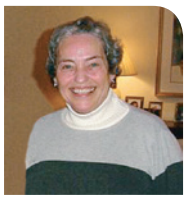
DETAILED CONTENTS

ABOUT THE **AUTHORS**



PRISCILLA LEMONE-KOEPLIN RN, DSN, FAAN

Priscilla LeMone-Koeplin spent most of her career as a nurse educator, teaching medical–surgical nursing and pathophysiology at all levels from diploma to doctoral students. She has a diploma in nursing from Deaconess College of Nursing (St Louis, Missouri), baccalaureate and master's degrees from Southeast Missouri State University, and a doctorate in nursing from the University of Alabama-Birmingham. She is retired as an Associate Professor Emeritus, Sinclair School of Nursing, University of Missouri, but continues to keep up to date in nursing both as an Adjunct Associate Professor at the Ohio State University, College of Nursing and as an author of nursing textbooks.

Dr LeMone-Koeplin won numerous awards for scholarship and teaching during her more than 30 years as a nurse educator. She is most honoured for receiving the Kemper Fellowship for Teaching Excellence from the University of Missouri, the Unique Contribution Award from the North American Nursing Diagnosis Association, and for being selected as a Fellow in the American Academy of Nursing. Dr LeMone-Koeplin currently lives in Ohio. She enjoys travelling, gardening, knitting and reading fiction.

She believes that her education gave her solid and everlasting roots in nursing. Her work with students has given her the wings that have allowed her love of nursing and teaching to continue through the years.

KAREN M. BURKE RN, MS

Karen Burke has been a nurse educator for much of her career, teaching basic and advanced medical–surgical nursing and pathophysiology. She retired as director of the nursing and health occupations programs at Clatsop Community College in Astoria, Oregon, subsequently serving as nursing education consultant and program manager for the Oregon State Board of Nursing. She currently provides consulting services for nursing and higher education.

Ms Burke earned her diploma in nursing from Emanuel Hospital School of Nursing in Portland, Oregon, later completing baccalaureate studies at Oregon Health & Science University, and a master's degree in nursing at the University of Portland. She has been actively involved in nursing education and clinical nursing education reform, as well as in initiatives to address the nursing faculty shortage. Ms Burke is co-author of another text, *Medical–Surgical Nursing Care* (3rd edition), with Elaine Mohn-Brown and Linda Eby.

Ms Burke highly values the nursing profession and the importance of providing a strong education in the art and science of nursing for students preparing to enter the profession, no matter which educational path is being pursued.

GERENE BAULDOFF RN, PhD, FAAN

Gerene Bauldoff is a Professor of Clinical Nursing at The Ohio State University College of Nursing in Columbus, Ohio. She has been a nurse educator for 14 years, teaching medical–surgical nursing, translational science and evidence-based practice courses at the baccalaureate, master's, and doctoral levels. Prior to her nursing educator role, her clinical background included home health nurse, lung transplant coordinator and pulmonary rehabilitation coordinator. Dr Bauldoff has a diploma from the Western Pennsylvania Hospital School of Nursing, Pittsburgh, Pennsylvania, and a BSN from LaRoche College in Pittsburgh. Her graduate education is from the University of Pittsburgh, with an MSN in medical–surgical nursing (cardiopulmonary clinical nurse specialist) and a PhD in nursing in 2001, training under Leslie Hoffman, PhD, RN, FAAN.

Dr Bauldoff is an active member of multiple professional organisations including the American Academy of Nursing (AAN), Sigma Theta Tau International Honor Society of Nursing, the American Association of Cardiovascular and Pulmonary

Rehabilitation (AACVPR), the American Thoracic Society Nursing Assembly and the American College of Chest Physicians (ACCP). She is a recognised expert in medical–surgical nursing, focusing on the care of the patient with chronic pulmonary disease, serving on committees focusing on patient-centred outcomes in pulmonary rehabilitation. She has been honoured with fellowships in the AAN, AACVPR and ACCP. In 2013, Dr Bauldoff was the keynote speaker at the Nanning Nursing Education Conference in Nanning, China, attended by representatives from more than 100 nursing schools in China.

Dr Bauldoff views nursing as the greatest profession, using scientific evidence to provide the highest quality of care while maintaining the personal relationship with patients and their families. Her experiences provide her with insights and lessons learned that she shares with her students.

Dr Bauldoff resides in central Ohio. She enjoys travelling, walking, bicycling, golf and spending time with her family and friends.

PAULA GUBRUD-HOWE RN, MS, EdD, FAAN

Paula Gubrud-Howe is Senior Associate Dean for Academic Affairs and an Associate Professor at Oregon Health and Science University (OHSU) School of Nursing. She has more than 25 years of experience as a nurse educator involving multiple levels of programs from LPN to doctoral education. Dr Gubrud-Howe is a founding leader and co-director of the Oregon Consortium for Nursing Education, an award-winning consortium that includes the five campuses of OHSU and nine community colleges. She also has more than 20 years of experience in medical–surgical nursing, critical care, home health and hospice. Dr Gubrud-Howe earned a baccalaureate degree in nursing from Walla Walla University (1980), an MS in community-based nursing from OHSU (1993) and an EdD in post-secondary education from Portland State University (2008). She is a frequently invited speaker at national and international nursing education conferences and consults with other states and countries on the development of competency-based curricula and nursing education consortiums designed to promote academic progression in nursing education. Her research activity is focused on clinical education redesign and the integration of simulation into nursing curricula.

Dr Gubrud-Howe is passionate about nursing and the opportunities it provides to members of the profession. She values the sacred relationship nurses experience with patients as they promote health, treat illness and provide comfort and palliative care. She believes the nation's health depends on highly qualified nurses who are dedicated to lifelong learning in pursuit of evidence-based, patient-centred care.

TRACY LEVETT-JONES RN, PhD, MEd & Work, BN, DipAppSc(Nur)

Professor Tracy Levett-Jones is the Deputy Head of School (Teaching and Learning), School of Nursing and Midwifery, and the Director of the Research Centre for Health Professional Education at the University of Newcastle. Her research interests include clinical reasoning, interprofessional education, empathy, belongingness, cultural competence, simulation and patient safety. Tracy has authored 10 books, the most recent being *Clinical reasoning: Learning to think like a nurse* and *Critical conversations for patient safety*, as well as over 150 book chapters, reports and peer-reviewed journal articles. Tracy has been the recipient of nine research awards and 10 teaching awards including an Australian Learning and Teaching Council (ALTC) Award for Teaching Excellence (2010), a NSW Minister for Education and Training Quality Teaching Award (2007) and a Pearson/Australian Nurse Teacher Society Nurse Educator of the Year Award (2011). She has been awarded nearly $2 million in grant funding and has led and been involved in a number of Category 1 funded projects.

TRUDY DWYER RN, PhD, MClinEdu, GCFlexLearn, BHlthScn(Nsg), NrCert, ICUNsgCert

Trudy Dwyer completed a hospital-based nursing program at the Rockhampton Hospital, Queensland, where she developed an enthusiasm for critical care nursing and travel. Trudy currently holds the position of Associate Professor (Research Intensive) at CQUniversity. She has extensive experience coordinating undergraduate courses/programs and research higher-degree supervision. Her research interests include patient safety, recognition of deterioration, resuscitation and simulation. She has published in international refereed scholarly journals, book chapters and is the co-author of the highly successful *Student nurse: Clinical survival guide*.

LORNA MOXHAM RN, PhD (CQU), MHN, DAS(Nsg) (MIHE), Med (UNSW), GCOH&S (CQU), GCQualMgmt (CQU), BHSc (UWS), Cert IV (Training & Assessment) (CQIT), FACMHN, FACON

Professor Lorna Moxham is a 3-year specialist hospital-trained psychiatric nurse. She completed her BHSc at the University of Western Sydney and is passionate about the nursing profession, actively contributing at regional, state, national and international levels. Lorna has spent time in regional Queensland, regional New South Wales and metropolitan New South Wales and has served on many ministerial committees as a member and chair. In addition, she has held several leadership and governance roles, both within the tertiary education sector and in nursing. Lorna is currently the inaugural Professor of Mental Health Nursing and also the leader of the Living Well, Longer theme in the Global Challenges Program at the University of Wollongong. Lorna has successfully supervised numerous higher degree by research students to on-time completion, all of whom have published their work. Lorna thinks of being a nurse as 'the very best job in the world'.

KERRY REID-SEARL RN, RM, PhD, BHSc (Nsg), MClinEdu, MRCNA, FCN

Kerry Reid-Searl is a Professor in the School of Nursing and Midwifery at CQUniversity. Kerry is a current clinician in the area of paediatrics. She has a long career as a nurse academic and has been involved in the undergraduate degree for 25 years. Kerry is also a supervisor of master's and PhD research students. Kerry's research interests include patient safety, simulation, paediatrics and wound care. Kerry has been the recipient of 10 teaching awards including two Australian Learning and Teaching Citations for her outstanding contribution to student learning and an Australian University Teaching Excellence Award. She was named Pearson/Australian Nurse Teacher Society Nurse Teacher of the Year in 2009 and in 2013 received the Simulation Australia Achievement award. Kerry has become known nationally and internationally for her pioneering work in creating, designing and researching two innovative simulation strategies called Mask Ed (KRS Simulation) and Pup Ed (KRS Simulation).

KAMAREE BERRY RN, PhD candidate, MEd Stds (Hon), PGDip Clinical Nursing (Perioperative), BN, MACN, RAA

Kamaree's career spans more than 20 years and commenced with the Australian Army where she trained as a medic and then became a nursing officer at the rank of lieutenant. She has been employed in the public, private and academic sectors in a number of roles spanning from an RN, senior lecturer and academic undergraduate chair to General Manager, Learning.

A successful career has provided her with the opportunity to teach at both undergraduate and postgraduate levels, along with employment within the corporate and commercial sector at a national level. Underpinning Kamaree's philosophy and values of learning, development and professional education is her strong conviction of innovative leadership and direction for both staff and students. She values the importance of continuing professional education and development; this has been acknowledged by her peers making use of her extensive expertise and contemporary approach to teaching and learning, curriculum development and review, program designs, staff and student mentorship, and currency on educational trends within the nursing profession across a number of specialties. She has been awarded a Bachelor of Nursing, Postgraduate Diploma Clinical Nursing—Perioperative, a Master of Educational Studies (Hons) and has completed her doctoral thesis.

KERYLN CARVILLE PhD, RN, STN (Cred)

Professor Primary Health Care & Community Nursing

Silver Chain Group and Curtin University, Western Australia.

Keryln has extensive clinical experience and is committed to research and education within the domains of wound and ostomy care. She was appointed a Fellow of the Australian Wound Management Association (now Wounds Australia) in 2006. She is Chair of the Australian Pressure Injury Advisory Panel and Chair Pan Pacific Pressure Injury Alliance, Chair of the Wounds Australia Wound Standards Committee and sits on the International Wound Infection Institute Committee. Keryln was awarded the Western Australia Health Lifetime Achievement Award for Nursing in 2010.

MAJELLA HALES RN, MAppSci, GCHE, BN

Majella Hales works as a casual academic at the Australian Catholic University in Brisbane. Originally hospital trained, she has worked in nursing for over 25 years. She maintains her clinical experience by undertaking agency shifts in critical care units across South-East Queensland and provides clinical facilitation for undergraduate nursing students for various local universities. Majella authored several chapters of Kozier & Erb's *Fundamentals of nursing* Volumes 1–3 and co-authored *Principles of pathophysiology* with Associate Professor Shane Bullock. Along with journal articles and conference presentations, she has also produced the skills DVD for Tollefson's *Clinical psychomotor skills* text and adapted the American case study resource *The neighbourhood*. Majella is a co-owner of Sciencopia, a company producing informative, novel and fun educational resources for academics, students and healthcare professionals. One of Sciencopia's first products—*Essential Aussie drugs: A little pocket book of common Aussie drug facts*—is a great resource for assisting individuals to improve their drug knowledge and safety in the ever-changing and complex world of pharmacology and drug administration.

NICOLE KNOX RN, BN, MN, GDipAdultEd, GCICU

Nicole Knox has been working in nursing for 20 years, including roles as a nursing academic, clinical nurse specialist, clinical educator and nurse unit manager.

The major part of Nicole's nursing career has been in critical care nursing, particularly intensive care, for which she completed a graduate certificate. She enjoys clinical education and this guided her decision to pursue a career in academia. She has worked in several universities in Sydney where her roles have included unit coordination, teaching and research. She is currently a sessional academic at Western Sydney University. She has a love of education and values the opportunity to introduce the next generation of nurses to the profession.

DEBRA RAYMOND RN, MCP, BHlthSc, DipHealthScNsg

Debra Raymond has been nursing since she was 15 years of age, starting in a nursing home as an Assistant in Nursing. She then completed her enrolled nursing aide course, worked as an EN and was encouraged to do further studies, from which she gained a Diploma of Health Science Nursing, Bachelor of Health Science and Master of Clinical Practice. She received an International Nurses Day award which supported her travels to France to present her research projects at the Emergency Medicine Conference.

The major part of Debra's nursing career has been in critical care nursing. Debra's enjoyment of education prompted her decision to enter academia. She then started facilitating nursing students in the clinical setting. She has continued in education and is now an Associate Lecturer. Debra is also a PhD candidate and unit coordinator for an undergraduate unit.

Debra believes that her career progression in the nursing profession has given her an appreciation of the endless opportunities in this wonderful, and at times challenging, profession. Her love for education and the wish to make a difference in nursing have guided her throughout her career.

Debra is married, and with the support of her husband and wonderful, talented daughter she will continue pursuing her goal of making a difference in her chosen nursing profession.

CONTRIBUTORS

We extend deep, sincere thanks to our contributors who gave their time, effort and expertise so willingly to the development and writing of chapters and resources that help foster our goal of achieving nursing excellence through building clinical competence.

Dr Sharyn Hunter, University of Newcastle

Dr Sarah Jeong, University of Newcastle

Prof Isabel Higgins, University of Newcastle

2nd edition: Ms Jenny Day, University of Newcastle

Dr Ann Clare Thorington Taylor, University of Newcastle

Dr Sharyn Hunter, University of Newcastle

Dr Sarah Jeong, University of Newcastle

Ms Deborah Armitage, University of Newcastle

Prof Diana Keatinge, University of Newcastle

Prof Isabel Higgins, University of Newcastle

Chapter 52 Nursing Care of People in Regional, Rural and Remote Areas of Australia

2nd and 3rd editions: Ms Leeanne Heaton, CQUniversity

PREFACE

This is a wonderful time to become a nurse in Australia, with opportunities that are exciting and far reaching. As always, there is a need for committed nurses whose practice is based on a strong foundation of knowledge, clinical skills and the ability to think critically in challenging and complex situations. This book has been written to help you develop these professional attributes and skills.

This third Australian edition of *Medical–surgical nursing: Critical thinking for person-centred care* will help prepare you for your nursing journey. It will challenge you to excel and support you as you learn.

Throughout this book, we demonstrate how competent nurses provide person-centred care that is empathetic, holistic and individualised, and is respectful of the person's age, ethnicity, culture and psychosocial status.

Our goal—helping you to excel as a nurse

In writing this book, our commitment has been to provide students with a strong knowledge base, an understanding of contemporary practice issues in Australia and the capacity for sound clinical reasoning. These professional attributes will allow you to provide nursing care that is safe and effective. This easily understood, straightforward Australian edition integrates the following concepts: epidemiology, pathophysiology, pharmacology, legal and ethical issues, therapeutic communication, interprofessional communication and cultural competence. The use of effective design principles and learning strategies such as advanced organisers, special features, colourful illustrations and critical thinking exercises will support your learning and application to practice.

This textbook has been designed to:

- emphasise a person-centred philosophy whereby the person who is the recipient of care is seen as an integral member of the team and consideration of their needs and wishes is paramount
- foster critical thinking and clinical reasoning skills as the basis for nursing excellence in clinical practice
- recognise the nurse's role as an essential member of the interprofessional healthcare team.

We are confident that this text will support your learning and professional practice, and we wish you well as you undertake your nursing journey.

Organisation

The book contains 52 chapters in 14 units. Units 1 and 2 provide an overview of medical–surgical nursing, the meaning of health and illness, and alterations in patterns of health in particular populations, contexts and situations. The remaining units are based on alterations in human structure and function. Each unit has a focus on altered health states and opens with an assessment chapter, which draws upon the student's prerequisite knowledge and serves to reinforce basic principles of anatomy and physiology as applied to assessment in both health and illness. Following the assessment chapter, each nursing care chapter focuses on major conditions and diseases and includes three key components:

1. ***Pathophysiology*** The discussion of each *major* illness or condition begins with incidence and prevalence, an overview of pathophysiology and disease manifestations and complications.
2. ***Interprofessional care*** The role of both nurses and the other members of the healthcare team in managing illness is then profiled. This section includes information about specific tests necessary for diagnosis, medications, surgery and treatments, fluid management, dietary management and complementary and alternative therapies.
3. ***Nursing care*** Nursing care within a context of priority nursing diagnoses and interventions is then provided and rationales outlined for each intervention. This section also takes into account that health promotion and illness prevention are critical nursing roles in contemporary healthcare.

Finally, for each major disorder or condition, a narrative *Nursing care plan* is provided with a brief case study, followed by the steps of the nursing process.

Chapter highlights This end-of-chapter section concludes with multiple-choice revision questions to reinforce comprehension of the chapter content. (The correct answers with rationales are found in the Instructors' Manual.)

Language and terminology

In developing this text we have used terminology that is familiar and applicable to most Australians. While person-centred care is most often used to reflect our philosophical stance, the term 'patient' is also used as appropriate throughout the text and according to the context of care being described.

Indigenous Australians

Throughout the text we have integrated issues relevant to the Indigenous Australian population. In covering these issues we have acknowledged the importance of using non-discriminatory and appropriate language to describe groups of people, policies and events, and have thus followed the guidelines set out by NSW Health in its publication *Communicating positively: A guide to appropriate Aboriginal terminology*.

Nursing diagnoses

In this updated edition of *Medical–surgical nursing* we refer to the well-known nursing process as a logical approach to managing nursing care. Within this process we refer to diagnostic terminologies that are typical of those used by Australian nurses.

What's new in the third edition

This edition of *Medical–surgical nursing* has two new features:

1. National Patient Safety Standards from the Australian Commission on Quality and Health Care. The relevant standards have been added to the chapters where applicable as they relate to patient safety .
2. Translation to practice boxes. These boxes focus on research into specific topics and how this relates to current nursing care and the application of evidence in clinical settings.

Other changes include:

- Chapter 1 'Medical–surgical nursing' includes a more detailed explanation of how to write a nursing diagnosis.
- All chapters have been updated with newer research and evidence-based practice throughout; Chapter 35 'Nursing care of people with ventilation disorders' has been updated with newer research with reference to the emerging zoonotic viral pneumonias SARS and MERS.
- Chapter 51 'Community care' (previously chapter 3) now resides In Unit 14 'Special topics in medical–surgical nursing'.

Visual engagement and accuracy

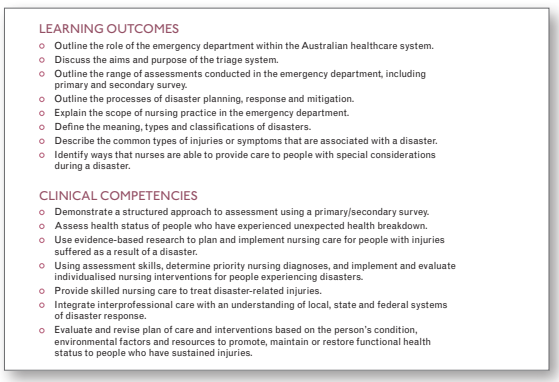
The authors understand the importance of not only making the text visually engaging but also ensuring that any visual representations accurately reflect nursing in Australia. For this reason the photographs featured in *Medical–surgical nursing* have been carefully selected to ensure that they accurately depict Australian nursing equipment, uniforms, clinical settings, processes and procedures.

Culturally competent nursing

Chapter 1 introduces the concept of culturally competent healthcare with particular attention to the culture and history of Indigenous peoples in Australia. *Focus on cultural diversity* boxes present cultural nursing in context and highlight the importance of acknowledging the dignity, culture, values, beliefs and rights of not only Indigenous Australians but also people from all cultural and ethnic backgrounds. These themes are threaded throughout the text, with direct reference to the Nursing and Midwifery Board of Australia's (NMBA) *Registered Nurse Standards for Practice (2016)*.

GUIDED **TOUR**

We carefully reviewed the US edition of this book to ensure current content and the necessary knowledge to educate the next generation of nurses in Australia. Key features of the Australian edition include:



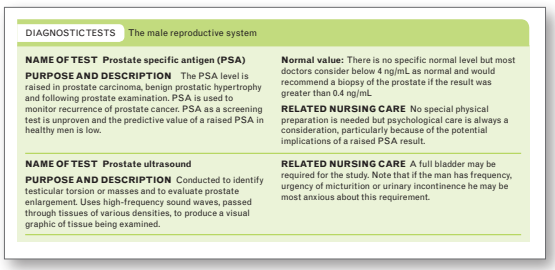
LEARNING OUTCOMES

- Outline the role of the emergency department within the Australian healthcare system.
- Discuss the aims and purpose of the triage system.
- Outline the range of assessments conducted in the emergency department, including primary and secondary survey.
- Outline the processes of disaster planning, response and mitigation.
- Explain the scope of nursing practice in the emergency department.
- Define the meaning, types and classifications of disasters.
- Describe the common types of injuries or symptoms that are associated with a disaster.
- Identify ways that nurses are able to provide care to people with special considerations during a disaster.

CLINICAL COMPETENCIES

- Demonstrate a structured approach to assessment using a primary/secondary survey.
- Assess health status of people who have experienced unexpected health breakdown.
- Use evidence-based research to plan and implement nursing care for people with injuries suffered as a result of a disaster.
- Using assessment skills, determine priority nursing diagnoses, and implement and evaluate individualised nursing interventions for people experiencing disasters.
- Provide skilled nursing care to treat disaster-related injuries.
- Integrate interprofessional care with an understanding of local, state and federal systems of disaster response.
- Evaluate and revise plan of care and interventions based on the person's condition, environmental factors and resources to promote, maintain or restore functional health status to people who have sustained injuries.

Learning Outcomes show you the knowledge you'll gain, while **Clinical Competencies** demonstrate how you will apply that knowledge.



DIAGNOSTIC TESTS The male reproductive system

NAME OF TEST **Prostate specific antigen (PSA)**

PURPOSE AND DESCRIPTION The PSA level is raised in prostate carcinoma, benign prostatic hypertrophy and following prostate examination. PSA is used to monitor recurrence of prostate cancer. PSA as a screening test is unproven and the predictive value of a raised PSA in healthy men is low.

Normal value: There is no specific normal level but most doctors consider below 4 ng/mL as normal and would recommend a biopsy of the prostate if the result was greater than 0.4 ng/mL

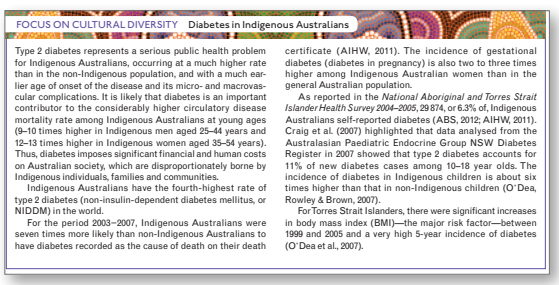
RELATED NURSING CARE No special physical preparation is needed but psychological care is always a consideration, particularly because of the potential implications of a raised PSA result.

NAME OF TEST **Prostate ultrasound**

PURPOSE AND DESCRIPTION Conducted to identify testicular torsion or masses and to evaluate prostate enlargement. Uses high-frequency sound waves, passed through tissues of various densities, to produce a visual graphic of tissue being examined.

RELATED NURSING CARE A full bladder may be required for the study. Note that if the man has frequency, urgency of micturition or urinary incontinence he may be most anxious about this requirement.

Diagnostic Tests include diagnostic test tables and a narrative summary. The tables include the name of the test, the purpose and description of the test, and related nursing care.



FOCUS ON CULTURAL DIVERSITY Diabetes in Indigenous Australians

Type 2 diabetes represents a serious public health problem for Indigenous Australians, occurring at a much higher rate than in the non-Indigenous population, and with a much earlier age of onset of the disease and its micro- and macrovascular complications. It is likely that diabetes is an important contributor to the considerably higher circulatory disease mortality rate among Indigenous Australians at young ages (9–10 times higher in Indigenous men aged 25–44 years and 12–13 times higher in Indigenous women aged 35–54 years). Thus, diabetes imposes significant financial and human costs on Australian society, which are disproportionately borne by Indigenous individuals, families and communities.

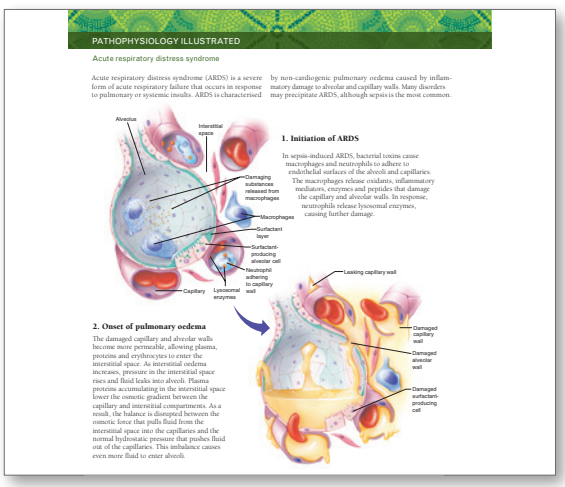
Indigenous Australians have the fourth-highest rate of type 2 diabetes (non-insulin-dependent diabetes mellitus, or NIDDM) in the world.

