolerance and/or metabolic syndrome. The use of thiazide diuretics as first-line therapy should be limited to older people, in whom the benefits of managing isolated systolic hypertension and preventing stroke with these agents are likely to outweigh the risk of diabetes onset. Beta-blockers are no longer recommended as first-line therapy in uncomplicated hypertension because of the increased risk of developing diabetes and the recently described trend towards worse outcomes in people treated with beta-blockers compared to those treated with other classes of antihypertensive drugs.

For people with stable, well-controlled hypertension who are already taking a beta-blocker, it is reasonable to continue the regimen unchanged.

The initial drug choice should be based on:

- age
- presence of associated clinical conditions or end-organ damage
- presence of other coexisting conditions that either favour or limit the use of particular drug classes
- potential interactions with other drugs
- implications for adherence
- cost.

Most classes of antihypertensive agents used as monotherapy lower BP by a similar average amount. However, the individual response to each agent is unpredictable.

People with heart failure, coronary heart disease (CHD) or diabetes may initially be treated with a beta-blocker. These drugs lower blood pressure, apparently by reducing peripheral vascular resistance. They may also reduce the amount of renin released by the kidneys by blocking beta$_1$-receptors in the kidney. Beta-blockers reduce the risk of complications such as heart failure and stroke. They are, however, relatively contraindicated for people with asthma or chronic obstructive pulmonary disease, because they promote bronchial constriction.

ACE inhibitors and ARBs also are commonly used in initial treatment of hypertension, particularly for people who are

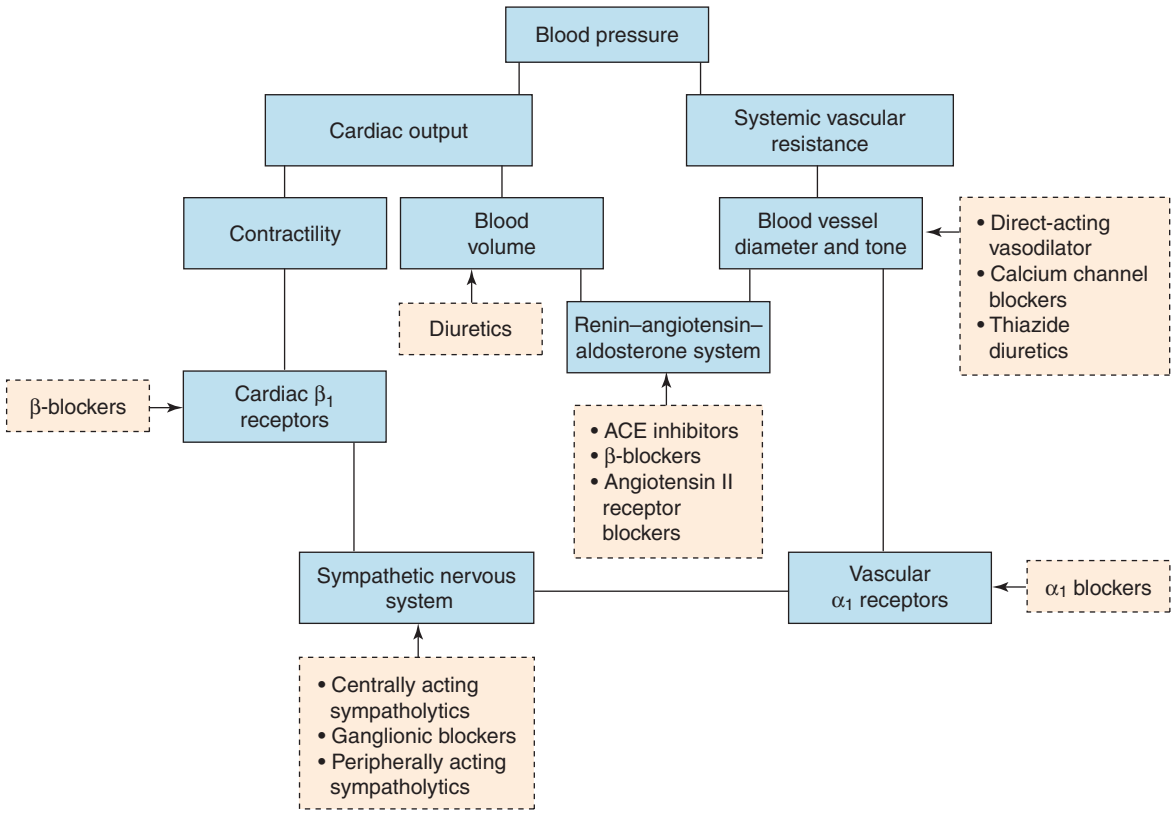

FIGURE 31.5 ■ Sites of antihypertensive drug action

diabetic or have heart failure, a history of myocardial infarction (MI) or chronic kidney disease. ACE inhibitors block formation of angiotensin II by inhibiting the action of angiotensin-converting enzyme. Angiotensin II is a potent vasoconstrictor that also stimulates aldosterone release from the adrenal gland; blocking its action prevents vasoconstriction and sodium and water retention resulting from aldosterone release. ARBs have a very similar effect, although their action is to block angiotensin II receptors, thus preventing its vasoconstrictive and volume expansion effects.

Several drug classes work through their ability to promote vasodilation and reduce peripheral vascular resistance. Alpha-blockers such as prazosin and terazosin block stimulation of alpha$_1$-receptors on arterioles and veins, preventing vasoconstriction. Because of their ability to dilate both arterioles and veins, alpha-blockers can cause significant orthostatic hypotension, particularly following the initial dose. Calcium channel blockers promote dilation of arterioles, the primary regulators of peripheral vascular resistance. These drugs can cause reflex tachycardia. Some calcium channel blockers, verapamil and diltiazem in particular, also suppress heart function, reducing stroke volume and cardiac output. Reflex tachycardia is minimal with these calcium channel blockers. Direct-acting vasodilators such as hydralazine and minoxidil also directly affect the arterioles, reducing peripheral vascular resistance. These drugs have little effect on veins, so the risk of orthostatic hypotension is minimal. They are, however, associated with reflex tachycardia and fluid retention, so rarely are administered as in single-drug treatment regimens.

Other factors considered in selecting drugs for treating hypertension include demographic characteristics of the person, concurrent conditions, quality of life, cost and possible interactions among prescribed drugs. In general, diuretics and calcium channel blockers are more effective for treating hypertension than beta-blockers or ACE inhibitors. Beta-blockers are preferred to treat hypertension with concurrent coronary heart disease and angina, but are contraindicated for those who have asthma or depression. Beta-blockers also reduce exercise tolerance and may adversely affect lifestyle for some people.

DRUG REGIMENS Treatment usually is initiated using a single antihypertensive drug at a low dose. Unless otherwise indicated, a diuretic is recommended as the initial drug of choice. The dose is slowly increased until optimal blood pressure control is achieved. If the drug does not effectively lower the blood pressure or has troubling side effects, a different drug from another class of antihypertensive medications is substituted. If, on the other hand, the drug is tolerated well but has not lowered blood pressure to the desired level, a second drug from another class may be added to the treatment regimen.

Treatment of people with stage 2 hypertension generally is more aggressive to minimise the risk of MI, heart failure or stroke. When the average blood pressure is greater than 200/120 mmHg, immediate therapy and possible hospitalisation is vital.

After a year of effective hypertension control, an effort may be made to reduce the dosage and number of drugs. This is known as step-down therapy. It is more successful in people who

MEDICATION ADMINISTRATION Antihypertensives

ALPHA-ADRENERGIC BLOCKERS

Alpha-adrenergic blocking agents block alpha-receptors in vascular smooth muscle, decreasing vasomotor tone and vasoconstriction. They also reduce serum levels of low-density lipoproteins (LDLs) and very-low-density lipoproteins (VLDLs). However, vasodilation may cause orthostatic hypotension and reflex stimulation of the heart, resulting in tachycardia and palpitations. A beta-blocker may be ordered to minimise this effect.

Nursing responsibilities

- Give the first dose at bedtime to minimise risk of fainting (called 'first-dose syncope'). If the first dose is given in the daytime (or if the dose is increased), instruct to remain in bed for 3 to 4 hours.
- Assess blood pressure and apical pulse before each dose and as indicated thereafter.

Health education for the person and family

- There is a risk of fainting after taking the first dose of this drug. Take the drug at bedtime to reduce this risk and do not drive or engage in other hazardous activities for 12 to 24 hours after the first dose.
- This drug may cause dizziness or light headedness. Change positions slowly and sit down if you become dizzy or light headed.
- Notify your primary care provider if you develop nasal congestion or impotence while taking this drug.
- Notify your doctor before discontinuing this medication.

ACE INHIBITORS AND ANGIOTENSIN II RECEPTOR ANTAGONISTS

Angiotensin-converting-enzyme (ACE) inhibitors lower blood pressure by preventing conversion of angiotensin I to angiotensin II. This in turn prevents vasoconstriction and sodium and water retention. Angiotensin II receptor blockers (ARBs) have the same effect, but they act by blocking the effect of angiotensin II on receptors. ACE inhibitors have been shown to reduce mortality in an Aboriginal community with a high prevalence of end-stage kidney failure (O'Dea, Rowley & Brown, 2007). Their primary adverse effects are persistent cough, first-dose hypotension and hyperkalaemia.

Nursing responsibilities

- Assess blood pressure and WBC before giving the first dose. Monitor blood pressure for 2 hours after the first dose and regularly thereafter.
- Administer PO 1 hour before meals; tablets may be crushed.
- Report changes in WBC or differential, hyperkalaemia or changes in serum urea or creatinine to the doctor.
- Do not administer to people with renal artery stenosis or who are pregnant.
- Immediately report and treat manifestations of angio-oedema (giant wheals and oedema of the tongue, glottis and pharynx). Initiate resuscitation measures as needed. Discontinue drug immediately and do not use in the future.

Health education for the person and family

- Report peripheral oedema, signs of infection or difficulty breathing to your primary care provider.
- Change position (lying to sitting and sitting to standing) slowly to prevent dizziness; sit down if dizziness or light headedness develops.
- Do not take a potassium supplement or use a potassium-based salt substitute while taking this drug unless prescribed by your doctor.
- Notify your doctor if you become pregnant while taking this drug. Although it is safe early in pregnancy, taking the drug during the second and third trimesters may harm the foetus.

BETA-ADRENERGIC BLOCKERS (BETA-BLOCKERS)

Beta-blockers are commonly used to control hypertension. They reduce blood pressure by preventing beta-receptor stimulation in the heart, thereby decreasing heart rate and cardiac output. Beta-blockers also interfere with renin release by the kidneys, decreasing the effects of angiotensin and aldosterone. Potential adverse effects of beta-blockers include bronchospasm, fatigue, sleep disturbances, nightmares, bradycardia, heart block, worsening of heart failure, gastrointestinal disturbances, impotence and increased triglyceride levels.

Nursing responsibilities

- Before giving initial dose, assess for contraindications to beta-blockers, such as asthma, chronic lung disease, bradycardia or heart block.
- Assess blood pressure and apical pulse before giving; notify primary care provider if vital signs are outside established parameters.
- Report adverse effects such as bradycardia, decreased cardiac output (fatigue, dyspnoea with exertion, hypotension, decreased level of consciousness), heart failure, heart block, bronchoconstriction (wheezing, dyspnoea) or altered blood glucose levels (in diabetic people).
- Carefully monitor responses of the older person.

Health education for the person and family

- Monitor blood pressure and pulse daily as instructed.
- Change position (lying to sitting and sitting to standing) slowly to prevent dizziness and possible falls.
- Report effects such as fatigue, lethargy and impotence to your primary care provider.
- Notify your doctor if you become short of breath or develop a cough or swelling of your extremities.
- If you have diabetes, check blood glucose levels more frequently because hypoglycaemia may develop with few symptoms.
- Talk to your primary care provider before taking any over-the-counter medications.
- Carry an adequate supply of the drug when travelling. Do not stop taking this drug without notifying your primary care provider.

CALCIUM CHANNEL BLOCKERS

Calcium channel blockers inhibit the flow of calcium ions across the cell membrane of vascular tissue and cardiac cells. In doing so, they relax arterial smooth muscle, lowering

MEDICATION ADMINISTRATION Antihypertensives (continued)

peripheral resistance through vasodilation. Calcium channel blockers can cause reflex tachycardia and some (e.g. verapamil and diltiazem) may impair cardiac function, worsening heart failure.

Nursing responsibilities

- Assess blood pressure, apical pulse and liver and renal function tests prior to giving these drugs.
- Calcium channel blockers may be given orally or intravenously.
- Do not administer verapamil or diltiazem to people with severe hypotension, sinus or atrioventricular blocks. Administer with caution to people also taking digoxin or a beta-blocker.
- Periodically monitor blood pressure and apical pulse during therapy. Promptly report signs of bradycardia, AV block or heart failure to the doctor.

Health education for the person and family

- Take blood pressure and pulse daily as taught. Notify your doctor if your pulse is less than 60 bpm or your blood pressure is not within the specified range.
- This drug may cause constipation. Drink six to eight glasses of water each day and increase fibre in diet.
- Report shortness of breath, weight gain or swelling in feet or ankles to your primary care provider.

THIAZIDE DIURETICS

These drugs inhibit reabsorption of sodium and chloride in the proximal (diluting) segment of the distal convoluted tubules. They also increase urinary secretion of water, chloride, potassium, magnesium, whereas excretion of uric acid and calcium is decreased. Indications include the treatment of mild to moderate hypertension and oedema associated with heart failure. They should be used with caution for people who have type 1 diabetes, gout, renal or hepatic impairment and in the elderly. These drugs are contraindicated in severe renal impairment, anuria, Addison's disease and in people with thiazide or sulfonamide hypersensitivity (Bryant & Knights, 2011, p. 515). Loop diuretics (e.g. frusemide) are not recommended as antihypertensive agents unless volume overload is present.

Nursing responsibilities

- Monitor closely if concurrent potassium supplementation or a potassium chloride salt substitute is ordered for people receiving a potassium-sparing diuretic. Hyperkalaemia and death have been reported with this combination.
- Use extreme caution in elderly people. Start with lowest dose possible, titrate slowly to achieve the desired effect.
- Monitor for diuresis and subsequent incontinence.
- Be alert to signs and symptoms of diuretic toxicity, such as anorexia, nausea, vomiting, confusion, increased weakness and paraesthesia of the extremities.
- When diuretic is to be discontinued, reduce the drug gradually to avoid the development of fluid retention and oedema.
- If plasma potassium concentration drops below the laboratory reference range during thiazide diuretic therapy, a potassium-sparing diuretic may be prescribed in combination with the thiazide.

Health education for the person and family

- Fluid intake should be discussed with the individual as many people refer to diuretics as 'water pills' and mistakenly believe they should restrict their fluid intake.
- Report any anorexia, nausea, vomiting, confusion or increased weakness of arms and legs to your health care provider.
- Do not decrease or discontinue medication without talking to your healthcare provider.
- Advise person their urinary output will be increased and they may experience incontinence. Provide education on managing same.

OTHER

Most of the drugs in this category are adjunctive therapies to those listed in the above categories. Please refer to pharmacology texts for guidance on the use of these additional drugs.

Source: Selected data in this box is adapted from National Heart Foundation (2010). *Guide to the management of hypertension 2008: Updated December 2010.* Retrieved from www.heartfoundation.org.au/SiteCollectionDocuments/HypertensionGuidelines2008QRG2010Update.pdf.

have made lifestyle modifications. Careful blood pressure monitoring is necessary during and after step-down therapy because the blood pressure often rises again to hypertensive levels.

Complementary therapies

Behavioural and mind–body therapies may be helpful for some people in lowering blood pressure. Blood pressure increases in response to physiological and psychological stress and anxiety. Mind–body therapies such as yoga and tai chi, meditation and guided imagery are designed to modify both physiological and cognitive aspects of the stress response. However, it is critical to understand that alternative medicines and foods can negatively influence conventional treatments. See the 'Translation to practice' box identifying the effects of green tea on antihypertensive medications.

Nursing care

Health promotion

Health promotion teaching and activities focus on the modifiable risk factors for hypertension. Advise and support all people (including children and adolescents) to stop or never start smoking. Discuss the risks of obesity, excess alcohol intake and a sedentary lifestyle. Encourage everyone to eat a diet rich in fruit and vegetables and low in total and saturated fat. Discuss the potential benefits of following a healthy diet. Advise all people to remain active and engage in aerobic exercise 5 or

TRANSLATION TO PRACTICE Evidence-based practice: green tea interferes with antihypertensive medication function

In a randomised, crossover study by Misaka et al. (2014), subjects were given a beta-blocker every day for 14 days. The subjects consumed green tea for a week, followed by water for the next week, concomitantly with administration and within 30 minutes of the dose to a volume of 700 mL. The effects of the green tea were significant and worrying. A reduction in plasma concentrations of 85% were demonstrated without changes in renal clearance, suggesting that the green tea probably reduced gastrointestinal absorption of the drug. Subsequently, desired antihypertensive and rate-slowing effects of the beta-blocker were markedly reduced.

IMPLICATIONS FOR NURSING

Understanding that the consumption of certain foods and beverages may significantly influence the effectiveness of prescribed drugs is critical. Nurses not only are responsible for administration of medications in both acute and community care situations, they are often the healthcare professional tasked with ensuring that individuals understand medication that they are prescribed.

CRITICAL THINKING IN PERSON-CENTRED CARE

1. Review the four concepts of pharmacokinetics: absorption, distribution, metabolism and excretion. Consider how each of these parameters may be influenced and what result this would have on an antihypertensive medication.
2. Grapefruit is known to interfere with over 80 medications, with more than half of these interactions resulting in potentially serious consequences (NPS Medicinewise, 2014). Research other foods and beverages and their influence on the effects of cardiovascular medication. Make a report that includes the food or beverage name and its effects.
3. How will this research influence your future practice?

more days a week. Discuss the stress-reducing benefits of exercise.

Offer blood pressure screening and refer individuals for follow-up as indicated.

Assessment

Absolute cardiovascular risk

The management plan for a person with hypertension should take into consideration the individual's absolute risk of cardiovascular disease. Absolute cardiovascular risk is the probability (expressed as a percentage) of an individual experiencing a cardiovascular event (e.g. myocardial infarction or stroke) during a predefined period of time (e.g. the next 5 years). Blood pressure is a major determinant of absolute cardiovascular risk. People at highest absolute risk include those with existing cardiovascular disease or those with multiple risk factors (e.g. diabetes, older age, overweight/obesity and dyslipidaemia).

The purposes of assessing absolute cardiovascular risk are to:

- identify other modifiable risk factors that require management
- predict who will benefit most from intervention and determine the appropriate management plan to reduce BP
- enable the person to understand the degree of urgency for reducing BP and correcting other risk factors.

The National Vascular Disease Prevention Alliance (NVPDA) (2012) has produced guidelines for the assessment and management of cardiovascular disease in Australia. The ultimate goal is to reduce a person's absolute risk. Risk management decisions can be made once these factors are considered.

Risk analysis in Aboriginal and Torres Strait Islander people is complex for numerous reasons including the increased prevalence of co-morbidity at a younger age than non-Indigenous Australians. Indigenous Australians also have an exceedingly high mortality, which has not reduced in the past 40 years despite targeted actions. Therefore, NVDPA recommends screening of Aboriginal and Torres Strait Islander people from 35 years of age (instead of 45 years as for non-Indigenous Australians), and the use of specifically designed absolute risk charts.

Absolute cardiovascular risk assessment is now recommended for all Australians aged 45–74 who are not already known to be at high risk, whether or not they have hypertension.

The management of hypertension should be based on a thorough clinical assessment that includes an estimate of the person's absolute risk of cardiovascular disease, as well as BP levels and other clinical investigations.

Assessment of absolute cardiovascular risk helps both the healthcare practitioners and the person understand the individual's overall risk profile and the potential benefit of preventive interventions. Figure 31.6 demonstrates when management of hypertension should be undertaken.

People who need immediate antihypertensive drug treatment include (but are not restricted to) those at high absolute cardiovascular risk (> 15% probability of a cardiovascular event within the next 5 years).

High cardiovascular risk can be assumed for the following groups of people without using a risk calculator:

- *Group A. People aged 75 years and over*. For almost all individuals aged ≥ 75 years, the absolute risk of a cardiovascular event in the next 5 years is > 15%.
- *Group B. People with existing cardiovascular disease*. Assume risk of a cardiovascular event > 15% in the next 5 years if either of the following present:
  - symptomatic cardiovascular disease (e.g. angina, myocardial infarction, chronic heart failure, stroke)
  - transient ischaemic attack, peripheral arterial disease
  - left ventricular hypertrophy diagnosed with electrocardiography or echocardiography.

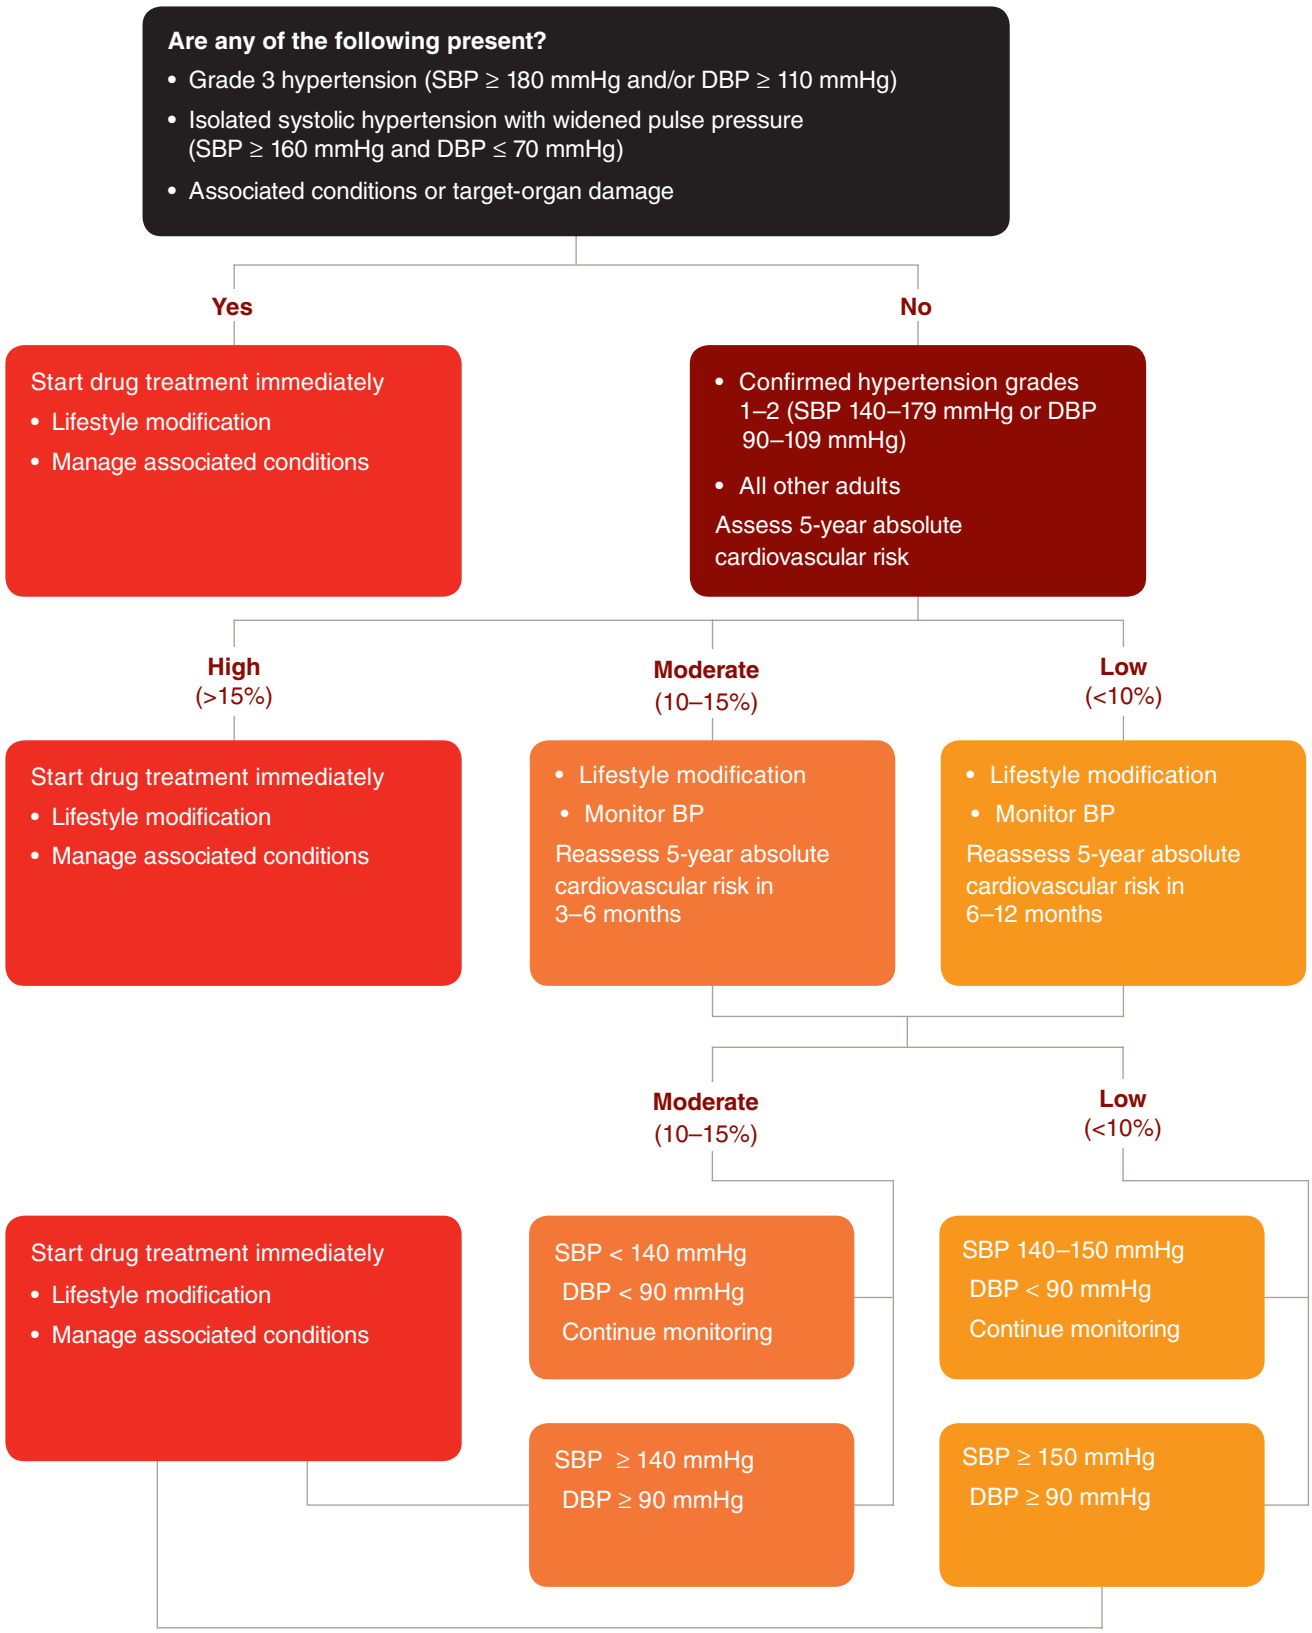

FIGURE 31.6 ■ When to initiate blood-pressure lowering medications

Source: NHF (2010). *Guide to the management of hypertension 2008: Updated December 2010.* © National Heart Foundation of Australia.

- *Group C. People with associated clinical conditions and end-organ disease*. For this group, assume risk of a cardiovascular event > 15% in the next 5 years. Antihypertensive drug treatment is required (e.g. to preserve renal function). For all other people, estimate absolute risk using Figure 31.6 (NHF, 2010).

Focused assessment of the person with hypertension includes:

- *Health history:* complaints of morning headache, cervical pain; cardiovascular or central nervous system manifestations; history of hypertension, renal disease, diabetes; family history of high blood pressure, heart failure or kidney disease; current medications.
- *Physical examination:* pulse rate, rhythm and character, jugular venous pulse and pressure, evidence of cardiac enlargement (displaced apex, extra heart sounds) or evidence of decompensation (basal crackles or wheeze on lung auscultation, peripheral oedema, abdominal signs, e.g. pulsatile liver).
- *Diagnostic tests:* blood analysis (sodium, potassium, chloride, bicarbonate, urea, creatinine, uric acid, haemoglobin, fasting glucose, total cholesterol, LDL-cholesterol, HDL-cholesterol, triglycerides, liver function tests).
  - *Electrocardiogram (ECG)* to detect conduction disturbances, arrhythmias, coronary heart disease or left ventricular hypertrophy. The presence of strain pattern (ST depression and T-wave inversion) is associated with increased cardiovascular risk in people with hypertension.
  - *Dipstick testing of urine* for blood and protein. If abnormal, proceed to urine microscopy. If proteinuria detected (≥ 1+ on dipstick), measure 24-hour urinary protein excretion.

Nursing diagnoses and interventions

All people with primary hypertension and their families need significant teaching to manage this chronic condition. Health maintenance is a high-priority problem. Depending on the stage of hypertension and concurrent illnesses, other appropriate nursing diagnoses may include *Imbalanced nutrition*, *Excess fluid volume* and *Risk of non-compliance*.

Ineffective health maintenance

Unhealthy lifestyle and behaviours can contribute to health problems such as hypertension. When hypertension has been identified, knowledge of the disease and its management is vital for the person. Willingness to take responsibility for hypertension management is central to effective blood pressure control. Adopting healthy lifestyle changes enhances drug therapy; in some cases, the need for medications may be eliminated or reduced. Because hypertension is often an asymptomatic disease and many antihypertensive drugs have unpleasant side effects, it is vital that the person understand the chronic progressive nature of the disease and its long-term consequences.

- Assist with identifying current behaviours that contribute to hypertension. The person must first identify contributory behaviours before they can change them. *Using knowledge of hypertension risk factors, the nurse can help identify behaviours and factors contributing to hypertension that can be changed. Including the family in this process is important to reduce potential sabotage of the person's efforts to adopt healthier behaviours.*
- Assist in developing a realistic health maintenance plan. *Preparing a health maintenance plan for the person does little to encourage personal responsibility for health. However, nurses can guide people in developing realistic goals and expectations for the treatment plan and modifying risk factors such as smoking, exercise, diet and stress.*
- Help the person and family identify strengths and weaknesses in maintaining health. *Discussing areas of the health maintenance plan that are working well and those that present difficulties can help to identify necessary changes in the plan and additional strategies for implementing it.*

Risk of non-compliance

Non-compliance, or failure to follow the identified treatment plan, is a continuing risk of any person with a chronic disease. Recommended lifestyle changes such as diet, exercise, restricted alcohol intake, stress reduction and smoking cessation often are difficult to maintain on a continuing basis. In addition, prescribed medications may have undesirable effects, whereas hypertension itself often has no symptoms or noticeable effects.

- Inquire about reasons for non-compliance with recommended treatment plan. Listen openly and without judging. *Non-threatening discussion of factors contributing to non-compliance validates the person's self-esteem and partnership in the treatment plan.*

CONSIDERATION FOR PRACTICE

Assess factors contributing to non-compliance, such as adverse drug effects. Suggest measures to manage adverse effects or, if indicated, contact the primary care provider about possible alternative drugs. Some adverse effects of antihypertensive drugs, such as gastric upset, light headedness or nocturia, may be easily managed by changing the timing of the drug dose. Others, such as fatigue, decreased exercise tolerance or impotence, may interfere with lifestyle and life roles to the extent that the person finds them intolerable.

- Evaluate knowledge of hypertension, its long-term effects and treatment. *Provide additional information and reinforce teaching as needed. Knowledge increases the sense of control, which also increases the likelihood of compliance with treatment.*
- Assist to develop realistic short-term goals for lifestyle changes. *Attempting to lose weight, exercise daily, stop smoking and dramatically change the diet all at the same time may be overwhelming, leading to a sense of failure. Smaller, gradual changes are more easily*

incorporated into lifestyle and daily activities, improving compliance.

CONSIDERATION FOR PRACTICE

Work with the person to develop mutual outcomes for the treatment plan. Discuss measures to improve compliance. The person has absolute control over compliance with the treatment plan. Demonstrating respect and involving the person in decision making and planning can improve compliance.

- Help the person identify cues and develop reminders (e.g. written notes, a medication box filled weekly) to assist with maintaining a schedule for exercise and medications. *Cues and other devices provide helpful reminders of activities and schedules until they are incorporated into habits.*
- Reassure the person that relapse into old habits and behaviours is common. Encourage avoiding feelings of guilt associated with relapse and use the circumstance to renew efforts to comply with treatment. *Guilt and feelings of failure can lead to further non-compliance unless the event is used to identify reasons for non-compliance and ways to prevent it from recurring in the future.*

Imbalanced nutrition: more than body requirements

The relationship between obesity, excess alcohol intake and hypertension is well documented. Hypertension is particularly associated with central obesity, identified by waist circumference greater than hip circumference. Although weight loss is difficult and takes commitment to changing eating and exercise habits, it is possible for most people to achieve.

- Assess usual daily food intake and discuss possible contributing factors to excess weight, such as sedentary lifestyle or using food as a reward or stress reliever. Inquire about diversional activities, exercise patterns and previous weight reduction efforts (e.g. participation in weight reduction programs or using fad or crash diets). *Assessment data provide clues about contributing factors to obesity, the person's knowledge base about the relationship between eating and exercise habits and weight, and safe weight loss strategies. This provides direction for further teaching and for developing a realistic weight reduction plan.*
- Mutually determine with the person a realistic target weight (e.g. loss of 10% of current body weight over a 6-month period). Regularly monitor weight. Encourage a system of non-food rewards for achieving small, incremental goals. *Setting weight loss goals helps formalise the process and provides motivation for continued progress. Developing realistic goals may be difficult; unrealistic goals, however, set the person up for failure. Continuous incremental weight loss provides reassurance that it can be achieved and promotes permanent weight reduction.*
- Refer to a dietitian for information about low-fat, low-kilojoule foods and eating plans. Focus on changing eating habits as opposed to 'following a diet'. *Focusing on changing eating habits promotes the sense that low-fat, low-kilojoule eating patterns should become a part of lifestyle, rather than a short-term measure to be endured until the weight loss goal is achieved.*
- Recommend participating in an approved weight loss program such as Weight Watchers. *Organised weight loss programs provide structure for a balanced weight reduction program, as well as mutual support from others trying to lose weight.*

Excess fluid volume

Excess fluid volume often contributes to hypertension by increasing the cardiac output. A number of factors associated with hypertension can cause excess fluid volume, including sodium retention and disruption of the renin–angiotensin–aldosterone system. In addition, some antihypertensive drugs, such as calcium channel blockers and vasodilators, can contribute to excess fluid in the interstitial spaces and peripheral oedema.

- Monitor intake and output and weigh daily (if in an acute or long-term care facility) or weekly (in the community). *Rapid weight changes (over days) more accurately reflect fluid balance than intake and output records. 1 L of fluid weighs 1 kg. Weight changes and intake and output records help monitor the effects of therapy.*
- Monitor for peripheral oedema (sacral oedema in the bedridden person). *Drugs such as vasodilators can cause fluid accumulation in interstitial tissues, leading to peripheral or dependent oedema. Adding a diuretic to the treatment plan may be necessary.*

CONSIDERATION FOR PRACTICE

Monitor blood pressure and other vital signs as indicated: every 1 to 2 hours or more frequently during acute hypertensive states; once a week or more frequently during initial treatment in the community. Vital signs are an indicator of fluid balance and the effectiveness of treatment. An elevated blood pressure, pulse and respiratory rate may indicate fluid retention, whereas orthostatic hypotension and tachycardia may indicate fluid volume deficit.

- Refer to a dietitian for teaching about a restricted sodium diet. Discuss the relationship between sodium intake and fluid retention. Provide opportunities to choose low-sodium foods from simulated menus. Support efforts and reassure that lifestyle changes such as consuming less sodium take time. *Knowledge provides the power to take control of sodium intake. Patience and perseverance are needed to succeed; positive reinforcement of efforts to change long-standing dietary patterns is important.*

CONSIDERATION FOR PRACTICE

Monitor laboratory values, such as urine-specific gravity, urea and creatinine, electrolytes and haematocrit and haemoglobin. Hypertension can alter renal perfusion and function, leading to fluid retention and altered laboratory values. Changes in urea and creatinine indicate impaired renal function, whereas changes in haematocrit and haemoglobin often reflect changes in fluid volume.

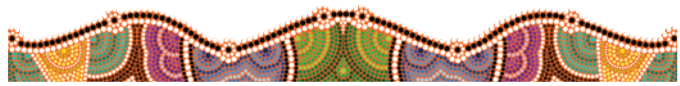
- Discuss the importance of adhering to treatment plans such as dietary restrictions and medication schedules. *Understanding the rationale for treatment measures promotes the person's sense of control and encourages compliance with the treatment regimen.*

Community-based care

Effective control of hypertension requires the person not only to participate in the plan of care, but also to take an active role in managing the disease. Treatment is managed in community settings, with regular visits to a clinic or office to monitor blood pressure and effects of treatment measures. Include the following topics in teachings about hypertension:

- Specific lifestyle changes recommended for the person and suggestions for implementing them. For example:
  - Increase activity gradually. Develop a realistic exercise program that is enjoyable and fits into lifestyle. Identify an exercise buddy for additional motivation. Activity and exercise, through a gradual conditioning of muscles and blood vessels, lower blood pressure by reducing peripheral vascular resistance. As the heart becomes conditioned and pumps more efficiently, kidney perfusion improves and intravascular volume falls, further reducing blood pressure. Exercise also reduces stress and contributes to weight loss and maintenance. Aerobic exercise, such as walking, jogging, swimming and cycling, are appropriate; isometric activities (such as weight lifting) should be avoided without doctor's approval.
  - Adopt healthy eating patterns, following a low-fat, low-cholesterol, moderate-sodium diet that also is rich in fruit and vegetables and includes at least two servings of low-fat milk or milk products daily. Do not give up if you slip into old eating habits on occasion; use such occasions to identify ways to avoid future lapses.
  - Stop smoking. Participating in organised smoking cessation programs or using aids such as nicotine patches can help.
  - Use alcohol in moderation if at all, consuming no more than 10–20 g of alcohol per day.
  - Use stress-reducing techniques such as meditation, relaxation, deep breathing and exercise to manage stress. Anger and hostility intensify vasoconstriction; channelling these emotions into more positive responses such as using a change process to modify factors that provoke these emotions can reduce their harmful effects on blood pressure.
- Prescribed medications, their intended effect, dose and timing, interactions and possible adverse effects. Discuss effects that should be reported to the doctor and those that can be managed by the person or that will diminish over time.
- The importance of monitoring blood pressure and regular visits to the primary care provider or hypertension clinic to monitor treatment. During follow-up visits, assess the blood pressure and specific laboratory work (such as serum urea, creatinine and electrolytes) to evaluate the disease and the effects of antihypertensive medications.

Refer the person to community blood pressure clinics and to home health services as needed for regular follow-up and reinforcement of teaching. Refer to a dietitian or to an organised weight loss program as indicated for further teaching and weight loss support. The 'Nursing care plan' below provides additional information about community-based care for the person with high blood pressure.



SECONDARY HYPERTENSION

Secondary hypertension is elevated blood pressure resulting from an identifiable underlying process. Prevalence is poorly documented but is often reported as between 5% and 10% of identified cases of hypertension (Sperati & Whaley-Connell, 2015). Kidney disease is the most common identifiable cause of high blood pressure in both adults and children. Other common identifiable causes of hypertension in adults include renovascular disease (reduced blood flow to the kidneys), disorders of the adrenal cortex, pheochromocytoma, coarctation of the aorta and sleep apnoea (O'Callaghan, Goh & Rong, 2013). The pathophysiology of selected causes of high blood pressure are summarised here:

- *Kidney disease*. Any disease that affects renal blood flow (e.g. renal artery stenosis) or renal function (e.g. glomerulonephritis, renal failure) can lead to hypertension. Disruption of the blood supply stimulates the renin–angiotensin–aldosterone system, with resulting vasoconstriction and sodium and water retention. Altered kidney function affects the elimination of water and electrolytes, leading to hypertension.
- *Coarctation of the aorta*. Coarctation of the aorta is narrowing of the aorta, usually just distal to the subclavian arteries. Reduced renal and peripheral blood flow stimulates the renin–angiotensin–aldosterone system and local vasoconstrictive responses, raising the blood pressure. A marked difference between pressures in the upper and lower extremities is common, with weak pulses and poor capillary refill in the lower extremities.
- *Endocrine disorders*. Adrenal gland disorders such as Cushing's syndrome and primary aldosteronism can cause hypertension. A rare tumour of the adrenal medulla, *pheochromocytoma*, causes persistent or intermittent hypertension. Other endocrine disorders such as hyperthyroidism and pituitary disorders also can lead to hypertension.
- *Neurological disorders*. Increased intracranial pressure causes an elevated blood pressure as the body attempts to maintain cerebral blood flow. Disorders that interfere with autonomic nervous system regulation (such as high spinal cord injury) may allow the sympathetic nervous system to predominate, increasing systemic vascular resistance and blood pressure.
- *Drug use*. Oestrogen and oral contraceptive use may lead to hypertension, possibly by prompting sodium and water retention and affecting the renin–angiotensin–aldosterone

NURSING CARE PLAN A person with hypertension

Margaret Simpson is a married, 49-year-old Anglo-Australian with six children whose ages range from 6 to 16 years. For the past 2 months, Mrs Simpson has had frequent morning headaches and occasional dizziness and blurred vision. At her annual health check 1 month ago, her blood pressure was 168/104 mmHg and 156/94 mmHg. She was instructed to reduce her fat and cholesterol intake, to avoid using salt at the table and to start walking for 30 to 45 minutes daily. Mrs Simpson returns to the clinic for follow up.

ASSESSMENT

While escorting Mrs Simpson to the exam room and obtaining her weight, blood pressure and history, Lisa Christos, RN, notices that Mrs Simpson seems restless and upset. Ms Christos says, 'You look upset about something. Is everything OK?' Mrs Simpson responds, 'Well, my head is throbbing and I'm sort of dizzy. I think I'm just overdoing it and not getting enough rest. You know, raising six children is a lot of work and expense. I just started working part time so we wouldn't get behind in our bills. I thought the extra money might relieve some of my stress, but I'm not so sure that's really happening. I'm not getting any better and I'm worried that I'll lose my job or become disabled and that my husband won't be able to manage the children by himself. I really need to go home, but first, I want to get rid of this awful headache. Would you please get me a couple of aspirin or something?'

Mrs Simpson's history shows a steady weight gain during the past 18 years. She has no known family history of hypertension. Physical findings include height 160 cm, weight 102 kg, T 37.2°C, P 100 regular, R 16, BP 180/115 mmHg (lying), 170/110 mmHg (sitting), 165/105mmHg (standing), average 10 point difference in readings between right and left arm (lower on left). Skin cool and dry, capillary refill 4 seconds right hand, 3 seconds left hand. Mrs Simpson's total serum cholesterol is 6.33 mmol/L (normal < 5.2 mmol/L). All other blood and urine studies are within normal limits. Based on analysis of the data, Mrs Simpson is started on enalapril 5 mg and placed on a low-fat, low-cholesterol, no-added-salt diet.

DIAGNOSES

- *Fatigue* related to effects of hypertension and stresses of daily life.
- *Imbalanced nutrition: more than body requirements* related to excessive food intake.
- *Ineffective health maintenance* related to inability to modify lifestyle.
- *Deficient knowledge* related to effects of prescribed treatment.

PLANNING

- Discuss strategies for achieving a realistic weight loss goal.
- Refer for a dietary consultation for further teaching about fat and sodium restrictions.
- Discuss stress-reducing techniques, helping identify possible choices.

Expected outcomes

- Reduce blood pressure readings to less than 150 systolic and 90 diastolic by return visit next week.
- Incorporate low-sodium and low-fat foods from a list provided into her diet.
- Develop a plan for regular exercise.
- Verbalise understanding of the effects of prescribed drug, dietary restrictions, exercise and follow-up visits to help control hypertension.

IMPLEMENTATION

- Teach to take own blood pressure daily and record it, bringing the record to scheduled clinic visits.
- Teach name, dose, action and side effects of antihypertensive medication.
- Instruct to walk for 15 minutes each day this week and to investigate swimming classes at the local pool.

EVALUATION

Mrs Simpson returns to the clinic 1 week later. Her average blood pressure is now 148/88 mmHg. She has lost 1 kg and states that her oldest daughter has suggested that they join a weight reduction program together. Mrs Simpson is walking for an average of 20 minutes each day. She verbalises an understanding of her medication and is taking it in the morning and before dinner each day. She met with the dietitian and discussed ways to reduce the sodium and fat in her diet. The dietitian provided a list of low-fat, low-sodium foods and recommended cookbooks to help Mrs Simpson modify her cooking. Mrs Simpson tells Ms Christos, 'I just can't believe how much better I feel already. My headaches are gone and I've actually lost some weight—and I feel motivated to keep going. If I had only known how much better I could feel! I don't expect I'll ever go back to my old habits again; it's just not worth it!'

CRITICAL THINKING IN THE NURSING PROCESS

1. Identify the factors that contributed to Mrs Simpson's hypertension. Which were modifiable and which were not?
2. What is the rationale for reducing sodium and fat in Mrs Simpson's diet?
3. Suppose that a hypertensive person is homeless and has no source of income. How could you help ensure that this person would follow the treatment plan? What would you do if the person did not follow it?
4. Discuss the role of stress in hypertension. What factors in Mrs Simpson's life contribute to her stress level?
5. Develop a plan of care for the nursing diagnosis *Low self-esteem* related to obesity.

REFLECTION ON THE NURSING PROCESS

1. Listening to people is an essential quality and skill. Discuss which essential cues in Mrs Simpson's presentation lead the nurse to question her further.
2. What health promotion strategies/programs could be advised for Mrs Simpson to engage in and how are they relevant to her presenting condition?

system. Stimulant drugs, such as cocaine and methamphetamines, increase systemic vascular resistance and cardiac output, resulting in hypertension.

- *Pregnancy*. About 10% of all pregnant women are hypertensive. Hypertension may pre-date pregnancy or occur as a direct response to the pregnancy. The mechanism of pregnancy-induced hypertension (PIH) is unclear. It is a significant cause of maternal and foetal morbidity and mortality and requires careful perinatal management.

The pattern of secondary hypertension varies, depending on its cause. Pheochromocytoma may cause attacks of hypertension that last for minutes to hours, accompanied by anxiety, palpitations, diaphoresis, pallor and nausea and vomiting. Primary aldosteronism may cause hypertension, weakness, paraesthesias, polyuria and nocturia (see Chapter 17). Symptoms of kidney disease accompany hypertension when a renal disorder is the cause.

The following diagnostic tests may be ordered to differentiate primary from secondary hypertension:

- *Renal function studies* and *urinalysis* to identify renal causes of hypertension. Elevated serum urea and creatinine, haematuria, proteinuria and casts often indicate kidney disease.
- *Serum potassium* is decreased in hyperaldosteronism.
- *Blood chemistries*, including serum electrolytes, glucose and lipid studies, are done to detect abnormalities indicative of endocrine or cardiovascular disease.
- *Intravenous pyelography (IVP), renal ultrasonography*, *renal arteriography* and *CT* or *MRI* may be done when secondary hypertension is suspected.

Interprofessional and nursing care for the person with secondary hypertension is the same as that for primary hypertension, discussed in the previous section. In addition, the underlying process is treated. See chapters covering specific disorders for more information about treatment measures.

HYPERTENSIVE CRISIS

Some people with hypertension may, for reasons not clearly understood, develop rapid, significant elevations in systolic and/or diastolic pressures. In a *hypertensive emergency* (or *malignant hypertension*), the systolic pressure is greater than 180 mmHg and the diastolic pressure is higher than 120 mmHg. Immediate treatment (within 1 hour) is vital to prevent cardiac, renal and vascular damage, and reduce morbidity and mortality. Intense cerebral artery spasms help protect the brain from excess pressure; however, cerebral oedema often develops. Prolonged severe hypertension damages the walls of the arterioles and renal blood vessels and may lead to intravascular coagulation and acute renal failure.

People presenting with a hypertensive emergency may have manifestations such as headache, confusion, swelling of the optic nerve (papilloedema), blurred vision, restlessness and motor and sensory deficits. Manifestations of hypertensive emergencies are listed in the box below.

Most hypertensive emergencies occur when people suddenly stop taking their medications or their hypertension is poorly controlled. Younger people (30 to 50 years old), Indigenous Australian men, pregnant women with pre-eclampsia and people with collagen and/or renal disease also are at higher risk of a hypertensive emergency (NHF, 2010).

The goal of care in hypertensive emergencies is to reduce the blood pressure by no more than 25% within minutes to 1 hour, then towards 160/100 within 2 to 6 hours. It is important to avoid rapid or excessive blood pressure decreases that may lead to renal, cerebral or cardiac ischaemia (Ventura & Reddy, 2014). Blood pressure is monitored frequently (every 5 to 30 minutes) during a hypertensive emergency. The serum urea, creatinine, calcium and total protein levels are carefully

MANIFESTATIONS Hypertensive emergencies

- Rapid onset
- Blurred vision, papilloedema
- Systolic pressure > 180 mmHg
- Diastolic pressure > 120 mmHg
- Headache
- Confusion
- Motor and sensory deficits

TABLE 31.2 Intravenous drugs used to treat hypertensive emergencies

DRUG	ONSET	DURATION	NURSING IMPLICATIONS
Sodium nitroprusside dihydrate	Seconds	1 to 2 min	• Effective, easy to titrate • May cause nausea, vomiting, muscle twitching, sweating • Use with caution in increased intracranial pressure
Glyceryl trinitrate	2 to 5 min	5 to 10 min	• Used when coronary ischaemia accompanies hypertension • May cause headache, vomiting • Tolerance may develop with prolonged use
Diazoxide	1 to 2 min	4 to 24 h	• Avoided in people with coronary artery disease • Used with beta-blockers and diuretics • Painful if it enters tissues
Hydralazine (Apresoline)	10 to 30 min	2 to 6 h	• May be used for hypertension associated with eclampsia • Avoided in people with CHD • May cause tachycardia, flushing, headache, vomiting, angina

monitored to help determine the prognosis for recovery. Drug treatment for malignant hypertension includes parenteral administration of a rapidly acting antihypertensive, such as the potent vasodilator sodium nitroprusside. Other vasodilating agents that may be used are outlined in Table 31.2. Management also focuses on treating any underlying or coexisting heart, kidney and CNS disorders.

Nursing care for people with a hypertensive emergency focuses on continuous monitoring of the blood pressure and titrating drugs (administered by intravenous bolus or infusion) as ordered to achieve desired blood pressure. Avoiding excessive or very rapid blood pressure reductions is as important as achieving the desired blood pressure readings. Reassure the person and family of the rapid effect of prescribed drugs. Provide psychological and emotional support as needed. Maintain an attitude of confidence that the treatment will achieve the desired effect. Following resolution of the hypertensive crisis, review causes of the crisis. Teach the person and family measures to effectively manage hypertension and prevent future hypertensive emergencies.

DISORDERS OF THE AORTA AND ITS BRANCHES

The aorta and its branches may be affected by occlusions, aneurysms and inflammations. These disorders may be chronic or acute and life threatening (e.g. a thoracic dissection). This section focuses on aneurysms of the aorta and its branches.

THE PERSON WITH AN ANEURYSM

An **aneurysm** is an abnormal dilation of a blood vessel, commonly at a site of a weakness or tear in the vessel wall. Aneurysms commonly affect the aorta and peripheral arteries because of the high pressure in these vessels. An aneurysm also may develop in the ventricular wall, usually affecting the left ventricle. Most arterial aneurysms are caused by arteriosclerosis or atherosclerosis; trauma also may lead to aneurysm formation.

Arterial aneurysms are most common in men over age 50, most of whom are asymptomatic at the time of diagnosis. Hypertension is a major contributing factor in the development of some types of aortic aneurysms.

FAST FACTS

- The incidence of aortic aneurysm-related deaths for males in Australia in 2013 was 573.
- The incidence of aortic aneurysm-related deaths for females in Australia in 2013 was 388.
- Aortic aneurysm and dissection in 2013 accounted for 0.65% of all deaths in Australia.

Source: ABS, 2015.

Pathophysiology and manifestations

Aneurysms form due to weakness of the arterial wall. The main structural proteins of the aorta are collagen and elastin. Collagen provides tensile strength of the vessel, preventing excessive dilation. Elastin allows vessel recoil, during which the vessel returns to its original size following systole. This recoil provides continued propulsion of the bolus of blood expelled from the ventricle. Elastin is a primary component of internal elastic lamina, which separates the intimal and medial layers of the aorta and of the media, the smooth muscle layer of the aorta. Destruction of elastin can lead to abnormal dilation of the vessel; collagen destruction can allow the vessel to rupture (Tseng, 2014).

True aneurysms are caused by slow weakening of the arterial wall due to the long-term, eroding effects of atherosclerosis and hypertension. True aneurysms affect all three layers of the vessel wall and most are fusiform and circumferential. *Fusiform aneurysms* are spindle shaped and taper at both ends. Circumferential aneurysms involve the entire diameter of the vessel (see Figure 31.7). They generally grow slowly but progressively. Their length and diameter vary considerably among people. A large fusiform aneurysm may affect most of the ascending aorta as well as a large portion of the abdominal aorta.

False aneurysms, also known as traumatic aneurysms, are caused by a traumatic break in the vessel wall rather than weakening of the vessel. They often are *saccular*, shaped like small outpouchings (sacs) on a portion of the vessel wall (see

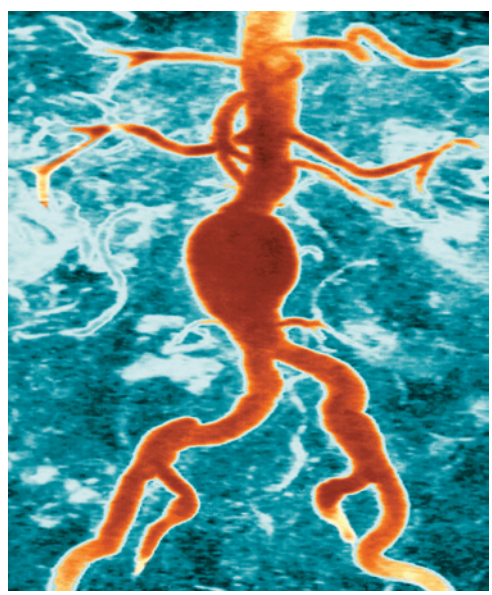


FIGURE 31.7 ■ A magnetic resonance angiogram (MRA) showing a circumferential aneurysm of the lower abdominal aorta

Source: Zephyr/Science Source.

Figure 31.8). A *berry aneurysm* is a type of saccular aneurysm. They are often small (less than 2 cm in diameter), caused by congenital weakness in the tunica media of the artery. Berry aneurysms are commonly found in the circle of Willis in the brain.

Dissecting aneurysms are unique, developing when a break or tear in the tunica intima and media allows blood to invade or *dissect* the layers of the vessel wall. The blood usually is contained by the adventitia, forming a saccular or longitudinal aneurysm.

Aneurysms affect different segments of the aorta and its branches. Their manifestations generally are due to pressure of the aneurysm on adjacent structures. Table 31.3 summarises the manifestations and complications of various types of aortic aneurysms.

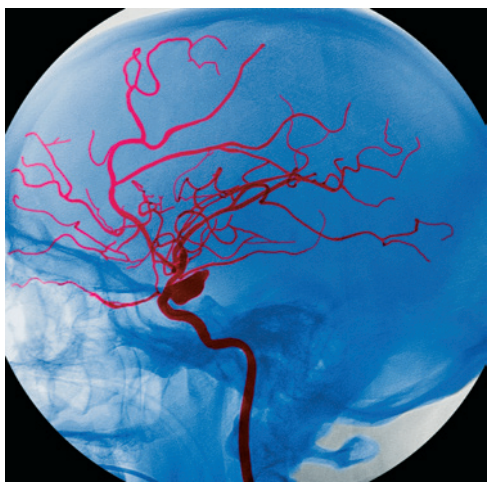

FIGURE 31.8 ■ An angiogram showing a saccular (berry) aneurysm in the carotid artery of a 50-year-old man

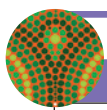
Source: Simon Fraser/RNC, Newcastle upon Tyne/Science Source.

Thoracic aortic aneurysms

*Thoracic aortic aneurysm*s (see Figure 31.9) account for about 10% of aortic aneurysms, with an annual incidence of about 6 per 100 000 people. They usually result from weakening of the aortic wall by arteriosclerosis and hypertension. Other causes include trauma, coarctation of the aorta, tertiary syphilis, fungal infections and Marfan syndrome. The syphilis spirochete can invade and weaken aortic smooth muscle, causing an aneurysm to develop as long as 20 years after the primary infection. Marfan syndrome fragments elastic fibres of the aortic media, weakening the vessel wall. The box below discusses genetic links associated with thoracic aortic aneurysms.

Thoracic aneurysms frequently are asymptomatic. When present, manifestations are caused by the effects of the aneurysm on blood flow (to the coronary arteries and great vessels of the head and upper body) and pressure placed by distended aorta on surrounding structures. Consequently, manifestations vary by the location, size and growth rate of the aneurysm. Substernal, neck or back pain may occur. Pressure on the



GENETIC CONSIDERATIONS
Thoracic aortic aneurysms

About 15–25% of people with aortic aneurysms have a family history of the disorder (Gong et al., 2015; Rahimi, 2014). A condition known as *cystic medial necrosis* is prevalent in people with Marfan syndrome and Ehlers–Danlos syndrome, inherited disorders involving connective tissues. In cystic medial necrosis, collagen and elastic fibres of the tunica media of the aorta degenerate. This loss of collagen and elastic tissues weakens the wall of the proximal aorta, leading to circumferential dilation of the ascending aorta and development of a fusiform aneurysm.

TABLE 31.3 Manifestations and complications of aortic aneurysms

TYPE OR LOCATION	MANIFESTATIONS	COMPLICATIONS
Thoracic	• May be asymptomatic • Back, neck or substernal pain • Dyspnoea, stridor or brassy cough if pressing on trachea • Hoarseness and dysphagia if pressing on oesophagus or laryngeal nerve • Oedema of the face and neck • Distended neck veins	• Rupture and haemorrhage
Abdominal	• Pulsating abdominal mass • Aortic calcification noted on x-ray • Mild to severe midabdominal or lumbar back pain • Cool, cyanotic extremities if iliac arteries are involved • Claudication (ischaemic pain with exercise, relieved by rest)	• Peripheral emboli to lower extremities • Rupture and haemorrhage
Aortic dissection	• Abrupt, severe, ripping or tearing pain in area of aneurysm • Mild or marked hypertension early • Weak or absent pulses and blood pressure in upper extremities • Syncope	• Haemorrhage • Kidney failure • MI, heart failure, cardiac tamponade • Sepsis • Weakness or paralysis of lower extremities

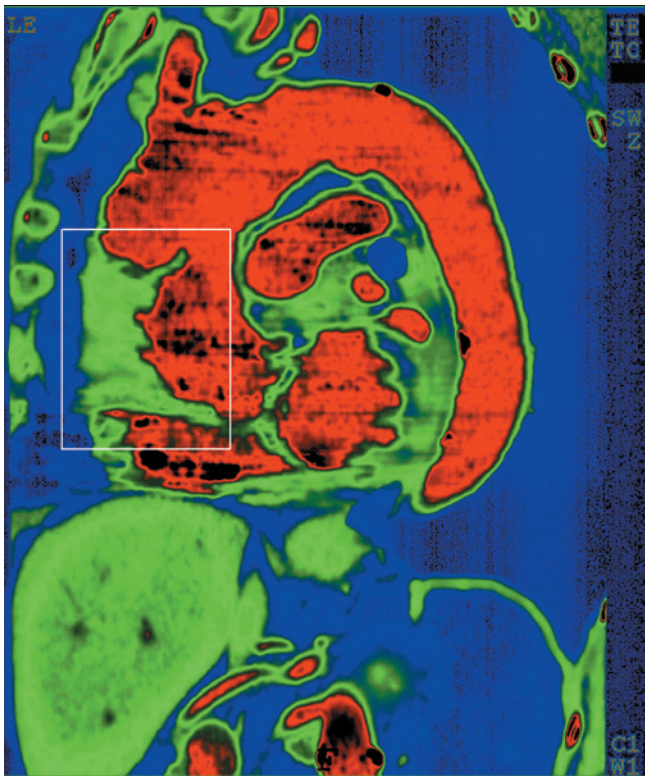


FIGURE 31.9 ■ In an aortic dissection, a tear in the intima and media of the artery allows blood to invade and dissect the wall of the aorta

Source: J. Cavallini/Custom Medical Stock Photo.

trachea, oesophagus, laryngeal nerve or superior vena cava may cause dyspnoea, stridor, cough, difficult or painful swallowing, hoarseness, oedema of the face and neck, and distended neck veins.

Aneurysms of the ascending aorta typically cause angina due to disruption of blood flow into the coronary arteries. Heart failure may develop as a result of disruption of the aortic valve and regurgitation of blood back into the left ventricle. Aneurysms of the aortic arch often cause dysphagia, dyspnoea, hoarseness, confusion and dizziness (due to disrupted cerebral blood flow). Thrombi that form within a thoracic aneurysm can embolise, causing a stroke, renal or mesenteric ischaemia, or ischaemia of the lower extremities. Aneurysms of the thoracic aorta tend to enlarge progressively and may rupture, causing death (Tseng, 2014).

Abdominal aortic aneurysms

Abdominal aortic aneurysms are associated with arteriosclerosis and hypertension. Increasing age and smoking are believed to contribute as well. Most abdominal aortic aneurysms are found in adults over age 70. The vast majority (over 90%) develop below the renal arteries, usually where the abdominal aorta branches to form the iliac arteries (Rahimi, 2014).

Most abdominal aneurysms are asymptomatic, but a pulsating mass in the mid and upper abdomen and a bruit over the mass are found on exam. When pain is present, it may be constant or intermittent, usually felt in the midabdominal region or lower back. Its intensity may range from mild discomfort to severe pain. Pain intensity often correlates with the size and severity of the aneurysm. Severe pain may indicate impending rupture.

Sluggish blood flow within the aneurysm may cause thrombi (blood clots) to form. These can become emboli (circulating clots), travelling to the lower extremities and occluding peripheral arteries. Aneurysms generally enlarge by approximately 0.2–0.8 mm/year; eventually they may rupture, resulting in haemorrhage and hypovolaemic shock. After acute rupture, the mortality rate is greater than 65%, even when emergency surgery is performed (Rahimi, 2014).

Popliteal and femoral aneurysms

Most popliteal and femoral aneurysms are due to arteriosclerosis. They are often bilateral and usually affect men.

Popliteal aneurysms (see Figure 31.10) may be asymptomatic. Manifestations, if any, are due to decreased blood flow to the lower extremity and include intermittent **claudication** (cramping or pain in the leg muscles brought on by exercise and relieved by rest), rest pain and numbness. A pulsating mass may be palpable in the popliteal fossa (behind the knee). Thrombosis and embolism are complications; gangrene may result, often necessitating amputation.

A *femoral aneurysm* usually is detected as a pulsating mass in the femoral area. The manifestations are similar to those of popliteal aneurysms, resulting from impaired blood flow. Femoral aneurysms may rupture.

Aortic dissections

Dissection is a life-threatening emergency caused by a tear in the intima of the aorta with haemorrhage into the media.

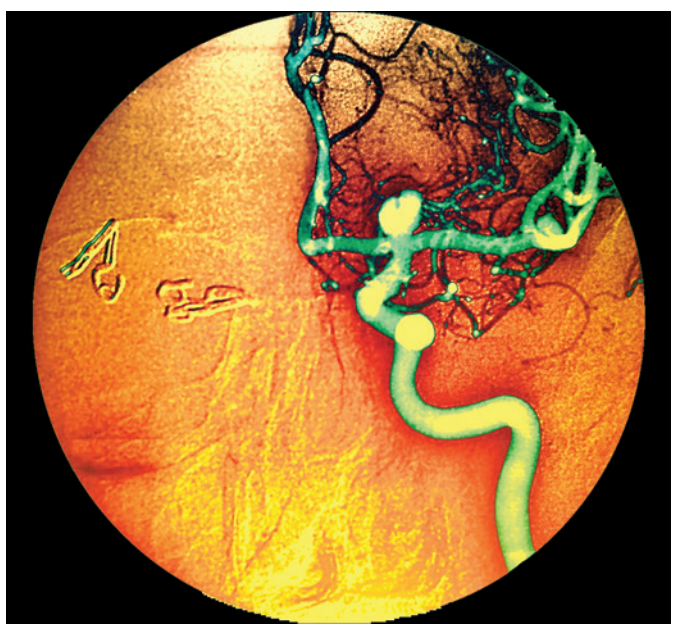

FIGURE 31.10 ■ An angiogram showing several popliteal aneurysms

Source: Zephyr/Science Source.

The haemorrhage dissects or splits the vessel wall, forming a blood-filled channel between its layers. Dissection can occur anywhere along the aorta. *Type A dissection* (also called *proximal dissection*) affects the ascending aorta; *type B dissection* (*distal dissection*) is limited to the descending aorta.

Hypertension is a major predisposing factor for aortic dissection, accounting for 70% of aortic dissections. Cystic medial necrosis (see the 'Genetic considerations' box above) also is a major risk factor. Other risk factors include male gender, advancing age, pregnancy, congenital defects of the aortic valve, coarctation of the aorta and inflammatory aortitis (Mancini, 2014).

Dissection of the thoracic aortic walls progresses along the length of the vessel, moving both proximally and distally. As the aneurysm expands, pressure may prevent the aortic valve from closing or may occlude the branches of the aorta. Descending aortic dissection may extend into the renal, iliac or femoral arteries.

The primary symptom of an aortic dissection is sudden, excruciating pain. The pain, often described as a ripping or tearing sensation, is usually over the area of dissection. Thoracic dissections cause chest or back pain. Other symptoms may include syncope, dyspnoea and weakness. The blood pressure may initially be increased, but rapidly falls and is often inaudible as the dissection occludes blood flow. Peripheral pulses are absent for the same reason.

Complications develop if major arteries are affected. Obstruction of the carotid artery causes neurological symptoms such as weakness or paralysis. The myocardium, kidneys or bowel may become ischaemic or infarct if blood flow to the coronary arteries, renal arteries or mesenteric artery is affected. Acute aortic regurgitation may develop with dissection of the ascending aorta. With treatment, the long-term prognosis is generally good, although the in-hospital mortality rate with medical management is approximately 60% and following surgery remains quite high at 30% (Mancini, 2014).

INTERPROFESSIONAL CARE

Most aneurysms are asymptomatic, detected through a routine physical examination. Treatment depends on the size of the aneurysm. Small, asymptomatic aneurysms may not be treated or are medically managed; large aneurysms (> 5 cm) at risk of rupture require surgery.

Diagnosis

Diagnostic studies done to establish the diagnosis and determine the size and location of the aneurysm may include:

- *chest x-ray* to visualise thoracic aortic aneurysms
- *abdominal ultrasonography* to diagnose abdominal aortic aneurysms
- *transoesophageal echocardiography* to identify the specific location and extent of a thoracic aneurysm and to visualise a dissecting aneurysm
- *contrast-enhanced CT* or *MRI* allows precise measurements of aneurysm size
- *angiography* uses contrast solution injected into the aorta or involved vessel to visualise the precise size and location of the aneurysm.

Medications

Thoracic aortic aneurysms may be treated with long-term beta-blocker therapy and additional antihypertensive drugs as needed to control heart rate and blood pressure.

People with aortic dissection are initially treated with intravenous beta-blockers to reduce the heart rate to about 60 bpm. Sodium nitroprusside infusion is started concurrently to reduce the systolic pressure to 120 mmHg or less. Calcium channel blockers also may be used. Constant monitoring of vital signs, haemodynamic pressures (via Swan–Ganz catheter; see Chapter 30 for more information about haemodynamic pressure monitoring) and urine output is vital to ensure adequate perfusion of vital organs.

Following surgical correction of an aneurysm, anticoagulant therapy may be initiated. Heparin therapy is used initially, with conversion to oral anticoagulation prior to discharge. Many people are maintained indefinitely on anticoagulant therapy; others may use lifelong, low-dose aspirin therapy to reduce the risk of clot formation.

Surgery

Operative repair of aortic aneurysms is indicated when the aneurysm is symptomatic or expanding rapidly. Ascending thoracic aneurysms of more than 5.5 cm and descending thoracic aneurysms of 6.5cm or more should be surgically repaired; asymptomatic abdominal aneurysms greater than 5 cm in diameter may be repaired, depending on the person's operative risk factors. It is recommended that individuals with Marfan syndrome or familial aneurysms should be repaired at 0.5 cm or sooner (Tseng 2014).

Endovascular aneurysm repairs (EVAR) are increasingly used to treat abdominal and thoracic aortic aneurysms. The use of EVAR to treat aortic dissections is in investigational stages. The stent, which consists of a metal sheath covered with polyester fabric or a woven polyester tube, usually is placed percutaneously via the femoral artery. Fluoroscopy is used to guide its placement. Both straight and bifurcated grafts are available. Endovascular stent placement results in a shorter hospital stay and lower treatment cost. EVAR is associated with fewer pulmonary, renal and cardiovascular complications than open surgical aneurysm repair in individuals as a planned treatment option prior to rupture. However, a recent Cochrane Review identified that there is currently no reliable evidence to suggest improvement in survival rate or reduction of late complications when using the endoscopic approach for individuals once the aorta is ruptured (Badger et al., 2014). The most common complication of endovascular aneurysm repair is persistent perfusion of the aneurysm (*endoleak*) caused by an ineffective seal at the proximal or distal end of the graft. Regular follow up with abdominal CT scans is necessary to detect this complication, which can develop at any time postoperatively. Numerous techniques exist to successfully manage endoleak, although there is no current evidence of any particular technique's superiority (Millen et al., 2015). On rare

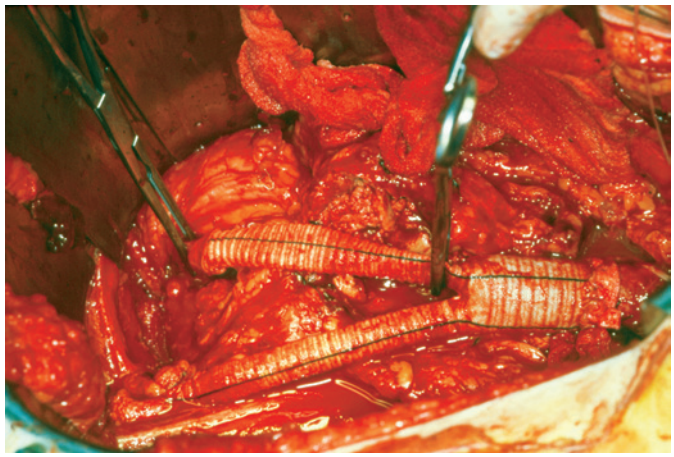

FIGURE 31.11 ■ Repair of an abdominal aortic aneurysm. The aorta is exposed and clamped between the renal and iliac arteries. Atherosclerotic plaque and thrombotic material are removed. A synthetic graft is used to replace the aneurysm. The aneurysm walls are then sutured around the graft

Source: Stevie Grand/Science Source.

occasions, the graft may be malpositioned or may migrate from the desired location.