For the period 2003–2007, Indigenous Australians were seven times more likely than non-Indigenous Australians to have diabetes recorded as the cause of death on their death certificate (AIHW, 2011). The incidence of gestational diabetes (diabetes in pregnancy) is also two to three times higher among Indigenous Australian women than in the general Australian population.

As reported in the *National Aboriginal and Torres Strait Islander Health Survey 2004–2005*, 29 874, or 6.3% of, Indigenous Australians self-reported diabetes (ABS, 2012; AIHW, 2011). Craig et al. (2007) highlighted that data analysed from the Australasian Paediatric Endocrine Group NSW Diabetes Register in 2007 showed that type 2 diabetes accounts for 11% of new diabetes cases among 10–18 year olds. The incidence of diabetes in Indigenous children is about six times higher than that in non-Indigenous children (O'Dea, Rowley & Brown, 2007).

For Torres Strait Islanders, there were significant increases in body mass index (BMI)—the major risk factor—between 1999 and 2005 and a very high 5-year incidence of diabetes (O'Dea et al., 2007).

Focus on Cultural Diversity boxes demonstrate how culture, age and gender produce differences in incidence, prevalence and mortality.



PATHOPHYSIOLOGY ILLUSTRATED

Acute respiratory distress syndrome

Acute respiratory distress syndrome (ARDS) is a severe form of acute respiratory failure that occurs in response to pulmonary or systemic insults. ARDS is characterised by non-cardiogenic pulmonary oedema caused by inflammatory damage to alveolar and capillary walls. Many disorders may precipitate ARDS, although sepsis is the most common.

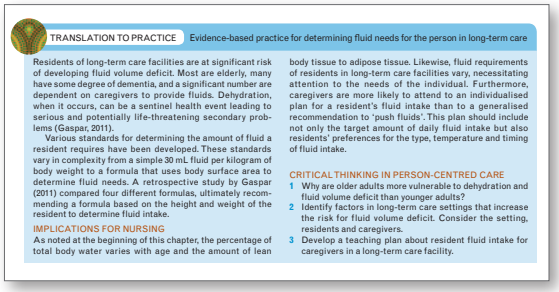
1. Initiation of ARDS

In sepsis-induced ARDS, bacterial toxins cause macrophages and neutrophils to adhere to endothelial surfaces of the alveoli and capillaries. The macrophages release oxidants, inflammatory mediators, enzymes and peptides that damage the capillary and alveolar walls. In response, neutrophils release lysosomal enzymes, causing further damage.

2. Onset of pulmonary oedema

The damaged capillary and alveolar walls become more permeable, allowing plasma, proteins and erythrocytes to enter the interstitial space. As interstitial oedema increases, pressure in the interstitial space rises and fluid leaks into alveoli. Plasma proteins accumulating in the interstitial space lower the osmotic gradient between the capillary and interstitial compartments. As a result, the balance is disrupted between the osmotic force that pulls fluid from the interstitial space into the capillaries and the normal hydrostatic pressure that pushes fluid out of the capillaries. This imbalance causes even more fluid to enter alveoli.

Pathophysiology Illustrated art brings physiological processes to life.



TRANSLATION TO PRACTICE Evidence-based practice for determining fluid needs for the person in long-term care

Residents of long-term care facilities are at significant risk of developing fluid volume deficit. Most are elderly, many have some degree of dementia, and a significant number are dependent on caregivers to provide fluids. Dehydration, when it occurs, can be a sentinel health event leading to serious and potentially life-threatening secondary problems (Gaspar, 2011).

Various standards for determining the amount of fluid a resident requires have been developed. These standards vary in complexity from a simple 30 mL fluid per kilogram of body weight to a formula that uses body surface area to determine fluid needs. A retrospective study by Gaspar (2011) compared four different formulas, ultimately recommending a formula based on the height and weight of the resident to determine fluid intake.

IMPLICATIONS FOR NURSING

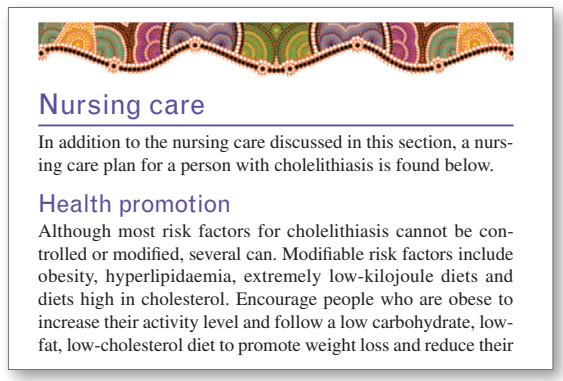
As noted at the beginning of this chapter, the percentage of total body water varies with age and the amount of lean body tissue to adipose tissue. Likewise, fluid requirements of residents in long-term care facilities vary, necessitating attention to the needs of the individual. Furthermore, caregivers are more likely to attend to an individualised plan for a resident's fluid intake than to a generalised recommendation to 'push fluids'. This plan should include not only the target amount of daily fluid intake but also residents' preferences for the type, temperature and timing of fluid intake.

CRITICAL THINKING IN PERSON-CENTRED CARE

1 Why are older adults more vulnerable to dehydration and fluid volume deficit than younger adults?
2 Identify factors in long-term care settings that increase the risk for fluid volume deficit. Consider the setting, residents and caregivers.
3 Develop a teaching plan about resident fluid intake for caregivers in a long-term care facility.

Translation to Practice boxes focus on how research relates to current nursing care and application of evidence in clinical settings.

Nursing Care sections detail the assessment and planning aspects relating to specific conditions and outlines potential pain and risks.

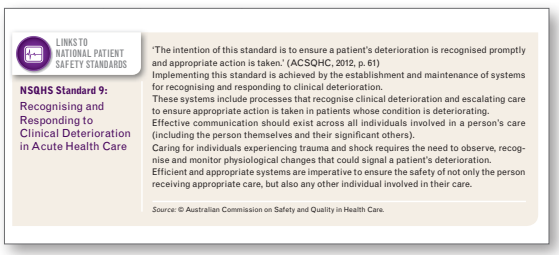


Nursing care

In addition to the nursing care discussed in this section, a nursing care plan for a person with cholelithiasis is found below.

Health promotion

Although most risk factors for cholelithiasis cannot be controlled or modified, several can. Modifiable risk factors include obesity, hyperlipidaemia, extremely low-kilojoule diets and diets high in cholesterol. Encourage people who are obese to increase their activity level and follow a low carbohydrate, low-fat, low-cholesterol diet to promote weight loss and reduce their



LINKS TO NATIONAL PATIENT SAFETY STANDARDS

NSQHS Standard 9:
Recognising and Responding to Clinical Deterioration in Acute Health Care

'The intention of this standard is to ensure a patient's deterioration is recognised promptly and appropriate action is taken.' (ACSQHC, 2012, p. 61)

Implementing this standard is achieved by the establishment and maintenance of systems for recognising and responding to clinical deterioration.

These systems include processes that recognise clinical deterioration and escalating care to ensure appropriate action is taken in patients whose condition is deteriorating.

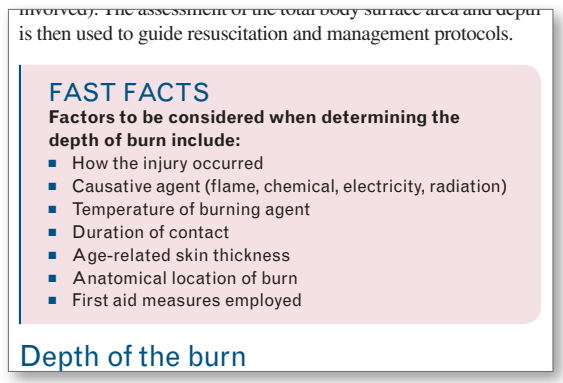
Effective communication should exist across all individuals involved in a person's care (including the person themselves and their significant others).

Caring for individuals experiencing trauma and shock requires the need to observe, recognise and monitor physiological changes that could signal a patient's deterioration.

Efficient and appropriate systems are imperative to ensure the safety of not only the person receiving appropriate care, but also any other individual involved in their care.

Source: © Australian Commission on Safety and Quality in Health Care.

Links to National Patient Safety Standards boxes appear in the chapters where applicable to demonstrate how concepts relate back to patient safety standards.



involved). The assessment of the total body surface area and depth is then used to guide resuscitation and management protocols.

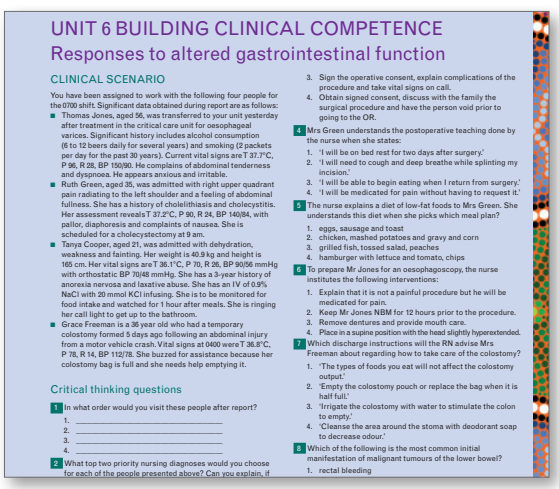
FAST FACTS

Factors to be considered when determining the depth of burn include:

- How the injury occurred
- Causative agent (flame, chemical, electricity, radiation)
- Temperature of burning agent
- Duration of contact
- Age-related skin thickness
- Anatomical location of burn
- First aid measures employed

Depth of the burn

Fast Facts boxes highlight and summarise important data about the prevalence and incidence of selected disorders in Australia, and of other featured content.



UNIT 6 BUILDING CLINICAL COMPETENCE

Responses to altered gastrointestinal function

CLINICAL SCENARIO

You have been assigned to work with the following four people for the 0700 shift. Significant data obtained during report are as follows:

- Thomas Jones, aged 56, was transferred to your unit yesterday after treatment in the critical care unit for oesophageal varices. Significant history includes alcohol consumption (6 to 12 beers daily for several years) and smoking (2 packets per day for the past 30 years). Current vital signs are T 37.7°C, P 96, R 28, BP 150/90. He complains of abdominal tenderness and dyspnoea. He appears anxious and irritable.
- Ruth Green, aged 35, was admitted with right upper quadrant pain radiating to the left shoulder and a feeling of abdominal fullness. She has a history of cholelithiasis and cholecystitis. Her assessment reveals T 37.2°C, P 90, R 24, BP 140/84, with pallor, diaphoresis and complaints of nausea. She is scheduled for a cholecystectomy at 9 am.
- Tanya Cooper, aged 21, was admitted with dehydration, weakness and fainting. Her weight is 40.9 kg and height is 165 cm. Her vital signs are T 36.1°C, P 70, R 26, BP 90/56 mmHg with orthostatic BP 70/48 mmHg. She has a 3-year history of anorexia nervosa and laxative abuse. She has an IV of 0.9% NaCl with 20 mmol KCl infusing. She is to be monitored for food intake and watched for 1 hour after meals. She is ringing her call light to get up to the bathroom.
- Grace Freeman is a 36 year old who had a temporary colostomy formed 5 days ago following an abdominal injury from a motor vehicle crash. Vital signs at 0400 were T 36.8°C, P 78, R 14, BP 112/78. She buzzed for assistance because her colostomy bag is full and she needs help emptying it.

Critical thinking questions

1 In what order would you visit these people after report?
1. _____
2. _____
3. _____
4. _____

2 What top two priority nursing diagnoses would you choose for each of the people presented above? Can you explain, if

3. Sign the operative consent, explain complications of the procedure and take vital signs on call.
4. Obtain signed consent, discuss with the family the surgical procedure and have the person void prior to going to the OR.

4 Mrs Green understands the postoperative teaching done by the nurse when she states:
1. 'I will be on bed rest for two days after surgery.'
2. 'I will need to cough and deep breathe while splinting my incision.'
3. 'I will be able to begin eating when I return from surgery.'
4. 'I will be medicated for pain without having to request it.'

5 The nurse explains a diet of low-fat foods to Mrs Green. She understands this diet when she picks which meal plan?
1. eggs, sausage and toast
2. chicken, mashed potatoes and gravy and corn
3. grilled fish, tossed salad, peaches
4. hamburger with lettuce and tomato, chips

6 To prepare Mr Jones for an oesophagoscopy, the nurse institutes the following interventions:
1. Explain that it is not a painful procedure but he will be medicated for pain.
2. Keep Mr Jones NBM for 12 hours prior to the procedure.
3. Remove dentures and provide mouth care.
4. Place in a supine position with the head slightly hyperextended.

7 Which discharge instructions will the RN advise Mrs Freeman about regarding how to take care of the colostomy?
1. 'The types of foods you eat will not affect the colostomy output.'
2. 'Empty the colostomy pouch or replace the bag when it is half full.'
3. 'Irrigate the colostomy with water to stimulate the colon to empty.'
4. 'Cleanse the area around the stoma with deodorant soap to decrease odour.'

8 Which of the following is the most common initial manifestation of malignant tumours of the lower bowel?
1. rectal bleeding

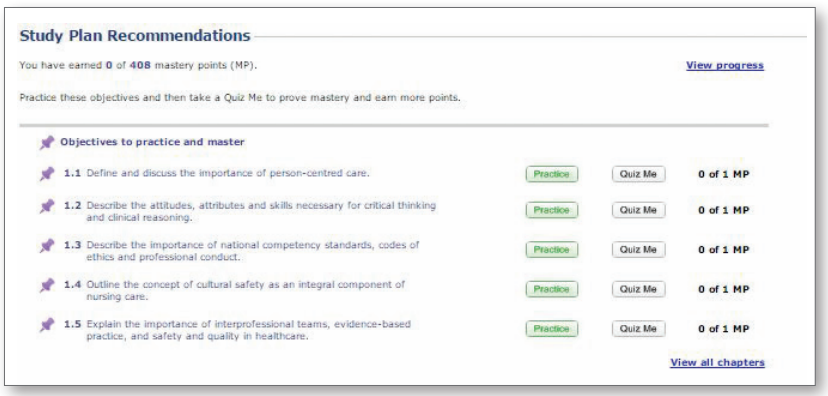
An end-of-unit review for each of the units, called **Building Clinical Competence**, synthesises what you have learned in the unit and applies the knowledge to specific cases. The feature includes:

- A **clinical scenario** involving a priority issue reflection piece that synthesises the underlying concepts and includes a variety of questions that allow students to apply different skills.
- A **case study** with concept map that further synthesises material using the nursing process.

STUDENT AND EDUCATOR **SUPPORT**

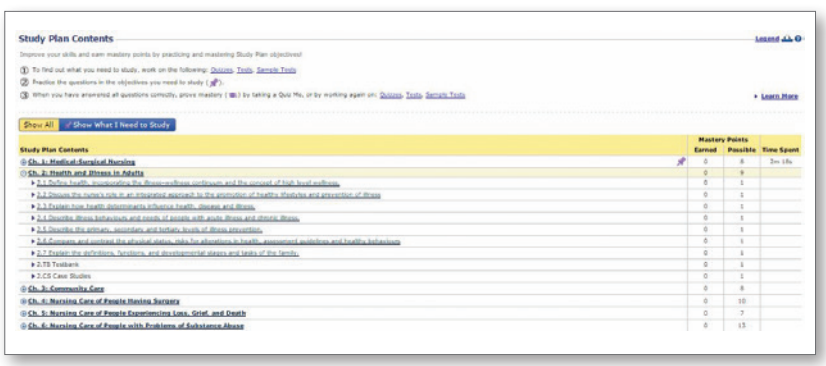
MyNursingLab for Medical–Surgical Nursing 3e

A guided tour for students and educators



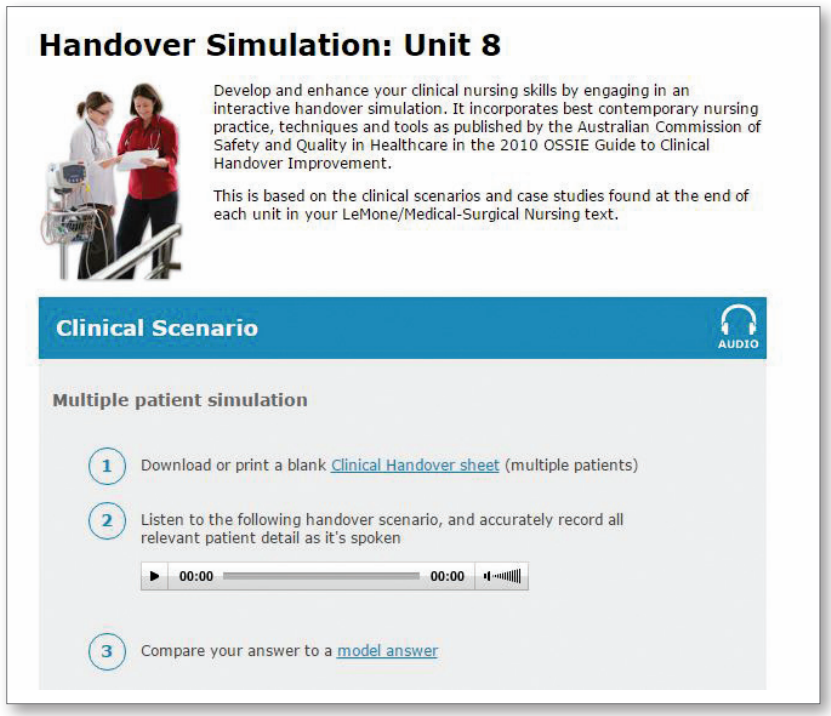
Study Plan: A study plan, tagged to the revised NMBA Standards allows students to clearly see which topics they have mastered and, more importantly, which they need to work on.

Practice: MyNursingLab comes with pre-loaded assignments covering in-chapter content, all of which are automatically graded.



Learning Resources: The following links to additional learning resources are incorporated into the Study Plan or Multimedia Library:

- the relevant section of the eText, so students can review key concepts
- video, simulation and case studies which ensure that each individual is able to comprehend the course material and apply it to real-world scenarios.



Educator resources

A suite of resources is provided to assist with delivery of the text, as well as to support teaching and learning:

- *Instructor's Manual.* This manual provides educators with detailed, accuracy-verified solutions to the in-chapter problems in the book.
- *Test Bank.* The Test Bank provides a wealth of accuracy-verified testing material. Updated for this new edition, each chapter offers a wide variety of question types arranged by learning objective and tagged by NMBA Standards. Each Test Bank question can also be assigned to students and auto-graded in MyNursingLab.
- *Digital Image PowerPoint Slides.* All the diagrams and tables from the text are available for lecturer use in chapter-based PowerPoint slides.

ACKNOWLEDGEMENTS

A collaborative adventure

Medical–surgical nursing: Critical thinking for person-centred care, third Australian edition, is the result of an exciting and productive collaboration between academic staff and clinicians across Australia. Authors and reviewers alike have been generous in sharing their expertise and crafting a textbook that is uniquely Australian and directly relevant to contemporary practice. The following people are to be acknowledged for carefully reviewing the chapters and providing a thoughtful and constructive critique:

Academic reviewers

Kerrie Coleman, Nurse Practitioner Complex Wound Management

Lydia Mainey, CQUniversity

Lecturer Deana Copley, Deakin University

Dr Rasika Jayasekara, Senior Lecturer, School of Nursing & Midwifery, University of South Australia

Dr Elisabeth Coyne Senior Lecturer, Griffith University

Mrs Clare Cole, Federation University Australia

Robyn Moroney, Western Sydney University

Mrs Ann Framp, Program Coordinator Bachelor of Nursing Science/Lecturer in Nursing, University of the Sunshine Coast

Ms Sharon Jacobs, Lecturer, Western Sydney University

Dr Marie Hutchinson, RN, RM PhD, Associate Professor, School of Health and Human Sciences, Southern Cross University

We also thank the editorial team at Pearson, including Mandy Sheppard, our senior portfolio manager; Anna Carter, our development editor; Sandra Goodall, senior project manager; Emma Gaulton, senior rights and permissions editor; and Katie Millar, lead editor and copy editor.

MAPPING TO THE NMBA *REGISTERED NURSE STANDARDS FOR* ***PRACTICE***

AUTHOR: Trish Burton

CHAPTER	STANDARD	CRITERIA	EVIDENCE-BASED EXAMPLES (INCLUDING PAGE NO.)
Unit 1 Dimensions of Medical–Surgical Nursing			
1	1. Thinks critically and analyses nursing practice	1.1. Accesses, analyses and uses the best available evidence, that includes research findings, for safe, quality practice	Employs clinical reasoning in applying the nursing process to knowledgeable, safe, person-centred, culturally safe care, in Table 1.1 Using critical thinking in the nursing process, p. 5
		1.2. Develops practice through reflection on experiences, knowledge, actions, feelings and beliefs to identify how these shape practice	Employs the Clinical Reasoning Cycle to inform nursing practice, in the Clinical Reasoning Cycle, p. 7
	4. Comprehensively conducts assessments	4.1. Conducts assessments that are holistic as well as culturally appropriate	Uses the nursing process as a model of patient care, in Table 1.1 Using critical thinking in the nursing process, p. 5
	5. Develops a plan for nursing practice	5.2. Collaboratively constructs nursing practice plans until contingencies, options, priorities, goals, actions, outcomes and time frames are agreed with the relevant people	Uses the nursing process as a model of patient care, in Table 1.1 Using critical thinking in the nursing process, p. 5
	6. Provides safe, appropriate and responsive quality nursing practice	6.1. Provides comprehensive, safe, quality practice to achieve agreed goals and outcomes that are responsive to the nursing needs of people	Uses the nursing process as a model of patient care, in Table 1.1 Using critical thinking in the nursing process, p. 5
	7. Evaluates outcomes to inform nursing practice	7.1. Evaluates and monitors progress towards the expected goals and outcomes	Uses the nursing process as a model of patient care, in Table 1.1 Using critical thinking in the nursing process, p. 5
2	1. Thinks critically and analyses nursing practice	1.1. Accesses, analyses and uses the best available evidence, that includes research findings, for safe, quality practice	Conducts an assessment that is sensitive to the risk factors of family developmental stages and tasks to person-centred care, in Table 2.10 Family-related risk factors for alterations in health, p. 31
	2. Engages in therapeutic and professional relationships	2.1. Communicates effectively, and is respectful of a person's dignity, culture, values, beliefs and rights	Is sensitive to the associated risk factors of family developmental stages and tasks for the person and family, in Table 2.10 Family-related risk factors for alterations in health, p. 31

CHAPTER	STANDARD	CRITERIA	EVIDENCE-BASED EXAMPLES (INCLUDING PAGE NO.)
	4. Comprehensively conducts assessments	4.1. Conducts assessments that are holistic as well as culturally appropriate	Conducts an assessment that is sensitive to the physical changes in the older adult years to promote, restore and maintain health when planning and implementing care, in Table 2.8 Physical changes in the older adult years, p. 28
	5. Develops a plan for nursing practice	5.1. Uses assessment data and best available evidence to develop a plan	Considers the physical changes in the older adult years in planning the care of the person, in Table 2.8 Physical changes in the older adult years, p. 28 Considers the risk factors of family developmental stages and associated tasks in planning the care of the person, in Table 2.10 Family-related risk factors for alterations in health, p. 31
	6. Provides safe, appropriate and responsive quality nursing practice	6.1. Provides comprehensive, safe, quality practice plans until contingencies, options, priorities, goals, actions, outcomes and time frames are agreed with the relevant people	Is cognisant of the physical changes in the older adult years in implementing care of the person, in Table 2.8 Physical changes in the older adult years, p. 28 The risk factors of family developmental stages and associated tasks are considered during the care of the person, in Table 2.10 Family-related risk factors for alterations in health, p. 31
Unit 2 Alterations in Patterns of Health			
3	1. Thinks critically and analyses nursing practice	1.4. Complies with legislation, regulations, policies, guidelines and other standards or requirements relevant to the context of practice when making decisions	Complies with the legal requirement of patient safety in the preoperative phase, pp. 52, 55, 56
		1.5. Uses ethical frameworks when making decisions	Is aware of advocate role in relation to person-informed consent, in Legal requirements, p. 37
	2. Engages in therapeutic and professional relationships	2.5. Advocates on behalf of people in a manner that respects the person's autonomy and legal capacity	Facilitates informed consent for the person, in Legal requirements, p. 37
		2.6. Uses delegation, supervision, coordination, consultation and referrals in professional relationships to achieve improved health outcomes	Notifies anaesthetist of all prescribed and over-the-counter drugs as surgical risk factors in care of the person, in Table 3.2 Nursing implications for surgical risk factors, p. 40 Works closely with the surgeon during the intraoperative and postoperative phases, p. 56
	4. Comprehensively conducts assessments	4.1. Conducts assessments that are holistic as well as culturally appropriate	Considers the assessment required for surgical risk factors in person-centred care, in Table 3.2 Nursing implications for surgical risk factors, pp. 38–39