An open surgical procedure in which the aneurysm is excised and replaced with a synthetic fabric graft is the standard treatment for expanding abdominal aortic aneurysms (see Figure 31.11). Although the aneurysm walls may be excised, they usually are left intact and used to cover the graft. Surgical repair of thoracic aneurysms is similar but more complex due to major vessels exiting at the aortic arch. Cardiopulmonary bypass is required if the ascending aorta is involved. The aortic valve also may be replaced during surgery. See the following box for nursing care of the person having surgery of the aorta.

Nursing care

Assessment

Focused assessment for the person with a suspected aortic aneurysm includes:

- *Health history:* complaints of chest, back or abdominal pain; extremity weakness; shortness of breath, cough, difficult or painful swallowing, hoarseness; history of hypertension, coronary heart disease, heart failure or peripheral vascular disease.
- *Physical examination:* vital signs, including blood pressure in upper and lower extremities; peripheral pulses; skin colour and temperature; neck veins; abdominal exam, including gentle palpation for masses and auscultation for bruits; neurological exam, including level of consciousness (LOC), sensation and movement of extremities.

Nursing diagnoses and interventions

Nursing care for people with an aneurysm of the aorta or its branches focuses on monitoring and maintaining tissue perfusion, relieving pain and reducing anxiety. Nursing care usually is acute, precipitated by a complication or surgical repair of the aneurysm.

Risk of ineffective tissue perfusion

People with aortic aneurysms are at risk of impaired tissue perfusion due to aneurysm rupture with resulting haemorrhage and lack of blood flow to tissues distal to the rupture. In addition, thrombi often form within the aneurysm and may become emboli, obstructing distal arterial blood flow.

CONSIDERATION FOR PRACTICE

Immediately report manifestations of impending rupture, expansion or dissection of the aneurysm: increased pain; discrepancy between upper and lower extremity blood pressures and peripheral pulses; increased mass size; change in LOC or motor or sensory function; laboratory results. Rapid expansion may indicate increased risk of rupture, with resulting haemorrhage, shock and possible death. Elective or planned surgery may rapidly become emergency surgery to prevent complications.

- Implement interventions to reduce the risk of aneurysm rupture:
  a. Maintain bed rest with legs flat.
  b. Maintain a calm environment, implementing measures to reduce psychological stress.
  c. Prevent straining during defecation and instruct to avoid holding the breath while moving.
  d. Administer beta-blockers and antihypertensives as prescribed.

  Activity, stress and the Valsalva manoeuvre increase blood pressure, increasing the risk of rupture. Elevating or crossing the legs restricts peripheral blood flow and increases pressure in the aorta or iliac arteries. Beta-blockers and antihypertensives often are ordered to reduce pressure in the dilated vessel.

CONSIDERATION FOR PRACTICE

Report manifestations of arterial thrombosis or embolism: absent peripheral pulses; a pale or cyanotic, cool extremity; severe, diffuse abdominal pain with guarding; or increased groin, lumbar or lower extremity pain. Sluggish blood flow within the aneurysm often causes thrombi to form. These thrombi can break loose, becoming emboli that can occlude peripheral arteries or arteries to the kidneys or mesentery. Arterial occlusion may necessitate emergency surgery to restore blood flow and prevent tissue infarct or gangrene.

- Continuously monitor cardiac rhythm. Report complaints of chest pain or changes in ECG tracing. Administer oxygen as indicated. *Aortic dissection and repair place the person at significant risk of MI, a major cause of postoperative mortality and morbidity (Kasper et al., 2015).*

NURSING CARE OF THE PERSON having surgery of the aorta

PREOPERATIVE CARE

- As time permits, provide routine preoperative care and teaching as outlined in Chapter 3. *People having vascular surgery have similar preoperative nursing care needs to other people having major abdominal or thoracic surgery. If emergency surgery is required, time for preoperative care and teaching may be limited.*
- Implement measures to reduce fear and anxiety:
  a. Orient to the intensive care unit, if appropriate.
  b. Describe and explain the reason for all equipment and tubes, such as cardiac monitors, ventilators, nasogastric tubes, urinary catheters, intravenous lines and fluids, and intra-arterial lines.
  c. Explain what to expect following surgery (sights, sounds, frequency of taking vital signs, dressings, pain relief measures, communication strategies).
  d. Allow time for questions and expression of fears and concerns.

  These explanations provide a sense of control for the person and family.
- Monitor for and implement care to reduce the risk of aneurysm rupture (see the following section). *People with a rapidly expanding or symptomatic aneurysm are at risk of rupture prior to surgical repair.*

POSTOPERATIVE CARE

- Provide routine postoperative care and specific measures as ordered by the doctor. *People undergoing aneurysm repair require nursing care similar to that provided to all people with major thoracic or abdominal surgery, in addition to specific measures related to vascular surgery.*
- Maintain fluid replacement and blood or volume expanders as ordered. Promptly report changes in vital signs, level of consciousness and urine output. *Hypovolaemic shock may develop due to blood loss during surgery, third spacing, inadequate fluid replacement, and/or haemorrhage if graft separation or leakage occurs.*

CONSIDERATION FOR PRACTICE

Monitor for and report manifestations of graft leakage:

a. ecchymoses of the scrotum, perineum or penis; a new or expanding haematoma
b. increased abdominal girth
c. weak or absent peripheral pulses; tachycardia; hypotension
d. decreased motor function or sensation in the extremities
e. fall in haemoglobin and haematocrit
f. increasing abdominal, pelvic, back or groin pain
g. decreasing urinary output (less than 30 mL/h)
h. decreasing CVP, pulmonary artery pressure or pulmonary artery wedge pressure.

These manifestations may signal graft leakage and possible haemorrhage. Pain may be due to pressure from an expanding haematoma or bowel ischaemia. Decreased renal perfusion causes the glomerular filtration rate and urine output to fall.

- Report manifestations of lower extremity embolism: pain and numbness in lower extremities, decreasing pulses and pale, cool or cyanotic skin. *Pulses may be absent for 4 to 12 hours postoperatively due to vasospasm; however, absent pulses with pain, changes in sensation and a pale, cool extremity are indicative of arterial occlusion.*
- Report manifestations of bowel ischaemia or gangrene: abdominal pain and distension, occult or fresh blood in stools, and diarrhoea. *Bowel ischaemia may result from an embolism or occur as a complication of surgery.*
- Report manifestations of impaired renal function: urine output less than 30 mL/h, fixed specific gravity, increasing serum urea and creatinine levels. *Hypovolaemia or clamping of the aorta during surgery may impair renal perfusion, leading to acute renal failure.*
- Report manifestations of spinal cord ischaemia: lower extremity weakness or paraplegia. *Impaired spinal cord perfusion may lead to ischaemia and impaired function.*

Rapid identification and treatment of this complication can reduce the risk of death or long-term adverse effects of MI.

CONSIDERATION FOR PRACTICE

Immediately report changes in mental status or symptoms of peripheral neurological impairment (weakness, paraesthesias, paralysis). The expanding aneurysm or dissection can affect carotid and cerebral blood flow or spinal cord perfusion, leading to neurological symptoms. Immediate restoration of blood flow is vital to prevent permanent neurological deficits.

Risk of injury

Potent antihypertensive drugs often are given intravenously to reduce the pressure on an expanding or dissecting aneurysm. Continuous monitoring of infusions and haemodynamic parameters such as arterial pressure, pulmonary pressures and cardiac output is vital to ensure that adequate tissue perfusion is maintained during infusions of these potent drugs.

- Continuously monitor arterial pressure and haemodynamic parameters as indicated. Promptly report results outside the specified parameters to the doctor. *Many of the drugs used are effective within minutes. Responses vary among individuals, particularly in the older adult, necessitating continuous monitoring.*
- Monitor urine output hourly. Report output less than 30 mL/h. *The kidneys are very sensitive to reduced perfusion pressure; inadequate renal blood flow can lead to acute kidney failure.*

CONSIDERATION FOR PRACTICE

Use an infusion control device for all drug infusions. These devices prevent accidental or inadvertent changes in the rate of the infusion and dose of the drug.

Anxiety

People with aortic aneurysms often are highly anxious because of the urgent nature of the disorder. The nurse must manage the anxiety levels of both the person and family members to effectively address physiological care needs. Stress reduction also is necessary to help maintain the blood pressure within desired limits.

- Explain all procedures and treatments, using simple and understandable terms. *Simplified explanations are necessary when anxiety levels interfere with learning and understanding.*
- Respond to all questions honestly, using a calm, empathetic but matter-of-fact manner. *Honesty with the person and family promotes trust and provides reassurance that the true nature of the situation is not being 'hidden' from them.*
- Provide care in a calm, efficient manner. *Using a calm manner, even during preparations for emergency surgery, reassures the person and family that although the situation is critical, the staff is prepared to handle things effectively.*
- Spend as much time as possible with the person. Allow supportive family members to remain with the person when possible. *The presence of a health professional and supportive family member reassures the person that they are not alone in facing this crisis.*

Community-based care

Topics to discuss when preparing people and their families for home care or care in a community-based setting depend on the treatment plan. Discuss the following topics when surgical repair is not immediately planned and the aneurysm will be monitored:

- measures to control hypertension, including lifestyle and prescribed drugs
- the benefits of smoking cessation
- manifestations of increasing aneurysm size or complications to report to the doctor.

Following surgery, discuss the following topics in preparing the person and family for home care:

- wound care and preventing infection; manifestations of impaired healing or infection to be reported
- prescribed antihypertensive and anticoagulant medications and their expected and unintended effects
- the importance of adequate rest and nutrition for healing
- measures to prevent constipation and straining at stool (such as increasing fluid and fibre in the diet)
- the importance of avoiding prolonged sitting, lifting heavy objects, engaging in strenuous exercise and having sexual intercourse until approved by the doctor (usually 6 to 12 weeks)
- signs and symptoms of complications to report to the doctor.

Provide referrals to a home health agency or community health service as necessary. Referrals are especially important for older adults and their caregivers, who may require additional assistance with the complex care needs.

DISORDERS OF THE PERIPHERAL ARTERIES

Disorders that impair peripheral arterial blood flow may be acute (e.g. arterial thrombosis) or chronic (e.g. peripheral arteriosclerosis). Chronic occlusive disorders may be due to structural defects of the arterial walls or spasm of affected arteries. Impaired peripheral arterial circulation limits the availability of oxygen and nutrients to the tissues and can have significant adverse effects. This section focuses on acute and chronic disorders affecting peripheral arteries. The nurse's role in caring for people with peripheral arterial disorders focuses on maintaining tissue perfusion and educating the person and family about the disorder and its management.

Physiology review

Peripheral arteries are the part of the systemic circulation that delivers oxygen and nutrients to the skin and the extremities. Arterial walls have three layers: the intima, which includes the endothelium and a layer of connective tissue and the basement membrane; the media, composed of smooth muscle and elastic fibres; and the adventitia, a thin layer of connective tissue that contains collagen and elastic fibres. The smooth muscle of peripheral arteries controls blood flow as it contracts and relaxes. Contraction narrows the vessel lumen (**vasoconstriction**), whereas smooth muscle relaxation expands the vessel (**vasodilation**). Peripheral arteries become progressively smaller; arterioles are less than 0.5 mm in diameter and are composed primarily of smooth muscle. The arterioles control blood flow through the capillary beds where gas, nutrient and waste product exchange occurs. Capillary walls are very thin, consisting of a single layer of endothelial cells surrounded by a thin basement membrane.

Blood flows from an area of higher pressure to an area of lower pressure. *Resistance* opposes blood flow. Resistance is created by friction of the blood itself, although the primary determinants of vascular resistance are the diameter and length of the blood vessel. See the physiology review section earlier in this chapter under 'Disorders of blood pressure regulation' for more information about factors that determine vessel resistance.

THE PERSON WITH PERIPHERAL VASCULAR DISEASE

Arteriosclerosis is the most common chronic arterial disorder, characterised by thickening, loss of elasticity and calcification of arterial walls. **Atherosclerosis** is a form of arteriosclerosis in which deposits of fat and fibrin obstruct and harden the arteries. In the peripheral circulation, these

pathological changes impair the blood supply to peripheral tissues, particularly the lower extremities. This is known as **peripheral vascular disease (PVD)** or peripheral artery disease (PAD).

Incidence and risk factors

PVD usually affects people over 65; men are more often affected than women. Rates of PVD are 20% higher among Indigenous Australians than among non-Indigenous Australians (ABS, 2014).

Risk factors for PVD are similar to those for atherosclerosis and CHD (see Chapter 29). The main preventable risk factors for peripheral vascular disease are diabetes, cigarette smoking, hypertension, hyperviscosity, hypercholesterolaemia and obesity (Stephens, 2014).

FAST FACTS

- PVD is a common manifestation of atherosclerosis, particularly in older men.
- Peripheral vascular disease (also known as peripheral artery disease) refers to diseases of arteries outside the heart and brain. It occurs when fatty deposits build up in the inner walls of these arteries and affect blood circulation, mainly in the arteries leading to the legs and feet. It ranges from asymptomatic disease, through to pain on walking, to pain at rest and limb-threatening reduced blood supply that can lead to amputation.
- Regular daily exercise is a primary intervention for all types of peripheral arterial disease to promote development of collateral circulation and maintain tissue perfusion.

Pathophysiology

The pathophysiology of atherosclerosis is detailed in Chapter 29. Atherosclerotic lesions involve both the intima and the media of the involved arteries. Lesions typically develop in large and midsized arteries, particularly the abdominal aorta, iliac, femoral popliteal, tibial peroneal arteries.

Plaque tends to form at arterial bifurcations. The vessel lumen is progressively obstructed, decreasing blood flow to the lower extremities. Tissue hypoxia or anoxia results. With gradual obstruction of the vessel, collateral circulation often develops. However, it is usually not adequate to supply tissue needs, especially when metabolic demand increases (e.g. during exercise). Manifestations typically develop only when the vessel is occluded by 60% or more.

Manifestations and complications

Pain is the primary symptom of peripheral atherosclerosis. Intermittent claudication—a cramping or aching pain in the calves of the legs, the thighs and the buttocks that occurs with a predictable level of activity—is characteristic of PVD. The pain is often accompanied by weakness and is relieved by rest.

Rest pain, in contrast, occurs during periods of inactivity. It is often described as a burning sensation in the lower legs. Rest pain increases when the legs are elevated and decreases when the legs are dependent (e.g. hanging over the side of the bed). The legs also may feel cold or numb along with the pain. Sensation is diminished and the muscles may atrophy.

Peripheral pulses may be decreased or absent. A bruit may be heard over large affected arteries, such as the femoral artery and the abdominal aorta. The legs are pale when elevated, but often are dark red when dependent (*dependent rubor*). The skin often is thin, shiny and hairless, with discoloured areas. Toenails may be thickened. Areas of skin breakdown and ulceration may be evident. Oedema may develop with severe PVD. See the box below for manifestations of peripheral atherosclerosis.

MANIFESTATIONS Peripheral atherosclerosis

- Intermittent claudication
- Rest pain
- Paraesthesias (numbness, decreased sensation)
- Diminished or absent peripheral pulses
- Pallor with extremity elevation, dependent rubor when dependent
- Thin, shiny, hairless skin; thickened toenails
- Areas of discolouration or skin breakdown

Complications of peripheral atherosclerosis include gangrene and extremity amputation, rupture of abdominal aortic aneurysms and possible infection and sepsis.

INTERPROFESSIONAL CARE

Management of peripheral vascular disease focuses on slowing the atherosclerotic process and maintaining tissue perfusion.

Diagnosis

Although PVD often can be diagnosed by the history and physical examination, diagnostic tests may be ordered to evaluate its extent. Non-invasive studies are often sufficient.

- *Segmental pressure measurements* use sphygmomanometer cuffs and a Doppler device to compare blood pressures between the upper and lower extremities (normally similar) and within different segments of the affected extremity. In PVD, the BP may be lower in the legs than in the arms.
- *Stress testing* using a treadmill provides functional assessment of limitations. In PVD, pressure at the ankle may decline even further with exercise, confirming the diagnosis. Evaluation for coronary heart disease may be done simultaneously during exercise testing (Kasper et al., 2015).
- *Doppler ultrasound* uses sound waves reflected off moving red blood cells within a vessel to evaluate blood flow. The impulses may be translated into an audible signal or a graphic waveform. With significant PVD, the waveform becomes progressively flatter as the transducer is moved distally along the affected vessel. Segmental pressures may be used to locate the site of obstruction.

- *Duplex Doppler ultrasound* combines the audible or graphic Doppler ultrasound with ultrasound imaging to identify arterial or venous abnormalities. Ultrasonic imaging provides views of the affected vessel, while Doppler ultrasound evaluates blood flow. *Colour-flow Doppler ultrasound (CDU)* provides colour images of the vessel and blood flow.
- *Transcutaneous oximetry* evaluates oxygenation of tissues.
- *Angiography* or *magnetic resonance angiography (MRA)* is done before revascularisation procedures to locate and evaluate the extent of arterial obstruction. For angiography, a contrast medium is injected and vessels are visualised using fluoroscopy and x-rays. MRA does not require injection of a contrast medium and may replace angiography.

See Chapter 28 for more information on diagnostic testing for PVD.

Medications

Drug treatment of peripheral atherosclerosis is less effective than it is for coronary heart disease. Medications to inhibit platelet aggregation, such as aspirin or clopidogrel, are ordered to reduce the risk of arterial thrombosis. Cilostazol, a platelet inhibitor with vasodilator properties, improves claudication. Pentoxifylline decreases blood viscosity and increases red blood cell flexibility, increasing blood flow to the microcirculation and tissues of the extremities. Parenteral vasodilator prostaglandins may be given on a long-term basis to decrease pain and facilitate healing in people with severe limb ischaemia (Kasper et al., 2015).

Treatments

Smoking cessation is vital. Nicotine not only promotes atherosclerosis but also causes vasospasm, further reducing blood flow to the extremities.

Meticulous foot care is vital to prevent ulceration and infection (see Box 31.5). Elastic compression stockings, which reduce circulation to the skin, are avoided. Elevating the head of the bed on blocks may help relieve rest pain. Regular, progressively strenuous exercise, such as 30 to 45 minutes of walking daily, is important. The person is taught to rest at the onset of claudication, resuming activity when the pain resolves.

Other measures to slow the process of atherosclerosis, such as controlling diabetes and hypertension, lowering cholesterol levels and weight loss, also are recommended. See the box below for care of the older adult.

Revascularisation

Revascularisation may be performed if symptoms are progressive, severe or disabling. Other indications for surgery include symptoms that significantly interfere with activities of daily living (ADLs), rest pain and pregangrenous or gangrenous lesions. Either non-surgical revascularisation procedures or surgery may be performed.

Non-surgical procedures include percutaneous transluminal angioplasty (PTA), stent placement or atherectomy. Techniques may include balloon angioplasty to dilate the narrowed lumen, mechanical atherectomy to remove plaque or laser or thermal angioplasty to vaporise the occluding material. In any case, a stent typically is placed at the time of PTA to maintain vessel patency. Iliac and femoral–popliteal PTA initially re-establish good blood flow and relieve symptoms in more than 80% of people. While the 3-year success rate is lower, stent placement improves the duration of symptom relief (Kasper et al., 2015). See Chapter 29 for more information about revascularisation procedures.

Surgical options include endarterectomy to remove occlusive plaque from the artery and bypass grafts. Knitted Dacron bypass grafts are commonly used. Both immediate and long-term graft patency is better with bypass grafting than with non-surgical revascularisation procedures, but the risk of operative complications such as myocardial infarction, stroke, infection and peripheral embolisation is higher (Kasper et al., 2015). Nursing care for the person having revascularisation surgery is similar to that provided for people having an aortic aneurysm repair (see the previous box).

Complementary therapies

Complementary therapies for peripheral vascular disease include interventions to improve circulation and to reduce

BOX 31.5 Foot care for the person with peripheral atherosclerosis

1. Keep legs and feet clean, dry and comfortable.
   - Wash legs and feet daily in warm water, using mild soap.
   - Pat dry using a soft towel; be sure to dry between the toes.
   - Apply moisturising cream to prevent drying.
   - Use powder on the feet and between the toes.
   - Buy shoes in the afternoon (when feet are largest); never buy shoes that are uncomfortable. Be sure toes have adequate room.
   - Wear a clean pair of cotton socks each day.
2. Prevent accidents and injuries to the feet.
   - Always wear shoes or slippers when getting out of bed.
   - Walk on level ground and avoid crowds, if possible.
   - Do not go barefoot.
   - Inspect legs and feet daily; use a mirror to examine backs of legs and bottoms of feet.
   - Have a professional foot care provider trim toenails and care for corns, calluses, ingrown toenails or athlete's foot.
   - Always check the temperature of the water before stepping into the tub.
   - Do not get the legs or tops of the feet sunburned.
   - Report leg or foot problems (increased pain, cuts, bruises, blistering, redness or open areas) to your healthcare provider.
3. Improve blood supply to the legs and feet.
   - Do not cross legs.
   - Do not wear garters or knee stockings.
   - Do not swim or wade in cold water.

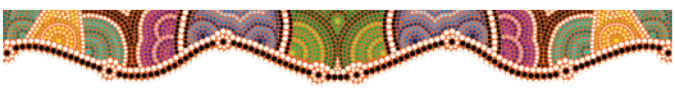
NURSING CARE OF THE OLDER ADULT Peripheral vascular disease

With ageing, blood vessels thicken and become less compliant. These changes reduce oxygen delivery to the tissues and impair carbon dioxide and waste product removal from the tissues. When normal effects of ageing combine with an increased risk of atherosclerosis, the risk of peripheral vascular disease is high.

HEALTH EDUCATION FOR THE PERSON AND FAMILY

The older adult with peripheral vascular disease requires the same care and teaching as other people. However, visual deficits and osteoarthritis may make foot care more difficult. Long-standing smoking habits are difficult to break. Mobility may be impaired by arthritis or the effects of neurological disorders. The person who lives alone may resist walking. Periodic visits by a community or home health nurse may be helpful, as may be encouraging the person to join a support group for stopping smoking, changing eating habits and taking part in regular activity.

stress. A number of complementary therapies may improve peripheral circulation, including aromatherapy with rosemary or vetiver; biofeedback; healing or therapeutic touch and massage; herbals such as ginkgo, garlic, cayenne, hawthorn and bilberry; and exercise, including yoga. Aromatherapy and yoga also may reduce stress, as can breathing exercises, meditation and counselling. In addition, complementary therapies to reduce atherosclerosis and lower cholesterol levels may slow the progress of PVD. Measures such as a very low-fat or vegetarian diet, including antioxidant nutrients or using vitamin C, vitamin E or garlic supplements, and traditional Chinese medicine may be useful.



Nursing care

Health promotion

Discuss healthy lifestyle habits with community and religious groups, schoolchildren and through the print media to reduce the incidence and slow the progression of atherosclerosis.

Strongly encourage all people to avoid smoking in the first place and to stop all forms of tobacco use. Discuss the adverse effects of smoking and the benefits of quitting. Provide information about dietary recommendations to maintain a healthy weight and optimal cholesterol levels. Discuss the benefits and importance of regular exercise. Finally, encourage people with cardiovascular risk factors to undergo regular screening for hypertension, diabetes and hyperlipidaemia.

Assessment

Focused assessment related to peripheral atherosclerosis includes the following:

- *Health history:* complaints of pain, its relationship to exercise or rest, timing, associated symptoms and relief measures; history of coronary heart disease, peripheral vascular disease, hyperlipidaemia, hypertension or diabetes; current medications; smoking history; usual diet and activity patterns.
- *Physical examination:* vital signs; strength and equality of peripheral pulses of all extremities; capillary refill; skin colour, temperature, hair distribution, presence of any discolourations or lesions; movement and sensation of lower extremities.

Nursing diagnoses and interventions

Impaired tissue perfusion is an obvious problem in peripheral atherosclerosis. Acute and chronic pain may interfere with ADLs, and ambulation may be limited. The possibility of losing a lower extremity is frightening.

Ineffective tissue perfusion: peripheral

Impaired blood flow to the lower extremities affects gas, nutrient and waste product exchange between the capillaries and cells. Oxygen and nutrient deprivation impairs cell function and tissue integrity, causing pain and impaired healing. Pain develops with exercise and when extremities are elevated.

- Assess peripheral pulses, pain, colour, temperature and capillary refill every 4 hours and as needed. Use a Doppler device if pulses are not palpable. Mark pulse locations with an indelible marker. *Assessment data provide a baseline for evaluating the effectiveness of interventions and identifies changes in arterial blood flow.*
- Position with extremities dependent. *Gravity promotes arterial flow to the dependent extremity, increasing tissue perfusion and relieving pain.*
- Discuss the benefits of regular exercise. *Exercise promotes development of collateral circulation to ischaemic tissues and slows the process of atherosclerosis.*
- Use a foot cradle and lightweight blankets, socks and slippers to keep extremities warm. Avoid electric heating pads or hot water bottles. *Keeping extremities warm conserves heat, prevents vasospasm and promotes arterial flow. External heating devices are avoided to reduce the risk of burns in the person with impaired sensation. A foot cradle protects tissues from compression by bed linen.*
- Encourage frequent position changes. Instruct to avoid crossing legs or using a pillow under the knees. *Position changes promote blood flow and reduce damage caused by pressure. Leg crossing and excessive flexion of the hip or knee joints can compress partially obstructed arteries and impair blood flow to distal tissues.*

CONSIDERATION FOR PRACTICE

Instruct to avoid smoking. If necessary, obtain an order for a nicotine patch or gum from the doctor. Refer to Quit Helpline for practical and ongoing support. Nicotine is a potent vasoconstrictor that further impairs arterial blood flow. Smoking cessation is a vital component of care. Nicotine patches and gum contain less nicotine than cigarettes and can help reduce the stress of smoking cessation.

Pain

Impaired blood flow results in tissue ischaemia. Metabolism shifts from an efficient aerobic process to an anaerobic process. Lactic acid and metabolic waste products accumulate in tissues, causing pain. Severe and cramping pain generally occurs with exercise early in the disease. Rest initially produces relief, similar to the process used to treat angina (see Chapter 29). As the disease progresses, pain develops with less exercise and often occurs even at rest. Rest pain disrupts sleep, the sense of wellbeing and has significant disruptive effects on life roles.

- Assess pain at least every 4 hours, using a standard pain scale. *Pain is a subjective experience. Using a standard pain scale allows evaluation of treatment measures in relieving pain and restoring blood flow.*
- Keep extremities warm. *Cooling leads to vasoconstriction, increasing pain. Warming the extremities promotes vasodilation and improves arterial flow, reducing pain.*
- Teach pain relief and stress reduction techniques such as relaxation, meditation and guided imagery. *Pain increases stress. The stress response leads to vasoconstriction, increasing pain. Stress reduction techniques, when combined with other measures to promote blood flow, can help reduce pain.*

Impaired skin integrity

People with PVD are at risk of impaired skin integrity as a result of oxygen and nutrient deprivation. Chronic tissue ischaemia leads to dry, scaly and atrophied skin. Pruritus can lead to scratching; minor injuries may go unnoticed due to impaired sensation. Impaired tissue healing can lead to ulceration, infection and potential gangrene.

- Provide meticulous daily skin care, keeping the skin clean and dry. Apply a moisturising cream to dry or scaly areas. *Intact skin is the body's first defence against bacterial invasion. Ischaemic tissues of the injured extremity provide an excellent medium for microorganism growth. Clean, dry, supple skin decreases the risk of breakdown.*
- Apply a bed cradle. *The bed cradle suspends bed linen over the legs, preventing them from placing pressure on extremities and injured tissues. Minimising pressure on the tissues promotes capillary blood flow.*
- Provide an egg-crate mattress, flotation pad, sheepskin or heel protectors. *Ischaemic tissues may be damaged by minor trauma such as that created by the shearing forces of skin against bed linen.*

CONSIDERATION FOR PRACTICE

Assess and document skin condition at least every 8 hours or with each home visit; or more frequently as indicated. Tissue ischaemia increases the risk of damage, even with minor trauma such as pressure from poorly fitting shoes or bed linens. Frequent inspection and documentation of skin condition is vital to identify early indicators of impaired skin integrity and reduce the risk of complications such as infection.

Activity intolerance

Pain and impaired perfusion of peripheral tissues may limit the person's ability to engage in desired activities, even impairing self-care.

- Assist with care activities as needed. *Severe claudication or rest pain may limit activities. Muscle atrophy of affected extremities is common, leading to fatigue and weakness.*
- Unless contraindicated, encourage gradual increases in duration and intensity of exercise. Teach to rest with extremities dependent when claudication develops, resuming activity after pain has abated. *Gradual increases in the duration and intensity of exercise promote development of collateral circulation, improve exercise tolerance, provide a sense of wellbeing and support self-esteem.*
- Provide diversional activities during periods of prescribed bed rest. Encourage relaxation techniques to reduce muscle tension. *Diversional activities help prevent boredom and stress associated with enforced rest. Relaxation techniques reduce vasoconstriction induced by stress, improving peripheral circulation.*
- Encourage frequent position changes and active range-of-motion exercises. Encourage self-care to the extent possible. *Position changes relieve pressure on tissues, improving capillary circulation and reducing tissue ischaemia. Range-of-motion exercises help prevent muscle atrophy and joint contractures. Self-care supports self-esteem.*

Community-based care

Discuss the following topics when preparing the person and family for home and community-based care (see the accompanying nursing care plan for additional community-based nursing interventions):

- smoking cessation strategies and ways to avoid second-hand smoke
- prescribed medications and anticoagulants, their purpose, doses, desired and adverse effects
- signs of excess bleeding to report to the doctor
- skin surveillance and foot care (see Box 31.5)
- recommended diet and exercise
- weight loss strategies if appropriate.

If revascularisation or surgery has been performed, include the following topics as appropriate:

- incision care

NURSING CARE PLAN A person with peripheral vascular disease

William Duffy, aged 69, is retired. His wife convinces him to see his doctor about his increasing leg pain with walking and other exercise.

ASSESSMENT

Katie Kotson, RN, obtains Mr Duffy's history before he sees his doctor. He states that he can only walk about a block before the pain in his calves gets so bad that he has to stop and rest. As a result, he has been less and less active, spending most of his time the past few months watching sports on television. He denies rest pain. He was diagnosed with type 2 diabetes about 15 years ago, which he manages with daily glibenclamide, an oral hypoglycaemic. He also has stable angina, for which he takes atenolol and an occasional glyceryl trinitrate tablet. His alcohol intake is moderate, averaging one to two beers per day, and he smokes about a packet of cigarettes per day. He states he tried to quit smoking after developing angina, but 'after nearly 50 years of smoking, I think that's impossible!'.

Physical exam findings include height 173 cm, weight 107 kg, BP 168/78, P 66, R 16, T 36.5°C; upper extremities warm and pink, normal hair distribution, pulses strong and equal; lower extremities below knees cool and ruddy when dependent, pale to pink when elevated, skin shiny, scant hair; posterior tibial pulses weak bilaterally; weak pedal pulse on R, unable to palpate on L; 1+ to 2+ oedema both feet and ankles.

The doctor finds that Mr Duffy's systolic blood pressure in his legs is an average of 28 mmHg lower than in his arms. He makes the diagnosis of peripheral atherosclerosis and schedules Mr Duffy for an exercise stress test with ankle pressure measurements before and after exercise and a colour-flow Doppler ultrasound. Mr Duffy is to return in 3 weeks after these studies have been completed.

DIAGNOSES

- *Activity intolerance* related to poor blood flow to lower extremities.
- *Ineffective health maintenance* related to smoking and lack of information about disease management.
- *Risk of impaired skin integrity* related to ischaemic tissues of legs and feet.
- *Risk of peripheral neurovascular dysfunction* related to impaired peripheral blood flow to lower extremities.

PLANNING

- With Mr and Mrs Duffy, plan strategies to start and maintain a program of regular exercise.
- Schedule an appointment with the dietitian to develop a low-kilojoule, low-fat and low-cholesterol diet that includes preferred foods and considers usual eating patterns.
- Plan meeting times with Mr Duffy to discuss prevention and risk factors including modifiable factors.

Expected outcomes

- Walk for at least 15 minutes three to four times per day, gradually increasing his pace and duration of exercise.
- Relate the benefits of smoking cessation.
- Identify strategies to improve chances for success in stopping smoking.
- Meet with dietitian before next visit to discuss dietary measures to promote weight loss and slow atherosclerosis.
- Verbalise an understanding of appropriate foot care measures.
- Identify measures to prevent inadvertent injury of feet and legs.

IMPLEMENTATION

- Teach about peripheral atherosclerosis and its relationship to Mr Duffy's symptoms.
- Instruct to warm up slowly and to stop exercise and rest for 3 minutes (or until pain is relieved) when claudication develops, then resume exercising.
- Discuss the effects of smoking on blood vessels.
- Help Mr Duffy identify smoking cessation strategies such as support groups, clinics and nicotine patches.
- Reinforce and supplement previous foot care teaching.
- Discuss effects of impaired circulation on sensation in feet and legs and measures to prevent injury.

EVALUATION

When Mr Duffy returns 3 weeks later, his diagnosis has been confirmed by the diagnostic studies. The doctor decides to continue conservative therapy, now prescribing atorvastatin to lower Mr Duffy's serum cholesterol level and cilostazol to reduce the risk of thrombosis and improve symptoms of claudication. Mr Duffy also asks his doctor for a prescription for nicotine patches, saying he is ready to quit smoking, but thinks he needs help to be successful. Mr and Mrs Duffy tell Nurse Kotson that they are walking before every meal and really enjoying being outside more. They plan to walk in the local shopping centre whenever the weather is poor. Mrs Duffy has bought an Australian Heart Foundation cookbook (*The Deliciously Healthy Cookbook*) and is carefully planning their meals. Mr and Mrs Duffy have both lost between 0.5 and 1 kg a week since the previous visit. Mr Duffy's skin on his legs and feet remains intact and he identifies the measures he is using to protect his lower extremities from injury.

CRITICAL THINKING IN THE NURSING PROCESS

1. What additional lifestyle changes related to peripheral atherosclerosis might be appropriate to suggest to Mr Duffy at this time? Why?
2. Explain the relationship between physical exercise and pain in the person with peripheral atherosclerosis. Compare this relationship to that between exercise and angina.
3. Mr Duffy uses a beta-blocker, atenolol, to prevent angina. Why is this drug not effective in preventing claudication?
4. Develop a nursing care plan for the nursing diagnosis *Imbalanced nutrition: more than body requirements*.

REFLECTION ON THE NURSING PROCESS

1. What strategies can be initiated to ensure Mr Duffy remains on track with improving his health?
2. Mr Duffy stated he tried to quit smoking after developing angina, but 'after nearly 50 years of smoking, I think that's impossible!'. What would the nurse assess to ensure he is compliant with improving his health?

- manifestations of complications (e.g. infection, graft leakage or thrombosis) to be reported to the doctor
- activity limitations.

Provide referrals to home health services, physical or occupational therapy and home maintenance assistance services as indicated. Consider resources such as Meals on Wheels for people who are severely limited by their disease.

THE PERSON WITH SELECTED PERIPHERAL ARTERIAL CONDITIONS

ACUTE ARTERIAL OCCLUSION

A peripheral artery may be acutely occluded by development of a thrombus (blood clot) or by an embolism. Blood flow to tissues supplied by the artery is impaired, resulting in acute tissue ischaemia and a risk of necrosis and gangrene.

Pathophysiology

Arterial thrombosis

A **thrombus** is a blood clot that adheres to the vessel wall. Thrombi tend to develop in areas where intravascular factors stimulate coagulation (e.g. where a vessel lumen is partially obstructed and its wall is damaged and roughened by atherosclerosis). Other disorders, such as infection or inflammation of the vessel wall or pooling of blood (e.g. in an aneurysm), also can prompt coagulation and thrombus formation (Piechota-Polanczyk et al., 2015). A developing thrombus can occlude arterial blood flow through the vessel, leading to ischaemia of tissues supplied by that artery. The extent of ischaemia depends on the size of the affected artery and the degree of collateral circulation. In gradual processes of arterial occlusion such as atherosclerosis, collateral vessels often develop to compensate for impaired arterial flow. The extent of collateral circulation affects the degree of tissue ischaemia distal to the thrombus.

Arterial embolism

An **embolism** is the sudden obstruction of a blood vessel by debris. A thrombus can break loose from the arterial wall to become a **thromboembolus**. Other substances also can become emboli: atherosclerotic plaque, masses of bacteria, cancer cells, amniotic fluid, bone marrow fat and foreign objects such as air bubbles or broken intravenous catheters. Regardless of cause, an embolus eventually lodges in a vessel that is too small to allow it to pass.

Arterial emboli often originate in the left side of the heart. They are associated with myocardial infarction, valvular heart disease, left-sided heart failure, atrial fibrillation or infectious heart diseases. Emboli from the left heart often enter the carotid arteries and become trapped in the cerebral circulation, causing neurological deficits. Thromboemboli that develop in the aorta or peripheral arterial circulation tend to lodge in areas where the arterial lumen is narrowed by atherosclerotic plaque and at arterial bifurcations.

Manifestations

The manifestations of arterial thrombosis and embolism are those of tissue ischaemia. Ischaemic tissues are painful, pale and cool or cold. Distal pulses are absent. Paraesthesias (numbness and tingling) develop in the extremity. Cyanosis and mottling are common. Paralysis and muscle spasms may develop in the affected extremity. A line of demarcation between normal and ischaemic tissue may be seen, particularly with embolism. Tissue below the line is cool or cold and pale, cyanotic or mottled. See the 'Manifestations' box below.

MANIFESTATIONS Acute arterial occlusion

- Pain
- Pallor or mottling
- Paraesthesias (numbness and tingling)
- Cool or cold skin
- Pulselessness distal to the blockage
- Possible paralysis, weakness or muscle spasms
- Possible line of demarcation; with pallor, cyanosis and cooler skin distal to the blockage (especially with arterial embolism)

Arterial occlusion can result in permanent vessel and limb damage. Complete arterial occlusion leads to tissue necrosis and gangrene unless blood flow is promptly restored.

INTERPROFESSIONAL CARE

Acute arterial occlusions may require emergency treatment to preserve the limb if the obstructed vessel is large or collateral circulation is minimal. If the limb is not in jeopardy, more conservative management may be initiated.

Diagnosis

The diagnosis of acute arterial occlusion often is apparent by the signs and symptoms. *Arteriography* is used to confirm the diagnosis, locate the occlusion and determine its extent.

Medications

Anticoagulation with intravenous heparin is initiated to prevent further clot propagation and recurrent embolism. Anticoagulation is continued with oral anticoagulants after discharge. See the section on venous thrombosis later in this chapter for more information about anticoagulant therapy.

Arterial thrombosis may be treated with intra-arterial fibrinolytic therapy using streptokinase, urokinase or tissue plasminogen activator (t-PA) (see Chapter 29). Lysis of the

thrombus or embolus is achieved in 50–80% of the cases (Papadakis, McPhee & Rabow, 2013).

Local intra-arterial injection of the fibrinolytic drug allows use of lower doses and reduces the bleeding risk associated with fibrinolytic drugs.

Surgery

Immediate embolectomy (within 4 to 6 hours) is the treatment of choice for acute arterial occlusion by an embolus to prevent tissue necrosis and gangrene. When the involved vessel is in an extremity, local anaesthesia and a special balloon-tipped catheter known as a Fogarty catheter may be used for people with a high surgical risk (Papadakis et al., 2013).

An embolus in the mesenteric circulation necessitates emergency laparotomy. The risk of complications and limb loss increases significantly if surgery is delayed by 12 or more hours. Potential major complications include compartment syndrome (see Chapter 38), acute respiratory distress syndrome (Chapter 36) or acute kidney failure (Chapter 27).

Arterial thrombosis also may be treated surgically, although the required surgery may be more extensive due to the length of the vessel involved. *Thromboendarterectomy* is done to remove the thrombus and plaque in the artery. An arterial graft may be required. Nursing care for people who have undergone embolectomy or thrombus removal is discussed in the nursing care section that follows.

Nursing care

Assessment

Nursing assessment for the person with an acute arterial occlusion is highly focused due to the emergency nature of the problem.

- *Health history:* complaints of pain, numbness, tingling or weakness in the involved extremity; history of atherosclerotic vessel disease, heart disease or recent invasive procedure (e.g. angiography, percutaneous revascularisation procedure).
- *Physical examination:* vital signs; peripheral pulses in both extremities; colour, temperature, sensation and movement of involved extremity; skin condition; presence of a line of demarcation.

Nursing diagnoses and interventions

Nursing care related to acute arterial occlusion focuses on protecting the affected extremity, managing anxiety and reducing the risk of complications related to anticoagulant therapy.

Ineffective tissue perfusion: peripheral

Protecting ischaemic tissue from injury prior to surgery or medical thrombolysis is vital. Following surgery, there is a risk of thrombosis at the graft site or impaired perfusion due to oedema of the surgical site.

CONSIDERATION FOR PRACTICE

Monitor extremity perfusion, comparing affected and unaffected extremities. Assess peripheral pulses (using the Doppler stethoscope as needed), skin temperature and colour, capillary refill, movement and sensation every 1 to 4 hours. Promptly report changes or complaints of increased or unrelieved pain. Propagation of a thrombus can further obstruct arterial flow, increasing tissue ischaemia. Following surgery, arterial spasms may cause a cyanotic, pulseless extremity; normal colour and pulses should return within 12 hours. A thrombus may form at the surgical site or within a graft, causing tissue ischaemia with pain and other manifestations of arterial occlusion. Further measures to restore circulation may be necessary.

- Maintain intravenous fluids as ordered. *Adequate circulating blood volume is necessary to maintain cardiac output and tissue perfusion.*
- Protect the extremity, keeping it horizontal or lower than the heart. Use a cradle to keep bedclothes off the extremity and a sheepskin or foam pad to protect it from hard or abrasive surfaces. Do not apply heat or cold. *Keeping the extremity lower than the heart promotes collateral blood flow. Ischaemic tissue is easily damaged by minimal trauma such as shearing by bed linen or heat or cold application.*
- Following surgery, avoid raising the knees, placing pillows under the knees or sitting with 90-degree hip flexion. *These activities may impair blood flow through the affected vessel.*

Anxiety

People with an acute arterial occlusion often are very anxious. The rapid and intense nature of preoperative activities can be overwhelming, increasing anxiety about the disorder and its outcome. Manifestations of anxiety may include trembling, palpitations, restlessness, dry mouth, helplessness, inability to relax, irritability, forgetfulness and lack of awareness of surroundings. Nursing measures focus on establishing trust and minimising the effects of anxiety to decrease surgical risk and improve recovery.

- Spend as much time as possible with the person. Provide opportunities to verbalise anxiety; offer reassurance and support. Support adaptive coping mechanisms. *The presence of a caring nurse provides a safe environment for expressing fears and anxieties. Coping mechanisms reduce the immediate perceived threat and increase the ability to deal with the situational crisis.*
- Perform required measures in an expedient but calm manner. *Calm, confident performance of treatment measures reassures the person and family that appropriate care is being given to treat the problem at hand.*
- Assess anxiety level at least every 8 hours; more often as needed. Intervene as indicated to reduce anxiety. *Assessment helps determine the intensity of anxiety, the person's ability to control it and directs interventions to reduce it.*
- Decrease sensory stimuli as much as possible. *Reducing environmental stimuli provides the person with a degree of control over anxiety.*

- Speak slowly and clearly and avoid unnecessary interruptions when listening. Give concise directions, focusing on the present. Involve the person in simple tasks and decisions to the extent possible. *High levels of anxiety interfere with learning. Keeping interactions focused on the present situation directs the person's focus and provides reassurance that it is the most important focus for the nurse as well. Providing opportunities for self-care and decision making reinforces the person's importance and power to control the situation.*

Altered protection

Fibrinolytic and/or anticoagulant therapy used to dissolve existing clots and prevent further clot formation increases the risk of bleeding. Close monitoring of physical status and laboratory data is vital, as are measures to reduce the risk of injury and bleeding.

- Monitor activated partial thromboplastin time (APTT) during heparin therapy and prothrombin time (PT) or International Normalized Ratio (INR) during oral anticoagulant therapy. Report values outside desired range. *The APTT, PT and INR are prolonged by anticoagulant therapy. Values higher than the desired range may indicate an increased risk of bleeding; values below the target may indicate inadequate anticoagulation.*
- Protect from injury: use side rails or other measures as needed to prevent falls; avoid parenteral injections and other invasive procedures as much as possible; hold firm pressure over injection and intravenous sites for 5 minutes and over arterial punctures for 20 minutes; use a soft toothbrush or sponge for oral care; use an electric razor for shaving. *Minor trauma can lead to extensive bleeding, particularly in the person who has received a fibrinolytic drug.*

CONSIDERATION FOR PRACTICE

Assess for and report manifestations of impaired clotting, including excessive incisional bleeding; prolonged oozing from injection sites; bleeding gums, nosebleed or haematuria; petechiae, bruising or purpura. Anticoagulants and fibrinbolytics interfere with the clotting cascade and may cause abnormal bleeding.

Community-based care

When preparing the person and family for home or community-based care related to an acute arterial occlusion, discuss the following topics as indicated:

- care of the incision
- manifestations of complications to be reported, including symptoms of infection or occlusion of the graft or artery
- long-term anticoagulant therapy, including the reason, prescribed dose, follow-up laboratory testing and appointments, interactions with other drugs and manifestations of excessive bleeding
- any activity restrictions or dietary modifications
- lifestyle modifications to slow atherosclerosis and control hypertension
- measures to promote peripheral circulation and maintain tissue integrity (see the discussion of peripheral atherosclerosis earlier in the chapter).

Refer for home care services (nursing care, physical therapy, housekeeping services) as indicated.

THE PERSON WITH THROMBOANGIITIS OBLITERANS

Thromboangiitis obliterans (also called *Buerger's disease*) is an occlusive vascular disease in which small and midsized peripheral arteries become inflamed and spastic, causing clots to form. This disease may affect either the upper or lower extremities; it often affects a leg or foot. Its exact aetiology is unknown.

Incidence and risk factors

Thromboangiitis obliterans primarily affects men under age 40 who smoke. Cigarette smoking is the single most significant cause of the disease. The disease is more prevalent in Asians and people of Eastern European descent. The incidence of HLA-B5 and 2A9 antigens is higher in people with thromboangiitis obliterans, suggesting a genetic link.

Pathophysiology and course

Inflammatory cells infiltrate the wall of small and midsized arteries in the feet and possibly the hands. This inflammatory process is accompanied by thrombus formation and vasospasms of arterial segments that impair blood flow. Adjacent veins and nerves also may be affected. As the disease progresses, affected vessels become scarred and fibrotic.

The course of the disease is intermittent with dramatic exacerbations and marked remissions. The disease may remain dormant for periods of weeks, months or years. As the disease progresses, collateral vessels are more extensively involved. Consequently, subsequent episodes are more intense and prolonged. Prolonged periods of tissue hypoxia increase the risk of tissue ulceration and gangrene.

Manifestations and complications

Pain in the affected extremities is the primary manifestation of thromboangiitis obliterans. Both claudication, cramping pain in the calves and feet or the forearms and hands, and rest pain in the fingers and toes may occur. Sensation is diminished. Eventually, the skin becomes thin and shiny and the nails are thickened and malformed. On examination, the involved digits and/or extremities are pale, cyanotic or ruddy, and cool or cold to touch. Distal pulses (e.g. the dorsalis pedis, posterior tibial, ulnar or radial) are either difficult to locate or absent, even with a Doppler device.

Painful ulcers and gangrene may develop in the fingers and toes as a result of severely impaired blood flow. Amputation may be necessary to remove necrotic tissue.

INTERPROFESSIONAL CARE

Diagnosis

Thromboangiitis obliterans usually is diagnosed by the history and physical examination. Doppler studies may be used to locate and determine the extent of the disease. Angiography and magnetic resonance imaging may also be used to evaluate the extent of the disease, but usually are unnecessary.

Lifestyle modifications

The one most important component in managing this disease is smoking cessation. While stopping smoking does not cure the disease, it may slow its extension to other vessels. With continued smoking, attacks become increasingly intense and last much longer, significantly increasing the risk of ulcerations and gangrene.

Additional conservative measures are used to prevent vasoconstriction, improve peripheral blood flow and prevent complications of chronic ischaemia. These measures include keeping extremities warm, managing stress, keeping affected extremities in a dependent position, preventing injury to affected tissues and regular exercise. Walking for 20 or more minutes several times a day is recommended.

Medications

There are no specific drugs for thromboangiitis obliterans. Calcium channel blockers such as diltiazem or verapamil, and/or oxpentifylline, which decrease blood viscosity and increase red blood cell flexibility to improve peripheral blood flow, may provide some symptom relief.

Surgery

Surgical approaches for thromboangiitis obliterans include sympathectomy or arterial bypass graft. Sympathectomy interrupts sympathetic nervous system input to affected vessels, reducing vasoconstriction and spasm. Arterial bypass grafts may be useful when larger vessels are affected by the disease. Amputation of an affected digit or extremity may be necessary if gangrene develops (see Chapter 38 for more information about amputation). Only portions of digits or of limbs (e.g. below the knee) are usually amputated, to preserve as much healthy tissue as possible.

The prognosis for thromboangiitis obliterans depends significantly on the person's ability and willingness to stop smoking. With smoking cessation and good foot care, the prognosis for saving the extremities is good, even though no cure is available.

Nursing care

Health promotion

Health promotion activities to prevent thromboangiitis obliterans focus on preventing smoking, especially in high-risk populations.

Assessment

Nursing assessment and care for people with this disease are similar to those provided for people with other arterial occlusive diseases. Nursing care focuses on promoting arterial circulation and preventing prolonged tissue hypoxia. Due to inflammation, spastic episodes may be unpredictable; care focuses on smoking cessation and relieving acute manifestations. In addition, postsurgical care is necessary if surgery has been performed. See the nursing care section for peripheral atherosclerosis, as well as nursing care of the postsurgical person (Chapter 3) and following amputation (Chapter 38).

Community-based care

Discuss the following topics when preparing people with thromboangiitis obliterans and their families for home or community-based care:

- absolute necessity of smoking cessation
- foot care
- protecting affected extremities from injury
- purpose, dose, desired and adverse effects, interactions and any precautions associated with prescribed medications
- signs and symptoms to report to the doctor.

THE PERSON WITH RAYNAUD'S DISEASE

Raynaud's disease and **Raynaud's phenomenon** are characterised by episodes of intense vasospasm in the small arteries and arterioles of the fingers and sometimes the toes (Hansen-Dispenza, 2014). Raynaud's disease and Raynaud's phenomenon differ only in terms of cause. Raynaud's disease has no identifiable cause; Raynaud's phenomenon occurs secondarily to another disease (such as collagen vascular diseases such as scleroderma and rheumatoid arthritis), other known causes of vasospasm or long-term exposure to cold or machinery (Hansen-Dispenza, 2014).

Raynaud's disease primarily affects young women between the ages of 20 and 40. Genetic predisposition may play a role in its development, although the actual cause is unknown. Table 31.4 compares thromboangiitis obliterans and Raynaud's disease.

Pathophysiology and manifestations

Raynaud's disease and Raynaud's phenomenon are characterised by spasms of the small arteries in the digits. The arterial spasms limit arterial blood flow to the fingers and possibly the toes. Initial attacks may involve only the tips of one or two fingers; with disease progression, the entire finger and all fingers may be affected.

The manifestations of Raynaud's occur intermittently when spasms develop. Raynaud's disease has been called the 'blue-white-red disease', because affected digits initially turn blue as blood flow is reduced due to vasospasm, then white as

TABLE 31.4 Comparison of Raynaud's disease and thromboangiitis obliterans

TOPIC	RAYNAUD'S DISEASE	THROMBOANGIITIS OBLITERANS
Aetiology	• Unknown • Possible genetic predisposition	• Cigarette smoking most probable single cause • Possible autoimmune response
Incidence/course of the disease	• Onset commonly between 15 and 45 years of age • Usually affects young women • Becomes progressively worse over time	• Occurs predominantly in men under age 40 • More common in people of Asian or European heritage • Intermittent course with exacerbations and remissions • Increased severity and duration of attacks over time
Triggering stimuli	• Emotional stress • Exposure to cold	• Cigarette smoking
Assessment findings	• Usually affects hands, sometimes toes • Pain becomes more severe and prolonged as disease progresses • 'Blue-white-red' changes in colour of hands with accompanying changes in skin temperature	• Claudication and pain • Numbness or diminished sensation • Cool, pale or cyanotic skin • Shiny, thin skin and white, malformed nails in affected extremities • Distal pulses difficult to find or absent • Trophic changes to nail beds • Ulceration and gangrene in later stages • Small, red, tender vascular cords in affected extremities
Management	• Avoid unnecessary cold exposure • Emphasise smoking cessation • Medications such as calcium channel or alpha-adrenergic blockers as indicated • Teach stress management	• Stop smoking (crucial) • Regular exercise • Protect extremities from cold injury • Teach stress management

circulation is more severely limited and, finally, very red as the fingers are warmed and the spasm resolves (see Figure 31.12). Sensory changes may occur during attacks, including numbness, stiffness, decreased sensation and aching pain.

The attacks tend to become more frequent and prolonged over time. With repeated attacks (and resultant decrease in oxygenation), the fingertips thicken and the nails become brittle. Ulceration and gangrene are serious complications that rarely occur.

FIGURE 31.12 ■ Fingers of a patient with Raynaud's phenomenon. Note the extreme pallor of the fifth digit in response to exposure to cold

Source: P. Stocklein/Custom Medical Stock Photo.

INTERPROFESSIONAL CARE

Diagnosis

Raynaud's disease and Raynaud's phenomenon are primarily diagnosed by the history and physical examination. There are no specific diagnostic tests for these disorders.

Medications

Vasodilators may be prescribed to provide symptomatic relief. Low doses of a sustained-release calcium channel blocker such as nifedipine or diltiazem may be prescribed. The alpha-adrenergic blocker prazosin also may reduce the frequency and severity of attacks. Transdermal glyceryl trinitrate (or longer-acting oral nitrates) helps some people by decreasing the amount of time necessary for the hands to return to normal following an attack (Papadakis et al., 2013).

Lifestyle modifications

Conservative measures are a mainstay of treatment. People are instructed to keep their hands warm, wearing gloves when outside in cold weather and kitchen gloves when handling cold items (e.g. when preparing and serving cold foods and cleaning

the refrigerator). Measures to avoid injury to the hands are taught. Sometimes attacks can be stopped by swinging the arms back and forth, increasing perfusion pressure in the small arteries by centrifugal force.

Smoking cessation is important. Stress reduction measures such as exercise, relaxation techniques, massage therapy, hobbies, aromatherapy and counselling are taught or suggested. Additional lifestyle habits that contribute to vascular health are encouraged, such as reducing dietary fat, increasing activity level and maintaining normal body weight.

Nursing care

Nursing care for the person with Raynaud's disease or Raynaud's phenomenon is primarily educative and supportive. Protecting the hands and feet from exposure to cold and trauma is the main teaching topic. Nursing diagnoses and interventions previously outlined for peripheral atherosclerosis also are appropriate for people with Raynaud's disease.

Community-based care

Reassure people with Raynaud's phenomenon that most people with the disorder experience only mild, infrequent episodes. Discuss the following topics in preparing the person for managing the disorder:

- Dress warmly, keeping the trunk and hands warm.
- Avoid unnecessary exposure to cold.
- Stop smoking or do not start.
- The use, purpose, desired and potential adverse effects of prescribed medications, if any.

DISORDERS OF VENOUS CIRCULATION

The two primary categories of venous system disorders are occlusive disorders and those related to ineffective venous blood flow. Impaired venous blood flow can lead to stasis and clotting, as well as tissue changes associated with venous congestion.

Physiology review

The venous system is a low-pressure system in comparison with the arterial circulation. Veins and venules are thin-walled, distensible vessels. While they contain smooth muscle that allows them to contract or expand, the media (muscle layer) of veins is significantly thinner than that of arteries. The low pressures in the venous system allow it to serve as a reservoir for blood. Stimulation by the sympathetic nervous system causes veins to contract, helping maintain vascular volume. The low-pressure venous system relies on skeletal muscle contractions and pressure changes in the abdomen and thorax to facilitate blood return to the heart. Unlike arteries, veins of the extremities contain valves to prevent retrograde blood flow.

THE PERSON WITH VENOUS THROMBOSIS

Venous thrombosis (also known as *thrombophlebitis*) is a condition in which a blood clot (thrombus) forms on the wall of a vein, accompanied by inflammation of the vein wall and some degree of obstructed venous blood flow.

Venous thrombi are more common than arterial thrombi because of lower pressures and flow within the venous system (Patel, 2014). Thrombi can form in either superficial or deep veins. **Deep venous thrombosis (DVT)** is a common complication of hospitalisation, surgery and immobilisation. Obstetric and orthopaedic procedures carry a higher risk of venous thrombosis; it may develop in more than 50% of people having orthopaedic surgery, particularly surgeries involving the hip or knee (Patel, 2014). Other significant risk factors for venous thrombosis include abdominal or thoracic surgery, certain cancers, trauma, pregnancy and use of oral contraceptives or hormone replacement therapy (see Box 31.6).

Pathophysiology

Three pathological factors, called *Virchow's triad*, are associated with thrombophlebitis: stasis of blood, vessel damage and increased blood coagulability. Vessel trauma stimulates the clotting cascade. Platelets aggregate at the site, particularly

BOX 31.6 Factors associated with venous thrombosis

- Immobilisation: myocardial infarction, heart failure, stroke, postoperative
- Surgery: orthopaedic, thoracic, abdominal, genitourinary
- Cancer: pancreatic, lung, ovary, testes, urinary tract, breast, stomach
- Trauma: fractures of the spine, pelvis, femur, tibia; spinal cord injury
- Pregnancy and delivery
- Hormone therapy: oral contraceptives, hormone replacement therapy
- Coagulation disorders

when venous stasis is present. Platelets and fibrin form the initial clot. Red blood cells are trapped in the fibrin meshwork and the thrombus propagates (grows) in the direction of blood flow. The inflammatory response is triggered, causing tenderness, swelling and erythema in the area of the thrombus. Initially the thrombus floats within the vein. Pieces of the thrombus may break loose and travel through the circulation as emboli. Fibroblasts eventually invade the thrombus, scarring the vein wall and destroying venous valves. Although patency of the vein may be restored, valve damage is permanent, affecting directional flow (Papadakis et al., 2013).

FAST FACTS

- DVT is a common complication of surgery and immobility. It usually develops in the deep veins of the calf (80%).
- Venous stasis (sluggish blood flow), altered blood coagulation and damage (e.g. inflammation) to blood vessels are precipitating factors for DVT.
- A thrombus or a portion of a thrombus may break loose, travelling through the venous system to the right side of the heart and into the pulmonary circulation, where it ultimately becomes lodged (pulmonary embolus).

Deep venous thrombosis

The deep veins of the legs, primarily in the calf and the pelvis, provide the most hospitable environment for venous thrombosis. Approximately 80% of deep venous thromboses begin in the deep veins of the calf, often propagating into the popliteal and femoral veins (see Figure 31.13) (Papadakis et al., 2013). DVT usually is asymptomatic; in some people, a pulmonary embolism may be the first indication.

MANIFESTATIONS When present, the manifestations of DVT are primarily due to the inflammatory process accompanying the thrombus. Calf pain, which may be described as tightness or a dull, aching pain in the affected extremity, particularly upon walking, is the most common symptom. Tenderness, swelling, warmth and erythema may be noted along the course of involved veins. The affected extremity may be cyanotic and often is oedematous. Rarely, a cord may be palpated over the affected vein. A positive Homan's sign (pain in the calf when the foot is dorsiflexed) is an unreliable indicator of DVT. See the 'Manifestations' box for a summary of the manifestations of deep and superficial venous thrombosis.

COMPLICATIONS The major complications of DVT are chronic venous insufficiency (see the next section of this chapter) and pulmonary embolism. Pulmonary embolism occurs when the clot fragments or breaks loose from the vein wall. As the clot travels, it moves through progressively larger veins and into the right side of the heart. From there it enters the pulmonary circulation, where it eventually occludes arterial flow to a portion of the lungs. The result is a mismatch between ventilation (air flow) and perfusion (blood flow) in a portion of the lungs. The effect on gas exchange depends on the size of the embolism and the vessel it occludes. See Chapter 36 for more information about pulmonary emboli.

MANIFESTATIONS Venous thrombosis

DEEP VENOUS THROMBOSIS

- Usually asymptomatic
- Dull, aching pain in affected extremity, especially when walking
- Possible tenderness, warmth, erythema along affected vein
- Cyanosis of affected extremity
- Oedema of affected extremity

SUPERFICIAL VENOUS THROMBOSIS

- Localised pain and tenderness over the affected vein
- Redness and warmth along the course of the vein
- Palpable cordlike structure along the affected vein
- Swelling and redness of surrounding tissue

Superficial venous thrombosis

Venous catheters and infusions are the primary risk factors for superficial venous thrombosis. Superficial venous thrombosis also may develop in conjunction with thromboangiitis obliterans, varicose veins or DVT. It may develop spontaneously in pregnant women or following delivery. In some cases, superficial venous thrombosis of the long saphenous vein is the earliest sign of an abdominal cancer such as pancreatic cancer (Papadakis et al., 2013).

Superficial venous thrombosis is marked by pain and tenderness at the site of the thrombus. A reddened, warm, tender cord extending along the affected vein can be palpated. The area surrounding the vein may be swollen and red (see the 'Manifestations' box).

INTERPROFESSIONAL CARE

It is important to differentiate venous thrombosis from other causes of extremity pain, such as cellulitis, muscle strain, contusion and lymphoedema. The history, physical examination and diagnostic tests are used to establish the diagnosis. Treatment focuses on preventing further clotting or extension of the clot and addressing underlying causes.

Diagnosis

- *Duplex venous ultrasonography* is a non-invasive test used to visualise the vein and measure the velocity of blood flow in the veins. Although the clot often cannot be visualised directly, its presence can be inferred by an inability to compress the vein during the examination.
- *Plethysmography* is a non-invasive test that measures changes in blood flow through the veins. It is often used in conjunction with Doppler ultrasonography.

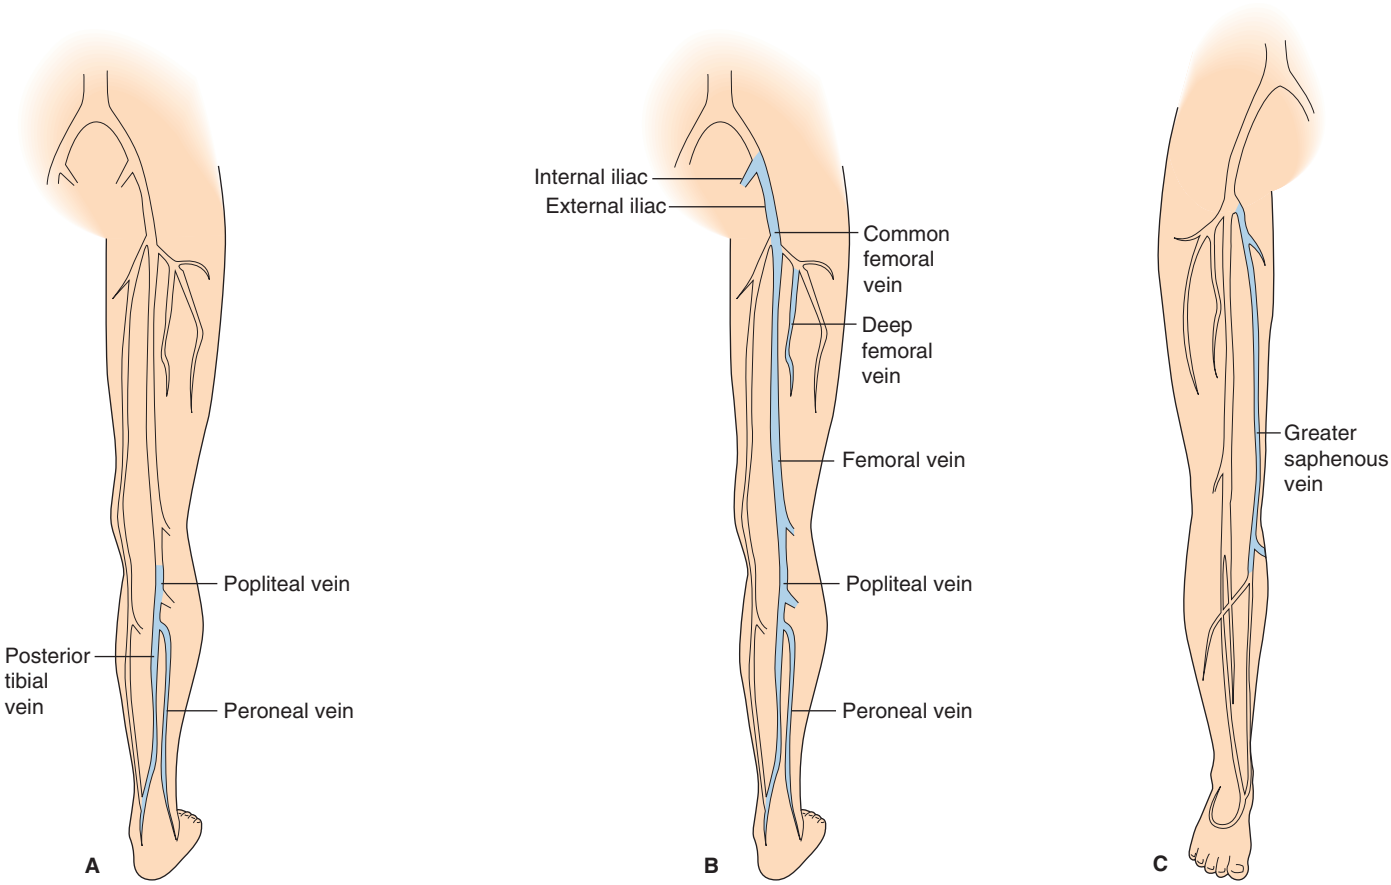


FIGURE 31.13 ■ Common locations of venous thrombosis. *A*, The most common sites of DVT. *B*, DVT extending from the calf to the iliac veins. *C*, Superficial venous thrombosis

Plethysmography is most valuable in diagnosing thromboses of larger or more superficial veins.

- *Magnetic resonance imaging (MRI)* is another non-invasive means of detecting DVT. It is particularly useful when thrombosis of the venae cavae or pelvic veins is suspected.
- *Ascending contrast venography* uses an injected contrast medium to assess the location and extent of venous thrombosis. Although invasive, expensive and uncomfortable, contrast venography is the most accurate diagnostic tool for venous thrombosis. It is used when the results of less invasive tests leave the diagnosis unclear (Papadakis et al., 2013).

Prophylaxis

Medications and other measures are used to prevent venous thrombosis when the risk is high. Low-molecular-weight (LMW) heparins prevent DVT in people who are undergoing general or orthopaedic surgery, experiencing acute medical illness or are on prolonged bed rest. Oral anticoagulation also may be used as a prophylactic measure in people with fractures or who are undergoing orthopaedic surgery.

Elevating the foot of the bed with the knees slightly flexed promotes venous return. Early mobilisation and leg exercises such as ankle flexion and extension assist venous flow by muscle compression. Intermittent pneumatic compression devices applied to the legs are effective to prevent DVT. They also are used when anticoagulation is contraindicated due to the increased risk of bleeding (Kasper et al., 2015). Elastic stockings are also used to prevent venous thrombosis in people at risk.

Medications

Anticoagulants to prevent clot propagation and enable the body's own lytic system to dissolve the clot are the mainstay of treatment for venous thrombosis. Fibrinolytic drugs such as streptokinase or tissue plasminogen activator (t-PA) may accelerate the process of clot lysis and prevent damage to venous valves. There is, however, no evidence that fibrinolytic therapy is more effective in preventing pulmonary embolism in people with existing DVT than anticoagulants (Kasper et al., 2015). It also significantly increases the risk of bleeding and haemorrhage.

Non-steroidal anti-inflammatory agents (NSAIDs) such as indomethacin or naproxen may be ordered to reduce inflammation in the veins and provide symptomatic relief, particularly for people with superficial venous thrombosis.

ANTICOAGULANTS Anticoagulants are given to prevent clot extension and reduce the risk of subsequent pulmonary embolism. See the 'Medication administration' box below for the nursing implications for anticoagulant therapy.

MEDICATION ADMINISTRATION Anticoagulant therapy

HEPARIN

Heparin interferes with the clotting cascade by inhibiting the effects of thrombin and preventing the conversion of fibrinogen to fibrin. This prevents the formation of a stable fibrin clot. At therapeutic levels, heparin prolongs the thrombin time, clotting time and activated partial thromboplastin time. When given intravenously, its effect is immediate. Given subcutaneously, its onset of action is within 1 hour. *Heparin-induced thrombocytopenia (HIT)* is a potential complication of therapy with unfractionated heparin. See Chapter 32 for more information about HIT and nursing responsibilities in monitoring for this dangerous potential complication.

Nursing responsibilities

- Assess for history of unexplained or active bleeding. Assess laboratory results for abnormal clotting profile or evidence of active bleeding.
- Give a test dose as indicated to people with a history of multiple allergies or a history of asthma.
- Administer by deep subcutaneous injection; abdominal sites are preferred. Avoid injecting within 5 cm of the umbilicus. Rotate sites. Do not aspirate prior to injecting or massage after the injection.
- Intravenous solutions may be diluted with dextrose, normal saline or Ringer's solution. Use an infusion pump.
- Keep protamine sulfate, a heparin antagonist, available to treat excessive bleeding.
- Monitor and report abnormal laboratory results and APTT values outside the desired range.
- Promptly report evidence of bleeding such as haematemesis, haematuria, bleeding gums or unexplained abdominal or back pain.

Health education for the person and family

- Report unusual bleeding or excessive menstrual flow.
- Use an electric razor and a soft-bristle toothbrush; prevent injury by clearing pathways, using a night light and other measures. Do not consume alcohol.
- Avoid contact sports while on anticoagulant therapy.
- Do not consume large amounts of food rich in vitamin K (yellow and dark green vegetables).
- Do not use aspirin or NSAIDs while on heparin therapy unless advised to do so by your doctor.
- Wear a MedicAlert® tag and advise all healthcare providers (including dentists and podiatrists) of therapy.

LOW-MOLECULAR-WEIGHT HEPARINS

Enoxaparin
Dalteparin
Sapropterin
Danaparoid

LMW heparins are the most bioavailable fraction of heparin. They provide a more precise and predictable anticoagulant effect than unfractionated heparins. Like unfractionated heparin, LMW heparin prevents conversion of prothrombin to thrombin, liberation of thromboplastin from platelets and formation of a stable clot. LMW heparins cannot be used interchangeably with each other or with unfractionated heparin. Although the risk of heparin-induced thrombocytopenia is significantly lower with LMW heparin, people who were previously treated with unfractionated heparin may develop HIT when treated with LMW heparin.

Nursing responsibilities

- Assess for evidence of active bleeding, a history of bleeding disorders or thrombocytopenia, or sensitivity to heparin, sulfites or pork products.
- Monitor for unusual or masked bleeding. PT and APTT levels may be within normal levels even in the presence of haemorrhage.
- Administer by deep subcutaneous injection into abdominal wall, thigh or buttocks. Rotate sites. Do not aspirate or massage.

Health education for the person and family

- Subcutaneous self-administration technique, timing of doses and site rotation. To minimise bruising, do not rub site after administering.
- Do not take aspirin, NSAIDs or other over-the-counter drugs unless recommended by your doctor.
- Promptly report excessive bruising or bleeding, chest pain, difficulty breathing, itching, rash or swelling to your healthcare provider.
- Keep follow-up appointments as scheduled.