CHAPTER	STANDARD	CRITERIA	EVIDENCE-BASED EXAMPLES (INCLUDING PAGE NO.)
	5. Develops a plan for nursing practice	5.1. Uses assessment data and best available evidence to develop a plan	Plans for the nursing implications for surgical risk factors in person-centred care, in Table 3.2 Nursing implications for surgical risk factors, pp. 38–39
			Ensures that the safety guidelines and checklists in the preoperative phase are included in the plan of care, pp. 52, 55, 56
			Includes in the plan that the older adult has an increased risk of complications in the postoperative period, in Table 3.6 Nursing interventions for older people having surgery, p. 61
	6. Provides safe, appropriate and responsive quality nursing practice	6.1. Provides comprehensive, safe, quality practice to achieve agreed goals and outcomes that are responsive to the nursing needs of people	Adheres to safety guidelines and completes checklists in the preoperative phase, pp. 52, 55, 56
			Nursing interventions are in response to the older adult having an increased risk of complications in the postoperative period, in Table 3.6 Nursing interventions for older people having surgery, p. 61
	7. Evaluates outcomes to inform nursing practice	7.1. Evaluates and monitors progress towards the expected goals and outcomes	Evaluates completed checklists in the preoperative phase, pp. 52, 55, 56
			Evaluates interventions to reduce the increased risk of complications in the postoperative period, in Table 3.6 Nursing interventions for older people having surgery, p. 61
4	2. Engages in therapeutic and professional relationships	2.2. Communicates effectively and is respectful of a person's dignity, culture, values, beliefs and rights	Promotes trust in the therapeutic relationship with the person experiencing loss and grief, in Nursing care plan, pp. 81–82
	4. Comprehensively conducts assessments	4.1. Conducts assessments that are holistic as well as culturally appropriate	Makes assessments for appropriate nursing interventions, in Box 4.3 Providing comfort for the person nearing death, p. 76
			Provides comprehensive nursing care for the person experiencing loss and grief, in Nursing care plan, pp. 81–82
	5. Develops a plan for nursing practice	5.1. Uses assessment data and best available evidence to develop a plan	Plans for appropriate nursing interventions, in Box 4.3 Providing comfort for the person nearing death, p. 76
			Plans for comprehensive nursing care for the person experiencing loss and grief, in Nursing care plan, pp. 81–82
	6. Provides safe, appropriate and responsive quality nursing practice	6.1. Provides comprehensive, safe, quality practice to achieve agreed goals and outcomes that are responsive to the nursing needs of people	Implements appropriate nursing interventions, in Box 4.3 Providing comfort for the person nearing death, p. 76
			Provides comprehensive nursing care for the person experiencing loss and grief, in Nursing care plan, pp. 81–82

CHAPTER	STANDARD	CRITERIA	EVIDENCE-BASED EXAMPLES (INCLUDING PAGE NO.)
	7. Evaluates outcomes to inform nursing practice	7.1. Evaluates and monitors progress towards the expected goals and outcomes	Evaluates appropriate nursing interventions, in Box 4.3 Providing comfort for the person nearing death, p. 76
			Evaluates comprehensive nursing care for the person experiencing loss and grief, in Nursing care plan, pp. 81–82
5	1. Thinks critically and analyses nursing practice	1.1. Accesses, analyses, and uses the best available evidence, that includes research findings, for safe, quality practice	Uses evidence-based research to plan and implement nursing care for people experiencing withdrawal symptoms of tobacco use, in Translation to practice, p. 90
	2. Engages in therapeutic and professional relationships	2.6. Uses delegation, supervision, coordination, consultation and referrals in professional relationships to achieve improved health outcomes	Refers person to healthcare professionals to assist with nicotine withdrawal, in Table 5.3 Guide for the management of nicotine-dependent inpatients, p. 89
			As part of collaborative care, consults and plans interventions in conjunction with the doctor and dietitian about management during alcohol withdrawal, in Nursing care plan, p. 107
	4. Comprehensively conducts assessments	4.1. Conducts assessments that are holistic as well as culturally appropriate	Assesses for nicotine withdrawal, in Table 5.3 Guide for the management of nicotine-dependent inpatients, p. 89; Translation to practice, p. 90
			Assesses for alcohol withdrawal, in Nursing care plan, p. 107
	5. Develops a plan for nursing practice	5.2. Collaboratively constructs nursing practice plans until contingencies, options, priorities, goals, actions, outcomes and time frames are agreed with the relevant people	Plans interventions for nicotine withdrawal, in Translation to practice, p. 90
			Plans specific interventions (stress management, coping skills, nutrition, relapse prevention and healthy lifestyle choices) for alcohol withdrawal, in Nursing care plan, p. 107
	6. Provides safe, appropriate and responsive quality nursing practice	6.1. Provides comprehensive, safe, quality practice to achieve agreed goals and outcomes that are responsive to the nursing needs of people	Provides interventions for nicotine withdrawal, in Table 5.3 Guide for the management of nicotine-dependent inpatients, p. 89; Translation to practice, p. 90
			Provides needs-specific nursing interventions for alcohol abuse and medical conditions, in Box 5.1 Principles of nursing care in relation to alcohol, p. 92
			Provides interventions for alcohol withdrawal, in Nursing care plan, p. 107
	7. Evaluates outcomes to inform nursing practice	7.1. Evaluates and monitors progress towards the expected goals and outcomes	Evaluates interventions for nicotine withdrawal, in Table 5.3 Guide for the management of nicotine-dependent inpatients, p. 89
			Evaluates interventions for alcohol withdrawal, in Nursing care plan, p. 107

CHAPTER	STANDARD	CRITERIA	EVIDENCE-BASED EXAMPLES (INCLUDING PAGE NO.)
6	2. Engages in therapeutic and professional relationships	2.6. Uses delegation, supervision, coordination, consultation and referrals in professional relationships to achieve improved health outcomes	In the disaster setting, communicates Disaster triage category, in Table 6.3 Disaster triage system, by category, p. 116
	4. Comprehensively conducts assessments	4.2. Uses a range of assessment techniques to systematically collect relevant and accurate information and data to inform practice	Initially assesses the person using the primary survey, in Table 6.3 Disaster triage system, by category, p. 116 Assesses the person with trauma, in Nursing care Plan, pp. 124–125
	5. Develops a plan for nursing practice	5.2. Collaboratively constructs nursing practice plans until contingencies, options, priorities, goals, actions, outcomes and time frames are agreed with the relevant people	Provides comprehensive nursing care for a person with trauma, in Nursing care Plan, pp. 124–125
		5.5. Coordinates resources effectively and efficiently for planned actions	In the disaster setting, plans the use of resources, in Table 6.3 Disaster triage system, by category, p. 116
	6. Provides safe, appropriate and responsive quality nursing practice	6.1. Provides comprehensive, safe, quality practice to achieve agreed goals and outcomes that are responsive to the nursing needs of people	Provides comprehensive nursing care for a person with trauma, in Nursing care plan, pp. 124–125
	7. Evaluates outcomes to inform nursing practice	7.1 Evaluates and monitors progress towards the expected goals and outcomes	Evaluates comprehensive nursing care for a person with trauma, in Nursing care plan, pp. 124–125
Unit 3 Pathophysiology and Patterns of Health			
7	4. Comprehensively conducts assessments	4.1. Conducts assessments that are holistic as well as culturally appropriate	Conducts a health assessment and maps pedigree, in Box 7.11 Adult indicators for a referral to a genetic specialist, p. 151
	5. Develops a plan for nursing practice	5.2. Collaboratively constructs nursing practice plans until contingencies, options, priorities, goals, actions, outcomes and time frames are agreed with the relevant people	Develops a nursing care plan, in Box 7.11 Adult indicators for a referral to a genetic specialist, p. 151 Develops a nursing care plan, including integrating genetic concepts into education for people and their families, in Education, p. 151
	6. Provides safe, appropriate and responsive quality nursing practice	6.1. Provides comprehensive, safe, quality practice to achieve agreed goals and outcomes that are responsive to the nursing needs of people	Delivers nursing care, in Box 7.11 Adult indicators for a referral to a genetic specialist, p. 151; Education, p. 151
	7. Evaluates outcomes to inform nursing practice	7.1. Evaluates and monitors progress towards the expected goals and outcomes	Evaluates a nursing care plan, in Box 7.11 Adult indicators for a referral to a genetic specialist, p. 151
8	1. Thinks critically and analyses nursing practice	1.5. Uses ethical frameworks when making decisions	Ensures the person is an active participant in planning nursing care, in Nursing care, pp. 176–177
	2. Engages in therapeutic and professional relationships	2.2. Communicates effectively and is respectful of a person's dignity, culture, values, beliefs and rights	Conducts education to promote pain relief, in Medication administration, p. 170

CHAPTER	STANDARD	CRITERIA	EVIDENCE-BASED EXAMPLES (INCLUDING PAGE NO.)
	4. Comprehensively conducts assessments	4.1. Conducts assessments that are holistic as well as culturally appropriate	Conducts a nursing assessment in relation to pain, in Nursing care, pp. 172–175 Makes assessments for a nursing care plan, in Nursing care, pp. 176–177
	5. Develops a plan for nursing practice	5.1. Uses assessment data and best available evidence to develop a plan	Conducts a nursing assessment, in Nursing care, pp. 172–175
		5.2. Collaboratively constructs nursing practice plans until contingencies, options, priorities, goals, actions, outcomes and time frames are agreed with the relevant people	Plans for administering medication safely and effectively, in Medication administration, p. 170 Develops a nursing care plan, in Nursing care, pp. 176–177 Revises plan of care according to the person's response to interventions and need for control, in Nursing care plan, p. 178
	6. Provides safe, appropriate and responsive quality nursing practice	6.1. Provides comprehensive, safe, quality practice to achieve agreed goals and outcomes that are responsive to the nursing needs of people	Administers medication safely and effectively, in Medication administration, p. 170
	7. Evaluates outcomes to inform nursing practice	7.1. Evaluates and monitors progress towards the expected goals and outcomes	Evaluates the person's response to pain relief measures throughout the nursing process, in Nursing care plan, pp. 173, 178
		7.2 Revises the plan based on the evaluation	Evaluates effectiveness of interventions to relieve pain, re-treats or adjusts doses of medication and intervenes as necessary, in Nursing care plan, p. 173
9	2. Engages in therapeutic and professional relationships	2.2. Communicates effectively and is respectful of a person's dignity, culture, values, beliefs and rights	Employs effective communication processes to facilitate education of the person, in Nursing care plan, p. 215
		2.6. Uses delegation, supervision, coordination, consultation and referrals in professional relationships to achieve improved health outcomes	Communicates nursing assessment of serum potassium levels and ECG findings to doctor, in Nursing care plan, p. 215
	4. Comprehensively conducts assessments	4.1. Conducts assessments that are holistic as well as culturally appropriate	Assesses a person with fluid volume excess, in Nursing care plan, p. 200 When caring for a person with hypokalaemia, carries out the processes involved in the assessment phase that specifically address the person's needs, in Nursing care plan, p. 211 When caring for a person with hyperkalaemia, carries out the processes involved in the assessment phase that specifically address the multidisciplinary team, in Nursing care plan, p. 215

CHAPTER	STANDARD	CRITERIA	EVIDENCE-BASED EXAMPLES (INCLUDING PAGE NO.)
	5. Develops a plan for nursing practice	5.2. Collaboratively constructs nursing practice plans until contingencies, options, priorities, goals, actions, outcomes and time frames are agreed with the relevant people	Plans for the administration of medication safely and effectively, in Medication administration, p. 210 Determines priority nursing diagnoses, based on assessment data, to select and implement individualised nursing interventions, in Nursing care plan, p. 211 Plans education for promoting a healthy diet and safe medication management, in Nursing care plan, p. 215 Integrates interprofessional care into care of a person with altered fluid, electrolyte and acid–base balance, in Nursing care plan, p. 215
	6. Provides safe, appropriate and responsive quality nursing practice	6.1. Provides comprehensive, safe, quality practice to achieve agreed goals and outcomes that are responsive to the nursing needs of people	Assesses and monitors the person's fluid, electrolyte and acid–base balance, in Nursing care plan, p. 200 Administers fluids and medications knowledgeably and safely, in Medication administration, p. 210 When caring for a person with hypokalaemia, carries out the processes involved in the implementation phase that specifically address the person's needs, in Nursing care plan, p. 211 Delivers pertinent information to the person and their family about diet and medications used to restore, promote and maintain fluid, electrolyte and acid–base balance, in Nursing care plan, p. 215 When caring for a person with hyperkalaemia, carries out the processes involved in the intervention phase that specifically address the multidisciplinary team, in Nursing care plan, p. 215
	7. Evaluates outcomes to inform nursing practice	7.1. Evaluates and monitors progress towards the expected goals and outcomes	When caring for a person with hyperkalaemia, carries out the processes involved in the evaluation phase that specifically address the multidisciplinary team, in Nursing care plan, p. 215
10	4. Comprehensively conducts assessments	4.2. Uses a range of assessment techniques to systematically collect relevant and accurate information and data to inform practice	Conducts assessment of a person with multi-trauma within the emergency department, in Nursing care plan, p. 258
	5. Develops a plan for nursing practice	5.1. Uses assessment data and best available evidence to develop a plan	Plans comprehensive nursing care for a person with multi-trauma within the emergency department, in Nursing care plan, p. 258

CHAPTER	STANDARD	CRITERIA	EVIDENCE-BASED EXAMPLES (INCLUDING PAGE NO.)
	6. Provides safe, appropriate and responsive quality nursing practice	6.1. Provides comprehensive, safe, quality practice to achieve agreed goals and outcomes that are responsive to the nursing needs of people	Demonstrates comprehensive nursing care for a person with multi-trauma within the emergency department, in Nursing care plan, p. 258
	7. Evaluates outcomes to inform nursing practice	7.1. Evaluates and monitors progress towards the expected goals and outcomes	Evaluates responses to medical and surgical interventions for people sustaining multi-trauma, in Nursing care plan, p. 258
11	1. Thinks critically and analyses nursing practice	1.1. Accesses, analyses and uses the best available evidence, that includes research findings, for safe, quality practice	Demonstrates awareness of the procedures for standard precautions for all hospitalised people, in Table 11.9 Transmission-based precautions, p. 312
	2. Engages in therapeutic and professional relationships	2.2. Communicates effectively and is respectful of a person's dignity, culture, values, beliefs and rights	Recognises that adherence to transmission-based precautions depends on effective communication with the person, in Table 11.9 Transmission-based precautions, p. 312
		2.6. Uses delegation, supervision, coordination, consultation and referrals in professional relationships to achieve improved health outcomes	Conducts education for taking antibiotic medication for an infection, which includes the person notifying the care provider about adverse effects, taking or avoiding specific foods and drugs, and fluid intake, in Medication administration, pp. 308–311
			Communicates contact precautions to prevent the spread of infection between people, healthcare professionals and visitors, Table 11.9 Transmission-based precautions, p. 312
	4. Comprehensively conducts assessments	4.1. Conducts assessments that are holistic as well as culturally appropriate	When caring for a person who requires immunisation, carries out the processes involved in the assessment, planning and implementation phases that specifically address the person's needs, in Nursing care plan, p. 295
			Assesses for a history of hypersensitivity to antibiotics, in Medication administration, pp. 308–311
		4.2. Uses a range of assessment techniques to systematically collect relevant and accurate information and data to inform practice	Conducts a comprehensive assessment for the detection of an infection, in Nursing care of the older adult, p. 305
	5. Develops a plan for nursing practice	5.1. Uses assessment data and best available evidence to develop a plan	Determines priority nursing diagnosis, based on assessment data, to select and implement individualised nursing interventions for people, in Nursing care plan, p. 295
			Plans for contact precautions to prevent the spread of infection between people, healthcare professionals and visitors, Table 11.9 Transmission-based precautions, p. 312

CHAPTER	STANDARD	CRITERIA	EVIDENCE-BASED EXAMPLES (INCLUDING PAGE NO.)
		5.4. Plans and negotiates how practice will be evaluated and the time frame of engagement 5.5. Coordinates resources effectively and efficiently for planned actions	Plans for antibiotic administration, which includes fluid dilution, length of administration and compatibility with other medications, in Medication administration, pp. 308–311
	6. Provides safe, appropriate and responsive quality nursing practice	6.1. Provides comprehensive, safe, quality practice to achieve agreed goals and outcomes that are responsive to the nursing needs of people	When caring for a person who requires immunisation, carries out the processes involved in the assessment, planning and implementation phases that specifically address the person's needs, in Nursing care plan, p. 295 At the intervention stage monitors the response of the person for adverse effects, including administration site and allergic reactions, in Medication administration, pp. 308–311 Coordinates contact precautions to prevent the spread of infection between people, healthcare professionals and visitors, Table 11.9 Transmission-based precautions, p. 312
	7. Evaluates outcomes to inform nursing practice	7.1. Evaluates and monitors progress towards the expected goals and outcomes	At the evaluation stage monitors the response of the person for adverse effects, including administration site and allergic reactions, in Medication administration, pp. 308–311
12	1. Thinks critically and analyses nursing practice	1.1. Accesses, analyses and uses the best available evidence, that includes research findings, for safe, quality practice	Recognises that taking antiretroviral nucleoside analogues can induce adverse reactions, as well as prolonging life, in Medication administration, p. 348 Uses evidence-based practice in providing nursing care for a person with HIV, in Nursing care plan, p. 354
	4. Comprehensively conducts assessments	4.1. Conducts assessments that are holistic as well as culturally appropriate	When caring for a person with HIV, carries out the processes involved in the assessment phase, in Nursing care plan, p. 354
	5. Develops a plan for nursing practice	5.1. Uses assessment data and best available evidence to develop a plan	Plans for safe nursing management of antiretroviral agents, in Medication administration, p. 348 Uses evidence-based practice to plan and implement nursing care for people with HIV, carries out the processes involved in the assessment, planning and intervention phases, in Nursing care plan, p. 354
	6. Provides safe, appropriate and responsive quality nursing practice	6.1. Provides comprehensive, safe, quality practice to achieve agreed goals and outcomes that are responsive to the nursing needs of people	Provides appropriate and safe nursing management of antiretroviral agents, in Medication administration, p. 348 When caring for a person with HIV, carries out the processes involved in the intervention phase, in Nursing care plan, p. 354

CHAPTER	STANDARD	CRITERIA	EVIDENCE-BASED EXAMPLES (INCLUDING PAGE NO.)
13	2. Engages in therapeutic and professional relationships	2.6. Uses delegation, supervision, coordination, consultation and referrals in professional relationships to achieve improved health outcomes	Communicates nursing assessment of any abnormalities for a person with cancer, in Box 13.11 Australia-modified Karnofsky Performance Scale, p. 392
			Works together with the healthcare team to provide optimal care, in Nursing care plan, pp. 394–395
			Refers the person to specific care providers in relation to groups of complications, in Box 13.13 When to call for help, p. 398
	4. Comprehensively conducts assessments	4.1. Conducts assessments that are holistic as well as culturally appropriate	Conducts a comprehensive health assessment for a person with cancer and provides ongoing monitoring of status, in Box 13.11 Australia-modified Karnofsky Performance Scale, p. 392
			When caring for a person with cancer, carries out the processes involved in the assessment phase that specifically address the person's needs, in Nursing care plan, pp. 394–395
			Provides individualised assessment of the person and family, in Nursing care plan, pp. 394–395
	5. Develops a plan for nursing practice	5.1. Uses assessment data and best available evidence to develop a plan	Provides appropriate and safe nursing management of chemotherapeutic drugs and adjunct agents, in Table 13.10 Classification of chemotherapeutic drugs, pp. 383–384
			Prioritises nursing diagnosis based on assessment data and implements appropriate nursing interventions for people with cancer during cancer diagnosis, treatment and rehabilitation, in Nursing care plan, pp. 394–395
			Uses the nursing process as a framework for planning individualised care and integrating interprofessional care for people with cancer to meet their healthcare needs, in Nursing care plan, pp. 394–395
			Designs and provides individualised education to the person and family to restore, promote and maintain the person's functional status, in Box 13.13 When to call for help, p. 398
	6. Provides safe, appropriate and responsive quality nursing practice	6.1. Provides comprehensive, safe, quality practice to achieve agreed goals and outcomes that are responsive to the nursing needs of people	Provides ongoing monitoring of status, in Box 13.11 Australia-modified Karnofsky Performance Scale, p. 392
			When caring for a person with cancer, carries out the processes involved in the intervention phase that specifically address the person's needs, in Nursing care plan, pp. 394–395

CHAPTER	STANDARD	CRITERIA	EVIDENCE-BASED EXAMPLES (INCLUDING PAGE NO.)
			Safely administers chemotherapeutic medications and other medications for pain, nausea and vomiting, mucositis or anaemia, in Table 13.10 Classification of chemotherapeutic drugs, pp. 383–384
			Provides individualised nursing care for the person and family, in Nursing care plan, pp. 394–395
			Conducts education for the recognition of complications and notifying the care provider of the complications, in Box 13.13 When to call for help, p. 398
	7. Evaluates outcomes to inform nursing practice	7.1. Evaluates and monitors progress towards the expected goals and outcomes	Assesses functional health status of people with cancer and monitors, documents and reports abnormal manifestations, in Box 13.11 Australia-modified Karnofsky Performance Scale, p. 392
			Evaluates individualised nursing care for the person and family, in Nursing care plan, pp. 394–395
Unit 4 Responses to Altered Integumentary Structure and Function			
14	2. Engages in therapeutic and professional relationships	2.6. Uses delegation, supervision, coordination, consultation and referrals in professional relationships to achieve improved health outcomes	Monitors the results of diagnostic tests and reports abnormal findings, in Diagnostic tests, pp. 419–420
	4. Comprehensively conducts assessments	4.2. Uses a range of assessment techniques to systematically collect relevant and accurate information and data to inform practice	Conducts a health history for a person with an alteration in the integument, in Functional health pattern interview, p. 417
			Conducts and /or assists in the collection of skin, blood and tissue samples, in Diagnostic tests, pp. 419–420
			Conducts a physical assessment for a person with an alteration in the integument, in Integumentary assessments, pp. 421–427
15	1. Thinks critically and analyses nursing practice	1.1. Accesses, analyses and uses the best available evidence, that includes research findings, for safe, quality practice	Recognises that people who are at risk of a pressure injury or have a pressure injury require specific nursing management protocols, in Box 15.13 Nursing care of the person at risk of a pressure injury and the person with a pressure injury, pp. 468–469
	2. Engages in therapeutic and professional relationships	2.2. Communicates effectively and is respectful of a person's dignity, culture, values, beliefs and rights	Provides information on how to manage dry skin and pruritis, in Box 15.1 Teaching to reduce dry skin and relieve pruritis, p. 432
		2.6. Uses delegation, supervision, coordination, consultation and referrals in professional relationships to achieve improved health outcomes	Works together with the healthcare team to provide optimal care for a person with a pressure injury, in Nursing care plan, pp. 469–470

CHAPTER	STANDARD	CRITERIA	EVIDENCE-BASED EXAMPLES (INCLUDING PAGE NO.)
	4. Comprehensively conducts assessments	4.2. Uses a range of assessment techniques to systematically collect relevant and accurate information and data to inform practice	When caring for a person with a pressure injury, carries out the processes involved in the assessment phase that specifically address the person's needs, in Box 15.13 Nursing care of the person at risk of a pressure injury and the person with a pressure injury, pp. 468–469; Nursing care plan, pp. 469–470
	5. Develops a plan for nursing practice	5.1. Uses assessment data and best available evidence to develop a plan of care	Plans for the safe nursing management of antifungal agents, in Medication administration, pp. 440–441
			Uses evidence-based research to plan nursing care for people with pressure injuries and skin tears, in Box 15.13 Nursing care of the person at risk of a pressure injury and the person with a pressure injury, pp. 468–469
		5.2. Collaboratively constructs nursing practice plans until contingencies, options, priorities, goals, actions, outcomes and time frames are agreed with the relevant people	When planning care for a person with a pressure injury, integrates interprofessional care, in Nursing care plan, pp. 469–470
		5.6. Plans nursing care in consultation with individuals/ groups, significant others and the interprofessional team	Plans an education session to promote the reduction of dry skin and relieving pruritis, in Box 15.1Teaching to reduce dry skin and relieve pruritis, p. 432
	6. Provides safe, appropriate and responsive quality nursing practice	6.1. Provides comprehensive, safe, quality practice to achieve agreed goals and outcomes that are responsive to the nursing needs of people	Conducts education to promote the self-care of pruritis, in Box 15.1 Teaching to reduce dry skin and relieve pruritis, p. 432
			Administers topical, oral and injectable medications used to treat integumentary disorders knowledgeably and safely, in Medication administration, pp. 440–441
			When caring for a person with a pressure injury, carries out the processes involved in the intervention phase that specifically address the person's needs, in Box 15.13 Nursing care of the person at risk of a pressure injury and the person with a pressure injury, pp. 468–469; Nursing care plan, pp. 469–470
	7. Evaluates outcomes to inform nursing practice	7.1. Evaluates and monitors progress towards the expected goals and outcomes	When caring for a person with a pressure injury, carries out the processes involved in the evaluation phase that specifically address the multidisciplinary team, in Nursing care plan, pp. 469–470
16	2. Engages in therapeutic and professional relationships	2.2. Communicates effectively and is respectful of a person's dignity, culture, values, beliefs and rights	Communicates in an effective way education to promote burn prevention, in Box 16.1 Burn prevention tips, p. 479