ORAL ANTICOAGULANT

Warfarin

Warfarin interferes with synthesis of vitamin-K-dependent clotting factors by the liver, leading to depletion of these factors. It has no effect on already circulating clotting factors or on existing clots. Warfarin inhibits extension of existing thrombi and the formation of new clots. Its action is cumulative and more prolonged than that of heparin.

Nursing responsibilities

- Assess laboratory results and history for evidence of abnormal bleeding.
- Multiple drugs affect the metabolism and protein binding of warfarin; note all medications and assess for interactions with warfarin.
- Do not give during pregnancy because warfarin may cause congenital malformations.
- Oral tablets may be crushed and given without regard to meals.
- Dilute intravenous warfarin with supplied dilutant; administer within 4 hours by direct intravenous injection at a rate of 25 mg/min.
- Keep vitamin K available to reverse effects of warfarin in the event of excessive bleeding or haemorrhage.
- Monitor PT or INR; report values outside the desired range.

Health education for the person and family

- If bleeding occurs (haematemesis, bright red or black tarry faeces, haematuria, bleeding gums, excessive bruising, etc.), do not take your prescribed dose and

(continued)

MEDICATION ADMINISTRATION Anticoagulant therapy (continued)

notify your doctor immediately. Report rash or manifestations of hepatitis (dark urine, malaise, yellow skin or sclera).
- Take your warfarin at the same time every day; do not change brands because their effects may differ.
- Menstrual bleeding may be slightly increased; contact your healthcare provider if it increases significantly. Use reliable birth control to prevent pregnancy while taking warfarin. Immediately contact your doctor if you think you may be pregnant.
- Take precautions to prevent injury and bleeding: use a soft-bristle toothbrush and electric razor, wear shoes and use a night light. Avoid participating in contact sports.
- Do not smoke, use alcohol or take any over-the-counter drugs unless specifically recommended by your doctor. Notify all healthcare providers, including dentists and podiatrists, of therapy. Wear a MedicAlert® tag.
- Obtain lab tests as scheduled and keep all scheduled follow-up appointments.

Anticoagulation is initiated with unfractionated heparin or low-molecular-weight (LMW) heparin. Following an initial intravenous bolus of 7500 to 10 000 units of unfractionated heparin, a continuous heparin infusion of 1000 to 1500 international units per hour (IU/h) is started. The dosage is calculated to maintain the activated partial thromboplastin time (APTT) at approximately twice the control or normal value. An infusion pump is used to deliver the prescribed dosage. Frequent monitoring of the infusion is an important nursing responsibility. Subcutaneous heparin injections may be used as an alternative to intravenous infusion in some instances.

LMW heparins are increasingly used to prevent and treat venous thrombosis. They do not require the close laboratory monitoring of unfractionated heparins. LMW heparin is administered subcutaneously in fixed doses once or twice daily, allowing for the option of community-based treatment. LMW heparins have additional advantages, in that they are more effective and carry lower risks for bleeding and thrombocytopenia than conventional, unfractionated heparins.

Oral anticoagulation with warfarin may be initiated concurrently with heparin therapy. Overlapping heparin and warfarin therapy for 4 to 5 days is important because the full anticoagulant effect of warfarin is delayed and it may actually promote clotting during the first few days of therapy (Papadakis et al., 2013). Warfarin doses are adjusted to maintain the INR at 2.0 to 3.0 (Kasper et al., 2015). Once this level is achieved, the heparin is discontinued and a maintenance dose of warfarin is prescribed to prevent recurrent thrombosis.

Anticoagulation generally is continued for at least 3 months. When DVT is recurrent or risk factors such as altered coagulability or cancer are present, anticoagulant therapy may be prolonged. Regular follow up is necessary to be sure prothrombin times (INR) remain within the desirable range for anticoagulation.

Treatments

Treatment of venous thrombosis also includes measures to relieve symptoms and reduce inflammation. With superficial venous thrombosis, applying warm, moist compresses over the affected vein, extremity rest and anti-inflammatory agents usually provide relief of symptoms.

Bed rest may be ordered for deep venous thrombosis. The duration of bed rest typically is determined by the extent of leg oedema. The legs are elevated 15 to 20 degrees, with the knees slightly flexed, above the level of the heart to promote venous return and discourage venous pooling. Elastic anti-embolism stockings (TEDS) or pneumatic compression devices are also frequently ordered to stimulate the muscle-pumping mechanism that promotes the return of blood to the heart. When permitted, walking is encouraged while avoiding prolonged standing or sitting. Crossing the legs also is avoided, as are tight-fitting garments or stockings that bind.

Surgery

Venous thrombosis usually is effectively treated with conservative measures and anticoagulation. In some cases, however, surgery is required to remove the thrombus, prevent its extension into deep veins or prevent the effects of embolisation.

Venous thrombectomy is done when thrombi lodge in the femoral vein and their removal is necessary to prevent pulmonary embolism or gangrene. Successful thrombus removal rapidly improves venous circulation. The duration of this effect varies.

When venous thrombosis is recurrent and anticoagulant therapy is contraindicated, a filter may be inserted into the vena cava to capture emboli from the pelvis and lower extremities, preventing pulmonary embolism. Several different filters are available (see Figure 31.14). The Greenfield filter is widely used for its ability to trap emboli within its apex while

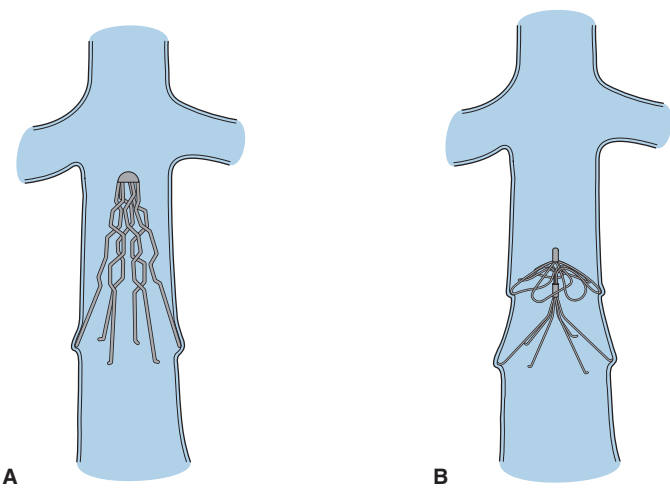

FIGURE 31.14 ■ Venal caval filters. *A*, Greenfield filter. *B*, Nitinol filter

maintaining patency of the vena cava. The filter can be inserted under fluoroscopy with local anaesthesia. Mortality and morbidity associated with the filter are very low.

Extensive thrombosis of the saphenous vein may necessitate ligation and division of the saphenous vein where it joins the femoral vein to prevent clot extension into the deep venous system. A vein affected by septic venous thrombosis is excised to control the infection. Antibiotic therapy also is initiated.

Nursing care

Health promotion

Prevention of venous thrombosis is an important component of nursing care for all at-risk people. Position people to promote venous blood flow from the lower extremities, with the feet elevated and the knees slightly bent. Avoid placing pillows under the knees and positions in which the hips and knees are sharply flexed. Use a recliner chair or footstool when sitting. Ambulation should be encouraged as soon as possible and a regular schedule of ambulation maintained throughout the day. Teach ankle flexion and extension exercises, and remind people to frequently perform them. Apply elastic compression stockings and pneumatic compression devices when appropriate. Instruct to avoid crossing legs when in bed or sitting. Inquire about possible prophylactic heparin or warfarin therapy for people undergoing orthopaedic surgery or other high-risk procedures. Frequently assess intravenous sites. Change the site and catheter as dictated by agency protocol and if evidence of local inflammation is noted.

Assessment

Assess people at risk of venous thrombosis for manifestations and risk factors.

- *Health history:* complaints of leg or calf pain, its duration and characteristics, and the effect of walking on the pain; history of venous thrombosis or other clotting disorders; current medications.
- *Physical examination:* inspect affected extremity for redness, oedema; palpate for tenderness, warmth, cordlike structures; body temperature.
- *Diagnostic tests:* clotting studies (activated partial thromboplastin time (APTT), prothrombin time (PT), International Normalized Ratio (INR)).

See the accompanying nursing care plan for an example of an assessment of a person with deep venous thrombosis.

Nursing diagnoses and interventions

In addition to the preventive measures identified earlier, priority nursing diagnoses for the person with venous thrombosis relate to pain, maintenance of tissue perfusion and integrity, and the potential adverse effects of prescribed treatments.

Pain

The pain associated with venous thrombosis results from inflammation of the involved vein. It may be aggravated by use of the involved extremity. Associated oedema and swelling may contribute to discomfort. Measures to reduce the inflammation often help relieve the pain.

- Regularly assess pain location, characteristics and level using a standardised pain scale. Report increasing pain or changes in its location or characteristics. *Tissue substances released during the inflammatory process can stimulate pain receptors. In addition, localised swelling presses on pain-sensitive structures in the area of the inflammation, contributing to discomfort. As inflammation and swelling are reduced, pain should abate. Continued or increasing pain may indicate extension of the thrombosis. Sudden chest pain may indicate a pulmonary embolism, necessitating immediate intervention.*
- Measure calf and thigh diameter of the affected extremity on admission and daily thereafter. Report increases promptly. *The inflammatory process causes vasodilation and increases vessel permeability, causing oedema of the affected extremity. Baseline and subsequent measurements provide a measure of treatment effectiveness.*
- Apply warm, moist heat to affected extremity at least four times daily, using warm, moist compresses or an aqua-K pad. *Moist heat penetrates tissues to a greater depth. Warmth promotes vasodilation, allowing reabsorption of excess fluid into the circulation. Vasodilation also reduces resistance within the affected vessel, reducing pain. As oedema subsides, pressure on surrounding tissues is relieved, thereby reducing pain.*
- Maintain bed rest as ordered. *Using leg muscles during walking exacerbates the inflammatory process and increases oedema. This, in turn, increases venous compression and pain.*

Ineffective tissue perfusion: peripheral

As thrombi develop, they occlude the lumen of the vein and obstruct blood flow. In addition, the accompanying inflammatory response may precipitate vessel spasms, further impairing arterial and venous blood flow and tissue perfusion. Impaired tissue perfusion, in turn, deprives tissues of nutrients and oxygen. As a result, distal tissues of the affected extremity are at risk of ulceration and infection.

CONSIDERATION FOR PRACTICE

Assess peripheral pulses, skin integrity, capillary refill times and colour of extremities at least every 8 hours. Report changes promptly. Assessment of both extremities allows comparison of the affected and unaffected limbs. Weak or absent pulses, impaired capillary refill or significant colour changes in the affected extremity may indicate extension of the thrombus or a possible complication.

- Assess skin of the affected lower leg and foot at least every 8 hours; more often as indicated. *Frequent assessment is important to rapidly detect early signs of tissue breakdown*

NURSING CARE PLAN A person with deep venous thrombosis

Mrs Opal Hipps, aged 75, lives alone with her dog, Roxy, in her family home in the western suburbs of Melbourne. She retired from her job at the post office 10 years ago and now spends a lot of time reading and watching television. Over the past week she has developed a vague aching pain in her right leg. She ignored the pain until last night when it developed into a much more severe pain in her right calf. She noticed that her right lower leg seemed larger than the left and it was very tender to the touch. After seeing her doctor and undergoing Doppler ultrasound studies, Mrs Hipps is admitted to the hospital with the diagnosis of deep venous thrombosis in the right leg. She is placed on bed rest and intravenous heparin. Michael Cookson, RN, is assigned to admit and care for Mrs Hipps.

ASSESSMENT

RN Cookson notices that Mrs Hipps was admitted 14 months ago for repair of a fractured femur. Mrs Hipps says, 'This business about a blood clot really has me worried.' She also tells Mr Cookson that she is worried about who will care for her dog while she is in the hospital. Physical findings include height 157 cm, weight 68 kg, T 37.3°C; vital signs within normal limits otherwise. Her left leg is warm and pink, with strong peripheral pulses and good capillary refill. Her right calf is dark red, very warm and dry to touch. It is tender to palpation. The right femoral and popliteal pulses are strong, but the pedal and posterior tibial pulses are difficult to locate. The right calf diameter is 1.27 cm larger than the left.

DIAGNOSES

- *Pain* related to inflammatory response in affected vein.
- *Anxiety* related to unexpected hospitalisation and uncertainty about the seriousness of her illness.
- *Ineffective tissue perfusion: peripheral* related to decreased venous circulation in the right leg.
- *Risk of impaired skin integrity* related to pooling of venous blood in the right leg.

PLANNING

- Plan time with Mrs Hipps to explain venous thrombosis and its treatment.
- Discuss arrangements for a friend or neighbour to care for Mrs Hipps's dog.
- Plan time to liaise with interprofessional team for assessment and interventions.

Expected outcomes

- Verbalise relief of right leg pain by day of discharge.
- Verbalise reduced anxiety by the second day of her hospitalisation.
- Demonstrate reduced right leg diameter by 0.65 cm by the fifth day of hospitalisation.
- Maintain intact skin in the right foot throughout the hospital stay.

IMPLEMENTATION

- Elevate legs, maintaining slight knee flexion, while in bed.
- Apply warm, moist compresses to right leg using a 2-hour-on, 2-hour-off schedule around the clock.
- Administer prescribed analgesics and evaluate effectiveness.
- Spend time with Mrs Hipps to explain venous thrombosis and its treatment.
- Arrange for a friend or neighbour to care for Mrs Hipps's dog.
- Apply anti-embolism stockings as ordered; remove for 30 minutes every 8 hours.
- Monitor laboratory values to assess effect of anticoagulant therapy; report values outside desired range.
- Assist with progressive ambulation when allowed.
- Inspect legs and feet and record findings every 8 hours.

EVALUATION

Seven days after admission, the pain in Mrs Hipps's right leg has subsided and the diameter of her right calf is equal to that of her left calf. Mrs Hipps admits to RN Cookson that her fears really relate to a cousin who was hospitalised for a similar problem and had his leg amputated. After talking about her condition and the steps she can take to prevent its recurrence, she is much less anxious. Before discharge, Mr Cookson reviews instructions for anti-embolism stockings, daily walking, warfarin schedule and scheduled follow-up appointment. Mrs Hipps's neighbour, Kate, has come to pick her up. As Mr Cookson is helping Mrs Hipps into the car, Kate hands her a small brown dog and says, 'I took good care of Roxy for you, but he's missed you.' Mrs Hipps smiles and assures Mr Cookson that she will call the number he provided if she has any questions.

CRITICAL THINKING IN THE NURSING PROCESS

1. Describe the pathophysiological reasons for the pain in Mrs Hipps's right leg.
2. How would you respond if Mrs Hipps tells you she does not have the money to buy the prescribed anticoagulant when she goes home?
3. How would you change your teaching and discharge planning if Mrs Hipps had difficulty caring for herself?
4. Design a plan of care for Mrs Hipps for the nursing diagnosis *Activity intolerance*.

REFLECTION ON THE NURSING PROCESS

1. Focusing on the elements of listening to the person, what in Mrs Hipps's case would be important when obtaining a patient history?
2. Discuss four priorities of education pertinent to Mrs Hipps's presentation.

and implementation of measures to protect vulnerable tissues. Early intervention allows healing and restoration of tissue integrity; allowed to continue, the process can lead to necrosis and potential gangrene.

- Elevate extremities at all times, keeping knees slightly flexed and legs above the level of the heart. *Elevation of the extremities promotes venous return and reduces peripheral oedema. Knee flexion promotes muscle relaxation.*
- Use mild soaps, solutions and lotions to clean the affected leg and foot daily. Pat dry after washing and apply a non-alcohol-based lotion or moisturising cream. *Daily*

CONSIDERATION FOR PRACTICE

Remove anti-embolic stockings or pneumatic compression device for 30 to 60 minutes during daily hygiene. Anti-embolic stockings and pneumatic compression devices exert pressure on the extremity and promote venous return. They can, however, impair perfusion of the dermis. Removing them periodically allows assessment of the underlying tissue and restores perfusion of the dermis, reducing the risk of skin breakdown. Their use may be continued following discharge to reduce the risk of recurrent venous thrombosis.

hygiene with non-drying soaps and solutions removes potential pathogens from the skin surface and maintains skin integrity and the first line of defence against infection. Caustic or harsh soaps or solutions can dry and crack the skin. Dry, cracked skin permits bacteria and other microorganisms to enter and infect the tissue, potentially leading to ulceration and venous gangrene.

- Use an egg-crate mattress or sheepskin on the bed as needed. *Egg-crate mattresses and sheepskins distribute weight more evenly, preventing excess pressure on affected tissues.*
- Encourage frequent position changes, at least every 2 hours while awake. *Frequent position changes reduce pressure on bony prominences and oedematous tissue, reducing the risk of tissue breakdown.*

Ineffective protection

Anticoagulant therapy interferes with the body's normal clotting mechanisms, increasing the risk of bleeding and haemorrhage.

- Monitor laboratory results, including the INR (prothrombin time), APTT, haemoglobin and haematocrit, as indicated. Report values outside the normal or desired range. *Coagulation studies are used to monitor the effect of anticoagulant medications. Values within the desired range prevent further clot development while carrying a low risk of bleeding and haemorrhage. A fall in the haemoglobin and haematocrit may indicate undetected bleeding.*

CONSIDERATION FOR PRACTICE

Assess for and promptly report evidence of bleeding, such as petechiae, bruising, bleeding gums, obvious or occult blood in vomitus, stool or urine, unexplained back or abdominal pain. Anticoagulants interfere with the ability to form a stable clot and prevent excessive bleeding. Even minor trauma such as tooth brushing or bumping into furniture can result in bleeding.

Impaired physical mobility

Although prolonged bed rest rarely is required, it is associated with many problems, including constipation, joint contractures, muscle atrophy and boredom. Nursing care goals include maintaining joint range of motion, minimising muscle atrophy and reducing boredom.

- Encourage active range-of-motion (ROM) exercises at least every 8 hours. Provide passive range of motion as needed. *ROM exercises maintain joint mobility and prevent contractures. Active range of motion (performed by the person) also helps prevent muscle atrophy and preserve function. While passive ROM exercises do not prevent muscle atrophy, they do maintain joint mobility.*
- Encourage frequent position changes, deep breathing and coughing. *Prolonged immobility can lead to impaired airway clearance and respiratory complications, such as atelectasis or pneumonia. Turning, coughing and deep breathing facilitate expulsion of secretions from the respiratory tract, airway clearance and alveolar ventilation.*
- Encourage increased fluid and dietary fibre intake. *Constipation is a frequent complication of immobility due to decreased gastrointestinal motility and loss of abdominal muscle strength. Increasing fluid and fibre intake helps maintain soft, easily expelled stools.*
- Assist with and encourage ambulation as allowed. *Ambulation promotes venous blood flow, helps maintain muscle tone and joint mobility, and increases the sense of wellbeing.*
- Encourage diversional activities such as reading, handiwork or other hobbies, television or video games, and socialising. *Boredom may lead to dozing and inertia, with little physical movement or mental stimulation, increasing the risk of complications of immobility.*

Risk of ineffective tissue perfusion: cardiopulmonary

A thrombus that forms in the deep veins of the legs or pelvis may break loose or fragment, becoming an embolism. Emboli that originate in the venous system usually become trapped in the pulmonary circulation (pulmonary embolism). Gas exchange in the affected area is impaired as blood flow ceases or is reduced to an area of the lungs that is well ventilated (see Chapter 35).

- Frequently assess respiratory status, including rate, depth, ease and oxygen saturation levels. *A mismatch of ventilation and perfusion can significantly affect gas exchange, leading to rapid, shallow respirations, dyspnoea and air hunger, and a fall in oxygen saturation levels.*
- Initiate oxygen therapy, elevate the head of the bed and reassure the person who is experiencing manifestations of pulmonary embolism. *Oxygen therapy and elevating the head of the bed promote ventilation and gas exchange in those alveoli that are well perfused, helping maintain tissue oxygenation. Reassurance helps reduce anxiety and slow the respiratory rate, promoting greater respiratory depth and alveolar ventilation.*

CONSIDERATION FOR PRACTICE

Immediately report complaints of chest pain and shortness of breath, anxiety or a sense of impending doom. The manifestations of pulmonary embolism are similar to those of myocardial infarction. Prompt intervention to restore pulmonary blood flow can reduce the risk of significant adverse effects.

Community-based care

Treatment measures for venous thrombosis may be initiated and carried out on an outpatient basis or continued for an extended period of time following hospital discharge. Include the following topics when teaching for home care:

- explanation of the disease process
- treatment measures, including laboratory tests and their purposes, medications and adverse effects that should be reported
- appropriate methods of heat application
- prescribed activity restrictions
- measures to prevent future episodes of venous thrombosis
- the importance of follow-up visits and laboratory tests as scheduled.

Refer people for community nursing services for continued assessment and reinforcement of teaching. Provide referrals for assistance with ADLs and home maintenance services as indicated. Consider referral for physical therapy if needed.

SELECTED PERIPHERAL VENOUS CONDITIONS

THE PERSON WITH CHRONIC VENOUS INSUFFICIENCY

Chronic venous insufficiency is a disorder of inadequate venous return over a prolonged period. Deep venous thrombosis (DVT) is the most frequent cause of chronic venous insufficiency. Other conditions, such as varicose veins or leg trauma, may contribute; in some instances, it develops without an identified precipitating cause (Kasper et al., 2015; Papadakis et al., 2013).

Pathophysiology

Following DVT, large veins may remain occluded, increasing the pressure in other veins of the extremity. This increased pressure distends the veins, separating valve leaflets and impairing their ability to close. DVT also damages valve leaflets, causing them to thicken and contract. The result is impaired unidirectional blood flow and deep vein emptying (Patel, 2014).

When venous valves are incompetent, the muscle-pumping action produced during activity cannot propel blood back to the heart. Venous blood collects and stagnates in the lower leg (**venous stasis**). Venous pressures in the calf and lower leg increase, particularly during ambulation. This increased pressure impairs arterial circulation to the lower extremities as well. The body's ability to provide sufficient oxygen and nutrients to the cells and remove metabolic waste products diminishes. Eventually, there is so little oxygen and nutrients that cells begin to die. The skin atrophies and subcutaneous fat deposits necrose. Breakdown of red blood cells in the congested tissues causes brown skin pigmentation (Flugman, 2014). Venous stasis ulcers develop. Congested tissues impair the body's ability to increase the supply of oxygen, nutrients and metabolic energy to heal the ulcer. As a result, the condition worsens and, over time, the ulcers enlarge. The congested venous circulation also prevents the blood from mounting effective inflammatory and immune responses, significantly increasing the risk of infection in the ulcerated tissue (Flugman, 2014).

Manifestations

Manifestations of chronic venous insufficiency include lower leg oedema, itching and discomfort of the affected extremity that increase with prolonged standing. The extremity is cyanotic. Recurrent stasis ulcers develop (see Figure 31.15), usually forming just above the ankle, on the medial or anterior aspect of the leg. They heal poorly, forming scar tissue that breaks down easily. Tissue surrounding the ulcer is shiny, atrophic and cyanotic, and there is a brownish pigmentation to the skin. Other skin changes may develop as well, such as

MANIFESTATIONS Chronic venous insufficiency

- Lower extremity oedema that worsens with standing
- Itching, dull leg discomfort or pain that increases with standing
- Thin, shiny, atrophic skin
- Cyanosis and brown skin pigmentation of lower leg and foot
- Possible weeping dermatitis
- Thick, fibrous (hard) subcutaneous tissue
- Recurrent ulcerations of medial or anterior ankle

FIGURE 31.15 ■ Chronic venous insufficiency. Note the discolouration of the ankle and the stasis ulcer

Source: Dr P. Marazzi/Science Source.

TABLE 31.5 Comparison of arterial and venous leg ulcers

FACTOR	ARTERIAL ULCERS	VENOUS ULCERS
Location	Toes, feet, shin	Over medial or anterior ankle
Ulcer appearance	Deep, pale	Superficial, pink
Skin appearance	Normal to atrophic Pallor on elevation Rubor on dependency	Brown discolouration Stasis dermatitis Cyanosis on dependency
Skin temperature	Cool	Normal
Oedema	Absent or mild	May be significant
Pain	Usually severe Intermittent claudication Rest pain	Usually mild Aching pain
Gangrene	May occur	Does not occur
Pulses	Decreased or absent	Normal

eczema or stasis dermatitis. Necrosis and fibrosis of subcutaneous tissue cause the affected area of the leg to feel hard and somewhat leathery to the touch, but even the slightest trauma to the area can produce serious tissue breakdown. See the box above for the manifestations of chronic venous insufficiency. Table 31.5 compares venous and arterial ulcers.

INTERPROFESSIONAL CARE

Collaborative care for the person with venous insufficiency focuses on relieving symptoms, promoting adequate circulation and healing and preventing tissue damage.

Diagnosis

The history and physical examination often establish the diagnosis of chronic venous insufficiency. Because a history of DVT is a major risk factor, careful evaluation of the past medical history and questioning of the person is important. There are no specific diagnostic tests to confirm the diagnosis of chronic venous insufficiency.

Lifestyle modifications

Conservative management of venous insufficiency focuses on reducing oedema and treating ulcerations. Prolonged standing or sitting is discouraged. Graduated compression hosiery is ordered for daytime use and frequent elevation of the legs and feet during the day is recommended. At night, the legs and feet should be elevated above the level of the heart by raising the foot of the mattress.

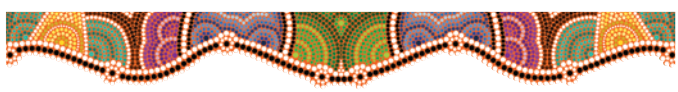
Treatment

Treatment of associated stasis dermatitis varies, based on the duration of the condition. Wet compresses of boric acid, buffered aluminium acetate (Burow's solution) or isotonic saline solution are applied to acute weeping dermatitis four times a day for 1-hour periods. Following the compress, a topical corticosteroid (such as 0.5% hydrocortisone cream) is applied. Bed rest is prescribed during the acute period. Stasis dermatitis that is subsiding or chronic may be treated with a topical corticosteroid, zinc oxide ointment or a topical broad-spectrum antifungal cream such as clotrimazole cream or miconazole cream (Papadakis et al., 2013).

Isotonic saline compresses or wet-to-dry dressings are applied to stasis ulcers to promote healing. A dilute topical antibiotic solution also may be used (Kasper et al., 2015). The ulcer may be treated by using a semi-rigid boot applied to the foot and lower leg. This device may be made of Unna's paste or Gauzetex bandage. Bony prominences must be well padded. The boot must be changed every 1 to 2 weeks, depending on the amount of drainage from the ulcer. This device often allows ambulatory treatment.

Surgery

A very large, chronic ulcer may require surgery. In this case, the incompetent veins are ligated, the ulcer is excised and the area is covered with a skin graft (see Chapter 16).



Nursing care

Education

Nursing care for the person with chronic venous insufficiency is primarily educative and supportive. Teaching includes the following recommendations:

- Elevate the legs while resting and during sleep. See the 'Translation to practice' box below for a nursing research study that suggests the supine position for resting.
- Walk as much as possible, but avoid sitting or standing for long periods of time.
- When sitting, do not cross your legs or allow pressure on the back of the knees (such as sitting on the side of the bed).
- Do not wear anything that pinches your legs (such as knee-high stockings, garters or girdles).

TRANSLATION TO PRACTICE Evidence-based practice for the person with venous leg ulcers

A study by Finlayson, Wu and Edwards (2015) analysed data from 250 adults recruited from two hospital and three community-based wound clinics. The study participants had healed leg ulcers of mostly venous aetiology. Various parameters were recorded and analysed for risk factors which may have contributed to recurrence of a leg ulcer and for protective factors which may have reduced the likelihood of leg ulcer recurrence.

The group discovered that the four key risk factors for recurrence of venous ulcers were age, history of deep venous thrombosis, history of multiple previous leg ulcers and total duration of the previous ulcer. The data also suggested that the protective factors preventing leg ulcer recurrence were leg elevation, walking and self-efficacy (*having control over one's ability to succeed*).

IMPLICATIONS FOR NURSING

The results of this study are important for nurses to understand factors that may promote or reduce the risk of a person developing recurrence of a leg ulcer. This knowledge can be used in education sessions and primary and community healthcare situations to reduce a person's morbidity or to predict the individuals who would most benefit from further support and information.

CRITICAL THINKING IN PERSON-CENTRED CARE

1. When designing an education session on venous leg ulcer recurrence, which identified factors are modifiable and which are non-modifiable? How will these considerations influence the information provided?
2. When designing an education session on venous leg ulcer recurrence, what specific information should be provided regarding the method and duration of leg elevation? What specific information should be provided regarding the distance, type and duration of walking? Can a nurse influence a person's self-efficacy? Explain.
3. How will this information influence your future practice when caring for individuals with current or previous venous ulcers?

- Wear elastic compression stockings as prescribed. They should be tighter over the feet than at the top of the leg. Be sure the tops of the stockings do not cut into your legs. Put them on after your legs have been elevated.
- Keep the skin on your feet and legs clean, soft and dry. Follow guidelines in Box 31.5 for care of the legs and feet.

The following nursing diagnoses may apply to the person with chronic venous insufficiency.

- *Disturbed body image* related to oedema and stasis ulcers on lower leg.
- *Ineffective health maintenance* related to lack of knowledge about disorder and prescribed treatments.
- *Risk of infection* related to ulcerations.
- *Impaired physical mobility* related to pain and oedema in lower legs.
- *Impaired skin integrity* related to presence of stasis ulcers.
- *Ineffective tissue perfusion: peripheral* related to incompetent venous valves.

See other sections of this chapter for specific nursing interventions related to many of these diagnoses. See the box below for nursing care for the older adult with chronic venous stasis.

THE PERSON WITH VARICOSE VEINS

Varicose veins are irregular, tortuous veins with incompetent valves. Varicosities may develop in any vein and may be called by other names, such as haemorrhoids in the rectum and varices in the oesophagus. Varicosities usually affect the veins of the lower extremities; the long saphenous vein is often affected and they also may develop in the short saphenous vein.

Incidence and risk factors

Varicose veins affect about 10–15% of men and 20–25% of women in industrialised nations (Sheehan, 2015). They are more common in women over age 35. Studies also suggest that the increased risk of varicose veins in women may relate to venous stasis during pregnancy. Ageing is a risk factor, possibly related to decreased exercise and other factors that contribute to venous stasis. People in occupations that involve prolonged standing (such as beauticians, salespeople and nurses) also have an increased incidence of varicose veins. Race is a risk factor: white-skinned people are more frequently affected than dark. The majority of people with primary varicose veins (those affecting superficial veins) have a family history of the disorder, suggesting a genetic link (Kasper et al., 2015). A person is at approximately 90% risk of developing varicose veins if both parents are affected, and approximately 62% risk if one parent is affected (Sheehan, 2015).

Most varicosities occur in the deep veins of the legs. Contributing causes include obesity, venous thrombosis, congenital arteriovenous malformations or sustained pressure on abdominal veins (as in pregnancy and/or the presence of abdominal tumours). The effects of gravity, produced by long periods of standing, are a major causative factor.

Pathophysiology

Varicose veins are classified as primary (with no involvement of deep veins) or secondary (caused by the obstruction of deep veins). In both cases, long-standing increased venous pressure stretches the vessel wall. This sustained stretching impairs the ability of the venous valves to close, causing them to become incompetent.

The erect position produces a twofold negative effect on the veins. When standing, the leg veins resemble vertical columns

NURSING CARE OF THE OLDER ADULT Chronic venous stasis

Disorders of venous stasis are common after the fifth decade of life. Ageing affects vessels and tissues, increasing the risk of venous insufficiency and varicose veins. In addition, mobility frequently declines with ageing, reducing the effect of the muscle pump in promoting venous return.

HEALTH EDUCATION FOR THE PERSON AND FAMILY

Regular exercise—walking, in particular—is an important part of the treatment plan. Safety when walking is an important issue for older people. Assess the person's mobility and stability during ambulation. If appropriate, suggest using a walker and quad-cane as needed. Assist older people holding jobs that require prolonged standing to identify strategies to minimise standing and incorporate periods of activity into their work.

HOME CARE

Following surgery or during treatment for stasis ulcers, older people may need additional assistance with home care and maintenance. Initiate referral to social services as needed to arrange for home nursing care, meals, assistance with ADLs and home maintenance services as indicated. In some instances, temporary placement in an extended care facility is necessary until the person and family can assume care.

and must withstand the full force of venous blood pressure. Prolonged standing, the force of gravity, lack of leg exercise and incompetent venous valves all weaken the muscle-pumping mechanism, reducing venous blood return to the heart. As standing continues, the amount of blood pooled in the veins increases, further stretching the vessel wall. The venous valves become increasingly incompetent.

Manifestations

Although varicose veins may be asymptomatic, most cause manifestations such as severe aching leg pain, leg fatigue, leg heaviness, itching or feelings of heat in the legs. The degree of valvular incompetence does not seem to correlate well with the extent of symptoms. The menstrual cycle tends to worsen symptoms, suggesting a possible correlation with hormonal factors in women. Assessment reveals obvious dilated, tortuous veins beneath the skin of the upper and lower leg. If varicose veins are long standing, the skin above the ankles may be thin and discoloured, with a brown pigmentation. (See the 'Manifestations' box below.)

Complications

Complications of varicose veins include venous insufficiency and stasis ulcers. Chronic stasis dermatitis may also develop. Superficial venous thrombosis may develop in varicose veins, especially during and after pregnancy, following surgery and in people on oestrogen therapy (oral contraceptives or hormone replacement therapy).

MANIFESTATIONS Varicose veins

- Severe, aching pain in the leg
- Leg fatigue, heaviness
- Itching of the affected leg (stasis dermatitis)
- Feelings of warmth in the leg
- Visibly dilated veins
- Thin, discoloured skin above the ankles
- Stasis ulcers

INTERPROFESSIONAL CARE

Varicose veins usually can be managed using conservative measures, although surgery may be required if symptoms are severe, when complications develop or for cosmetic reasons.

Diagnosis

While varicose veins often are diagnosed by the history and physical examination, diagnostic tests may be ordered.

- *Doppler ultrasonography* or *duplex Doppler ultrasound* may be performed to identify specific locations of incompetent valves. This test is particularly useful before surgery to identify valves that allow reflux of blood from the femoral, popliteal or peripheral deep veins into the superficial veins (Papadakis et al., 2013).
- *Trendelenburg test* may be performed to determine the underlying cause of superficial venous insufficiency. The leg is elevated, then an elastic tourniquet is placed around the distal thigh. The varicosities then are observed as the person stands. When valves of the deep veins are incompetent, the veins remain flat on standing; they rapidly distend when the superficial venous valves are the underlying cause.

Treatments

Although there is no real cure, conservative measures are the core of treatment for most people with uncomplicated varicose veins. These measures often relieve symptoms and prevent complications by improving venous circulation and relieving pressure on venous tissues. Properly fitted graduated compression stockings are commonly prescribed. They compress the veins, propelling blood back to the heart. Compression stockings augment the muscle pumping action of the legs. When worn during times of prolonged standing and in combination with frequent leg elevation, compression stockings often prevent progression of the condition and development of complications.

Regular, daily walking also is important. Prolonged sitting and standing are discouraged, although elevating the legs for specified periods during the day is beneficial. Leg elevation

promotes venous return, prevents venous stasis and decreases leg heaviness and fatigue.

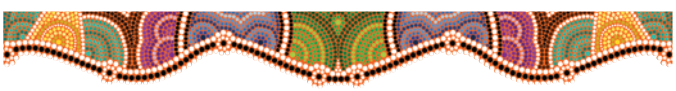
COMPRESSION SCLEROTHERAPY In compression sclerotherapy, a sclerosing solution is injected into the varicose vein and a compression bandage is applied for a period of time. This obliterates the vein. Venous blood is rerouted through healthy vessels whose valves are not compromised. Compression sclerotherapy may be used to treat small, symptomatic varicosities. It may be the primary treatment or it may be used in conjunction with varicose vein surgery. While compression sclerotherapy may be done for cosmetic reasons, complications such as phlebitis, tissue necrosis or infection may occur and need to be considered prior to the procedures.

Surgery

Surgical treatment of varicose veins generally is reserved for people who are very symptomatic, experience recurrent superficial venous thrombosis, and/or develop stasis ulcers. The objective of surgery is to remove the diseased veins. It may be considered for cosmetic reasons.

Surgery usually involves extensive ligation and stripping of the greater and lesser saphenous veins (Kasper et al., 2015). The evening before surgery, the surgeon marks all incompetent superficial and perforating varicose veins with a permanent ink marker. Under either regional or general anaesthesia, the greater saphenous vein is removed and the connected smaller tributaries that have not naturally clotted off are tied off. Multiple small incisions may be made over the varicosities, allowing removal of the affected segments of the vein. Incompetent tributaries that communicate with larger vessels also are ligated. For people with less extensive disease or people seeking cosmetic improvement, surgery may involve only the removal of the lesser saphenous vein through an incision in the popliteal fossa.

Postoperative care includes applying pressure bandages for a minimum of 6 weeks, elevating the extremities to minimise postoperative oedema and gradually increasing amounts of ambulation. Sitting and standing are prohibited during the initial recovery period and are gradually reintroduced as deemed appropriate by the surgeon.



Nursing care

Health promotion

Health promotion activities to reduce the incidence of varicose veins include teaching all people, particularly young women, the benefits of regular exercise continued over the lifetime. Discuss the effect of prolonged sitting or standing on the legs and encourage the person whose occupation involves these activities to periodically get up and move or to sit with the legs elevated. Encourage everyone to maintain normal weight for his or her height.

Assessment

Focused assessment of the person with varicose veins includes the following:

- *Health history:* complaints of leg pain, aching, heaviness or fatigue; ankle swelling; history of venous thrombosis.
- *Physical examination:* visible, dilated, tortuous superficial veins in lower extremities.

Nursing diagnoses and interventions

In planning and providing nursing care for people with varicose veins, emphasis is placed on the importance of health teaching to manage the symptoms of varicose veins, particularly because there is no cure for the disease. Nursing care for people who have undergone surgical treatment for varicose veins focuses on assessing and promoting wound healing and preventing infection. Nursing diagnoses may include those related to pain, impaired tissue perfusion and skin integrity, and a risk of impaired neurovascular function.

Chronic pain

Varicose veins can lead to pooling of venous blood in the lower extremities. Venous congestion can cause a dull ache or feeling of pressure in the legs, particularly after prolonged standing. As venous pressure rises, arterial circulation and delivery of oxygen and nutrients to tissues is impaired. Tissue ischaemia contributes to the pain. The pain associated with varicose veins tends to be chronic, developing and progressing gradually over a long period of time.

- Assess pain, including its intensity, duration and aggravating and relieving factors. *Pain assessment allows collaborative planning with the person to identify appropriate interventions.*
- Inquire about current measures being used by the person to manage pain and its effects. Ask about the effectiveness of current management strategies and the desire to change. *Chronic pain management ultimately falls to the person. Strategies to address the pain must meet the person's needs.*

CONSIDERATION FOR PRACTICE

Suggest keeping a diary of pain intensity, timing, precipitating events and effectiveness of relief measures. Systematic tracking of pain is an important measure in improving its management.

- Teach and reinforce non-pharmacological pain management strategies such as progressive relaxation, imagery, deep breathing, distraction and meditation. *The effectiveness of such strategies is well documented. Non-pharmacological measures provide a variety of options for controlling pain while maintaining independence. These measures also can reduce reliance on analgesics.*
- Collaborate with the person to establish a pain control plan. *Collaborative planning for pain management increases the person's sense of control and reduces powerlessness. This, in turn, enhances the ability to cope with pain and its effects.*
- Regularly evaluate the effectiveness of planned interventions and pain management strategies. *Regular evaluation allows*

modification of the care plan as needed, as well as providing a measure of disease progression. Increasing or poorly controlled pain may necessitate additional collaborative interventions to manage the disorder.

Ineffective tissue perfusion: peripheral

Varicose veins and venous stasis impair delivery of nutrients and oxygen to peripheral tissues as elevated venous pressures interfere with blood flow through the capillary beds. Improving venous blood flow reduces venous pressures and promotes arterial flow to peripheral tissues.

- Assess peripheral pulses, capillary refill, skin colour and temperature, and extent of oedema. *Assessment of arterial flow and tissue perfusion provides baseline and continuing data for evaluating the effectiveness of interventions.*
- Teach application and use of properly fitted elastic graduated compression stockings. *Elastic compression stockings compress the veins, promoting venous return from the lower extremities. During ambulation, the stockings enhance the blood-pumping action of the muscles. Because elastic stockings inhibit blood flow through small superficial vessels, they should be removed at least once each day for at least 30 minutes.*

CONSIDERATION FOR PRACTICE

Instruct to maintain a program of regular exercise, such as walking for 20 to 30 minutes several times a day. Exercise stimulates circulation and promotes blood flow through the vascular system. When ambulation is restricted, active ROM exercises help maintain muscle tone, joint mobility and venous return.

- Advise to elevate the legs for 15 to 20 minutes several times a day and to sleep with the legs elevated above the level of the heart. *Elevating the legs promotes venous return, reducing tissue congestion and improving arterial circulation. Improved venous return also increases the cardiac output and renal perfusion, promoting elimination of excess fluid and decreasing peripheral oedema.*

Risk of impaired skin integrity

Ineffective venous valve function impairs venous return and increases venous pressures. These increased pressures oppose arterial blood flow and the delivery of oxygen and nutrients to the cells. As a result, tissues are vulnerable to any additional insult and may break down.

- Assess lower extremity colour, temperature and moisture, and for evidence of pressure or breakdown, on admission and at each visit. *Initial and continuing assessment allows timely detection of early signs of skin and tissue breakdown. This, in turn, allows early institution of measures to prevent further tissue damage and promote healing.*
- Teach foot and skin care measures such as daily cleansing with non-drying soap, gentle drying and lotions to prevent skin dryness and cracking. *Cleansing removes potentially harmful microorganisms and stimulates circulation. Care is taken to keep the skin moist and supple, promoting its function as the first line of defence against infection.*
- Discuss the importance of adequate nutrition and fluid intake. *Adequate nutrients are necessary to maintain tissue integrity and promote healing. A diet high in protein, carbohydrates and vitamins and minerals promotes growth and maintenance of skin cells, provides energy and helps prevent skin breakdown. Adequate hydration helps maintain the moisture and turgor of skin, reducing the risk of drying and breakdown.*

Risk of peripheral neurovascular dysfunction

Severe varicose veins can lead to chronic venous insufficiency, impaired arterial circulation and, ultimately, disrupted sensation in the affected extremity. Impaired neurological function increases the person's risk of injury and infection of the extremity, because minor trauma may go unnoticed.

- Assess circulation, sensation and movement of the lower extremities. *Disrupted circulation and venous congestion may interfere with sensory and motor function of the affected extremity. The potential for nerve and muscle involvement is especially high in people with venous stasis ulcers.*
- Teach measures to protect the extremities from injury, such as always wearing shoes or firm slippers, cotton socks to absorb moisture and testing the temperature of bath water with a thermometer or the upper extremities before stepping in. *Sensation in the lower extremities may be affected by poor circulation, necessitating additional measures to protect the legs and feet from injury.*

CONSIDERATION FOR PRACTICE

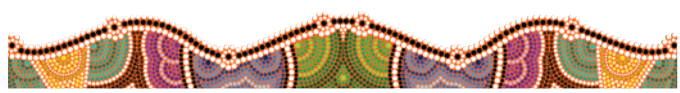
Instruct to report signs of neurovascular dysfunction, such as numbness, coldness, pain or tingling of an extremity. Early recognition of neurovascular dysfunction facilitates institution of interventions to prevent complications. Because the postoperative hospital stay following varicose vein surgery or venous stasis ulcer repair is brief, manifestations of neurovascular dysfunction may initially be detected by the person. Careful assessment and prompt reporting help prevent potential complications such as skin breakdown, infection and nerve damage.

Community-based care

Most people with varicose veins provide self-care at home. Include the following topics when preparing the person and family for home care:

- leg elevation and exercise program
- application and use of graduated elastic compression stockings
- foot and leg care (see Box 31.5 earlier in this chapter)
- measures to avoid injury and skin breakdown
- symptoms or potential complications to report to the doctor.

Provide information about suppliers of elastic stockings and any other required supplies. If venous stasis ulcers have developed, consider referral to home health services for regular assessment of healing and additional teaching.



DISORDERS OF THE LYMPHATIC SYSTEM

The lymphatic system, which includes the lymphatic vessels and the lymph nodes, is a unique part of the circulatory system. The lymphatic system returns plasma and plasma proteins filtered out of the capillaries from interstitial tissues to the bloodstream. This fluid is called *lymph*. The lymphatic system consists of closed capillaries leading to larger lymphatic venules and lymphatic veins. These vessels contain smooth muscle and one-way valves that help move fluid towards the heart. Lymphatic vessels share the same sheath as arteries and veins; arterial pulsations and skeletal muscle contractions compress the lymphatic vessels to assist in maintaining lymph flow. As lymph moves through the lymphatic system, it is filtered through thousands of bean-shaped lymph nodes clustered along the vessels. Within these nodes, phagocytes remove foreign material from the lymph, preventing it from entering the bloodstream.

GENETIC CONSIDERATIONS
Primary lymphoedema

- Primary lymphoedema develops as a result of agenesis, hypoplasia or obstruction of lymphatic vessels.
- *Congenital lymphoedema* appears shortly after birth; two other forms of lymphoedema develop later, one at the time of puberty (*lymphoedema praecox*), the other usually after age 35 (*lymphoedema tarda*).
- Congenital lymphoedema and lymphoedema praecox may be inherited as an autosomal dominant trait with variable penetrance.
- Lymphoedema also may be inherited (although less commonly) as an autosomal or sex-linked recessive disorder (Rossy, 2015).

THE PERSON WITH LYMPHATIC SYSTEM COMPROMISE

Lymphadenopathy

Lymphadenopathy, enlarged lymph nodes, may be localised or generalised. Localised lymphadenopathy usually results from an inflammatory process (e.g. streptococcal pharyngitis or an infected wound). The node enlarges as lymphocytes and monocytes proliferate within the node to destroy infectious material. Palpable lymph nodes often develop in response to minor trauma or a localised infection. Generalised lymphadenopathy usually is associated with malignancy or disease. Malignant cells or other abnormal cells invade the node, causing it to enlarge.

Lymphangitis, inflammation of the lymph vessels draining an infected area of the body, is characterised by a red streak along the inflamed vessels, pain, heat and swelling. Fever and chills also may be present. Local lymph nodes are swollen and tender.

Treatment for lymphadenopathy and lymphangitis focuses on identifying and treating the underlying condition. Elevating the body part and applying heat to inflamed lymphatic vessels help reduce swelling and promote blood flow to the affected area.

Lymphoedema

Lymphoedema may be a primary or a secondary disorder resulting from inflammation, obstruction or removal of lymphatic vessels. It is characterised by extremity oedema due to accumulation of lymph. *Primary lymphoedema* is uncommon, affecting about 1 in 10 000 people. It affects females more frequently than males and may be associated with a genetic disorder such as Turner's syndrome or Klinefelter's syndrome. (See the accompanying 'Genetic considerations' box.)

Secondary lymphoedema is an acquired condition, resulting from damage, obstruction or removal of lymphatic vessels. The most common worldwide cause of secondary lymphoedema is *filariasis*, infestation of the lymphatic vessels by filaria, a nematode worm. Other important causes of secondary lymphoedema include recurrent episodes of bacterial lymphangitis, obstruction of lymph vessels by tumours and surgical or radiation treatment for breast cancer (Kasper et al., 2015).

Pathophysiology and manifestations

Obstruction of lymph drainage prevents fluid and protein molecules from interstitial tissues from returning to the circulation. The protein molecules increase the osmotic pressure in interstitial tissues, drawing in additional fluid that causes oedema in the soft tissues. One or both extremities may be affected.

The oedema begins distally, progressing up the limb to involve the entire extremity. Initial oedema is soft and pitting; with chronic congestion, subcutaneous tissues become fibrotic, causing thick, rough skin and a woody texture of the limb (*brawny oedema*). In contrast, the oedema associated with venous disorders is softer and the skin often is hyperpigmented with evidence of stasis dermatitis. Lymphoedema generally is painless, although the limb may feel heavy.

INTERPROFESSIONAL CARE

Interprofessional care for the person with lymphoedema focuses on relieving oedema and preventing or treating infection. The disorder may be difficult to treat effectively and can lead to progressive disability due to the weight and awkwardness of the affected extremity.

Diagnosis

Abdominal or pelvic ultrasound and CT scans are used to detect obstructing lesions. MRI can show oedema and identify lymph nodes and enlarged lymphatic vessels. More invasive procedures such as lymphangiography and radioactive isotope

studies may occasionally be necessary to identify the lymphatic defect causing lymphoedema.

- *Lymphangiography* uses injected contrast media to illustrate lymphatic vessels on x-rays. Organic dyes are used to identify a distal lymphatic vessel and then a contrast medium is injected into the vessel for visualisation of the lymphatic system of the limb. In primary lymphoedema, lymph vessels are absent or hypoplastic (underdeveloped). In secondary lymphoedema, lymph channels often are dilated; it may be possible to determine the level of obstruction (Rossy, 2015).
- *Lymphoscintigraphy* involves injecting a radioactively tagged substance into distal subcutaneous tissues of the extremity, then mapping its flow through the lymphatic system. The pattern of lymph fluid distribution and transport is abnormal in people with lymphoedema.

Treatments

Meticulous skin and foot care is vital to prevent infection in the affected extremity. Shoes should always be worn to reduce the risk of injury. Careful cleansing and use of emollient lotions are recommended to prevent drying of the skin. Exercise is encouraged, as are frequent periods of leg elevation. The foot of the bed is raised by 15 to 20 degrees at night to promote lymph flow. Elastic graduated compression stockings may be ordered for use during the day. In some cases, an intermittent pneumatic compression device to reduce oedema may be prescribed for home use.

Antibiotics are given to prevent and treat infection, which can be recurrent and difficult to eradicate. Diuretic therapy may be used intermittently, particularly when primary lymphoedema is exacerbated by the menstrual cycle or seasonal variability (Papadakis et al., 2013).

People who do not respond to conservative treatment measures or who experience recurrent episodes of cellulitis and lymphangitis may require surgical treatment. Microvascular techniques may be used to create anastomoses between obstructed lymphatic vessels and adjacent veins, providing channels to redirect lymph into the venous system. Successful surgery may improve both extremity function and its cosmetic appearance (Papadakis et al., 2013).

Nursing care

Nursing care for people with lymphatic disorders focuses on reducing oedema, preventing tissue damage related to the oedema and promoting effective coping with the effect of the disorder on body image and function.

Nursing diagnoses and interventions

Nursing diagnoses for the person with lymphoedema may include *Impaired tissue integrity*, *Excess fluid volume* and *Disturbed body image*.

Impaired tissue integrity

Obstructed lymphatic flow leads to fluid congestion of the interstitial spaces of subcutaneous tissue. The resulting oedema compresses and damages tissues of the affected extremity. Subcutaneous tissues become fibrotic, reducing their protective functions of shock absorption and insulation. In addition, obstructed lymphatic flow reduces the effectiveness of lymph nodes in filtering and removing foreign material and pathogens from the body. This increases the risk of local tissue infection such as *cellulitis*, a diffuse bacterial infection of the skin. Cellulitis increases the risk of skin and tissue breakdown and, if not effectively treated, can lead to sepsis.

CONSIDERATION FOR PRACTICE

Frequently inspect the skin of the affected extremity, documenting condition with each assessment. Promptly report areas of pallor, redness or apparent inflammation. Breaks in the skin surface allow microbial invasion and increase the risk of infection. Prompt identification and treatment of any lesions is vital to prevent further tissue breakdown and infection.

- Apply well-fitting elastic graduated compression stockings or intermittent pneumatic pressure devices as ordered. *Elastic stockings and/or pneumatic pressure devices oppose the movement of fluid out of capillaries and improve its reabsorption into vascular spaces for transportation back to the heart.*
- Instruct to elevate the extremities while seated and during sleep. *Elevation of the extremities diminishes venous congestion, promotes venous return, facilitates arterial circulation and tissue perfusion and helps reduce the accumulation of excess fluids in interstitial spaces of the affected extremity.*

CONSIDERATION FOR PRACTICE

Remove elastic stockings and intermittent pressure devices every 8 hours or at each home visit to inspect the underlying skin for evidence of redness, irritation, dryness or breakdown. Elastic graduated compression stockings, anti-embolic stockings and pneumatic compression devices compress small vessels nourishing the skin and subcutaneous tissue. Periodic removal not only allows inspection of the underlying skin, but also allows restoration of blood flow to these small vessels and the tissues.

CONSIDERATION FOR PRACTICE

Use preventive skin care devices as indicated. Collected fluid in the affected extremity increases its weight and interferes with regular movement. The increased weight places greater pressure on surfaces of the limb that come in contact with furniture. Protective devices such as egg-crate foam, sheepskin, pillows or padding help prevent tissue compression, promoting circulation and reducing the risk of skin and tissue breakdown.

- Keep skin clean and dry, especially in interdigital spaces. Teach skin and foot care to the person and family. *Clean, dry skin provides the first line of defence against infection. Significant limb oedema can interfere with reaching the*

distal extremity and cleaning interdigital spaces. The dark, moist spaces between the toes are an excellent environment for bacterial growth. Teaching fosters self-care and independence, as well as preparing the person and family to manage this often chronic condition.

- Discuss the importance of adhering to the therapeutic regimen. *Lymphoedema generally is a chronic condition; effective management requires active person participation in planning and implementing care to reduce oedema and maintain tissue integrity.*

Excess fluid volume

In lymphoedema, obstruction, destruction or congenital malformation of lymphatic vessels interferes with the normal circulation of lymphatic fluid. As a result, lymph collects in the subcutaneous tissues of the affected extremity, causing excess fluid volume of that extremity. Some people may benefit from intermittent diuretic therapy and dietary sodium restriction.

- Discuss the rationale for restricted sodium intake if ordered. Teach ways to maintain the recommended sodium restriction and assist to choose foods that are low in sodium. *Sodium causes retention of extracellular water; restricting dietary sodium may help prevent additional fluid accumulation in interstitial spaces.*
- During acute periods, assess the affected extremity daily for increased oedema; measure girth of the extremity using consistent technique. *The size of the affected extremity provides a measure of the effectiveness of ordered interventions and progression of the disorder.*

CONSIDERATION FOR PRACTICE

Monitor intake and output and/or weight (daily or weekly). Use consistent scales, timing and clothing for accurate weight measurements. Intake and output records and short-term changes in weight reflect fluid balance. Measures of fluid balance permit evaluation of the effectiveness of interventions such as restricted sodium intake and diuretic therapy.

Disturbed body image

The disproportionate size of an extremity or extremities due to lymphoedema can profoundly affect body image. During early stages of the disease, conservative measures may effectively reduce the oedema and size of the affected limb. However, as the disease progresses, conservative measures may become less effective, leading to more permanent disfigurement. Mobility may be impaired and the person may develop an increasingly negative self-perception.

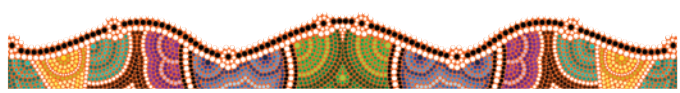
- Encourage discussions about usual coping patterns and perception of self. *Knowledge of existing coping patterns and behaviours helps the nurse assess the person's ability to cope with the current situation. This knowledge is then used to reinforce effective coping mechanisms and help develop more effective coping strategies. This exchange also allows the person to voice feelings related to actual or perceived changes in body image.*
- Accept the person's perception of self and of the impact of the changes in appearance. *Non-judgmental acceptance of the person's view of self and of the effects of changes in appearance builds trust and promotes rapport. A trusting relationship promotes the person's ability to take an active role in managing the disorder, participate in healthcare decisions and adhere to the plan of care. Non-judgmental listening also promotes mutual respect and demonstrates caring and compassion.*
- Encourage active participation in self-care. Assist with identifying alternative self-care strategies when the extent of oedema interferes with performing some aspects of self-care such as trimming toenails or washing feet. *The person initially may have difficulty viewing or touching the affected body part. Gentle encouragement and support from the nurse helps the person assume self-care and accept the affected body part. Brainstorming to identify alternative care strategies promotes the person's independence even when total self-care is not feasible.*

Community-based care

When preparing the person with chronic lymphoedema and family to manage the disorder, include the following teaching topics:

- recommended program of exercise and elevation of the extremity
- foot and skin care
- use of elastic graduated compression stockings and/or intermittent pressure devices
- importance of wearing elastic stockings during the majority of waking hours, removing them once during the daytime and while sleeping
- measures to prevent infection in the affected extremity, such as wearing gloves while gardening
- signs and symptoms to report to the healthcare provider (e.g. manifestations of tissue breakdown or infection, increasing oedema or evidence of compromised circulation)
- use and precautions associated with any prescribed medications
- sodium-restricted diet if ordered.

Provide information about contacts for questions and make referrals as needed. Evaluate the need for home health, home maintenance assistance and other services such as physical or occupational therapy.



CHAPTER HIGHLIGHTS

- Essential hypertension, blood pressure of 140/90 mmHg or higher with no clearly identified cause, rarely causes symptoms but is a major risk factor for coronary heart disease, heart failure, stroke and renal insufficiency.
- Prehypertension, a newly identified category, is an average blood pressure of 120–139/80–89 mmHg. People with prehypertension are advised to make lifestyle changes indicated for hypertension (weight loss, exercise, dietary changes, limited alcohol intake and stress reduction), but generally are not treated with medications unless other risk factors such as diabetes or kidney disease are present.
- Systolic hypertension, an elevated systolic blood pressure without elevation of the diastolic pressure, is common in older adults and contributes to complications such as coronary heart disease and stroke.
- Cardiovascular disease in Indigenous Australians is 30% more common than in non-Indigenous Australians.
- Risk factors for cardiovascular disease are more common in Indigenous Australians than in non-Indigenous Australians: diabetes is four times as common, smoking daily and obesity are twice as common.
- Medications to treat hypertension include diuretics, alpha- and beta-adrenergic blockers, ACE inhibitors and angiotensin II blockers, calcium channel blockers and vasodilators. A combination of two or more drugs often is required for effective blood pressure control.
- Aneurysms, abnormal dilation of a blood vessel, commonly affect the aorta and the iliac arteries, particularly in older men. A slowly expanding abdominal aortic aneurysm that does not produce symptoms or impair flow through the renal arteries may not be repaired, particularly in an older person. Percutaneously inserted endovascular splints provide an alternative to surgery for abdominal aortic aneurysms.
- Peripheral vascular disease, obstruction or occlusion of peripheral arteries by atherosclerotic plaque, is common and a leading cause of disability and amputation.
- Smoking cessation and regular daily exercise are key components of treatment for peripheral vascular disorders such as atherosclerosis, thromboangiitis obliterans and Raynaud's disease.
- Venous thrombosis, particularly of the deep veins of the legs and pelvis, develops as a result of venous stasis, blood vessel damage and increased coagulability of the blood. The developing clot may fragment or break loose, becoming an embolus that typically lodges in the pulmonary circulation (pulmonary embolus). Chronic venous insufficiency and venous stasis may develop as a result of deep venous thrombosis.
- Prophylactic anticoagulation and mobilisation of the person are the primary preventive measures for venous thrombosis. Monitoring coagulation studies and assessing for evidence of bleeding (overt or covert) are important nursing measures for the person on anticoagulant therapy.
- Lymphadenopathy (enlarged lymph nodes), lymphangitis (inflammation of the lymph vessels) and lymphoedema are the most common disorders affecting the lymph system.

CONCEPT CHECK

1 A potential blood donor whose blood pressure is found to average 180/106 mmHg on two different readings tells the nurse, 'I don't understand how it could be so high—I feel just fine.' The appropriate response by the nurse is:

1 'This is probably just a false reading due to "white coat syndrome". Don't worry about it.'
2 'It is unusual that you are not having some symptoms such as severe headaches and nosebleeds.'
3 'High blood pressure often has few or no symptoms; that's why it is called the "silent killer".'
4 'You probably should have your blood pressure rechecked in 3 months or so and then follow up with your primary care provider if it is still high.'

2 The nurse teaching a person about a healthy diet determines that additional teaching is necessary when the person states:

1 'I'm glad I can still eat as much pasta as usual; I was afraid I would have to give up my weekly lasagna.'
2 'It will be a challenge to incorporate all those servings of fruit and vegetables into my diet.'
3 'Having a handful of nuts when the pre-dinner "munchies" hit is a good idea.'
4 'I will enjoy having frozen yogurt as my bedtime snack on occasion.'

3 The nurse teaching a person about his new prescription for Co-Diovan, a combination angiotensin II receptor blocker and thiazide diuretic, includes which of the following in his instructions? (Select all that apply.)

1 Use a potassium-based salt substitute to prevent hypokalaemia while taking this drug.
2 Use caution when rising from bed or a chair to prevent dizziness.
3 Take the drug at bedtime to reduce the risk of falling due to light headedness.
4 Report a persistent disruptive cough to your doctor.
5 You may stop taking this drug once your blood pressure is within the normal range for 2 months.

4 A person is complaining of new-onset calf and foot pain. The nurse notes that the leg below the knee is cool and pale and that dorsalis pedis and posterior tibial pulses are absent. The priority nursing intervention is to:

1 notify the doctor
2 place a cradle over the leg to prevent pressure from bedding
3 position the leg flat, supported in anatomical position
4 prepare to initiate heparin therapy

5 An 86-year-old person with a newly diagnosed abdominal aortic aneurysm wonders if he will need surgery to repair the aneurysm, even though he feels fine. The nurse's response is based on the knowledge that:

1 the risk of surgical repair is lower than the risk that the aneurysm will rupture
2 opening the abdomen for the surgical procedure greatly increases the risk of rupture

3 surgery is indicated for type A aneurysms
4 a percutaneously inserted endovascular stent may be considered because of his age

6 An expected assessment finding in a person with peripheral atherosclerosis would be:
1 pallor of the legs and feet when dependent
2 increased hair growth on the affected extremity
3 higher blood pressure readings in the affected extremity
4 impaired sensation in the affected extremity

7 All of the following are appropriate home care measures for the person with peripheral vascular disease. Place them in order of priority.
1 foot and leg care
2 smoking cessation
3 daily inspection of feet and legs
4 regular daily exercise
5 weight loss strategies

8 The nurse evaluates her teaching of a person admitted with deep venous thrombosis as effective when the person states:
1 'I'll use a hard-backed, upright chair when sitting instead of my recliner.'
2 'I'll get my blood drawn as scheduled and notify the doctor if I have any unusual bleeding or bruising.'
3 'I understand why I am not allowed to exercise for the next 6 weeks and will take it easy.'
4 'I'll have my wife buy a low-cholesterol cookbook and we'll make an appointment with the dietitian to learn about a low-fat, low-cholesterol diet.'

9 A person with visible varicose veins tells the nurse that she wants to have surgery to remove them, because 'my legs ache every evening and they are really ugly!'. The most appropriate response would be:
1 'Often measures such as elevating your legs and elastic stockings can relieve the discomfort associated with varicose veins.'
2 'Surgery will have a good cosmetic effect, but will not relieve the discomfort associated with varicose veins.'
3 'All varicose veins should be surgically removed to restore adequate blood flow to your legs and prevent gangrene.'
4 'Surgery is never indicated unless the varicose veins are interfering with circulation. Have you tried cosmetic measures to cover them up?'

10 Which of the following nursing interventions is of highest priority for the person with lymphoedema?
1 Elevate affected extremities at night.
2 Assist to don elastic compression stockings during the day.
3 Carefully dry and apply emollient lotion to affected extremities after bathing.
4 Reinforce the importance of taking prescribed diuretics.

CHAPTER 32

NURSING CARE OF PEOPLE WITH HAEMATOLOGICAL DISORDERS

LIZ RYAN

KEY TERMS

LEARNING OUTCOMES

- Relate changes in erythrocyte morphology to the pathophysiological effects resulting in red blood cell disorders.
- Identify the care and health management principles for individuals experiencing red blood cell disorders.
- Describe the main types of leukaemia, and examine their major health management principles.
- Discuss indications, complications and management practices for a person receiving bone marrow and stem cell transplant.
- Differentiate between Hodgkin's disease and non-Hodgkin's lymphoma.
- Compare and contrast the pathophysiology, manifestations and management for people experiencing bleeding disorders.

CLINICAL COMPETENCIES

- Assess effects of haematological disorders and prescribed treatments on a person's functional health status.
- Monitor and document continuing assessment data, including laboratory test results, subjective and objective information, and reporting data outside the normal or expected range.
- Based on knowledge of pathophysiology, prescribed treatment and assessed data, identify and prioritise nursing diagnoses for people with haematological disorders.
- Use nursing research and evidence-based practice to identify and implement individualised nursing interventions for the person with a haematological disorder.
- Safely and knowledgeably administer prescribed medications and treatments for people with haematological disorders.
- Collaborate with the interprofessional care team to plan and provide coordinated, effective care for people with haematological disorders.
- Provide appropriate teaching for people with haematological disorders, evaluating learning and the need for continued reinforcement of information.
- Use continuing assessment data to revise the plan of care as needed to restore, maintain or promote functional health in the person with a haematological disorder.

Disorders affecting blood and blood-forming organs have effects that range from minor disruptions in daily activities to major life-threatening crises. People with haematological disorders need holistic nursing care, including emotional support and care for problems involving major body systems.

This chapter focuses on health changes resulting from changes in red cells, white cells, platelets and clotting factors. Before proceeding with this chapter, read Chapter 28 which provides a review of the physiology of blood and its formation as well as important information about assessing those with haematological disorders.

RED BLOOD CELL DISORDERS

Red blood cells (RBCs) transport oxygen to body tissues and help return carbon dioxide to the lungs for excretion. Alterations in the number, size, shape or composition of RBCs affect their ability to effectively carry out these functions. Anaemia, the most common RBC disorder, is an abnormally low RBC count or reduced haemoglobin content. Polycythaemia is an abnormally high RBC count.

THE PERSON WITH ANAEMIA

Anaemia is an abnormally low number of circulating RBCs, low haemoglobin concentration, or both. Decreased numbers of circulating RBCs is the usual cause of anaemia. This may result from blood loss, inadequate RBC production or increased RBC destruction. Insufficient or defective haemoglobin within RBCs contributes to anaemia. Depending on its severity, anaemia may affect all major organ systems.

FAST FACTS

- Iron deficiency anaemia, a nutritional anaemia, is the most common type of anaemia.
- Blood loss anaemia may be acute, resulting from haemorrhage, or chronic, resulting from chronic blood loss (e.g. menstrual flow, slow GI bleeding).

Physiology review

As blood flows through the pulmonary vascular system, oxygen diffuses from alveoli into capillary blood. The majority of the oxygen binds reversibly with the haemoglobin in red blood cells; only about 3% of the oxygen remains in solution in the blood. When the blood reaches the capillaries serving body tissues, oxygen is released from the haemoglobin molecule and diffuses out of the capillary to reach the cells. The amount of oxygen that reaches the tissues depends on a number of factors, including:

- available oxygen in the alveoli
- diffusing surface and capacity of the lungs
- number of red blood cells and the amount and type of haemoglobin they contain
- ability of the cardiovascular system to transport blood and oxygen to the tissues.

For more information about red blood cells and haemoglobin, and their production and function, see Chapter 28.

Pathophysiology and manifestations

A number of different pathological mechanisms can lead to anaemia (see Box 32.1). Regardless of the cause, every type of anaemia reduces the oxygen-carrying capacity of the blood due to a deficiency of RBCs or haemoglobin, leading to tissue hypoxia. The resulting effects on a person depend on the severity of the anaemia, how quickly it develops and other factors such as age and health status.

When anaemia develops gradually and the RBC reduction is moderate, successful compensatory mechanisms may result in few symptoms except when the oxygen needs of the body increase due to exercise or infection. Symptoms develop as

BOX 32.1 Pathophysiological mechanisms of anaemia

Decreased RBC production

- Altered haemoglobin synthesis
- Iron deficiency
- Thalassaemia
- Chronic inflammation
- Altered DNA synthesis
- Vitamin B_{12} or folic acid malabsorption or deficiency
- Bone marrow failure
- Aplastic anaemia (stem cell dysfunction)
- Red cell aplasia
- Myeloproliferative leukaemia
- Cancer metastasis, lymphoma
- Chronic infection or inflammation, physical and emotional fatigue

Increased RBC loss or destruction

- Acute or chronic blood loss
- Haemorrhage or trauma
- Chronic gastrointestinal bleeding, menorrhagia
- Increased haemolysis
- Hereditary cell membrane disorders
- Defective haemoglobin—sickle cell anaemia or trait
- Pyruvate kinase (PK) or glucose-6-phosphate dehydrogenase (G6PD) deficiency affecting glycolysis or cell oxidation
- Immune mechanisms and disorders (e.g. blood reaction, hypersensitivity responses, autoimmune disorders)
- Splenomegaly and hypersplenism
- Infection
- Erythrocyte trauma (e.g. due to cardiopulmonary bypass, haemolytic uraemic syndrome)

RBCs and haemoglobin levels are further reduced. Pallor of the skin, mucous membranes, conjunctiva and nail beds develops as a result of blood redistribution to vital organs and lack of haemoglobin (see Figure 32.1). As tissue oxygenation decreases, the heart and respiratory rates rise in an attempt to increase cardiac output and tissue perfusion. Tissue hypoxia may cause angina, fatigue, dyspnoea on exertion and night cramps. It also stimulates erythropoietin release; increased erythropoietin activity stimulates RBC production in the bone marrow and may lead to bone pain. Cerebral hypoxia can lead to headache, dizziness and dim vision. Heart failure may develop in severe anaemia.

With rapid blood loss, blood volume is decreased as well as the oxygen-carrying capacity of the blood. Initial manifestations include tachycardia and tachypnoea; the skin may be pale, cool and clammy as peripheral vessels constrict to maintain blood flow to the heart and brain. With significant blood loss, signs of circulatory shock may occur, including hypotension, tachycardia, decreased level of consciousness and oliguria. With chronic bleeding, fluid shifts from the interstitial spaces into the vessels, in an effort to maintain blood volume. Blood viscosity is reduced, which may result in a systolic heart murmur. See the following multisystem effects of anaemia.

Anaemia is categorised by cause: blood loss, nutritional, haemolytic and bone marrow suppression. The pathophysiology and specific manifestations of these types of anaemias follow.

Blood loss anaemia

When anaemia results from acute or chronic bleeding, RBCs and other blood components (such as iron) are lost from the body. With acute blood loss, circulating volume decreases. As a result, cardiac output falls. Compensatory mechanisms are activated to maintain the cardiac output: the heart rate increases and peripheral blood vessels constrict. Vessels in the liver, a blood storage organ, also constrict, increasing circulating volume. Fluid shifts from the interstitial spaces into the vascular compartment to maintain blood volume, diluting the cellular components of the blood and reducing its viscosity. If haemorrhage continues, compensatory mechanisms become less effective, increasing the risk of shock and circulatory failure (see Chapter 10).

FIGURE 32.1 ■ The skin of the person with anaemia appears pale beside that of a person with a normal haemoglobin and haematocrit

Source: ©Westminster Hospital/Science Source.

In acute blood loss, circulating RBCs are of normal size and shape (*normocytic*). Early in the haemorrhage, the RBC count, haemoglobin and haematocrit may be normal; as fluid shifts from the interstitial space into the vascular space to maintain circulating volume, the RBC count, haemoglobin and haematocrit fall. If sufficient iron is available, haemoglobin levels and the number of circulating RBCs return to normal within 3 to 4 weeks after the bleeding episode. Chronic blood loss, on the other hand, depletes iron stores as RBC production attempts to maintain the RBC supply. The resulting RBCs are *microcytic* (small) and *hypochromic* (pale).