CHAPTER	STANDARD	CRITERIA	EVIDENCE-BASED EXAMPLES (INCLUDING PAGE NO.)
	4. Comprehensively conducts assessments	4.2. Uses a range of assessment techniques to systematically collect relevant and accurate information and data to inform practice	When caring for a person with a major burn, carries out the processes involved in the assessment phase that specifically address the person's needs, in Nursing care plan, pp. 502–504
	5. Develops a plan for nursing practice	5.1. Uses assessment data and best available evidence to develop a plan	Plans education to promote burn prevention, in Box 16.1 Burn prevention tips, p. 479
		5.2. Collaboratively constructs nursing practice plans until contingencies, options, priorities, goals, actions, outcomes and time frames are agreed with the relevant people	When caring for a person with a major burn, carries out the processes involved in the planning phase that specifically address the person's needs, in Nursing care plan, pp. 502–504
	6. Provides safe, appropriate and responsive quality nursing practice	6.1. Provides comprehensive, safe, quality practice to achieve agreed goals and outcomes that are responsive to the nursing needs of people	Provides teaching appropriate for prevention of burns, in Box 16.1 Burn prevention tips, p. 479 When caring for a person with a major burn, carries out the processes involved in the intervention phase that specifically address the person's needs, in Nursing care plan, pp. 502–504
Unit 5 Responses to Altered Endocrine Function			
17	2. Engages in therapeutic and professional relationships	2.6. Uses delegation, supervision, coordination, consultation and referrals in professional relationships to achieve improved health outcomes	Monitors the results of diagnostic tests and reports abnormal findings, in Diagnostic tests, pp. 520–524
	4. Comprehensively conducts assessments	4.1. Conducts assessments that are holistic as well as culturally appropriate	Conducts a health history for a person with an alteration in the endocrine system, in Functional health pattern interview, pp. 518–519
		4.2. Uses a range of assessment techniques to systematically collect relevant and accurate information and data to inform practice	Conducts and/or assists in the collection of blood and urine samples, and radiographical studies, in Diagnostic tests, pp. 520–524 Conducts a physical assessment for a person with an alteration in the endocrine system, in Endocrine assessments, pp. 525–527
18	1. Thinks critically and analyses nursing practice	1.1. Accesses, analyses and uses the best available evidence, that includes research findings, for safe, quality practice	Recognises that a person who is prescribed medication for hyperthyroidism requires specific medication management protocols education, in Medication administration, p. 534
	2. Engages in therapeutic and professional relationships	2.2. Communicates effectively and is respectful of a person's dignity, culture, values, beliefs and rights	Communicates effectively health education information to promote safe administration of anti-thyroid preparations, in Medication administration, p. 540

CHAPTER	STANDARD	CRITERIA	EVIDENCE-BASED EXAMPLES (INCLUDING PAGE NO.)
		2.3. Recognises that people are the experts in the experience of their life	Conducts person-centred education to promote appropriate administration and storage of medication for hypothyroidism, in Medication administration, p. 540
	4. Comprehensively conducts assessments	4.1. Conducts assessments that are holistic as well as culturally appropriate	When caring for a person with hypothyroidism, carries out the processes involved in the assessment phase that specifically address the person's needs, in Nursing care plan, p. 542
			Conducts a comprehensive nursing assessment with consideration of the manifestations of Cushing's syndrome and Addison's disease, in Manifestations, pp. 547, 551
		4.2. Uses a range of assessment techniques to systematically collect relevant and accurate information and data to inform practice	Assesses respiratory function, in Nursing care of the person, p. 535
	5. Develops a plan for nursing practice	5.1. Uses assessment data and best available evidence to develop a plan	Plans to provide appropriate teaching for self-medicating with thyroid hormone, in Medication administration, p. 534
			Plans education to ensure the person knows that hormone replacement is for life and knows how to take medications, in Medication administration, p. 540
			Determines priority nursing diagnoses, based on assessed data, to select and implement individualised nursing interventions for a person with hypothyroidism, in Nursing care plan, p. 542
	6. Provides safe, appropriate and responsive quality nursing practice	6.1. Provides comprehensive, safe, quality practice to achieve agreed goals and outcomes that are responsive to the nursing needs of people	Conducts education to promote safe administration of anti-thyroid preparations, in Medication administration, p. 534
			Implements respiratory management of the person having a thyroidectomy, in Nursing care of the person, p. 535
			Conducts education to promote adherence to medication regime for hypothyroidism, in Medication administration, p. 540
			When caring for a person with hypothyroidism, carries out the processes involved in the intervention phase that specifically address the person's needs, in Nursing care plan, p. 542
	7. Evaluates outcomes to inform nursing practice	7.1. Evaluates and monitors progress towards the expected goals and outcomes	Evaluates respiratory management of the person having a thyroidectomy, in Nursing care of the person, p. 535

CHAPTER	STANDARD	CRITERIA	EVIDENCE-BASED EXAMPLES (INCLUDING PAGE NO.)
19	2. Engages in therapeutic and professional relationships	2.3. Recognises that people are the experts in the experience of their life	Conducts person-centred education to promote administration of: insulin via injection, in Medication administration, p. 571; oral hypoglycaemic agents, in Medication administration, pp. 577–578; foot care, in Meeting individualised needs, p. 593
	4. Comprehensively conducts assessments	4.1. Conducts assessments that are holistic as well as culturally appropriate	When caring for a person with type 1 diabetes, carries out the processes involved in the assessment phase that specifically address the person's needs, in Nursing care plan, pp. 592–593
			Make assessments for appropriate nursing care for the person with type 1 diabetes, in Nursing care plan, pp. 592–593
		4.2. Uses a range of assessment techniques to systematically collect relevant and accurate information and data to inform practice	Assesses for patterns of hypoglycaemia and hyperglycaemia in people with diabetes mellitus and provides ongoing monitoring of the status of the person, in Box 19.6 Guidelines for insulin adjustment, p. 574
	5. Develops a plan for nursing practice	5.1. Uses assessment data and best available evidence to develop a plan	Determines priority nursing diagnoses, based on assessed data, to select and implement individualised nursing interventions for the person with type 1 diabetes, in Nursing care plan, pp. 592–593
		5.2. Collaboratively constructs nursing practice plans until contingencies, options, priorities, goals, actions, outcomes and time frames are agreed with the relevant people	Plans for education to promote administration of: insulin via injection, in Medication administration, p. 571; oral hypoglycaemic agents, in Medication administration, pp. 577–578
			Devises a teaching plan for the relationship of hygiene, neuropathy and impaired microcirculation to infection; teaches the principles and procedures of effective foot care, in Meeting individualised needs, p. 593
		5.4. Plans and negotiates how practice will be evaluated and the time frame of engagement	Plans for the administration of medication safely and effectively, in Box 19.7 Techniques to minimise painful injections, p. 575
			Provides safe and appropriate nursing care for the person with type 1 diabetes, in Nursing care plan, pp. 592–593
	6. Provides safe, appropriate and responsive quality nursing practice	6.1. Provides comprehensive, safe, quality practice to achieve agreed goals and outcomes that are responsive to the nursing needs of people	Assesses for patterns of hypoglycaemia and hyperglycaemia in people with diabetes mellitus and provides ongoing monitoring of the status of the person, in Box 19.6 Guidelines for insulin adjustment, p. 574
			Administers medication safely and effectively, in Box 19.7Techniques to minimise painful injections, p. 575

CHAPTER	STANDARD	CRITERIA	EVIDENCE-BASED EXAMPLES (INCLUDING PAGE NO.)
			When caring for a person with type 1 diabetes, carries out the processes involved in the planning phase that specifically address the person's needs, in Nursing care plan, pp. 592–593
			Provides safe and appropriate nursing care for the person with type 1 diabetes, in Nursing care plan, pp. 592–593
			Conducts education to promote administration of: insulin via injection, in Medication administration, p. 571; oral hypoglycaemic agents, in Medication administration, pp. 577–578
			Conducts education to promote effective foot care in diabetics, in Meeting individualised needs, p. 593
	7. Evaluates outcomes to inform nursing practice	7.1. Evaluates and monitors progress towards the expected goals and outcomes	Evaluates for patterns of hypoglycaemia and hyperglycaemia in people with diabetes mellitus and provides ongoing monitoring of the status of the person, in Box 19.6 Guidelines for insulin adjustment, p. 574
			Evaluates nursing care for the person with type 1 diabetes, in Nursing care plan, pp. 592–593

AUTHOR: Trish Burton

CHAPTER	STANDARD	CRITERIA	EVIDENCE-BASED EXAMPLES (INCLUDING PAGE NO.)
Unit 6 Responses to Altered Gastrointestinal Function			
20	2. Engages in therapeutic and professional relationships	2.6. Uses delegation, supervision, coordination, consultation and referrals in professional relationships to achieve improved outcomes	Monitors the results of diagnostic tests and reports abnormal findings, in Diagnostic tests, pp. 619–623
	4. Comprehensively conducts assessments	4.1. Conducts assessments that are holistic as well as culturally appropriate	Conducts a health history for a person with an alteration or at risk of alterations in nutrition and gastrointestinal function, in Functional health pattern interview, pp. 616–617
		4.2. Uses a range of assessment techniques to systematically collect relevant and accurate information and data to inform practice	Conducts and/or assists in the collection of gastric secretions, blood and tissue samples, and radiographical studies, in Diagnostic tests, pp. 619–623
			Conducts a physical assessment of nutritional status and the gastrointestinal system, in Nutritional and Gastrointestinal assessments, pp. 624–633
21	1. Thinks critically and analyses nursing practice	1.3. Respects all cultures and experiences, which includes responding to the role of family and community that underpin the health of Aboriginal and Torres Strait Islander peoples and people of other cultures	Considers the person's cultural background when providing care, in Nursing care plan, p. 654
	2. Engages in therapeutic and professional relationships	2.3. Recognises that people are the experts in the experience of their life	Conducts education that is sensitive to the person's age group and experiences, in Meeting individualised needs, p. 646
		2.6. Uses delegation, supervision, coordination, consultation and referrals in professional relationships to achieve improved outcomes	Notifies the doctor in relation to hypersensitivity to iodine or seafood, in Medication administration, p. 650
			Includes dietitian in the evaluation of nutritional needs, in Nursing care plan, p. 654

CHAPTER	STANDARD	CRITERIA	EVIDENCE-BASED EXAMPLES (INCLUDING PAGE NO.)
	4. Comprehensively conducts assessments	4.1. Conducts assessments that are holistic as well as culturally appropriate	When caring for a person with obesity, carries out the processes involved in the assessment phase that specifically address the person's needs, in Nursing care plan, p. 644
			Provides comprehensive assessment for a person with malnutrition, in Nursing care plan, p. 654
			Includes cultural practices in relation to nutritional assessment of the person and subsequent planning, in Nursing care plan, p. 654
		4.2. Uses a range of assessment techniques to systematically collect relevant and accurate information and data to inform practice	Monitors vitamin and mineral manifestations, in Medication administration, p. 650
	5. Develops a plan for nursing practice	5.1. Uses assessment data and best available evidence to develop a plan	Uses assessment data to determine priority nursing diagnoses and to select and implement nursing interventions for a person with obesity, in Nursing care plan, p. 644
			Plans and provides family teaching to restore, promote and maintain nutritional status in the older person, in Meeting individualised needs, p. 646
			Plans for safe nursing management of medication, in Medication administration, p. 650
			Adapts cultural values and variations into the plan of care for a person with a nutritional disorder, in Nursing care plan, p. 654
		5.2. Collaboratively constructs nursing practice plans until contingencies, options, priorities, goals, actions, outcomes and time frames are agreed with the relevant people	Integrates interprofessional care into the plan of care for a person with malnutrition, in Nursing care plan, p. 654
	6. Provides safe, appropriate and responsive quality nursing practice	6.1. Provides comprehensive, safe, quality practice to achieve agreed goals and outcomes that are responsive to the nursing needs of people	When caring for a person with obesity, carries out the processes involved in the intervention phase that specifically address the person's needs, in Nursing care plan, p. 644
			Conducts education for maintaining nutritional status, in Meeting individualised needs, p. 646
			Implements medication management of the person, in Medication administration, p. 650
			Administers medications and enteral and parenteral nutrition knowledgeably and safely, in Medication administration, p. 650

CHAPTER	STANDARD	CRITERIA	EVIDENCE-BASED EXAMPLES (INCLUDING PAGE NO.)
			Provides comprehensive nursing care for a person with malnutrition, in Nursing care plan, p. 654
	7. Evaluates outcomes to inform nursing practice	7.1. Evaluates and monitors progress towards expected goals and outcomes	Evaluates medication management of the person, in Medication administration, p. 650
			Provides comprehensive nursing care for a person with malnutrition, in Nursing care plan, p. 654
22	1. Thinks critically and analyses nursing practice	1.1. Accesses, analyses and uses the best available evidence, that includes research findings, for safe, quality practice	Incorporates evidence-based practice in relation to peptic ulcer disease, in Nursing care plan, p. 691
		1.2. Practises within a professional and ethical nursing framework	Considers the person's cultural background when providing care, in Nursing care plan, p. 667
	2. Engages in therapeutic and professional relationships	2.2. Communicates effectively and is respectful of a person's dignity, culture, values, beliefs and rights	Is sensitive to the needs of the person with gastric cancer and their family in relation to diagnosis, in Nursing care plan, p. 698
		2.6. Uses delegation, supervision, coordination, consultation and referrals in professional relationships to achieve improved outcomes	Includes dietitian in the evaluation of nutritional needs, in Nursing care plan, p. 667
	4. Comprehensively conducts assessments	4.1. Conducts assessments that are holistic as well as culturally appropriate	Demonstrates assessment in nursing care for a person with oral cancer, in Nursing care plan, p. 667
			When caring for a person with oral cancer, carries out the processes involved in the assessment phase that specifically address the person's energy needs and enteral feeding, in Nursing care plan, p. 667
			Includes evidence-based practice in relation to the assessment of the person with peptic ulcer disease, in Nursing care plan, p. 691
			When caring for a person with gastric cancer, carries out the processes involved in the assessment, planning and intervention phases that specifically address the person's needs, in Nursing care plan, p. 698
	5. Develops a plan for nursing practice	5.1. Uses assessment data and best available evidence to develop a plan	Constructs and revises individualised plans of care considering the culture and values of the person with oral cancer, in Nursing care plan, p. 667
			Plans for safe nursing management of medication for GORD, gastritis and peptic ulcer disease, in Medication administration, pp. 671–672
			Plans nursing care using evidence-based research for the person with peptic ulcer disease, in Nursing care plan, p. 691

CHAPTER	STANDARD	CRITERIA	EVIDENCE-BASED EXAMPLES (INCLUDING PAGE NO.)
			When caring for a person with gastric cancer, determine priority nursing diagnoses and interventions based on assessed data, in Nursing care plan, p. 698
		5.2. Collaboratively constructs nursing practice plans until contingencies, options, priorities, goals, actions, outcomes and time frames are agreed with the relevant people	When caring for a person with oral cancer, coordinates and integrates interprofessional care into the plan of care that specifically address the person's energy needs and enteral feeding, in Nursing care plan, p. 667
			Plans and provides the person with gastric cancer and their family with education to promote, maintain and restore functional health in relation to diet, pain management and diagnosis, in Nursing care plan, p. 698
	6. Provides safe, appropriate and responsive quality nursing practice	6.1. Provides comprehensive, safe, quality practice to achieve agreed goals and outcomes that are responsive to the nursing needs of people	Demonstrates comprehensive nursing care for a person with oral cancer, in Nursing care plan, p. 667
			When caring for a person with oral cancer, carries out the processes involved intervention phase that specifically address the person's energy needs and enteral feeding, in Nursing care plan, p. 667
			Administers medications and prescribed care knowledgeably and safely, in Medication administration, pp. 671–672
			Conducts education for a person with gastric cancer and their family in relation to diet, pain management and diagnosis, in Nursing care plan, p. 698
			When caring for a person with gastric cancer, carries out the processes involved in the intervention phase that specifically address the person's needs, in Nursing care plan, p. 698
	7. Evaluates outcomes to inform nursing practice	7.1. Evaluates and monitors progress towards expected goals and outcomes	Evaluates responses to comprehensive nursing care for a person with oral cancer, in Nursing care plan, p. 667
23	2. Engages in therapeutic and professional relationships	2.6. Uses delegation, supervision, coordination, consultation and referrals in professional relationships to achieve improved outcomes	Includes dietitian in the planning of nutritional needs, in Nursing care plan, p. 750
	4. Comprehensively conducts assessments	4.1. Conducts assessments that are holistic as well as culturally appropriate	Provides an assessment for a person having an ileostomy, in Nursing care of the person, pp. 746–747
			Provides an assessment for a person with ulcerative colitis, in Nursing care plan, p. 750

CHAPTER	STANDARD	CRITERIA	EVIDENCE-BASED EXAMPLES (INCLUDING PAGE NO.)
			When caring for a person with colorectal cancer, carries out the processes involved in the assessment phase that specifically address the person's needs, in Nursing care plan, p. 766
		4.2. Uses a range of assessment techniques to systematically collect relevant and accurate information and data to inform practice	During the postoperative phase fluid status, nasogastric drainage, wound assessment and gastrointestinal assessment are ongoing so the plan of care can be revised to ensure optimal care for a person having bowel surgery, in Nursing care of the person, p. 762
	5. Develops a plan for nursing practice	5.1. Uses assessment data and best available evidence to develop a plan	Plans for safe nursing management of laxative medication, in Medication administration, pp. 708–709
			Plans for comprehensive nursing care for a person having an ileostomy, in Nursing care of the person, pp. 746–747
			Revises plan of care when necessary to provide effective interventions promoting, maintaining or restoring functional health status to a person having bowel surgery, in Nursing care of the person, p. 762
			Determines priority nursing diagnoses, based on assessed data, to select and implement individualised nursing interventions for a person with colorectal cancer, in Nursing care plan, p. 766
		5.2. Collaboratively constructs nursing practice plans until contingencies, options, priorities, goals, actions, outcomes and time frames are agreed with the relevant people	Integrates interprofessional care into care of a person with ulcerative colitis, in Nursing care plan, p. 750
	6. Provides safe, appropriate and responsive quality nursing practice	6.1. Provides comprehensive, safe, quality practice to achieve agreed goals and outcomes that are responsive to the nursing needs of people	Administers medications used in the management of bowel disorders knowledgeably and safely, in Medication administration, pp. 708–709
			Provides skilled care to a person following the formation of an ileostomy, in Nursing care of the person, pp. 746–747
			Provides comprehensive nursing care for a person with ulcerative colitis, in Nursing care plan, p. 750
			When caring for a person with colorectal cancer, carries out the processes involved in the intervention phase that specifically address the person's needs, in Nursing care plan, p. 766
	7. Evaluates outcomes to inform nursing practice	7.1. Evaluates and monitors progress towards expected goals and outcomes	Evaluates responses to comprehensive nursing care for a person having an ileostomy, in Nursing care of the person, pp. 746–747

CHAPTER	STANDARD	CRITERIA	EVIDENCE-BASED EXAMPLES (INCLUDING PAGE NO.)
			Evaluates responses to comprehensive nursing care for a person with ulcerative colitis, in Nursing care plan, p. 750
24	1. Thinks critically and analyses nursing practice	1.1. Accesses, analyses and uses the best available evidence, that includes research findings, for safe, quality practice	Recognises that preoperative education, discharge planning and postoperative pain management are part of an effective pain management strategy, in Translation to practice, p. 788
		1.2. Practises within a professional and ethical nursing framework	Considers the person's cultural background when providing care, in Nursing care plan, p. 789
	2. Engages in therapeutic and professional relationships	2.2. Communicates effectively and is respectful of a person's dignity, culture, values, beliefs and rights	Describes to the person the steps in the procedure of paracentesis, in Box 24.5 Nursing implications for abdominal paracentesis, p. 806
			Provides verbal and written information about medication and complications of cirrhosis, in Nursing care plan, p. 809
		2.3. Recognises that people are the experts in the experience of their life	Involves person in the decision making for home-based care post acute pancreatitis, in Nursing care plan, p. 818
		2.6. Uses delegation, supervision, coordination, consultation and referrals in professional relationships to achieve improved outcomes	Reports active postoperative bleeding, in Nursing care of the person, p. 789
			Involves the social worker for referral to community services, in Nursing care plan, p. 809
	4. Comprehensively conducts assessments	4.1. Conducts assessments that are holistic as well as culturally appropriate	Includes evidence-based practice in relation to the assessment of the person for pain management post laparoscopic cholecystectomy, in Translation to practice, p. 788
			Includes cultural practices in relation to nutritional assessment of the person with cholelithiasis and subsequent planning, in Nursing care plan, p. 789
			Assesses the person with alcoholic cirrhosis, in Nursing care plan, p. 809
			Assesses the person with a resection of the pancreas, in Nursing care of the person, p. 820
		4.2. Uses a range of assessment techniques to systematically collect relevant and accurate information and data to inform practice	Monitors for postoperative bleeding, in Nursing care of the person, p. 789
	5. Develops a plan for nursing practice	5.1. Uses assessment data and best available evidence to develop a plan	Uses evidence-based practice to revise the plan of care for the person and subsequent planning for pain management post laparoscopic cholecystectomy, in Translation to practice, p. 788

CHAPTER	STANDARD	CRITERIA	EVIDENCE-BASED EXAMPLES (INCLUDING PAGE NO.)
			Integrates psychosocial, cultural and spiritual considerations into the plan of care for a person with cholelithiasis, in Nursing care plan, p. 789
			Prepares people for and understands the purpose and significance of the procedure of paracentesis, in Box 24.5 Nursing implications for abdominal paracentesis, p. 806
			Plans comprehensive nursing care for a person with a resection of the pancreas, in Nursing care of the person, p. 820
		5.2. Collaboratively constructs nursing practice plans until contingencies, options, priorities, goals, actions, outcomes and time frames are agreed with the relevant people	Integrates a plan for dietary, pharmacological and other interprofessional measures into nursing care and teaching of the person with alcoholic cirrhosis, in Nursing care plan, p. 809
			Plans for appropriate person and family education to promote, maintain and restore functional health status for the person with post-acute pancreatitis, in Nursing care plan, p. 818
	6. Provides safe, appropriate and responsive quality nursing practice	6.1. Provides comprehensive, safe, quality practice to achieve agreed goals and outcomes that are responsive to the nursing needs of people	Monitors for postoperative bleeding, in Nursing care of the person, p. 789
			Educates the person in relation to the procedure of paracentesis, in Box 24.5 Nursing implications for abdominal paracentesis, p. 806
			Provides comprehensive nursing care for a person with alcoholic cirrhosis, in Nursing care plan, p. 809
			Conducts education for home-based care post acute pancreatitis, in Nursing care plan, p. 818
			Provides comprehensive nursing care for a person with a resection of the pancreas, in Nursing care of the person, p. 820
	7. Evaluates outcomes to inform nursing practice	7.1. Evaluates and monitors progress towards expected goals and outcomes	Monitors for, documents and reports expected and unexpected manifestations of postoperative bleeding, in Nursing care of the person, p. 789
			Evaluates nursing care for a person with alcoholic cirrhosis, in Nursing care plan, p. 809
			Evaluates nursing care for a person with a resection of the pancreas, in Nursing care of the person, p. 820

CHAPTER	STANDARD	CRITERIA	EVIDENCE-BASED EXAMPLES (INCLUDING PAGE NO.)
Unit 7 Responses to Altered Urinary Elimination			
25	2. Engages in therapeutic and professional relationships	2.6. Uses delegation, supervision, coordination, consultation and referrals in professional relationships to achieve improved outcomes	Monitors the results of diagnostic tests and reports abnormal findings, in Diagnostic tests, pp. 837–841
	4. Comprehensively conducts assessments	4.1. Conducts assessments that are holistic as well as culturally appropriate	Conducts a health history for a person with an alteration or at risk of alterations in urinary elimination, in Functional health pattern interview, p. 836
		4.2. Uses a range of assessment techniques to systematically collect relevant and accurate information and data to inform practice	Conducts and/or assists in the collection of urine and blood samples and radiographical studies, in Diagnostic tests, pp. 837–841
			Conducts a physical assessment of the renal system, in Renal assessments, pp. 842–843
26	1. Thinks critically and analyses nursing practice	1.1. Accesses, analyses and uses the best available evidence, that includes research findings, for safe, quality practice	Understands that insertion of catheter to a specific length that is gender specific and the use of aseptic technique are part of an effective urinary management strategy, in Translation to practice, p. 854
	2. Engages in therapeutic and professional relationships	2.2. Communicates effectively and is respectful of a person's dignity, culture, values, beliefs and rights	Communicates therapeutically, in Nursing care plan, pp. 880–881
		2.6. Uses delegation, supervision, coordination, consultation and referrals in professional relationships to achieve improved outcomes	Reports low urine output, in Nursing care of the person, p. 851
			Includes the Continence Nurse Advisor in the provision of care that specifically addresses the person's urinary elimination via stoma, in Nursing care plan, pp. 868–869
	4. Comprehensively conducts assessments	4.1. Conducts assessments that are holistic as well as culturally appropriate	Assesses the person with a bladder tumour, in Nursing care plan, pp. 868–869
			Assesses the functional health status of a person with a urinary tract disorder, in Nursing care of the older adult, pp. 874–875
		4.2. Uses a range of assessment techniques to systematically collect relevant and accurate information and data to inform practice	Monitors for postoperative bleeding and urine output, in Nursing care of the person, p. 851
			During the postoperative phase monitoring urine output, catheter drainage, stoma assessment and electrolytes is ongoing to ensure optimal care for a person having a cystectomy and urinary diversion, in Nursing care of the person, p. 868
			During the postoperative phase urine output, catheter drainage and wound assessment are ongoing to ensure optimal care for a person with a bladder neck suspension, in Nursing care of the person, p. 879

CHAPTER	STANDARD	CRITERIA	EVIDENCE-BASED EXAMPLES (INCLUDING PAGE NO.)
	5. Develops a plan for nursing practice	5.1. Uses assessment data and best available evidence to develop a plan	Plans for safe nursing management of medication, in Medication administration, p. 850
			The preoperative phase involves education, stoma preparation and bowel care, and during the postoperative phase monitoring urine output, catheter drainage, stoma assessment and electrolytes is ongoing to ensure optimal care for a person with a cystectomy and urinary diversion, in Nursing care of the person, p. 868
			Uses evidence-based research to plan and insert a urinary catheter, in Translation to practice, p. 874
			When caring for a person with a urinary problem, carries out the processes involved in the planning phase that specifically address the person's needs, in Nursing care of the older adult, pp. 874–875
			Recognises that the preoperative phase involves education and that during the postoperative phase urine output, catheter drainage and wound assessment are ongoing to ensure optimal care for a person with a bladder neck suspension, in Nursing care of the person, p. 879
		5.2. Collaboratively constructs nursing practice plans until contingencies, options, priorities, goals, actions, outcomes and time frames are agreed with the relevant people	Integrates the interprofessional plan of care into care for a person with a bladder tumour, in Nursing care plan, pp. 868–869
			Plans education for prevention and self-care of urinary incontinence, in Nursing care plan, pp. 880–881
	6. Provides safe, appropriate and responsive quality nursing practice	6.1. Provides comprehensive, safe, quality practice to achieve agreed goals and outcomes that are responsive to the nursing needs of people	Knowledgeably and safely administers prescribed medications for people with urinary tract disorders, in Medication administration, p. 850
			The preoperative phase involves education, stoma preparation and bowel care, and during the postoperative phase monitoring urine output, catheter drainage, stoma assessment and electrolytes is ongoing to ensure optimal care for a person with a cystectomy and urinary diversion, in Nursing care of the person, p. 868
			Provides comprehensive nursing care for a person with a bladder tumour, in Nursing care plan, pp. 868–869
			When caring for a person with a urinary problem, carries out the processes involved in the intervention phase that specifically address the person's needs, in Nursing care of the older adult, pp. 874–875