Nutritional anaemias

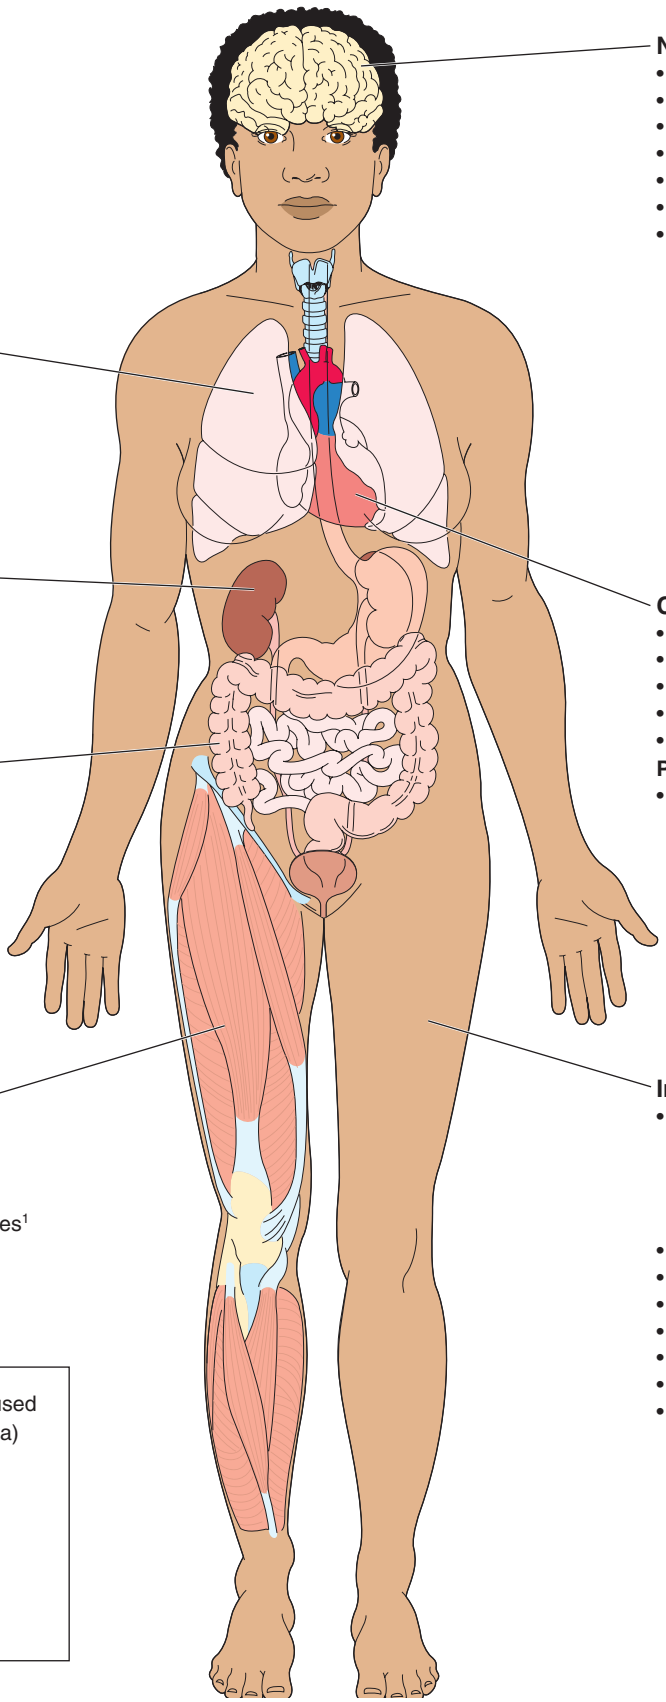
A number of different nutrients are required for normal red blood cell development (erythropoiesis). Iron is a key nutrient necessary for haemoglobin synthesis. In addition, adequate supplies of protein (and its building blocks, amino acids), vitamins and other minerals are required. The B group vitamins, particularly B_{12} (cobalamin) and folate (B_9), play a key role in RBC development. Vitamins C and E are also necessary. Nutritional anaemias result from nutrient deficits that affect RBC formation or haemoglobin synthesis. The nutrient deficit may be caused by inadequate diet, malabsorption of the nutrient, or an increased need for the nutrient. The most common types of nutritional anaemias are iron deficiency anaemia, vitamin B_{12} anaemia and folic acid deficiency anaemia. Vitamin B_{12} and folic acid anaemias are sometimes called *megaloblastic* anaemias, because enlarged nucleated RBCs called megaloblasts are seen in these anaemias.

IRON DEFICIENCY ANAEMIA **Iron deficiency anaemia** is the most common type of anaemia. It develops when the supply of iron is inadequate for optimal RBC formation, as the body cannot synthesise haemoglobin without iron. Normally, the body efficiently recycles and stores iron, reusing much of the iron contained in RBCs that are removed from circulation due to age or damage. However, small amounts of iron are continually lost in the faeces; therefore adequate iron intake is necessary for normal haemoglobin synthesis and RBC production. Iron deficiency anaemia results in fewer numbers of RBCs, microcytic and hypochromic RBCs, as well as malformed RBCs (*poikilocytosis*) (see Figure 32.2).

Excessive iron loss due to chronic bleeding is the usual cause of iron deficiency anaemia in adults. Menstrual blood loss is the most common cause in adult females. Iron deficiency anaemia also may result from inadequate dietary iron intake (less than 1 mg/day), malabsorption syndromes or the increased iron requirements associated with pregnancy and lactation. Box 32.2 summarises common causes of iron deficiency anaemia.

Iron deficiency anaemia is particularly common in older adults. Chronic, occult (hidden) blood loss may occur from slowly bleeding peptic ulcers, gastrointestinal inflammation,

MULTISYSTEM EFFECTS OF ANAEMIA



Neurological
- Paraesthesias[4]
- Proprioception deficits[4]
- Headache[5]
- Fainting[5]
- Forgetfulness[5]
- Pain[6]
- Behavioural disturbances (pica)[3]

Respiratory
- Increased rate
- Dyspnoea on exertion

Urinary
- Haemoglobinuria[7]

Cardiovascular
- Tachycardia
- Palpitations
- Systolic murmur
- Ventricular hypertrophy
- Angina

Potential complication
- Heart failure[6]

Gastrointestinal
- Diarrhoea[4]
- Anorexia[5]
- Nausea[5]
- Gallstones[6]
- Splenomegaly[1]
- Abdominal pain[6]

Integumentary
- Pallor
  - Skin
  - Mucous membranes
  - Conjunctiva
  - Nail beds
- Jaundice[1]
- Petechiae[2]
- Purpura[2]
- Spoon-shaped nails[3]
- Cheilosis[3]
- Sore, beefy red tongue[4]
- Chronic leg ulcers[6]

Musculoskeletal
- Night cramps[5]
- Bone pain
- Joint pain[6]
- Bone deformity and fractures[1]

Key (symptoms usually caused by a specific form of anaemia)
1 Haemolytic anaemias
2 Aplastic anaemia
3 Iron deficiency anaemia
4 Pernicious anaemia
5 Vitamin B_{12} anaemia
6 Sickle cell anaemia
7 G6PD anaemia

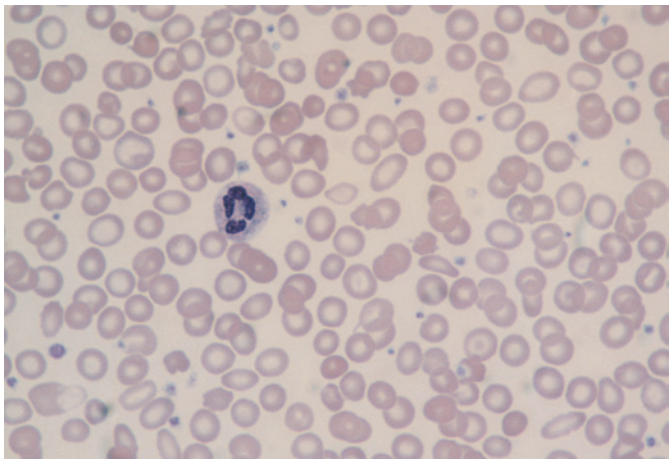


FIGURE 32.2 ■ A blood smear showing RBCs characteristically seen in iron deficiency anaemia. Note the pale colour of the RBCs (hypochromic). Many of the cells also are smaller than normal (microcytic) and misshapen, reducing their oxygen-carrying capacity

Source: © Dr E. Walker/Science Source.

BOX 32.2 Causes of iron deficiency anaemia

- Dietary deficiencies
- Vegetarian diet
- Inadequate protein intake
- Decreased absorption
- Partial or total gastrectomy
- Chronic diarrhoea
- Malabsorption syndromes
- Increased metabolic requirements
- Pregnancy
- Lactation
- Blood loss
- Gastrointestinal bleeding (especially due to ulcers or chronic aspirin use)
- Menstrual losses
- Chronic haemoglobinuria

haemorrhoids and cancer. Inadequate dietary iron intake also contributes to anaemia in the older adult. Access to transportation may limit fresh food consumption, a factor contributing to poor iron intake among all adults, especially people with limited or fixed incomes.

Manifestations In addition to the general manifestations of anaemia described earlier, chronic iron deficiency may lead to brittle, spoon-shaped nails; cheilosis (cracks at the corners of the mouth); a smooth, sore tongue; and *pica* (a craving for unusual substances, such as clay or starch).

VITAMIN B_{12} DEFICIENCY ANAEMIA

Vitamin B_{12} is necessary for DNA synthesis and is almost exclusively found in foods derived from animals. *Vitamin B_{12} deficiency anaemia* occurs when inadequate vitamin B_{12} is consumed or, more commonly, when it is poorly absorbed from the gastrointestinal tract. Deficiency of this vitamin impairs cell division and maturation of the cell nucleus, especially in rapidly proliferating RBCs. As a result, macrocytic (large), misshapen (oval rather than concave) RBCs with thin membranes are produced. Great numbers of these large, immature RBCs enter the circulation. These cells are fragile, incapable of carrying adequate amounts of oxygen and have a shortened lifespan.

Failure to absorb dietary vitamin B_{12} is called **pernicious anaemia**. It develops due to lack of intrinsic factor, a substance secreted by the gastric mucosa. Intrinsic factor binds with vitamin B_{12} and travels with it to the ileum, where the vitamin is absorbed. In the absence of intrinsic factor, vitamin B_{12} cannot be absorbed into the body, most commonly seen in elderly people.

Vitamin B_{12} deficiency may also result from other malabsorption disorders and dietary factors. Resection of the stomach or ileum, loss of pancreatic secretions and chronic gastritis can affect vitamin B_{12} absorption. Dietary deficiencies of vitamin B_{12} are rare, usually occurring only among strict vegetarians.

Manifestations Manifestations of vitamin B_{12} deficiency anaemia develop gradually as bodily stores of the vitamin are depleted. Pallor or slight jaundice and weakness develop. In pernicious anaemia, a smooth, sore, beefy red tongue and diarrhoea may occur. Because vitamin B_{12} is important for neurological function, paraesthesia (altered sensations, such as numbness or tingling) in the extremities and problems with proprioception (the sense of one's position in space) develop. These manifestations may progress to difficulty maintaining balance due to spinal cord damage. Central nervous system (CNS) manifestations of relatively short duration (a few months) are reversible with treatment, but may be permanent if treatment is delayed (Katzung, Masters & Trevor, 2012; Papadakis, McPhee & Rabow, 2013).

FOLIC ACID DEFICIENCY ANAEMIA

Like vitamin B_{12}, folic acid is required for DNA synthesis and normal maturation of red blood cells. *Folic acid deficiency anaemia* is characterised by fragile, megaloblastic (large and immature) cells. Folic acid is found in green leafy vegetables, fruit, cereals and meats, and is absorbed from the intestines.

Folic acid deficiency anaemia due to inadequate intake is more common among people who are chronically undernourished. This includes older adults, alcoholics and the drug addicted. Alcoholics are especially at risk because alcohol suppresses folate metabolism, which forms folic acid. Increased folic acid requirements also may lead to anaemia, with pregnant women at greatest risk. Infants and teenagers can also develop temporary folic acid deficiencies during periods of rapid growth. Impaired folic acid absorption and metabolism can cause folic acid deficiency anaemia. Malabsorption disorders, such as coeliac sprue (a hereditary gastrointestinal disorder characterised by inability to metabolise amino acids found in gluten), and certain medications, such as methotrexate and some chemotherapeutic agents, may be contributing factors. Causes of folic acid deficiency anaemia are summarised in Box 32.3.

BOX 32.3 Causes of folic acid deficiency anaemia

- Inadequate dietary intake
  At risk:
  a. Older adults
  b. Alcoholics
  c. People receiving total parenteral nutrition (TPN)
- Increased metabolic requirements
  At risk:
  a. Pregnant women
  b. Infants and teenagers
  c. People undergoing haemodialysis
  d. People with forms of haemolytic anaemia
- Folic acid malabsorption and impaired metabolism
  a. Coeliac sprue
  b. Chemotherapeutic agents, folate antagonists (methotrexate, pentamidine) or anticonvulsants
  c. Alcoholism

Manifestations The manifestations develop gradually as folic acid stores are depleted. Signs and symptoms may include pallor, progressive weakness and fatigue, shortness of breath and heart palpitations. Manifestations similar to those associated with vitamin B_{12} anaemia, such as glossitis, cheilosis and diarrhoea, are common. No neurological symptoms occur with folic acid deficiency anaemia, thus helping to differentiate it from vitamin B_{12} deficiency anaemia. These two nutritional anaemias do, however, sometimes coexist.

Maternal levels of folic acid are strongly associated with the prevention of neural tube defects (NTD). NTDs, including spina bifida, encephalocoele and anencephaly, result from the failure of the spinal cord or brain to develop normally during early foetal development, often before pregnancy is recognised. The seriousness of these abnormalities is reflected by the fact that fewer than 40% of babies affected survive to birth. People born with an NTD, especially those with spina bifida, will experience lifelong disability. Hence the National Health and Medical Research Council (2005) recommends folic acid supplements for 3 months preconception and during the first trimester of pregnancy.

Haemolytic anaemias

Haemolytic anaemias are characterised by premature destruction (*lysis*) of RBCs. When RBCs break down, iron and other by-products of their destruction remain in the plasma. RBC lysis (haemolysis) may occur within the circulatory system or due to phagocytosis by white blood cells (WBCs) such as circulating monocytes and macrophages in the spleen. In response to haemolysis, the haematopoietic activity of bone marrow increases, leading to increased reticulocytes (immature RBCs) in circulating blood. Most types of haemolytic anaemia are characterised by normocytic and normochromic RBCs.

There are many different causes of haemolytic anaemia (see Box 32.4). The cause may be *intrinsic*, arising from disorders within the RBC itself, or *extrinsic*, originating outside the RBC. Intrinsic disorders include cell membrane defects, defects in haemoglobin structure and function, and inherited enzyme deficiencies. See the accompanying 'Focus on cultural diversity' box for more information about inherited intrinsic RBC disorders associated with haemolytic anaemia. Extrinsic causes of haemolytic anaemia include drugs, bacterial and other toxins, and trauma. This section discusses sickle cell anaemia, thalassaemia, acquired haemolytic anaemia and glucose-6-phosphate dehydrogenase (G6PD) anaemia.

BOX 32.4 Causes of haemolytic anaemia

Intrinsic
- RBC cell-membrane defects
- Haemoglobin structure defects (e.g. sickle cell anaemia, thalassaemia)
- Inherited enzyme defects (e.g. G6PD deficiency (glucose-6-phosphate dehydrogenase deficiency))

Extrinsic
- Drugs, chemicals
- Toxins and venoms
- Bacterial and other infections
- Trauma, burns
- Mechanical damage (prosthetic heart valves)

SICKLE CELL ANAEMIA **Sickle cell anaemia** is a hereditary, chronic haemolytic anaemia. It is characterised by episodes of *sickling*, during which RBCs become abnormally crescent shaped. The disorder is transmitted as an autosomal recessive genetic defect (see Figure 32.3). This defect causes synthesis of an abnormal form of haemoglobin (HbS) within red blood cells. Sickle cell anaemia can significantly shorten lifespan, with most deaths occurring due to infection (Huether & McCance, 2013).

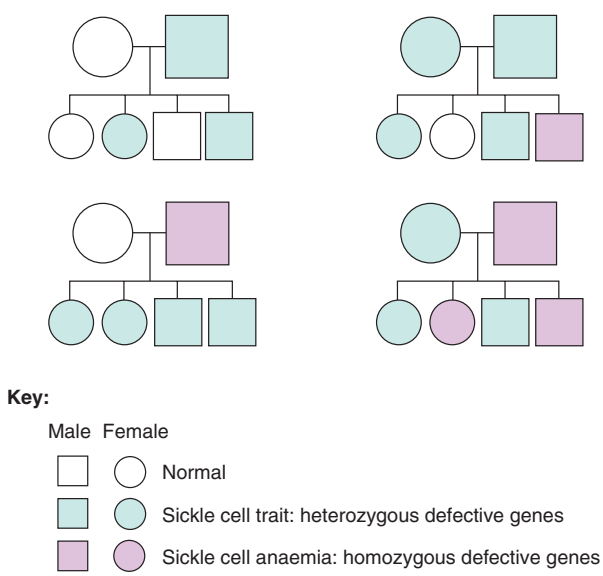

FIGURE 32.3 ■ Inheritance pattern for sickle cell anaemia

The disease is one of the most common inherited conditions worldwide and is most common among people from African, Middle Eastern and Southern Europe populations, as well as from India, Pakistan, South America and the Caribbean (see 'Focus on cultural diversity' box below). However, in Australia this disease is quite rare, with the majority of cases originating from New South Wales. Of the children born in Australia with sickle cell anaemia, more than half were from South-East Asia and the Middle East (Argent et al., 2012).

The HbS gene changes the structure of the beta chain of the haemoglobin molecule. When hypoxaemia develops and HbS is deoxygenated, it crystallises into rod-like structures. Clusters of these rods form long chains that deform the erythrocyte into a crescent or sickle shape (see Figure 32.4). The sickled cells tend to clump together and obstruct capillary blood flow, causing ischaemia and possible infarction of surrounding tissue. See the following 'Pathophysiology illustrated: sickle cell anaemia'.

When normal oxygen tension is restored, the sickled RBCs resume their normal shape; that is, they 'unsickle'. Repeated episodes of sickling and unsickling weaken RBC cell membranes. The weakened RBCs are haemolysed and removed. Consequently, the normal lifespan of RBCs is greatly reduced in sickle cell anaemia, increasing the demand for RBC production. Conditions likely to trigger sickling include hypoxia, low environmental or body temperature, excessive exercise, anaesthesia, dehydration, infections or acidosis.

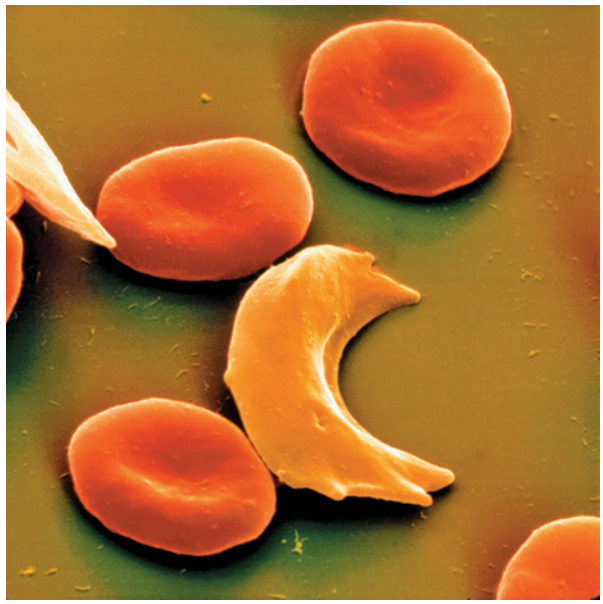

FIGURE 32.4 ■ Blood smear containing normal red blood cells and sickle cells

Source: © Eye of Science/Science Source.

Manifestations and complications The acute and chronic manifestations of sickle cell anaemia arise from episodes of RBC sickling. Sickling causes general manifestations of haemolytic anaemia, including pallor, fatigue, jaundice and irritability. Extensive sickling can precipitate a crisis due to occluded circulation, impaired erythropoiesis or sequestration of large amounts of blood in the liver or spleen.

A vaso-occlusive or thrombotic crisis occurs when sickling develops in the microcirculation. Obstruction of blood flow triggers vasospasm that halts all blood flow in the vessel. Lack of blood flow leads to tissue ischaemia and infarction. Vaso-occlusive crises are painful and last an average of 4 to 6 days. Infarction of small vessels in the extremities causes painful swelling of the hands and feet; large joints also may be affected. Priapism (persistent, painful erection of the penis) may develop. Abdominal pain may signal infarction of abdominal organs and structures. Infarction may affect bone marrow or lead to aseptic necrosis of affected bones. Stroke may result from cerebral vessel occlusion (Huether & McCance, 2013; Marieb & Hoehn, 2014). Skin ulcers may develop as the result of occluded vessels supplying the dermis. Repeated infarcts associated with sickling can affect the structure and function of nearly every organ system. People with sickle cell disease may develop an

FOCUS ON CULTURAL DIVERSITY Inherited haemolytic anaemias

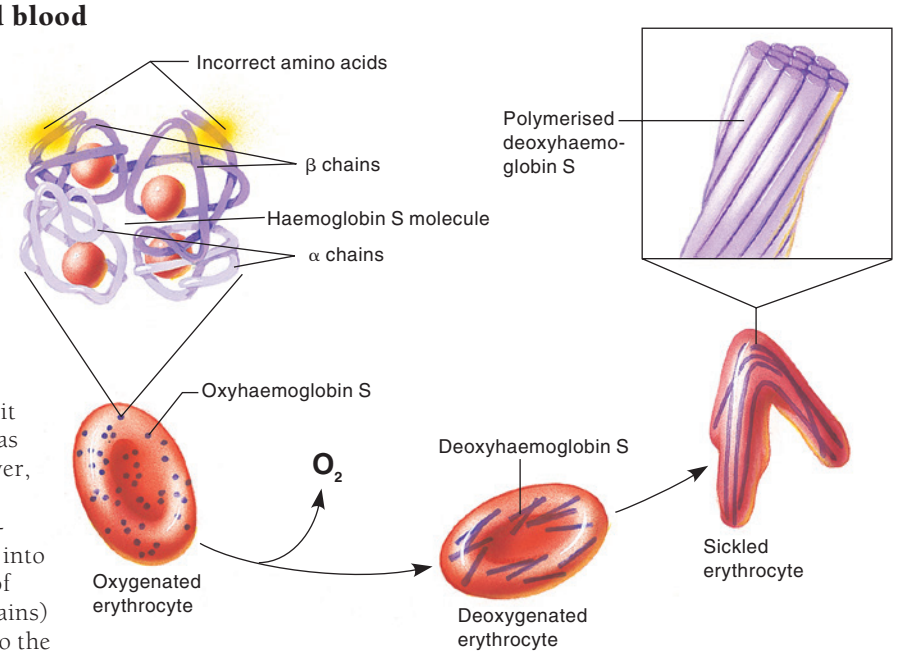
- Sickle cell disease is one of the most common inherited conditions of haemoglobin in the world.
- It is projected that the number of children born with sickle cell anaemia will increase from 305 800 in 2010 to 404 200 by 2050, with Nigeria and the Democratic Republic of Congo needing most assistance in prevention and management strategies (Piel et al., 2013).
- People from Central and South America, the Caribbean, Saudi Arabia and India, and Mediterranean countries such as Greece, Italy, Lebanon and Turkey, are affected. Additionally, peoples from sub-Saharan African countries are also at risk. The World Health Organization (WHO) (2013) estimates that 1 in 500 African-American births and 1 in every 1000 to 1400 Hispanic-American births are affected by sickle cell disease.
- Immigration of sub-Saharan African and Indian subcontinent peoples means that sickle cell disease is becoming more prevalent in Australia.
- Alpha-thalassaemia primarily affects people of South-East Asian, Indian, Chinese or Filipino ancestry. However, the disorder also occurs in other groups, including people from the Pacific Islands and New Zealand, and some Indigenous Australian communities in the Northern Territory and the north of Western Australia.
- Indigenous populations from the Kimberley region of Australia have the greatest incidences of thalassaemia in Australia (Babey & Manias, 2013).

Sickle cell anaemia

Haemoglobin S and red blood cell sickling

Sickle cell anaemia is caused by an inherited autosomal recessive defect in Hb synthesis. Sickle cell haemoglobin (HbS) differs from normal haemoglobin only in the substitution of the amino acid valine for glutamine in both beta chains of the haemoglobin molecule.

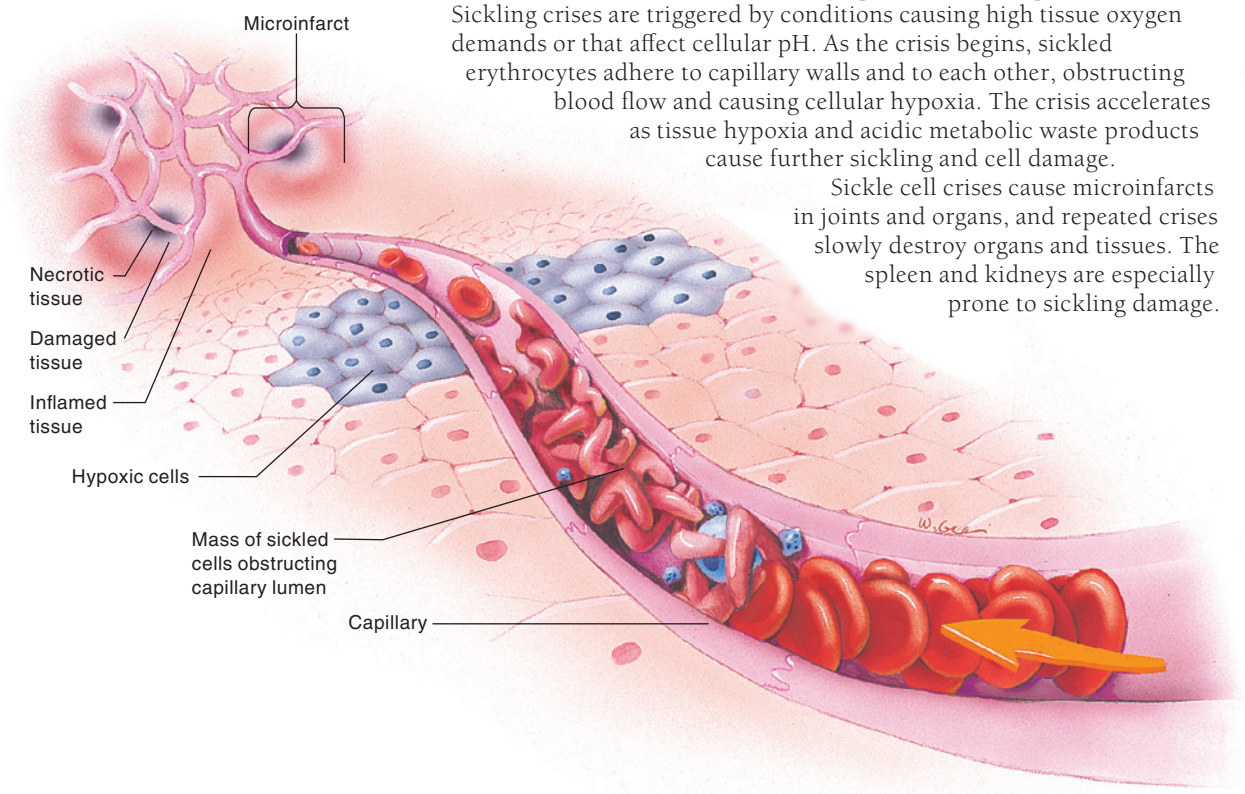
When HbS is oxygenated, it has the same globular shape as normal haemoglobin. However, when HbS offloads oxygen, it becomes insoluble in intracellular fluid and crystallises into rodlike structures. Clusters of rods form polymers (long chains) that bend the erythrocyte into the characteristic crescent shape of the sickle cell.



The sickle cell disease process

Sickle cell disease is characterised by episodes of acute painful crises. Sickling crises are triggered by conditions causing high tissue oxygen demands or that affect cellular pH. As the crisis begins, sickled erythrocytes adhere to capillary walls and to each other, obstructing blood flow and causing cellular hypoxia. The crisis accelerates as tissue hypoxia and acidic metabolic waste products cause further sickling and cell damage.

Sickle cell crises cause microinfarcts in joints and organs, and repeated crises slowly destroy organs and tissues. The spleen and kidneys are especially prone to sickling damage.



enlarged spleen and liver, renal insufficiency, gallstones and other manifestations of organ dysfunction. *Acute chest syndrome*, a symptom complex that includes fever, chest pain, an increasing WBC count and pulmonary infiltrates, may develop, as well as other pulmonary complications such as pneumonia, pulmonary infarction and pulmonary embolism. Treatment for sickle cell crisis is still predominately blood transfusion, but there have been recent advances in the use of nitric oxide inhalation for its vasodilatory properties (Marieb & Hoehn, 2014).

The shortened RBC lifespan and compromised erythropoiesis can lead to profound *aplastic anaemia* in sickle cell disease. *Sequestration crises* are marked by pooling of large amounts of blood in the liver and spleen. This sickle cell crisis only occurs in children, but is thought to be the cause of deaths in early childhood related to sickle cell disease (Huether & McCance, 2013).

THALASSAEMIA The **thalassaemias** are inherited disorders of haemoglobin synthesis in which either the alpha or the beta chains of the haemoglobin molecule are missing or defective. This leads to deficient haemoglobin production and fragile hypochromic, microcytic RBCs called *target cells* because of their distinctive bull's-eye appearance.

Thalassaemia usually affects certain populations. People of Mediterranean descent (southern Italy and Greece) are more likely to have beta-defect thalassaemias (often called *Cooley's anaemia* or Mediterranean anaemia). People of Asian ancestry, especially from Thailand, the Philippines and China, more often have alpha-defect thalassaemia. As with sickle cell anaemia, only one defective beta-chain forming gene may be present (*beta-thalassaemia minor*), causing mild symptoms; or both may be defective (*beta-thalassaemia major*), leading to more severe symptoms. Children with thalassaemia major rarely reach adulthood, although repeated blood transfusions may extend their lifespan (Huether & McCance, 2013). Four genes are responsible for alpha chain formation; one, two, three or all four may be defective. In the last case (*alpha-thalassaemia major*), death is inevitable and usually occurs in utero. Genetic studies and counselling are recommended for people at risk of this illness.

Manifestations and complications People with thalassaemia minor are often asymptomatic. When manifestations do occur, they include mild to moderate anaemia, mild splenomegaly, bronze skin colouring and bone marrow hyperplasia. The major form of the disease causes severe anaemia, heart failure and liver and spleen enlargement from increased red cell destruction. Fractures of the long bones, ribs and vertebrae may result from bone marrow expansion and thinning due to increased haematopoiesis. Jaundice may develop due to haemolysis, as well as hepatomegaly and splenomegaly. Accumulation of iron in the heart, liver and pancreas following repeated transfusions for treatment may eventually cause failure of these organs.

ACQUIRED HAEMOLYTIC ANAEMIA *Acquired haemolytic anaemia* results from haemolysis due to factors outside of the RBC. Causes of acquired haemolytic anaemias include:

- mechanical trauma to RBCs produced by prosthetic heart valves, severe burns, haemodialysis or radiation
- autoimmune disorders
- bacterial or protozoal infection
- immune-system-mediated responses, such as transfusion reactions
- drugs, toxins, chemical agents or venoms.

The manifestations of acquired haemolytic anaemia depend on the extent of haemolysis and the body's ability to replace destroyed RBCs. The anaemia itself often is mild to moderate as erythropoiesis increases to replace the destroyed RBCs. The spleen enlarges as it removes damaged or destroyed RBCs. If the breakdown of haem units exceeds the liver's ability to conjugate and excrete bilirubin, jaundice develops. When the condition is severe, bone marrow expands and bones may be deformed or may develop pathological fractures. The severity of generalised manifestations of anaemia (tachycardia, pallor, etc.) depends on the degree of anaemia and deficiency of tissue oxygenation.

GLUCOSE-6-PHOSPHATE DEHYDROGENASE (G6PD) ANAEMIA *Glucose-6-phosphate dehydrogenase (G6PD) anaemia* is caused by a hereditary defect in RBC metabolism. It is relatively common in people of African and Mediterranean descent. The defective gene is located on the X chromosome and therefore affects more males than females. There are many variations of this genetic defect.

G6PD is an enzyme that catalyses glycolysis, the process in which an RBC derives cellular energy. A defect in G6PD action causes direct oxidation of haemoglobin, damaging the RBC. Haemolysis usually occurs only when the affected person is exposed to stressors (e.g. drugs such as aspirin, sulfonamides or vitamin K derivatives) that increase the metabolic demands on RBCs. The G6PD deficiency impairs the necessary compensatory increase in glucose metabolism and causes cellular damage. Damaged RBCs are destroyed over a period of 7 to 12 days.

When exposed to a stressor triggering G6PD anaemia, symptoms develop within several days. These may include pallor, jaundice, haemoglobinuria (haemoglobin in the urine) and an elevated reticulocyte count. As new RBCs develop, counts return to normal.

Aplastic anaemia

In **aplastic anaemia**, the bone marrow fails to produce all three types of blood cells, leading to *pancytopenia*. Normal bone marrow is replaced by fat. Fortunately, aplastic anaemia is rare. *Fanconi anaemia* is a rare aplastic anaemia caused by defects of DNA repair. The underlying cause of about 50% of acquired aplastic anaemia is unknown (*idiopathic aplastic anaemia*). Other cases follow stem cell damage caused by exposure to radiation or certain chemical substances such as benzene, arsenic, nitrogen mustard, certain antibiotics (especially chloramphenicol) and chemotherapeutic drugs (Huether & McCance, 2013; Marieb & Hoehn, 2014). Aplastic anaemia also may occur with viral infections such as mononucleosis, hepatitis C and HIV disease.

In aplastic anaemia, the number of stem cells in the bone marrow is significantly reduced. The stem cell pool may be less

than 1% of normal when the disease is recognised. Anaemia develops as the bone marrow fails to replace RBCs that have reached the end of their lifespan. Remaining RBCs may be normochromic and normocytic, or may be large with increased mean corpuscular volume.

MANIFESTATIONS Manifestations of aplastic anaemia vary with the severity of the pancytopenia. Its onset usually is insidious, but may be sudden. Manifestations include fatigue, pallor, progressive weakness, exertional dyspnoea, headache and, ultimately, tachycardia and heart failure. Platelet deficiency leads to bleeding problems; bleeding gums, excessive bruising and nosebleeds may be the initial symptoms. A deficiency of white blood cells increases the risk of infection, causing manifestations such as sore throat and fever.

INTERPROFESSIONAL CARE

Ensuring adequate tissue oxygenation is the priority of care in treating anaemia. Specific therapy is determined by the underlying cause of the disorder. Usual treatments include medications, dietary modifications, blood replacement or supportive interventions. Table 32.1 outlines interprofessional care measures for selected types of anaemia.

Diagnosis

When anaemia is suspected, the following laboratory and diagnostic tests may be ordered:

- *Full blood count (FBC)* is done to determine blood cell counts, haemoglobin, haematocrit and red blood cell indices. The severity of the anaemia and the shape, volume and iron content of the RBCs can help determine the cause of anaemia.
- *Iron levels* and *total iron-binding capacity* are performed to detect iron deficiency anaemia. A low serum iron concentration and elevated total iron-binding capacity are indicative of iron deficiency anaemia.
- *Serum ferritin* is low due to depletion of the total iron reserves available for haemoglobin synthesis. Ferritin is an iron-storage protein produced by the liver, spleen and bone marrow. Ferritin mobilises stored iron when metabolic needs are higher than dietary intake.
- *Sickle cell test* is a screening test to evaluate haemolytic anaemia and detect HbS.
- *Haemoglobin electrophoresis* separates normal haemoglobin from abnormal forms. It is used to evaluate haemolytic anaemia, diagnose thalassaemia and differentiate sickle cell trait from sickle cell disease.
- *Schilling test* measures vitamin B_{12} absorption before and after intrinsic factor administration to differentiate between pernicious anaemia and intestinal malabsorption of the vitamin. A 24-hour urine sample is collected following administration of radioactive vitamin B_{12}. Lower than normal levels of the tagged B_{12} when intrinsic factor is given concurrently indicate malabsorption rather than pernicious anaemia.
- *Bone marrow examination* is done to diagnose aplastic anaemia. In aplastic anaemia, normal marrow elements are significantly decreased as they are replaced by fat cells. Nursing implications for bone marrow collection are described in the 'Nursing care of the person having bone marrow studies' box in Chapter 28.
- *Quantitative assay of G6PD* may be performed to confirm a diagnosis of glucose-6-phosphate dehydrogenase deficiency.

Medications

Medications used to treat anaemia depend on its cause. Iron replacement therapy is ordered for iron deficiency anaemia. Supplemental iron may be given by mouth or parenterally. Intravenous administration of iron is becoming more common, particularly in those with an acute deficiency and in anaemia associated with chronic GI blood loss, chronic renal failure and other chronic conditions that increase the need for blood cell production (e.g. cancers). When administering iron intravenously it needs to be diluted in normal saline and infused slowly to reduce the risk of anaphylaxis (MIMS, 2013). The risk of

LINKS TO NATIONAL PATIENT SAFETY STANDARDS

NSQHS Standard 7:
Blood and Blood Products

'The intention of this standard is to ensure that the patients who receive blood and blood products do so appropriately and safely.' (ACSQHC, 2011, p. 48)

Implementing this standard is achieved by the establishment of systems to ensure safe and appropriate prescription and administration of blood and blood products. These systems include processes facilitating accurate documentation, storage, transport, use and disposal. Effective communication regarding risks, benefits and use should exist between all individuals involved in a person's care (including the person themself and their significant others).

Caring for individuals experiencing haematological conditions will often result in the need to administer blood or blood products in order to manage the person's condition. As with any biological material, various risks are involved in all facets of this treatment. Efficient and appropriate systems are imperative to ensure the safety of not only the person receiving the product, but also any other individual involved in their care.

Source: © Australian Commission on Safety and Quality in Health Care.

TABLE 32.1 Interprofessional care focus for major anaemias

TYPE OF ANAEMIA	INTERPROFESSIONAL CARE
Iron deficiency anaemia	• Increased dietary intake of iron-rich foods • Oral or parenteral iron supplements
Vitamin B_{12} deficiency	• Increased dietary intake of foods containing vitamin B_{12} (e.g. meats, eggs and dairy products) • Oral or parenteral vitamin B_{12} supplements • Parenteral vitamin B_{12} for deficiency due to malabsorption or lack of intrinsic factor
Folic acid deficiency	• Increased dietary intake of foods rich in folic acid (folate) • Oral folic acid supplements • Folic acid supplements recommended for women who are pregnant or may become pregnant to prevent neural tube defects

Sickle cell anaemia	• Treatment is primarily supportive
	• Hydroxyurea 10–30 mg/kg per day
	• Sickle cell crisis:
	  • Rest
	  • Oxygen therapy to maintain SaO_2
	  • Narcotic analgesia
	  • Vigorous hydration
	  • Treatment of precipitating factors
	  • Nitric oxide inhalation
	• Acute chest syndrome:
	  • Careful hydration; haemodynamic monitoring
	  • Oxygen therapy
	  • Transfusion
	• Folic acid supplements
	• Blood transfusions during surgery or pregnancy as necessary
	• Genetic counselling recommended

Thalassaemia	• Regular blood transfusions • Folic acid supplements • Possible splenectomy • Genetic counselling
Aplastic anaemia	• Withdrawal of the causative agent, if known • Blood transfusions • Bone marrow transplant as indicated • Stem cell transplant—donor blood, umbilical cord blood, bone marrow sources

anaphylaxis is a major concern when iron dextran is given intravenously. Other parenteral iron solutions, including intravenous sodium ferric gluconate and iron sucrose (Venofer), carry a much lower risk of adverse and allergic reactions (Bryant & Knights, 2015; Crisp et al., 2013). For intramuscular administration of iron, a large deep muscle such as the ventrogluteal muscle is the preferred site. Utilising the Z track method of injection is recommended for the intramuscular administration of iron because it decreases irritation and staining and assists with sealing the medication in muscle tissue (Crisp et al., 2013).

Parenteral vitamin B_{12} is given when malabsorption or lack of intrinsic factor leads to vitamin B_{12} deficiency anaemia. Folic acid is ordered for women of childbearing age, pregnant women and those with folic acid deficiency or sickle cell anaemia to meet the increased demands of the bone marrow. Hydroxyurea, a drug that promotes foetal haemoglobin production, may be prescribed for people with sickle cell disease, particularly those with frequent crises or severe disease. Resulting increased levels of foetal haemoglobin interfere with the sickling process and reduce the incidence of painful crises. Nursing implications for people receiving iron, vitamin B_{12} and folic acid are found in the 'Medication administration' box below.

Erythropoietin may be ordered for people with low erythropoietin levels (e.g. those with chronic renal failure) and anaemia associated with other chronic diseases. Erythropoietin (Aranesp) is given subcutaneously or intravenously and may be given as often as three times a week in chronic renal failure. Because erythropoietin stimulates RBC production, adequate iron must be present. People receiving erythropoietin may require regular intravenous iron therapy as well.

Immunosuppressive therapy with antithymocyte globulin (ATG), corticosteroids and cyclosporine may be used to treat aplastic anaemia. Androgens may stimulate blood cell production in some people with aplastic anaemia. See Chapter 12 for more information about immunosuppression.

Nutrition

Dietary modifications are recommended for nutritional deficiency anaemias, such as iron deficiency anaemia, vitamin B_{12} deficiency anaemia or folic acid deficiency anaemia. Box 32.5 identifies good sources of dietary iron, folic acid and vitamin B_{12}.

MEDICATION ADMINISTRATION Drugs to treat anaemia

IRON SOURCES

Ferric carboxymaltose (Ferinject)
Ferrous sulfate (Ferro-Gradumet, Fefol, FGF)
Ferro fumerate (Ferro-tab)
Iron polymaltose (Ferrosig)
Iron sucrose (Venofer)

Iron preparations are normally taken by mouth and are absorbed from the gastrointestinal tract. They are given to treat anaemias resulting from iron deficiency or blood loss. When absorbed, iron combines with transferrin. This complex then is transported to the bone marrow and incorporated into haemoglobin.

Nursing responsibilities

- Prior to giving the drug, assess for use of drugs that might interact with iron (e.g. antacids, allopurinol, chloramphenicol, tetracyclines, vitamin E), gastrointestinal bleeding and manifestations of anaemia.
- Administer iron preparations with orange juice to enhance absorption.
- If using an elixir, give it through a straw to prevent staining the teeth.
- Monitor for manifestations of iron toxicity: nausea, diarrhoea or constipation; symptoms of anaphylactic shock (extreme cases).
- Monitor haemoglobin and reticulocyte counts.
- If the person is also taking tetracyclines, schedule the dose of iron 2 hours before the tetracycline (iron reduces the absorption of tetracyclines).
- When administering IM or IV, monitor closely for anaphylaxis.

Health education for the person and family

- Gastrointestinal side effects may be reduced by taking iron with food (but not milk, which decreases absorption).
- Stools may be dark green or black; this is harmless.
- Increase fluids and fibre in diet to decrease constipation.

VITAMIN B_{12} SOURCES

Cyanocobalamin oral, parenteral

Cyanocobalamin is used to treat vitamin B_{12} deficiencies or malabsorption and pernicious anaemia. It is rapidly absorbed when administered orally or by injection and it is stored in the liver. Intrinsic factor is necessary for absorption from the gastrointestinal tract.

Nursing responsibilities

- Do not expose crystalline injection to light.
- Assess for other drugs that might interfere with the therapeutic response: chloramphenicol, cimetidine, colchicine and timed-release potassium decrease its effectiveness.
- Do not mix cyanocobalamin in a syringe with other medications.
- Administer parenteral doses intramuscularly or deep subcutaneously to decrease local irritation.
- Monitor haemoglobin, RBC counts, reticulocyte counts and potassium levels.

Health education for the person and family

- A burning sensation with injection is temporary.
- Avoid alcohol, which interferes with absorption.
- If used to treat pernicious anaemia, the medication must be taken for life.

FOLIC ACID SOURCES

Folic acid (folate)

Synthetic folic acid is used to treat folic acid deficiency and megaloblastic or macrocytic anaemia. It is absorbed from the gastrointestinal tract and stored in the liver.

Nursing responsibilities

- Prior to giving the medication, assess for use of drugs that alter its effect: corticosteroids, methotrexate, oral contraceptives, phenytoin, sulfonamides.
- Do not mix folic acid with other medications in the same syringe.
- Monitor for possible hypersensitivity response of skin rash.

Health education for the person and family

- Large doses of folic acid may cause the urine to become darker yellow.
- Excess alcohol intake increases folic acid requirements.

Blood transfusion

Blood transfusions may be indicated to treat anaemias resulting from major blood loss, such as from trauma or major surgery and severe anaemia regardless of cause. In acute haemorrhage, whole blood may be given to replace both blood cells and volume. A unit of packed red blood cells may be given when anaemia is severe and the person demonstrates cardiovascular instability or compromise. Blood transfusions are fully discussed in Chapter 10.

Complementary therapies

Complementary healthcare practitioners may recommend specific plant enzymes to treat nutritional anaemias. There is limited quality evidence that complementary therapies can assist with the pathology or symptoms of anaemia.

Nursing care

For nursing care specific for a person with folic acid deficiency anaemia, see the accompanying nursing care plan.

Health promotion

Nursing measures to prevent anaemia focus on teaching good dietary habits to everyone, regardless of age. Stress the importance of consuming adequate amounts of iron, folate and the B vitamins. Provide a list of dietary sources of these nutrients. Discuss alternate iron sources with those with vegetarian diets and teach them that foods high in vitamin C enhance the

BOX 32.5 Dietary sources of iron, folic acid and vitamin B_{12}

Iron

Iron in the diet comes from two sources. *Haem iron* makes up about one-half of the iron from animal sources. *Non-haem iron* includes the remaining iron from animal sources and all the iron from plants, legumes and nuts. Haem iron promotes absorption of non-haem iron from other foods when both forms are consumed at the same time. Absorption of non-haem iron is also enhanced by vitamin C and inhibited by tea and coffee.

Sources of haem iron

- Beef
- Chicken
- Egg yolk
- Oysters
- Pork loin
- Turkey
- Veal

Sources of non-haem iron

- Bran flakes
- Brown rice
- Wholegrain breads
- Oatmeal
- Dried fruits
- Leafy green vegetables
- Dried beans

Sources of folic acid

- Green leafy vegetables
- Broccoli
- Organ meats
- Eggs
- Wheat germ
- Asparagus
- Liver
- Milk
- Yeast
- Kidney beans

Sources of vitamin B_{12}

- Liver
- Prawns and oysters
- Eggs
- Milk
- Kidney
- Meats (muscle)
- Cheese

absorption of iron from grains, legumes and other sources. Emphasise the importance of adequate iron intake in women of childbearing age and older adults. Stress the increased need for these nutrients during pregnancy and discuss strategies to ensure an adequate intake.

Assessment

Assessment data to collect for people with suspected anaemia include:

- *Health history:* complaints of shortness of breath with activity, fatigue, weakness, dizziness or fainting, palpitations; history of previous anaemia, bleeding episodes; menstrual history (if appropriate); medications; chronic diseases; usual diet and patterns of alcohol intake or cigarette smoking.
- *Physical examination:* general appearance, skin colour; vital signs, including temperature; heart and lung sounds; peripheral pulses, capillary refill; abdominal tenderness; obvious bleeding or bruising.
- *Diagnostic tests:* FBC, haemoglobin and haematocrit; bone marrow studies; specialised tests (e.g. haemoglobin electrophoresis, Schilling test).

Nursing diagnoses and interventions

Anaemia affects circulating oxygen levels and tissue oxygenation. Priority nursing diagnoses include activity intolerance, altered oral mucous membranes and self-care deficits. With acute blood-loss anaemia, risk of insufficient cardiac output also is a priority. People with sickle cell disease have specific needs related to the effects of the disease on tissue perfusion. See the section on disseminated intravascular coagulation later in this chapter for nursing interventions appropriate to ineffective tissue perfusion, associated pain and maintaining oxygenation.

Activity intolerance

Anaemia causes weakness and shortness of breath on exertion. These symptoms are due to decreased circulating oxygen levels secondary to low haemoglobin levels. Weakness, fatigue and/or vertigo may occur even during activities of daily living, including those associated with self-care, home life, job performance and social roles.

- Help identify ways to conserve energy when performing necessary or desired activities. *Modifying the approach to a particular activity may reduce cardiorespiratory symptoms and activity-related fatigue. Alternative ways of performing tasks (e.g. sitting when performing hygiene care and kitchen tasks) may reduce oxygen demands. In some cases, assistance from others is necessary to conserve energy and reduce symptoms.*
- Help the person and family establish priorities for tasks and activities. *Because family members may need to assume responsibility for additional tasks, the plan's success depends on mutually established goals.*
- Assist to develop a schedule of alternating activity and rest periods throughout the day. *Rest periods decrease oxygen needs, reducing strain on the heart and lungs and allowing restoration of homeostasis before further activities.*
- Encourage 8 to 10 hours of sleep at night. *Rest decreases oxygen demands and increases available energy for morning activities.*
- Monitor vital signs before and after activity. *Vital signs provide a measure of activity tolerance. Increased heart and respiratory rates or a change in blood pressure may indicate intolerance of the activity.*
- Discontinue activity if any of the following occurs:
  a. complaints of chest pain, breathlessness or vertigo
  b. palpitations or tachycardia that does not return to normal within 4 minutes of resting
  c. bradycardia
  d. tachypnoea or dyspnoea
  e. decreased systolic blood pressure.

  These changes may signify cardiac decompensation due to insufficient oxygenation. The intensity, duration or frequency of the activity needs to be reduced.

- Instruct the person not to smoke. *Smoking causes vasoconstriction and increases carbon monoxide levels in the blood, interfering with tissue oxygenation.*

Impaired oral mucous membrane

Glossitis and cheilosis may occur with nutritional deficiencies of iron, folate and vitamin B_{12}. The tongue and lips become very red and fissures or cracks may form at the corners of the mouth.

- Monitor condition of lips and tongue daily. *Glossitis and cheilosis increase the risk of bleeding and infection and may require medical treatment. Pain and discomfort may interfere with oral intake, further worsening the nutritional deficiency.*
- Use a mouthwash of saline, saltwater or half-strength peroxide and water to rinse the mouth every 2 to 4 hours. Avoid alcohol-based mouthwashes. *This cleanses and soothes oral mucous membranes. Alcohol-based mouthwashes further irritate and dry oral tissues.*
- Provide frequent oral hygiene (after each meal and at bedtime) with a soft-bristle toothbrush or sponge. *Removing food debris from painful fissures promotes comfort. A soft toothbrush reduces irritation or bleeding of oral mucosa. Keeping the oral cavity clean also reduces the risk of infection.*
- Apply a petroleum-based lubricating jelly or ointment to the lips after oral care. *Lubricating ointment helps to retain moisture, facilitate healing and protect the lips from other drying agents.*
- Instruct to avoid hot, spicy or acidic foods. *Such foods may further irritate and dry mucous membranes.*
- Encourage soft, cool, bland foods. *Foods that are soothing to the mucous membranes promote comfort and help maintain adequate food and fluid intake. Minimising oral pain may also promote compliance with oral care routines.*

NURSING CARE PLAN A person with folic acid deficiency anaemia

Iris Matthews is a 76-year-old widow who lives alone. She tells Lisa Kennedy RN, the practice nurse in the general practice surgery, that she liked to cook when her husband was alive, but preparing an entire meal just for herself seems senseless. She relates that her typical day's menu includes tea for breakfast, a ham sandwich and tea for lunch, a cup of soup, a few biscuits and a glass of milk for dinner.

ASSESSMENT

Mrs Matthews's nursing history includes a 9 kg weight loss since her husband died 8 months ago. She states that she sometimes has heart palpitations and always feels weak. Physical assessment shows: 37.1°C, P 110, R 22, BP 90/52. Skin warm, pale and dry. Diagnostic tests indicate folic acid deficiency anaemia. Mrs Matthews is started on an oral folic acid supplement and instructed about foods containing folic acid.

DIAGNOSES

- *Activity intolerance* related to weakness secondary to decreased tissue oxygenation.
- *Imbalanced nutrition: less than body requirements* related to lack of motivation to cook and understanding of nutritional needs, as manifested by weight loss of 9 kg and folic acid deficiency.
- *Deficient knowledge* related to lack of information about a well-balanced diet and foods containing folic acid.

PLANNING

- Discuss foods required for a well-balanced diet, as well as dietary sources of folic acid.
- Discuss the importance of taking the folic acid supplement. Advise to continue taking it even after she begins to feel better.

Expected outcomes

- Verbalise and understand the importance of taking folic acid supplements and eating a balanced diet.
- Gain at least 0.45 kg per week.
- Return to previous level of physical energy.
- Consume a balanced diet, including foods containing folic acid.

IMPLEMENTATION

- Develop a balanced dietary plan with Mrs Matthews that includes food preferences and foods that are easy and quick to prepare.
- Include foods that contain folic acid, or assist her in organising supplements.
- Help Mrs Matthews develop a schedule of activities that provides adequate rest and energy for cooking.

EVALUATION

Mrs Matthews gained 0.5 kg during the first week of treatment. She has met with a dietitian and has a better understanding of nutritional needs. She states that she can prepare hot meals when she schedules a rest period before and after lunch. She has provided written and verbal information about the folic acid supplement and diet. Mrs Matthews verbalises understanding, stating, 'I will continue to take the folic acid until the doctor tells me to stop. I'm beginning to enjoy cooking again, now that I have a reason to cook!' Ms Kennedy contacts the local seniors group to determine if Mrs Matthews is able to participate in the local Meals on Wheels program.

CRITICAL THINKING IN THE NURSING PROCESS

1. What is the pathophysiological basis for Mrs Matthews's abnormal vital signs during her initial assessment?
2. Design a week's menu that includes foods high in folic acid.
3. Why was Mrs Matthews placed on a folic acid supplement in addition to dietary modifications?
4. Why is the older adult at increased risk of developing folic acid deficiency anaemia? Consider physiological, economic and social factors.

REFLECTION ON THE NURSING PROCESS

1. Outline the most important communication and education points you have learned from this case study.
2. How can you use this information in your practice?

- Encourage eating four to six small meals daily with high protein and vitamin content. *Small, frequent meals may be better tolerated, increasing intake. Nutrient-rich meals promote healing of the mucous membranes.*

Risk of decreased cardiac output

Cardiac output may be affected by acute bleeding and volume loss or by heart failure resulting from severe anaemia. In addition, impaired tissue oxygenation leads to an increased respiratory rate and dyspnoea.

- Monitor vital signs, breath sounds and apical pulse. *Increased cardiac workload can affect the blood pressure, heart and respiratory rates. Increased blood flow can lead to heart murmur or abnormal heart sounds such as S_3 or S_4. Tachypnoea and dyspnoea may affect the depth of respirations, alveolar ventilation and blood and tissue oxygenation.*
- Assess for pallor, cyanosis and dependent oedema. *Blood is shunted to the vital organs, causing vasoconstriction of skin vessels. This, in addition to lower levels of haemoglobin, causes pallor. Cyanosis, especially of the lips and nail beds, indicates inadequate oxygenation of blood. Dependent oedema occurs in response to right ventricular failure.*

CONSIDERATION FOR PRACTICE

Report signs of decreased cardiac output to the medical officer. Severe anaemia can lead to heart failure, necessitating additional treatment.

- Closely monitor for manifestations of anaphylaxis (urticaria, erythema or flushing, oedema, wheezing, dyspnoea, nausea and vomiting, anxiety) when administering parenteral iron preparations, particularly iron dextran. Immediately notify the doctor and prepare to administer prescribed drugs such as adrenaline as ordered. Institute cardiopulmonary resuscitation measures as necessary. *Anaphylaxis, a systemic type I hypersensitivity (allergic) reaction, is a risk when administering parenteral iron preparations—iron dextran, in particular. Anaphylaxis can lead to severe cardiopulmonary compromise, necessitating emergency measures to preserve life.*

Self-care deficit

Energy expenditures for activities of daily living (ADLs) may cause oxygen demands to exceed supply in the person with severe anaemia.

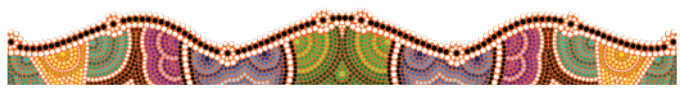
- Assist with ADLs, such as bathing, grooming and eating, as needed. *Assistance decreases energy expenditures and tissue requirements for oxygen, reducing cardiac workload.*
- Discuss the importance of rest periods prior to such activities as dressing. *Rest reduces oxygen demand and cardiac workload. The person who is able to perform self-care in ADLs maintains independence, self-esteem and morale.*

Community-based care

With the exception of anaemia resulting from acute haemorrhage, most people with anaemia are treated in the home and community setting. Include the following topics when preparing the person and family for home care:

- nutritional strategies to address deficiencies
- prescribed medications, vitamins or mineral supplements, and their appropriate use, intended effect, possible adverse effects, and interactions with food or other medications
- energy conservation strategies
- other recommended treatment measures and follow up
- if the anaemia is genetically transmitted, such as sickle cell anaemia, include inheritance patterns of the disorder, symptoms of crisis and manifestations to report to the doctor.

Provide referrals for counselling to facilitate decisions about pregnancy as indicated. Also refer for nutritional assistance and teaching, home healthcare or assistance with self-care and home maintenance activities as indicated. Older adults with nutritional anaemias may benefit from community services such as Meals on Wheels.



THE PERSON WITH MYELODYSPLASTIC SYNDROME

Myelodysplastic syndrome (MDS) is a group of blood disorders characterised by abnormal-appearing bone marrow and cytopenia (low numbers of circulating blood cells). MDS is not a single disease; at least five variations of the disorder have been identified. Anaemia that does not respond to treatment (*refractory anaemia*) is a characteristic of most forms of myelodysplasia.

Idiopathic MDS primarily affects older adults; men have a slightly higher incidence of the disorder than women. Risk factors for secondary MDS include exposure to environmental toxins such as cigarette smoke, benzene, radiation, radiation therapy or chemotherapy for cancer treatment, and other anaemias such as aplastic anaemia or, more rarely, Fanconi's anaemia (American Cancer Society, 2011; National Heart, Lung and Blood Institute, 2012).

FAST FACTS

- Idiopathic or primary MDS accounts for 70–80% of all identified cases.
- 20–30% of MDS cases occur as a secondary condition, related to factors such as age, smoking or exposure to environmental toxins, radiation, chemotherapy or other risk factors (Chantal et al., 2014; Demakos & Linebaugh, 2005).

Pathophysiology

MDS is a stem cell disorder in which stem cells fail to reproduce and differentiate into the various types of blood cells. The genetic components of stem cells (nuclear DNA and/or

mitochondrial DNA) are altered, The bone marrow loses its ability to produce normal blood cells, instead producing abnormal (*dysplastic*) cells, and ineffective haematopoiesis results. With significant alterations, leukaemia (proliferation of abnormal white blood cells) may develop in people with MDS.

Manifestations

Anaemia is the predominant early manifestation of MDS. The person may develop symptoms of the anaemia with increasing fatigue, weakness, dyspnoea and pallor. In many cases, the disorder is asymptomatic, identified when a routine blood test shows anaemia. Splenomegaly may develop, leading to discomfort and a feeling of fullness in the left upper quadrant of the abdomen. Hepatomegaly also may develop, leading to right upper quadrant discomfort. Thrombocytopenia can lead to abnormal bleeding tendencies, and neutropenia increases the risk of infection (Svensson et al., 2014).

INTERPROFESSIONAL CARE

People with MDS require long-term supportive care and therapy to maintain their quality of life. Stem cell transplant offers the only real hope for cure in MDS. See the 'Interprofessional care' section of 'The person with leukaemia' later in this chapter for more information about stem cell transplant and associated nursing care.

Diagnosis

- The *FBC* reveals anaemia. Although anaemia may be the only abnormality of the blood count, the WBC count also may be low, as may the platelet count. Abnormalities of size and shape may be noted in all blood cells.
- The *bone marrow* often appears normal, although precursor cells may have an abnormal appearance. Increased numbers of myeloblasts (granulocyte precursor cells) may be present in the bone marrow.
- *Serum erythropoietin*, *vitamin B_{12}*, *serum iron*, *total iron-binding capacity*, *ferritin levels* and *RBC folate levels* are drawn to help guide supportive therapy.

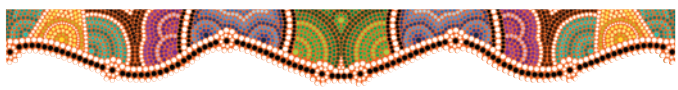
Treatment

Management of MDS is based on the severity of the disease. Several classification systems are available, including the French–American–British (FAB) classification system, the International Prognostic Scoring System (IPSS) and the World Health Organization classification system (Leukaemia Foundation, 2014). These systems are used to guide therapy for the person with MDS. One third of newly diagnosed patients with MDS are classed as high risk, with poor prognosis and survival rates (Svensson et al., 2014).

All those with MDS require monitoring, with regular GP visits and pathology evaluations. Psychosocial support is provided to assist the person and their family in dealing with a chronic, progressive and ultimately fatal disease.

People with MDS may require frequent red blood cell transfusions to treat the predominant anaemia. Each unit of packed RBCs contains 250 to 300 mg of iron. The body is unable to excrete this excess iron, so it accumulates, leading to problems such as endocrine dysfunction, cirrhosis, pericarditis and heart failure. *Iron chelation therapy* is used to remove excess iron from the body. Desferrioxamine (Desferal) is administered by slow intravenous infusion or continuous subcutaneous infusion using an infusion pump to maintain a normal or negative iron balance. This drug is relatively safe, although local skin reactions such as rash and urticaria may develop. An oral form of the drug, ferriprox, is available but is not widely used.

Blood cell growth factors may be administered to stimulate stem cell development in MDS, although the response rate is low. Platelet transfusions are given when bleeding occurs due to low platelet levels. Antibiotic therapy is initiated for bacterial infections (Leukaemia Foundation, 2014). Chemotherapy regimens similar to those employed to treat leukaemia may be used, but rarely are effective in treating MDS. Azacitidine (Vidaza), an antileukaemic agent that acts on abnormal blood-forming cells in the bone marrow, is more effective in treating MDS than standard chemotherapy regimens, and is now one of the first-line treatments for high-risk MDS patients (Svensson et al., 2014). As previously noted, stem cell transplant offers the only hope for cure. This high-risk therapy, however, is reserved for higher-risk people. Factors such as age, functional ability and other existing disease conditions help guide the decision to undergo stem cell transplant (Leukaemia Foundation, 2014).



Nursing care

Nursing diagnoses and interventions

Activity intolerance and the need for education about this disorder are the priorities of nursing care for the person with MDS being managed in a community-based setting. Although neutropenia and thrombocytopenia may accompany the anaemia of MDS, these problems are less common. See the section of this chapter on leukaemia for additional potential nursing diagnoses and interventions for the person with MDS.

Activity intolerance

The person with MDS experiences fatigue, weakness and shortness of breath on exertion related to the lack of RBCs and ineffective oxygen transport. These symptoms may affect the person's ability to maintain self-care, home life, job performance and social roles.

- Monitor vital signs, breath sounds and apical pulse. *Increased cardiac workload due to anaemia and impaired oxygen transport can affect the blood pressure, heart and respiratory rates. Increased blood flow can lead to heart murmur or abnormal heart sounds such as S_3 or S_4. Accumulated iron can lead to pericarditis and a pericardial friction rub.*
- Help identify energy-conserving ways of performing necessary or desired activities. *Alternative ways of*

performing tasks (e.g. sitting while performing hygiene measures) may reduce oxygen demands and fatigue.
- Help the person and family establish priorities for tasks and activities. *Because family members may need to assume responsibility for additional tasks, the plan's success depends on mutually established goals.*
- Suggest planning recreational activities following a transfusion and adjusting activity level between transfusions to match energy and minimise fatigue. *The person with MDS will have more energy and activity tolerance following a transfusion when RBC counts, haemoglobin and haematocrit approach normal levels and oxygen transport is optimal.*
- Encourage 8 to 10 hours of sleep at night. *Rest decreases oxygen demands and increases available energy for morning activities.*
- Discontinue activity if any of the following occurs:
  a. complaints of chest pain, breathlessness or vertigo
  b. palpitations or tachycardia that does not return to normal within 4 minutes of resting
  c. bradycardia
  d. tachypnoea or dyspnoea
  e. decreased systolic blood pressure.

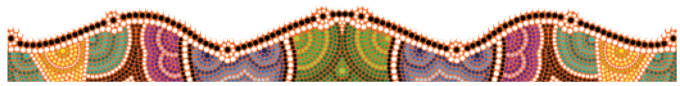
  These changes may signify cardiac decompensation due to insufficient oxygenation. The intensity, duration or frequency of the activity needs to be reduced.
- Instruct the person not to smoke. *Smoking causes vasoconstriction and increases carbon monoxide levels in the blood, interfering with tissue oxygenation.*

Risk of ineffective health maintenance

MDS is a chronic, usually progressive disorder, requiring active management to maintain functional status and quality of life. Regular visits to the doctor may be necessary. In addition, the person or family members may need to learn to administer iron chelation therapy or chemotherapy drugs and measures to prevent complications. The chronic nature of the disorder, and the often advanced age of the person and family caregivers, may interfere with effective management of the disorder.
- Assess knowledge of the disorder and the related treatments. *Assessment allows identification of knowledge gaps and provides a basis on which to provide additional information. Impaired disease management may be due to lack of knowledge or an inability to learn and perform psychomotor skills (e.g. administration of parenteral drug therapy).*
- Provide information about the disorder, its effects and prescribed medications and treatments. *Individualised instruction is more effective than general, possibly irrelevant information. The person and caregivers need to be able to identify and manage possible adverse effects of drug therapy, as well as recognise potential complications to be reported to the doctor.*
- Provide emotional support, expressing confidence in the person's and caregivers' abilities to manage care. *Emotional support helps the person and family caregivers incorporate the care regimen into their lifestyle.*
- Provide supervised learning and practice opportunities for administering parenteral medications if ordered. *Successful practice sessions instil confidence in the ability to manage care and provide an opportunity for questions and exploring alternatives.*

Community-based care

The person with myelodysplastic syndrome needs information about this chronic and ultimately fatal disease. Provide information about the various treatment options available, including management of any infusion device if ordered. Discuss the timing of and options for stem cell transplant and assist the person to evaluate the potential benefits and risks of this treatment option.



THE PERSON WITH POLYCYTHAEMIA

Polycythaemia, or *erythrocytosis*, is an excess of red blood cells characterised by a haematocrit higher than 55%. The two main types of polycythaemia are primary and secondary. A third type of polycythaemia, relative polycythaemia, results from a fluid volume deficit, not excess RBCs.

FAST FACTS

- *Primary polycythaemia* (*polycythaemia vera*) is uncommon.
  - In primary polycythaemia, RBC production is increased.
  - Primary polycythaemia more commonly affects men of European Jewish ancestry between the ages of 40 and 70.
- *Secondary polycythaemia* (*erythrocytosis*) is the most common form of polycythaemia.
  - Secondary polycythaemia occurs when erythropoietin levels are elevated.
  - It may affect people of any age or origin.
  - It usually develops in response to hypoxia (living at a high altitude, smoking or chronic lung disease).
- *Relative polycythaemia* occurs due to fluid deficit, not excess RBCs.
  - In relative polycythaemia the total RBC count is normal.
  - The haematocrit is elevated because of increased cell concentration.
  - It is corrected by rehydration.

Pathophysiology

Primary polycythaemia

Primary polycythaemia, or polycythaemia vera (PV), is a neoplastic stem cell disorder characterised by overproduction of RBCs and, to a lesser extent, white blood cells and platelets. It is classified as a myeloproliferative disorder. Its cause is unknown. In PV, colonies of endogenous erythroid stem cells develop. These colonies produce RBCs in the absence of erythropoietin, leading to excess RBC production.

MANIFESTATIONS Initially, PV is asymptomatic and the diagnosis may be made during routine blood tests. Its manifestations are caused by increased blood volume and viscosity. Hypertension is common and may lead to complaints of headaches, dizziness and vision and hearing disruptions. Venous stasis causes *plethora*, a ruddy, red colour of the face, hands, feet and mucous membranes. This often is accompanied by severe, painful itching of the fingers and toes. Retinal and cerebral vessels may be engorged. Hypermetabolism develops, causing weight loss and night sweats. Mental status may be altered, leading to drowsiness or delirium.

Thrombosis and haemorrhage are potential complications of PV. Thrombosis may cause transient ischaemic attacks, angina or manifestations of peripheral vascular disease. Gastrointestinal bleeding may occur and portal hypertension may develop.

Secondary polycythaemia

Secondary polycythaemia, or erythrocytosis, is increased numbers of RBCs in response to excess erythropoietin secretion or prolonged hypoxia. Secondary polycythaemia is the most common form of polycythaemia.

Abnormally high erythropoietin levels can result from kidney disease or erythropoietin-secreting tumours (e.g. renal cell carcinoma). Chronic hypoxia that stimulates erythropoietin release is a more common cause of secondary polycythaemia. People living at high altitudes where the atmospheric oxygen pressure is lower develop a degree of polycythaemia, as do people with chronic heart or lung disease and smokers. Abnormal haemoglobin that forms tighter bonds with oxygen also may lead to secondary polycythaemia. Blood doping in sport causes a purposeful artificial polycythaemia. Red blood cells are drawn off and stored, and the body responds by producing erythropoietin and increasing RBC production. The stored cells are reinfused, thus producing excess RBC or polycythaemia. This was done to increase the oxygen-carrying capacity for the athlete, but has since been banned (Marieb & Hoehn, 2014).

MANIFESTATIONS The manifestations of secondary polycythaemia are similar to those of primary polycythaemia. Splenomegaly, however, does not develop. Early symptoms often are overshadowed by the manifestations of the underlying disorder. For the manifestations of polycythaemia, see the box below.

MANIFESTATIONS Polycythaemia

- Hypertension
- Headache, tinnitus, blurred vision
- Plethora: dark redness of the lips, feet, ears, fingernails and mucous membranes
- Splenomegaly (polycythaemia vera)
- Severe pruritus, extremity pain
- Weight loss, night sweats
- Gastrointestinal bleeding
- Intermittent claudication
- Symptoms from thrombosis within various organs

INTERPROFESSIONAL CARE

Diagnosis

In polycythaemia vera, serum erythropoietin levels are low. Bone marrow studies show hyperplasia of all haematopoietic elements. With secondary polycythaemia, serum erythropoietin levels usually are high and bone marrow studies show only red stem cell hyperplasia.

Treatments

For secondary polycythaemia, treatment focuses on the underlying cause of the disorder. It is a physiological response in people living at high altitudes and, unless the haematocrit is too high or oxygen saturation levels are low, no treatment is usually necessary. Smokers are urged to quit. Measures to raise oxygen saturation levels and reduce tissue hypoxia often will relieve the polycythaemia. People with both primary and secondary polycythaemia benefit from periodic phlebotomy, removing 300 to 500 mL of blood, to keep blood volume and viscosity within normal levels. For PV, chemotherapeutic agents such as hydroxyurea may be used to suppress marrow function but may increase the risk of developing leukaemia (discussed later in this chapter). Pruritus may be relieved by antihistamines or may require more aggressive treatment with interferon alpha or other treatments. Aspirin may be prescribed daily to control thrombosis without increasing the risk of bleeding.

Nursing care

Preventing polycythaemia begins with educating children and adults about the dangers of smoking. Measures to reduce risk factors for cardiovascular disease also may be beneficial.

This chronic condition is managed in community-based settings unless a complication develops. Teach the person and family the importance of maintaining adequate hydration and increasing fluid intake during hot weather and when exercising. Discuss measures to prevent blood stasis: elevating legs and feet when sitting, using support stockings and continuing treatment measures. Instruct to report manifestations of thrombosis (leg or calf pain, chest pain, neurological symptoms) or bleeding (black, tarry stools, vomiting of blood or coffee-grounds emesis) immediately. Monitor the haematocrit and cell counts throughout treatment.

Examples of nursing diagnoses appropriate for the person with polycythaemia follow:

- *Pain* related to effects of altered blood flow in distal extremities.
- *Risk of ineffective tissue perfusion* related to sluggish blood flow and increased risk of thrombosis.

WHITE BLOOD CELL AND LYMPHOID TISSUE DISORDERS

Important disorders of the white blood cells (WBCs) and lymphoid tissue include the leukaemias, multiple myeloma and malignant lymphomas (Hodgkin's disease and non-Hodgkin's lymphoma). Review the physiology of WBCs and lymphoid tissues and assessment of their function in Chapter 28 before proceeding with this section.

THE PERSON WITH LEUKAEMIA

Leukaemia (literally, 'white blood') is a group of chronic malignant disorders of white blood cells and white blood cell precursors. Precursor cells are stem cells that have developed to the stage where they are committed to forming a particular kind of new blood cell. All leukaemias start in the bone marrow where developing blood cells, usually developing white cells, undergo a malignant change.

In leukaemia, the usual ratio of red to white blood cells is reversed. Leukaemias are characterised by replacement of bone marrow by malignant immature white blood cells, abnormal immature circulating WBCs and infiltration of these cells into the liver, spleen and lymph nodes throughout the body. There are four main types of leukaemia. They are discussed later in this section.

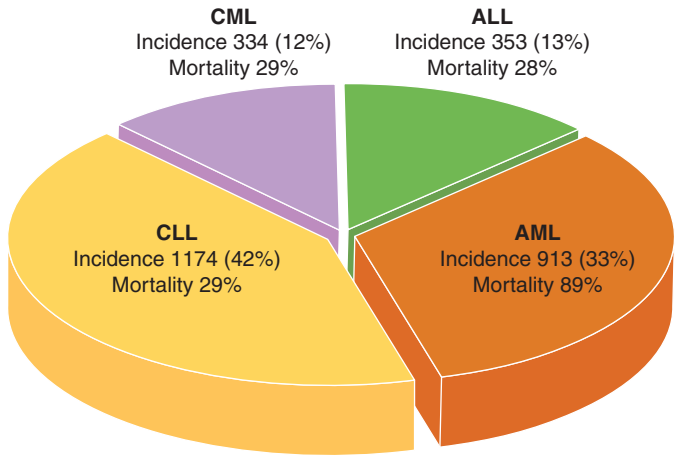


FIGURE 32.5 ■ Australian incidence and mortality data for the four main types of leukaemia, 2011

ALL = acute lymphoblastic leukaemia. AML = acute myeloid leukaemia. CLL = chronic lymphocytic leukaemia. CML = chronic myeloid leukaemia.

Source: Generated using data from the Australian Cancer Incidence and Mortality (ACIM) books, 2015a–d.

Incidence and risk factors

Although leukaemia is often thought of as a childhood disease, it is diagnosed 10 times more often in adults than in children; the majority over 50 years old (Leukaemia Foundation, 2014). Each year in Australia, over 3000 people are diagnosed with leukaemia, making it the seventh most common type of cancer in men and the eighth most common type of cancer in women (Australian Institute of Health and Welfare (AIHW), 2014). See Figure 32.5 for leukaemia incidence and mortality statistics.

Although the cause of most leukaemia is unknown, certain risk factors have been identified. Men are affected more frequently than women. People with certain genetic disorders such as Down syndrome have a higher incidence of leukaemia. Environmental risk factors play a role as well. Risk factors for myeloid leukaemia include cigarette smoking and chemicals such as benzene (present in cigarette smoke and petrol). Exposure to ionising radiation increases the risk of several types of leukaemia. People who have undergone treatment for cancer have an increased risk. The human T-cell leukaemia/lymphoma virus-1, a retrovirus, is known to cause certain leukaemias and lymphomas (Leukaemia Foundation, 2014).

Physiology review

White blood cells are the most diverse of the cellular components of the blood. White blood cells arise from three different precursor cells: myeloblasts, which further differentiate into the granular leucocytes (granulocytes), neutrophils, eosinophils and basophils; monoblasts, which mature into circulating monocytes and ultimately into macrophages; and lymphoblasts, which become lymphocytes and mature in lymphoid tissue to B cells and T cells.

As a whole, the primary function of WBCs is to help maintain the body's immune defences. Neutrophils, the most numerous WBC in circulation, are active phagocytes, the first cells to arrive to injured tissue. Monocytes and macrophages also are phagocytic cells that dispose of foreign and waste material from tissues. Eosinophils and basophils are more specialised. Eosinophils are primarily involved in allergic responses and parasitic infections. Basophils are actively involved in the inflammatory response, releasing substances such as histamine and heparin into inflamed tissues. Lymphocytes, the smallest of the WBCs, are an integral part of the immune system. B cells are part of the humoral immune response, producing antibodies to specific antigens. T cells are part of the cell-mediated immune response. For more information about the inflammatory and immune responses, see Chapter 12. The normal WBC count and differential are presented in Table 32.2 (Van Leeuwen, Poelhuis-Leth & Blandh, 2013).

Pathophysiology

Leukaemia begins with malignant transformation of a single stem cell. Leukaemic cells proliferate slowly, but do not differentiate normally. They have a prolonged lifespan and accumulate in the bone marrow. As they accumulate, they compete with the proliferation of normal cells. Leukaemic cells do not function as mature WBCs and are ineffective in the inflammatory and immune processes. Leukaemic cells replace normal

TABLE 32.2 Normal white blood cell count and differential

LABORATORY TEST	VALUE
WBC count	3.7–11.0 × 10^9/L
Differential WBC count:	
Neutrophils	2.0–7.5 × 10^9/L
Eosinophils	0.05–0.5 × 10^9/L
Basophils	< 0.1 × 10^9/L
Lymphocytes	1.5–3.7 × 10^9/L
Monocytes	0.2–0.4 × 10^9/L

haematopoietic elements in the marrow. Because erythrocyte- and platelet-producing cells are crowded out, severe anaemia, splenomegaly and bleeding difficulties result.

Leukaemic cells leave the bone marrow and travel through the circulatory system, infiltrating other body tissues such as the central nervous system, testes, skin, gastrointestinal tract and the lymph nodes, liver and spleen. Death usually is due to internal haemorrhage and infections.

Manifestations

The general manifestations of leukaemia (regardless of type) result from anaemia, infection and bleeding. These include pallor, fatigue, tachycardia, malaise, lethargy and dyspnoea on exertion. Infection may cause fever, night sweats, oral ulcerations and frequent or recurrent respiratory, urinary, integumentary or other infections. Increased bleeding due to thrombocytopenia leads to bruising, petechiae, bleeding gums and bleeding within specific organs and tissues. Multisystem effects of leukaemia are shown below.

Other manifestations result from leukaemic cell infiltration, increased metabolism and increased leucocyte destruction. Infiltration of the liver, spleen, lymph nodes and bone marrow causes pain and tissue swelling in the involved areas. Meningeal infiltration may cause manifestations of increased intracranial pressure, such as headache, altered level of consciousness, cranial nerve impairment, nausea and vomiting. Infiltration of the kidneys may affect renal function, with decreased urine output and increased blood urea nitrogen and creatinine. Increased metabolism causes heat intolerance, weight loss, dyspnoea on exertion and tachycardia. Destruction of large numbers of WBCs releases substantial amounts of uric acid into the circulation; uric acid crystals may obstruct renal tubules, causing renal insufficiency.

Without treatment, leukaemia is invariably fatal, usually due to complications of leukaemic cell infiltration of bone marrow or vital organs. With treatment, prognosis varies. The overall 5-year survival rate is 48% (Leukaemia Foundation, 2014). Survival rates differ by type of leukaemia: people with acute myeloid leukaemia can have a 10–30% 5-year survival rate, with a mean of 24%, favouring the younger generation in response to treatment. Those with chronic lymphocytic leukaemia may not even require treatment, or may need it only after 10 years or more, as their 5-year survival rate is around 73% (Leukaemia Foundation, 2010; Cancer Council Australia, 2015; Australian Cancer Research Foundation, 2012). The types, pathology, manifestations and treatment for the major leukaemias are outlined in Table 32.3.

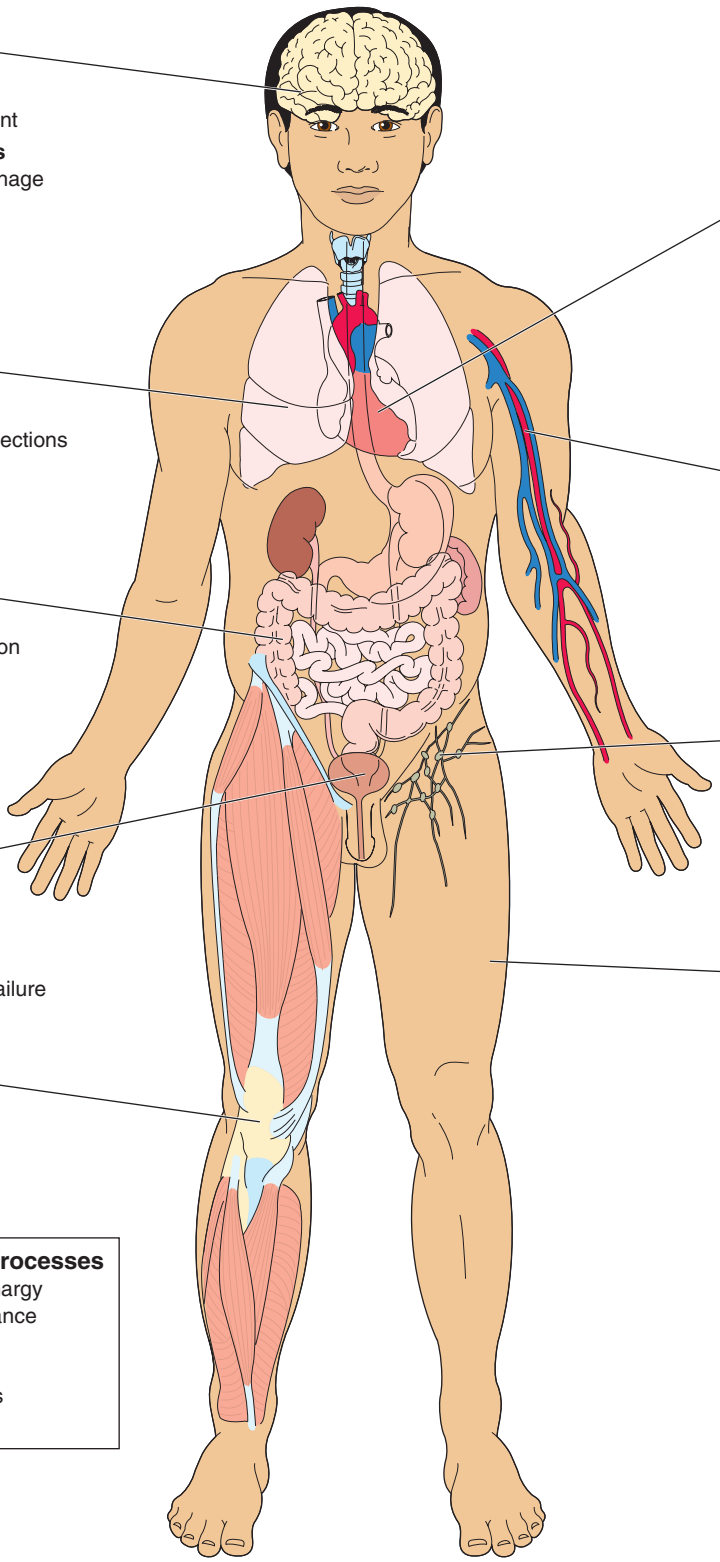
Classifications

Leukaemias are classified by their acuity and by the predominant cell type involved. The *acute* leukaemias are characterised by an acute onset, rapid disease progression and immature or undifferentiated blast cells. *Chronic* leukaemias, on the other hand, have a gradual onset, prolonged course and abnormal, mature-appearing cells. *Lymphocytic* (or *lymphoblastic*) leukaemias involve immature lymphocytes and their precursor cells in the bone marrow. Lymphocytic leukaemias infiltrate

TABLE 32.3 Major types of leukaemia

CLASSIFICATION	CHARACTERISTICS	MANIFESTATIONS	TREATMENT
Acute lymphoblastic leukaemia (ALL)	Primarily affects children and young adults; leukaemic cells may infiltrate CNS	Recurrent infections; bleeding; pallor, bone pain, weight loss, sore throat, fatigue, night sweats, weakness	Chemotherapy; bone marrow transplant (BMT) or stem cell transplant (SCT)
Chronic lymphocytic leukaemia (CLL)	Primarily affects older adults; insidious onset and slow, chronic course	Fatigue; exercise intolerance; lymphadenopathy and splenomegaly; recurrent infections, pallor, oedema, thrombophlebitis	Often requires no treatment; chemotherapy; BMT
Acute myeloid leukaemia (AML)	Common in older adults, may affect children and young adults. Strongly associated with toxins, genetic disorders and treatment of other cancers	Fatigue, weakness, fever; anaemia; headache; bone and joint pain; abnormal bleeding and bruising; recurrent infection; lymphadenopathy, splenomegaly and hepatomegaly	Chemotherapy; SCT
Chronic myeloid leukaemia (CML)	Primarily affects adults; early course slow and stable, progressing to aggressive phase in 3–4 years	Early: weakness, fatigue, dyspnoea on exertion; possible splenomegaly Later: fever, weight loss, night sweats	Interferon alpha; chemotherapy with imatinib, hydroxyurea and combination chemotherapy

MULTISYSTEM EFFECTS OF LEUKAEMIA



Neurological
- Headache
- Altered LOC
- Cranial nerve impairment

Potential complications
- Subarachnoid haemorrhage
- Retinal haemorrhage
- Seizures, coma

Respiratory
- Dyspnoea on exertion
- Pharyngitis, sore throat
- Frequent respiratory infections

Potential complication
- Pulmonary bleeding

Gastrointestinal
- Anorexia, nausea
- Oral ulcerations, infection
- Bleeding gums
- Gingival hyperplasia (gum overgrowth)
- Abdominal pain
- Hepatomegaly
- Occult GI bleeding

Urinary
- Urinary tract infection
- Haematuria

Potential complication
- Renal insufficiency or failure

Musculoskeletal
- Weakness
- Bone tenderness, pain
- Joint pain

Cardiovascular
- Tachycardia, palpitations
- Orthostatic hypotension
- Heart murmurs
- Haematomas
- Oedema

Potential complications
- Haemorrhage
- Thrombophlebitis

Hematological
- Anaemia
- Thrombocytopenia
- Leucopenia
- Bleeding (epistaxis)
- Splenomegaly

Potential complication
- DIC

Immunological
- Frequent or recurrent infections
- Lymphadenopathy

Potential complications
- Abscesses
- Septicaemia

Integumentary
- Skin and mucous membrane pallor
- Petechiae
- Bruising, purpura
- Ulcerations
- *Chloromas* (skin infiltrations near bony prominences)

Metabolic processes
- Malaise, lethargy
- Heat intolerance
- Diaphoresis
- Chills, fever
- Night sweats
- Weight loss

TABLE 32.4 FAB classification of acute leukaemia

TYPE	CLASS	PREDOMINANT CELLS	PROGNOSIS
Acute lymphocytic leukaemia	L_1	Immature lymphoblasts	> 90% remission rate in children
	L_2	Mature lymphoblasts	Relapse common after 2 or more years of remission
Acute myeloid leukaemia	M_0	Undifferentiated cells	Poor
	M_1	Immature myeloblasts	Good; complete response in 65% or more
	M_2	Mature myeloblasts	Good for 2 or more years of remission
	M_3	Promyelocytes	Good in adults
	M_4	Myelocytes and monocytes	Poorest in adults
	M_5	Poorly or well-differentiated monocytes	Poor
	M_6	Predominant erythroblasts	Variable
	M_7	Megakaryocytes	Poor

the spleen, lymph nodes, CNS and other tissues. *Myeloid* (also called *myelogenous*, *myelocytic* or *myeloblastic*) leukaemias involve myeloid stem cells in the bone marrow, interfering with the maturation of all types of blood cells, including granulocytes, RBCs and thrombocytes (Huether & McCance, 2013). Acute lymphoblastic leukaemia is the most common type of leukaemia in children. In adults, acute myeloid leukaemia and chronic lymphocytic leukaemia are the most common types (Huether & McCance, 2013). In summary, the general types of leukaemia are as follows:

- acute myeloid (myeloblastic) leukaemia (AML)
- chronic myeloid (myelogenous) leukaemia (CML)
- acute lymphocytic (lymphoblastic) leukaemia (ALL)
- chronic lymphocytic leukaemia (CLL).

This general system of classifying leukaemias does not differentiate subtypes of acute leukaemias. The FAB system for classifying acute leukaemias further differentiates acute leukaemias by the predominant cell involved and the degree of cell differentiation (see Table 32.4).

Acute myeloid leukaemia

Acute myeloid leukaemia (AML) is characterised by uncontrolled proliferation of myeloblasts (the precursors of granulocytes) and hyperplasia of the bone marrow and spleen (see Figure 32.6). Treatment induces complete remission in 66% of people, although only about 30–40% achieve cure or long-term remission (Huether & McCance, 2013).

The manifestations of AML result from neutropenia and thrombocytopenia. Decreased neutrophils lead to recurrent severe infections, such as pneumonia, septicaemia, abscesses and mucous membrane ulceration. The manifestations of thrombocytopenia include petechiae, purpura, ecchymoses (bruising), epistaxis (nosebleeds), haematomas, haematuria and gastrointestinal bleeding. Bone infarctions or subperiosteal infiltrates of leukaemic cells may cause bone pain. Anaemia is a late manifestation, causing fatigue, headaches, pallor and dyspnoea on exertion. Death usually results from infection or haemorrhage.

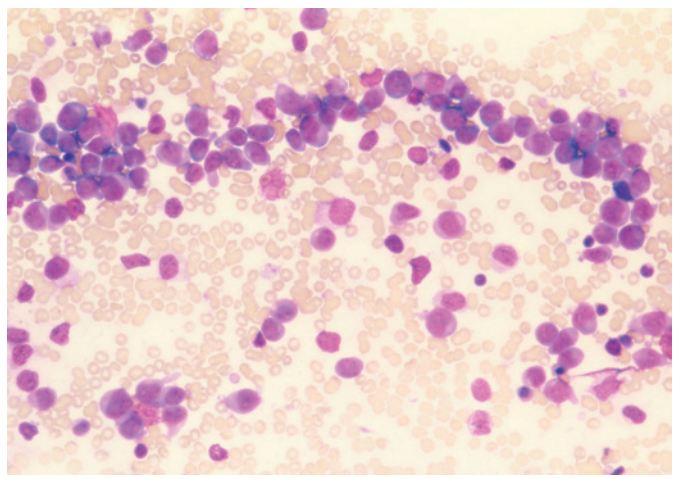


FIGURE 32.6 ■ A blood smear from the bone marrow of a person with acute myeloid leukaemia. Note the abnormally large number of myelocyte WBCs (stained purple) among the small RBCs

Source: Dr Gopal Murti/Science Source.

Bone marrow aspiration shows a proliferation of immature WBCs. The FBC shows thrombocytopenia and normocytic, normochromic anaemia.

Chronic myeloid leukaemia

Chronic myeloid leukaemia (CML) is characterised by abnormal proliferation of all bone marrow elements. This type of leukaemia constitutes approximately 15% of adult leukaemias, and 0.03% of all diagnosed cancers. It affects men more frequently than women. The onset of CML is most common after the age of 50, although it is seen in children and adolescents as well (Leukaemia Foundation, 2014).

CML is usually associated with a chromosome abnormality called the Philadelphia chromosome, a balanced translocation of chromosome 22 to chromosome 9 (see Figure 32.7). The fusion gene produced by this translocation, known as *bcr/abl*,

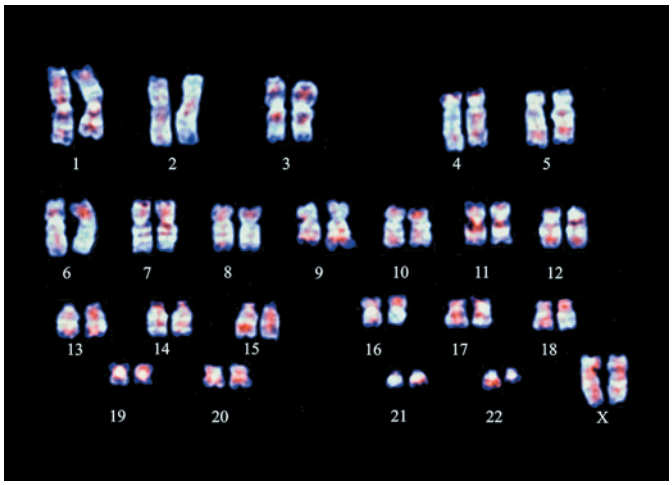

FIGURE 32.7 ■ The Philadelphia chromosome. Note the chromosomes of pairs 9 and 22. In each instance, the left-hand chromosome of the pair is normal, whereas an exchange of material between chromosomes has made the right-hand chromosome 9 larger and the right-hand chromosome 22 smaller. In stem cells within the bone marrow, the chromosome 22 defect leads to chronic myeloid leukaemia

Source: © Addenbrooke's Hospital/Science Source.

is an *oncogene* capable of initiating a malignancy. Very large doses of ionising radiation also may induce CML in some people (Papadakis et al., 2013). The incidence of CML in Australia has increased from around 200 to 330 new cases each year, with excessive radiation the only recognised cause (Leukaemia Foundation, 2014).

People with CML are often asymptomatic in the early stages and, in fact, are often diagnosed when a routine blood test reveals abnormal cell counts. Anaemia causes weakness, fatigue and dyspnoea on exertion. The spleen often is enlarged, causing abdominal discomfort. Within 3 to 4 years, disease progresses to a more aggressive phase. Rapid cell proliferation and hypermetabolism cause fatigue, weight loss, sweating and heat intolerance. The spleen enlarges, leading to a sensation of abdominal fullness and discomfort. Platelet function is affected in this stage, leading to bleeding and increased bruising. Finally, the disease evolves to acute leukaemia, with blast cell proliferation. This stage, known as the *terminal blast crisis phase*, is characterised by significant constitutional manifestations, splenomegaly and infiltration of leukaemic cells into the skin, lymph nodes, bones and CNS (Huether & McCance, 2013). Survival following the onset of this final stage averages only 2 to 4 months.

Acute lymphocytic leukaemia

Acute lymphocytic leukaemia (ALL) is the most common type of leukaemia in children and young adults. In adults, ALL is rarely seen until late middle age and then its incidence increases with ageing. Genetic factors may play a role in its development, particularly the *bcr/abl* translocation also implicated in CML.

Most (80%) cases of ALL result from malignant transformation of B cells, with the remaining 20% arising from T cells. The malignant cells resemble immature lymphocytes (*lymphoblasts*); however, they do not mature or function effectively to maintain immunity. These lymphoblasts accumulate in the bone marrow, lymph nodes and spleen, as well as in circulating blood. Some types of lymphoma (discussed later in this chapter) are thought to represent a later stage of the same disease.

The onset of ALL is usually rapid. Lymphoblasts proliferating in bone marrow and peripheral tissues crowd the growth of normal cells (see Figure 32.8). Normal haematopoiesis is suppressed, leading to thrombocytopenia, leucopenia and anaemia. Manifestations of infections, bleeding and anaemia develop. Bone pain resulting from rapid generation of marrow elements, lymphadenopathy and liver enlargement are also common. Infiltration of the CNS causes headaches, visual disturbances, vomiting and seizures.

The FBC shows an elevated WBC count with increased lymphocytes on the differential. RBC and platelet counts are decreased. Bone marrow studies reveal a hypercellular marrow with growth of lymphoblasts. Combination chemotherapy produces complete remission in 80–90% of adults with ALL.

Chronic lymphocytic leukaemia

Chronic lymphocytic leukaemia (CLL) is characterised by proliferation and accumulation of small, abnormal, mature lymphocytes in the bone marrow, peripheral blood and body tissues. The abnormal cells are usually B lymphocytes that are unable to produce adequate antibodies to maintain normal immune function. Only about 5% of CLL involves T cells (Noonan, 2007). CLL occurs more commonly in adults, especially in older adults (median age 65). CLL is the least common type of the major leukaemias.

CLL has a slow onset and is often diagnosed during a routine physical examination. If symptoms are present, they usually include vague complaints of weakness or malaise. Possible

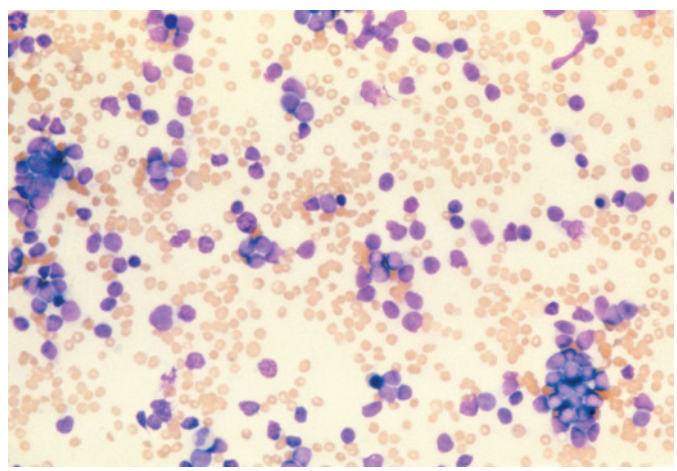

FIGURE 32.8 ■ A blood smear from the bone marrow of a person with acute lymphocytic leukaemia. Note the abnormally large number of lymphocytes (stained purple) crowding the bone marrow. As a result, normal production of RBCs, functional WBCs and platelets is suppressed

Source: Dr Gopal Murti/Science Source.

clinical findings include anaemia, infection and enlarged lymph nodes, spleen and liver. As in other leukaemias, bone marrow hyperplasia is present. Erythrocyte and platelet counts are reduced. Leucocyte counts may either be elevated or reduced, but abnormal cells are always present. In CLL, years may elapse before treatment is required. Survival of this disease averages approximately 7 years.

INTERPROFESSIONAL CARE

Treatment for leukaemia focuses on achieving remission or cure and relieving symptoms. The methods of treatment may include chemotherapy, radiation therapy and bone marrow or stem cell transplantation. Cure is more often achieved in children with acute leukaemia than in adults, although long-term remissions (disease-free periods with no signs or symptoms) often can be achieved.

Diagnosis

The following diagnostic tests are ordered when leukaemia is suspected:

- *FBC* with differential is done to evaluate cell counts, haemoglobin and haematocrit levels, and the number, distribution and morphology (size and shape) of WBCs.
- *Platelets* are measured to identify possible thrombocytopenia secondary to the leukaemia and the risk of bleeding.
- *Bone marrow examination* provides information about cells within the marrow, the type of erythropoiesis and the maturity of erythropoietic and leucopoietic cells.
- Table 32.5 outlines usual diagnostic test results in the various forms of leukaemia.

Chemotherapy

Single agent or combination chemotherapy is the treatment of choice for most types of leukaemia, with the goal of eradicating leukaemic cells and producing remission. Table 32.6 outlines typical chemotherapy regimens for different types of leukaemia. Combination chemotherapy reduces drug resistance and toxicity and interrupts cell growth at various stages of the cell cycle, producing a complementary effect of the drugs used. Cancer treatment with chemotherapy is discussed in detail in Chapter 13.

Chemotherapy for leukaemia generally is divided into the induction phase and post-remission therapy. During *induction*, drug doses are high to eradicate leukaemic cells from the bone marrow. These high doses often also damage stem cells and interfere with production of normal blood cells. Circulating mature blood cells are not affected because they are no longer dividing. The degree of bone marrow suppression is influenced by a number of factors, including age, nutritional status, concurrent chronic diseases such as impaired liver or renal function, the drug and drug dose, and prior treatment.

Colony-stimulating factors (CSFs), also called haematopoietic growth factors, often are administered to 'rescue' the bone marrow following induction chemotherapy. CSFs are cytokines that regulate the growth and differentiation of blood cells. Factors that support neutrophil maturation, *granulocyte-macrophage CSF (GM-CSF)* and *granulocyte CSF (G-CSF)*, are commonly used. Bone pain is a common side effect of therapy with these agents. People may also experience fevers, chills, anorexia, muscle aches and lethargy.

Once remission has been achieved, post-remission chemotherapy is continued to eradicate any additional leukaemic cells, prevent relapse and prolong survival. A single chemotherapeutic agent, combination therapy or bone marrow transplant may be used for post-remission treatment.

Radiation therapy

Radiation therapy damages cellular DNA. While the cell continues to function, it cannot divide and multiply. Cells that divide rapidly, such as bone marrow and cancer cells (radiosensitive cells), respond quickly to radiation therapy. Although

TABLE 32.5 Diagnostic findings by type of leukaemia

TEST	AML	CML	ALL	CLL
RBC count	Low	Low	Low	Low

Lymphoblasts			Present	
Lymphocytes				Present

TABLE 32.6 Chemotherapeutic regimens used to treat leukaemia

Acute myeloid leukaemia	• Cytarabine (Cytoxan, an alkylating agent), *with* daunorubicin (Cerubidine, an antitumour antibiotic) *or* idarubicin (Idamycin, an antitumour antibiotic)
Chronic myeloid leukaemia	• Imatinib mesylate (Gleevec) or dasatinib (*bcr/abl* tyrosine kinase (enzyme) inhibitors), nilotinib (Tasigna) (2nd generation tyrosine kinase inhibitor)
	• Hydroxyurea (a DNA inhibitor) if imatinib not tolerated
Acute lymphocytic leukaemia	• Daunorubicin (Cerubidine, an antitumour antibiotic) *with* vincristine (Oncovin, a plant alkaloid) *with* prednisone *with* asparaginase
Chronic lymphocytic leukaemia	• Fludarabine (Fludara, an antimetabolite) *or* chlorambucil (Chloromycetin, an antitumour antibiotic)
	• Cyclophosphamide (Cytoxan, an alkylating agent), vincristine and prednisone
	• Cyclophosphamide, doxorubicin (Adriamycin, an antitumour antibiotic), vincristine and prednisone

normal cells are affected, they are better able to recover from the damage caused by the radiation than are cancer cells. The types of delivery, effects and toxicities of radiation are discussed in greater detail in Chapter 13.

Bone marrow transplant

Bone marrow transplant (BMT) is the treatment of choice for some types of leukaemia (see Table 32.3). BMT often is used in conjunction with or following chemotherapy or radiation. There are two main categories of BMT: in allogeneic BMT, the bone marrow of a healthy donor is infused into the person with the illness; in autologous BMT, the person is infused with their own bone marrow.

ALLOGENEIC BMT *Allogeneic BMT* uses bone marrow cells from a donor (often from a sibling with closely matched tissue antigens; closely matched unrelated donors also may be used). Prior to allogeneic BMT, high doses of chemotherapy and/or total body irradiation are used to destroy leukaemic cells in the bone marrow. The donor's bone marrow is aspirated (see Figure 32.9) and infused through a central venous line into the recipient. Prior to BMT and re-establishment of bone marrow function, the person is critically ill and at significant risk of infection and bleeding due to depletion of WBCs and platelets.

AUTOLOGOUS BMT *Autologous BMT* uses the person's own bone marrow to restore bone marrow function after chemotherapy or radiation. This procedure is often called *bone marrow rescue*. In autologous BMT, about 1 L of bone marrow is aspirated (usually from the iliac crests) during a period of disease remission. The bone marrow is then frozen and stored for use after treatment. If relapse occurs, lethal doses of chemotherapy or radiation are given to destroy the immune system and malignant cells and to prepare space in the bone marrow for new cells. The filtered bone marrow is then thawed and infused intravenously through a central line. The infused marrow cells slowly become a part of the person's bone marrow, the neutrophil count increases and normal haematopoiesis takes place.

As in allogeneic BMT, the person is critically ill during the period of bone marrow destruction and immunosuppression. The person is hospitalised in a private room for 6 to 8 weeks or more. Potential complications include malnutrition, infection and bleeding.

FIGURE 32.9 ■ Allogeneic bone marrow transplant. Bone marrow from the donor is aspirated, then filtered and infused into the recipient

Source: © Simon Fraser/Science Source.

Stem cell transplant

Allogeneic **stem cell transplant (SCT)** is an alternative to bone marrow transplant. SCT results in complete and sustained replacement of the recipient's blood cell lines (WBCs, RBCs and platelets) with cells derived from the donor stem cells.

Donors must have tissue that is closely matched with that of the recipient. Prior to harvesting, haematopoietic growth factors, including G-CSF and GM-CSF, are administered to the donor for 4 to 5 days. This increases the concentration of stem cells in peripheral blood, allowing it to be used for the transplant instead of bone marrow. Peripheral blood is removed and white cells are separated from the plasma, then administered via a large central venous catheter. Large concentrations of stem cells also are present in umbilical cord blood. This may be stored and used (Ballen, Gluckman & Broxmeyer, 2013).

The recipient undergoes similar treatment prior to SCT as for BMT. The risks of infection and other complications, as well as graft-versus-host disease, are similar.

Graft-versus-host disease

Allogeneic BMT or SCT may precipitate *graft-versus-host disease (GVHD)*, which develops in up to 80% of all people receiving an allogeneic BMT or SCT, depending on their risk factors (Dignam et al., 2012). In GVHD, immune cells of the donated bone marrow identify the recipient's body tissue as foreign. Consequently, T lymphocytes in the donated marrow attack the liver, skin and GI tract, causing skin rashes progressing to desquamation (loss of skin), diarrhoea, GI bleeding and liver damage. *Acute GVHD* develops within days or weeks of the transplant and is usually marked by a pruritic, maculopapular rash that begins on the palms and soles of the feet and may extend over the entire body. Vaso-occlusive disease of the liver affects up to 25% of allogeneic bone marrow transplant recipients, with jaundice and elevated liver function tests (Grossman & Mattson, 2013). *Chronic GVHD* develops later, 100 or more days after the transplant, affecting 20–50% of people who survive 6 months or more following allogeneic BMT or SCT. It may follow acute GVHD or develop in people with no prior symptoms. GVHD is treated with antihistamines, calcineurin inhibitors, antibiotics and steroids. Immunosuppressant drugs such as thalidomide are now not recommended as being effective, but sirolimus (Rapamycin) has been shown to be more useful. Other second-line treatments can be trialled depending on severity of symptoms and response to treatment. Such agents include extracorporeal photopheresis, anti-TNF antibodies and interleukin-2 receptor antibodies (Dignam et al., 2012).

Biological therapy

Cytokines such as interferons and interleukins are biological agents that may be used to treat some leukaemias. These agents modify the body's response to cancer cells; in some cases they are cytotoxic as well. Interferons are a complex group of messenger proteins normally produced in response to antigens such as viruses (see Chapter 11). They have multiple effects, including moderating immune function and inhibiting abnormal cell proliferation and growth. Side effects commonly associated with interferon therapy include flu-like symptoms, persistent fatigue and lethargy, weight loss and muscle and joint pain.

Complementary therapies

Although many complementary and alternative medicine therapies have been purported to treat cancer in general, at this time none has been shown to have sustained benefit in treating leukaemia. Clinical trials have demonstrated the efficacy of both coping skills training (relaxation and imagery) and hypnosis to significantly reduce oral discomfort associated with leukaemia and its treatment.

Nursing care

For nursing care specific to the person undergoing diagnostic testing for leukaemia, see the accompanying nursing care plan.

Health promotion

Health promotion activities related to leukaemia include teaching about leukaemia risk factors, particularly those that can be controlled. Discuss the potential dangers of exposure to ionising radiation and certain chemicals such as benzene. Encourage all persons to avoid smoking cigarettes. Discuss genetic counselling with people at high risk of having a child with Down syndrome (women over age 35).

Assessment

Focused assessment data related to leukaemia include:

- *Health history:* complaints of fatigue, weakness, dyspnoea on exertion, frequent infections, sore throat, night sweats, bleeding gums or nosebleeds; recent weight loss; exposure to ionising radiation (multiple x-rays, residence near a site of radiation or atomic testing) or chemicals (occupational); prior treatment for cancer; history of an immune disorder.
- *Physical examination:* skin and mucous membranes for bruising, purpura, petechiae, ulcers or lesions; pallor; vital signs, including orthostatic vitals; heart and lung sounds; abdominal examination; stool for occult blood.
- *Diagnostic tests:* blood count with differential; bone marrow studies.

Nursing diagnoses and interventions

When caring for the person with leukaemia, the nurse considers the chronic and life-threatening nature of the disease as well as the effects of treatment. See the 'Translation to practice' box below. Priority nursing problems may include *Risk of infection*, *Imbalanced nutrition: less than body requirements*, *Impaired oral mucous membranes*, *Ineffective protection (bleeding)* and *Anticipatory grieving*.

Risk of infection

Changes in white blood cell function impair the immune and inflammatory responses in leukaemia, increasing the risk of infection. WBCs may be immature and ineffective or, in some cases, deficient. Chemotherapy or radiation therapy further depresses bone marrow function and increases the risk of infection.

- Promptly report manifestations of infection: fever, chills, throat pain, cough, chest pain, burning on urination, purulent drainage and itching and burning in vaginal or rectal areas. *Prompt reporting allows timely intervention to prevent overwhelming infection and sepsis.*
- Institute infection protection measures:
  a. Maintain protective isolation as indicated.
  b. Ensure meticulous hand hygiene among all people in contact with the person.
  c. Assist as needed with appropriate hygiene measures.
  d. Restrict visitors with colds, flu or infections.
  e. Provide oral hygiene after every meal.
  f. Avoid invasive procedures when possible, including injections, intravenous catheters, catheterisations and rectal and vaginal procedures. When necessary, use strict aseptic technique for all invasive procedures and monitor carefully for infection.

NURSING CARE PLAN A person with acute myelocytic leukaemia

Catherine Cole is a 37-year-old secretary who lives with her husband, Ray, and teenage daughter, Amy, in an apartment in a large metropolitan area. About 2 months ago, Mrs Cole began to tire easily and experience night sweats several times a week. She also noted that she was pale, bruised easily and was having heavier menstrual periods. Blood tests ordered by her local general practitioner (GP) are abnormal. She is admitted for a bone marrow biopsy.

ASSESSMENT

Mary Grant, RN, obtains a nursing history and physical assessment for Mrs Cole. Catherine tells her, 'I'm so tired and I have these bruises all over me. I'm so afraid of the results of the bone marrow examination. I don't know what we will do if I have cancer.' Mrs Cole clutches her husband's hand and begins to cry. Physical assessment data include height 156 cm; weight, 48.1 kg; vital signs: T 36.5°C, P 102, R 22, BP 130/82. Numerous petechiae scattered over trunk and arms; ecchymoses noted on lower right arm and right calf. Oral mucosa is red, with several small ulcerations in buccal areas.

Blood count shows reduced RBCs, haemoglobin and haematocrit levels. The WBC is high, with myeloblasts seen on differential. The platelet count is very low. A tentative diagnosis of acute myelogenous leukaemia is made.

DIAGNOSES

- *Risk of infection* related to altered WBC production and immune function.
- *Ineffective protection* related to reduced platelet count and risk of bleeding.
- *Impaired oral mucous membrane* secondary to anaemia and reduced platelets.
- *Fatigue related to anaemia.*
- *Anxiety* related to fear of leukaemia diagnosis.

PLANNING

- Monitor and reduce the risk of infection and bleeding.
- Assist with management of self-care issues.
- Assist with management of emotional state.

Expected outcomes

- Remain free of infection.
- Experience no significant bleeding.
- Have intact oral mucous membranes.
- Manage self-care activities despite fatigue.
- Develop strategies for managing anxiety.

IMPLEMENTATION

- Place in a private room, if available.
- Limit visitors to immediate family/significant others for the present (consider cultural implications around family, illness and hospitalisation).
- Instruct all staff, the family and person to carefully wash hands. Post a sign on the door and over the washbasin in the room as a reminder.
- Record vital signs every 4 hours.
- Avoid invasive procedures unless absolutely necessary.
- Monitor for bleeding every 4 hours, including skin, oral mucosa, abdominal assessment, body fluids and menstrual pad count.
- Instruct to perform oral hygiene every 2 to 4 hours, using a soft-bristle toothbrush.
- Ask the dietitian to work with Mrs Cole to identify preferred foods. Instruct to avoid foods that may damage oral mucosa, such as very hot, very cold or highly acidic or spicy foods.
- Provide for periods of rest alternating with activity.
- Teach about the bone marrow biopsy. Allow time for questions and to talk through fears.
- Refer to the oncology nurse specialist for further teaching and support.
- Refer to an oncology social worker where economic or social challenges are pressing.
- Provide written and/or online links to further information and support services for people living with a diagnosis of acute myelocytic leukaemia.

EVALUATION

The bone marrow biopsy confirms the diagnosis of acute myelogenous leukaemia. Mrs Cole is very upset, but calms as the doctor and the oncology nurse discuss treatment plans and the possibility of remission. She decides to have outpatient chemotherapy. During her hospital stay, Mrs Cole remained free of infection or further bleeding. She tells RN Grant that her mouth feels better, although it is still painful. During routine assessment, Mrs Cole remarks, 'You know, I was so scared when I came here, but I think I am a little less so now. Sometimes not knowing what is wrong is worse than knowing.'

CRITICAL THINKING IN THE NURSING PROCESS

1. Describe how alterations in WBCs can increase a person's susceptibility to infection.
2. List sources of potential infection for the hospitalised person.
3. What is the rationale for having the person do her own oral and physical hygiene?
4. Outline a teaching plan for this person and her family for home care to prevent infection.
5. Develop a care plan for Mrs Cole for the nursing diagnosis *Activity intolerance*.

REFLECTION ON THE NURSING PROCESS

1. What are the take-home points that you have learned from this case study?
2. How can you use them in your daily practice area? Where will you find further information about this disease and its effects on people who live with it?

These precautions minimise exposure to bacterial, viral and fungal pathogens. Infection is the main cause of death in people with leukaemia. Mucous membranes are especially susceptible to breakdown and infection as a result of tissue damage from chemotherapy or radiation.

- Monitor vital signs, including temperature and oxygen saturation, every 4 hours. Report temperature spikes with chilling, tachypnoea, tachycardia, restlessness, change in PaO_2 and hypotension. *The inflammatory response may be impaired in leukaemia, masking signs of infection until*

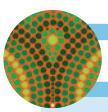
sepsis develops, indicated by manifestations such as those above.

- Monitor neutrophil levels (measured in cubic millimetres) for relative risk of infection:
  - 2.0 to 2.5 $\times 10^9$/L: no risk
  - 1.0 to 2.0 $\times 10^9$/L: minimal risk
  - 0.5 to 1.0 $\times 10^9$/L: moderate risk
  - Below 0.5 $\times 10^9$/L: severe risk.
  - *Neutrophils are the first line of defence against infection. As levels decrease, the risk of infection increases.*
- Explain infection precautions and restrictions and their rationale; explain that these measures are usually temporary. *Understanding of these aspects by the person and family increases compliance and lowers the risk of infection.*

Imbalanced nutrition: less than body requirements

The person with leukaemia may have difficulty meeting nutritional needs due to increased metabolism, fatigue, loss of appetite from radiation, nausea and vomiting from chemotherapy, or painful oral mucous membranes that make chewing and swallowing difficult and/or painful.

- Weigh regularly and evaluate weight loss over time to determine degree of malnutrition. *A weight loss of 10–20% may indicate malnutrition. A minimum intake of nutrients is necessary for health and tissue repair; cancer increases metabolic needs over this basal requirement. Weight loss occurs when metabolic requirements are not met. Both the disease process and its treatment can interfere with nutrient intake.*
- Address causative or contributing factors to inadequate food and fluid intake:
  a. Provide mouth care before and after meals; use a soft toothbrush or sponges as necessary.
  b. Provide liquids with different textures and tastes.
  c. Increase liquid intake with meals.
  d. Reduce intake of milk and milk products, which makes mucus more tenacious.
  e. Assist to a sitting position for eating.
  f. Ensure that the environment is clean and odour free.
  g. Provide medications for pain or nausea 30 minutes before meals, if prescribed.
  h. Provide rest periods before meals.
  i. Offer small, frequent meals including low-fat, high-kilojoule foods throughout the day.



TRANSLATIONTO PRACTICE Evidence-based practice for people with acute leukaemia and lymphoma

People with acute leukaemia and malignant lymphoma experience a number of distressing manifestations of their disease, including malaise and fatigue, fever, night sweats, infections and possible haemorrhage. Treatments such as radiation therapy and chemotherapy often have numerous adverse effects as well, including anorexia and nausea, stomatitis, lethargy, malaise and fatigue. In studies, people in remission from acute leukaemia or malignant lymphoma were surveyed regarding physical problems, their view of help they received and how supported they felt afterwards, and the impact of the disease and treatment on their current life, including what stressors played the largest part (Jones et al., 2015; Parry et al., 2011).

Jones et al. (2015) outlined changing stressors impacting on quality of life dependent on the age of the person in remission. They clustered post-treatment distress into physical, emotional and economic clusters. There was less distress with increasing age, but the physical impact, predominately fatigue, remained larger throughout the ages. Parry et al. (2010) in their study found that there was limited follow up and continuity of care post active treatment, and ongoing needs were not met, suggesting that there is a need for nurses to continue with care and resources beyond the actual treatment time. Patients felt abandoned and unsupported once treatment had been completed, but stressors still continued. They were not aware of the psychological support that was necessary.

IMPLICATIONS FOR NURSING

Nurses need to actively focus their care on the physical problems experienced during treatment, especially energy loss and nutritional problems. Overwhelming fatigue interferes with the person's ability to provide self-care, but its effects may not be readily apparent to nurses. People need to become equipped to deal with the remission phase as well as the treatment phase, and feel safe and supported when home from treatment. The long-term effects physically, emotionally and financially indicate a need for continued follow-up care, teaching, resource availability and ongoing access to support, with possible referral to counselling services as required.

CRITICAL THINKING IN PERSON-CENTRED CARE

1. Explain the physiological responses to malignancies and cancer treatments that cause fatigue, malaise and nutritional problems.
2. People undergoing treatment for leukaemia, malignant lymphoma and other cancers may have few outward manifestations of their disease or responses to treatment. Discuss how this apparent wellbeing may affect nurses' perceptions of care needs.
3. How may continued physical and emotional problems of fatigue and lack of psychological and sexual energy affect family relations?
4. Develop a nursing care plan for a person with acute leukaemia to address the nursing diagnosis of *Ineffective sexuality patterns* related to fatigue and lack of energy.
5. Appreciate the experiences of people who live with these diseases. Everyone's experience is different. Read the stories of people who are living with leukaemias, lymphomas, myeloma or a related blood disorder. Available from Leukaemia Australia: www.leukaemia.org.au/web/aboutdiseases/living_patientsstories.php.

j. Provide commercial supplements, such as Ensure.
k. Avoid painful or unpleasant procedures immediately before or after meals.
l. Suggest measures to improve food tolerance, such as eating dry foods when arising, consuming salty foods if allowed and avoiding very sweet, rich or greasy foods.

Anorexia, nausea and vomiting, diarrhoea, stomatitis, taste changes and dysphagia often make eating difficult during cancer treatment when good nutrition is most important. Maintaining nutritional status decreases morbidity and mortality by preventing weight loss, improving the response to treatment, minimising adverse effects and improving quality of life. Small, frequent meals are often better tolerated, especially high-protein, high-kilojoule foods.

Impaired oral mucous membrane

Stomatitis, inflammation and ulceration of the oral mucous membrane, is common in leukaemia. Chemotherapy can further impair the integrity of constantly dividing oral tissues.

- Inspect the buccal region, gums, sublingual area and the throat daily for swelling or lesions. Ask about oral pain or burning. *Breakdown of the oral mucous membrane increases the risk of infection and bleeding, causes pain and discomfort with eating and swallowing, and may cause swelling that interferes with the airway.*
- Culture any oral lesions. *Herpes simplex virus and* Candida *(yeast) are more common in those with neutropenia. Herpes lesions are usually red, raised, fluid-filled blisters;* Candida *causes a white coating and patches of white plaque.*
- Assist with mouth care and oral rinses with saline or a baking soda solution. Apply lip balm to the lips to prevent dryness and cracking. *These measures help prevent infection and increase comfort.*
- Encourage use of soft-bristle toothbrush or sponge to clean teeth and gums. *Toothbrushes with hard bristles may abrade inflamed mucosa, causing bleeding and increasing the risk of infection.*
- Administer medications as ordered to treat infection or relieve pain. *Topical antifungal agents such as nystatin may be prescribed to treat* Candida *infections. Topical anaesthetics such as lignocaine may be prescribed to relieve discomfort and facilitate good oral care.*
- Instruct to avoid alcohol-based mouthwashes, citrus fruit juices, spicy foods, very hot or very cold foods, alcohol and crusty foods. Suggest bland, cool foods and cool liquids at least every 2 hours. *Avoiding mucosa-traumatising foods and liquids increases comfort; bland, cool foods and liquids cause the least pain. Intake of adequate fluids is necessary to prevent dehydration.*
- If the patient is undergoing treatments such as haematopoetic stem cell transplant they may benefit from palifermin—a recombinant human keratinocyte growth factor-1, which decreases the duration and incidence of mucositis (BMJ Best Practice, 2015).

Ineffective protection

Bleeding is the second most common cause of leukaemia deaths. As platelet counts decrease, the risk of bleeding increases (see the section later in this chapter on thrombocytopenia). Tumour lysis syndrome also is a risk in people with leukaemia who are undergoing their initial treatment with chemotherapy. Tumour lysis syndrome develops when a large number of malignant cells are destroyed by treatment with chemotherapy or radiation. The resultant by-products of cell lysis can overwhelm the body's ability to effectively eliminate them, leading to hyperkalaemia, hyperphosphataemia with secondary hypocalcaemia and hyperuricaemia.

- Assess vital signs every 4 hours and body systems every shift for bleeding:
  a. skin and mucous membranes for petechiae, ecchymoses and purpura
  b. gums, nasal membranes and conjunctiva for bleeding
  c. vomitus, stool and urine for visible or occult blood
  d. vaginal bleeding
  e. prolonged bleeding from puncture sites
  f. neurological changes such as headache, visual changes, altered mentation, decreased level of consciousness, seizures
  g. abdomen for complaints of epigastric pain, diminished bowel sounds, increasing abdominal girth, rigidity or guarding.

  Early identification of bleeding helps prevent significant blood loss and potential shock. Internal haemorrhage may lead to tachycardia, hypotension, pallor and diaphoresis. Bleeding into the lungs may cause dyspnoea; bleeding into the abdomen causes increased girth, pain and guarding. Intracranial bleeding affects mental status and level of consciousness.
- Avoid invasive procedures such as rectal temperatures and suppositories, vaginal douches, suppositories, tampons, urinary catheterisation and parenteral injections if possible. *Diagnostic procedures such as biopsy or lumbar puncture should not be done if the platelet count is low and there is risk of bleeding. Invasive procedures can cause tissue trauma and bleeding. Procedures that use large-bore needles should be delayed until the platelet count is increased.*
- Apply pressure to injection sites for 3 to 5 minutes and to arterial punctures for 15 to 20 minutes. *Pressure prevents prolonged bleeding by prompting haemostasis and clot formation.*
- Instruct to avoid forcefully blowing or picking the nose, forceful coughing or sneezing, and straining to have a bowel movement. *These activities can damage mucous membranes, increasing the risk of bleeding.*
- Monitor and promptly report abnormal blood levels of electrolytes, uric acid, urea nitrogen and creatinine, or manifestations of tumour lysis syndrome. *Significant alterations in electrolyte levels can lead to complications such as cardiac arrhythmias, muscle weakness or tetany, paraesthesias and mental status changes. Excess uric acid can compromise renal function and lead to metabolic acidosis and gout.*

- Maintain adequate hydration and administer prescribed medications such as allopurinol and diuretics as ordered. *Hydration is vital to maintain renal function and promote elimination of tumour lysis by-products. Allopurinol reduces the risk of uric acid crystallisation in the kidneys and other tissues* (Bryant & Knights, 2015).

Anticipatory grieving

The diagnosis of cancer and a potentially life-threatening illness causes actual or perceived losses, such as loss of function, independence, normal appearance, friends, self-esteem and self. Grieving is the emotional response to those losses. The adaptive process of mourning a loss and resolving grief is called grief work; grief work cannot begin until a loss is acknowledged. See Chapter 4 for a detailed discussion of grief and loss.

- Discuss roles of the person and family and ways in which they managed stressful situations in the past. Assess coping strategies and their effectiveness. Help identify sources of strength and support. Discuss changing roles resulting from leukaemia diagnosis and its effect on spiritual, social and economic status and usual lifestyle. Evaluate cultural or ethnic factors that affect grief reactions. *Grieving is a normal response to a real or potential loss that begins at the time of diagnosis. The timing, duration and intensity of grief and responses to grief may differ among family members. Share information on diagnosis, role change and physical loss among all family members to build the foundation for mutual understanding and trust.*
- Use therapeutic communication skills to facilitate open discussion of losses and provide permission to grieve. *Encouraging discussion of the meaning of the loss helps decrease some of the anxiety associated with loss. This in turn allows the person and their family to examine the current situation and compare it with past situations that they have coped with successfully.*
- Provide information about agencies that may help in resolving grief and make referrals as indicated. Consider self-help groups, cancer support groups and bereavement groups. *Participating in support groups with others who are anticipating or experiencing a similar loss can decrease feelings of isolation.*

Community-based care

Person and family teaching for home care after treatment for leukaemia focuses on encouraging self-care, providing information about the disease and the treatment, preventing infection and injury, and promoting nutrition. Teaching topics for each of these areas are as follows.

Encouraging self-care

- Hygiene measures and energy conservation during self-care activities.
- Oral hygiene, including using a soft-bristle toothbrush several times daily; avoiding flossing.
- Reporting lesions, bleeding or signs of infection promptly.
- Maintaining a balance of rest and activity.

Information about leukaemia and treatment

- Bone marrow function, the pathophysiology of leukaemia and potential complications of leukaemia.
- Prognosis for the specific type of leukaemia.
- Treatment measures such as chemotherapy, radiation, bone marrow or stem cell transplant, their purpose and effects, where treatment is available, and potential adverse effects or risks.
- Community, regional and national resources for people with leukaemia.

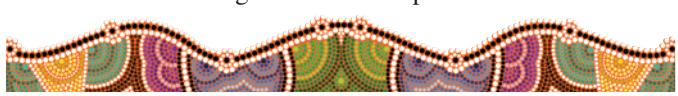
Preventing infection and injury

- Handwashing and other measures to reduce exposure to pathogens, such as avoiding people who are ill and avoiding crowds.
- Avoiding food-borne illnesses by washing fruits and vegetables, proper food storage.
- Dental hygiene measures.
- Avoiding immunisations.
- Manifestations to report: fever, chills, burning on urination, foul-smelling urine, vaginal or rectal discharge, skin lesions.
- Avoiding contact sports or strenuous exercise if platelet count is low.
- Using an electric razor for shaving, avoiding rectal or vaginal suppositories, vaginal tampons or enemas.
- Increasing dietary fibre and using a bulk-forming laxative as needed to prevent straining.
- Avoiding over-the-counter or prescription drugs that interfere with platelet function (see Box 32.6).
- The importance of reporting any bleeding (nosebleeds, rectal bleeding, vomiting blood, excessive menstrual periods, blood in the urine, bleeding gums, bruises or collections of blood under the skin) or changes in behaviour to the healthcare provider.

Promoting nutrition

- Eating several small, low-fat, high-kilojoule meals and drinking five to eight glasses of water daily; ensure culturally appropriate food choices available.
- Reporting continued weight loss, loss of appetite or inability to eat for 24 hours.
- Discussing dietary needs with the dietitian.

Assistance with physical care, finances and transportation may be required following discharge, especially for people who live in rural and remote locations. Refer the person and family to social services, support groups, home-care services as needed and other agencies that can provide needed services.



THE PERSON WITH MALIGNANT LYMPHOMA

Lymphomas are malignancies of lymphoid tissue. They are characterised by the proliferation of lymphocytes, histiocytes (resident monocytes or macrophages) and their precursors or derivatives. Lymphomas are closely related to lymphocytic leukaemias. Some experts consider them to be different forms or stages of the same disease processes.

BOX 32.6 Medications that may interfere with platelet function

Over-the-counter medications

- Aspirin and salicylates, including:
  - Ecotrin
  - Aspalgin
  - Astrix
  - Cartier
  - Cardiprin
- NSAIDs such as:
  - Naproxen
  - Ibuprofen

Prescription medications

- Aspirin-containing analgesics
- Chemotherapy drugs
- Antibiotics such as penicillin
- Carbamazepine (Tegretol)
- Colchicine
- Dipyridamole (Persantin)
- Gold salts
- Heparin
- Quinine derivatives
- Sulfonamides
- Thiazide diuretics

Although there are many types of malignant lymphoid cells, at this time lymphomas commonly are identified as Hodgkin's disease or non-Hodgkin's lymphoma.

Incidence and risk factors

In Australia, over 5400 people are diagnosed with lymphoma each year; lymphoma is the sixth most common cancer for both men and women (AIHW, 2014). The incidence of non-Hodgkin's lymphoma has nearly doubled since 1970, but currently has stabilised, primarily due to a fall in its incidence related to HIV infection and AIDS. The incidence of Hodgkin's disease has significantly declined since 1990 (Leukaemia Foundation, 2014). See Figure 32.10 for Australian lymphoma incidence and mortality statistics.

While the cause of lymphoma is unknown, some risk factors have been identified. Immunosuppression due to drug therapy following organ transplant or to HIV disease increases the risk of non-Hodgkin's lymphoma. Infectious agents such as HTLV-1 and Epstein–Barr virus (EBV) also have been identified as risk factors. Others may include occupational herbicide or chemical exposure (Leukaemia Foundation, 2014).

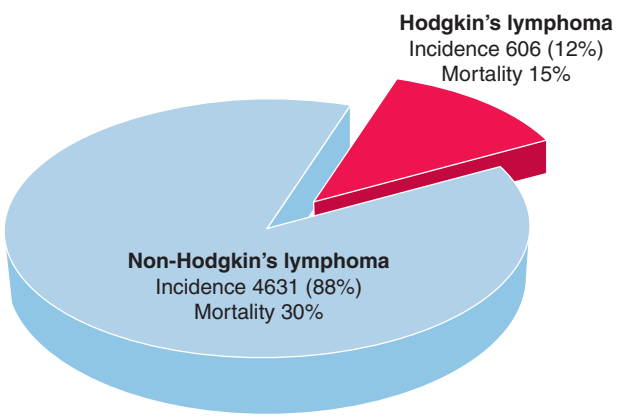


FIGURE 32.10 ■ Australian incidence and mortality data for the lymphomas, 2011

Source: Generated using data from the Australian Cancer Incidence and Mortality (ACIM) books (2015e, f).

Pathophysiology

Hodgkin's disease

Hodgkin's disease is a rare lymphatic cancer, occurring most often in people between the ages of 15 and 35. Approximately 400 new cases of Hodgkin's disease are diagnosed each year in Australia (Leukaemia Foundation, 2014). The exact cause of Hodgkin's disease is unknown, but both EBV infection and genetic factors appear to play a role in its development. Hodgkin's disease is one of the most curable cancers and most people with Hodgkin's lymphoma can be cured. While as many as 60–90% of people with localised disease achieve cure with a normal lifespan, there may be an increased risk of a second cancer occurrence throughout life (Leahy, 2008).

Hodgkin's disease develops in a single lymph node or chain of nodes, spreading to adjoining nodes. Involved lymph nodes contain *Reed–Sternberg cells* (malignant cells) surrounded by host inflammatory cells. These malignant cells secrete inflammatory mediator substances, attracting inflammatory cells to the tumour site. They may invade almost any tissue in the body. The spleen often is involved; as the disease progresses, the liver, lungs, digestive tract and CNS may be affected (Huether & McCance, 2013). Rapid proliferation of abnormal lymphocytes impairs the immune response, especially cell-mediated immune responses. Infections are common.

Hodgkin's disease is classified as classic Hodgkin's disease or as nodular-lymphocyte-predominant Hodgkin's disease. The classic form of the disease accounts for 95% of all cases; nodular-lymphocyte-predominant Hodgkin's is rare. Classic Hodgkin's can be further divided into four subtypes by cells identified within the tumour, but the subtype does not affect the prognosis.

MANIFESTATIONS The most common symptom of Hodgkin's disease is one or more painlessly enlarged lymph nodes, usually in the cervical or subclavicular region. Systemic manifestations such as persistent fever, night sweats, fatigue and weight loss are associated with a poorer prognosis for the disease. Late symptoms such as malaise, pruritus and anaemia indicate spread of the disease (Leukaemia Foundation, 2014). The spleen may be enlarged and other organ systems such as

the lungs and gastrointestinal tract are occasionally involved, causing difficulty breathing or bloating symptoms.

Non-Hodgkin's lymphoma

Non-Hodgkin's lymphoma is a diverse group of lymphoid tissue malignancies that do not contain Reed–Sternberg cells. **Non-Hodgkin's lymphomas** tend to arise in peripheral lymph nodes and spread early to tissues throughout the body. Non-Hodgkin's lymphoma is more common than Hodgkin's disease, affecting an estimated 4550 people in Australia annually, as opposed to around 600 diagnosed with Hodgkin lymphoma types (Leukaemia Foundation, 2014). Older adults are more often affected and it occurs more frequently in men than in women. Like Hodgkin's disease its cause is unknown, although both genetic and environmental factors (e.g. viral infections such as EBV, human T-cell leukaemia/lymphoma virus-1 or -2 and HIV) are thought to play a role.

As in most malignancies, non-Hodgkin's lymphoma begins as a single transformed cell; it may arise from T cells, B cells or tissue macrophages (histocytes). The primary types of non-Hodgkin's lymphomas are identified in Table 32.7. Although non-Hodgkin's lymphoma usually arises in a lymph node, it can originate in any lymphoid tissue. It tends to spread early and unpredictably to other lymphoid tissues and organs. Extranodal spread may involve the nasopharynx, GI tract, bone, CNS, thyroid, testes and soft tissue.

The prognosis for non-Hodgkin's lymphoma ranges from excellent to poor, depending on the identified cell type and grade of differentiation. Low-grade tumours (better differentiated) tend to be less aggressive and more curable. Higher-grade tumours often are disseminated at the time of diagnoses and have a poorer prognosis.

MANIFESTATIONS The early manifestations of non-Hodgkin's lymphoma are similar to those for Hodgkin's disease. Painless lymphadenopathy may be localised or widespread (see Figure 32.11). Systemic manifestations such as fever, night sweats, fatigue and weight loss may be present, but are less common in non-Hodgkin's lymphoma. Organ system involvement may cause symptoms such as abdominal pain, nausea and vomiting. Headaches, peripheral or cranial nerve symptoms, altered mental status or seizures may signal CNS involvement.

The manifestations and clinical features of Hodgkin's disease and non-Hodgkin's lymphoma are compared in Table 32.8.

Course

In both Hodgkin's disease and non-Hodgkin's lymphoma, the stage of the disease, the presence of systemic manifestations and factors such as age help determine the prognosis. The prognosis is good when the disease is localised to one or two node regions. Factors such as anaemia, thrombocytopenia and older age reduce the likelihood of disease cure.

TABLE 32.7 Subtypes of non-Hodgkin's lymphoma

SUBTYPE	INCIDENCE	COURSE AND PROGNOSIS
B-cell lymphomas		
Diffuse large B-cell lymphomas	Most common adult type (40–50% of adult lymphomas) More common in males Incidence increases with ageing	Aggressive tumour 45–50% cure rate
Follicular lymphoma	Accounts for 40% of adult lymphomas, rare in children Incidence increases with ageing	Bone marrow frequently involved, course slow, indolent 72% 5-year survival
Extranodal marginal zone lymphoma (MALT lymphoma)	Accounts for about 5% of adult lymphomas, rare in children Incidence increases with ageing More common in Italy	Presents with tumours outside lymphatic system: GI tract, lung, thyroid, urinary tract, skin, CNS. Slow, indolent course 74% 5-year survival
Mantle cell lymphoma	Accounts for 3–4% of adult lymphomas, rare in children Predominantly affects older men (74%)	Aggressive, difficult to cure 27% 5-year survival
Burkitt lymphoma	Rare in adults (< 1% of lymphomas), more common in children (~30% NHL)	Rapidly progressive but responds well to therapy 45% 5-year survival
T-cell lymphomas		
Precursor T-cell lymphoblastic leukaemia/lymphoma	More common in children and young adults More common in males than females	Can present either as ALL or lymphoma Aggressive disease 26% 5-year survival
Peripheral T-cell lymphoma	Most common T-cell lymphoma in adults	Often presents as disseminated disease 25% 5-year survival
Mycosis fungoides/cutaneous T-cell lymphoma	Onset typically during mid-fifties; more common in African Americans	Cutaneous lymphoma Slow course, progressing from patchy skin lesions to plaque to cutaneous tumours

INTERPROFESSIONAL CARE

Chemotherapy and radiation therapy, either alone or in combination, are the primary treatments for Hodgkin's and non-Hodgkin's lymphomas. Use of monoclonal antibodies to target lymphoma cells and bone marrow and peripheral stem cell transplants are under investigation for treating lymphomas as well. See the previous section on treatment of leukaemia for more information about these transplants.

Diagnosis

The following diagnostic tests may be ordered for lymphomas:

- *FBC* often shows a mild normochromic, normocytic anaemia in Hodgkin's disease; other findings in Hodgkin's disease may include leucocytosis with high neutrophil and eosinophil counts and an elevated erythrocyte sedimentation rate (ESR). In non-Hodgkin's lymphoma, the FBC typically remains normal until late in the disease, when pancytopenia may develop.
- An *ESR* is done to identify possible inflammatory causes of lymph node enlargement.
- *Blood studies* of major organ function (including liver function tests and renal function studies) are performed to identify possible organ involvement. Serum LDH levels and protein electrophoresis also may be done when Hodgkin's disease is suspected.
- *Chest x-ray* is done to identify possible enlarged mediastinal lymph nodes and pulmonary involvement.
- *CT scans* of the chest, abdomen and pelvis are performed to identify abnormal or enlarged nodes.
- *Positron emission tomography (PET* or *gallium scans)* may be performed in diagnosing the disease, as well as to evaluate the effectiveness of treatment.
- *Biopsy* of the largest, most central enlarged lymph node and of the bone marrow is done to establish the diagnosis for both Hodgkin's disease and non-Hodgkin's lymphoma. The presence of Reed–Sternberg cells confirms the diagnosis of Hodgkin's disease.

Staging

Staging is used to determine the extent of the disease and appropriate treatment (Leukaemia Foundation, 2011). The staging system used in Australia is the Ann Arbor Staging System (AIHW, 2011), which assesses the extent and severity of lymphomas. The stages are:

- Stage I: involvement of a single lymph node region or lymphoid structure (e.g. spleen, thymus, lymphoid tonsillar tissue).
- Stage II: involvement of two or more lymph node regions on the same side of the diaphragm.
- Stage III: involvement of lymph node regions or structures on both sides of the diaphragm.
  - III_1: limited to upper abdomen (spleen, splenic, coeliac or portal nodes).
  - III_2: involvement of lower abdominal nodes (para-aortic, iliac or mesenteric).
- Stage IV: involvement of an extranodal site (not proximal or contiguous with an involved node) such as the liver, lung or pleura, bone or bone marrow, or skin.

TABLE 32.8 Features and manifestations of Hodgkin's disease and non-Hodgkin's lymphoma

FEATURE OR MANIFESTATION	HODGKIN'S DISEASE	NON-HODGKIN'S LYMPHOMA
Lymphadenopathy	Localised to a single node or chain, often cervical, subclavicular or mediastinal	Multiple peripheral nodes, nodes of the mesentery often involved
Spread	Orderly and continuous	Diffuse and unpredictable
Extranodal involvement	Rare	Early and common
Bone marrow involvement	Uncommon	Common
Fever, night sweats, weight loss	Common	Uncommon until disease is extensive
Other manifestations	Fatigue, pruritus, splenomegaly; anaemia, neutrophilia	Abdominal pain, nausea, vomiting; dyspnoea, cough; CNS symptoms; lymphocytopenia

The presence or absence of systemic symptoms is indicated by either an 'A' (no systemic symptoms) or 'B' (systemic symptoms of fever, night sweats, weight loss), or 'E' is used when lymphoma has spread to an area or organ outside the lymph nodes. The letter is always placed after the stage; for example, 2A or 4E (Leukaemia Foundation, 2011).

Chemotherapy

Combination chemotherapy is used to treat both Hodgkin's disease and non-Hodgkin's lymphoma. In both cases, chemotherapy often is followed by radiation therapy to involved lymph node regions. The choice of drug combination depends on the stage of the disease as well as the person's age and general condition. Combination regimens used may include CHOP (cyclophosphamide, doxorubicin, vincristine and prednisone); ABVD (doxorubicin, bleomycin, vinblastine and dacarbazine); MOPP (nitrogen mustard, vincristine, procarbazine and prednisone); and ChlVPP (chlorambucil, vinblastine, procarbazine and prednisone). These regimens also may be combined in alternating months to reduce the adverse effects and improve tumour cell kill. More than 75% of people with Hodgkin's disease who do not have systemic symptoms achieve complete remission with treatment. The prognosis for those with non-Hodgkin's lymphoma varies by the type and stage of the disease. For more information about nursing care of the person receiving combination chemotherapy, see Chapter 13.

Radiation therapy

Radiation therapy may be the primary treatment for early-stage Hodgkin's disease, although early chemotherapy is becoming more common. In later stages and in non-Hodgkin's lymphoma it is usually combined with chemotherapy. Many lymphomas are highly responsive to radiation. The involved lymph node region is treated, with careful shielding to protect unaffected areas and minimise the extent of radiation burn and normal cell destruction (see Figure 32.12). If the disease is advanced, total nodal irradiation may be done. See Chapter 13 for nursing care of the person receiving radiation therapy.

Stem cell transplant

Autologous peripheral blood stem cell transplant (PBSCT) is a treatment option for people who experience remission of malignant lymphoma. Autologous PBSCT uses the person's own stem cells to restore bone marrow function after chemotherapy or radiation. In autologous PBSCT, stem cells are obtained from peripheral blood following chemotherapy and treatment with colony-stimulating factors to promote development of normal blood cells. The blood containing these normal stem cells is then frozen and stored for use after treatment. If relapse occurs, lethal doses of chemotherapy or radiation are given to destroy the immune system and malignant cells. The frozen blood is then thawed and infused intravenously through a peripheral line. The infused stem cells become a part of the person's bone marrow and normal haematopoiesis takes place.