CHAPTER	STANDARD	CRITERIA	EVIDENCE-BASED EXAMPLES (INCLUDING PAGE NO.)
			Includes evidence-based practice in relation to the insertion of a urinary catheter, in Translation to practice, p. 874
			Provides effective nursing care for the person undergoing surgery of the bladder neck, in Nursing care of the person, p. 879
			Conducts education for home-based urinary incontinence, in Nursing care plan, pp. 880–881
	7. Evaluates outcomes to inform nursing practice	7.1. Evaluates and monitors progress towards expected goals and outcomes	Evaluates responses to nursing care for a person with a bladder tumour, in Nursing care plan, pp. 868–869
			Recognises that the preoperative phase involves education and that during the postoperative phase urine output, catheter drainage and wound assessment are ongoing to ensure optimal care for a person with a bladder neck suspension, in Nursing care of the person, p. 879
		7.2. Revises the plan based on the evaluation	Evaluates personal responses, revising plan of care as needed to promote, maintain or restore functional health of the individual with a cystectomy and urinary diversion, in Nursing care of the person, p. 868
27	2. Engages in therapeutic and professional relationships	2.2. Communicates effectively and is respectful of a person's dignity, culture, values, beliefs and rights	Communicates therapeutically, in Medication administration, p. 893
			Involves person in the decision making for health management, in Nursing care plan, p. 927
			When caring for a person with end-stage kidney disease, involves the person and the interprofessional team in addressing the person's needs, in Nursing care plan, p. 927
		2.6. Uses delegation, supervision, coordination, consultation and referrals in professional relationships to achieve improved outcomes	Consults the dietitian for menu planning that specifically addresses the person's needs, in Nursing care plan, p. 927
			When caring for a person with end-stage kidney disease, involves the person and the interprofessional team in addressing the person's needs, in Nursing care plan, p. 927
	4. Comprehensively conducts assessments	4.1. Conducts assessments that are holistic as well as culturally appropriate	When caring for a person with acute kidney injury, carries out the processes involved in the assessment phase that specifically address the person's needs, in Nursing care plan, p. 896
			Recognises that pre-, intra- and post-dialysis care must ensure optimal management for a person requiring intermittent haemodialysis, in Nursing care of the person, p. 918

CHAPTER	STANDARD	CRITERIA	EVIDENCE-BASED EXAMPLES (INCLUDING PAGE NO.)
			When caring for a person with end-stage kidney disease, carries out the processes involved in the assessment phase that specifically address the person's needs, in Nursing care plan, p. 927
		4.2. Uses a range of assessment techniques to systematically collect relevant and accurate information and data to inform practice	During the postoperative phase monitoring urine output, catheter drainage, fluid and electrolyte balance, vital signs and wound assessment is ongoing to ensure optimal care for a person receiving a kidney transplant, in Nursing care of the person, p. 925
		4.3. Works in partnership to determine factors that affect, or potentially affect, the health and wellbeing of people and populations to determine priorities for action and/or referral	When caring for a person with end-stage kidney disease, involves the person and the interprofessional team when addressing the person's needs, in Nursing care plan, p. 927
	5. Develops a plan for nursing practice	5.1. Uses assessment data and best available evidence to develop a plan	Assesses the person for medication education appropriate to a person with acute kidney injury and their personal circumstances, in Medication administration, p. 893
			Plans that pre-, intra- and post-dialysis care ensures optimal management for a person requiring intermittent haemodialysis, in Nursing care of the person, p. 918
			Plans for the preoperative phase of education, dialysis and immunosuppressive medication, and during the postoperative phase monitoring urine output, catheter drainage, fluid and electrolyte balance, vital signs and wound assessment is ongoing to ensure optimal care for a person receiving a kidney transplant, in Nursing care of the person, p. 925
			Based on assessment data, determines priority nursing diagnoses and interventions for a person with end-stage kidney disease, in Nursing care plan, p. 927
		5.2. Collaboratively constructs nursing practice plans until contingencies, options, priorities, goals, actions, outcomes and time frames are agreed with the relevant people	Collaborates with the person and other members of the interprofessional team to prioritise and implement care, in Nursing care plan, p. 927

CHAPTER	STANDARD	CRITERIA	EVIDENCE-BASED EXAMPLES (INCLUDING PAGE NO.)
	6. Provides safe, appropriate and responsive quality nursing practice	6.1. Provides comprehensive, safe, quality practice to achieve agreed goals and outcomes that are responsive to the nursing needs of people	Conducts education for administering medications for acute kidney injury, in Medication administration, p. 893 Monitors, documents and reports unexpected or abnormal manifestations in a person with acute kidney injury, in Nursing care plan, p. 896 Provides appropriate and effective nursing care for a person requiring intermittent haemodialysis, in Nursing care of the person, p. 918 The preoperative phase involves education, dialysis and immunosuppressive medication, and during the postoperative phase monitoring urine output, catheter drainage, fluid and electrolyte balance, vital signs and wound assessment is ongoing to ensure optimal care for a person receiving a kidney transplant, in Nursing care of the person, p. 925 When caring for a person with end-stage kidney disease, carries out the processes involved in the intervention phase that specifically address the person's needs, in Nursing care plan, p. 927
	7. Evaluates outcomes to inform nursing practice	7.1. Evaluates and monitors progress towards expected goals and outcomes	When caring for a person with acute kidney injury, carries out the processes involved in the evaluation phase that specifically address the person's needs, in Nursing care plan, p. 896 Recognises that pre-, intra- and post-dialysis care must ensure optimal management for a person requiring intermittent haemodialysis, in Nursing care of the person, p. 918
		7.2. Revises the plan based on the evaluation	Evaluates responses to care, revising the plan of care as needed to promote, maintain or restore functional health status for a person with a kidney transplant, in Nursing care of the person, p. 925
Unit 8 Responses to Altered Cardiovascular Function			
28	2. Engages in therapeutic and professional relationships	2.6. Uses delegation, supervision, coordination, consultation and referrals in professional relationships to achieve improved outcomes	Monitors the results of diagnostic tests and reports abnormal findings, in Diagnostic tests, pp. 958–960
	4. Comprehensively conducts assessments	4.1. Conducts assessments that are holistic as well as culturally appropriate	Conducts a health history for a person with an alteration or at risk of alterations in cardiac, haematological or lymphatic function, in Functional health pattern interview, pp. 956–957

CHAPTER	STANDARD	CRITERIA	EVIDENCE-BASED EXAMPLES (INCLUDING PAGE NO.)
		4.2. Uses a range of assessment techniques to systematically collect relevant and accurate information and data to inform practice	Conducts and/or assists in the collection of blood and fluid samples, and electrocardiograph and radiographical studies, in Diagnostic tests, pp. 958–960
			Conducts an electrocardiograph and interprets tracing, in Box 28.1 Electrocardiogram, pp. 960–963
			Conducts a physical assessment of the cardiac, haematological, peripheral vascular and lymphatic systems, in Cardiac assessments, pp. 969–978
29	2. Engages in therapeutic and professional relationships	2.6. Uses delegation, supervision, coordination, consultation and referrals in professional relationships to achieve improved health outcomes	Advises consultation with the doctor if adverse reaction occurs, in Medication administration, p. 992
			When caring for a person with acute myocardial infarction, notifies medical officer of dangerous arrhythmias, in Nursing care plan, pp. 1016–1017
			When caring for a person with supraventricular tachycardia, notifies doctor of changes in vital signs and ECG, in Nursing care plan, p. 1037
	4. Comprehensively conducts assessments	4.1. Conducts assessments that are holistic as well as culturally appropriate	When caring for a person with coronary heart disease, carries out the processes involved in the assessment phase that specifically address the person's needs, in Nursing care of the person, pp. 1003–1005
			When caring for a person with acute myocardial infarction, carries out the processes involved in the assessment phase that specifically address the person's needs, in Nursing care plan, pp. 1016–1017
			When caring for a person with supraventricular tachycardia, carries out the processes involved in the assessment phase that specifically address the person's needs, in Nursing care plan, p. 1037
		4.2. Uses a range of assessment techniques to systematically collect relevant and accurate information and data to inform practice	Recognises that the preoperative phase involves education and laboratory and diagnostic tests, and during the postoperative phase monitoring vital signs, haemodynamic monitoring, heart sounds, urine output, chest drainage and fluid and electrolyte balance, and administration of drugs are ongoing to ensure optimal care for a person with a coronary artery bypass graft, in Nursing care of the person, pp. 1003–1005

CHAPTER	STANDARD	CRITERIA	EVIDENCE-BASED EXAMPLES (INCLUDING PAGE NO.)
	5. Develops a plan for nursing practice	5.1. Uses assessment data and best available evidence to develop a plan	Plans for education for administering medications for lowering cholesterol, in Medication administration, p. 992 Plans for safe nursing management of medication, in Medication administration, pp. 996–997 Interprets assessment data, determines priorities of care and develops and implements individualised nursing interventions for the person with coronary heart disease, in Nursing care of the person, pp. 1003–1005 Plans for the preoperative phase of education and laboratory and diagnostic tests, and during the postoperative phase monitoring vital signs, haemodynamic monitoring, heart sounds, urine output, chest drainage and fluid and electrolyte balance, and administration of drugs are ongoing to ensure optimal care for a person with a coronary artery bypass graft, in Nursing care of the person, pp. 1003–1005
		5.2. Collaboratively constructs nursing practice plans until contingencies, options, priorities, goals, actions, outcomes and time frames are agreed with the relevant people	Integrates multidisciplinary care into nursing care planning and implementation for a person with supraventricular tachycardia, in Nursing care plan, p. 1037
	6. Provides safe, appropriate and responsive quality nursing practice	6.1. Provides comprehensive, safe, quality practice to achieve agreed goals and outcomes that are responsive to the nursing needs of people	Provides appropriate teaching for administering medications for lowering cholesterol, in Medication administration, p. 992 Administers medications and treatments to people with coronary heart disease and arrhythmias safely and knowledgeably, in Medication administration, pp. 996–997 When caring for a person with coronary heart disease, carries out the processes intervention phase that specifically address the person's needs, in Nursing care of the person, pp. 1003–1005 The preoperative phase involves education and laboratory and diagnostic tests, and during the postoperative phase monitoring vital signs, haemodynamic monitoring, heart sounds, urine output, chest drainage and fluid and electrolyte balance, and administration of drugs are ongoing to ensure optimal care for a person with a coronary artery bypass graft, in Nursing care of the person, pp. 1003–1005

CHAPTER	STANDARD	CRITERIA	EVIDENCE-BASED EXAMPLES (INCLUDING PAGE NO.)
			When caring for a person with acute myocardial infarction, carries out the processes involved in the implementation phase that specifically address the person's needs, in Nursing care plan, pp. 1016–1017
			When caring for a person with supraventricular tachycardia, carries out the processes involved in the implementation phase that specifically address the person's needs, in Nursing care plan, p. 1037
	7. Evaluates outcomes to inform nursing practice	7.1. Evaluates and monitors progress towards expected goals and outcomes	Evaluates the effectiveness of nursing interventions, revising or modifying the plan of care as needed to promote, maintain or restore functional health for the person with a coronary artery bypass graft, in Nursing care of the person, pp. 1003–1005
			Monitors the person with coronary heart disease or arrhythmias for expected and unexpected manifestations, in Nursing care plan, pp. 1016–1017
30	1. Thinks critically and analyses nursing practice	1.1. Accesses, analyses and uses the best available evidence, that includes research findings, for safe, quality practice	Incorporates evidence-based practice in relation to mitral valve prolapse, in Nursing care plan, pp. 1082–1083
	2. Engages in therapeutic and professional relationships	2.2. Communicates effectively and is respectful of a person's dignity, culture, values, beliefs and rights	Communicates therapeutically, in Nursing care of the older adult, p. 1046
		2.6. Uses delegation, supervision, coordination, consultation and referrals in professional relationships to achieve improved outcomes	Collaborates with the medical staff, dietitian and physiotherapist, in Nursing care plan, p. 1056
	4. Comprehensively conducts assessments	4.1. Conducts assessments that are holistic as well as culturally appropriate	When caring for a person with heart failure, carries out the processes involved in the assessment phase that specifically address the person's dietary and physiotherapy requirements, in Nursing care plan, p. 1056
			Includes evidence-based assessment in relation to providing nursing care for mitral valve prolapse, in Nursing care plan, pp. 1082–1083
		4.2. Uses a range of assessment techniques to systematically collect relevant and accurate information and data to inform practice	When evaluating nursing care for a person with heart failure, reinforces medication knowledge, in Nursing care plan, p. 1056
	5. Develops a plan for nursing practice	5.1. Uses assessment data and best available evidence to develop a plan	Plans appropriate education and community-based care for the person with heart failure, in Nursing care of the older adult, p. 1046

CHAPTER	STANDARD	CRITERIA	EVIDENCE-BASED EXAMPLES (INCLUDING PAGE NO.)
			Plans appropriate and safe nursing management of medication, in Medication administration, pp. 1053–1054
			Plans nursing care for a person with heart failure, reinforces medication knowledge, in Nursing care plan, p. 1056
			Plans and prioritises evidence-based, individualised care for the person with mitral valve prolapse, in Nursing care plan, pp. 1082–1083
		5.2. Collaboratively constructs nursing practice plans until contingencies, options, priorities, goals, actions, outcomes and time frames are agreed with the relevant people	Actively participates in planning and coordinating interprofessional care for the person with heart failure, in Nursing care plan, p. 1056
	6. Provides safe, appropriate and responsive quality nursing practice	6.1. Provides comprehensive, safe, quality practice to achieve agreed goals and outcomes that are responsive to the nursing needs of people	Conducts education for heart failure, in Nursing care of the older adult, p. 1046
			Administers prescribed medications and treatments to individuals with cardiac disorders, in Medication administration, pp. 1053–1054
			When caring for a person with heart failure, carries out the processes involved in the intervention phase that specifically address the person's dietary and physiotherapy requirements, in Nursing care plan, p. 1056
			Includes evidence-based practice in relation to providing nursing care for mitral valve prolapse, in Nursing care plan, pp. 1082–1083
	7. Evaluates outcomes to inform nursing practice	7.1. Evaluates and monitors progress towards expected goals and outcomes	When caring for a person with heart failure, carries out the processes involved in the assessment, planning, intervention and evaluation phases that specifically address the person's dietary and physiotherapy requirements, in Nursing care plan, p. 1056
			Evaluates the effectiveness of nursing care, revising the plan of care as needed to promote, maintain or restore functional health status of the person with heart failure, in Nursing care plan, p. 1056
			Evaluates evidence-based nursing care for mitral valve prolapse, in Nursing care plan, pp. 1082–1083
31	1. Thinks critically and analyses nursing practice	1.1. Accesses, analyses and uses the best available evidence, that includes research findings, for safe, quality practice	Incorporates evidence-based practice in relation to deep vein thrombosis, in Nursing care plan, p. 1132

CHAPTER	STANDARD	CRITERIA	EVIDENCE-BASED EXAMPLES (INCLUDING PAGE NO.)
	2. Engages in therapeutic and professional relationships	2.2. Communicates effectively and is respectful of a person's dignity, culture, values, beliefs and rights	Communicates therapeutically, in Medication administration, pp. 1129–1130
		2.6. Uses delegation, supervision, coordination, consultation and referrals in professional relationships to achieve improved outcomes	Consults the dietitian for the person's dietary requirements, in Nursing care plan, p. 1107
	4. Comprehensively conducts assessments	4.1. Conducts assessments that are holistic as well as culturally appropriate	When caring for a person with hypertension, carries out the processes involved in the assessment phase that specifically address the person's dietary requirements, in Nursing care plan, p. 1107
			Assesses evidence-based practice in relation to providing nursing care for deep vein thrombosis, in Nursing care plan, p. 1132
	5. Develops a plan for nursing practice	5.1. Uses assessment data and best available evidence to develop a plan	Uses research and evidence-based plans to provide individualised care for the person with deep vein thrombosis, in Nursing care plan, p. 1132
		5.2. Collaboratively constructs nursing practice plans until contingencies, options, priorities, goals, actions, outcomes and time frames are agreed with the relevant people	Collaborates with the interprofessional care team in planning care for a person with hypertension, in Nursing care plan, p. 1107
			Plans person-centred and family teaching for anticoagulant therapy, in Medication administration, pp. 1129–1130
		5.6. Plans nursing care in consultation with individuals/groups, significant others and the interprofessional team	Plans safe nursing management of medication, in Medication administration, pp. 1100–1101
	6. Provides safe, appropriate and responsive quality nursing practice	6.1. Provides comprehensive, safe, quality practice to achieve agreed goals and outcomes that are responsive to the nursing needs of people	When caring for a person with hypertension, carries out the processes involved in the intervention phase that specifically address the person's dietary requirements, in Nursing care plan, p. 1107
			Safely and knowledgeably administers medications, in Medication administration, pp. 1100–1101
			Conducts education for anticoagulant therapy, in Medication administration, pp. 1129–1130
			Includes evidence-based practice in relation to providing nursing care for deep vein thrombosis, in Nursing care plan, p. 1132

CHAPTER	STANDARD	CRITERIA	EVIDENCE-BASED EXAMPLES (INCLUDING PAGE NO.)
	7. Evaluates outcomes to inform nursing practice	7.1. Evaluates and monitors progress towards expected goals and outcomes	When caring for a person with hypertension, carries out the processes involved in the evaluation phase that specifically address the person's dietary requirements, in Nursing care plan, p. 1107
			Evaluates evidence-based nursing care for deep vein thrombosis, in Nursing care plan, p. 1132
32	1. Thinks critically and analyses nursing practice	1.1. Accesses, analyses and uses the best available evidence, that includes research findings, for safe, quality practice	Incorporates evidence-based practice in relation to Hodgkin's disease, in Nursing care plan, p. 1182
	2. Engages in therapeutic and professional relationships	2.2. Communicates effectively and is respectful of a person's dignity, culture, values, beliefs and rights	Communicates therapeutically, in Nursing care plan, p. 1159
		2.6. Uses delegation, supervision, coordination, consultation and referrals in professional relationships to achieve improved outcomes	Notifies the performance of handwashing as per protocol, in Nursing care plan, p. 1172
			Notifies doctor if bleeding occurs, in Nursing care plan, p. 1192
	4. Comprehensively conducts assessments	4.1. Conducts assessments that are holistic as well as culturally appropriate	Assesses for education for folic acid deficiency anaemia, in Nursing care plan, p. 1159
			When a person has a definitive diagnosis of acute myelocytic leukaemia, ensures further assessment is conducted, in Nursing care plan, p. 1172
			When caring for a person with acute myelocytic leukaemia, carries out the processes involved in the assessment phase that specifically address the person's dietary requirements, in Nursing care plan, p. 1172
			Assesses for evidence-based practice in relation to providing nursing care for Hodgkin's disease, in Nursing care plan, p. 1182
			When caring for a person with haemophilia, carries out ongoing assessment, in Nursing care plan, p. 1192
	5. Develops a plan for nursing practice	5.1. Uses assessment data and best available evidence to develop a plan	Plans for safe nursing management of medication, in Medication administration, p. 1157
			Plans for appropriate education for the person with folic acid deficiency anaemia, in Nursing care plan, p. 1159
			Uses continuing assessment data to revise the plan of care as needed to restore, maintain or promote functional health in the person with a acute myelocytic leukaemia, in Nursing care plan, p. 1172

CHAPTER	STANDARD	CRITERIA	EVIDENCE-BASED EXAMPLES (INCLUDING PAGE NO.)
			Based on knowledge of pathophysiology, prescribed treatment and assessed data, identifies and prioritises nursing diagnoses for a person with Hodgkin's disease, in Nursing care plan, p. 1182
			Includes evidence-based practice in plan for providing nursing care for Hodgkin's disease, in Nursing care plan, p. 1182
		5.2. Collaboratively constructs nursing practice plans until contingencies, options, priorities, goals, actions, outcomes and time frames are agreed with the relevant people	Collaborates with the interprofessional care team to plan coordinated, effective care for a person with acute myelocytic leukaemia, in Nursing care plan, p. 1172
	6. Provides safe, appropriate and responsive quality nursing practice	6.1. Provides comprehensive, safe, quality practice to achieve agreed goals and outcomes that are responsive to the nursing needs of people	Safely and knowledgeably administers prescribed medications, in Medication administration, p. 1157
			Conducts education for folic acid deficiency anaemia, in Nursing care plan, p. 1159
			When a person has a definitive diagnosis of acute myelocytic leukaemia, ensures further intervention is conducted, in Nursing care plan, p. 1172
			Uses nursing research and evidence-based practice to implement individualised nursing interventions for a person with Hodgkin's disease, in Nursing care plan, p. 1182
	7. Evaluates outcomes to inform nursing practice	7.1. Evaluates and monitors progress towards expected goals and outcomes	Evaluates education for folic acid deficiency anaemia, in Nursing care plan, p. 1159
			When a person has a definitive diagnosis of acute myelocytic leukaemia, ensures further evaluation is conducted, in Nursing care plan, p. 1172
			When caring for a person with acute myelocytic leukaemia, carries out the processes involved in the evaluation phase that specifically addresses the person's dietary requirements, in Nursing care plan, p. 1172

MAPPING TO THE NMBA *REGISTERED NURSE STANDARDS FOR* ***PRACTICE***

AUTHOR: Trish Burton

CHAPTER	STANDARD	CRITERIA	EVIDENCE-BASED EXAMPLES (INCLUDING PAGE NO.)
Unit 9 Responses to Altered Respiratory Function			
33	2. Engages in therapeutic and professional relationships	2.6. Uses delegation, supervision, coordination, consultation and referrals in professional relationships to achieve improved health outcomes	Monitors the results of diagnostic tests and reports abnormal findings, in Diagnostic tests, pp. 1215–1217
	4. Comprehensively conducts assessments	4.1. Conducts assessments that are holistic as well as culturally appropriate	Conducts a health history for a person with an alteration or at risk of alteration in respiratory function, in Sample documentation, p. 1212 Conducts a physical assessment for a person with an alteration in the respiratory system, in Respiratory assessments, pp. 1217–1219
	4. Comprehensively conducts assessments	4.2. Uses a range of assessment techniques to systematically collect relevant and accurate information and data to inform practice	Conducts and/or assists in the collection of respiratory secretions, blood samples, tissue samples, pleural fluid, pulse oximetry and radiographical studies, in Diagnostic tests, pp. 1215–1217
34	1 Thinks critically and analyses nursing practice	1.1. Accesses, analyses and uses the best available evidence, that includes research findings, for safe, quality practice	Incorporates evidence-based practice in relation to nasal packing, in Nursing care of the person, p. 1239
	2. Engages in therapeutic and professional relationships	2.2. Communicates effectively and is respectful of a person's dignity, culture, values, beliefs and rights	Communicates therapeutically, in Nursing care plan, p. 1252
	4. Comprehensively conducts assessments	4.1. Conducts assessments that are holistic as well as culturally appropriate	Includes evidence-based practice in relation to the assessment of the person and subsequent planning and implementation for peritonsillar abscess, in Nursing care plan, p. 1233 Provides comprehensive nursing care for a person with a total laryngectomy, in Nursing care plan, p. 1252
	5. Develops a plan for nursing practice	5.1. Uses assessment data and best available evidence to develop a plan	Provides appropriate and safe nursing management of medication, in Medication administration, p. 1224 Uses nursing research and evidence-based practice to plan and implement nursing care for the person with a peritonsillar abscess, in Nursing care plan, p. 1233

CHAPTER	STANDARD	CRITERIA	EVIDENCE-BASED EXAMPLES (INCLUDING PAGE NO.)
			Provides comprehensive nursing care for a person with a total laryngectomy, in Nursing care plan, p. 1252
		5.2. Collaboratively constructs nursing practice plans until contingencies, options, priorities, goals, actions, outcomes and time frames are agreed with the relevant people	Provides appropriate education plan for the person and family in relation to diet and pain management, in Nursing care plan, p. 1252
	6. Provides safe, appropriate and responsive quality nursing practice	6.1. Provides comprehensive, safe, quality practice to achieve agreed goals and outcomes that are responsive to the nursing needs of people	Safely and knowledgeably administers medications, in Medication administration, p. 1224
			Includes evidence-based practice in relation to the assessment of the person and subsequent planning and implementation for peritonsillar abscess, in Nursing care plan, p. 1233
			Provides safe and effective nursing care for a person with a total laryngectomy, in Nursing care plan, p. 1252
			Conducts education for diet and pain management, in Nursing care plan, p. 1252
	7. Evaluates outcomes to inform nursing practice	7.1. Evaluates and monitors progress towards the expected goals and outcomes	Provides comprehensive nursing care for a person with a total laryngectomy, in Nursing care plan, p. 1252
35	1. Thinks critically and analyses nursing practice	1.1. Accesses, analyses and uses the best available evidence, that includes research findings, for safe, quality practice	Incorporates evidence-based practice in relation to pneumonia, in Nursing care plan, p. 1270
	2. Engages in therapeutic and professional relationships	2.2. Communicates effectively, and is respectful of a person's dignity, culture, values, beliefs and rights	Communicates therapeutically, in Nursing care of the older adult, p. 1275
	4. Comprehensively conducts assessments	4.1. Conducts assessments that are holistic as well as culturally appropriate	Uses the nursing process and evidence-based nursing research to plan and implement individualised nursing care for pneumonia, in Nursing care plan, p. 1270
			Conducts education for self-managing tuberculosis, in Nursing care plan, p. 1280
			When caring for a person having lung surgery, carries out the processes involved in the assessment and planning phases that specifically address the person's needs, in Nursing care of the person, pp. 1301–1302
	5. Develops a plan for nursing practice	5.1. Uses assessment data and best available evidence to develop a plan	Includes evidence-based practice in relation to the assessment of the person and subsequent planning and implementation for pneumonia, in Nursing care plan, p. 1270