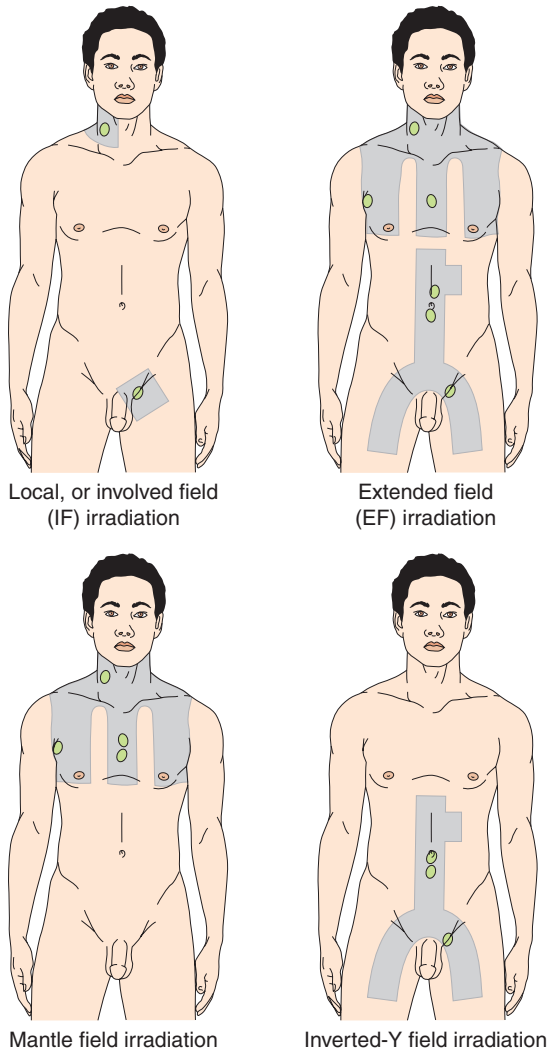

FIGURE 32.12 ■ Patterns of radiation therapy used to treat lymphoma based on the location and extent of the disease

The person is critically ill during the period of bone marrow destruction and immunosuppression, and is hospitalised in a private room for 6 to 8 weeks or more. See the accompanying 'Translation to practice' box for discussion of fatigue related to autologous PBSCT.

Complications of treatment

Both chemotherapy and radiation therapy may have long-term effects. Permanent sterility is common, especially in older adults. Bone marrow depression can lead to immunosuppression, anaemia and bleeding. Secondary cancers and cardiac injury are the most serious late adverse effects of treatment. Chemotherapy regimens using the MOPP or a related protocol carry a risk of acute leukaemia. Cancers such as breast or lung cancer may develop 10 or more years after thoracic radiation. Thoracic radiation also increases the risk of coronary heart disease and hypothyroidism (Sausville & Longo, 2015).

TRANSLATION TO PRACTICE Evidence-based practice: risk factors for depression and fatigue among hematopoietic cell transplant (HCT) recipients

Fatigue and depression are common adverse effects of chemotherapy and radiation therapy in people undergoing cancer treatment. Fatigue is prevalent, affecting 80–100% of people undergoing standard chemotherapy and often leading to lost work time and difficulty maintaining functional roles within the family and society. A study by Jim et al. (2015) found that depression and fatigue levels were closely linked, with increasing fatigue severity leading to greater levels of depression. The cohort most susceptible to ongoing fatigue and depression were female, younger in age, had chronic pain issues and had received peripheral blood stem cells. There were high rates of depression and fatigue, with 13% reporting depression classed as moderated to severe, and 42% reporting fatigue that was moderate to severe.

IMPLICATIONS FOR NURSING

This study suggests that nurses should assess for fatigue and depression in people following stem cell transplant (SCT). Nursing measures to help conserve the person's energy are appropriate to manage fatigue. Early screening, referral and intervention for fatigue may actually reduce the intensity of fatigue at its peak. Nurses can use this information to prepare people for common symptom patterns following SCT, thus reducing anxiety and concern that their condition may be declining rather than improving after SCT. Families and caregivers are also at risk of depression and psychological distress and should be screened accordingly. Assessment tools to measure fatigue and depression in people undergoing SCT can be incorporated into nursing care. Majhail et al. (2012) recommend screening 6–12 months post transplantation, and then annually thereafter.

CRITICAL THINKING IN PERSON-CENTRED CARE

1. The average age of participants (N = 1869) in this study was 56 years; 53% were male, 47% female. Does this sample reflect your local demographic of people undergoing haematopoietic cell transplant? How can information about the sample be used to guide application of study findings to the general population of people undergoing this treatment? To older adults? To adolescents and young adults?
2. In this study, participants who were female, younger, and had chronic pain or secondary malignancy were at greater risk of depression and fatigue. How would understanding of this result improve your care for individuals who have received haematopoietic stem cell transplant?
3. Interestingly, myeloablative regimen, total body irradiation dose and cytomegalovirus status was not predictive of depression or fatigue. What is the significance of this finding?

Nursing care

Assessment and priority nursing care for the person with lymphoma follows. See also the nursing care plan later in this section for application of nursing care strategies for a person with Hodgkin's disease.

Assessment

Focused assessment of the person with Hodgkin's disease or non-Hodgkin's lymphoma includes:

- *Health history:* complaints of enlarged lymph node(s), fever, night sweats, weight loss, fatigue or general malaise, abdominal pain, respiratory symptoms, numbness or tingling of extremities, visual changes or changes in mentation; history of infectious mononucleosis, HIV disease or other immunosuppressive disorders.
- *Physical examination:* mental status exam; inspect and palpate lymph nodes (cervical, subclavicular, axillary and inguinal) for enlargement, tenderness; heart and lung sounds; abdominal examination for tenderness, masses, liver or spleen enlargement.
- *Diagnostic tests:* FBC, haemoglobin and haematocrit, ESR; serum blood results; x-ray, scan and biopsy results.

Nursing diagnoses and interventions

Nursing care of the person with malignant lymphoma involves both physical and emotional support during diagnosis and treatment. Common nursing care problems include impaired protection due to bone marrow suppression, fatigue, nausea and altered body image. See the nursing care section for leukaemia, above, for specific nursing interventions for *Ineffective protection*.

Fatigue

General malaise and fatigue may accompany malignant lymphoma and are side effects of chemotherapy. In addition, the physical and psychological stress of dealing with a chronic, debilitating disease and its treatment may cause fatigue.

- Inquire about feelings of malaise (a vague feeling of body weakness or discomfort) and fatigue (a pervasive, drained feeling that cannot be eliminated). *Both malaise and fatigue are subjective experiences with physiological, situational and psychological components.*
- Encourage verbalisation of feelings about the impact of the disease and fatigue on lifestyle. *Discussion of feelings helps the person clarify values and may assist in identifying priorities.*
- Encourage enjoyable but quiet activities, such as reading, listening to music or hobbies. Enjoyable activities help decrease feelings of fatigue. *Quiet activities conserve energy while yielding a sense of accomplishment.*

- Encourage establishing priorities and including rest periods or naps when scheduling daily activities. *This provides a sense of control over activities and helps maintain self-esteem. Scheduled rest periods help restore energy and decrease fatigue.*
- Encourage delegation of some responsibilities to family members. *Delegation helps maintain the person's involvement and role in family decisions and responsibilities, while conserving energy for those activities identified as high priority by the person.*
- Identify and encourage the person to use energy-saving equipment. *Performing tasks with less exertion and in less time helps conserve energy.*
- Encourage a diet high in carbohydrates and fluids. *A high-carbohydrate diet helps maintain muscle glycogen stores. A liberal fluid intake promotes excretion of metabolic by-products that may contribute to malaise and fatigue.*

Nausea

The effects of malignant lymphoma and its treatment with chemotherapy and/or radiation therapy can contribute to nausea and interfere with nutritional status. Nausea, a sensation of abdominal fullness and fear of vomiting often limit food intake. See also the nursing diagnosis of *Imbalanced nutrition* in the section on leukaemia, above, for additional interventions.

- Assess precipitating factors for nausea and/or vomiting, the frequency of vomiting and relief measures used by the person. *Careful assessment allows development of interventions tailored to the person's situation and needs.*

CONSIDERATION FOR PRACTICE

Provide ordered anti-emetics before chemotherapy is started. Administering prescribed anti-emetics before chemotherapy helps prevent nausea and the psychological association of nausea with chemotherapy.

- Teach measures to prevent or relieve nausea and vomiting:
  a. Eat cracker biscuits and suck on hard lollies.
  b. Eat soft, bland foods that are cold or at room temperature.
  c. Avoid unpleasant odours and get fresh air.
  d. Eat prior to but not immediately before chemotherapy.
  e. Use distraction or progressive muscle relaxation when nauseated.
  f. If vomiting occurs, gradually resume oral intake with frequent sips of clear liquids or ice, progressing to bland foods.

  Cracker biscuits and lollies often relieve queasiness, whereas hot, spicy, sweet or strong-smelling foods may increase nausea. Alternative nausea relief measures may be effective.
- Provide small feedings of high-kilojoule, high-protein foods and fluids. *This increases nutritional intake.*
- Assist with oral care, general hygiene and environmental control of temperature, appearance and odours. *These measures enhance appetite.*
- Identify and provide preferred foods. *This promotes nutritional intake.*
- Assist to a sitting position during and immediately after meals. *The sitting position helps decrease early feelings of fullness.*

Disturbed body image

The diagnosis of cancer is often devastating to the sense of trust in and the perception of one's body. Radiation and chemotherapy lead to changes in appearance and body function (e.g. hair loss, reduced libido and infertility), further altering body image. Reactions to this diagnosis vary and may include refusal to look in a mirror or discuss the effects of the disease or treatment, unwillingness to participate in rehabilitation, inappropriate treatment decisions, increasing dependence on others or refusal to provide self-care, hostility, withdrawal and signs of grieving.

- Assess perception of body image through subjective information such as:
  a. what the person likes most and least about their body
  b. pre-illness perception of people who are sick or have a disability
  c. current understanding of health and limitations imposed by illness or treatment
  d. feelings about the illness and its effect on perception of self and others.

  Body image is one's mental idea or picture of the body. It is based on past and present experiences and includes components of one's actual body and emotional responses to that body. Body image changes constantly. There is often a time lag between an actual body change and the changed body image; during this time, the diagnosis, teaching and treatment may be rejected.
- Discuss the risk of and measures to cope with alopecia. Suggest wearing wigs, scarves, hats or caps. Teach proper scalp care using baby shampoo or mild soap, a soft brush, sunscreen and mineral oil to reduce itching. If eyelashes and eyebrows are lost, teach eye protection, such as wearing eyeglasses and caps with wide brims. *Chemotherapeutic agents attack rapidly dividing cells such as those responsible for hair growth. Hair loss usually begins 1 to 2 weeks after initiation of chemotherapy, with maximum loss 1 to 2 months later. Alopecia may range from thinning to total hair loss. Regrowth depends on the treatment schedule and doses; however, it usually begins 2 to 3 months after treatment ends. New hair may be softer, more curly and slightly different in colour. Teaching and emotional support help the person anticipate hair loss, discuss its potential effect on body image and learn self-care techniques.*
- Discuss available resources for financial assistance with purchase of wigs, including assistance from the Australian Cancer Council. *A well-matched wig (or one the colour the person has always wished for!) can help maintain a positive body image.*

Sexual dysfunction

Sexual dysfunction may result from the malignancy and the effects of radiation and chemotherapy. Reproductive tissues are made of rapidly dividing cells and cancer treatment may cause

NURSING CARE PLAN A person with Hodgkin's disease

Max Patterson, RN, aged 28, is the nurse manager of a thoracic critical care unit in a large teaching hospital. Lately he has been more tired than usual, often wakes up at night covered with sweat and just does not feel well. He had thought that his symptoms were due to a viral illness and his busy work schedule. However, yesterday morning Max noticed a large swollen area on the right side of his neck. He made an appointment with his general practitioner who found a large cervical lymph node. A biopsy of the node and a CT scan of the chest were scheduled.

ASSESSMENT

David Smart, RN, the practice nurse at the medical centre, obtains a nursing history and assessment of Mr Patterson. His physical examination is essentially normal, with the exception of the enlarged node, which is not tender to palpation. When Mr Patterson is weighed, he tells RN Smart that he has lost 3.2 kg in the past 2 months. In reviewing the results of the blood studies, RN Smart notes mild anaemia and an increased neutrophil count. The lymph node biopsy shows Reed–Sternberg cells. The doctor and RN Smart tell Mr Patterson that the findings indicate stage 1B Hodgkin's disease but that the prognosis is very good. The doctor recommends a short course of combination chemotherapy followed by radiation therapy to involved sites.

DIAGNOSES

- *Anxiety* related to the diagnosis of Hodgkin's disease and effects of treatment on job performance.
- *Risk of infection* related to potential bone marrow depression due to chemotherapy.
- *Fatigue* related to effects of cancer, chemotherapy and radiation therapy.

PLANNING

- Reduce anxiety through discussion and education.
- Improve and extend energy levels.
- Monitor and reduce risk of infection.

Expected outcomes

- Verbalise reduced anxiety.
- Remain free of infection.
- Identify and use methods to preserve energy.

IMPLEMENTATION

- Encourage person to consider a leave of absence from work during course of treatment.
- Discuss joining a support group for people with cancer.
- Provide information about the illness, combination chemotherapy and radiation therapy.
- Reinforce knowledge of actions to decrease the risk of infection.
- Discuss ways to decrease fatigue and maintain energy:
- Take a 1- to 2-hour nap once or twice a day.
- Avoid overexertion during weekends and time off.
- Maintain a well-balanced diet.

EVALUATION

When Mr Patterson returns the following week to begin chemotherapy, he brings his friend Nina to meet RN Smart and asks him to discuss his treatment with her. Mr Patterson says, 'I am still really scared, but being able to talk about this with Nina will help a lot.' Mr Patterson has made arrangements to take 4 months' leave from work, with the understanding that his job will be held for him. He states that he will have some problems with money but is working them out. He also says he feels that taking a daytime sleep is silly but that he will rest to maintain his energy level. Mr Patterson and Nina express confidence that he will be cured and say they plan to be active members of the cancer support group—even after recovery.

CRITICAL THINKING IN THE NURSING PROCESS

1. Discuss the rationale for treating Hodgkin's disease with chemotherapy and radiation.
2. Design a teaching plan to help Mr Patterson prevent infection while he is at home.
3. What effect does the diagnosis of cancer have on the developmental tasks of a young adult?
4. Develop a care plan for Mr Patterson for the nursing diagnosis of *Ineffective role performance*.

REFLECTION ON THE NURSING PROCESS

1. What are the take-home points that you have learned within this case study?
2. How can you use them within your daily practice?
3. Where would you find good-quality information for a person in Mr Patterson's situation?

temporary or permanent sterility, changes in menstruation and changes in libido.

- Encourage discussion of actual or potential sexual dysfunction or sterility with the person and significant other. *People may be reluctant to discuss this unintended effect of treatment unless encouraged.*
- Assess knowledge, provide information and clarify misconceptions. Discuss realistic measures for coping (e.g. sperm banking prior to chemotherapy or radiation therapy). *People and their partners may be unclear about expected effects on sexuality, reproduction and the permanency of these effects.*
- Refer for counselling as indicated. *Sexual counselling can help the person and partner develop alternative strategies for expressing their sexuality.*

Risk of impaired skin integrity

Malignant lymphomas may cause significant pruritus and drenching night sweats. As a result, skin integrity may be impaired. In addition, radiation therapy can cause superficial burns, which also may affect skin integrity.

- Frequently assess skin, especially in areas undergoing radiation. *Early identification of lesions allows timely*

treatment and can prevent further disruption of this important line of defence against infection.

- Provide and teach measures to promote comfort and relieve itching: use cool water and a mild soap to bathe; blot (rather than rub) dry skin; apply plain cornflour or non-perfumed lotion or powder to the skin unless contraindicated, being careful not to clog pores; use lightweight blankets and clothing; maintain adequate humidity and a cool room temperature; wash bedding and clothes in mild detergent and put them through a second rinse cycle. *Pruritus is aggravated by excessive warmth, excessive dryness, rough fabrics, fatigue and stress. Lotions and some powders may be contraindicated during radiation therapy.*

Community-based care

When teaching the person and family for home care, include the following topics in addition to those previously identified for specific nursing diagnoses:

- information about the illness, planned treatment and anticipated side effects of treatment
- skin care and measures to relieve itching and protect areas of radiation
- symptoms to report to the doctor, including those of vertebral compression (decreased sensation or strength in lower extremities)
- use of analgesics and alternative relief strategies for abdominal pain and peripheral neuropathies
- respiratory care if mediastinal nodes are enlarged or lungs or pleurae are involved
- planning activities of daily living to ensure adequate rest and exercise
- measures to relieve nausea and maintain adequate nutrition.

Refer the person and their family members to the local oncology clinic, cancer support group or Cancer Council for information, assistance and counselling. A list of state and local agencies that offer information about malignant lymphoma and financial assistance can be obtained from the Leukaemia Foundation: www.leukaemia.org.au.

THE PERSON WITH MULTIPLE MYELOMA

Multiple myeloma is a malignancy in which plasma cells multiply uncontrollably and infiltrate the bone marrow, lymph nodes, spleen and other tissues. *Plasma cells* are B-cell lymphocytes that develop to produce antibodies (immunoglobins).

Incidence and risk factors

The incidence of multiple myeloma is increasing slightly, with an estimated 1500 people diagnosed each year in Australia (Leukaemia Foundation, 2014). The incidence of multiple myeloma increases with age, rarely occurring before age 40, and 80% of new cases occur over the age of 60, more frequently in men than in women (Huether & McCance, 2013). Its cause is unknown. Possible contributing factors include genetic alterations, radiation exposure, oncogenic virus, inflammatory stimuli and chronic antigenic stimulation. The risk of developing multiple myeloma is higher in people of lower socioeconomic status. This increased risk may relate to environmental factors such as poor housing, occupational hazards, poor nutritional status and other physical and psychosocial stressors such as exposure to infectious agents.

Pathophysiology

Malignant plasma cells arise from one clone (*monoclonal*) of B cells that produce abnormally large amounts of a particular immunoglobin called the *M protein*. This abnormal protein interferes with normal antibody production and impairs the humoral immune response. It also increases blood viscosity and may damage kidney tubules. As myeloma cells proliferate, they replace the bone marrow and infiltrate the bone itself. Cortical bone is progressively destroyed by tumour growth and enzymes produced by myeloma cells. These enzymes facilitate bone destruction, its infiltration by tumour cells, development of new blood vessels to sustain the tumour and growth of myeloma cells (Huether & McCance, 2013). Affected bones (primarily the vertebrae, ribs, skull, pelvis, femur, clavicle and scapula) are weakened and may break without trauma (*pathological fracture*). With disease progression, malignant cells spread via the bloodstream to invade other organs (see Figure 32.13).

Manifestations

The disease develops slowly, with many people diagnosed during evaluation for unrelated problems. Manifestations of multiple myeloma are due to its effects on the bone and the impaired immune response due to M-protein production. The most common presenting problem is bone pain that is usually felt in the back or ribs and is increased with movement (Leukaemia Foundation, 2014). With progression of the disease, the pain may increase in severity and become more localised. Rapid bone destruction releases calcium from the bone, leading to hypercalcaemia and manifestations of neurological dysfunction, such as lethargy, confusion and weakness.

As functional antibody formation decreases and the humoral immune response is suppressed, recurrent infections develop. Cell-mediated immunity remains intact. Bence Jones proteins are found in the urine in multiple myeloma. These proteins are toxic to the renal tubules and may lead to renal failure with azotaemia and uraemia. (See Chapter 27 for more information about renal failure.)

About 15% of people with multiple myeloma die within 3 months of the diagnosis. More frequently, the disease course is chronic, progressing more rapidly with each relapse after remission. The acute terminal stage of the disease is marked by pancytopenia and widespread organ infiltration by myeloma cells (Huether & McCance, 2013).

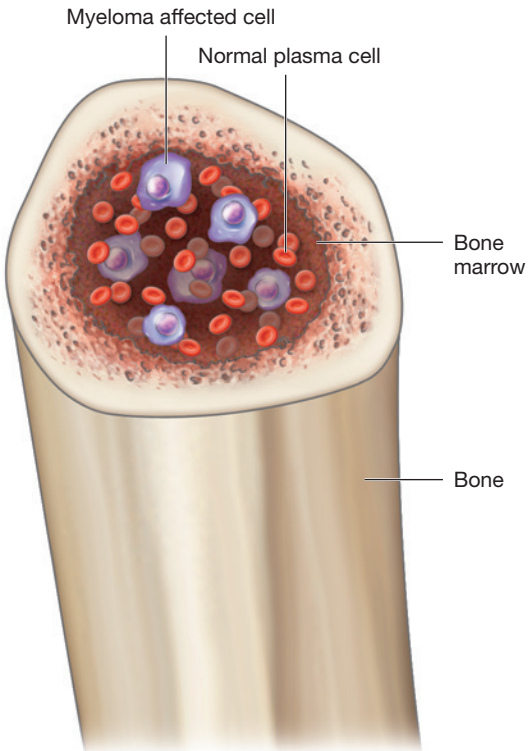

FIGURE 32.13 ■ An illustration of the progress of multiple myeloma in a male. Abnormal plasma cells proliferate uncontrollably, gradually replacing bone marrow and infiltrating bone itself. As the disease progresses, these cells spread to other organs via the bloodstream

INTERPROFESSIONAL CARE

Diagnosis and staging

Diagnostic tests for multiple myeloma include the following:

- *X-rays* and other radiological studies of the bone may reveal multiple punched-out lesions.
- *Bone marrow examination* shows an abnormal number of immature plasma cells.
- *FBC* shows moderate to severe anaemia and the *ESR* usually is elevated.
- *Protein electrophoresis* shows a spike of one type of antibody, usually immunoglobulin G (IgG).
- *Serum calcium, creatinine, uric acid* and *blood urea nitrogen (BUN)* levels often are elevated.
- *Urinalysis* shows Bence Jones protein in the urine.
- *Biopsy* of myeloma lesions confirms the diagnosis of multiple myeloma.

Staging of multiple myeloma is based on the haemoglobin and serum calcium levels, the amount of abnormal protein present and the degree of bone involvement.

Treatment

There is no cure for multiple myeloma. In some people, active observation is indicated, as the disease may continue with a slow, *indolent* (sluggish, not developing or progressing) course for many years (Leukemia Foundation, 2014). When indicated by disease stage or progression, standard treatment includes induction chemotherapy followed by stem cell transplant and maintenance chemotherapy to control progression of the disease. Supportive care is provided to reduce complications of the disease and their effects.

Combination chemotherapy with an alkylating agent melphalan (Alkeran), cyclophosphamide (Cytoxan) or chlorambucil (Chloromycetin)) and prednisone administered for 4 to 7 days every 4 to 6 weeks is commonly used. Chemotherapy typically reduces bone pain, hypercalcaemia, anaemia and the number of infections (Fauci et al., 2008). Novel therapies that include immunomodulatory drugs and proteasome inhibitors can contribute to improved survival rates and better response rates when compared to conventional chemotherapy. Localised radiation therapy may be used to treat painful bone lesions. High-dose chemotherapy followed by peripheral allogeneic stem cell transplant (SCT) may be more effective in achieving a cure, but is associated with a high mortality rate. When autologous SCT is used, granulocyte colony-stimulating factor is administered prior to harvesting and preserving peripheral stem cells for transplant.

Supportive care may include treatment of hypercalcaemia with hydration, possible bisphosphonate therapy to reduce bone loss (see Chapter 39) and calcium, vitamin D and fluoride supplements to support bone structure. Plasma exchange therapy (plasmapheresis) to remove circulating M proteins is used as needed to treat acute renal failure. Infections are treated promptly when they develop.

Nursing care

Assessment

Focused assessment data for the person with multiple myeloma include the following:

- *Health history:* complaints of back or bone pain, onset, duration and intensity; complaints of weakness, fatigue, anorexia; history of frequent or recurrent infections; neurological symptoms such as numbness and tingling or clumsiness.
- *Physical examination:* level of consciousness and mental status; mobility, gait; localised tenderness or pain, bony crepitus with movement or palpation; movement and sensation in extremities.

Nursing diagnoses and interventions

Nursing care of the person with multiple myeloma focuses on problems of chronic pain, impaired mobility and the risk of injury. Risk of infection is a major nursing care focus; see the previous section on leukaemia for specific interventions to reduce this risk. Other nursing care needs are similar to those

of people with other cancers and chronic pain. See Chapters 8 and 13 for additional specific nursing interventions for these problems.

Chronic pain

People with multiple myeloma typically experience chronic back pain and deep bone pain as myeloma cells saturate the bone marrow and invade the bone structure. Pathological fractures are a common and reoccurring problem.

- Assess pain, including intensity (use a standard pain scale), onset, duration, precipitating factors and effective relief measures. *Identifying the intensity, causes and precipitating factors of pain helps determine and evaluate effective pain relief measures.*
- Determine position of greatest comfort and assist as needed into this position. *The person is best able to identify positions that minimise pain, but may need assistance with repositioning.*
- Support position with pillows. *Bony prominences may be painful due to infiltrates. Pillows can help relieve pressure on these prominences, thus reducing pain.*
- Provide uninterrupted rest periods. *Adequate rest facilitates pain relief and improves pain tolerance.*
- Teach adjunctive pain relief strategies such as relaxation or guided imagery. *A combination of pharmacological and non-pharmacological methods provides better management of chronic pain, especially bone pain.*
- Teach effective analgesic use, including the family in instruction. *Analgesics are most effective when taken before pain becomes severe. People and their families may be reluctant to use prescription analgesics on a regular basis.*
- Report unrelieved pain to the doctor. *A different analgesic or addition of an adjunctive medication such as a non-steroidal anti-inflammatory drug (NSAID) may be needed to effectively control pain.*

Impaired physical mobility

Painful bony infiltrates and pathological fractures may limit mobility. A brace or splint may be used to protect extremities or support the back. In addition, persistent weakness associated with the cancer and anaemia may limit the person's ability to participate in usual activities.

- Assist to change position at least every 2 hours. *Assistance with repositioning is necessary due to weakness. Frequent repositioning improves comfort and reduces the risk of impaired skin and tissue integrity.*

CONSIDERATION FOR PRACTICE

Gently support extremities during repositioning. Weakened extremities due to infiltration of bone by myeloma cells and muscle atrophy from lack of use increase the risk of pathological fractures.

- Provide a trapeze to assist with repositioning. *A trapeze provides better leverage, allowing the person to assist with repositioning and providing a degree of independence. The ability to participate in self-care improves self-esteem.*

Risk of injury

The bone involvement of multiple myeloma places the person at high risk of pathological and traumatic fractures. Pathological fractures can occur with simple activities such as turning or reaching for an item. The spine usually is affected; the ribs and bones of the extremities also may be at risk of fracture.

- Place needed items close at hand. *Straining to reach objects increases the risk of falling or sustaining other injury.*
- Provide safety measures to prevent falls from bed: place the bed in a low position, use side rails as indicated and place the call bell within reach. *Safety measures help prevent accidental injury. A secure environment minimises risk and helps prevent falls.*
- Provide shoes with non-skid soles, a clear pathway, adequate lighting and a level surface free of scatter rugs or other hazards when ambulating. Provide a walker as needed for support and security. *Weight-bearing exercise promotes bone repair. Safety measures, such as an unobstructed pathway and a firm walking surface, help prevent falls.*

Community-based care

When teaching persons and their families for home care, include the following topics:

- strategies for home maintenance management
- signs and symptoms of complications to be reported to the doctor (e.g. symptoms of vertebral and extremity fractures)
- manifestations of infection to report: fever and chills; increased malaise, fatigue or weakness; cough with or without sputum; sore throat; dysuria, nocturia, frequency, urgency or malodourous urine.

Provide referrals for home health and home maintenance services, physical or occupational therapy, social services and hospice care as appropriate.

THE PERSON WITH NEUTROPENIA

Leucopenia is a decrease in the total circulating white blood cell count. Although any type of WBC may be affected, neutrophils, which make up the majority of WBCs, are affected most often. *Neutropenia* is a decrease in circulating neutrophils, usually less than 1×10^9/L to 1.5×10^9/L. Neutropenia may be either congenital or acquired, developing secondarily to prolonged infection, haematological disorders, starvation or autoimmune disorders (such as rheumatoid arthritis). Chemotherapy and other drugs can suppress the bone marrow. Neutropenia develops in approximately half of people undergoing chemotherapy to treat cancer. *Agranulocytosis* is severe neutropenia, with less than 0.5×10^9/L. Numbers of other granulocytes also are reduced. It is usually due to impaired leucocyte formation in the bone marrow or increased cell destruction in circulating blood. Agranulocytosis significantly increases the risk of infection. *Aplastic anaemia* affects production of all blood cells, resulting in anaemia, thrombocytopenia and agranulocytosis.

Pathophysiology and manifestations

Neutrophils are an integral component of the immune response. They are phagocytes, drawn to and activated by infection and inflammation to engulf and degrade invading microorganisms. Their lifespan in peripheral blood is short, less than 1 day. When *granulopoiesis* (the development and maturation of granulocytes) in the bone marrow is suppressed, the number of circulating neutrophils falls rapidly. As a result, the body's ability to defend itself against infection is significantly reduced.

The manifestations of neutropenia reflect the resulting impaired immunity and inflammatory response. Opportunistic bacterial, fungal and protozoal infections develop, commonly affecting the respiratory tract and mucosa of the mouth, GI tract and vagina. Malaise, chills and fever with extreme weakness and fatigue are common manifestations.

INTERPROFESSIONAL CARE

The diagnosis of neutropenia is made based on the person's manifestations, risk factors and the FBC. The total white blood count is low, 4×10^9/L.

Haematopoietic growth factors such as granulocyte-macrophage colony-stimulating factor are administered to stimulate granulocyte maturation and differentiation. Infections are treated with antibiotic therapy. Protective isolation procedures may be initiated to prevent exposure to pathogens. When neutropenia is related to chemotherapy, cancer treatment often must be halted, at least temporarily, to allow the bone marrow to recover.

Nursing care

The primary nursing care focus is early identification of neutropenia and protecting the person from infection. The WBC count is monitored on a regular basis and any decline reported to the doctor. Protective isolation may be indicated, including restricting the number of visitors and people with apparent illness. See *Risk of infection* in the earlier section on leukaemia for specific nursing interventions for the person with neutropenia.

PLATELET AND COAGULATION DISORDERS

Platelet and coagulation disorders affect **haemostasis**, control of bleeding. Haemostasis maintains a relatively steady state of blood volume, blood pressure and blood flow through injured vessels. Bleeding disorders result from deficient platelets, disruption of the clotting cascade or a combination of factors.

THE PERSON WITH THROMBOCYTOPENIA

Thrombocytopenia is a platelet count of less than 150×10^9/L of blood. It can lead to abnormal bleeding. A continuing decline in circulating platelets can lead to spontaneous bleeding and haemorrhage from minor trauma (see Figure 32.14). Bleeding due to platelet deficiency usually occurs in small vessels, causing manifestations such as *petechiae* and *purpura*. The mucous membranes of the nose, mouth, GI tract and vagina often bleed. Serious and potentially fatal bleeding may occur when the platelet count is less than 150×10^9/L.

Thrombocytopenia results from one of three mechanisms: decreased production, increased sequestration in the spleen or accelerated destruction. Primary thrombocytopenia that leads to increased platelet destruction is discussed below. Secondary thrombocytopenia may be caused by aplastic anaemia, bone marrow malignancy, infection, radiation therapy or drug therapy (see Box 32.7). Heparin therapy is the most common drug-induced thrombocytopenia; it is included in the discussion that follows. Platelet sequestration usually is due to an enlarged spleen. Up to 80% of platelets may be removed from circulation with significant splenomegaly (Huether & McCance, 2013). Finally, thrombocytopenia may result from premature platelet destruction associated with disseminated intravascular coagulation (DIC).

Physiology review

Effective control of bleeding requires a series of complex interactions between the damaged tissue and blood vessel, platelets, clotting factors and processes to dissolve clots once bleeding has been controlled. Platelets are formed in the bone marrow under

FIGURE 32.14 ■ Significant ecchymosis of the eyelid associated with minor trauma in a person with thrombocytopenia

BOX 32.7 Selected causes of secondary thrombocytopenia

Diseases
- Vitamin B_{12} anaemia
- Folic acid anaemia
- Aplastic anaemia
- Leukaemia
- Alcoholism
- DIC
- Infectious mononucleosis
- Viral infections
- HIV disease

Drugs
- Thiazide diuretics
- Aspirin
- Ibuprofen
- Indomethacin
- Naproxen
- Sulfonamides
- Phenytoin
- Cimetidine
- Digoxin
- Frusemide
- Heparin
- Morphine

Treatments
- Radiation therapy
- Chemotherapy
- Massive transfusion of stored blood

control of thrombopoietin, a protein produced by the liver, kidney, smooth muscle and bone marrow. Platelets are attracted to the damaged vessel wall, where they aggregate and release mediators that activate the clotting process. See Chapter 28 for a more complete discussion about platelets, clotting and haemostasis.

Pathophysiology

The two types of primary thrombocytopenia are immune thrombocytopenic purpura and thrombotic thrombocytopenic purpura.

Immune thrombocytopenic purpura

Immune thrombocytopenic purpura (ITP), also known as *idiopathic thrombocytopenic purpura*, is an autoimmune disorder in which platelet destruction is accelerated. In ITP, proteins on the platelet cell membrane stimulate autoantibody production, usually IgG antibodies. These autoantibodies adhere to the platelet membrane. Although the platelets function normally, the spleen reacts to them as being foreign and destroys the altered platelets after only 1 to 3 days of circulation.

MANIFESTATIONS The manifestations of ITP are due to bleeding from small vessels and mucous membranes. Petechiae and purpura develop, often on the anterior chest, arms, neck and oral mucous membranes. Bruising also may be apparent. As bleeding progresses, epistaxis (nosebleed), haematuria, excess menstrual bleeding and bleeding gums occur. Spontaneous intracranial bleeding is rare but does occur. Associated symptoms include weight loss, fever and headache.

INCIDENCE AND COURSE Acute ITP affects people of any age following a viral illness (Kessler, 2014). Acute ITP typically lasts only 1 to 2 months, resolving without long-term consequences. In its chronic form, ITP typically affects adults between ages 20 and 50; women are affected more often than men. Its onset is insidious. Chronic (or adult) ITP often occurs in people with other immune-associated disorders such as systemic lupus erythematosus or HIV disease.

Thrombotic thrombocytopenic purpura

Thrombotic thrombocytopenic purpura (TTP) is a rare disorder in which thrombi occlude arterioles and capillaries of the microcirculation. Many organs are affected, including the heart, kidneys and brain. The incidence of TTP is increasing (Huether & McCance, 2013). Its cause is unknown. Platelet aggregation is a key feature of the disorder. As RBCs circulate through partially occluded vessels, they fragment, leading to haemolytic anaemia.

MANIFESTATIONS TTP may be acute, the more common and severe form, or chronic. Acute idiopathic TTP may be fatal within months if untreated. The manifestations of TTP include purpura and petechiae and neurological symptoms such as headache, seizures and altered consciousness.

Heparin-induced thrombocytopenia

Heparin-induced thrombocytopenia (HIT) develops as a result of an abnormal response to heparin therapy. Unfractionated heparin carries a greater potential to precipitate HIT; it can, however, develop in people receiving low-molecular-weight heparin who have previously been treated with unfractionated heparin. See Chapter 31 for further discussion of heparin therapy and the forms of heparin.

Heparin is a protein that occurs naturally in human tissues and inflammatory cells. It can react directly with platelets, causing them to agglutinate (clump) and be removed from circulation by phagocytosis. This form of HIT, called type I HIT, typically causes mild thrombocytopenia. The more severe form, type II HIT, results from an immune reaction to heparin. In type II HIT, heparin forms an immune complex with a platelet protein known as platelet factor 4 (PF4). This complex acts as a foreign antigen in some people, stimulating antibody production. The antibody binds with the heparin–PF4 complex and these heparin–PF4–antibody complexes subsequently bind with circulating platelets, causing them to aggregate. As affected platelets aggregate, they are removed from circulation, leading to thrombocytopenia. In addition, small pieces of platelets can break loose, stimulating the clotting cascade and the development of thrombosis (clotting). The thrombocytopenia and thrombosis can be reversed by prompt withdrawal of heparin therapy, and an alternative replacement commenced (Lee & Arepally, 2013).

MANIFESTATIONS Despite thrombocytopenia, bleeding is usually a manifestation of HIT, probably because of the increased tendency to form clots that deplete clotting factors. The person may develop manifestations of an arterial thrombosis (severe pain, paresthesias, pallor and cool skin temperature, and pulselessness distal to the arterial occlusion) or of venous thrombosis (oedema, redness and warmth of the affected area). On rare occasions, an intravenous bolus of unfractionated heparin can precipitate an acute inflammatory response with manifestations that may mimic an acute pulmonary embolism: fever, chills, hypertension, tachycardia, dyspnoea, chest pain and cardiopulmonary arrest.

INTERPROFESSIONAL CARE

The diagnosis of thrombocytopenia is based on history, manifestations and diagnostic test results. Management focuses on treating or removing any causative factors and treating the platelet deficiency.

Diagnosis

The following diagnostic tests are used to identify thrombocytopenia:

- *FBC with platelet count* is done to evaluate blood cell counts, haemoglobin and haematocrit.
- *Antinuclear antibodies (ANA)* are measured to assess for autoantibodies and identify possible contributing disorders such as systemic lupus erythematosus.
- *Serological studies* for hepatitis viruses, cytomegalovirus (CMV), EBV, toxoplasma and HIV may be done. Serological testing also may be performed when HIT is suspected.
- *Bone marrow examination* evaluates for aplastic anaemia and megakaryocyte production.

Medications

Oral glucocorticoids, such as prednisone, are prescribed to suppress the autoimmune response. Many people who respond to glucocorticoid treatment relapse when the drug is withdrawn, however. Immunosuppressive drugs such as azathioprine, cyclophosphamide and cyclosporin may be used.

Prompt withdrawal of heparin therapy is vital when HIT is the cause of thrombocytopenia. All sources of heparin are removed, including heparin used to flush intravenous or other catheters and heparin-coated catheters. A non-heparin anticoagulant such as lepirudin (Refludan), a thrombin inhibitor, may be used. It is a recombinant form of hirudin, originally isolated from the salivary glands of leeches. Its primary adverse effect is bleeding; as a protein, it also can stimulate antibody development, resulting in rare instances of anaphylaxis. Argatroban is a synthetic direct thrombin inhibitor with a short half-life. It clears quickly when the infusion is discontinued, an advantage if excessive bleeding develops or invasive procedures must be performed.

Treatments

Platelet transfusions may be required to treat acute bleeding due to thrombocytopenia. Platelets are prepared from fresh whole blood; one unit contains 30 to 60 mL of platelet concentrate. The expected increase in platelets after one unit is infused is 10 000/mL. *Plasmapheresis*, or *plasma exchange therapy*, is the primary treatment for acute thrombotic thrombocytopenic purpura. The person's plasma is removed and replaced with fresh frozen plasma to remove autoantibodies, immune complexes and toxins.

Surgery

A *splenectomy* (surgical removal of the spleen) is the treatment of choice if the person with ITP relapses when glucocorticoids are discontinued. The spleen is the site of platelet destruction and antibody production. This surgery often cures the disorder, although relapse may occur years after splenectomy.

Nursing care

Assessment

- *Health history:* complaints of bruising with minor or no trauma, bleeding gums, nosebleed, heavy or prolonged menstrual periods, black, tarry or bloody stools, haematemesis, headache, fever or neurological symptoms; recent weight loss; recent viral or other illness; current and recent medications; exposure to toxins; previous exposure to heparin.
- *Physical examination:* skin and mucous membranes for colour, temperature, petechiae, purpura or bruises; vital signs; weight; mental status and level of consciousness; heart and breath sounds; abdominal exam; body fluids for occult blood.
- *Diagnostic tests:* FBC, haemoglobin and haematocrit, platelet count; serological and ANA test results; bone marrow examination results.

Nursing diagnoses and interventions

Inadequate platelets impair haemostasis, placing the person at risk of bleeding. Bleeding gums, an early sign of the disorder, affect oral mucous membrane integrity as well.

Ineffective protection

Bleeding is a serious complication associated with thrombocytopenia. As platelet counts decrease, the risk of bleeding increases. The risk is minimal with counts greater than 100×10^9/L, moderate when the count is around 50×10^9/L and significant when the count falls below 20×10^9/L.

- Monitor vital signs, heart and breath sounds every 4 hours. Frequently assess for other manifestations of bleeding:
  a. skin and mucous membranes for petechiae, ecchymoses and haematoma formation
  b. gums, nasal membranes and conjunctiva for bleeding
  c. overt or occult blood in emesis, urine or stool
  d. vaginal bleeding
  e. prolonged bleeding from puncture sites
  f. neurological changes: headache, visual changes, altered mental status, decreasing level of consciousness, seizures
  g. abdominal: epigastric pain, absence of bowel sounds, increasing abdominal girth, abdominal guarding or rigidity.

  Early identification of bleeding is important to prevent serious blood loss and shock.

CONSIDERATION FOR PRACTICE

Avoid invasive procedures such as rectal temperatures, urinary catheterisation and parenteral injections to the extent possible. Diagnostic procedures such as biopsy or lumbar puncture should be avoided if the platelet count is less than 150×10^9/L. Invasive procedures can cause tissue trauma and bleeding. Procedures that use large-bore needles should be delayed until the platelet count is increased.

- Apply pressure to puncture sites for 3 to 5 minutes; apply pressure to arterial puncture sites for 15 to 20 minutes. *Pressure promotes haemostasis and clot formation.*
- Instruct to avoid forcefully blowing the nose or picking crusts from the nose, straining to have a bowel movement and forceful coughing or sneezing. *These activities increase the risk of external and internal bleeding.*

Impaired oral mucous membranes

Thrombocytopenia frequently leads to bleeding of the gums and oral mucosa. As a result, risk of infection and impaired nutrition increases.

- Frequently assess the mouth for bleeding. Inquire about oral pain or tenderness. *Breakdown of oral mucous membranes increases the risk of infection and bleeding and causes discomfort with eating.*
- Encourage use of a soft-bristle toothbrush or sponge to clean teeth and gums. *Hard bristles may abrade oral mucosa, causing bleeding and increasing the risk of infection.*
- Instruct to rinse the mouth with saline every 2 to 4 hours. Apply petroleum jelly to lips as needed to prevent dryness and cracking. *Saline mouth rinses and petroleum jelly help maintain oral tissue integrity and promote cleansing and healing.*
- Instruct to avoid alcohol-based mouthwashes, very hot foods, alcohol and crusty foods. Teach to drink cool liquids at least every 2 hours. *Avoiding foods and liquids that traumatise oral mucosa increases comfort; fluid intake prevents dehydration and helps maintain mucous membrane integrity.*

Community-based care

In the adult, ITP often is a chronic disorder that the person and their family must learn to manage. Secondary thrombocytopenia may be either acute or chronic. Discuss the following topics when preparing the person and family for home care:

- nature of the disorder, its usual course and the treatment plan
- use of and desired and potential adverse effects of prescribed medications
- risks and benefits of surgery or treatments such as plasma replacement therapy
- the importance of follow-up tests and visits for care
- measures to reduce the risk of bleeding: safety measures such as a soft-bristle toothbrush, electric razor, avoidance of contact sports and hazardous activities, and avoiding medications that further interfere with platelet function (see Box 32.6).

Refer for home health or other community services (e.g. housekeeping, shopping) as indicated.

THE PERSON WITH HAEMOPHILIA

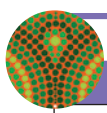
Haemophilia is a group of hereditary clotting factor disorders that lead to persistent and sometimes severe bleeding (see the accompanying 'Genetic considerations' box). Although often considered a disease of children, haemophilia may be diagnosed in adults. Deficiencies of three clotting factors—VIII, IX and XI—account for 90–95% of the bleeding disorders collectively called haemophilia (Huether & McCance, 2013).

Physiology review

When tissue injury occurs, platelets collect at the site, adhering to the damaged vessel wall (the platelet plug). Activation of the clotting cascade, a sequential process of interactive reactions of clotting factors, is vital to form a stable clot. Clotting factors are plasma proteins primarily produced by the liver. A number of these factors require the presence of vitamin K for synthesis and activation. Once the clot has been formed and stabilised, it begins to retract, pulling together the edges of the damaged blood vessel to initiate the healing process.

Pathophysiology

Haemophilia A (or *classic haemophilia*) is the most common type of haemophilia, caused by deficiency or dysfunction of clotting factor VIII. It is transmitted as an X-linked recessive disorder from mothers to sons (see Figure 32.15). The genetic defect of haemophilia A on the X chromosome may cause deficient factor VIII production or a defective form of the protein. When the concentration of the clotting factor is 5–35% of normal, the disease is *mild*. Bleeding is infrequent and usually associated with trauma. Concentrations of 1–5% of normal result in *moderate* disease. Again, bleeding usually occurs secondarily to trauma. *Severe* haemophilia occurs when concentrations are less



GENETIC CONSIDERATIONS
Focus on haemophilia

The incidence and pattern of inheritance for the forms of haemophilia differ:

- Haemophilia A occurs in about 1 in 10 000 male births, transmitted on the X chromosome: each male offspring has a 50% risk of inheriting the defective gene; each female offspring has a 50% risk of becoming a carrier.
- Haemophilia B occurs in about 1 in 100 000 male births, transmitted on the X chromosome.
- von Willebrand's disease affects about 1 in 100–500 people, usually inherited as an autosomal dominant trait: offspring of an affected person have a 50% risk of inheriting the trait and the disorder.
- Factor XI deficiency inherited as an autosomal recessive trait: each offspring of a carrier and an unaffected individual has as 50% risk of inheriting the trait; each offspring of two carriers has a 50% risk of being a carrier and a 25% risk of having the disorder. This deficiency is common in Ashkenazi Jews.

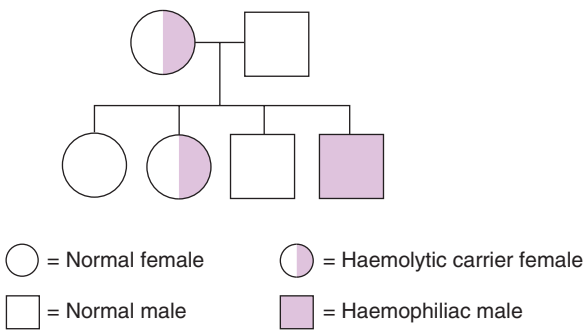


FIGURE 32.15 ■ The inheritance pattern of haemophilia A and B. Both are transmitted as X-linked recessive disorders. Females may be carriers, but males develop these disorders

than 1% of normal. Bleeding is frequent, often occurring without trauma (Fauci et al., 2008; Huether & McCance, 2013).

Haemophilia B (also called *Christmas disease*) accounts for about 15% of cases and is caused by a deficiency in factor IX. Despite the difference in clotting factor deficits, haemophilia A and B are clinically identical.

von Willebrand's disease, often considered a type of haemophilia, is the most common hereditary bleeding disorder (Grossman & Mattson, 2013). It is caused by a deficit of or defective von Willebrand (vW) factor, a protein that mediates platelet adhesion (Papadakis et al., 2013). Reduced levels of factor VIII often also are present, because vW factor carries factor VIII. This clotting disorder affects men and women equally. Bleeding associated with von Willebrand's disease rarely is severe. It often is diagnosed when prolonged bleeding follows surgery or a dental extraction.

Factor XI deficiency (or *haemophilia C*) is usually a mild disorder, identified when postoperative bleeding is prolonged. A comparison of the types of haemophilia is found in Table 32.9.

People with haemophilia form a platelet plug at the site of bleeding, but the clotting factor deficit impairs formation of a stable fibrin clot. The effect of vW factor deficiency is somewhat different, in that platelet aggregation at the site of injury is impaired. In either case, prolonged or extensive bleeding may result. Often bleeding occurs in response to injury or as a result of surgery. However, a severe clotting factor deficit can lead to spontaneous bleeding into the joints (*haemarthrosis*), deep tissues and CNS. Haemarthrosis often causes joint deformity and disability, usually of the elbows, hips, knees and ankles.

Manifestations

The following are manifestations of haemophilia:

- haemarthrosis
- easy bruising and cutaneous haematoma formation with minor trauma (e.g. an injection)
- bleeding from the gums and prolonged bleeding following minor injuries or cuts
- gastrointestinal bleeding, with haematemesis (vomiting blood), occult blood in the stools, gastric pain or abdominal pain
- spontaneous haematuria or epistaxis (nosebleed)
- pain or paralysis due to the pressure of haematomas on nerves
- intracranial haemorrhage is a potentially life-threatening manifestation of haemophilia.

INTERPROFESSIONAL CARE

Treatment of haemophilia focuses on preventing and/or treating bleeding, primarily by replacing deficient clotting factors. Specific treatment depends on the severity of the disorder and the specific factor deficiency. Care may be complicated by hepatitis or HIV disease in people with haemophilia treated with clotting factor concentrates prepared from multiple units of donated blood. Today, routine testing of all blood, improved blood donor screening and current methods of treating haemophilia have significantly reduced the risk of these blood-borne diseases.

Diagnosis

The following laboratory tests may be ordered:

- *Serum platelet levels* are measured and are usually normal.
- *Coagulation studies* such as APTT, bleeding time and prothrombin time are used to screen for haemophilia when abnormal bleeding occurs. APTT is increased in all types of haemophilia. Prothrombin time is unaffected in these

TABLE 32.9 Types of haemophilia

TYPE/NAME	DEFICIENCY	CHARACTERISTICS	TREATMENT
Haemophilia A (classic haemophilia)	Factor VIII	Transmitted by females; occurs primarily in males; bleeding time normal; coagulation time prolonged	Factor VIII concentrate or cryoprecipitate
Haemophilia B	Factor IX	Transmitted by females; occurs primarily in males; bleeding time normal; coagulation time prolonged	Factor IX (Christmas disease concentrate)
von Willebrand's disease	vW factor Factor VIII	Occurs in both females and males; bleeding time and coagulation time are both prolonged	Cryoprecipitate and desmopressin acetate (DDAVP)
Factor XI deficiency	Factor XI	Occurs in both males and females; the activated partial thromboplastin time is prolonged	Fresh frozen plasma

disorders but may be measured to rule out other disorders. Bleeding time is prolonged in von Willebrand's disease but normal in haemophilia A and B.

- *Factor assays* are performed; factor VIII is decreased in haemophilia A and often in von Willebrand's disease, factor IX is decreased in haemophilia B and factor XI in haemophilia C.
- *Amniocentesis* or *chorionic villus sampling* is used to identify the genetic defect of haemophilia when there is a known family history of the disease.

Medications

Deficient clotting factors are replaced regularly, as a prophylactic measure before surgery and dental procedures, and to control bleeding. Clotting factors may be given as fresh frozen plasma, cryoprecipitates or concentrates. Factor levels are measured on a regular basis to determine whether the treatment is adequate. Clotting factors are often self-administered and may be taken on either a regular or intermittent schedule.

Fresh frozen plasma replaces all clotting factors (including both factor VIII and factor IX) except platelets. When the cause of bleeding is not yet determined, fresh frozen plasma may be administered intravenously until a definitive diagnosis is made.

Haemophilia A is usually treated with either heat-treated factor VIII concentrate (heat treating reduces the risk of transmitting disease) or recombinant factor VIII. Although recombinant factor VIII, produced using recombinant DNA technology, eliminates the risk of viral disease transmission, its use is limited by cost. The dose of factor VIII is determined by the severity of the deficit and the presence or prospect of active bleeding (e.g. planned surgery).

Desmopressin acetate (DDAVP) may be given to people with mild haemophilia A or von Willebrand's disease prior to minor surgeries. This drug causes release of factor VIII and will raise blood levels two- or threefold for several hours, reducing the risk of bleeding and the need for clotting factor concentrate (Papadakis et al., 2013).

Factor IX concentrate (administered intravenously) is used to treat haemophilia B. Because factor IX concentrates also contain a number of other proteins, there is risk of thrombosis with recurrent use. They are used judiciously, only when needed. Products produced by recombinant technology or that are monoclonally purified carry a lower risk of stimulating thrombus formation (Fauci et al., 2008). Fresh frozen plasma replaces factor XI and is used when necessary. It may be given daily until the risk of bleeding decreases.

Factor VIII concentrates contain functional vW factor and may be used to treat von Willebrand's disease. Aspirin is avoided in all types of haemophilia.

Nursing care

Although primary responsibility for care falls to the person and family, nursing care presents challenges. For additional assessment and nursing care strategies for a person with haemophilia, see the accompanying nursing care plan.

Health promotion

Encourage people with a family history of haemophilia or bleeding disorders to seek genetic counselling during their family planning process. Although tests are available for the haemophilia gene, the technology to correct the disorder in utero does not yet exist. See Chapter 7.

Assessment

While severe haemophilia usually is diagnosed in childhood, milder cases may not be identified until surgery, invasive dental work or a traumatic injury causes extensive or prolonged bleeding. Focused assessment related to haemophilia includes the following:

- *Health history:* previous bleeding episodes with or without trauma; history of easy bruising, haematomas, epistaxis, bleeding gums, haematuria, vomiting blood or joint pain; aspirin use; family history of haemophilia or bleeding disorders.
- *Physical examination:* vital signs; bruising or bleeding of skin or mucous membranes; mental status; abdominal assessment; presence of joint deformity, decreased range of motion.
- *Diagnostic tests:* FBC including haemoglobin, haematocrit and platelet count; clotting factor assays; tests for occult blood (urine, stool, emesis); x-ray and scan results for evidence of bleeding.

Nursing diagnoses and interventions

Impaired blood clotting, the need for continuing care and disease management, and the risk of genetic transmission of haemophilia are priority problems for the person with haemophilia.

Ineffective protection

The inability to form stable clots and stem bleeding from injured blood vessels creates a significant risk for the person with haemophilia. Nursing care measures focus on preventing injury and protecting the skin from damage.

- Monitor for signs of bleeding, including haematomas, ecchymoses and purpura, as well as surface oozing or bleeding. Check emesis and stool for occult blood. *Bleeding may occur in cutaneous tissues as well as internal organs. Bleeding in the upper gastrointestinal tract may not be readily apparent in the stool.*
- Notify the doctor of any apparent bleeding. *Prompt intervention with administration of clotting factor concentrate decreases the risk of haemorrhage and subsequent hypovolaemia.*
- Avoid intramuscular injections, rectal temperatures and enemas. *These can pose a risk of tissue and vascular trauma, which can precipitate bleeding.*
- Use safety measures in personal care. For example, use an electric razor rather than a razor blade to shave. *Use of an electric razor minimises the opportunity to develop superficial cuts that may result in bleeding.*
- If bleeding occurs, control blood loss using gentle pressure, ice or a topical haemostatic agent, such as topical thrombin. *Direct pressure occludes bleeding vessels. Ice, a vasoconstrictor, may facilitate bleeding control, as do topical haemostatic agents.*

- Instruct to avoid activities that increase the risk of trauma, including contact sports and physical exertion associated with job performance, and to eliminate safety hazards in the home. *Depending on the severity of the clotting factor deficit, even minor trauma can lead to serious bleeding episodes. Safer activities such as non-contact sports (e.g. swimming, golf) and occupations that do not require physical labour may be substituted.*

Risk of ineffective health maintenance

Haemophilia is a chronic disorder, requiring active management to prevent and control bleeding and complications. Frequent visits to the doctor or clinic may be necessary. In addition, the person may need to learn to self-administer clotting factors and measures to prevent complications. The lifelong nature of the disorder may interfere with compliance, especially during early adulthood.

- Assess knowledge of disorder and the related treatments. Assessment allows identification of knowledge gaps and provides a basis on which to provide additional information. *Impaired disease management may be due to lack of knowledge or a conscious decision not to follow the recommendations of the healthcare provider.*
- Provide information about the bleeding disorder and prescribed medications and treatments. *Individualised instruction is more effective than general, possibly irrelevant information.*
- Provide emotional support, expressing confidence in the person's self-care abilities. *Emotional support helps the person incorporate the care regimen into their lifestyle.*
- Provide supervised learning and practice opportunities for administering clotting factors and topical haemostatic agents. *Successful practice sessions instil confidence in the ability to manage care and provide an opportunity for questions and exploring alternatives.*

Community-based care

Discuss the following topics when preparing the person with a bleeding disorder and the family for home care:

- Recognising the manifestations of internal bleeding: pallor, weakness, restlessness, headache, disorientation, pain, swelling. These manifestations

NURSING CARE PLAN A person with haemophilia

John Cruise is a 20-year-old TAFE student. He is admitted to the emergency department with a nosebleed that began when he fell during a touch football game. It has continued to bleed for over an hour.

ASSESSMENT

Mr Cruise states that he has haemophilia and realises that playing contact sport 'is probably a dumb thing to do'. He adds that he has not had any recent bleeding episodes. An icebag and manual pressure are applied in the emergency department. The doctor orders factor VIII concentrate to be administered. Physical assessment findings are 36.2°C, BP 118/64, R 18. Skin pale but warm. Laboratory tests reveal a prolonged APTT and a normal bleeding time and PT. Following treatment, Mr Cruise's bleeding subsides.

DIAGNOSES

- *Risk of aspiration* related to uncontrolled nosebleed.
- *Non-compliance* with activity recommendations.
- *Ineffective protection* related to lack of clotting factor VIII.

PLANNING

- Monitoring and reduction of potential complications required.
- Education required regarding disease risks and how to treat symptoms.

Expected outcomes

- Maintain an open airway.
- Maintain vital signs within his usual range.
- Exhibit no further signs of bleeding.
- Identify sports and recreation activities in which he can safely participate.
- Verbalise self-care measures to control bleeding.

IMPLEMENTATION

- Monitor vital signs and for further signs of bleeding.
- Assess airway and auscultate breath sounds.
- Review emergency measures to help stop bleeding.
- Reiterate the importance of seeking prompt medical attention if bleeding should occur.
- Advise regarding the importance of wearing a MedicAlert® bracelet identifying him as a haemophiliac.
- Discuss alternative non-contact sports and recreational activities.

EVALUATION

On discharge, Mr Cruise has no further signs of bleeding, shock or aspiration. He is able to verbalise methods to help stop local bleeding and the importance of seeking medical attention promptly when bleeding continues. Mr Cruise agrees to stop at a local chemist on the way home to order a MedicAlert® bracelet. In addition, Mr Cruise verbalises an understanding of the importance of avoiding contact sports and has identified swimming and golf as alternative leisure activities that he might enjoy.

CRITICAL THINKING IN THE NURSING PROCESS

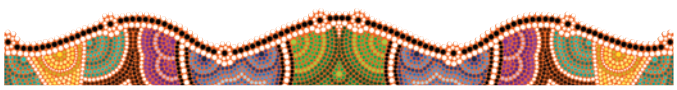
1. What is the pathophysiological basis for the bleeding that occurs in haemophilia A and B?
2. What was Mr Cruise's priority nursing diagnosis? Why?
3. Why is family planning a special consideration with a person who has haemophilia?
4. Outline a plan to teach the family of a person diagnosed with haemophilia how to administer an intravenous infusion.
5. Develop a care plan for Mr Cruise for the nursing diagnosis of *Impaired social interaction*. Consider Mr Cruise's age and developmental level in creating the plan.

REFLECTION ON THE NURSING PROCESS

1. What are the take-home messages you have learned in this case study?
2. How can they be used within your daily practice?

require emergency medical care and should be reported immediately.
- Applying cold packs and immobilising the joint for 24 to 48 hours if haemarthrosis occurs.
- Using analgesics for pain; avoiding prescription and over-the-counter drugs containing aspirin.
- Ensuring a safe home environment (e.g. padding sharp edges of furniture, using transition lighting or a night light, avoiding scatter rugs and wearing protective gloves when working in the house or garden).
- Using safe grooming practices such as electric razors.
- Wearing a MedicAlert® bracelet in case of accident.
- Practising good dental hygiene to decrease potential tooth decay and extractions. If dental procedures are necessary, discuss the need for prophylactic factor administration with the dentist and doctor.
- Following safer sex practices.
- Preparing and administering intravenous medications.

Refer the person and family to a local haemophilia or bleeding disorders support group. Provide contact information for national organisations and support services, such as the Australian Haemophilia Foundation: www.haemophilia.org.au.



THE PERSON WITH DISSEMINATED INTRAVASCULAR COAGULATION

Disseminated intravascular coagulation (DIC) is a disruption of haemostasis characterised by widespread intravascular clotting and bleeding. It may be acute and life threatening or relatively mild. DIC is a clinical syndrome that develops as a complication of a wide variety of other disorders (see Box 32.8). Sepsis is the most common cause of DIC. Gram-negative and gram-positive bacteria as well as viruses, fungi and protozoal infections may lead to DIC (Huether & McCance, 2013).

Pathophysiology

DIC is triggered by endothelial damage, release of tissue factors into the circulation or inappropriate activation of the clotting cascade by an endotoxin. Both the intrinsic and the extrinsic clotting cascade may be activated, although the extrinsic cascade usually is the one activated. Extensive thrombin entering the systemic circulation overwhelms natural anticoagulants, leading to unrestricted clot formation (Huether & McCance, 2013). Clotting may be localised to an individual organ or widespread with deposition of small thrombi and emboli throughout the microvasculature (Fauci et al., 2008). The widespread clotting consumes clotting factors (prothrombin, platelets, factor V and factor VIII, in particular) and activates fibrinolytic processes with anticoagulant production. As a result, haemorrhage occurs (see Figure 32.16).

The sequence of DIC follows:

1. Endothelial damage, tissue factors or toxins stimulate the clotting cascade.
2. Excess thrombin within the circulation overwhelms naturally occurring anticoagulants.

BOX 32.8 Conditions that may precipitate disseminated intravascular coagulation

Tissue damage
- Trauma: burns, gunshot wounds, frostbite, head injury
- Obstetric complications: septic abortion, abruptio placentae, amniotic fluid embolus, retained dead foetus
- Neoplasms: acute leukaemia, adenocarcinomas
- Haemolysis
- Fat embolism

Vessel damage
- Aortic aneurysm
- Acute glomerulonephritis
- Haemolytic uraemic syndrome

Infections
- Bacterial infection or sepsis
- Viral or mycotic infections
- Parasitic or rickettsial infection

3. Widespread clotting occurs within the microvasculature.
4. Thrombi and emboli impair tissue perfusion, leading to ischaemia, infarction and necrosis.
5. Clotting factors and platelets are consumed faster than they can be replaced.
6. Clotting activates fibrinolytic processes, which begin to break down clots.
7. Fibrin degradation products (FDPs, potent anticoagulants) are released, contributing to bleeding.
8. Clotting factors are depleted, the ability to form clots is lost and haemorrhage occurs.

Manifestations

The manifestations of DIC result from both clotting and bleeding, although bleeding is more obvious, especially in acute DIC. Bleeding ranges from oozing blood following an injection to frank haemorrhage from every body orifice (see the 'Manifestations' box below). Chronic DIC may be asymptomatic or may present with peripheral cyanosis, thrombosis and pre-gangrenous changes in the fingers and toes, nose and

MANIFESTATIONS DIC

- Frank haemorrhage from incisions
- Oozing of blood from punctures, intravenous catheter sites
- Purpura, petechiae, bruising
- Cyanosis of extremities
- Gastrointestinal bleeding or haemorrhage
- Dyspnoea, tachypnoea, bloody sputum
- Tachycardia, hypotension
- Haematuria, oliguria, acute renal failure
- Manifestations of increased intracranial pressure: decreased level of consciousness, pupillary, motor and sensory changes
- Mental status changes

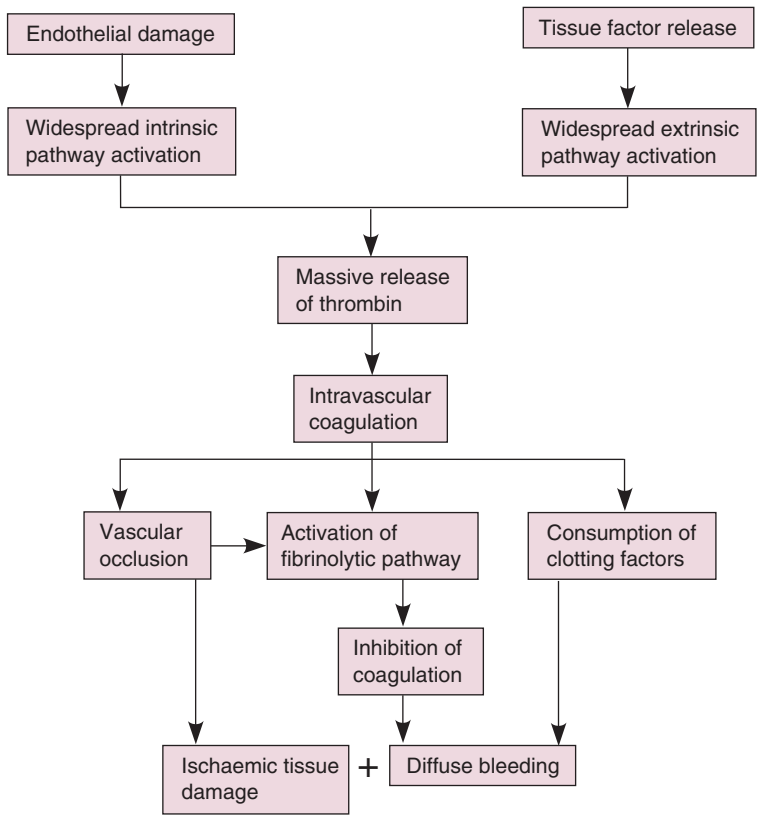


FIGURE 32.16 ■ Disseminated intravascular coagulation (DIC). Endothelial cell injury or release of tissue factors activates the intrinsic or extrinsic clotting pathway (or both). As a result, numerous microthrombi form throughout the vasculature, causing ischaemic tissue damage. Simultaneously, rapid consumption of clotting factors and activation of fibrinolytic mechanisms trigger widespread bleeding

genitalia with superficial thrombophlebitis, as well as deep venous thrombosis (Papadakis et al., 2013; Hampton, 2012).

INTERPROFESSIONAL CARE

Treatment of DIC is directed towards treating the underlying disorder and preventing further bleeding or massive thrombosis. Prompt treatment stabilises the person, reduces complications and allows recovery to occur; it does not cure DIC.

Diagnosis

Diagnostic tests are used to confirm the diagnosis of DIC and evaluate the risk of haemorrhage.

- *FBC* and *platelet count* are used to evaluate the haemoglobin, haematocrit and number of circulating platelets. *Schistocytes*, fragmented RBCs, may be noted due to cell trapping and damage within fibrin thrombi. The platelet count is decreased.
- *Coagulation studies* show prolonged prothrombin time (PT), *partial thromboplastin time (PTT)* and thrombin time, and a *low fibrinogen level* due to depletion of clotting factors. The fibrinogen level helps predict bleeding in DIC: as it falls, the risk of bleeding increases.
- *Fibrin degradation products (FDPs)* or *fibrin split products (FSPs)*, and plasma D-dimers are increased due to the fibrinolysis that occurs with DIC (Hampton, 2012).

Treatment

When bleeding is the major manifestation of DIC, fresh frozen plasma and platelet concentrates are given to restore clotting factors and platelets. Heparin, although controversial, may be administered. Heparin interferes with the clotting cascade and may prevent further clotting factor consumption due to uncontrolled thrombosis. It is used when bleeding is not controlled by plasma and platelets, as well as when the person has manifestations of thrombotic problems such as acrocyanosis and possible gangrene. Long-term heparin therapy (administered by injection or continuous infusion using a portable pump) may be necessary for people with chronic DIC.

Nursing care

Assessment

Nurses can be instrumental in identifying early manifestations of DIC, facilitating timely intervention. Focused nursing assessment for DIC includes:

- *Health history:* recent abortion (spontaneous or therapeutic) or current pregnancy; presence of a known malignant

tumour; history of abnormal bleeding episodes or a haematological disorder.
- *Physical examination:* bleeding from puncture wounds (e.g. injections), IV sites, incisions; haematuria, obvious or occult blood in emesis or stool, epistaxis, other abnormal bleeding; vital signs; heart and breath sounds; abdominal assessment, including girth, contour, bowel sounds, tenderness or guarding to palpation; colour, temperature, skin condition of hands, feet and digits; petechiae or purpura of skin, mucous membranes.
- *Diagnostic tests:* FBC with haemoglobin, haematocrit; platelet count; coagulation studies; evaluations of organ system function (e.g. liver and renal function tests); CT scans of the head and abdomen.

Nursing diagnoses and interventions

People with acute DIC often are critically ill, with multiple nursing care needs. Priority nursing diagnoses discussed in this section focus on impaired tissue perfusion and gas exchange, pain and fear. Septic shock may precipitate DIC; haemorrhagic shock may occur as a complication of DIC. See Chapter 10 for nursing diagnoses and interventions related to these problems.

Ineffective tissue perfusion

Thrombi and emboli forming throughout the microcirculation affect the perfusion of multiple organs and tissues. Additionally, bleeding due to clotting factor consumption affects cardiac output and blood flow to these tissues.
- Assess extremity pulses, warmth and capillary refill. Monitor level of consciousness (LOC) and mental status. *Monitoring central and peripheral tissue perfusion facilitates early treatment of impaired perfusion.*
- Carefully reposition person at least every 2 hours. *Position changes facilitate circulation and tissue perfusion and also provide an opportunity to assess for purpura, pallor and bleeding.*
- Discourage crossing the legs and do not elevate the knees on the bed or with a pillow. *These positions may impair arterial and venous flow to the lower legs and feet, increasing vascular stasis and the risk of thrombosis.*
- Minimise use of tape on the skin, using binders, non-adhesive dressings and other devices as needed. *Preventing skin trauma reduces the risk of bleeding and potential infection.*

CONSIDERATION FOR PRACTICE

Promptly report complaints of chest pain, changes in mental status, LOC, tissue perfusion, respirations, gastrointestinal function and urinary output. Chest pain or respiratory changes (tachypnoea, dyspnoea, orthopnoea) may be due to angina, pulmonary embolism or bleeding into lung tissue. Changes in mentation or LOC can indicate cerebral ischaemia. A painful, pale and cold extremity with no or diminished pulses indicates arterial occlusion. Prompt intervention is critical to save the extremity. Acute abdominal pain, decreased bowel sounds and GI bleeding may indicate mesenteric occlusion, a surgical emergency. Decreased urine output may signify renal artery thrombosis; renal failure may develop.

Impaired gas exchange

Microclots in the pulmonary vasculature are likely to interfere with gas exchange in the person with DIC.
- Monitor oxygen saturation continuously. Administer oxygen as required/ordered. *Oxygen saturation levels are a non-invasive means of assessing gas exchange. Supplemental oxygen promotes gas exchange and reduces cardiac work, relieving dyspnoea.*

CONSIDERATION FOR PRACTICE

Monitor arterial blood gas results; report abnormal results to the doctor. Low PaO_2 and rising $PaCO_2$ levels indicate impaired gas exchange and may signify the need for additional treatment.

- Place in Fowler's or high-Fowler's position as tolerated. *Elevating the head of the bed improves diaphragmatic excursion and alveolar ventilation.*
- Maintain bed rest. *Bed rest reduces oxygen demands and cardiac work.*
- Encourage deep breathing and effective coughing. *Increased respiratory depth and clearance of secretions from airways improves alveolar ventilation and oxygenation.*
- Cautious nasotracheal suctioning may be instituted if cough is ineffective or an endotracheal tube is in place. *Removal of secretions facilitates ventilation and oxygenation. However, care must be used to minimise suction-induced hypoxia and airway trauma.*
- Administer analgesics and anti-anxiety drugs as needed to control pain and anxiety. Provide reassurance and comfort measures. *Pain and anxiety increase the respiratory rate and decrease the depth of respirations, reducing effective ventilation and gas exchange.*

Pain

Both the underlying cause of DIC and tissue ischaemia from microvascular clots can cause pain. Identifying the aetiology of pain is important to identify potential complications or harmful effects of DIC and to institute effective treatment.
- Use a standard pain scale to evaluate and monitor pain and analgesic effectiveness. *Monitoring pain and response to medication facilitates development of an appropriate and effective treatment plan.*
- Handle extremities gently. *Gentle handling reduces the risk of further injury to, and pain in, ischaemic tissues.*
- Apply cool compresses to painful joints. *Application of cold decreases pain through the gate-control mechanism, inhibiting the dorsal horn of the spinal cord and reducing the sensation of pain.*

CONSIDERATION FOR PRACTICE

Notify the doctor promptly of new or a sudden increase in pain, especially when accompanied by changes in assessment findings. New or increased complaints of pain may signify increased circulatory impairment and ischaemic changes in tissues such as the heart, bowel or extremities. Circulation to a painful, pale or cyanotic, or cold extremity may be occluded by an arterial clot. Prompt intervention is necessary to save the extremity. Acute abdominal pain may signify mesenteric occlusion, a surgical emergency. Anginal pain may indicate occlusion of coronary arteries.

CONSIDERATION FOR PRACTICE

Continuously monitor effects of analgesics and mental and respiratory status. Analgesics may mask manifestations of neurological impairment due to thromboembolism and may depress the respiratory centre, further impairing gas exchange. Judicious analgesic administration with careful monitoring is vital to safely provide effective pain relief.

Fear

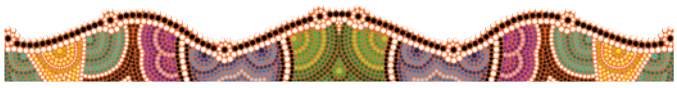
The underlying serious illness and a complication such as DIC result in an uncertain prognosis, often accompanied by fear.

- Encourage the person and family to verbalise concerns. *This helps the person and family identify their concerns and frame questions.*
- Answer questions truthfully. Providing honest answers is vital to developing a therapeutic nurse–individual relationship. *Accurate responses allow the person and their family to set priorities as they plan for an uncertain future.*
- Help the person and family identify coping strategies to manage this significant situational stressor. *Implementing past effective coping methods may provide the skills to manage the current crisis.*
- Provide emotional support. *The presence of a caring nurse helps reduce the fear and anxiety associated with a crisis.*
- Maintain a calm environment. *A calm environment provides reassurance that the situation is in control, reduces anxiety and promotes rest.*
- Respond promptly when the person calls for help. *Prompt response to expressed needs helps develop a trusting relationship and a sense of security that assistance is readily available.*
- Teach relaxation techniques. *Relaxation techniques can reduce muscle tension and other signs of anxiety. Gaining control over physical responses can help the person gain a sense of control over the situation.*

Community-based care

Although the immediate crisis of acute DIC is resolved prior to discharge, the person may have some continuing effects of the disorder, such as impaired tissue integrity of distal extremities. Teach the person and family about specific care needs, such as foot care (see Box 31.6) or dressing changes. Provide instruction about any continuing medications and follow-up care.

People with chronic DIC may require continuing heparin therapy, using either intermittent subcutaneous injections or a portable infusion pump. Teach the person and family members how to administer the injection or manage the infusion pump. Provide a referral to home healthcare or a home intravenous management service for assistance. Discuss the manifestations of excessive bleeding or recurrent clotting that need to be reported to the doctor.



CHAPTER HIGHLIGHTS

- Anaemia is the most common disorder of the red blood cells; nutritional deficiencies are the most common causes of anaemia. Its manifestations relate to the function of RBCs and haemoglobin, transporting oxygen to the cells: fatigue, increased respiratory and heart rates, shortness of breath with activity and pallor.
- Genetically transmitted disorders such as sickle cell disease and thalassaemia can cause significant anaemia and associated problems in affected populations. These people require teaching and episodic acute care for crises such as vaso-occlusive crisis in sickle cell disease.
- Nursing care related to anaemia is primarily educational to prepare the person for effective self-care, including diet, prescribed medications and measures to prevent sickling episodes (for those with sickle cell disease).
- Leukaemia and lymphomas are the primary disorders of white blood cells and lymphoid tissues.
- Manifestations of the leukaemias reflect the altered ability of abnormal WBCs to perform effective immune surveillance and crowding of the bone marrow and other organs by rapidly proliferating cells. Frequent sore throats, increased risk of infection and manifestations of anaemia and thrombocytopenia are seen, as well as an enlarged spleen and abdominal pain.
- Four major subgroups of leukaemia are identified: acute and chronic myeloid leukaemias, and acute and chronic lymphocytic (or lymphoblastic) leukaemias. The primary population affected differs for each of these leukaemias, as does their course.
- Genetic alterations and certain viruses are linked to the development of leukaemia, as are exposure to chemotherapy drugs, environmental toxins and ionising radiation.
- Lymphocytic leukaemias and lymphomas are closely related disorders.
- Nursing care for people with leukaemia and lymphoma focuses on reducing the risk of infection and bleeding, managing the effects of chemotherapy and radiation therapy and, in some cases, caring for people before and after bone marrow or stem cell transplant.

- The major risks associated with bone marrow and stem cell transplant are infection prior to, and immediately following, the transplant; and graft-versus-host disease, a potentially fatal condition. A pruritic rash and desquamation of the palms and soles; abdominal pain, nausea and diarrhoea; and jaundice and elevated liver enzymes are common early manifestations of GVHD.
- The treatment of and nursing care for people with lymphomas (including Hodgkin's disease and non-Hodgkin's lymphoma) is similar to that provided for people with leukaemia.
- Multiple myeloma is a malignancy of plasma cells, which are B lymphocytes that produce antibodies. Circulating M proteins and Bence Jones proteins in the urine are seen in multiple myeloma. The usual presenting manifestation is bone pain. Pathological fractures and hypercalcaemia are common complications of multiple myeloma as bone is destroyed.
- Bleeding and clotting disorders can result from either inadequate platelets (thrombocytopenia) or disruption of the clotting mechanisms (haemophilia, DIC). Petechiae and purpura are common manifestations of bleeding/clotting disorders.
- Haemophilias are genetically transmitted disorders. Haemophilia A and B are transmitted on the X chromosome (sex-linked) from mother to son. von Willebrand's disease, the most common bleeding disorder, is transmitted as an autosomal dominant disorder and affects men and women equally.
- Haemophilias are treated by replacement of the missing clotting factor and measures to prevent injury and bleeding.
- Disseminated intravascular coagulation is a disorder of widespread microvascular clotting. It commonly is precipitated by sepsis, but also may occur with conditions such as major trauma, malignancy or as an obstetric emergency.
- In DIC, platelets and clotting factors are consumed by the abnormal clotting processes, leading to the manifestations of bleeding, including frank haemorrhage, haematuria, oozing blood from parenteral and intravenous injection sites, and GI bleeding. Blood flow to organs and tissues is compromised by clot formation, leading to manifestations such as cyanosis of extremities, abdominal pain, kidney failure and changes in mental status and level of consciousness. Nursing care is supportive, focusing on administering prescribed treatments and monitoring and supporting cardiovascular, respiratory and kidney function.

CONCEPT CHECK

1 In assessing a woman with moderate anaemia, the nurse would expect to find which of the following?
1 haematocrit 45%
2 pulse rate 140
3 complaints of shortness of breath with exercise
4 WCC 150×10^9/L

2 The nurse caring for a person after gastric resection observes carefully for evidence of nutritional deficiency anaemia related to malabsorption, including:
1 numbness and tingling of extremities
2 steatorrhoea
3 dark yellow or bronze skin colour
4 bone pain

3 The nurse caring for a person with acute myeloid leukaemia plans which of the following nursing interventions during hospitalisation? (Select all that apply.)
1 Place in a private room.
2 Implement airborne infection control precautions.
3 Assist with oral hygiene after meals.
4 Monitor rectal temperature q4h.
5 Request soft, bland diet.

4 The nurse caring for a person with lymphoma who is being started on chemotherapy regimens understands that chemotherapy drugs are used in combination to:
1 target malignant cells in different organs
2 prevent the development of adverse effects
3 target different phases of the cell cycle
4 support growth and development of normal cells

5 A person with multiple myeloma calls the home health nurse complaining of new-onset severe back pain. The appropriate response by the nurse is to:
1 reassure the person that bone pain is expected with this disease
2 inquire about the person's use of NSAIDs and analgesics to manage pain
3 suggest use of a back brace to reduce pain
4 notify the doctor of the onset of new pain

6 The nurse observes reddish-purple spots and areas of purple bruising on a newly admitted person. Which laboratory results support this assessment finding?
1 haematocrit 28%
2 platelets 100×10^9/L
3 INR 4.0
4 WCC 150×10^9/L

7 A person whose husband has haemophilia asks if her newborn baby girl could have the disease. The nurse's response is based on the knowledge that:
1 the most common forms of haemophilia are transmitted as sex-linked recessive disorders; her daughter is at risk of carrying the defective gene
2 because haemophilia is a sex-linked recessive disorder carried on the Y chromosome, her daughter has no risk of having or carrying the disease
3 haemophilia is an autosomal dominant disorder; therefore, her daughter has a 50% chance of having the disorder
4 although haemophilia is genetically transmitted, its pattern of inheritance is unknown and her daughter will need to be tested for the defective gene

8 The nurse administering platelets to a person with disseminated intravascular coagulation (DIC) understands that the intended effect of this treatment is to:
1 replace specific clotting factors
2 promote intravascular clotting
3 restore tissue oxygenation
4 replace depleted platelets

UNIT 8 BUILDING CLINICAL COMPETENCE

Responses to altered cardiac function

CLINICAL SCENARIO

You have been assigned to work with the following four people for the 0700 shift on a cardiac telemetry unit. Significant data obtained during report are as follows:

- Betty Williams, aged 62, was admitted with acute anterior MI and had successful fibrinolytic therapy 3 days ago. Significant history includes type 2 diabetes, angina, hypertension and a history of smoking (1.5 to 2 packets per day for 45 years). Her CCU course was uneventful. Current vital signs are T 37.2°C, P 76, R 16, BP 148/88. Cardiac monitor shows normal sinus rhythm with no ectopy. She has been pain free since her glyceryl trinitrate infusion was titrated off in the CCU 2 days ago. Lung sounds are clear.
- Arnold Markus, aged 71, was admitted with acute heart failure 2 days ago, treated and stabilised in the CCU, and transferred to the cardiac telemetry unit. Current vital signs are T 36.9°C, P 88, R 18, BP 112/74. Cardiac monitor shows normal sinus rhythm with new isolated premature ventricular contractions (PVCs). Lung sounds are clear in upper lobes with crackles in the left base and he was able to sleep intermittently during the night using 2 pillows.
- Theresa Cartwright is a 34-year-old female admitted for anticoagulant therapy after developing a deep venous thrombosis after a fall down the steps and hitting her calf. She was started on heparin yesterday and needs blood drawn for an activated partial thromboplastin time (APTT) to determine her morning dose of heparin.
- Scott Jacoby is a 25 year old with Down syndrome. He was admitted yesterday with an upper respiratory infection. On assessment he was pale, T 38.3°C, P 100, R 30 with dyspnoea on exertion, BP of 118/86 and multiple bruises and petechiae on his arms and legs. He is scheduled for a bone marrow examination this morning.

Critical thinking questions

1 In what order would you visit these people after report?

1.
2.
3.
4.

2 What top two priority nursing diagnoses would you choose for each of the people presented above? Can you explain, if asked, the rationale for your choices?

	Priority Nursing Diagnosis #1	Priority Nursing Diagnosis #2
Betty Williams		
Arnold Markus		
Theresa Cartwright		
Scott Jacoby		

3 You are completing a beginning-of-shift assessment with Mr Markus. Which of the following items would take priority?

1. rhythm strip analysis
2. lung sounds
3. oxygen saturation
4. heart sounds

4 The charge nurse tells you that the monitor at the nursing station shows that Mr Markus is having an increase in PVCs. You would be most concerned after reviewing a rhythm strip if the PVCs had which of the following characteristics?

1. a frequency of 4 per minute
2. could be felt by the person
3. were unifocal in morphology
4. fell on the T wave of the preceding beat

5 Ms Williams rings the call bell and tells you that she is having pressure in her chest. On assessment, she rates it as a 5. Which of the following nursing actions should take priority?

1. Obtain a full symptom assessment.
2. Administer a prn glyceryl trinitrate tablet SL.
3. Call for an electrocardiogram.
4. Notify the doctor.

6 Which is the most important for you to report when caring for Mr Jacoby?

1. constipation and straining with bowel movements
2. fever and burning on urination
3. weight loss and decreased appetite
4. dyspnoea and shortness of breath with exercising

7 When a person is placed on warfarin therapy, which laboratory studies would you expect to draw? (Select all that apply.)

1. activated partial thromboplastin time (APTT)
2. International Normalized Ratio (INR)
3. partial thromboplastin time (PTT)
4. full blood cell count (FBC)
5. white blood cell count (WBC)
6. prothrombin time (PT)

8 Mrs Cart wright needs further teaching regarding anticoagulant therapy when she makes which statement?

1. 'The heparin will be continued for four to five days for the Coumadin to reach a good effect.'
2. 'I need to continue to have blood drawn to watch my drug levels as long as I am taking these drugs.'
3. 'I cannot continue to take birth control pills while I am taking these drugs.'
4. 'I need to take the medication at the same time every day for the drug to be effective.'

9 After a person has undergone mitral valve replacement surgery, the nurse would be most concerned about possible risks to medication therapy if the person had a history of which of the following disorders listed in the medical record?

1. glaucoma
2. gout
3. duodenal ulcer
4. osteoarthritis

10 Which nursing diagnosis has the highest priority for the person with varicose veins?

1. *Body image disturbance*
2. *Impaired tissue perfusion*
3. *Activity intolerance*
4. *Risk of infection*

11 Which is a priority teaching instruction for the person with a history of Raynaud's disease?

1. Enter a smoking cessation program.
2. Reduce dietary fats and carbohydrates.
3. Wear gloves and socks in cold weather.
4. Begin an exercise program.

12 A prescription for the calcium channel blocker diltiazem is ordered for a person with hypertension. What will the nurse instruct the person regarding medication administration?

1. Limit fluids to decrease the development of peripheral oedema.
2. Notify the doctor for a pulse of less than 60 bpm.
3. Increase fibre in the diet as diarrhoea may be a side effect.
4. Report tachycardia and an increase in blood pressure.

13 A person with history of haemophilia fell and cut his leg while bushwalking. Which intervention should the person perform until help arrives?

1. Apply a tourniquet above the cut.
2. Splint the leg to prevent movement.
3. Apply pressure to the femoral artery.
4. Apply gentle pressure over the cut.

CASE STUDY

Grace Schmidt is a 49-year-old female who works as a teacher at a high school. She comes to the medical centre complaining of a throbbing headache and dizziness. Her height and weight are 162 cm and 111 kg. Upon assessment her vital signs are P 100, R 16, BP lying is 180/115, sitting is 170/110 and standing is 165/105. Her skin is cool and dry. Her capillary refill is 4 seconds. She denies smoking, drinks an occasional glass of wine and does not participate in a regular exercise program. She states that her job can be stressful at times. Nutrition assessment indicates a diet high in fats and sodium. She denies any family history of hypertension or heart disease. She is married and has a daughter and son who live in the same town. A medical diagnosis of hypertension is determined.

Based on Mrs Schmidt's assessment, blood pressure readings and weight, the priority nursing diagnosis of *Ineffective health maintenance* is identified for planning nursing care.

UNIT 9

RESPONSES TO ALTERED RESPIRATORY FUNCTION

CHAPTER 33

A PERSON-CENTRED APPROACH TO ASSESSING THE RESPIRATORY SYSTEM

MAJELLA HALES

KEY TERMS

LEARNING OUTCOMES

- Describe the anatomy, physiology and functions of the respiratory system.
- Explain the mechanics of ventilation.
- Differentiate between oxygen and carbon dioxide transport and how affinity influences loading and unloading.
- Examine investigations and observations important for assessing a person's respiratory system function.
- Demonstrate accurate interpretation of data obtained from a person requiring review of their respiratory system.

CLINICAL COMPETENCIES

- Conduct and document a health history for people at risk of or currently experiencing alterations in the respiratory system.
- Conduct and document a physical assessment of respiratory structures and functions.
- Monitor the results of diagnostic tests and report abnormal findings.

EQUIPMENT NEEDED

- Tongue depressor
- Penlight
- Nasal speculum
- Metric ruler
- Marking pen
- Stethoscope with diaphragm

The respiratory system provides the cells of the body with oxygen and eliminates carbon dioxide, formed as a waste product of cellular metabolism. The events in this process, called respiration, are:

- *Pulmonary ventilation:* Air is moved into and out of the lungs.
- *External respiration:* Exchange of oxygen and carbon dioxide occurs between the alveoli and the blood.
- *Gas transport:* Oxygen and carbon dioxide are transported to and from the lungs and the cells of the body via the blood.
- *Internal respiration:* Exchange of oxygen and carbon dioxide occurs between the blood and the cells.

ANATOMY, PHYSIOLOGY AND FUNCTIONS OF THE RESPIRATORY SYSTEM

The respiratory system functions as a whole, but is divided into the upper respiratory system and the lower respiratory system for discussion of respiratory disorders in the following chapters.

THE UPPER RESPIRATORY SYSTEM

The upper respiratory system serves as a passageway for air moving into the lungs and carbon dioxide moving out to the external environment (see Figure 33.1). As air moves through these structures, it is cleaned, humidified and warmed.

The nose

The nose is the external opening of the respiratory system. The external nose is given structure by the nasal, frontal and maxillary bones as well as by plates of hyaline cartilage. The nostrils (also called the external nares) are two cavities within the nose, separated by the nasal septum. These cavities open into the nasal portion of the pharynx through the internal nares. The nasal cavities just behind the nasal openings are lined with skin that contains hair follicles, sweat glands and sebaceous glands. The nasal hairs filter the air as it enters the nares. The rest of the cavity is lined with mucous membranes that contain olfactory neurons and goblet cells that secrete thick mucus. The mucus not only traps dust and bacteria but also contains lysozyme, an enzyme that destroys bacteria as they enter the nose. As mucus and debris accumulate, mucosal ciliated cells move them towards the pharynx, where they are swallowed. The mucosa is highly vascular, warming air that moves across its surface.

Three structures project outward from the lateral wall of each nasal cavity: the superior, middle and inferior turbinates. The turbinates cause air entering the nose to become turbulent and also increase the surface area of mucosa exposed to the air. As air moves through this area, heavier particles of debris drop out and are trapped in the mucosa of the turbinates.

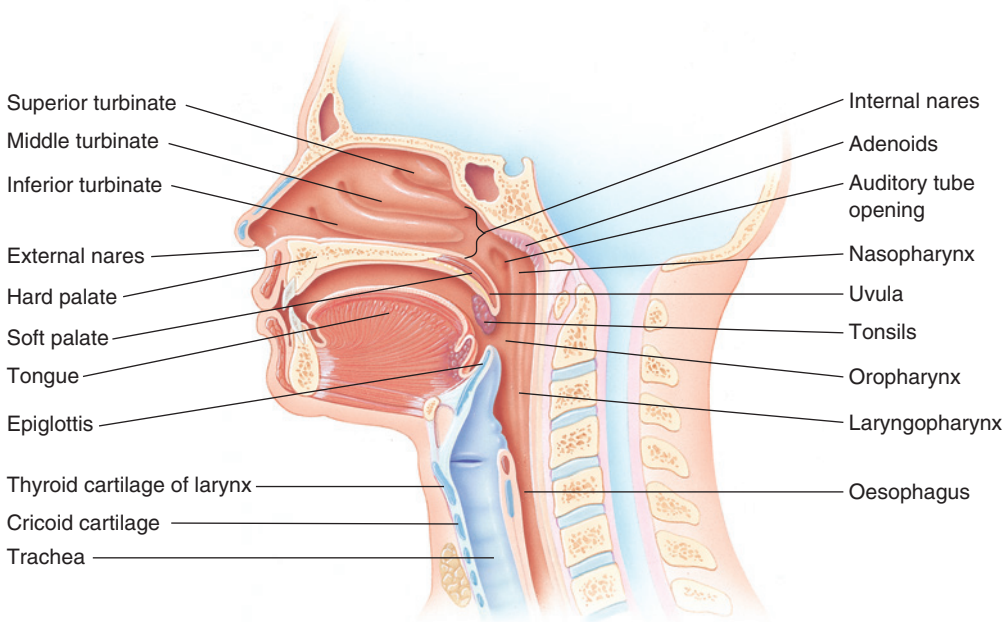

FIGURE 33.1 ■ The upper respiratory system

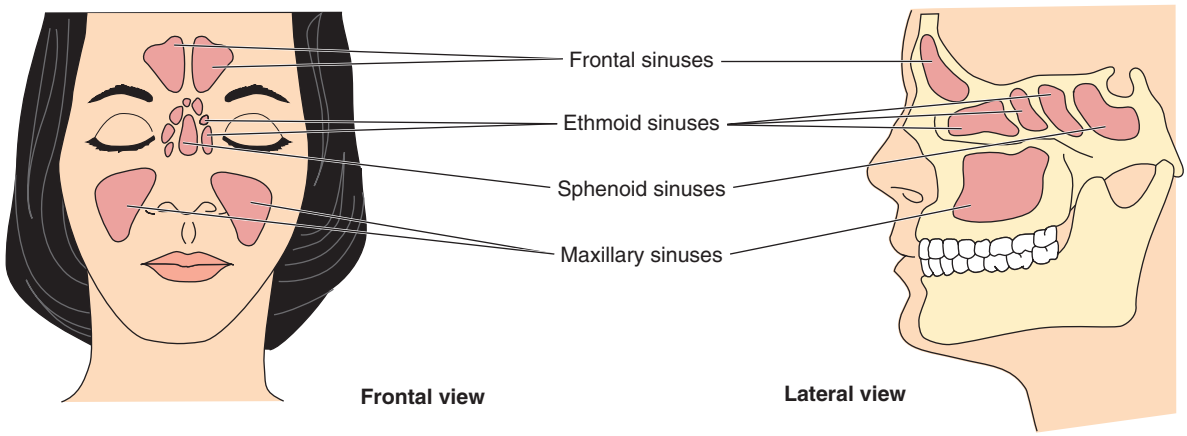

FIGURE 33.2 ■ Sinuses—frontal and lateral views

The sinuses

The nasal cavity is surrounded by paranasal sinuses (see Figure 33.2), located in the frontal, sphenoid, ethmoid and maxillary bones. Sinuses lighten the skull, assist in speech and produce mucus that drains into the nasal cavities to help trap debris.

The pharynx

The pharynx, a funnel-shaped passageway approximately 13 cm long, extends from the base of the skull to the level of the C6 vertebra. The pharynx serves as a passageway for both air and food. It is divided into three regions: the nasopharynx, the oropharynx and the laryngopharynx.

The nasopharynx serves only as a passageway for air. Located beneath the sphenoid bone and above the level of the soft palate, the nasopharynx is continuous with the nasal cavities. This segment is lined with ciliated epithelium, which continues to move debris from the nasal cavities to the pharynx. Masses of lymphoid tissue (the tonsils and adenoids) are located in the mucosa high in the posterior wall; these tissues trap and destroy infectious agents entering with the air. The auditory (eustachian) tubes also open into the nasopharynx, connecting it with the middle ear.

The oropharynx lies behind the oral cavity and extends from the soft palate to the level of the hyoid bone. It serves as a passageway for both air and food. An upward rise of the soft palate prevents food from entering the nasopharynx during swallowing. The oropharynx is lined with stratified squamous epithelium that protects it from the friction of food and damage from the chemicals found in food and fluids.

The laryngopharynx extends from the hyoid bone to the larynx. It is also lined with stratified squamous epithelium and serves as a passageway for both food and air. Air does not move into the lungs while food is being swallowed and moved into the oesophagus.

The larynx

The larynx is approximately 5 cm long. It opens superiorly at the laryngopharynx and is continuous inferiorly with the trachea. The larynx provides an airway and directs air and food into the proper passageway. As long as air is moving through the larynx, its inlet is open; however, the inlet closes during swallowing. The larynx also contains the vocal cords, necessary for voice production.

The larynx is formed by cartilages, connected by ligaments and membranes. The thyroid cartilage is formed by the fusion of two cartilages; the fusion point is visible as the Adam's apple. The cricoid cartilage lies below the thyroid cartilage; other pairs of cartilages form the walls of the larynx. The epiglottis, also a cartilage, normally projects upwards to the base of the tongue; however, during swallowing the larynx moves upwards and the epiglottis tips to cover the opening to the larynx. If anything other than air enters the larynx, a cough reflex expels the foreign substance before it can enter the lungs. This protective reflex does not work if the person is unconscious or has a decreased level of consciousness that results in an inability to manage this reflex.

The trachea

The trachea begins at the inferior larynx and descends anteriorly to the oesophagus to enter the mediastinum, where it divides to become the right and left primary bronchi of the lungs. The trachea is approximately 12 to 15 cm long and 2.5 cm in diameter. It contains 16 to 20 C-shaped rings of cartilage joined by connective tissue. The mucosa lining the trachea consists of pseudostratified ciliated columnar epithelium containing seromucous glands that produce thick mucus. Dust and debris in the inspired air are trapped in this mucus, moved towards the throat by the cilia and then either swallowed or coughed out through the mouth.

THE LOWER RESPIRATORY SYSTEM

The lower respiratory system includes the lungs and the bronchi (see Figures 33.3 and 33.4).

The lungs

The centre of the thoracic cavity is filled by the *mediastinum*, which contains the heart, great blood vessels, bronchi, trachea and oesophagus. The mediastinum is flanked on either side by the lungs (see Figure 33.3). Each lung is suspended in its own pleural cavity, with the anterior, lateral and posterior lung surfaces lying close to the ribs. The hilus, on the mediastinal surface of each lung, is where blood vessels of the pulmonary

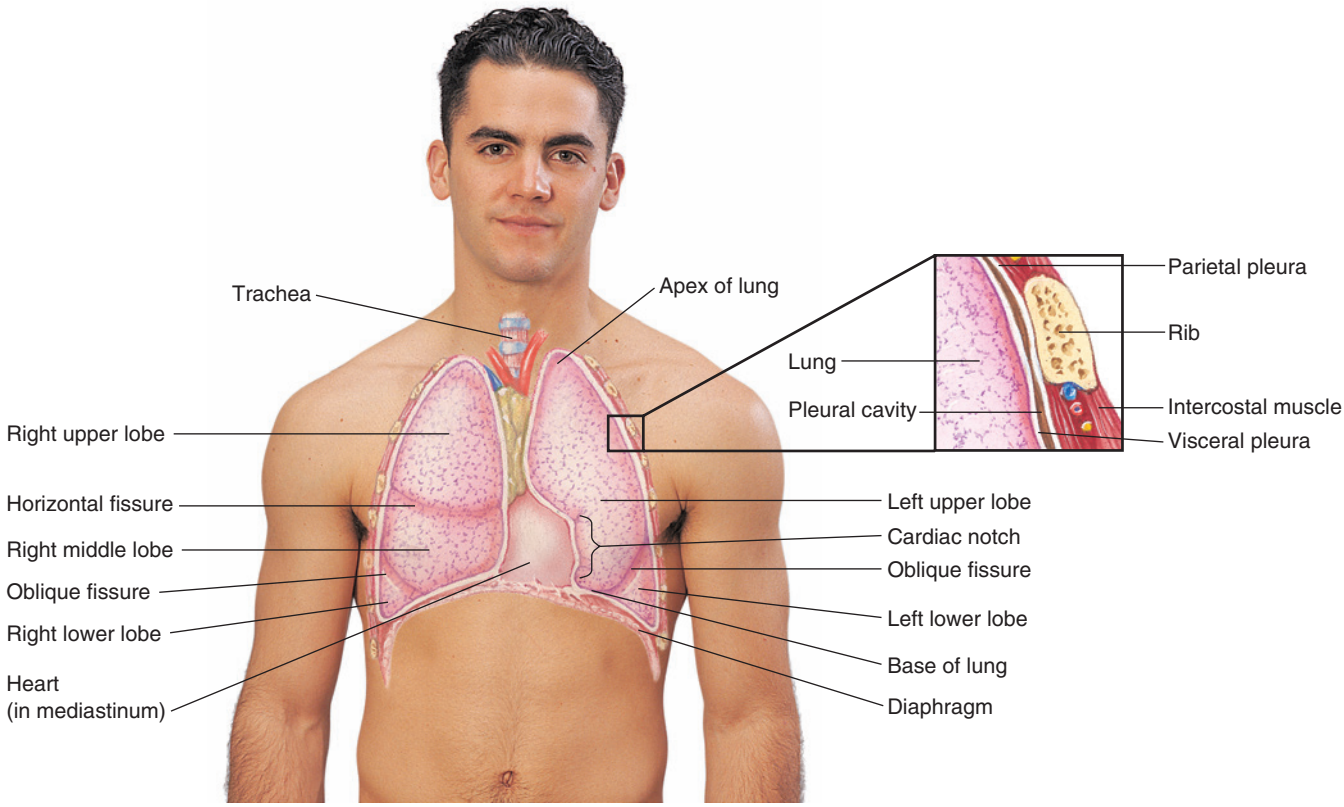

FIGURE 33.3 ■ The lower respiratory system, showing the location of the lungs, the mediastinum and layers of visceral and parietal pleura

and circulatory systems enter and exit the lungs. The primary bronchus also enters in this area. The apex of each lung lies just below the clavicle, whereas the base of each lung rests on the diaphragm. The lungs are elastic connective tissue, called stroma, and are soft and spongy.

The two lungs differ in size and shape. The left lung is smaller and has two lobes, whereas the right lung has three lobes. Each of the lung lobes contains a different number of bronchopulmonary segments, separated by connective tissue. There are 8 segments in the two lobes of the left lung and 10 segments in the three lobes of the right lung.

The vascular system of the lungs consists of the pulmonary arteries, which deliver blood to the lungs for oxygenation, and the pulmonary veins, which deliver oxygenated blood to the heart. Within the lungs, the pulmonary arteries branch into a pulmonary capillary network that surrounds the alveoli. Lung tissue receives its blood supply from the bronchial arteries and drains by the bronchial and pulmonary veins.

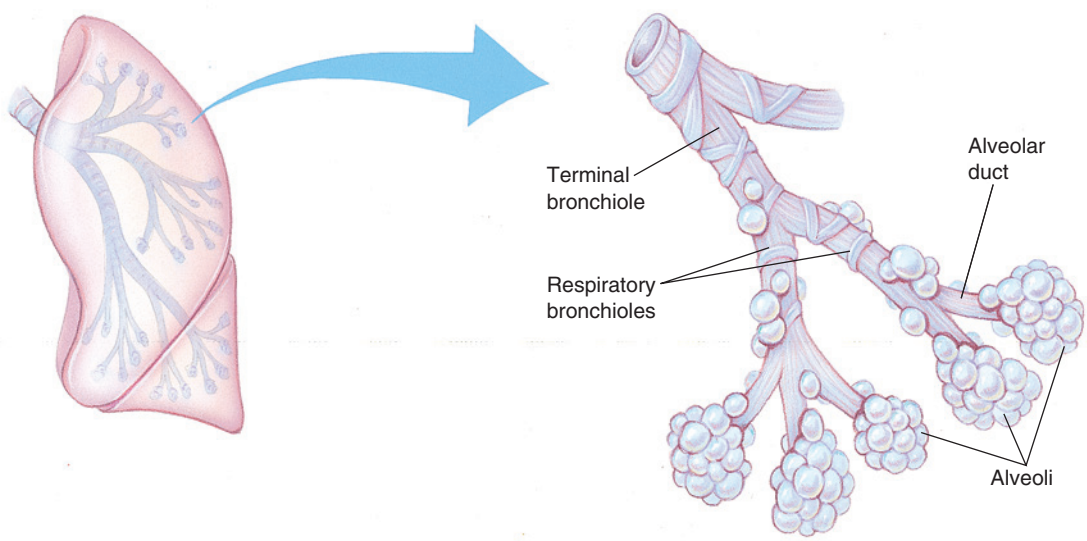

FIGURE 33.4 ■ Respiratory bronchi, bronchioles, alveolar ducts and alveoli

The pleura

The pleura is a double-layered membrane that covers the lungs and the inside of the thoracic cavities (see Figure 33.3). The parietal pleura lines the thoracic wall and mediastinum. It is continuous with the *visceral pleura*, which covers the external lung surfaces. The pleura produces pleural fluid, a lubricating, serous fluid that allows the lungs to move easily over the thoracic wall during breathing. The pleura's two layers also cling tightly together and hold the lungs to the thoracic wall. The structure of the pleura creates a slightly negative pressure in the pleural space (which is a potential rather than an actual space), necessary for lung function.

The bronchi and alveoli

The trachea divides into right and left primary bronchi; in comparison to the left primary bronchus, the right primary bronchus is shorter, wider and situated more vertically (making aspiration of foreign bodies into the right primary bronchus more likely). The point where the trachea divides is innervated with sensory neurons; activities such as tracheal suctioning may induce coughing and bronchospasm from stimulation of these neurons. These main bronchi subdivide into the secondary (lobar) bronchi, with the right middle lobe bronchus being smaller in diameter and length, and sometimes bending sharply near its bifurcation. The secondary bronchi then branch into the tertiary (segmental) bronchi and then into smaller and smaller bronchioles, ending in the terminal bronchioles (see Figure 33.4). These branching passageways collectively are called the bronchial or respiratory tree. From the terminal bronchioles, air moves into the respiratory bronchioles (air sacs), which further branch into alveolar ducts that lead to alveolar sacs and then to the alveoli. During inspiration, air enters the lungs through the primary bronchus and then moves through the increasingly smaller passageways of the lungs to the alveoli, where oxygen and carbon dioxide exchange occurs in the process of external respiration. During expiration, the carbon dioxide is expelled.

Alveoli cluster around the alveolar sacs, which open into a common chamber called the atrium. The adult lung has approximately 300 million alveoli, providing an enormous surface for gas exchange (Grossman & Mattson, 2013). Alveoli have extremely thin walls of a single layer of squamous epithelial cells over a very thin basement membrane. The external surface of the alveoli is covered with pulmonary capillaries. The alveolar and capillary walls form the respiratory membrane. Gas exchange across the respiratory membrane occurs by simple diffusion. The alveolar walls also contain cells that secrete a surfactant-containing fluid, necessary for maintaining a moist surface and reducing the surface tension of the alveolar fluid to help prevent collapse of the lungs.

The rib cage and intercostal muscles

The lungs are protected by the bones of the rib cage and the intercostal muscles. There are 12 pairs of ribs, which all articulate with the thoracic vertebrae (see Figure 33.5). Anteriorly, the first 7 ribs articulate with the body of the sternum. The 8th, 9th and 10th ribs articulate with the cartilage immediately above the ribs. The 11th and 12th ribs are called floating ribs, because they are unattached.

The sternum has three parts: the manubrium, the body and the xiphoid process. The junction between the manubrium and the body of the sternum is commonly called the angle of Louis. The depression above the manubrium is called the suprasternal notch.

The spaces between the ribs are called the intercostal spaces. Each intercostal space is named for the rib immediately above it (e.g. the space between the third and fourth ribs is designated as the third intercostal space). The intercostal muscles between the ribs, along with the diaphragm, are called the inspiratory muscles.

MECHANICS OF VENTILATION

Many factors affect ventilation and respiration. Those discussed here include changes in volume and capacity; air pressures; oxygen, carbon dioxide and hydrogen ion concentrations in the blood; airway resistance, lung compliance and elasticity; and alveolar surface tension.

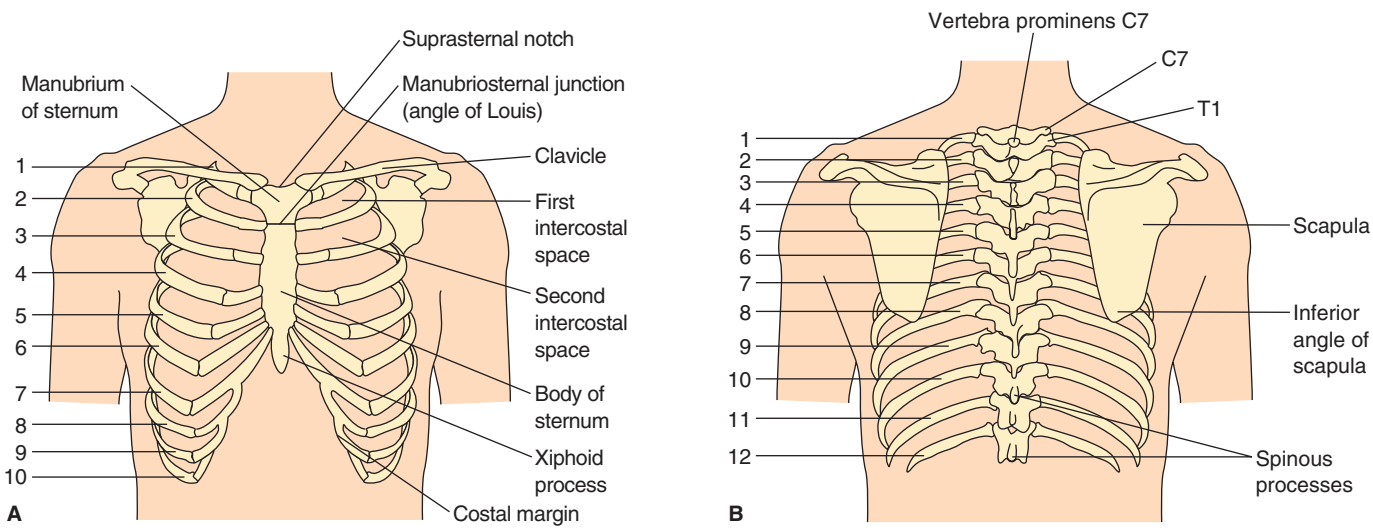

FIGURE 33.5 ■ *A*, Anterior rib cage, showing intercostal spaces. *B*, Posterior rib cage

Respiratory volume and capacity

Respiratory volume and capacity are affected by gender, age, weight and health status.

- **Tidal volume (TV)** is the amount of air (approximately 500 mL) moved in and out of the lungs with each normal, quiet breath.
- *Inspiratory reserve volume (IRV)* is the amount of air (approximately 2100 to 3100 mL, depending on body size) that can be inhaled forcibly over the tidal volume.
- *Expiratory reserve volume (ERV)* is the volume of air (approximately 1000 mL) that can be forced out over the tidal volume.
- The *residual volume* is the volume of air (approximately 1100 mL) that remains in the lungs after a forced expiration.
- **Vital capacity (VC)** refers to the sum of TV + IRV + ERV and is approximately 4500 mL in the healthy person.
- About 150 mL of air never reaches the alveoli (the amount remaining in the passageways) and is called anatomical dead space volume.

Pulmonary function tests measure these and other respiratory volumes and capacities and are discussed in Box 33.1.

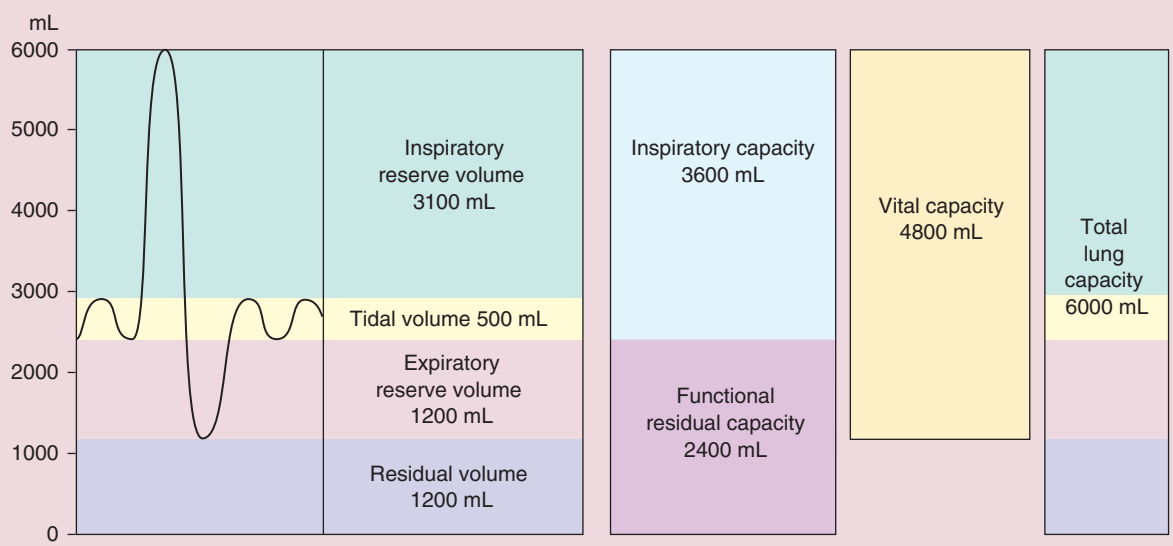
BOX 33.1 Pulmonary function tests

Pulmonary function tests (PFTs) are performed in a pulmonary function laboratory. After preparing the person, a nose clip is applied and the person breathes into a spirometer or body plethysmograph, a device for measuring and recording lung volume in litres versus time in seconds. The person is instructed how to breathe for specific tests; for example, to inhale as deeply as possible and then exhale to the maximal extent possible. Using measured lung volumes, respiratory capacities are calculated to assess pulmonary status. The specific values determined by PFTs and illustrated in the figure include the following.

- *Total lung capacity (TLC)* is the total volume of the lungs at their maximum inflation. Four values are used to calculate TLC:
  1. *tidal volume (TV)*, the volume inhaled and exhaled with normal quiet breathing (also called total volume)
  2. *inspiratory reserve volume (IRV), the maximum amount that can be inhaled over and above a normal inspiration*
  3. *expiratory reserve volume (ERV)*, the maximum amount that can be exhaled following a normal exhalation
  4. *residual volume (RV)*, the amount of air remaining in the lungs after maximal exhalation.
- *Vital capacity (VC)* is the total amount of air that can be exhaled after a maximal inspiration. It is calculated by adding together the IRV, TV and ERV.
- *Inspiratory capacity* is the total amount of air that can be inhaled following a normal quiet exhalation. It is calculated by adding the TV and IRV.
- *Functional residual capacity (FRC)* is the volume of air left in the lungs after a normal exhalation. The ERV and RV are added to determine the FRC.
- *Forced expiratory volume (FEV1)* is the amount of air that can be exhaled in 1 second.
- *Forced vital capacity (FVC)* is the amount of air that can be exhaled forcefully and rapidly after maximum air intake.
- *Minute volume (MV)* is the total amount or volume of air breathed in 1 minute.

In older people, residual capacity is increased and vital capacity is decreased. These age-related changes result from the following:

- calcification of the costal cartilage and weakening of the intercostal muscles, which reduce movement of the chest wall
- vertebral osteoporosis, which decreases spinal flexibility and increases the degree of kyphosis, further increasing the anterior–posterior diameter of the chest
- diaphragmatic flattening and loss of elasticity.



The relationship of lung volumes and capacities. Volumes (mL) shown are for an average adult male

Air pressures

Pulmonary ventilation depends on volume changes within the thoracic cavity. A change in the volume of air in the thoracic cavity leads to a change in the air pressure within the cavity. Because gases always flow along their pressure gradients, a change in pressure results in gases flowing into or out of the lungs to equalise the pressure.

The pressures normally present in the thoracic cavity are intrapulmonary and intrapleural pressure. The intrapulmonary pressure, within the alveoli of the lungs, rises and falls constantly as a result of the acts of ventilation (inhalation and exhalation). The intrapleural pressure, within the pleural space, also rises and falls with the acts of ventilation, but it is always less than (or negative to) the intrapulmonary pressure. Intrapulmonary and intrapleural pressures are necessary not only to expand and contract the lungs, but also to prevent their collapse.

Pulmonary ventilation has two phases: inspiration, during which air flows into the lungs; and expiration, during which gases flow out of the lungs. The two phases make up a single breath and normally occur from 12 to 20 times each minute. Inspiration occurs generally in a 1:2 ratio. A single inspiration lasts for approximately 1 to 1.5 seconds, whereas an expiration lasts for approximately 2 to 3 seconds.

During inspiration, the diaphragm contracts and flattens out to increase the vertical diameter of the thoracic cavity (see Figure 33.6). The external intercostal muscles contract, elevating the rib cage and moving the sternum forward to expand the lateral and anteroposterior diameter of the thoracic cavity, decreasing intrapleural pressure. The lungs stretch and the intrapulmonary volume increases, decreasing intrapulmonary pressure slightly below atmospheric pressure. Air rushes into the lungs as a result of this pressure gradient until the intrapulmonary and atmospheric pressures equalise.

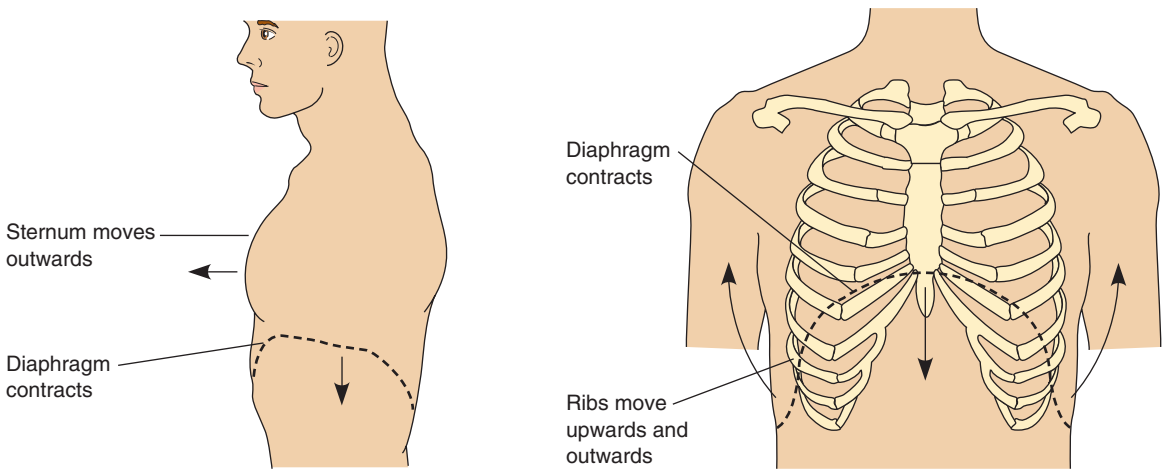


FIGURE 33.6 ■ Respiratory inspiration: lateral and anterior views. Note the volume expansion of the thorax as the diaphragm flattens

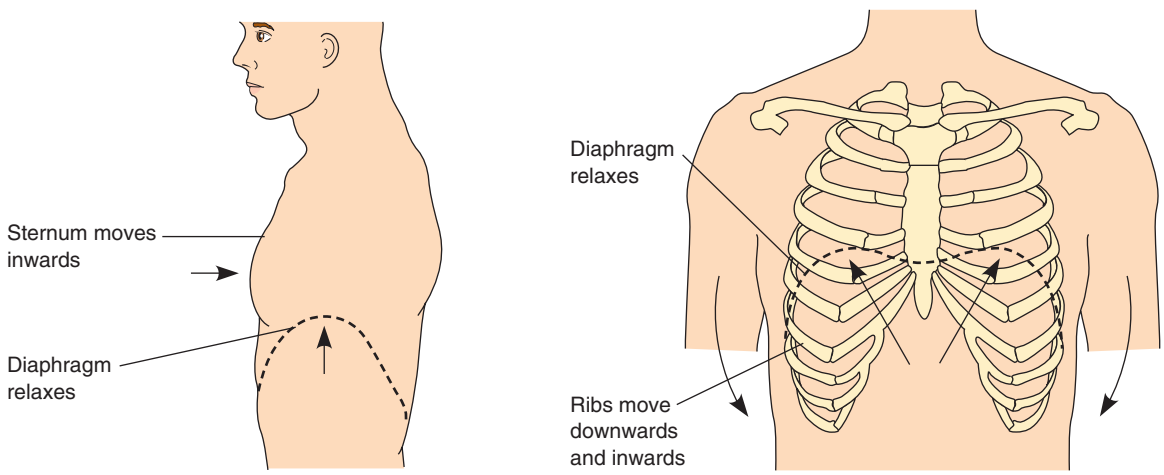

FIGURE 33.7 ■ Respiratory expiration: lateral and anterior views

Expiration is primarily a passive process that occurs as a result of the elasticity of the lungs (see Figure 33.7). The inspiratory muscles relax, the diaphragm rises, the ribs descend and the lungs recoil. Both the thoracic and the intrapulmonary pressures increase, compressing the alveoli. The intrapulmonary pressure rises to a level greater than atmospheric pressure and gases flow out of the lungs.

Oxygen, carbon dioxide and hydrogen ion concentrations

The rate and depth of respirations are controlled by respiratory centres in the medulla oblongata and pons of the brain and by chemoreceptors located in the medulla and in the carotid and aortic bodies. The centres and chemoreceptors respond to changes in the concentration of oxygen, carbon dioxide and hydrogen ions in arterial blood. For example, when carbon dioxide concentration increases or the pH decreases, the respiratory rate increases. This process is further described in Chapter 9.

Airway resistance, lung compliance and elasticity

Respiratory passageway resistance, lung compliance and lung elasticity also affect respiration.

- Respiratory passageway resistance is created by the friction encountered as gases move along the respiratory passageways, by constriction of the passageways (especially the larger bronchioles), by accumulations of mucus or infectious material, and by tumours. As resistance increases, gas flow decreases.
- **Lung compliance** depends on the elasticity of the lung tissue and the flexibility of the rib cage. Compliance is decreased by factors that decrease the elasticity of the lungs, block the respiratory passageways or interfere with movement of the rib cage.
- Lung elasticity is essential for lung distension during inspiration and lung recoil during expiration. Decreased elasticity from disease such as emphysema impairs respiration.

Alveolar surface tension

A liquid film of mostly water covers the alveolar walls. At any gas–liquid boundary, the molecules of liquid are more strongly attracted to each other than to gas molecules. This produces a state of tension, called surface tension, which draws the liquid molecules even more closely together. The water content of the alveolar film compacts the alveoli and aids in the lungs' recoil during expiration. In fact, if the alveolar film were pure water, the alveoli would collapse between breaths.

Surfactant, a lipoprotein produced by the alveolar cells, interferes with this adhesiveness of the water molecules, reducing surface tension and helping to expand the lungs. With insufficient surfactant, the surface tension forces can become great enough to collapse the alveoli between breaths, requiring tremendous energy to reinflate the lungs for inspiration.

GAS TRANSPORT AND AFFINITY

Blood gases

Gases are transported by the blood to provide cells with oxygen and to remove carbon dioxide produced during cellular activities.

Oxygen transport and unloading

Oxygen is carried in the blood either bound to haemoglobin or dissolved in the plasma. Oxygen is not very soluble in water, so almost all oxygen that enters the blood from the respiratory system is carried to the cells of the body by haemoglobin. This combination of haemoglobin and oxygen is called **oxyhaemoglobin**.

Each haemoglobin molecule is made of four polypeptide chains, with each chain bound to an iron-containing haem group. The iron groups are the binding sites for oxygen; each haemoglobin molecule can bind with four molecules of oxygen.

Oxygen binding is rapid and reversible. It is affected by temperature, blood pH, partial pressure of oxygen (PO_2), partial pressure of carbon dioxide (PCO_2) and serum concentration of an organic chemical called 2,3-DPG. These factors interact to ensure adequate delivery of oxygen to the cells.

The relative saturation of haemoglobin depends on the PO_2 of the blood, as illustrated in the oxygen–haemoglobin dissociation curve (see Figure 33.8).

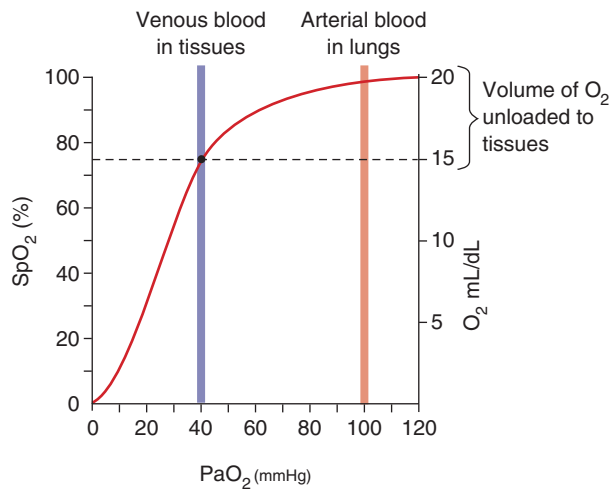

FIGURE 33.8 ■ Oxygen–haemoglobin dissociation curve. The percentage of O_2 saturation of haemoglobin and total blood oxygen volume are shown for different oxygen partial pressures (PO_2). Arterial blood in the lungs is almost completely saturated. During one pass through the body, about 25% of haemoglobin-bound oxygen is unloaded to the tissues. Thus, venous blood is still about 75% saturated with oxygen. The steep portion of the curve shows that haemoglobin readily off-loads or on-loads oxygen at PO_2 levels below about 50 mmHg

- Under normal conditions, the haemoglobin in arterial blood is 97.4% saturated with oxygen. Haemoglobin is almost fully saturated at a PO_2 of 70 mmHg. As arterial blood flows through the capillaries, oxygen is unloaded, so that the oxygen saturation of haemoglobin in venous blood is 75% under normal conditions.
- The affinity of oxygen and haemoglobin decreases as the temperature of body tissues increases above normal. As a result, less oxygen binds with haemoglobin and oxygen unloading is enhanced. Conversely, as the body is chilled, oxygen unloading is inhibited.
- The oxygen–haemoglobin bond is weakened by increased hydrogen ion concentrations. As blood becomes more acidotic, oxygen unloading to the tissues is enhanced. The same process occurs when the partial pressure of carbon dioxide increases because this decreases the pH.
- The organic chemical 2,3-DPG is formed in red blood cells and enhances the release of oxygen from haemoglobin by binding to it during times of increased metabolism (as when body temperature increases). This binding alters the structure of haemoglobin to facilitate oxygen unloading.

Carbon dioxide transport

Active cells produce about 200 mL of carbon dioxide each minute; this amount is exactly the same as that excreted by the lungs each minute. Excretion of carbon dioxide from the body requires transport by the blood from the cells to the lungs. Carbon dioxide is transported in three forms: dissolved in plasma, bound to haemoglobin and as bicarbonate ions in the plasma (the largest amount is in this form.)

The amount of carbon dioxide transported in the blood is strongly influenced by the oxygenation of the blood. When the PO_2 decreases, with a corresponding decrease in oxygen saturation, increased amounts of carbon dioxide can be carried in the blood. Carbon dioxide entering the systemic circulation from the cells causes more oxygen to dissociate from haemoglobin, in turn allowing more carbon dioxide to combine with haemoglobin and more bicarbonate ions to be generated. This situation is reversed in the pulmonary circulation, where the uptake of oxygen facilitates the release of carbon dioxide.

ASSESSING A PERSON'S RESPIRATORY FUNCTION

Respiratory system function is assessed by findings from a health assessment interview to collect subjective data, a physical assessment to collect objective data and diagnostic tests. Sample documentation of an assessment of the respiratory system is included in the box below.

Health assessment interview

A health assessment interview to determine problems with respiratory structure and function may be conducted during a health screening, may focus on a chief complaint (such as shortness of breath) or may be part of a total health assessment. If the person has a problem with respiratory function, analyse its onset, characteristics, course, severity, precipitating and relieving factors, and any associated symptoms, noting the timing and circumstances. For example, ask the person:

- Describe the problems you are having with your breathing. Is your breathing more difficult if you lie flat? Is it painful to breathe in or out?
- When did you first notice that your cough was becoming a problem? Do you cough up mucus? What colour is the mucus?
- Have you had nosebleeds in the past?

During the interview, carefully observe the person for difficulty in breathing, pausing to breathe in the middle of a sentence, hoarseness, changes in voice quality, audible wheeze and cough. Ask about present health status, medical history, family health history and risk factors for illness.

To determine present health status, ask about pain in the nose, throat or chest. Information about cough includes what type of cough, when it occurs and how it is relieved. The person should describe any sputum associated with the cough. Is the person experiencing any dyspnoea (difficult or laboured breathing)? How is the dyspnoea associated with activity levels and time of day? Is the person having chest pain? How is this related to activity and time of day? Note the severity, type and location of the pain. Explore problems with swallowing, smelling or taste. Also ask about nosebleeds and nasal or sinus stuffiness or pain, and about current medication use, aerosols or inhalants, and oxygen use.

SAMPLE DOCUMENTATION
Assessment of respiratory function

14/4/2014 NURS 1100	57-year-old male, history of smoking two packets cigarettes/day for 37 years; continues to smoke despite previous discussions. Works as a fibreglass boat builder. No family history of cancer or TB. States he has trouble breathing, especially at night. Often sleeps on a recliner 'to breathe better'. Complains of a cough, but denies sputum production. Diagnosed 3 years ago with emphysema. Colour of face is dusky red. Fingernails pink. No digital clubbing observed. Respirations 30/min, unlaboured, regular. (Respiration rate varies from 26 to 32 on visits to the clinic.) SpO_2 91%. Afebrile, heart rate 104 bpm; BP 134/78. Thoracic assessment L = R, intercostal recession, barrel chest, and use of accessory muscles of respiration. Diminished lung sounds noted bilaterally in lower lobes. Crackles present in upper lobes, not cleared by coughing. Discussed with RMO. For oxygen via nasal prongs at 2 Lpm. Will review within a few hours. RN Nguyen L NGUYEN RN

TABLE 33.1 Age-related changes in the respiratory system

AGE-RELATED CHANGE	SIGNIFICANCE
• ↓elastic recoil of lungs during expiration because of less elastic collagen and elastin. • Loss of skeletal muscle strength in the thorax and diaphragm. • Alveoli are less elastic, more fibrotic and have fewer functional capillaries. • Cough is less effective. • PO_2 reduces as much as 15% by age 80.	The older adult often has an increased anterior–posterior chest diameter, with kyphosis and barrel chest. There is a reduction in vital capacity and an increase in residual volume, with decreased effectiveness in coughing up phlegm or sputum. All of these changes greatly increase the risk of respiratory infections (such as pneumonia), especially if the person becomes immobile. They also mean that respiratory infections are more difficult to treat.

Document past medical history by asking questions about a history or family history of allergies, asthma, bronchitis, emphysema, pneumonia, tuberculosis or congestive heart failure. Other questions include a history of surgery or trauma to the respiratory structures and a history of other chronic illnesses such as cancer, kidney disease and heart disease and medications used. The person's personal lifestyle, environment and occupation may provide clues to risk factors for actual or potential health problems. Ask the person about a history of smoking and/or exposure to environmental chemicals (including smog), dust, vapours, animals, coal dust, asbestos, fumes or pollens. Other risk factors include a sedentary lifestyle and obesity. Also ask the person about use of alcohol and illicit substances.

Physical assessment

Physical assessment of the respiratory system may be performed either as part of a total assessment or alone for a person with known or suspected problems. The techniques used to assess the respiratory system are inspection, palpation, percussion and auscultation. In addition, note the person's level of consciousness, restlessness and anxiety level, and assess the colour of the lips and nail beds. Normal age-related findings for the older adult are summarised in Table 33.1.

The room should be warm and well lit. Ask the person to remove all clothing above the waist; give them a gown to wear during the examination. Conduct the examination with the person in the sitting position. Prior to the examination, collect all necessary equipment and explain the techniques to the person to decrease anxiety.

Diagnostic tests

The results of diagnostic tests of respiratory function are used to support the diagnosis of a specific disease, to provide information to identify or modify the appropriate medications or therapy used to treat the disease, and to help nurses monitor the person's response to treatment and nursing care interventions. Diagnostic tests to assess the structures and functions of the respiratory system are described in the 'Diagnostic tests' box below and summarised in the bulleted list below. More information is included in the discussion of specific disorders in Chapters 34, 35 and 36.

- Sputum tests include a culture and sensitivity to identify organisms causing infections as well as the most effective antibiotic to treat the infection, an acid-fast smear and culture to identify the tuberculosis bacillus and cytology to identify malignancies (see Procedure 33.1).
- Arterial blood gases are conducted to evaluate alterations in acid–base balances.
- Pulse oximetry is used to evaluate or monitor the oxygen saturation of the blood.
- Many different radiological examinations are used to diagnose respiratory disorders, including a chest x-ray to evaluate structures and tissues, a computed tomography (CT) scan to differentiate pathological conditions, magnetic resonance imaging (MRI) to more accurately identify abnormal masses and fluid accumulation, a positron emission tomography (PET) to identify lung cancers and a pulmonary angiogram to identify various disorders including pulmonary emboli and emphysema.
- A bronchoscopy is a direct visualisation of the larynx, trachea and bronchi. During the test, lesions can be identified, foreign bodies or mucus plugs removed, and tissue taken for biopsy. In addition, a biopsy of lung tissue may be done through an incision through the chest wall.
- A thoracentesis, when done for diagnostic purposes, is conducted to obtain a specimen of pleural fluid.

Regardless of the type of diagnostic test, the nurse is responsible for explaining the procedure and any special preparation needed, for assessing for medication use that may affect the outcome of the tests, for supporting the person during the examination as necessary, for documenting the procedures as appropriate and for monitoring the results of the tests.

Genetic considerations

When conducting a health assessment interview and a physical assessment, it is important for the nurse to consider genetic influences on the health of the adult. During the health assessment interview, ask about family members with health problems affecting respiratory function. In addition, ask about a family history of emphysema, asthma, cystic fibrosis or lung cancer. During the physical assessment, assess for any manifestations that might indicate a genetic disorder (see the 'Genetic considerations' box). If data are found to indicate genetic risk factors or alterations, ask about genetic testing and refer for appropriate genetic counselling and evaluation. Chapter 7 provides further information about genetics in medical–surgical nursing.

PROCEDURE 33.1 Obtaining a sputum specimen

GATHER SUPPLIES

- Sterile sputum container, specimen cup or mucus trap
- Mouth care supplies
- Sterile suction kit, if necessary
- Gloves

BEFORE THE PROCEDURE

If the sputum specimen is to establish the initial diagnosis, obtain the specimen before starting oxygen and/or antibiotic therapy. Antibiotics reduce the bacterial count, making it difficult to identify the infecting organism. Oxygen therapy dries mucous membranes, making it more difficult to obtain a specimen. Unless otherwise instructed, obtain the specimen early in the morning, just after awakening. Respiratory secretions tend to pool during sleep; it is easier to obtain a specimen before normal coughing and daily activity have cleared them.

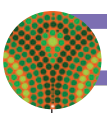
Provide for privacy and explain the procedure. Emphasise the importance of coughing deeply to obtain sputum from the lower respiratory tract, avoiding expectoration of saliva. Increasing fluid intake prior to obtaining the specimen can help liquefy secretions, making them easier to expectorate.

DURING THE PROCEDURE

1. Provide for mouth care prior to obtaining the specimen to reduce contamination by oral flora.
2. Instruct to cough deeply several times, expectorating mucus into the container.
3. Close the container securely.
4. Label the container according to the institution's requirements, usually with the person's name, date of birth, hospital identification number, time and date, signature of specimen collector and any special conditions, such as antibiotic or oxygen therapy. Enclose specimen container in a specimen bag and send to the laboratory with the pathology request slip, or refrigerate as ordered to preserve the specimen.
5. To obtain a specimen by suctioning:
   - Provide mouth care.
   - Obtain a sterile mucus trap. Using aseptic technique, attach the trap to the suction apparatus between the suction catheter and tubing.
   - Pre-oxygenate for suctioning as needed.
   - Perform tracheal suctioning using aseptic technique via the nasotracheal route, endotracheal tube or tracheostomy. Lubricate the catheter with sterile normal saline. Do not apply suction as the catheter is being inserted into the trachea; apply suction for no longer than 10 seconds while withdrawing the catheter.
   - If the secretion remains in the tubing of the trap, suction sterile water into the trap to encourage the secretion into the container section.
   - Detach the mucus trap; close and label. Reattach the catheter and clear the suction catheter and tubing with normal saline after removing the mucus trap. Dispose of equipment appropriately.
   - Label the specimen as identified above before sending to the laboratory.
6. A sputum specimen also may be obtained during a bronchoscopy procedure.

AFTER THE PROCEDURE

Provide mouth care as needed. Teach the importance of completing all ordered antibiotic prescriptions to ensure complete eradication of microorganisms. Document the time and date that the specimen was obtained; and note colour, consistency and odour of sputum.



GENETIC CONSIDERATIONS Respiratory disorders

- Deficiency of alpha-1 antitrypsin (a protein that protects the body from damage by its immune cells) is caused by a mutation of a gene located on chromosome 14. Deficiency of this protein leaves the lung susceptible to emphysema.
- Asthma is a respiratory disease which affects 10% of the population. Although mortality has declined substantially in the past 20 years, it remains high in Australia compared with international rates. Unacceptably, over 350 people died from asthma in 2011 (Poulos et al., 2014). It is an obstructive respiratory condition and is associated with inheritable factors.
- The prevalence of cystic fibrosis in Australia in 2013 was 3235, with 92 new cases diagnosed, and mortality was 38 (Cystic Fibrosis Australia, 2015). All gene defects result in defective transport of chloride and sodium by epithelial cells. As a result, the amount of sodium chloride is increased in body secretions. Thick mucus is produced that clogs the lungs, leads to infection and blocks pancreatic enzymes from reaching the intestines to digest food.
- Lung cancer is the fifth most common cancer in Australia and accounts for almost 19% of all cancer deaths (Cancer Australia, 2015). A familial history of lung cancer increases the risk of developing lung cancer, and small-cell lung cancer has a definite genetic component. In addition, researchers have found that people with lung cancer who never smoked are more likely than smokers to have one of two genetic mutations linked to the disease.

DIAGNOSTIC TESTS The respiratory system

NAME OF TEST Sputum studies
- Culture and sensitivity
- Acid-fast bacilli smear and culture
- Cytology

PURPOSE AND DESCRIPTION Culture and sensitivity of a single sputum specimen is performed to diagnose bacterial infections, identify the most effective antibiotic and evaluate treatment.

Sputum is examined for presence of acid-fast bacillus, specifically tuberculosis. A series of three early-morning sputum specimens is used.

Sputum is examined for presence of abnormal (malignant) cells. A single sputum specimen is collected in a special container of fixative solution.

RELATED NURSING CARE See Procedure 33.1 for obtaining a sputum specimen. Sputum specimens may also be obtained during bronchoscopy (described later) if the person is unable to provide a specimen.

NAME OF TEST Arterial blood gases (ABGs)

PURPOSE AND DESCRIPTION This test of arterial blood is performed to assess alterations in acid–base balance caused by a respiratory disorder, a metabolic disorder or both. A pH of less than 7.35 indicates acidosis and a pH of more than 7.45 indicates alkalosis (see Chapter 9). To determine a respiratory cause, assess the $PaCO_2$: If pH is decreased and $PaCO_2$ is increased, respiratory acidosis is indicated.

Normal values:
pH: 7.35–7.45
$PaCO_2$: 35–45 mmHg
PaO_2: 75–100 mmHg
HCO_{3-}^{-}: 22–26 mEq/L
BE: ± 2 mEq/L

RELATED NURSING CARE Arterial blood is collected in a heparinised needle and syringe. Sample is placed on an ice bag and taken immediately to the lab. If the person is receiving oxygen, you are required to indicate this on the lab slip. Apply pressure to puncture site for 2–5 minutes post test or longer if needed. Do not collect blood from the same arm used for an IV infusion as this can make the results of the test inaccurate.

NAME OF TEST Pulse oximetry

PURPOSE AND DESCRIPTION This non-invasive test is used to evaluate or monitor oxygen saturation of the blood. A device that uses infrared light is attached to an extremity (most commonly the finger, but can also be the toe, earlobe, nose or forehead) and light is passed through the tissues or reflected off bony structures.

Normal value: 95–100%

RELATED NURSING CARE Assess for factors that may alter findings, including faulty placement, movement, dark skin colour, acrylic nails, ambient light, peripheral hypothermia, and peripheral vasoconstriction.

NAME OF TEST Chest x-ray

PURPOSE AND DESCRIPTION Chest x-rays are used to identify abnormalities in chest structure and lung tissue, for diagnosis of diseases and injuries of the lungs, and to monitor treatment.

RELATED NURSING CARE Remove any metal objects around area such as jewellery or brassieres containing underwire.

NAME OF TEST Computed tomography (CT)

PURPOSE AND DESCRIPTION CT of the thorax may be performed when x-rays do not show some areas well, such as the pleura and mediastinum. It is also performed to differentiate pathological conditions (such as tumours, abscesses and aortic aneurysms), to identify pleural effusion and enlarged lymph nodes and to monitor treatment. Images are shown in cross-section.

RELATED NURSING CARE Need to assess whether the person is able to lie still for extended periods and is not claustrophobic.

NAME OF TEST Magnetic resonance imaging (MRI)

PURPOSE AND DESCRIPTION An MRI of the thorax is used to diagnose alterations in lung tissue more difficult to visualise by CT scan and to identify abnormal masses and fluid accumulation.

RELATED NURSING CARE Assess for any metallic implants (such as pacemaker, pacemaker wires, implants) or history of metal shavings etc in eyes. Also assess for any metal worn on the body. Test will not be performed if present.

(continued)

DIAGNOSTIC TESTS The respiratory system (continued)

NAME OF TEST Positron emission tomography (PET)

PURPOSE AND DESCRIPTION This relatively non-invasive test, when used to examine the lungs, is performed to identify lung nodules (cancers). The person is given a radioactive substance and cross-sectional images are displayed on a computer. Radiation from PET is only 25% of that from a CT scan.

RELATED NURSING CARE No alcohol, coffee or tobacco is allowed for 24 hours prior to the test. Encourage increased fluid intake post-test to help eliminate the radioactive material.

NAME OF TEST Pulmonary angiography

PURPOSE AND DESCRIPTION This test is performed to identify pulmonary emboli, tumours, aneurysms, vascular changes associated with emphysema and pulmonary circulation. A catheter is inserted into the brachial or femoral artery, threaded into the pulmonary artery and dye is injected. Electrocardiograph leads are applied to the chest for cardiac monitoring. Images of the lungs are taken.

RELATED NURSING CARE Monitor injection site and pulses distal to the site after the test.

NAME OF TEST Pulmonary ventilation–perfusion scan (V/Q scan)

PURPOSE AND DESCRIPTION This test is performed to measure breathing (ventilation) and circulation (perfusion) in all parts of the lungs. A perfusion scan is performed by injecting radioactive albumin into a vein and scanning the lungs. A ventilation scan is performed by scanning the lungs as the person inhales radioactive gas. A decreased uptake of radioisotope during the perfusion scan indicates a blood flow problem, such as from a pulmonary embolus or pneumonitis. A decreased uptake of gas during the ventilation scan may indicate airway obstruction, pneumonia or chronic obstructive pulmonary disease (COPD).

RELATED NURSING CARE No special preparation is needed other than ensuring the person has a patent intravenous catheter.

NAME OF TEST Bronchoscopy

PURPOSE AND DESCRIPTION A bronchoscopy is the direct visualisation of the larynx, trachea and bronchi through a bronchoscope to identify lesions, remove foreign bodies and secretions, obtain tissue for biopsy and improve tracheobronchial drainage (see Figure 33.9). During the test, a catheter brush or biopsy forceps can be passed to obtain secretions or tissue for examination for cancer.