CHAPTER	STANDARD	CRITERIA	EVIDENCE-BASED EXAMPLES (INCLUDING PAGE NO.)
			Develops measures to promote ventilation and gas exchange for a person with chest tubes, in Nursing care of the person, p. 1288
			When caring for a person having lung surgery, carries out the processes involved in the assessment and planning phases that specifically address the person's needs, in Nursing care of the person, pp. 1301–1302
		5.2. Collaboratively constructs nursing practice plans until contingencies, options, priorities, goals, actions, outcomes and time frames are agreed with the relevant people	Conducts education for self-managing tuberculosis, in Nursing care of the older adult, p. 1277
			Conducts education for self-managing tuberculosis, in Nursing care plan, p. 1282
	6. Provides safe, appropriate and responsive quality nursing practice	6.1. Provides comprehensive, safe, quality practice to achieve agreed goals and outcomes that are responsive to the nursing needs of people	Includes evidence-based practice in relation to the assessment of the person and subsequent planning and implementation for pneumonia, in Nursing care plan, p. 1272
			Plans and provides appropriate teaching for health promotion in a person with tuberculosis, in Nursing care of the older adult, p. 1275
			Conducts education for self-managing tuberculosis, in Nursing care plan, p. 1280
			When caring for a person with chest tubes, carries out the processes involved in the planning and intervention phases that specifically address the person's needs, in Nursing care of the person, p. 1288
	7. Evaluates outcomes to inform nursing practice	7.1. Evaluates and monitors progress towards the expected goals and outcomes	Evaluates the effectiveness of nursing interventions and teaching, revising strategies and teaching plans as needed, in Nursing care plan, p. 1280
36	1. Thinks critically and analyses nursing practice	1.1. Accesses, analyses and uses the best available evidence, that includes research findings, for safe, quality practice	Incorporates evidence-based practice in relation to ARDS, in Nursing care plan, p. 1364
	4. Comprehensively conducts assessments	4.1. Conducts assessments that are holistic as well as culturally appropriate	Provides appropriate and safe nursing management of medication, in Medication administration, pp. 1318–1319
			Provides comprehensive nursing care for a person with COPD, in Nursing care plan, pp. 1331–1332
			Includes evidence-based practice in relation to the assessment of the person and subsequent planning and implementation for ARDS, in Nursing care plan, p. 1364

CHAPTER	STANDARD	CRITERIA	EVIDENCE-BASED EXAMPLES (INCLUDING PAGE NO.)
			When caring for a person with ARDS, carries out the processes involved in the assessment and planning phases that specifically address the person's needs, in Nursing care plan, p. 1364
	5. Develops a plan for nursing practice	5.1. Uses assessment data and best available evidence to develop a plan	Provides appropriate and safe nursing management of medication, in Medication administration, pp. 1318–1319
			Provides comprehensive nursing care for a person with COPD, in Nursing care plan, pp. 1331–1332
			Uses data and knowledge of the effects of ARDS and prescribed treatment to identify priority nursing diagnoses and to plan care for a person with ARDS, in Nursing care plan, p. 1364
			Uses the nursing process and evidence-based nursing research to plan and implement individualised nursing care for individuals with ARDS, in Nursing care plan, p. 1364
	6. Provides safe, appropriate and responsive quality nursing practice	6.1. Provides comprehensive, safe, quality practice to achieve agreed goals and outcomes that are responsive to the nursing needs of people	Coordinates safe interprofessional care and administers prescribed medications, in Medication administration, pp. 1318–1319
			Provides comprehensive nursing care for a person with COPD, in Nursing care plan, pp. 1331–1332
			Includes evidence-based practice in relation to the assessment of the person and subsequent planning and implementation for ARDS, in Nursing care plan, p. 1364
	7. Evaluates outcomes to inform nursing practice	7.1. Evaluates and monitors progress towards the expected goals and outcomes	Provides appropriate and safe nursing management of medication, in Medication administration, pp. 1318–1319
			Evaluates the effectiveness of nursing interventions and teaching, revising strategies and teaching plans as needed, in Nursing care plan, pp. 1331–1332
Unit 10 Responses to Altered Musculoskeletal Function			
37	2. Engages in therapeutic and professional relationships	2.6. Uses delegation, supervision, coordination, consultation and referrals in professional relationships to achieve improved health outcomes	Monitors the results of diagnostic tests and reports abnormal findings, in Diagnostic tests, pp. 1382–1383
	4. Comprehensively conducts assessments	4.1. Conducts assessments that are holistic as well as culturally appropriate	Conducts a health history for a person with an alteration in musculoskeletal function, in Functional health pattern interview, p. 1379
			Conducts a physical assessment of the musculoskeletal system, in Musculoskeletal assessments, pp. 1383–1388

CHAPTER	STANDARD	CRITERIA	EVIDENCE-BASED EXAMPLES (INCLUDING PAGE NO.)
		4.2. Uses a range of assessment techniques to systematically collect relevant and accurate information and data to inform practice	Conducts and/or assists in the collection of blood samples, tissue samples, synovial fluid, radiographical studies, electrical activity and nerve conduction, in Diagnostic tests, pp. 1382–1383
38	1. Thinks critically and analyses nursing practice	1.1. Accesses, analyses and uses the best available evidence, that includes research findings, for safe, quality practice	Incorporates evidence-based practice in relation to pin site care, in Box 38.4 Nursing interventions for people in traction, p. 1401
	2. Engages in therapeutic and professional relationships	2.2. Communicates effectively and is respectful of a person's dignity, culture, values, beliefs and rights	Conducts education for cast care, sling application, neurovascular assessment, exercise, pain medication and complications, in Box 38.6 Nursing interventions for people with fractures of the humerus, p. 1405
		2.6. Uses delegation, supervision, coordination, consultation and referrals in professional relationships to achieve improved health outcomes	Provides appropriate and safe nursing interventions for people with internal fixation, in Box 38.5 Nursing interventions for people with internal fixation, p. 1403
			Collaborates with the community nurse, physiotherapist and occupational therapist, in Nursing care plan, pp. 1409–1410
	4. Comprehensively conducts assessments	4.1. Conducts assessments that are holistic as well as culturally appropriate	Includes evidence-based practice in relation to the assessment of the person and subsequent planning and implementation for pin site care, in Box 38.4 Nursing interventions for people in traction, p. 1401
			Provides appropriate and safe nursing management of a cast, in Nursing care of the person, p. 1402
			When caring for a person with a hip fracture, carries out the processes involved in the assessment, planning and implementation phases that specifically address the person's needs, in Nursing care plan, pp. 1409–1410
			When caring for a person with a hip fracture, carries out the processes involved in the assessment, planning, intervention and evaluation phases that specifically address the person's nursing in the community, physiotherapy and occupational therapy requirements, in Nursing care plan, pp. 1409–1410
	5. Develops a plan for nursing practice	5.1. Uses assessment data and best available evidence to develop a plan	Uses evidence-based research to plan and implement nursing care for people with skeletal pin sites, in Box 38.4 Nursing interventions for people in traction, p. 1401
			Provides appropriate and safe nursing management of a cast, in Nursing care of the person, p. 1402

CHAPTER	STANDARD	CRITERIA	EVIDENCE-BASED EXAMPLES (INCLUDING PAGE NO.)
			Determines priority nursing diagnoses, based on assessed data, to select and implement individualised nursing interventions for a person with a hip fracture, in Nursing care plan, pp. 1409–1410
		5.2 Collaboratively constructs nursing practice plans until contingencies, options, priorities, goals, actions, outcomes and time frames are agreed with the relevant people	Provides education appropriate for prevention and self-care of traumatic injuries of the musculoskeletal system in relation to cast care, sling application, neurovascular assessment, exercise, pain medication and complications, in Box 38.6 Nursing interventions for people with fractures of the humerus, p. 1405
			Integrates interprofessional care into care of people with musculoskeletal trauma, in Nursing care plan, pp. 1409–1410
	6. Provides safe, appropriate and responsive quality nursing practice	6.1. Provides comprehensive, safe, quality practice to achieve agreed goals and outcomes that are responsive to the nursing needs of people	Includes evidence-based practice in relation to the assessment of the person and subsequent planning and implementation for pin site care, in Box 38.4 Nursing interventions for people in traction, p. 1401
			Provides skilled cast care, in Nursing care of the person, p. 1402
			Conducts education for cast care, sling application, neurovascular assessment, exercise, pain medication and complications, in Box 38.6 Nursing interventions for people with fractures of the humerus, p. 1405
			When caring for a person with a hip fracture, carries out the processes involved in the assessment, planning and implementation phases that specifically address the person's needs, in Nursing care plan, pp. 1409–1410
			When caring for a person with a hip fracture, carries out the processes involved in the assessment, planning, intervention and evaluation phases that specifically address the person's nursing in the community, physiotherapy and occupational therapy requirements, in Nursing care plan, pp. 1409–1410
	7. Evaluates outcomes to inform nursing practice	7.1. Evaluates and monitors progress towards the expected goals and outcomes	Provides appropriate and safe nursing management of a cast, in Nursing care of the person, p. 1402
			When caring for a person with a hip fracture, carries out the processes involved in the assessment, planning, intervention and evaluation phases that specifically address the person's nursing in the community, physiotherapy and occupational therapy requirements, in Nursing care plan, pp. 1409–1410

CHAPTER	STANDARD	CRITERIA	EVIDENCE-BASED EXAMPLES (INCLUDING PAGE NO.)
39	2. Engages in therapeutic and professional relationships	2.2. Communicates effectively and is respectful of a person's dignity, culture, values, beliefs and rights	Provides verbal and written information about rheumatoid arthritis, in Nursing care plan, pp. 1457–1458
		2.6. Uses delegation, supervision, coordination, consultation and referrals in professional relationships to achieve improved health outcomes	Collaborates with the community nurse and physiotherapist, in Nursing care plan, pp. 1446–1447
	4. Comprehensively conducts assessments	4.1. Conducts assessments that are holistic as well as culturally appropriate	When caring for a person with osteoporosis, carries out the processes involved in the assessment, planning and implementation phases that specifically address the person's needs, in Nursing care plan, p. 1428
			When caring for a person with osteoarthritis, carries out the processes involved in the assessment, planning, intervention and evaluation phases that specifically address the multidisciplinary team, in Nursing care plan, pp. 1446–1447
			Provides comprehensive nursing care for a person with rheumatoid arthritis, in Nursing care plan, pp. 1457–1458
			Provides appropriate and safe nursing management of surgical debridement for osteomyelitis, in Nursing care of the person, p. 1470
	5. Develops a plan for nursing practice	5.1. Uses assessment data and best available evidence to develop a plan	Provides appropriate and safe nursing management of medication, in Medication administration, p. 1427
			Determines priority nursing diagnoses, based on assessed data, to select and implement individualised nursing interventions for a person with osteoporosis, in Nursing care plan, p. 1428
			Provides appropriate and safe nursing management of surgical debridement for osteomyelitis, in Nursing care of the person, p. 1470
		5.2. Collaboratively constructs nursing practice plans until contingencies, options, priorities, goals, actions, outcomes and time frames are agreed with the relevant people	Integrates interprofessional care into care of a person with osteoarthritis, in Nursing care plan, pp. 1446–1447
			Provides a teaching plan appropriate for community-based self-care of rheumatoid arthritis, in Nursing care plan, pp. 1457–1458
		5.3. Documents, evaluates and modifies plans accordingly to facilitate the agreed outcomes	Revises plan of care as needed to provide effective interventions to promote, maintain or restore functional health status for a person with osteoarthritis, in Nursing care plan, pp. 1446–1447

CHAPTER	STANDARD	CRITERIA	EVIDENCE-BASED EXAMPLES (INCLUDING PAGE NO.)
	6. Provides safe, appropriate and responsive quality nursing practice	6.1. Provides comprehensive, safe, quality practice to achieve agreed goals and outcomes that are responsive to the nursing needs of people	When caring for a person with osteoporosis, carries out the processes involved in the assessment, planning and implementation phases that specifically address the person's needs, in Nursing care plan, p. 1428
			Administers topical, oral and injectable medications knowledgeably and safely, in Medication administration, p. 1432
			When caring for a person with osteoarthritis, carries out the processes involved in the assessment, planning, intervention and evaluation phases that specifically address the multidisciplinary team, in Nursing care plan, pp. 1446–1447
			Provides comprehensive nursing care for a person with osteoarthritis, in Nursing care plan, pp. 1446–1447
			Conducts education for self-managing rheumatoid arthritis, in Nursing care plan, pp. 1457–1458
			Provides skilled care of people having a surgical debridement for osteomyelitis, in Nursing care of the person, p. 1470
	7. Evaluates outcomes to inform nursing practice	7.1. Evaluates and monitors progress towards the expected goals and outcomes	When caring for a person with osteoarthritis, carries out the processes involved in the assessment, planning, intervention and evaluation phases that specifically address the multidisciplinary team, in Nursing care plan, pp. 1446–1447
			Provides comprehensive nursing care for a person with osteoarthritis, in Nursing care plan, pp. 1446–1447
			Provides appropriate and safe nursing management of surgical debridement for osteomyelitis, in Nursing care of the person, p. 1470
Unit 11 Responses to Altered Neurological Function			
40	2. Engages in therapeutic and professional relationships	2.6. Uses delegation, supervision, coordination, consultation and referrals in professional relationships to achieve improved health outcomes	Monitors the results of diagnostic tests and reports abnormal findings, in Diagnostic tests, pp. 1503–1506
	4. Comprehensively conducts assessments	4.1. Conducts assessments that are holistic as well as culturally appropriate	Conducts a health history for a person with an alteration in neurological function, in Functional health pattern interview, pp. 1501–1502
			Conducts a physical assessment of the neurological system, in Neurological assessments, pp. 1507–1513
		4.2. Uses a range of assessment techniques to systematically collect relevant and accurate information and data to inform practice	Conducts and/or assists in the collection of CSF fluid, radiographical studies, blood flow, electrical activity and nerve conduction, in Diagnostic tests, pp. 1503–1506

CHAPTER	STANDARD	CRITERIA	EVIDENCE-BASED EXAMPLES (INCLUDING PAGE NO.)
			Conducts a physical assessment of the neurological system, in Neurological assessments, pp. 1507–1513
41	1. Thinks critically and analyses nursing practice	1.1. Accesses, analyses and uses the best available evidence, that includes research findings, for safe, quality practice	Incorporates evidence-based practice in relation to seizure disorder, in Nursing care plan, p. 1542
	2. Engages in therapeutic and professional relationships	2.2. Communicates effectively and is respectful of a person's dignity, culture, values, beliefs and rights	Communicates therapeutically, in Nursing care plan, p. 1542
		2.6. Uses delegation, supervision, coordination, consultation and referrals in professional relationships to achieve improved health outcomes	Communicates nursing assessment to the doctor, in Nursing care plan, p. 1536
			Reports seizure activity, in Nursing care plan, p. 1557
	4. Comprehensively conducts assessments	4.1. Conducts assessments that are holistic as well as culturally appropriate	When caring for a person with a migraine headache, carries out the processes involved in the assessment, planning, intervention and evaluation phases that specifically address the multidisciplinary team, in Nursing care plan, p. 1536
			Provides appropriate and safe nursing management of a person with a subdural haematoma, in Nursing care plan, p. 1551
			Conducts a nursing assessment for a person with bacterial meningitis, in Nursing care plan, p. 1557
			Provides comprehensive nursing care for a person with bacterial meningitis, in Nursing care plan, p. 1557
			When caring for a person with a brain tumour, carries out the processes involved in the assessment, planning and implementation phases that specifically address the person's needs, in Nursing care plan, p. 1564
	5. Develops a plan for nursing practice	5.1. Uses assessment data and best available evidence to develop a plan	Provides appropriate and safe nursing management of medication, in Medication administration, p. 1527
			Provides appropriate and safe nursing management of a person with a subdural haematoma, in Nursing care plan, p. 1551
			Determines priority nursing diagnoses, based on assessed data, to select and implement individualised nursing interventions for a person with a brain tumour, in Nursing care plan, p. 1564

CHAPTER	STANDARD	CRITERIA	EVIDENCE-BASED EXAMPLES (INCLUDING PAGE NO.)
		5.2. Collaboratively constructs nursing practice plans until contingencies, options, priorities, goals, actions, outcomes and time frames are agreed with the relevant people	Integrates interprofessional care into care of a person with a migraine headache, in Nursing care plan, p. 1536 Provides appropriate teaching and evidence-based practice to facilitate community-based care to promote safety and prevent injury, and to provide information and support necessary for long-term care of a person with a seizure disorder, in Nursing care plan, p. 1542
		5.3. Documents, evaluates and modifies plans accordingly to facilitate the agreed outcomes	Revises plan of care as needed to provide effective interventions to promote, maintain or restore functional health status for a person with bacterial meningitis, in Nursing care plan, p. 1557
	6. Provides safe, appropriate and responsive quality nursing practice	6.1. Provides comprehensive, safe, quality practice to achieve agreed goals and outcomes that are responsive to the nursing needs of people	Administers oral and injectable medications knowledgeably and safely, in Medication administration, p. 1527 When caring for a person with a migraine headache, carries out the processes involved in the assessment, planning, intervention and evaluation phases that specifically address the multidisciplinary team, in Nursing care plan, p. 1536 Conducts education for seizure disorder, in Nursing care plan, pp. 1542 Provides skilled care to a person with a subdural haematoma, in Nursing care plan, p. 1551 Conducts a nursing assessment for a person with bacterial meningitis, in Nursing care plan, p. 1557 Provides comprehensive nursing care for a person with bacterial meningitis, in Nursing care plan, p. 1557 When caring for a person with a brain tumour, carries out the processes involved in the assessment, planning and implementation phases that specifically address the person's needs, in Nursing care plan, p. 1564
	7. Evaluates outcomes to inform nursing practice	7.1. Evaluates and monitors progress towards the expected goals and outcomes	When caring for a person with a migraine headache, carries out the processes involved in the assessment, planning, intervention and evaluation phases that specifically address the multidisciplinary team, in Nursing care plan, p. 1536 Provides appropriate and safe nursing management of a person with a subdural haematoma, in Nursing care plan, p. 1551

CHAPTER	STANDARD	CRITERIA	EVIDENCE-BASED EXAMPLES (INCLUDING PAGE NO.)
			Assesses functional status of people with intracranial disorders and monitors, documents and reports abnormal findings, in Nursing care plan, p. 1557
			Provides comprehensive nursing care for a person with bacterial meningitis, in Nursing care plan, p. 1557
42	1. Thinks critically and analyses nursing practice	1.1. Accesses, analyses and uses the best available evidence, that includes research findings, for safe, quality practice	Incorporates evidence-based practice in relation to rapid treatment of stroke, in Translation to practice, p. 1577
	2. Engages in therapeutic and professional relationships	2.2. Communicates effectively and is respectful of a person's dignity, culture, values, beliefs and rights	Communicates therapeutically, in Meeting individualised needs, p. 1601
		2.6. Uses delegation, supervision, coordination, consultation and referrals in professional relationships to achieve improved health outcomes	Collaborates with the community nurse, in Nursing care plan, p. 1579
	4. Comprehensively conducts assessments	4.1. Conducts assessments that are holistic as well as culturally appropriate	Provides appropriate and safe nursing management of a person having a carotid endarterectomy, in Nursing care of the person, p. 1576
			Includes evidence-based practice in relation to the assessment of the person and subsequent planning, implementation and evaluation of stroke, in Translation to practice, p. 1577
			When caring for a person with a stroke, carries out the processes involved in the assessment, planning, intervention and evaluation phases that specifically address the multidisciplinary team, in Nursing care plan, p. 1586
			Provides comprehensive nursing care for a person with a stroke, in Nursing care plan, p. 1579
			When caring for a person with an SCI, carries out the processes involved in the assessment, planning and implementation phases that specifically address the person's needs, in Nursing care plan, p. 1593
	5. Develops a plan for nursing practice	5.1. Uses assessment data and best available evidence to develop a plan	Provides appropriate and safe nursing management of medication, in Medication administration, p. 1590
			Provides appropriate and safe nursing management of a person with a carotid endarterectomy, in Nursing care of the person, p. 1576

CHAPTER	STANDARD	CRITERIA	EVIDENCE-BASED EXAMPLES (INCLUDING PAGE NO.)
		5.2. Collaboratively constructs nursing practice plans until contingencies, options, priorities, goals, actions, outcomes and time frames are agreed with the relevant people	Uses evidence-based research to promote early recognition and treatment of the warning signs of a stroke, in Translation to practice, p. 1577 Integrates interprofessional care into care of a person with a stroke, in Nursing care plan, p. 1579 Determine priority nursing diagnoses, based on assessed data, to select and implement individualised nursing interventions for a person with an SCI, in Nursing care plan, p. 1593 Provides appropriate teaching to facilitate self-care of a ruptured intervertebral disc, in Meeting individualised needs, p. 1601
		5.3. Documents, evaluates and modifies plans accordingly to facilitate the agreed outcomes	Revises plan of care as needed to provide effective interventions to promote, maintain or restore functional health status for a person with a stroke, in Nursing care plan, p. 1579
	6. Provides safe, appropriate and responsive quality nursing practice	6.1. Provides comprehensive, safe, quality practice to achieve agreed goals and outcomes that are responsive to the nursing needs of people	Provides skilled care to a person with a carotid endarterectomy, in Nursing care of the person, p. 1576 Includes evidence-based practice in relation to the assessment of the person and subsequent planning, implementation and evaluation of stroke, in Translation to practice, p. 1577 When caring for a person with a stroke, carries out the processes involved in the assessment, planning, intervention and evaluation phases that specifically address the multidisciplinary team, in Nursing care plan, p. 1579 Provides comprehensive nursing care for a person with a stroke, in Nursing care plan, p. 1579 Administers oral medications knowledgeably and safely, in Medication administration, p. 1590 When caring for a person with an SCI, carries out the processes involved in the assessment, planning and implementation phases that specifically address the person's needs, in Nursing care plan, p. 1593 Conducts education for self-managing a ruptured intervertebral disc, in Meeting individualised needs, p. 1601
	7. Evaluates outcomes to inform nursing practice	7.1. Evaluates and monitors progress towards the expected goals and outcomes	Provides appropriate and safe nursing management of a person with a carotid endarterectomy, in Nursing care of the person, p. 1576

CHAPTER	STANDARD	CRITERIA	EVIDENCE-BASED EXAMPLES (INCLUDING PAGE NO.)
			Includes evidence-based practice in relation to the assessment of the person and subsequent planning, implementation and evaluation of stroke, in Translation to practice, p. 1577
			When caring for a person with a stroke, carries out the processes involved in the assessment, planning, intervention and evaluation phases that specifically address the multidisciplinary team, in Nursing care plan, p. 1579
			Provides comprehensive nursing care for a person with a stroke, in Nursing care plan, p. 1579
43	1. Thinks critically and analyses nursing practice	1.1. Accesses, analyses and uses the best available evidence, that includes research findings, for safe, quality practice	Incorporates evidence-based practice in relation to MS, in Nursing care plan, p. 1624
	2. Engages in therapeutic and professional relationships	2.6. Uses delegation, supervision, coordination, consultation and referrals in professional relationships to achieve improved health outcomes	Collaborates with the physiotherapist and occupational therapist, in Nursing care plan, p. 1630
	4. Comprehensively conducts assessments	4.1. Conducts assessments that are holistic as well as culturally appropriate	Provides comprehensive nursing care for a person with AD, in Nursing care plan, pp. 1612–1613
			Includes evidence-based practice in relation to the assessment of the person and subsequent planning and implementation of nursing care for MS, in Nursing care plan, p. 1624
			Provides comprehensive nursing care for a person having plasmapheresis, in Nursing care of the person, p. 1641
			When caring for a person with PD, carries out the processes involved in the assessment, planning, intervention and evaluation phases that specifically address the multidisciplinary team, in Nursing care plan, p. 1630
			When caring for a person with myasthenia gravis, carries out the processes involved in the assessment, planning and implementation phases that specifically address the person's needs, in Nursing care plan, p. 1643
	5. Develops a plan for nursing practice	5.1. Uses assessment data and best available evidence to develop a plan	Provides appropriate and safe nursing management of medication, in Medication administration, p. 1611
			Uses evidence-based research to design nursing interventions specific to the needs of ageing people with MS, in Nursing care plan, p. 1624
			Provides comprehensive nursing care for a person having plasmapheresis, in Nursing care of the person, p. 1641

CHAPTER	STANDARD	CRITERIA	EVIDENCE-BASED EXAMPLES (INCLUDING PAGE NO.)
			Determines priority nursing diagnoses, based on assessed data, to select and implement individualised nursing interventions for a person with myasthenia gravis, in Nursing care plan, p. 1643
		5.2. Collaboratively constructs nursing practice plans until contingencies, options, priorities, goals, actions, outcomes and time frames are agreed with the relevant people	Integrates interprofessional care for a person with PD, in Nursing care plan, p. 1630
		5.3. Documents, evaluates and modifies plans accordingly to facilitate the agreed outcomes	Revises plan of care as needed to provide effective interventions to promote, maintain or restore functional health status of a person with AD, in Nursing care plan, pp. 1612–1613
	6. Provides safe, appropriate and responsive quality nursing practice	6.1. Provides comprehensive, safe, quality practice to achieve agreed goals and outcomes that are responsive to the nursing needs of people	Administers oral and injectable medications knowledgeably and safely, in Medication administration, p. 1611
			Provides comprehensive nursing care for a person with AD, in Nursing care plan, pp. 1612–1613
			Includes evidence-based practice in relation to the assessment of the person and subsequent planning and implementation of nursing care for MS, in Nursing care plan, p. 1624
			When caring for a person with PD, carries out the processes involved in the assessment, planning, intervention and evaluation phases that specifically address the multidisciplinary team, in Nursing care plan, p. 1630
			Provides skilled care for a person having plasmapheresis, in Nursing care of the person, p. 1641
			When caring for a person with myasthenia gravis, carries out the processes involved in the assessment, planning and implementation phases that specifically address the person's needs, in Nursing care plan, p. 1643
	7. Evaluates outcomes to inform nursing practice	7.1. Evaluates and monitors progress towards the expected goals and outcomes	Provides comprehensive nursing care for a person with AD, in Nursing care plan, pp. 1612–1613
			When caring for a person with PD, carries out the processes involved in the assessment, planning, intervention and evaluation phases that specifically address the multidisciplinary team, in Nursing care plan, p. 1630
			Provides comprehensive nursing care for a person having plasmapheresis, in Nursing care of the person, p. 1641

CHAPTER	STANDARD	CRITERIA	EVIDENCE-BASED EXAMPLES (INCLUDING PAGE NO.)
Unit 12 Responses to Altered Visual and Auditory Function			
44	2. Engages in therapeutic and professional relationships	2.6. Uses delegation, supervision, coordination, consultation and referrals in professional relationships to achieve improved health outcomes	Monitors the results of diagnostic tests and reports abnormal findings, in Diagnostic tests, pp. 1667; 1678
	4. Comprehensively conducts assessments	4.1. Conducts assessments that are holistic as well as culturally appropriate	Conducts a health history for a person with an alteration in visual function, in Functional health pattern interview, p. 1665
		4.2. Uses a range of assessment techniques to systematically collect relevant and accurate information and data to inform practice	Conducts and/or assists in the collection of refraction, intraocular pressure and radiographical studies, in Diagnostic tests, p. 1667
			Conducts a physical assessment of the auditory system, in Ear and hearing assessments, pp. 1679–1680
45	1. Thinks critically and analyses nursing practice	1.1. Accesses, analyses and uses the best available evidence, that includes research findings, for safe, quality practice	Incorporates evidence-based practice in relation to the nursing care of blindness, in Nursing care of the person, p. 1684
	2. Engages in therapeutic and professional relationships	2.2. Communicates effectively and is respectful of a person's dignity, culture, values, beliefs and rights	Communicates therapeutically, in Nursing care of the person, p. 1690
		2.3. Recognises that people are the experts in the experience of their life	Involves person with decision making, in Nursing care of the person, p. 1684
		2.6. Uses delegation, supervision, coordination, consultation and referrals in professional relationships to achieve improved health outcomes	Collaborates with the social worker, in Nursing care plan, p. 1703
	4. Comprehensively conducts assessments	4.1. Conducts assessments that are holistic as well as culturally appropriate	When caring for a person with glaucoma and cataracts, carries out the processes involved in the assessment, planning and implementation phases that specifically address the person's needs, in Nursing care plan, p. 1703
			When caring for a person with glaucoma and cataracts, carries out the processes involved in the assessment, planning, intervention and evaluation phases that specifically address the multidisciplinary team, in Nursing care plan, p. 1703
	5. Develops a plan for nursing practice	5.1. Uses assessment data and best available evidence to develop a plan	Plans and implements appropriate and individualised evidence-based nursing interventions and education for blindness, in Nursing care of the person, p. 1684
			Provides appropriate and safe nursing management of a person who is having eye surgery, in Nursing care of the person, p. 1690

CHAPTER	STANDARD	CRITERIA	EVIDENCE-BASED EXAMPLES (INCLUDING PAGE NO.)
			Provides appropriate and safe nursing management of medication, in Medication administration, p. 1701
			Using assessed data, determines priority nursing interventions and care for a person with glaucoma and cataracts, in Nursing care plan, p. 1703
		5.2. Collaboratively constructs nursing practice plans until contingencies, options, priorities, goals, actions, outcomes and time frames are agreed with the relevant people	Collaborates with other members of the healthcare team to provide effective care for a person with glaucoma and cataracts, in Nursing care plan, p. 1703
	6. Provides safe, appropriate and responsive quality nursing practice	6.1. Provides comprehensive, safe, quality practice to achieve agreed goals and outcomes that are responsive to the nursing needs of people	Includes evidence-based practice in relation to the planning and implementation of nursing care for blindness, in Nursing care of the person, p. 1684
			Provides appropriate care and education for a person who is having eye surgery, in Nursing care of the person, p. 1690
			Safely and effectively administers eye medications, in Medication administration, p. 1701
			When caring for a person with glaucoma and cataracts, carries out the processes involved in the assessment, planning and implementation phases that specifically address the person's needs, in Nursing care plan, p. 1703
			When caring for a person with glaucoma and cataracts, carries out the processes involved in the assessment, planning, intervention and evaluation phases that specifically address the multidisciplinary team, in Nursing care plan, p. 1703
	7. Evaluates outcomes to inform nursing practice	7.1. Evaluates and monitors progress towards the expected goals and outcomes	When caring for a person with glaucoma and cataracts, carries out the processes involved in the assessment, planning, intervention and evaluation phases that specifically address the multidisciplinary team, in Nursing care plan, p. 1703
Unit 13 Responses to Altered Reproductive Function			
46	2. Engages in therapeutic and professional relationships	2.6. Uses delegation, supervision, coordination, consultation and referrals in professional relationships to achieve improved health outcomes	Monitors the results of diagnostic tests and reports abnormal findings, in Diagnostic tests, pp. 1736–1737
	4. Comprehensively conducts assessments	4.2. Uses a range of assessment techniques to systematically collect relevant and accurate information and data to inform practice	Conducts a health history for a man with an alteration in the male reproductive system, in Functional health pattern interview, p. 1735

CHAPTER	STANDARD	CRITERIA	EVIDENCE-BASED EXAMPLES (INCLUDING PAGE NO.)
			Conducts and/or assists in the collection of blood samples and cell and tissue samples, and radiographical studies, in Diagnostic tests, pp. 1736–1737
			Conducts a physical assessment of the female reproductive system, in Female reproductive assessments, pp. 1751–1754
47	1. Thinks critically and analyses nursing practice	1.1. Accesses, analyses and uses the best available evidence, that includes research findings, for safe, quality practice	Incorporates evidence-based practice in relation to discharge education, in Translation to practice, p. 1777
	4. Comprehensively conducts assessments	4.1. Conducts assessments that are holistic as well as culturally appropriate	Provides appropriate and safe nursing management of a man having a prostatectomy, in Nursing care of the man, pp. 1771–1772
			Includes evidence-based practice in relation to the assessment of the person and subsequent planning, implementation and evaluation of discharge education, in Translation to practice, p. 1777
			Provides comprehensive nursing care for a man with prostate cancer, in Nursing care plan, p. 1780
			When caring for a man with prostate cancer, carries out the processes involved in the assessment, planning and implementation phases that specifically address the man's needs, in Nursing care plan, p. 1780
	5. Develops a plan for nursing practice	5.1. Uses assessment data and best available evidence to develop a plan	Provides appropriate and safe nursing management of a man having a prostatectomy, in Nursing care of the man, pp. 1771–1772
			Uses evidence-based research to provide information and education to men having a radical prostatectomy, in Translation to practice, p. 1777
			Determines priority nursing diagnoses, based on assessed data, to select and implement individualised nursing interventions for a man with prostate cancer, in Nursing care plan, p. 1780
		5.3. Documents, evaluates and modifies plans accordingly to facilitate the agreed outcomes	Revises plan of care as needed to provide effective interventions to promote, maintain or restore functional health status for a man with prostate cancer, in Nursing care plan, p. 1780
	6. Provides safe, appropriate and responsive quality nursing practice	6.1. Provides comprehensive, safe, quality practice to achieve agreed goals and outcomes that are responsive to the nursing needs of people	Provides skilled care to a man undergoing prostate surgery, in Nursing care of the man, pp. 1771–1772

CHAPTER	STANDARD	CRITERIA	EVIDENCE-BASED EXAMPLES (INCLUDING PAGE NO.)
			Includes evidence-based practice in relation to the assessment of the person and subsequent planning, implementation and evaluation of discharge education, in Translation to practice, p. 1777
			Provides comprehensive nursing care for a man with prostate cancer, in Nursing care plan, p. 1780
			When caring for a man with prostate cancer, carries out the processes involved in the assessment, planning and implementation phases that specifically address the man's needs, in Nursing care plan, p. 1780
	7. Evaluates outcomes to inform nursing practice	7.1. Evaluates and monitors progress towards the expected goals and outcomes	Includes evidence-based practice in relation to the assessment of the man and subsequent planning, implementation and evaluation of discharge education, in Translation to practice, p. 1777
			Provides appropriate and safe nursing management of a man having a prostatectomy, in Nursing care of the man, pp. 1771–1772
			Provides comprehensive nursing care for a man with prostate cancer, in Nursing care plan, p. 1780
48	1. Thinks critically and analyses nursing practice	1.1. Accesses, analyses and uses the best available evidence, that includes research findings, for safe, quality practice	Incorporates evidence-based practice in relation to breast and cervical cancer, in Translation to practice, p. 1823
		1.2. Develops practice through reflection on experiences, knowledge, actions, feelings and beliefs to identify how these shape practice	Incorporates evidence-based practice in relation to breast and cervical cancer, in Translation to practice, p. 1823
	2. Engages in therapeutic and professional relationships	2.2. Communicates effectively and is respectful of a person's dignity, culture, values, beliefs and rights	Communicates therapeutically, in Meeting individualised needs, p. 1785
		2.6. Uses delegation, supervision, coordination, consultation and referrals in professional relationships to achieve improved health outcomes	Collaborates with the counsellor and dietitian, in Nursing care plan, pp. 1800–1801
	4. Comprehensively conducts assessments	4.1. Conducts assessments that are holistic as well as culturally appropriate	Provides appropriate and safe nursing management of a woman having a hysterectomy, in Nursing care of the woman, p. 1793
			When caring for a woman with endometriosis, carries out the processes involved in the assessment, planning, intervention and evaluation phases that specifically address the multidisciplinary team, in Nursing care plan, pp. 1800–1801

CHAPTER	STANDARD	CRITERIA	EVIDENCE-BASED EXAMPLES (INCLUDING PAGE NO.)
			When caring for a woman with cervical cancer, carries out the processes involved in the assessment, planning and implementation phases that specifically address the woman's needs, in Nursing care plan, pp. 1803–1804
			Provides comprehensive nursing care for a woman with breast cancer, in Nursing care plan, p. 1821
			Includes evidence-based practice in relation to the assessment of the person and subsequent planning of nursing care for breast and cervical cancer, in Translation to practice, p. 1823
	5. Develops a plan for nursing practice	5.1. Uses assessment data and best available evidence to develop a plan	Provides appropriate and safe nursing management of a woman having a hysterectomy, in Nursing care of the woman, p. 1793
			Determines priority nursing diagnoses, based on assessed data, to select and implement individualised nursing interventions for a woman with cervical cancer, in Nursing care plan, pp. 1803–1804
			Provides appropriate and safe nursing management of medication, in Medication administration, p. 1818
			Uses evidence-based research to design interventions to promote early diagnosis and treatment of all Australian women with cervical and breast cancer, with particular focus on the health disparities for women from areas of social disadvantage; for example, women living in remote and rural areas of Australia or Indigenous women, in Translation to practice, p. 1823
		5.2. Collaboratively constructs nursing practice plans until contingencies, options, priorities, goals, actions, outcomes and time frames are agreed with the relevant people	Provides health education appropriate for community-based self-care of sexual function, in Meeting individualised needs, p. 1785
			Integrates an interprofessional approach into care for a woman with endometriosis, in Nursing care plan, pp. 1800–1801
		5.3. Documents, evaluates and modifies plans accordingly to facilitate the agreed outcomes	Revises plan of care as needed to provide effective interventions to promote, maintain or restore functional health status to a woman with breast cancer, in Nursing care plan, p. 1821
	6. Provides safe, appropriate and responsive quality nursing practice	6.1. Provides comprehensive, safe, quality practice to achieve agreed goals and outcomes that are responsive to the nursing needs of people	Conducts education for self-managing sexual function, in Meeting individualised needs, p. 1785

CHAPTER	STANDARD	CRITERIA	EVIDENCE-BASED EXAMPLES (INCLUDING PAGE NO.)
			Provides skilled care for a woman having a hysterectomy, in Nursing care of the woman, p. 1793
			When caring for a woman with endometriosis, carries out the processes involved in the assessment, planning, intervention and evaluation phases that specifically address the multidisciplinary team, in Nursing care plan, pp. 1800–1801
			Provides comprehensive nursing care for a woman with breast cancer, in Nursing care plan, p. 1821
			When caring for a woman with cervical cancer, carries out the processes involved in the assessment, planning and implementation phases that specifically address the woman's needs, in Nursing care plan, pp. 1803–1804
			Administers medications knowledgeably and safely, in Medication administration, p. 1818
	7. Evaluates outcomes to inform nursing practice	7.1. Evaluates and monitors progress towards the expected goals and outcomes	Provides appropriate and safe nursing management of a woman having a hysterectomy, in Nursing care of the woman, p. 1793
			When caring for a woman with endometriosis, carries out the processes involved in the assessment, planning, intervention and evaluation phases that specifically address the multidisciplinary team, in Nursing care plan, pp. 1800–1801
			Provides comprehensive nursing care for a woman with breast cancer, in Nursing care plan, p. 1821
49	2. Engages in therapeutic and professional relationships	2.2. Communicates effectively and is respectful of a person's dignity, culture, values, beliefs and rights	Provides written and verbal information for self-managing syphilis, in Nursing care plan, pp. 1844–1845
		2.6. Uses delegation, supervision, coordination, consultation and referrals in professional relationships to achieve improved health outcomes	Collaborates with relationship counsellor, in Nursing care plan, pp. 1844–1845
	4. Comprehensively conducts assessments	4.1. Conducts assessments that are holistic as well as culturally appropriate	When caring for a person with gonorrhoea, carries out the processes involved in the assessment, planning and implementation phases that specifically address the person's needs, in Nursing care plan, p. 1841
			Provides comprehensive nursing care for the person who has syphilis, in Nursing care plan, pp. 1844–1845

CHAPTER	STANDARD	CRITERIA	EVIDENCE-BASED EXAMPLES (INCLUDING PAGE NO.)
			When caring for a person with syphilis, carries out the processes involved in the assessment, planning, intervention and evaluation phases that specifically address the multidisciplinary team, in Nursing care plan, pp. 1844–1845
	5. Develops a plan for nursing practice	5.1. Uses assessment data and best available evidence to develop a plan	Provides appropriate and safe nursing management of medication, in Medication administration, p. 1835
			Determines nursing priorities and selects and implements individualised nursing intervention for a person with gonorrhoea, in Nursing care plan, p. 1841
		5.2. Collaboratively constructs nursing practice plans until contingencies, options, priorities, goals, actions, outcomes and time frames are agreed with the relevant people	Integrates interprofessional care into care of a person with syphilis, in Nursing care plan, pp. 1844–1845
			Conducts education for self-managing syphilis, in Nursing care plan, pp. 1844–1845
		5.3. Documents, evaluates and modifies plans accordingly to facilitate the agreed outcomes	Revises plan of care as needed to provide effective interventions to promote, maintain or restore functional health status for the person who has syphilis, in Nursing care plan, pp. 1844–1845
	6. Provides safe, appropriate and responsive quality nursing practice	6.1. Provides comprehensive, safe, quality practice to achieve agreed goals and outcomes that are responsive to the nursing needs of people	Administers topical medications knowledgeably and safely, in Medication administration, p. 1835
			When caring for a person with gonorrhoea, carries out the processes involved in the assessment, planning and implementation phases that specifically address the person's needs, in Nursing care plan, p. 1841
			When caring for a person with syphilis, carries out the processes involved in the assessment, planning, intervention and evaluation phases that specifically address the multidisciplinary team, in Nursing care plan, pp. 1844–1845
			Provides teaching appropriate for prevention, control and self-care of syphilis, in Nursing care plan, pp. 1844–1845
			Provides comprehensive nursing care for the person who has syphilis, in Nursing care plan, pp. 1844–1845

CHAPTER	STANDARD	CRITERIA	EVIDENCE-BASED EXAMPLES (INCLUDING PAGE NO.)
	7. Evaluates outcomes to inform nursing practice	7.1. Evaluates and monitors progress towards the expected goals and outcomes	When caring for a person with syphilis, carries out the processes involved in the assessment, planning, intervention and evaluation phases that specifically address the multidisciplinary team, in Nursing care plan, pp. 1844–1845
			Provides comprehensive nursing care for the person who has syphilis, in Nursing care plan, pp. 1844–1845
Unit 14 Special Topics in Medical–Surgical Nursing			
50	1. Thinks critically and analyses nursing practice	1.1. Accesses, analyses and uses the best available evidence, that includes research findings, for safe, quality practice	Incorporates the Recovery Model as the framework for mental healthcare, in Recovery, pp. 1860–1863
	4. Comprehensively conducts assessments	4.1. Conducts assessments that are holistic as well as culturally appropriate	Conducts a mental state assessment of the person, in Box 50.4 Components of a mental state assessment, p. 1864
			Includes evidence-based practice in relation to the assessment of the person and subsequent planning and implementation of mental health nursing care, in Recovery, pp. 1860–1863
	5. Develops a plan for nursing practice	5.1. Uses assessment data and best available evidence to develop a plan	Uses an evidence-based approach to design interventions which promote Recovery, in Recovery, pp. 1860–1863
	6. Provides safe, appropriate and responsive quality nursing practice	6.1. Provides comprehensive, safe, quality practice to achieve agreed goals and outcomes that are responsive to the nursing needs of people	Includes evidence-based practice in relation to the assessment of the person and subsequent planning and implementation of mental health nursing care, in Recovery, pp. 1860–1863
51	1. Thinks critically and analyses nursing practice	1.2. Practises within a professional and ethical nursing framework	Incorporates primary care principles in nursing service delivery, in Primary healthcare and primary care, pp. 1882–1884
	4. Comprehensively conducts assessments	4.1. Conducts assessments that are holistic as well as culturally appropriate	Provides comprehensive nursing care for the person and the community, in Primary healthcare and primary care, pp. 1882–1884
	5. Develops a plan for nursing practice	5.1. Uses assessment data and best available evidence to develop a plan	Incorporate the principles of primary care into the provision of nursing care in the regional, rural and remote setting, in Primary healthcare and primary care, pp. 1882–1884
	6. Provides safe, appropriate and responsive quality nursing practice	6.1. Provides comprehensive, safe, quality practice to achieve agreed goals and outcomes that are responsive to the nursing needs of people	Provides comprehensive nursing care for the person and the community, in Primary healthcare and primary care, pp. 1882–1884
	7. Evaluates outcomes to inform nursing practice	7.1. Evaluates and monitors progress towards the expected goals and outcomes	Provides comprehensive nursing care for the person and the community, in Primary healthcare and primary care, pp. 1882–1884
52	1. Thinks critically and analyses nursing practice	1.2. Practises within a professional and ethical nursing framework	Practises cultural safety, in Indigenous health considerations in regional, rural and remote areas, pp. 1897–1898

CHAPTER	STANDARD	CRITERIA	EVIDENCE-BASED EXAMPLES (INCLUDING PAGE NO.)
	2. Engages in therapeutic and professional relationships	2.2. Communicates effectively and is respectful of a person's dignity, culture, values, beliefs and rights	Establishes a therapeutic relationship based on trust, in Establishing boundaries, p. 1905
		2.6. Uses delegation, supervision, coordination, consultation and referrals in professional relationships to achieve improved health outcomes	Consults and/or refers to specialist healthcare individuals/organisations, in Acute assessment and emergency nursing care, pp. 1901–1905
	4. Comprehensively conducts assessments	4.1. Conducts assessments that are holistic as well as culturally appropriate	Provides culturally sensitive nursing care with the person and the community as active participants, in Indigenous health considerations in regional, rural and remote areas, pp. 1897–1898
			Conducts comprehensive assessment of the person and subsequent planning, implementation and evaluation of care, including referral and transfer, in Acute assessment and emergency nursing care, pp. 1901–1905
			Provides comprehensive nursing care for a person in the community, in Establishing boundaries, p. 1905
	5. Develops a plan for nursing practice	5.1. Uses assessment data and best available evidence to develop a plan	Uses assessment findings to determine initial nursing care, referral and transfer as deemed necessary, in Acute assessment and emergency nursing care, pp. 1901–1905
		5.2. Collaboratively constructs nursing practice plans until contingencies, options, priorities, goals, actions, outcomes and time frames are agreed with the relevant people	Provides culturally sensitive nursing care with the person and the community as active participants, in Indigenous health considerations in regional, rural and remote areas, pp. 1897–1898
			Uses professional communication skills to develop therapeutic relationships and establish professional boundaries when working in regional, rural and remote communities, in Establishing boundaries, p. 1905
	6. Provides safe, appropriate and responsive quality nursing practice	6.1. Provides comprehensive, safe, quality practice to achieve agreed goals and outcomes that are responsive to the nursing needs of people	Provides culturally safe nursing care, pp. 1897–1898
			Conducts comprehensive assessment of the person and subsequent planning, implementation and evaluation of care, including referral and transfer, in Acute assessment and emergency nursing care, pp. 1901–1905
			Provides comprehensive nursing care for a person in the community, in Establishing boundaries, p. 1905

CHAPTER	STANDARD	CRITERIA	EVIDENCE-BASED EXAMPLES (INCLUDING PAGE NO.)
	7. Evaluates outcomes to inform nursing practice	7.1. Evaluates and monitors progress towards the expected goals and outcomes	Provides culturally sensitive nursing care with the person and the community as active participants, in Indigenous health considerations in regional, rural and remote areas, pp. 1897–1898 Conducts comprehensive assessment of the person and subsequent planning, implementation and evaluation of care, including referral and transfer, in Acute assessment and emergency nursing care, pp. 1901–1905 Provides comprehensive nursing care for a person in the community, in Establishing boundaries, p. 1905

UNIT 1

DIMENSIONS OF MEDICAL–SURGICAL NURSING

CHAPTER 1

MEDICAL–SURGICAL NURSING

TRACY LEVETT-JONES, LORINDA PALMER

KEY TERMS

LEARNING OUTCOMES

- Define and discuss the importance of person-centred care.
- Describe the attitudes, attributes and skills necessary for critical thinking when providing nursing care.
- Outline the stages of the nursing process.
- Outline the stages of the Clinical Reasoning Cycle and how it was designed to positively impact on patient safety.
- Describe the importance of national competency standards, codes of ethics and codes of professional conduct as guidelines for accountable and professional nursing practice.
- Outline the concept of cultural competence as an integral component of nursing care.
- Discuss some of the legal and ethical dilemmas evident in medical–surgical nursing.
- Discuss the roles and functions of the nurse as caregiver, educator, advocate, leader/manager and researcher.

CLINICAL COMPETENCIES

- Demonstrate critical thinking and clinical reasoning when providing evidence-based, safe, person-centred and culturally competent nursing care.
- Provide clinical care within a framework that integrates, as appropriate, the medical–surgical nursing roles of caregiver, educator, advocate, leader/manager and researcher.

Medical–surgical nursing is one component in a suite of nursing services that provide healthcare within an interprofessional approach. The descriptors 'medical' or 'surgical' nursing are broad and you will encounter many specialty practice areas within the general category of medical–surgical nursing; for example, acute care, day surgery, community mental health, general practice, renal dialysis satellite centres and outpatient clinics.

The person with whom and for whom nursing care is designed and implemented may range in age from late teens to 100 years of age or even older. Medical–surgical nursing focuses on a person's response to actual or potential alterations in health and takes into account their history, community and social support network. The wide range of ages, cultural and linguistic diversity and variety of healthcare needs specific to each person make medical–surgical nursing a dynamic, challenging and rewarding area of nursing practice.

Medical–surgical nursing includes the promotion of health, prevention of illness and the care of ill, disabled and dying people across the lifespan and in diverse practice contexts. Nurses are responsible for the provision of safe, empathetic, person-centred, evidence-based care. They communicate and collaborate with patients, families and other health professionals to promote health and wellbeing. Nursing care is guided by clear thinking processes and professional, ethical and legal frameworks. This chapter provides a broad overview of the clinical practice of medical–surgical nursing, including the roles and functions of the medical–surgical nurse.

PERSON-CENTRED CARE

The terms '*person*' and '*patient*' denote the individual who is the recipient of care and may be used interchangeably, depending on the context of care. In this book we generally use the term 'person' as this aligns with the concept of person centred.

Person-centred care means seeing the *person*, not just the patient or their disease process. That is, we speak of a *person* with a disease; for example, 'In bed 4 is Mr Johns who has had an appendectomy'; rather than 'the appendectomy in bed 4', or 'Joanne requires assistance with her meals' rather than 'Joanne is a feed'.