RELATED NURSING CARE Provide routine preoperative care as ordered. Bronchoscopy is an invasive procedure requiring conscious sedation or anaesthesia. *Care provided prior to the procedure is similar to that provided before many minor surgical procedures.*

HEALTH EDUCATION FOR THE PERSON AND FAMILY

- Fibre-optic bronchoscopy requires 30 to 45 minutes to complete. It may be done at the bedside, in a special procedure room or in the surgical suite.
- The procedure usually causes little pain or discomfort because an anaesthetic is given. You will be able to breathe during the bronchoscopy.
- Some voice hoarseness and a sore throat are common following the procedure. Throat lozenges or warm saline gargles may help relieve discomfort.
- You may develop a mild fever within the first 24 hours following the procedure. This is a normal response.
- Persistent cough, bloody or purulent sputum, wheezing, shortness of breath or chest pain may indicate a complication. Notify your doctor if they develop.

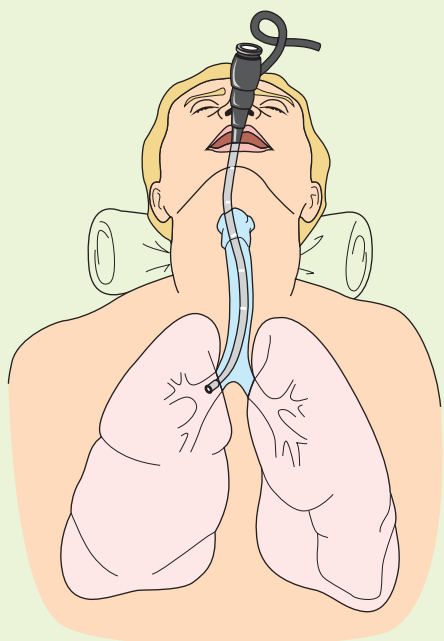


FIGURE 33.9 ■ Fibre-optic bronchoscopy

DIAGNOSTICTESTS The respiratory system (continued)

NAME OF TEST Lung biopsy

PURPOSE AND DESCRIPTION Performed to obtain tissue to differentiate benign from malignant tumours of the lungs. May be performed during a bronchoscopy or by surgical procedure.

RELATED NURSING CARE Same as for bronchoscopy or the same as for a thoracotomy (incision through the chest wall) if a surgical biopsy is performed.

NAME OF TEST Thoracentesis

PURPOSE AND DESCRIPTION Performed to obtain a specimen of pleural fluid for diagnosis (and used as a procedure to remove pleural fluid or instil medication). A large-bore needle is inserted through the chest wall and into the pleural space. Following the procedure, a chest x-ray is taken to check for a pneumothorax.

RELATED NURSING CARE Nursing care of the person having a thoracentesis is provided in Chapter 35.

RESPIRATORY ASSESSMENTS

Technique/normal findings	Abnormal findings
Nasal assessment Inspect the nose for changes in size, shape or colour. *The nose should be midline in the face, of the same colour as the face and the nares should be symmetrical.*	■ The nose may be asymmetrical as a result of previous surgery or trauma. ■ The skin around the nostrils may be red and swollen with allergies or upper respiratory infections.
Inspect the nasal cavity. Use an otoscope with a broad, short speculum. Gently insert the speculum into each of the nares and assess the condition of the mucous membranes and the turbinates. *The septum should be midline with pink mucosa and without drainage.*	■ The septum may be deviated. ■ Perforation of the septum may occur with chronic cocaine abuse. ■ Red mucosa indicates infection. ■ Purulent drainage indicates nasal or sinus infection. ■ Allergies may be indicated by watery nasal drainage, pale turbinates and polyps on the turbinates.
Assess ability to smell (cranial nerve I, olfactory). Ask the person to breathe through one nostril while pressing the other one closed. Ask the person to close their eyes. Place a substance with an aromatic odour under the person's nose (use ground coffee or alcohol) and ask the person to identify the odour. Test each nostril separately. *This test is usually done only if the person has problems with the sense of smell, but the person should be able to distinguish different odours.*	■ Changes in the ability to smell may be the result of damage to the olfactory nerve or to chronic inflammation of the nose. ■ Zinc deficiency may cause a loss of the sense of smell.
Sinus assessment Palpate the frontal and maxillary sinuses. *The sinuses should not be tender to palpation.*	■ Frontal and maxillary sinuses are tender to palpation with allergies or sinus infections.
Thoracic assessment Assess respiratory rate. *The normal respiratory rate is 12 to 20 breaths per minute.*	■ **Tachypnoea** (rapid respiratory rate) is seen in atelectasis (collapse of lung tissue following obstruction of the bronchus or bronchioles), pneumonia, asthma, pleural effusion, pneumothorax, congestive heart failure, anxiety and in response to pain. ■ Damage to the brainstem from a stroke or head injury may result in either tachypnoea or **bradypnoea** (low respiratory rate). ■ Bradypnoea is seen with some circulatory disorders, lung disorders and as a side effect of some medications. ■ **Apnoea**, cessation of breathing lasting from a few seconds to a few minutes, may occur following a stroke or head trauma, as a side effect of some medications or following airway obstruction.

Technique/normal findings	Abnormal findings
Inspect the anteroposterior diameter of the chest. *The anteroposterior diameter of the chest should be less than the transverse diameter. Normal ratio is 1:2.*	■ The anteroposterior diameter is equal to the transverse diameter in barrel chest, which typically occurs with emphysema.
Inspect for intercostal retraction or bulging. *There should be no retraction or bulging.*	■ Retraction of intercostal spaces may be seen in asthma. ■ Bulging of intercostal spaces may be seen in pneumothorax.
Inspect and palpate for chest expansion. Place your hands with the fingers spread apart palm down on the person's posterolateral chest. Gently press the skin between your thumbs (see Figure 33.10). Ask the person to breathe deeply. As the person inhales, watch your hands for symmetry of movement. *Chest expansion should be bilaterally symmetrical with the examiner's hands moving 5 to 10 cm apart.*	■ Thoracic expansion is decreased on the affected side in atelectasis, pneumonia, pneumothorax and pleural effusion. ■ Bilateral chest expansion is decreased in emphysema.

FIGURE 33.10 ■ Palpating for chest expansion

Gently palpate the location and position of the trachea. *The trachea should be midline.*	■ The trachea shifts to the unaffected side in pleural effusion and pneumothorax and shifts to the affected side in atelectasis.
Palpate for tactile fremitus. Ask the person to say 'ninety-nine' as you palpate at three different levels for a vibratory sensation called tactile fremitus, which occurs as sound waves from the larynx travel through patent bronchi and lungs to the chest wall. *Fremitus is symmetrical and easily palpated in the upper regions of the lungs.*	■ Tactile fremitus is decreased in atelectasis, emphysema, asthma, pleural effusion and pneumothorax. It is increased in pneumonia if the bronchus is patent.
Percuss the lungs for dullness over shoulder apices and over anterior, posterior and lateral intercostal spaces (see Figure 33.11). *The normal percussion tone over normal lung tissue is resonance.*	■ Dullness is heard in people with atelectasis, lobar pneumonia and pleural effusion. ■ Hyper-resonance is heard in those with chronic asthma, emphysema and pneumothorax.

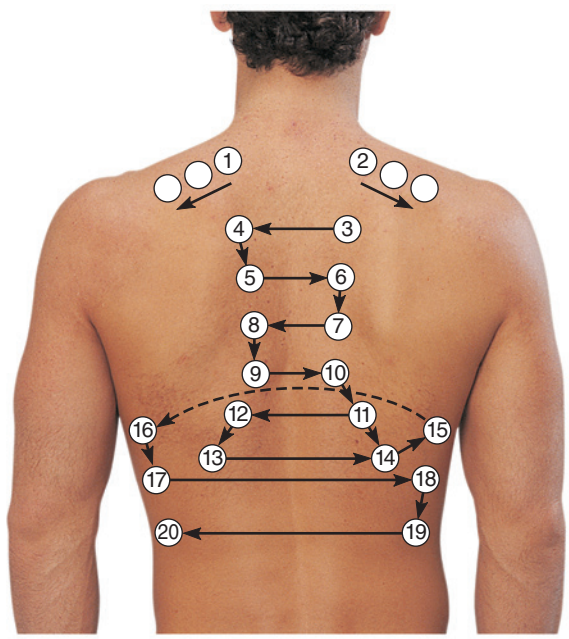

FIGURE 33.11 ■ Sequence for lung percussion

Technique/normal findings	Abnormal findings
Percuss the posterior chest for diaphragmatic excursion. Systematic percussion of the posterior chest from a level of lung resonance to the level of diaphragmatic dullness reveals *diaphragmatic excursion*, a measurement of the level of the diaphragm. First percuss downward over the posterior thorax while the person exhales fully and holds the breath. Mark the spot at which the sound changes from resonant to dull. Then ask the person to inhale and hold the breath while you percuss downward again to note the descent of the diaphragm. Again mark the spot where the sound changes. *Measure the difference in diaphragmatic excursion, which normally varies from about 3 to 5 cm (see Figure 33.12).*	■ Diaphragmatic excursion is decreased in emphysema, ascites, on the affected side in pleural effusion and in pneumothorax. ■ A high level of dullness or a lack of excursion may indicate atelectasis or pleural effusion.

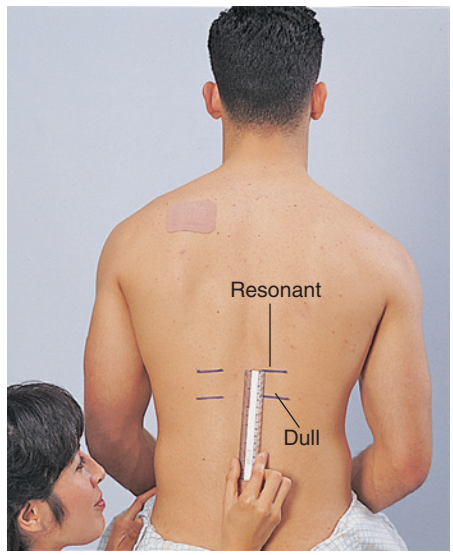

FIGURE 33.12 ■ Measuring diaphragmatic excursion

Breath sound assessment

Auscultate the lungs for breath sounds with the diaphragm of the stethoscope by having the person take slow deep breaths through the mouth. Listen over anterior, posterior and lateral intercostal spaces (see Figure 33.13). *The three different types of normal breath sounds are vesicular, bronchovesicular and bronchial (see Table 33.2).*

- Bronchial breath sounds (expiration > inspiration) and bronchovesicular breath sounds (inspiration = expiration) are heard over lungs filled with fluid or solid tissue.
- Breath sounds are decreased or diminished over atelectasis, emphysema, asthma, pleural effusion and pneumothorax.
- Breath sounds are increased over lobar pneumonia.
- Breath sounds are absent over collapsed lung, surgical removal of lung, pleural effusion and primary bronchus obstruction.

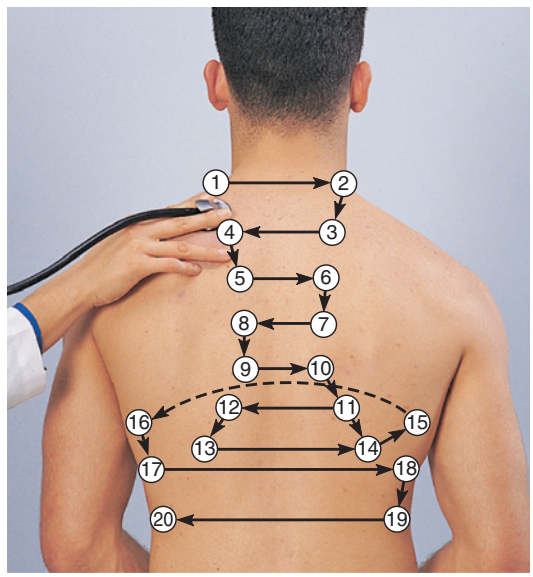

FIGURE 33.13 ■ Sequence for lung auscultation

Auscultate for crackles, wheezes and friction rubs. If crackles or wheezes are heard, ask the person to cough and note if adventitious sound is cleared. *Normally, there are no crackles, wheezes or friction rubs.*

- **Crackles** (short, discrete, crackling or bubbling sounds) may be noted in pneumonia, bronchitis and congestive heart failure.
- **Wheezes** (continuous, musical sounds) may be heard in people with bronchitis, emphysema and asthma.
- A **friction rub** is a loud, dry, creaking sound that indicates pleural inflammation.

Auscultate voice sounds where any abnormal breath sound is noted by having the person say 'ninety-nine' (bronchophony); whisper 'one, two, three' (whispered pectoriloquy); and say 'ee' (egophony). *Normally, these sounds are heard by the examiner, but are muffled.*

- Voice sounds are decreased or absent over areas of atelectasis, asthma, pleural effusion and pneumothorax.
- Voice sounds are increased and clearer over lobar pneumonia.
- When testing egophony, the sound becomes louder and changes to 'a' over areas of consolidation or compression.

TABLE 33.2 Normal breath sounds

TYPE OF BREATH SOUND	CHARACTERISTICS
Vesicular	• Soft, low-pitched, gentle sounds • Heard over all areas of the lungs except the major bronchi • Have a 3:1 ratio for inspiration and expiration, respectively
Bronchovesicular	• Medium pitch and intensity of sounds • Have a 1:1 ratio, with inspiration and expiration being equal in duration • Heard anteriorly over the primary bronchus on each side of the sternum and posteriorly between the scapulae
Bronchial	• Loud, high-pitched sounds • Gap between inspiration and expiration • Have a 2:3 ratio for inspiration and expiration, respectively • Heard over the manubrium

TRANSLATION TO PRACTICE

Evidence-based practice: nursing care of dyspnoea, the 6th vital sign in individuals with COPD

Research by Bailey et al. (2013) discussed the concept that in individuals with a chronic obstructive respiratory disease, the type, quality and duration of dyspnoea should be quantified and considered as the 6th vital sign. The recommendation is that the characteristics of a person's dyspnoea can convey a greater understanding of the respiratory compromise that person may be experiencing.

IMPLICATIONS FOR NURSING

Historically, measuring vital signs called for the quantification of an individual's respiratory rate as the lone parameter recorded for the respiratory system. Bailey et al.'s research indicated that collecting and undertaking a more comprehensive analysis of the characteristics of a person's dyspnoea may encourage faster or different intervention. Nurses need to be aware of the presence of dyspnoea rating scales such as the Medical Research Council (MRC) scale so that acute deterioration may be identified more readily.

CRITICAL THINKING IN PERSON-CENTRED CARE

1 In this study, the findings indicated that enhanced identification of deterioration and improved management may result from a formal assessment and documentation of a person's dyspnoea. How will you accommodate these findings into the health management plan of people with respiratory compromise in the future?
2 How will the findings of this study impact on the assessment of and care that you give to a person with chronic obstructive pulmonary disease?

FOCUS ON CULTURAL DIVERSITY

Are we working cooperatively with our Pacific partners to control multidrug-resistant tuberculosis at our borders?

An article by Kirby (2013) on multidrug-resistant tuberculosis on Australia's northern border, called 'Extensively drug-resistant tuberculosis hovers threateningly at Australia's door', discussed the spread of multidrug-resistant tuberculoses from Papua New Guinea to the Torres Strait and Australia's northern coast.

Implications for nursing

The Department of Health (2015) reported that 88% of all cases of people newly diagnosed with tuberculosis (TB) in 2013 occurred in individuals born overseas. The rate of TB in overseas-born individuals is 19 times higher than for those born in Australia (Toms et al., 2015). Although there has been a 45% reduction is mortality since 1990, there is still a worrying prevalence of TB and multidrug-resistant TB (MDR-TB) in Papua New Guinea. World Health Organization (WHO) reports suggest that up to 24% of people who have been treated for TB have developed MDR-TB. In comparison, Australia's MDR-TB rate is estimated at between 2.3% and 4.2% (WHO, 2015).

Critical thinking in person-centred care

1. How could you find out more information about the epidemiology of tuberculosis within the local region?
2. How might cultural and language diversity complicate care of persons requiring treatment for tuberculosis?
3. How might people with cultural and language diversity contribute to multidrug-resistant tuberculosis following discharge? Identify mechanisms and interventions to avoid this occurrence.

CHAPTER HIGHLIGHTS

- The respiratory system is divided into the upper respiratory system and the lower respiratory system.
- The upper respiratory system functions mostly as protection, filtration and the conductive section directing air to the lower respiratory system.
- The lower system has some conducting function but is largely responsible for provision of oxygen and elimination of carbon dioxide.
- Critical factors affecting ventilation and respiration include changes in volume and capacity; air pressures; oxygen, carbon dioxide and hydrogen ion concentrations in the blood; airway resistance, lung compliance and elasticity; and alveolar surface tension.
- Important components of a health history for an individual with a respiratory condition should include questions which can elicit answers to onset, characteristics, course, severity, precipitating and relieving factors, and any associated symptoms.
- Physical assessment techniques for assessing the respiratory system of an individual include inspection, palpation, percussion and auscultation. Other factors that should be noted include the person's level of consciousness, restlessness and anxiety level, and the colour of the lips and nail beds.

CONCEPT CHECK

1 Where is the apex of each lung located?
1. in the mediastinum
2. resting on the diaphragm
3. within the parietal pleura
4. just below the clavicle

2 Which physiological process is involved in gas exchange at the respiratory membrane?
1. facilitated transport
2. active transport
3. simple diffusion
4. hydrostatic pressure

3 Which structures cover the external surface of the alveoli?
1. terminal bronchioles
2. pulmonary arteries
3. pulmonary veins
4. pulmonary capillaries

4 Which process is initiated between oxygen and haemoglobin as the temperature of body tissues increases?
1. oxygen unloading is enhanced
2. oxygen unloading is inhibited
3. respiratory rate is decreased
4. lung compliance is increased

5 Which of the following questions should be included when conducting a health history to identify a genetic risk of respiratory disease?
1. 'Tell me how many colds you have each year.'
2. 'Has anyone in your family had a stroke or heart attack?'
3. 'Has lung cancer ever been diagnosed in your family?'
4. 'Do your children have trouble breathing at night?'

6 While auscultating the person's breath sounds, you note continuous musical sounds. You document these sounds as:
1. murmurs
2. wheezes
3. crackles
4. rales

7 The person you are assessing has had a lung removed. What type of breath sound would you expect to assess over the affected side?
1. resonance
2. crackles
3. bronchovesicular
4. absent

8 While assessing the person with a left pneumothorax you note decreased diaphragmatic excursion on the left. What would you do next?
1. Notify the doctor immediately.
2. Document the assessment.
3. Repeat the assessment several times.
4. Tell the person to hold their breath.

CHAPTER 34

NURSING CARE OF PEOPLE WITH UPPER RESPIRATORY DISORDERS

MAJELLA HALES

KEY TERMS

coryza 1223
epistaxis 1236
influenza 1225
laryngectomy 1247
laryngitis 1234
pertussis 1234
pharyngitis 1231
rhinitis 1223
rhinoplasty 1240
sinusitis 1229
sleep apnoea 1242
tonsillitis 1231

LEARNING OUTCOMES

- Discuss the causes and implications of individuals experiencing selected infectious or inflammatory disorders of the upper respiratory system.
- Explore the occurrence and management of people experiencing obstructive conditions to the upper respiratory system such as trauma, epistaxis or surgery.
- Describe the critical considerations related to caring for a person with laryngeal obstruction from trauma or obstructive sleep apnoea.
- Examine the biopsychosocial implications and potential outcomes for a person with laryngeal tumour.

CLINICAL COMPETENCIES

- Assess functional health status of people with upper respiratory tract disorders, using data to identify and prioritise holistic nursing care needs.
- Use nursing research and evidence-based practice to plan and implement nursing care for people with upper respiratory disorders.
- Provide safe and effective nursing care for people having surgery involving the upper respiratory system and/or with a tracheostomy.
- Safely and knowledgeably administer medications and prescribed treatments for people with disorders of the upper respiratory tract.
- Provide appropriate teaching for the person and family affected by upper respiratory tract disorders.
- Evaluate the effectiveness of care, reassessing and modifying the plan of care as needed to achieve desired outcomes.

Upper respiratory disorders may affect the nose, paranasal sinuses, tonsils, adenoids, larynx and pharynx. Upper respiratory disorders may be minor, such as the common cold. However, a patent upper airway is necessary for effective breathing. Acute and even life-threatening problems develop when upper airway patency is affected (e.g. by laryngeal oedema). Upper respiratory disorders can affect breathing, communication and body image. When breathing is compromised because of swelling, bleeding or accumulation of secretions, fear and anxiety may develop.

Nursing care focuses on maintaining the airway, managing pain and symptoms, promoting effective communication and providing psychological support for the person and family. Prior to proceeding with this chapter, review the anatomy and physiology, diagnostic tests and assessment of the upper respiratory system in Chapter 33 as needed.

INFECTIOUS AND INFLAMMATORY DISORDERS OF THE UPPER RESPIRATORY SYSTEM

Constant exposure of the upper respiratory tract to the environment makes it vulnerable to a variety of infectious and inflammatory conditions. Although most upper respiratory infections and inflammations are minor, complications may result. In the older adult, the risk of serious problems following an upper respiratory infection can be significant.

Rhinitis, inflammation of the nasal cavities, is the most common upper respiratory disorder. Rhinitis may be either acute or chronic. *Acute viral rhinitis*, or the common cold, is discussed below. Chronic rhinitis includes allergic, vasomotor and atrophic rhinitis. *Allergic rhinitis*, or hay fever, results from a sensitivity reaction to allergens such as plant pollens. It tends to occur seasonally. The aetiology of *vasomotor rhinitis* is unknown. Although its manifestations are similar to those of allergic rhinitis, it is not linked to allergens. *Atrophic rhinitis* is characterised by changes in the mucous membrane of the nasal cavities.

THE PERSON WITH VIRAL UPPER RESPIRATORY TRACT INFECTION

Viral upper respiratory tract infections (URTIs, or the common cold) are the most common respiratory tract infections and are among the most common human diseases. URTIs are highly contagious and are prevalent in schools and work environments.

FAST FACTS

- Rhinoviruses are the most common cause of viral URTIs (Rajnik, 2014).
- Colds due to rhinovirus are more common in early autumn and late spring.
- More than 100 different serotypes of rhinovirus have been identified.
- Parainfluenza viruses, respiratory syncytial virus (RSV), coronaviruses and adenoviruses also can cause URTIs (Lee & Bishop, 2015).

Pathophysiology

More than 200 strains of virus cause URTI, including rhinoviruses, adenoviruses, parainfluenza viruses, coronaviruses and respiratory syncytial virus. (See the section that follows for more information about RSV.) Occasionally, more than one virus may be present. Viruses causing acute URTIs spread by aerosolised droplet nuclei during sneezing or coughing, or by direct contact. The virus usually spreads when the hands and fingers pick it up from contaminated surfaces and carry it to the eyes and mucous membranes of the susceptible host. People who have been infected are highly contagious, shedding the virus for a few days prior to and after the appearance of symptoms. Although immunity is produced to the individual virus strain, the number of viruses causing URTI ensures that most people continue to experience colds throughout their lifetimes.

Viscous mucus secretions in the upper respiratory tract trap invading organisms, preventing contamination of more vulnerable areas. Cells of the upper respiratory tract are infected when the virus attaches to receptors on the cell. Local immunological defences, such as secretory IgA antibodies in respiratory secretions, then attempt to inactivate the antigen, producing a local inflammatory response. The mucous membranes of the nasal passages swell and become hyperaemic and engorged. Mucus-secreting glands become hyperactive. These responses to the virus produce the typical manifestations of viral URTI.

Manifestations and complications

Acute viral URTI often presents as the common cold. Nasal mucous membranes appear red (*erythematous*) and *boggy* (swollen). Swollen mucous membranes, local vasodilation and secretions cause nasal congestion. Clear, watery secretions lead to **coryza**, profuse nasal discharge. Sneezing and coughing are common. Sore throat is common and may be the initial symptom. Systemic manifestations of acute viral URTI may include low-grade fever, headache, malaise and muscle aches. Symptoms generally last for a few days up to 2 weeks. Although acute viral URTI is typically mild and self-limited, its effects on the immune defences of the upper respiratory tract can increase the risk of more serious bacterial infections, such as sinusitis or otitis media.

INTERPROFESSIONAL CARE

Because most acute viral upper respiratory tract infections are self-limiting, self-care is appropriate and encouraged. Medical treatment is usually required only when complications such as sinusitis or otitis media develop.

Diagnosis of acute viral URTI is usually based on the history and physical examination. Diagnostic testing may be indicated if a complication such as bacterial infection is suspected. A white blood count (WBC) may be ordered to assess for leucocytosis (an elevated WBC). Cultures of purulent discharge may also be obtained.

Treatment is symptomatic. Adequate rest, maintaining fluid intake and avoiding chilling help relieve systemic symptoms such as fever, malaise and muscle ache. Instruct people to cover the mouth and nose with tissues when coughing or sneezing, dispose of soiled tissues appropriately and wash hands thoroughly. Additionally, avoiding crowds and maintaining a distance of 1 metre from others helps prevent spread of the infection to others.

Medications

Medications may be recommended to shorten the duration of the illness and relieve symptoms. Mild decongestants or over-the-counter (OTC) antihistamines may help relieve coryza and nasal congestion. Nasal sprays such as phenylephrine rapidly relieve nasal congestion, but may lead to dependence and rebound congestion if used for more than a few days at a time. Warm saltwater gargles, throat lozenges or mild analgesics may be used for sore throat. Although no specific antiviral therapy has been shown to be effective in shortening the duration of a URTI, experimental vaccines to prevent acute viral URTI are in developmental stages. For the nursing implications of decongestants and common antihistamines, see the 'Medication administration' box below.

Complementary therapies

Currently there is little evidence to demonstrate that complementary therapies are useful in the management of respiratory infections. Herbal remedies, such as echinacea and garlic, may have antiviral and antibiotic effects (Kumar & Ramaiah, 2011). Echinacea is also thought to stimulate the immune system, improving the body's response to infection. Taken at the first sign of infection, echinacea may reduce the duration and symptoms, although clinical trials have shown no consistent benefit (Karsch-Völk et al., 2014). Studies of the use of garlic in acute respiratory tract infections also suggest limited or uncertain effectiveness (Lissiman, Bhasale & Cohen, 2012).

Vitamin C is also promoted as a measure to reduce the severity and duration of URTI. Again, however, little consistent

MEDICATION ADMINISTRATION Decongestants and antihistamines

DECONGESTANTS

Decongestants promote vasoconstriction, reducing the inflammation and oedema of nasal mucosa and relieving nasal congestion. They are very effective when applied topically (by nasal spray) because of their rapid onset of action. However, the duration of effect is short, followed by vasodilation and rebound congestion. Because of their rapid effect and short duration, these preparations are habit forming. Chronic use may lead to rhinitis medicamentosa, a rebound phenomenon of drug-induced nasal irritation and inflammation.

Nursing responsibilities

- Assess for contraindications, such as hypertension or chronic heart disease. These drugs stimulate the sympathetic nervous system, increasing peripheral vascular resistance, blood pressure and heart rate.
- Evaluate medication regimen for potential interactions such as antihypertensive medications and monoamine oxidase (MAO) inhibitors.

Health education for the person and family

- Do not use more than the recommended dose.
- Check with the doctor before taking decongestants if you are taking any prescription medications or are being treated for high blood pressure or heart disease.
- Use nasal sprays for no more than 3 to 5 days.
- Increase fluid intake to relieve mouth dryness.
- These drugs may cause nervousness, shakiness or difficulty sleeping. Stop the drug if these effects occur.
- In some states, drugs containing pseudoephedrine may require a prescription or be kept behind the counter to reduce its use in preparing methamphetamine.

ANTIHISTAMINES

Antihistamines are widely available with and without a prescription. They are frequently combined with decongestants in over-the-counter cold and allergy preparations. Antihistamines relieve the systemic effects of histamine and dry respiratory secretions through an anticholinergic effect. Most antihistamines cause drowsiness; non-sedating forms are less likely to interfere with alertness. Diphenhydramine is used in numerous over-the-counter sleep aids as well as in cold and allergy preparations.

Nursing responsibilities

- Before administering or recommending these drugs, assess for possible contraindications, including the following:
  - acute asthma or lower respiratory disease that may be aggravated by drying of secretions
  - hypersensitivity to antihistamines
  - glaucoma (increased intraocular pressure)
  - impaired gastrointestinal motility or obstruction
  - prostatic hypertrophy or other urinary tract obstruction
  - heart disease.
- For people who must remain alert while on antihistamine therapy, recommend non-sedating forms.

Health education for the person and family

- Do not drive or operate machinery while taking over-the-counter or prescription forms of antihistamines known to be sedating.
- Stop the drug and notify your doctor immediately if you develop confusion, excessive sedation, chest tightness, wheezing, bleeding or easy bruising while taking antihistamines.
- Do not use alcohol or other central nervous system depressants while taking antihistamines.
- Hard lollies, chewing gum, ice chips and liquids help relieve mouth dryness caused by antihistamines.

benefit is demonstrated in well-designed rigorous clinical trials. It is possible that zinc helps reduce the length and severity of a cold; however, it can cause nausea and other gastrointestinal issues (Fashner, Ericson & Werner, 2012).

Aromatherapy with essential oils such as basil, cedarwood, eucalyptus, frankincense, lavender, marjoram, peppermint or rosemary may reduce congestion and promote comfort and recovery. Teach people that these essential oils are to be used only for inhalation, not for internal consumption.

Nursing care

Health promotion

Most importantly, people can limit their incidence of acute viral URTI by frequent handwashing and avoiding exposure to crowds. Maintaining good general health and stress-reducing activities support the immune system and help prevent acute viral URTI. Teach the person that becoming chilled or going out in the rain does not cause colds and that URTI are more likely to occur during periods of physical or psychological stress.

Community-based care

The primary nursing role in caring for people with acute viral URTI is educational. Self-care is appropriate for most people unless the problem is recurrent or a complication occurs. Acute viral URTI may interfere with work and recreational activities. Unless limited by symptoms, normal daily activities and roles usually can be maintained. Additional rest during the acute phase of illness is recommended. Additional fluid intake and a well-balanced diet help support the immune response, hastening recovery.

Include the following topics in teaching for home care:

- using disposable tissues to cover the mouth and nose while coughing or sneezing to reduce airborne spread of the virus
- blowing the nose with both nostrils open to prevent infected matter from being forced into the eustachian tubes
- washing hands frequently, especially after coughing or sneezing, to limit viral transmission
- using OTC preparations for symptomatic relief; precautions related to the sedating effects of antihistamines
- limiting use of nasal decongestants to every 4 hours for only a few days at a time to prevent rebound effect.

THE PERSON WITH RESPIRATORY SYNCYTIAL VIRUS

Respiratory syncytial virus (RSV) is a common virus that is the primary cause of respiratory illnesses in young children and the majority of lower respiratory disease in infants. Older children and adults also are commonly and repetitively infected by RSV, but the disease is milder, usually presenting as a common cold. However, older adults and people who are immunocompromised may develop severe pneumonitis when exposed to RSV (Walsh & Falsey, 2012). Mortality rates for RSV are higher in older adults and people who are immunocompromised (Krilov, 2015).

RSV is transmitted in much the same way as other URTIs: via contaminated hands or objects, and by coarse droplets spread by coughing and sneezing. The incubation period is 4 to 6 days.

In adults, the manifestations of RSV are those of other common URTIs, including rhinorrhoea, sore throat and cough. Headache, malaise and low-grade fever may occur. In older adults, RSV may present as lower respiratory infection with fever or pneumonia (Krilov, 2015). While the illness also presents as URTI in infants, it is more likely to progress to pneumonia, bronchiolitis and tracheobronchiolitis in this population.

Treatment for adults with upper respiratory RSV is symptomatic (see the preceding section on URTI). When the lower respiratory tract is involved, hydration and other measures to mobilise respiratory secretions are important. Intubation and mechanical ventilation may be necessary if hypoxia develops. Nursing care is supportive. The focus of nursing care for the adult with URTI manifestations of RSV is on teaching for self-care, identification of complications and prevention of viral spread. When lower respiratory symptoms are present, nursing care is similar to that provided for people with pneumonia (see Chapter 35).

THE PERSON WITH INFLUENZA

Influenza, or *flu*, is a highly contagious viral respiratory disease characterised by coryza, fever, cough and systemic symptoms such as headache and malaise. In 2014 in Australia, seasonal influenza notifications peaked in August in all states/territories (Department of Health, 2015a). However, this often varies slightly by year and region. Figure 34.1 shows the number of laboratory-confirmed influenza notifications per 100 000 since 2010. It is interesting to note

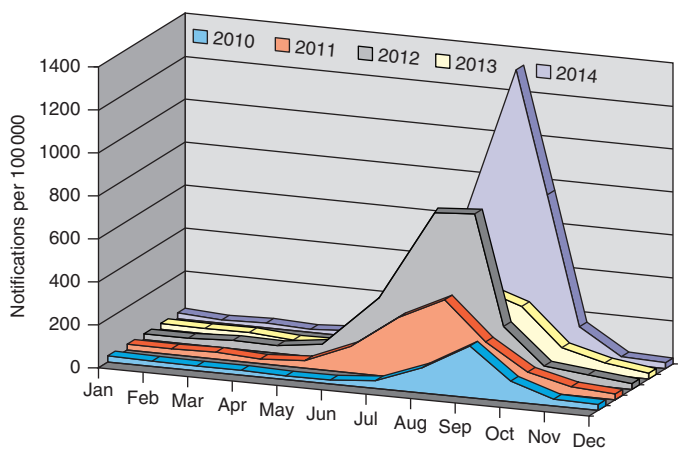

FIGURE 34.1 ■ Laboratory-confirmed influenza notifications per 100 000, Australia 2010–2014

Source: Derived using data from National Notifiable Diseases Surveillance System (NNDSS) (Department of Health, 2015b). *Notifications of influenza by month and year.* Retrieved from www9.health.gov.au/cda/source/cda-index.cfm.

that 2014 was a particularly busy year with almost two-and-a-half times the number of notifications than 2013. At the time of publication, the notifications for 2015 were again higher than the previous year when comparing the progress through the influenza season.

Influenza usually occurs in epidemics or pandemics, although sporadic cases do occur. Localised outbreaks of influenza usually occur about every 1 to 3 years. Global epidemics (pandemics) are less frequent, developing every 10 to 15 years until the past two decades. A recently identified strain of influenza A, H1N1 (swine flu), reached pandemic stage in 2009 and is currently classified in the post-pandemic stage. It demonstrated the ability to spread between humans. This strain of virus is thought to be a reassortment of four known strains of influenza A virus subtype H1N1, one strain originating from humans, one from birds and two from swine. See Box 34.1 for more information about swine influenza.

Although influenza tends to be mild and self-limited in healthy adults, older adults and people with chronic heart or pulmonary disease have a high incidence of complications (such as pneumonia) and a higher risk of mortality related to the disease and its complications (Rothberg & Haessler, 2010).

Pathophysiology

Influenza virus is transmitted by airborne droplet and direct contact. Three main strains of the virus have been identified as influenza A virus, influenza B virus and influenza C virus. Influenza A is responsible for most infections and the most severe outbreaks of influenza. This is primarily due to its ability to alter its surface antigens, bypassing previously developed immune defences to the virus. New strains of influenza virus are named according to the strain, geographical origin and the year the strain was identified (e.g. A/Taiwan/89). Surface antigens of the specific virus may be used to further differentiate influenza A viruses. Outbreaks of influenza B virus are generally less extensive and less severe than those caused by influenza A virus. Illness associated with influenza C virus is mild and often goes unrecognised.

The incubation period for influenza is short, only 18 to 72 hours. The virus infects the respiratory epithelium. It rapidly replicates in infected cells and is released to infect neighbouring cells. Inflammation leads to necrosis and shedding of serous and ciliated cells of the respiratory tract. This allows extracellular fluid to escape, producing rhinorrhoea. With recovery, serous

FAST FACTS

- Type A influenza viruses are found in many animals including birds, bats, pigs, whales, horses, seals and humans (Centers for Disease Control, 2014).
- Type A influenza is believed to have caused four pandemics: 1918 (Spanish flu), 1957 (Asian flu), 1968 (Hong Kong flu) and most recently the H1N1 'swine flu' in 2009 (worldwide).
- Type B influenza viruses are commonly found in humans and often are responsible for influenza outbreaks but not pandemics.
- Type C influenza viruses, found in humans, pigs and dogs, typically cause mild respiratory infections (National Institute of Allergy and Infectious Diseases, 2012).

BOX 34.1 Focus on swine influenza

On 11 June 2009, the World Health Organization (WHO) declared the worldwide pandemic alert level at 6. The alert levels are defined by spread more than by severity of illness and are classified as follows:

Phase 1: influenza virus circulating among animals (most commonly birds); however, no virus has been reported in humans.

Phase 2: a virus circulating among animals is known to have caused infection in humans.

Phase 3: sporadic cases or clusters of disease have been found; however, level of human-to-human transmission is not severe enough to cause community spread.

Phase 4: human-to-human transmission of virus able to cause 'community-level outbreaks'. Indicates a significant increase in risk of a pandemic but does not necessarily mean that a pandemic is a foregone conclusion.

Phase 5: human-to-human spread of the virus into at least two countries in one WHO region. While most countries will not be affected at this stage, the declaration of Phase 5 is a strong signal that a pandemic is imminent.

Phase 6: community-level outbreaks in at least one other country in a different WHO region in addition to the criteria defined in Phase 5. Designation of this phase will indicate that a global pandemic is underway (WHO, 2009).

The alert was released relating to an influenza A strain subtype H1N1 (commonly referred to as 'swine flu') which was initially identified in April 2009 in Mexico. This strain, however, was thought to be in existence in pigs for a number of years before its transmission to humans. By June the outbreak had reached a global level, and in August 2010 WHO declared the world to be in the post-pandemic phase. In 2009 in Australia, revised data reported 37636 cases of pandemic (H1N1), of which 191 people died (Department of Health, 2015c).

Symptoms of 'swine flu' mimic those of seasonal flu and may include fever, sneezes, sore throat, muscle/joint aches and pains, coughs and headache. The virus is spread by coughs and sneezes or by touching contaminated surfaces before touching the mouth or nose. WHO has released a number of fact sheets targeted at educating the community regarding correct handwashing techniques and techniques to limit the spread of the virus.

Currently the only treatment is by antiviral medications (e.g. Tamiflu). In the last quarter of 2009, a monovalent vaccine (Panvax®) was introduced by the Commonwealth Serum Laboratories in Australia; however, from December 2010, expired supplies were withdrawn (Department of Health, 2015d). Since 2010, the formulation against the commonly circulating A(H1N1)pdm09 strain has been included in the seasonal trivalent vaccine (Department of Health, 2015d).

cells are replaced more rapidly than ciliated cells, leading to continued cough and coryza. Systemic manifestations of influenza likely are caused by release of inflammatory mediators such as tumour necrosis factor alpha, interleukin-alpha and interleukin-6. The humoral and cell-mediated immune responses are activated by influenza infection and are supplemented by other local and systemic responses (such as interferons). Viral shedding lasts 5–10 days, starting just before the onset of symptoms; however, young children and immunocompromised individuals may shed for much longer (Derlet, 2015).

Manifestations

Infection with influenza virus produces one of three syndromes: uncomplicated nasopharyngeal inflammation, viral upper respiratory infection followed by bacterial infection, or viral pneumonia. The onset is rapid; profound malaise may develop in a matter of minutes.

Manifestations of influenza include abrupt onset of chills and fever, malaise, muscle aches and headache. Respiratory manifestations include dry, non-productive cough, sore throat, substernal burning and coryza (see the box below). Acute symptoms subside within 2 to 3 days, although fever may last as long as a week. The cough may be severe and productive. Along with fatigue and weakness, the cough can persist for days or several weeks.

MANIFESTATIONS Influenza

RESPIRATORY MANIFESTATIONS
- Coryza
- Cough, initially dry becoming productive
- Substernal burning
- Sore throat

SYSTEMIC MANIFESTATIONS
- Fever and chills
- Malaise
- Muscle aches
- Fatigue

Complications

The respiratory epithelial necrosis caused by influenza increases the risk of secondary bacterial infections. Sinusitis and otitis media are frequent complications of influenza. Tracheobronchitis, inflammation of the trachea and bronchi, may develop. Although tracheobronchitis is not a serious health risk, its manifestations may persist for up to 3 weeks.

Influenza is clearly linked to an increased risk of pneumonia, particularly in older adults. Changes in respiratory function associated with ageing, including decreased effectiveness of cough and increased residual lung volume, pose little risk in the healthy older adult but greatly increase the risk of pneumonia associated with influenza. Primary influenza viral pneumonia, while uncommon, is a serious complication that may be fatal. It typically develops within 48 hours of the onset of influenza, often in people with pre-existing heart valve or pulmonary disease. Influenza pneumonia progresses rapidly and can cause hypoxaemia and death within a few days. Bacterial pneumonia is more likely to occur in older at-risk adults but may also affect otherwise healthy adults. It usually presents as a relapse of influenza, with a productive cough and evidence of pneumonia on the chest x-ray. See Chapter 35 for more information about pneumonia.

Other respiratory complications of influenza include exacerbation of chronic obstructive pulmonary disease (COPD), chronic bronchitis or asthma. Sinusitis (discussed later in this chapter) may also develop.

Reye's syndrome is a rare but potentially fatal complication of influenza. Although it is more likely to affect children, it also has been identified in older adults. It is most often associated with influenza B virus. Reye's syndrome develops within 2 to 3 weeks after the onset of influenza. It has a 30% mortality rate. Hepatic failure and encephalopathy develop rapidly in people with Reye's syndrome.

While uncommon, other potential complications of influenza include myositis (inflammation of skeletal muscles), myocarditis (inflammation of the heart muscle) and central nervous system (CNS) disorders such as encephalitis and Guillain–Barré syndrome.

INTERPROFESSIONAL CARE

Preventing community outbreaks and protecting vulnerable populations (e.g. older adults and people with chronic diseases) are the primary focus for interprofessional care related to influenza. Medical treatment of influenza focuses on establishing the diagnosis, providing symptomatic relief and preventing complications.

Prevention

Preventing influenza by immunising at-risk populations is an important aspect of care. Immunisation with polyvalent (containing antigens of several viral strains) influenza virus vaccine is largely effective in preventing influenza infection for several months to a year (Derlet, 2015). Annual immunisation is recommended for at-risk people, including people over the age of 65, residents of nursing homes, adults and children with chronic cardiopulmonary disorders (e.g. asthma) or chronic metabolic diseases such as diabetes, and healthcare workers who have frequent contact with high-risk people. Additionally, family members of at-risk people should be vaccinated to reduce the person's risk of exposure. The vaccine is given in autumn, prior to the annual winter outbreak.

Diagnosis

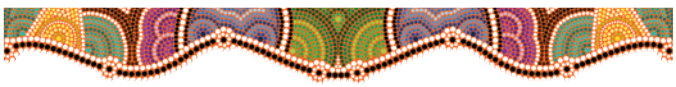
The diagnosis of influenza is based on history, clinical findings and knowledge of an influenza outbreak in the community. A chest x-ray and WBC count may be done to rule out complications such as pneumonia. The WBC count is commonly decreased in influenza; bacterial infections usually cause increased WBCs.

Medications

Yearly immunisation with influenza vaccine is the single most important measure to prevent or minimise symptoms of

influenza. About 5% of people experience mild symptoms of low-grade fever, malaise or myalgia for up to 24 hours after vaccination. Because the vaccine is produced in eggs, it should not be given to people who are allergic to egg protein. Serious adverse reactions to influenza vaccine are rare. *Guillain–Barré syndrome*, an acute neurological disorder characterised by muscle weakness and distal sensory loss, has been associated with certain batches of vaccine.

Over-the-counter analgesics such as aspirin, paracetamol or non-steroidal anti-inflammatory drugs (NSAIDs) provide symptomatic relief of fever and muscle ache. Antitussives may decrease cough, promoting rest. Antibiotics are not indicated unless secondary bacterial infection occurs.



Nursing care

Health promotion

Stress the importance of yearly influenza vaccination for people in high-risk groups and their families. Teach about spread of the disease, including measures to reduce the risk of contracting influenza, such as avoiding crowds and people who are ill.

Assessment

Unless there is a known outbreak of influenza in the community, it can be difficult to differentiate the manifestations of influenza from those of other URTIs.

- *Health history:* known exposure to virus; current symptoms, their onset and duration; presence of dyspnoea, chest pain, productive cough, facial pain or pressure in sinus areas; current medications, history of influenza vaccine; chronic diseases such as heart disease, COPD or diabetes; known medication allergies.
- *Physical examination:* general appearance; vital signs including temperature; skin colour; lung sounds; abdominal exam.
- *Diagnostic tests:* WBC, throat and sputum cultures, and chest x-ray for evidence of bacterial infection or pneumonia.

Nursing diagnoses and interventions

Although the symptoms of influenza are distressing, most people with the illness provide self-care and do not contact a healthcare provider. Recommendations to rest in bed during the acute phase of the illness and to limit activities until recovery are appropriate for influenza.

Severe disease or complications of influenza may necessitate hospitalisation for respiratory support and management. For these people, nursing care focuses on maintaining airway clearance, breathing patterns and adequate rest.

Ineffective breathing pattern

Muscle aches, malaise and elevated temperature may increase the respiratory rate and alter the depth of respirations, decreasing effective alveolar ventilation. Shallow respirations also increase the risk of *atelectasis* (lack of ventilation in an area of lung).

CONSIDERATION FOR PRACTICE

Monitor respiratory rate and pattern. Tachypnoea and/or rapid, shallow respirations may impair effective alveolar ventilation and gas exchange.

- Pace activities to provide for periods of rest. *Tachypnoea increases the work of breathing, causing fatigue; fatigue, in turn, can further impair ventilation and reduce the effectiveness of coughing.*
- Elevate the head of the bed. *The upright position improves lung excursion and reduces the work of breathing by lowering the diaphragm, moving abdominal contents downwards, creating less resistance to diaphragmatic excursion and slightly decreasing venous return.*

Ineffective airway clearance

Swelling and congestion of mucous membranes, extracellular fluid exudate and impaired ciliary action due to cell damage increase the risk of impaired airway clearance in influenza. The older adult is at particular risk because of normally reduced ciliary activity and increased lung compliance.

CONSIDERATION FOR PRACTICE

Monitor the effectiveness of cough and ability to remove airway secretions. Fatigue and general malaise may impair the ability to cough effectively and mobilise secretions.

- Maintain adequate hydration. Assess mucous membranes and skin turgor for evidence of dehydration. *Fever and decreased oral fluid intake may lead to dehydration and increased viscosity of secretions. Thick, viscous secretions are more difficult to expectorate.*
- Increase the humidity of inspired air with a bedside humidifier. *Increasing the water content of inhaled air helps loosen thick secretions and soothe mucous membranes.*
- Teach effective cough techniques. Administer analgesics as ordered. *The huff cough is effective to maintain open airways and it spares energy. (See Box 36.4 in Chapter 36 for teaching of this technique.) Relieving muscle ache increases the ability to cough effectively.*

Disturbed sleep pattern

Airway congestion, malaise, muscle aches and persistent cough may interfere with the ability to rest, increasing fatigue and prolonging recovery.

- Assess sleep patterns using subjective and objective information. *The person may appear to be sleeping but not achieving normal sleep patterns because of influenza symptoms. Both subjective and objective data are important to accurately assess sleep.*

CONSIDERATION FOR PRACTICE

If necessary, request a cough suppressant for night-time use. Cough suppressants are not recommended during the day because coughing promotes airway clearance. They may, however, be necessary at night to allow rest.

- Provide antipyretic and analgesic medications at or shortly before bedtime. *These drugs promote comfort by reducing fever and relieving muscle aches.*

Risk of infection

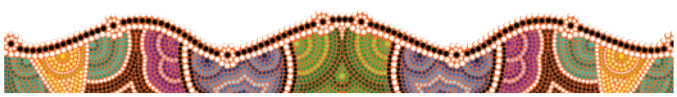
Infection control measures are recommended to prevent person-to-person transmission of influenza and to control influenza outbreaks in healthcare facilities.

- Use standard precautions and encourage all staff and visitors to frequently wash hands. *Handwashing is a primary infection control measure for infections transmitted via respiratory secretions.*
- Instruct people and visitors to control respiratory secretions by using tissues and to maintain a distance of at least 1 metre from others when coughing or sneezing. Handkerchiefs are not recommended due to spread of contaminants with multiple use. Provide masks for people and visitors who are unable to control secretions. *Limiting the spread of aerosolised secretions by covering the nose and mouth and maintaining distance from other people can reduce the spread of the disease to vulnerable populations.*
- Use droplet precautions for people with suspected or confirmed influenza: private room, masks for caregivers and visitors, and a mask for the person when being transported within the facility. *These measures limit the spread of respiratory secretions.*

Community-based care

Encourage appropriate self-care for people with influenza. Discuss the following topics related to home care:

- Increase rest during the acute, febrile phase of the illness.
- Maintain a liberal fluid intake even if anorexic.
- Appropriately use OTC medications for symptom relief.
- Employ hygiene measures such as using disposable tissues and frequent handwashing to reduce spread of the disease.
- Know manifestations of potential complications of influenza to report to the primary care provider.



THE PERSON WITH SINUSITIS

Sinusitis is inflammation of the mucous membranes of one or more of the sinuses (see Figure 33.2 in Chapter 32). Sinusitis is a common condition that usually follows an upper respiratory infection such as acute viral upper respiratory infection or influenza. Common causative organisms include streptococci, *S. pneumoniae, Haemophilus influenzae* and staphylococci. The risk of sinusitis is higher when the immune system is suppressed by immunosuppressive drugs or HIV infection. Sinusitis is common and difficult to treat in people who have AIDS.

Physiology review

The sinuses (or *paranasal sinuses*) are air-filled cavities in the facial bones that open into the turbinates of the nasal cavity. They are lined with ciliated mucous membranes that help move fluid and microorganisms out of the sinuses into the nasal cavity. The sinuses normally are sterile. Air within the sinuses has lower oxygen content than inspired air.

Pathophysiology

Sinusitis develops when nasal mucous membranes swell or other disorders obstruct sinus openings, impairing drainage. Mucus secretions collect in the sinus cavity, serving as a medium for bacterial growth. The nasal and sinus mucous membranes are continuous; therefore, bacteria generally spread to the sinuses via the opening into the nasal turbinates. The inflammatory response provoked by bacterial invasion draws serum and leucocytes to the area to combat the infection, increasing swelling and pressure.

Any process that impairs drainage from the sinuses may precipitate sinusitis. These include nasal polyps, deviated septum, rhinitis, tooth abscess or swimming or diving trauma. In hospitalised people, sinusitis may develop following prolonged nasotracheal intubation. Usually more than one sinus is infected. The frontal and maxillary sinuses are usually involved in adults.

Sinusitis may be acute or chronic. Chronic sinusitis results when acute sinusitis is untreated or inadequately treated. With continued infection, bacteria can become isolated, producing chronic inflammation. Over time, mucous membranes become thickened. Fungal infections may cause chronic infections, especially in immunosuppressed people. Other factors that may contribute to chronic sinusitis are smoking, a history of allergy and habitual use of nasal sprays or inhalants.

Manifestations and complications

The person with acute sinusitis often looks sick. Manifestations of sinusitis include pain and tenderness across the infected sinuses, headache, fever and malaise. The pain usually increases with leaning forward. When the maxillary sinuses are involved, pain and pressure are felt over the cheek. The pain may be referred to the upper teeth. Frontal sinusitis causes pain and tenderness across the lower forehead. Infection of the ethmoid sinus produces retro-orbital pain and pain over the high lateral aspect of the nose. Sphenoid sinusitis, the rarest form, may cause pain in the occiput, vertex or middle of the head. Symptoms often worsen for 3 to 4 hours after awakening and then become less severe in the afternoon and evening as secretions drain. The intensity and location of headache pain may change as sinuses drain. In acute sinusitis, the pain is usually constant and severe. In chronic sinusitis, the pain is described as dull and may be constant or intermittent.

Other symptoms include nasal congestion, purulent nasal discharge and bad breath. The nasal mucous membrane is red and swollen. Purulent drainage may be noted at the opening to the middle turbinate. This may be the only sign of chronic sinusitis. Swallowed secretions irritate and inflame the throat and may cause nausea or vomiting.

Complications develop when the infection spreads to surrounding structures (see Box 34.2). These include periorbital abscess or cellulitis, cavernous sinus thrombosis, meningitis, brain abscess or sepsis. Eustachian tube oedema may lead to hearing loss.

BOX 34.2 Potential complications of sinusitis

Local complications
- Orbital cellulitis
- Subperiosteal abscess
- Orbital abscess
- Cavernous sinus thrombosis
- Mucocoele
- Osteomyelitis

Intracranial complications
- Meningitis
- Epidural abscess
- Subdural abscess
- Brain abscess
- Venous sinus thrombosis

INTERPROFESSIONAL CARE

Treatment of sinusitis focuses on restoring drainage of obstructed sinuses, controlling infection, relieving pain and preventing complications.

Diagnosis

The diagnosis of acute sinusitis usually can be made using the history and physical exam. Diagnostic studies such as computed tomography (CT) scan or sinus x-rays generally are done only when sinusitis is persistent, chronic or recurrent. See Chapter 33 for more information about diagnostic studies and their nursing implications.

- *Sinus x-rays* are evaluated. Sinuses are normally translucent because they are filled with air; affected sinuses appear cloudy or opaque. A visible air–fluid level or thickening of the sinus mucosa may be seen in infected sinuses.
- *CT scan* is a more sensitive indicator of acute and chronic sinusitis and often is performed without preceding x-rays.
- *Magnetic resonance imaging (MRI)* may be ordered if malignancy of the sinus is suspected.

Medications

Antibiotic therapy directed at the usual organisms causing sinusitis typically is prescribed. Amoxicillin (possibly combined with clavulanate (Augmentin)) or cefaclor are commonly used antibiotics for sinusitis. Antibiotic therapy is continued for 10 to 14 days; occasionally a longer course is prescribed to prevent relapse. If the sinusitis does not respond to treatment with oral antibiotics, hospitalisation and intravenous antibiotic therapy may be required. See Chapter 11 for nursing care related to antibiotic therapy.

Oral or topical (in the form of nasal sprays) decongestants such as pseudoephedrine or phenylephrine are also prescribed to reduce mucosal oedema and promote sinus drainage. Antihistamines may decrease nasal congestion and facilitate sinus drainage, but they also tend to increase the viscosity of secretions and hinder drainage. For this reason, they may not be as effective as decongestants. Saline nose drops or sprays promote sinus drainage, as does inhalation of warm steam. Aerobic exercise also promotes mucus flow and may be recommended.

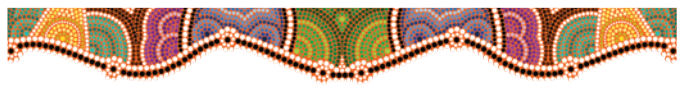
CONSIDERATION FOR PRACTICE

To administer topical drugs, the person's head is tilted backwards and to the side on which the drops are to be instilled. The person may need to remain in position for 5 minutes to allow the drops to reach the posterior nares.

Surgery

People who do not respond to pharmacological measures and who experience persistent facial pain, headache or nasal congestion may require *endoscopic sinus surgery*. People who have endoscopic sinus surgery usually do not require nasal packing postoperatively. Instead, frequent nasal cleaning and irrigation with normal saline are performed. The person is instructed to sneeze with the mouth open and avoid blowing the nose, lifting or straining for a week following surgery.

Antral irrigation can be done in the doctor's office under local anaesthesia. Saline solution is instilled into the maxillary sinus to irrigate the area and wash out the sinus of purulent exudate. The person is seated with the head forward and mouth open to allow drainage of the solution through the nose and mouth. A culture of the exudate may be obtained to determine appropriate antibiotic therapy.



Nursing care

Health promotion

Measures to prevent sinusitis are those that promote nasal drainage: encouraging liberal fluid intake, judicious use of nasal decongestants as needed and treating any obstructive process. Encourage individuals with URTI to blow their nose with both nares open. Advise people that use of saline nasal sprays can help maintain patency of the opening to the sinuses, promoting drainage and reducing the risk of obstruction and infection.

Assessment

Focused assessment of the person with suspected sinusitis includes the following:

- *Health history:* complaints of frontal or periorbital headache, cheek, teeth or ear pain; timing of pain and changes in intensity over course of the day; nasal discharge or post-nasal drip; other symptoms; previous sinus problems; current medications, known medication allergies.
- *Physical examination:* general appearance; vital signs including temperature; inspect nasal and pharyngeal mucous membranes; percuss sinuses for tenderness.
- *Diagnostic tests:* WBC and differential, cultures of sinus drainage, sinus x-rays or other imaging studies.

Nursing diagnoses and interventions

The person with sinusitis is often acutely uncomfortable. Obstructed and congested sinuses cause pain and pressure that increase with position changes and leaning forward. Treatment usually is community based, making education the key nursing role. When the person is hospitalised for intravenous antibiotic therapy or sinus surgery, pain and nutritional considerations are the priority for nursing care.

Pain

Although sinus surgery is relatively minor, both the incision and postoperative swelling can cause discomfort. Nasal packing, if used, contributes to the discomfort.

- Assess pain using a standardised pain scale. Administer analgesics as ordered. *Relief of pain promotes a feeling of wellbeing and enhances recovery.*
- Apply ice packs to the nose. *Cold compresses reduce swelling, control bleeding and provide local analgesia.*
- Elevate the head of the bed to Fowler's or high-Fowler's position for 24 to 48 hours after surgery. *Elevating the operative site minimises tissue swelling and promotes comfort.*

Imbalanced nutrition

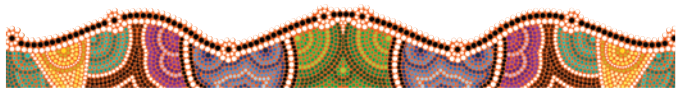
Postoperatively, the sense of smell, an appetite stimulus, is diminished by nasal packing. Mouth discomfort from the incision and numbness of the upper teeth also may affect appetite and eating.

- Provide clear liquid diet progressing to soft foods as tolerated. High-kilojoule dietary supplements may be used. *A progressive diet is used to assess the ability to swallow without choking and allay fears. Foods high in kilojoules and nutritional value provide for metabolic and healing requirements.*
- Monitor intake, output and weight. *This information allows assessment of overall fluid balance and the adequacy of dietary intake.*
- Elevate the head of the bed during meals. *The upright position facilitates swallowing and minimises risk of aspiration.*

Community-based care

Teaching for people with sinusitis and their families focuses on following through with appropriate treatment and promoting comfort. Discuss the following topics when preparing for home care:

- The importance of completing the entire course of prescribed antibiotics to achieve cure and prevent the development of antibiotic-resistant bacteria. Assist in developing a schedule that helps ensure all doses are taken.
- Measures to prevent superinfections (such as vaginitis or oral thrush) during the prolonged course of treatment (e.g. consume 200 g of yoghurt containing live bacterial cultures daily while on antibiotics).
- Use of systemic or topical decongestants to promote sinus drainage.
- Maintaining a liberal fluid intake to reduce the viscosity of mucus drainage.
- Use of a humidifier or steam inhalation to promote sinus drainage.
- Sleeping with the head of the bed elevated to a 45-degree angle and on the unaffected side to promote drainage of affected sinuses.
- Application of a warm, moist pack to the area of pain and tenderness to promote comfort.
- Notify the doctor if symptoms do not improve with treatment or if signs of a complication develop, such as increased pain and redness and swelling on the side of the nose or around the eyes.
- Postoperative instructions to prevent bleeding, such as avoiding blowing the nose for 7 to 10 days and avoiding strenuous activity such as heavy lifting for about 2 weeks.
- Use of saline nasal sprays postoperatively to keep the nasal mucosa moist.



THE PERSON WITH PHARYNGITIS OR TONSILLITIS

Pharyngitis, acute inflammation of the pharynx, is one of the most commonly identified clinical problems. Although it is usually viral in origin, pharyngitis may also be caused by bacterial infection. *Group A beta-hemolytic streptococcus* (strep throat) is the most common cause of bacterial pharyngitis. Other bacteria that may cause pharyngitis include *Neisseria gonorrhoeae*, a Gram-negative diplococcus that is sexually transmitted, *Mycoplasma* and *Chlamydia trachomatis*.

Tonsillitis is acute inflammation of the palatine tonsils. Although it is sometimes viral in origin, tonsillitis is usually due to streptococcal infection. The incidence of streptococcal infections is greatest between late autumn and spring, especially in cold climates. Viral tonsillitis may occur in epidemics in people living in crowded conditions, such as children in boarding schools.

Pathophysiology and manifestations

Pharyngitis and tonsillitis are contagious and spread by droplet nuclei. Incubation varies from a few hours to several days, depending on the organism. Viral infections are communicable for 2 to 3 days. Symptoms usually resolve within 3 to 10 days after onset.

Viral pharyngitis may be attributed to the same viruses as cause the common cold: rhinovirus, coronavirus or parainfluenza virus. Pharyngitis caused by adenovirus, influenza virus or Epstein–Barr virus (associated with infectious mononucleosis) may be particularly severe.

Acute pharyngitis causes pain and fever. The pain may vary from a scratchy sore throat to one so painful that swallowing is difficult. Streptococcal pharyngitis is usually marked by an abrupt onset, with fever of 38.3°C or higher, severe sore throat with dysphagia, malaise and often arthralgias and myalgias. Anterior lymph nodes are often enlarged and tender. Exudate (pus) may be seen on the pharynx and tonsils (see Figure 34.2). By contrast, the onset of viral pharyngitis is often gradual, with manifestations of low-grade fever, sore throat, mild hoarseness, headache and rhinorrhoea. The pharyngeal membranes appear mildly red with vascular congestion. Infectious mononucleosis, caused by the Epstein–Barr virus, often presents as acute pharyngitis, with visible patches of exudate on the pharynx or tonsils. The cervical lymph nodes are enlarged and tender as well. See the accompanying box for the manifestations of pharyngitis and tonsillitis.

In tonsillitis, the tonsils appear bright red and oedematous. White exudate is present on the tonsils; pressing on a tonsil may produce purulent drainage. The uvula may also be reddened and swollen. Cervical lymph nodes are usually tender and enlarged.

The person with tonsillitis complains of a sore throat, difficulty swallowing, general malaise, fever and otalgia (pain referred to the ear). Manifestations are often more severe in adolescents and

FIGURE 34.2 ■ The appearance of the oral pharynx and tonsils in acute pharyngitis and tonsillitis

Source: © Biophoto Associates/Science Source.

adults than in children. Infection may extend via the eustachian tubes to cause acute otitis media. This may lead to further damage such as spontaneous rupture of the eardrums and mastoiditis. See Chapter 45 for more information about otitis media.

MANIFESTATIONS Pharyngitis and tonsillitis

LOCAL
- Sore throat
- Possible dysphagia and ear pain
- Tender, swollen anterior cervical lymph nodes
- Hoarse voice
- Red, swollen pharyngeal mucous membranes and/or tonsils
- Possible visible exudate on pharyngeal membranes and/or tonsils

GENERAL
- Fever
- General malaise
- Arthralgia, myalgia

Complications

Although bacterial pharyngitis may be mild and indistinguishable from viral pharyngitis by its signs and symptoms, it can lead to significant complications such as abscess, scarlet fever, toxic shock syndrome, rheumatic fever or acute post-streptococcal glomerulonephritis.

Peritonsillar abscess, or *quinsy*, is a potential complication of tonsillitis. It usually results from group A beta-haemolytic streptococcus infection extending from the tonsils to the surrounding tissue. The abscess causes pus formation behind the tonsil with marked swelling and asymmetrical deviation of the uvula. The degree of swelling may make it difficult to swallow anything other than liquids. The person may exhibit thickening of the voice, drooling and trismus (a tonic contraction of the muscles of mastication).

Rare (1–3%) but serious complications of streptococcal pharyngitis and tonsillitis include acute glomerulonephritis and rheumatic fever, abnormal immune responses to the infection. Acute glomerulonephritis generally presents with sudden onset of haematuria, proteinuria and, less commonly, hypertension and oedema within 7 to 10 days after the acute infection. Rheumatic fever typically presents 3 to 5 weeks after acute infection with fever, painful or swollen joints, rash and heart murmur. Other complications of bacterial infection include sinusitis, otitis media, mastoiditis and cervical adenitis.

INTERPROFESSIONAL CARE

Both viral and bacterial pharyngitis are usually self-limited diseases. However, because of the risk of serious complications associated with streptococcal sore throat, an effort is usually made to establish an accurate diagnosis and treat bacterial pharyngitis.

Diagnosis

A *throat swab* is obtained and examined for streptococcus antigen. These tests allow rapid identification of the antigen but are not highly sensitive. When the test is positive, treatment for strep throat is initiated. If the test is negative, the swab is cultured to ensure that streptococcus organisms are not present. Even throat cultures are not always accurate, with approximately 10% false negative and 20% false positive results.

A *full blood count (FBC)* may be done on severely ill people or to rule out other causes of pharyngitis. The WBC count is usually normal or low in viral infections and elevated in bacterial infections.

Medications

Antipyretics and mild analgesics such as aspirin or paracetamol provide symptomatic relief for throat pain and associated myalgias. Penicillin is the drug of choice for group A streptococci. Erythromycin or amoxicillin may be used if the person is allergic to penicillin. Antibiotic therapy is continued for at least 10 days. The person is no longer contagious after 24 hours of antibiotic therapy.

Surgery

Tonsillectomy (surgical removal of the tonsils) is indicated for recurrent or chronic infections that have not responded to antibiotic therapy, hypertrophy of the tonsils with risk of airway obstruction, peritonsillar abscess, repeated attacks of purulent otitis media and tonsil malignancy. Adenoid tissue usually is removed at the same time. Bleeding is the most significant postoperative complication of tonsillectomy and may develop up to 2 weeks following the surgery.

Nursing care

Because of the risk of significant complications associated with streptococcal pharyngitis, encourage all individuals

with symptoms that persist for several days or that include fever, lymphadenopathy and myalgias to seek evaluation and treatment.

Home care is appropriate for acute uncomplicated pharyngitis. Treatment focuses on adequate rest and relief of symptoms. A liquid or soft diet is useful when swallowing is difficult. Increased fluid intake is encouraged, especially when febrile. Warm saline gargles, moist inhalations and application of an ice collar are soothing to the sore throat.

Following tonsillectomy, ensure a patent airway by placing the person in semi-Fowler's position with the head turned to the side to allow secretions to drain from the mouth and pharynx. Keep the airway in place until the gag and swallowing reflexes have returned. Apply an ice collar to reduce swelling and pain. Notify the surgeon immediately if excessive bleeding or haemorrhage occurs. If there is no bleeding, allow water and ice chips as desired. Warm saline mouthwashes are helpful in managing thick oral secretions following tonsillectomy. A liquid or semi-liquid diet is recommended for several days.

Community-based care

Discuss the following topics when preparing the person for home care:

- the importance of completing the full 10 days of antibiotic therapy if prescribed
- using warm saline gargles or throat lozenges for symptomatic relief
- signs and symptoms of possible complications of streptococcal infection such as glomerulonephritis or rheumatic fever
- monitoring temperature in the morning and evening until well to ensure that the infection has not spread to deeper tissues
- proper use and disposal of tissues and frequent handwashing to prevent spreading the infection to others.

For the person who has had a peritonsillar abscess drainage or tonsillectomy, provide the following instructions:

- postoperative mouth and throat care

NURSING CARE PLAN A person with peritonsillar abscess

Monica Wunderman, aged 27, was recently treated for tonsillitis caused by infection by group A streptococcus. She presents to the emergency department 10 days later appearing acutely ill. She states that her throat is so sore that she has difficulty swallowing even liquids. Barbara Wallace, the ED nurse, completes an assessment of Ms Wunderman.

ASSESSMENT

Findings include T 38.8°C. An acutely swollen and reddened area of the soft palate is noted in her mouth, half occluding the orifice from the mouth into the pharynx. Yellow exudate is present. A diagnosis of peritonsillar abscess is made. Needle aspiration of the abscess is performed.

DIAGNOSES

- *Acute pain* related to peritonsillar swelling manifested by difficulty swallowing.
- *Risk of airway compromise* related to pain and swelling manifested by inability to clear secretions and difficulty swallowing.
- *Nutritional imbalance* related to insufficient oral intake manifested by lack of appetite and pain when eating and difficulty swallowing fluids.

PLANNING

- Evaluate current medication regimen and effectiveness of same.
- Evaluate ability to clear secretions and volume of secretions being produced.
- Evaluate current oral intake and assess the need for further nutritional supplements.

Expected outcomes

- Have minimal or no pain.
- Maintain a patent airway as demonstrated by normal respiratory rate and rhythm.
- Maintain optimal fluid intake as evidenced by consumption of fluids and semi-liquid foods, moist mucous membranes, normal skin turgor and normal temperature.

IMPLEMENTATION

- Teach that ice-cold fluids may be easier to swallow than hot or room-temperature beverages and may provide a local analgesic effect.
- Advise to avoid citrus juices, hot or spicy foods, and rough-textured foods for 1 week.
- Teach pain management strategies such as applying an ice collar as desired and gargling with warm saline or mouthwash solution every 1 to 2 hours for the first 24 to 48 hours after aspiration of the abscess.
- Instruct to take medications as prescribed.

EVALUATION

When Ms Wallace contacts Ms Wunderman by telephone 2 days after her visit to the emergency department, she reports complete relief of symptoms. She is afebrile, taking fluids without difficulty and has had no difficulty breathing. She has not experienced any pain.

CRITICAL THINKING IN THE NURSING PROCESS

1. Describe common symptoms of infectious or inflammatory diseases of the upper airway and discuss methods of symptom relief.
2. Describe common pharmacological interventions for these disorders.
3. Which themes of nursing diagnoses emerge for people with these types of disorders?

REFLECTION ON THE NURSING PROCESS

1. Which communication and education strategies could you use for people with peritonsillar abscess to improve their knowledge regarding this condition without negatively impacting on their presenting symptoms?
2. Outline what you have learned from this case study and how you will apply this knowledge to your current practice.

- avoiding use of aspirin for 2 weeks to reduce the risk of postoperative bleeding
- manifestations of bleeding to report to the doctor. (Delayed haemorrhage may occur for up to 1 week post surgery.)

THE PERSON WITH A LARYNGEAL INFECTION

The larynx, located between the upper airways and the lungs, protects the lower respiratory tract from inhaled substances other than air and allows speech. The larynx includes the epiglottis, which covers the larynx during swallowing, and the glottis or vocal cords. Either portion of the larynx may become inflamed.

Epiglottitis

Epiglottitis, inflammation of the epiglottis, is an uncommon disorder that presents as a medical emergency. *H. influenzae* infection is the most common cause of epiglottitis. Epiglottitis is a rapidly progressive cellulitis that begins between the base of the tongue and the epiglottis. The epiglottis itself becomes swollen and inflamed; swelling of adjacent tissues pushes the epiglottis posteriorly. This swelling and oedema threaten the airway. Adults usually present with a 1- to 2-day history of sore throat, *odynophagia* (painful swallowing), dyspnoea and possibly drooling and stridor.

Using a tongue blade to view the oropharynx is avoided; this may precipitate laryngospasm and airway obstruction. The epiglottis is visualised using a flexible fibre-optic laryngoscope to establish the diagnosis. The epiglottis appears red, swollen and oedematous. Nasotracheal intubation may be required to ensure airway patency. The person may be admitted to a critical care unit and intravenous antibiotic therapy is initiated. Ceftriaxone may be prescribed. Dexamethasone, a systemic corticosteroid, is also given to suppress the inflammatory response and rapidly reduce swelling of the epiglottis.