Person-centred nurses are empathetic, respectful, ethical, open-minded and self-aware. They have a profound sense of personal responsibility for actions (moral agency) and place the 'person' at the centre of healthcare, considering the person's needs and wishes as paramount (McCormack & Titchen, 2001; Redman & Lynn, 2004). Integral to person-centred care is therapeutic communication and the nurse's commitment to understanding the person's beliefs and values, life history and cultural and/or linguistic diversity. Person-centred care is central to safe, effective and competent nursing practice. There is a body of evidence indicating that person-centred care results in improved patient outcomes; for example, decreased mortality (Meterko et al., 2010), fewer medication errors (Bolster & Manias, 2010), decreased infection and readmission rates (Isaac et al., 2010) and improved quality of life for people with dementia (Chenoweth et al., 2009).

CRITICAL THINKING

Critical thinking is a complex collection of cognitive skills and affective habits of the mind and has been described as the process of analysing and assessing thinking with a view to improving it (Paul & Elder, 2007). Critical thinking includes the ability to think about one's own thinking; this is called metacognition. To think like a nurse requires you to learn the knowledge, ideas, skills, concepts and theories of nursing, and develop your intellectual capacities to become a disciplined, self-directed, critical thinker capable of clinical reasoning (Paul & Elder, 2007). Critical thinking requires practice so that it becomes integral to your clinical decision making. Learning activities are included throughout this book to provide opportunities for practising critical thinking.

Thinking critically involves more than just cognitive (knowledge) skills. It is strongly influenced by one's attitudes and mental habits. To think critically, you must focus your attention on your attitudes and how they affect your thinking. These attitudes and mental habits include the following:

- Being able to think independently so that you make clinical decisions based on sound thinking and judgment. This means, for example, that you are not influenced by negative comments from other health professionals about a person.
- Being willing to listen to and be fair in your evaluation of others' ideas and beliefs. This involves listening carefully to other ideas and thoughts, and making decisions based on what you have learned instead of how you feel.
- Having empathy and practising empathy in a person-centred way by being able to put yourself in the place of another to better understand that person. For example, if you put yourself in the place of the person with severe pain, you are better able to understand why they are so upset when pain medications are late.
- Being fair minded, just and considerate of all viewpoints before making a decision. This means you consider the viewpoints of others that may be different from yours before reaching a conclusion. You also realise that you are constantly learning from others. You are not afraid to say, 'I don't know the answer to that question, but I will find out and let you know.'
- Being disciplined so that you do not stop at easy answers, but continue to consider alternatives.
- Being creative and self-confident. Nurses often need to consider different ways of providing care and constantly look for improved and more cost-effective methods. Confidence in your decision making is enhanced through effective critical thinking.

The major critical thinking skills are divergent thinking, reasoning, clarifying and reflection. A description of each follows.

Divergent thinking is having the ability to weigh the importance of information. This means that when you collect data (information/cues) from a person, you can sort out the data that are relevant for the care of that person from the data that are not

relevant and then explore alternatives before reaching a conclusion. Abnormal data are usually considered relevant; normal data are helpful but may not change the care you provide.

Reasoning is having the ability to discriminate between facts and guesses. By using known facts, problems are solved and decisions are made in a systematic, logical way. For example, when you take a pulse you must know the parameters of the normal pulse rate for a person of this age, the types of medications the person is taking that may alter their pulse rate, and the emotional and physical state of the person. Based on these facts, you are able to decide if the pulse rate is normal or abnormal.

Clarifying involves noting similarities and differences and sifting out unnecessary information to help focus on the present situation. For example, when caring for a person with persistent (chronic) pain, you must know the definition of persistent pain and the similarities and differences between acute pain and persistent pain.

Reflection is a crucial professional activity and one that is intrinsic to learning. It is not simply introspection but is a deliberate, orderly and structured intellectual activity (Bolton, 2001). It allows nurses to process their experience and explore their understanding of what they are doing, why they are doing it and the impact it has on themselves and others (Levett-Jones, 2007). When this activity is developed and enhanced in relation to personal and professional practice, reflection becomes a purposeful activity that leads to improvement in practice and better patient outcomes.

THE NURSING PROCESS

The **nursing process** has been described as a tool that helps nurses to think critically in order to provide a competent level of care (Alfaro-LeFevre, 2009). The activities within the nursing process define a nursing model of care, differentiating nursing from other helping professions. The nursing process can be used in any setting. The purpose of care may be to promote wellness, maintain health, restore health or facilitate coping with disability or death. Regardless of the purpose of care, the planned process of nursing allows for the inclusion of specific, holistic and person-centred care. The five steps or phases in the nursing process are assessment, diagnosis, planning, implementation and evaluation. These steps are interrelated and interdependent (see Figure 1.1).

This textbook assumes that students already have a basic understanding of the nursing process and are now ready to expand and apply that knowledge to people with medical–surgical health problems. The overview in this book serves only as a review; for more information students should read the case studies in the nursing care chapters throughout the three volumes of this textbook. Table 1.1 articulates the links between the steps of the nursing process steps and the corresponding critical thinking applications.

Assessment

Assessment is usually listed as the first step of the nursing process, but in actuality it is a critical element in each of the steps. It begins with the person's first encounter with the healthcare system and continues as long as the person requires care. During assessment, data (cues or pieces of information) about the person's health status are collected, validated, organised, clustered into patterns and communicated either verbally or in written form. Assessment serves as the basis for deriving an accurate nursing diagnosis, for planning and implementing both initial and ongoing care, and for evaluating the effectiveness of the care provided.

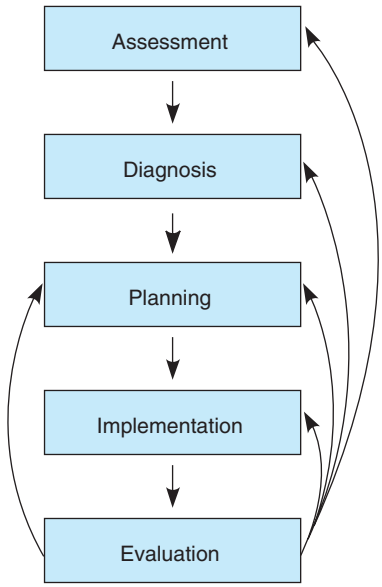

FIGURE 1.1 ■ The nursing process. Steps of the nursing process. Notice that the steps are interrelated and interdependent. For example, evaluation of the person might reveal the need for further assessment, additional nursing diagnoses and/or a revision of the plan of care

The data that the nurse collects must be holistic; that is, the nurse must carefully consider all dimensions of an individual (physical, mental, social, emotional and spiritual). The data collected are both objective and subjective. Information that the nurse perceives by the senses is *objective data*; it is seen, heard, touched or smelled and can be verified by another person (e.g. blood pressure, temperature, pulse or the presence of infected drainage). Information that is perceived only by the person experiencing it (e.g. pain, dizziness or anxiety) is *subjective data*.

Nurses assess people in two ways: through an initial assessment and through focused assessments. The initial assessment of the person, conducted through a nursing history and physical assessment, is necessary to accumulate comprehensive baseline data about health responses, to identify specific factors that contribute to these responses in an individual and to facilitate mutually established goals and outcomes of care.

Focused assessments (e.g. respiratory assessment) enable the nurse to evaluate nursing actions and make decisions about whether to continue or change interventions to meet outcomes. They also provide structure for the documentation of nursing care. In addition, focused assessments enable the nurse to identify responses to a disease process or treatment modality not present during the initial assessment, or to monitor the

TABLE 1.1 Using critical thinking in the nursing process

NURSING PROCESS STEP	CRITICAL THINKING SKILLS	QUESTIONS TO CHECK YOUR THINKING
Assessment	Selecting the correct assessment instrument Making reliable observations Distinguishing relevant from irrelevant data Distinguishing important from unimportant data Validating data Organising data Categorising data according to a framework Recognising assumptions	What assumptions am I making about the person? Are my data correct and accurate? How reliable are my sources? What data are important? Relevant? What biases do I have that might cause me to miss important information? Am I listening carefully to get the person's and family's perspective? Do I have all the facts? What other data might I need?
Diagnosis	Finding patterns and relationships among cues Identifying gaps in the data Making inferences Suspending judgment when lacking data Making interdisciplinary connections Stating the problem Examining assumptions Comparing patterns with norms Identifying factors contributing to the problem	Do I know what is within normal limits for the data? Do I have enough data to make a valid inference? What biases might I have that could affect how I see the person's problems? Do I have enough data to make a nursing diagnosis or should I make a 'possible' diagnosis? What other problems might this data suggest other than the one that seems most obvious to me?
Planning	Forming valid generalisations Transferring knowledge from one situation to another Developing evaluative criteria Hypothesising Making interprofessional connections Prioritising the person's problems Generalising principles from other sciences	Do I need help to plan interventions or am I qualified to do it? Did I remember to give high priority to the problems the person and family identified as important? What are the most important problems we need to address? What interventions worked in similar situations? Is this situation similar enough to merit using them with this person? Are there other plans that might be more agreeable to the person and therefore more likely to work? Why do I expect these interventions to be effective? Based on what knowledge?
Implementation	Applying knowledge to perform interventions Using interventions to test hypotheses	Has the person's condition changed since the plan was made? Have I overlooked any new developments? What is the person's initial response to the intervention? Are there any safety issues I have overlooked?
Evaluation	Deciding whether hypotheses are correct Making criterion-based evaluations	What are the person's responses after the interventions? Have I overlooked anything? Do the data indicate that goals were met? Does the person feel their goals were met? Does the person trust me enough to give honest answers? Am I sure the problem is really resolved? What might we have done that would have been more effective? What nursing care is still needed, if any?

status of an actual or potential problem previously identified (Alfaro-LeFevre, 2009).

To make accurate and holistic assessments, nurses must have and use a wide variety of knowledge and skills. The ability to assess the physical, emotional and mental status of the person is essential, as is the ability to use effective communication techniques. Nurses must be knowledgeable in pathophysiology and pharmacology and be able to identify abnormal

laboratory and diagnostic test data. Finally, nurses must have a solid foundation of nursing knowledge and skills that will enable them to interpret assessment data and to use that interpretation as the basis for individualised care.

Diagnosis

The nurse examines each cluster of data (or pattern) derived from the assessment to develop appropriate nursing diagnoses. Nursing diagnoses are clinical judgments about a person's actual or potential health problems. Nursing diagnoses provide the basis for determining nursing interventions to achieve outcomes for which the nurse is accountable. Nurses then develop and implement a plan of care to address health concerns and prevent illness.

Writing a nursing diagnosis

A nursing diagnosis is generally written in two or three parts and often joined by the phrases 'related to' and 'manifested by'. The first part of the statement is the issue or problem that has been identified from the examination of the data collected during the patient assessment. The part of the statement that follows the phrase 'related to' identifies the physical, psychosocial, cultural, spiritual and/or environmental factors (aetiologies) that cause or contribute to the occurrence of the problem.

Many nurses write nursing diagnoses using the following method:

1. The problem.
2. The aetiology of the problem, which identifies the related factors.
3. The signs and symptoms, which are the defining characteristics of the problem and are indicated by the phrase 'manifested or evidenced by'.

Examples of nursing diagnoses include:

- *Faecal incontinence* related to loss of sphincter control, manifested by frequent and involuntary passage of stool.
- *Acute pain* related to inadequate education about patient-controlled analgesia (PCA) use, manifested by withdrawal, grimacing, restlessness and guarded positioning.
- *Fatigue* related to the side effects of chemotherapy, evidenced by exhaustion when undertaking activities of daily living.

Planning

During the planning step, the nurse identifies appropriate evidence-based nursing interventions (actions) and outcomes to improve health and/or to prevent or ameliorate ill health. These outcomes are usually developed collaboratively by the person and nurse and identify what the person will be able to do as a result of the care provided (Alfaro-LeFevre, 2009). For example, '30 minutes following administration of analgesic medication the person reports a reduction in pain from 8 to 3 on the numeric rating scale'.

Implementation

The implementation step is the action phase of the nursing process during which the nurse carries out planned interventions. Ongoing assessment of the person before, during and after the intervention is an essential component of implementation. Although the plan may be appropriate, many factors can influence how the person responds, making a revision to the plan necessary. For example, the nurse would not be able to encourage fluid intake if the person became nauseous. Additionally, the nurse should be aware of the interrelated nature of nursing interventions. For example, while giving a bed bath the nurse can assess the person's skin condition and at the same time use therapeutic communication to provide comfort.

Documenting interventions is the final component of implementation and is a legal requirement. Many different methods are used to document care, including problem-oriented charting, charting by exception and electronic documentation. Additionally, systems assessments are becoming increasingly common for documentation of progress notes and the development of nursing care plans.

Evaluation

The evaluation step allows the nurse to determine whether the actions taken were effective and whether to continue, revise or terminate the plan of care. The outcome criteria (goals) that were established during the planning step provide the basis for evaluation. Although evaluation is listed as the last part of the nursing process, it takes place continuously throughout each person's care. To evaluate a plan, the nurse collects data from the person and their clinical records. If the outcomes have not been accomplished, the nurse must modify the nursing diagnoses, outcomes or plan.

The nursing process in clinical practice

Experienced nurses may not consciously stop and consider each step of the nursing process. For example, when caring for a person who is haemorrhaging, the nurse would use all five steps simultaneously to meet critical, life-threatening needs. In contrast, when considering long-term needs for a person with a chronic illness or disability, the nurse makes in-depth assessments, mutually determines goals with the person, and provides documentation through a written plan of care that can be developed over time and revised as necessary by all nurses providing care. As a nurse becomes an expert clinician, the nursing process becomes so much a part of their practice that they may not even consciously consider it while providing care (Benner, 1984)

CLINICAL REASONING

Clinical reasoning is often used interchangeably with the terms 'clinical judgment', 'problem solving', 'decision making' and 'critical thinking'. While in some ways the terms are similar, clinical reasoning is a cyclical process that often leads to a series of linked clinical encounters. **Clinical reasoning** can be defined as 'the process by which nurses (and other clinicians) collect cues, process the information, come to an understanding of a person's problem or situation, plan and implement interventions, evaluate outcomes, and reflect on and learn from the process' (Levett-Jones et al., 2010, p. 516; Hoffman, 2007). Clinical reasoning can be influenced by the nurse's assumptions, perspectives, attitudes and preconceptions (McCarthy,

2003) and the capacity for self-awareness of one's cognitive biases is essential to patient safety.

Over the past decade research has identified the need for an explicit and sophisticated model to both explain how expert nurses think and as a foundation for nursing education (Levett-Jones et al., 2010, p. 516; Hoffman, 2007). A model titled the Clinical Reasoning Cycle (CRC) was developed by Australian nurse researchers to clearly articulate how nurses use sophisticated thinking skills to inform their practice decisions and enhance patient safety (see Figure 1.2). The CRC builds upon the nursing process framework and represents the multifaceted and increasingly complex nature of nursing care, and the necessity to respond appropriately to patients' needs, particularly in emergent, non-routine and unpredictable clinical situations. The CRC is integral to students' developing ability to 'think like a nurse' and its explicit meta-cognitive and reflective processes aim to identify and prevent cognitive errors that may lead to adverse patient outcomes. Nurses with inadequate clinical reasoning skills often fail to detect and appropriately respond to patient deterioration (Aiken et al., 2003). Poor clinical reasoning and critical thinking skills have been identified as a factor in more than 50% of adverse clinical events (Wilson et al., 1995).

The Clinical Reasoning Cycle consists of eight main stages or steps: *consider the patient situation, collect cues, process information, identify problems and priorities, establish goals, take action, evaluate outcomes and reflect on process and new learning.*

ACCOUNTABLE AND RESPONSIBLE NURSING PRACTICE

The Australian Nursing and Midwifery Accreditation Council (ANMAC) is responsible for accreditation of nursing and midwifery programs while the Nursing and Midwifery Board of Australia (NMBA) has responsibility for professional registration, professional codes, standards and competency issues.

In Australia there are three key documents that form the basic framework for accountable and responsible practice as a Registered Nurse. These are:

1. Nursing and Midwifery Board of Australia (NMBA) The *National Registered Nurse Standards for Practice (2016).*
2. Nursing and Midwifery Board of Australia (NMBA) *Code of Ethics for Nurses in Australia (2008).*
3. Nursing and Midwifery Board of Australia (NMBA) *Code of Professional Conduct for Nurses in Australia (2008).*

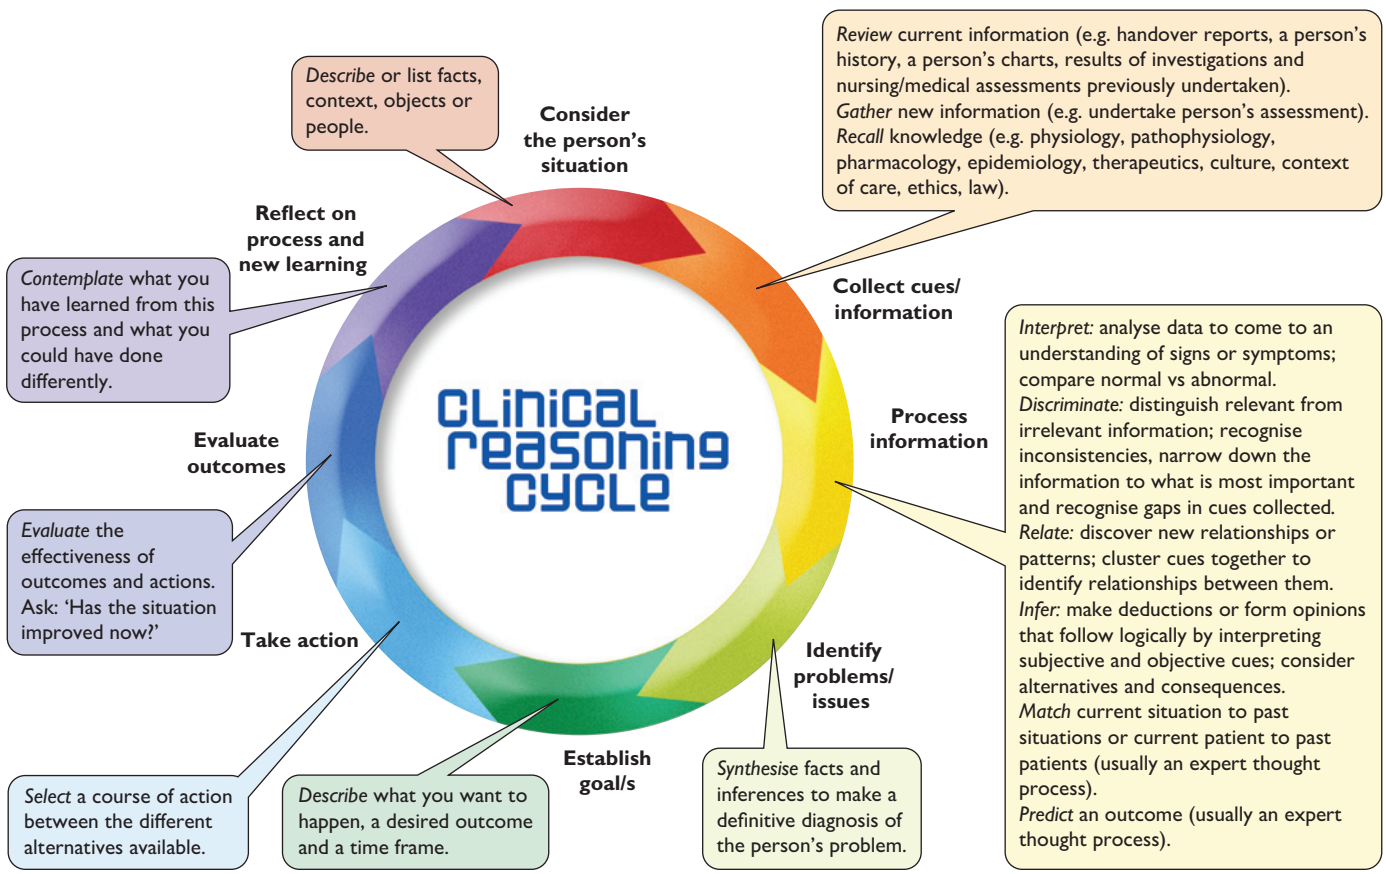

FIGURE 1.2 ■ The clinical reasoning process with descriptors

Source: T. Levett-Jones (2013). *Clinical reasoning: Learning to think like a nurse*, p. 7; adapted from T. Levett-Jones et al. (2010). The 'five rights' of clinical reasoning: An educational model to enhance nursing students' ability to identify and manage clinically 'at risk' patients. *Nurse Education Today*, *30*(6), 515–520.

These key documents are supported by other published practice standards and guidelines such as decision-making frameworks, position statements, professional boundaries and practice guidelines.

Nursing and Midwifery Board of Australia (NMBA) *National Registered Nurse Standards for Practice*

The *National Registered Nurse Standards for Practice (2016)* were developed to promote a national approach to nursing in Australia. These standards are an integral component of the nursing regulatory framework that assists nurses to deliver safe and competent care. They are the standards by which a nurse's performance is assessed to obtain and retain registration to practise as a nurse in Australia. As the ever-changing healthcare needs and expectations of Australians impact on quality and safety within the healthcare system, so must practice standards be regularly reviewed by the nursing profession. The NMBA standards for practice were reviewed and updated during 2015 and were published early in 2016. The standards are organised into domains, as illustrated in Box 1.1.

NMBA Code of Ethics

The NMBA (2013a) *Code of Ethics for Nurses in Australia (2008)* is framed by principles and standards from the United Nations and the World Health Organization (WHO) (1974). The code outlines the nursing profession's commitment to respect, promote, protect and uphold the fundamental rights of people who are both the recipients and providers of nursing and healthcare. The code provides nurses with a reference point from which to reflect on the conduct of themselves and others. It is also a guide to ethical decision making and practice (NMBA, 2013a).

BOX 1.1 Domains of the Nursing and Midwifery Board of Australia (NMBA) *National Registered Nurse Standards for Practice*

1. Thinks critically and analyses nursing practice	Nurses use a variety of thinking strategies, research and best available evidence in making decisions and providing safe, quality nursing practice within a person-centred framework.
2. Engages in therapeutic and professional relationships	Nursing practice is based on purposefully engaging in the formation and maintenance of effective therapeutic and professional relationships. This includes collegial generosity in the context of interdisciplinary and professional relationships.
3. Maintains fitness for practice and participates in lifelong learning	Registered Nurses, as regulated health professionals, are responsible and accountable for ensuring they are safe and have the capability for practice. This includes ongoing self-management and responding when there are concerns about other health professionals' fitness for practice. Registered Nurses are responsible for their professional development and contribute to the development of others. They are also responsible for providing information and education to enable people to make decisions and take action in relation to their health.
4. Comprehensively conducts assessments	Registered Nurses accurately conduct comprehensive and systematic assessments, analyse information and data and communicate outcomes as the basis of practice.
5. Develops a plan for nursing practice	Registered Nurses are responsible for the planning and communication of nursing practice. Agreed plans are developed in partnership. They are based on the Registered Nurse's comprehensive assessment, use of evidence and judgment that is documented and communicated to all the relevant persons.
6. Provides safe, appropriate and responsive quality nursing practice	Registered Nurses delegate and implement person-centred, quality and ethical goal-directed actions. These are based on comprehensive and systematic assessment, and the best available evidence to achieve planned outcomes.
7. Evaluates outcomes to inform nursing practice	Registered Nurses take responsibility for the evaluation of practice based on agreed outcomes to plan and revise practice accordingly.

BOX 1.2 Nursing and Midwifery Board of Australia Code of Ethics for Nurses—Value Statements

1. Nurses value quality nursing care for all people.
2. Nurses value respect and kindness for self and others.
3. Nurses value the diversity of people.
4. Nurses value access to quality nursing and healthcare for all people.
5. Nurses value informed decision making.
6. Nurses value a culture of safety in nursing and healthcare.
7. Nurses value ethical management of information.
8. Nurses value a socially, economically and ecologically sustainable environment promoting health and wellbeing.

Source: Nursing and Midwifery Board of Australia (NMBA) (2013a). *Code of Ethics for Nurses in Australia (2008).* © Nursing and Midwifery Board of Australia, www.nursingmidwiferyboard.gov.au/Codes-Guidelines-Statements/Professional-standards.aspx.

In addition, the *International Council of Nurses' (ICN) Code of Ethics for Nurses* (2012) specifies what nurses are accountable for in terms of people, practice, society, co-workers and the profession. The philosophical base for the ICN code is that nurses are responsible for promoting health, preventing illness, restoring health and alleviating suffering. The *Code of Ethics for Nurses in Australia* should be read in conjunction with the ICN code and related ICN position statements (NMBA, 2013a). Box 1.2 lists the eight value statements to which the Australian nursing profession is committed.

NMBA Code of Professional Conduct

Professional conduct is defined as the manner in which a person behaves while acting in a professional capacity. The *Code of Professional Conduct for Nurses in Australia (2008)* sets the minimum standards for practice that a professional person is expected to uphold, both within and outside professional domains, in order to ensure the 'good standing' of the nursing profession (NMBA, 2013b). This code is a companion to, and should be read in conjunction with, the *Code of Ethics for Nurses in Australia (2008)* (NMBA, 2013a). The code describes ten conduct statements, which are listed in Box 1.3.

BOX 1.3 NMBA Code of Professional Conduct Statements

1. Nurses practise in a safe and competent manner.
2. Nurses practise in accordance with the standards of the profession and broader health system.
3. Nurses practise and conduct themselves in accordance with laws relevant to the profession and practice of nursing.
4. Nurses respect the dignity, culture, ethnicity, values and beliefs of people receiving care and treatment, and of their colleagues.
5. Nurses treat personal information obtained in a professional capacity as private and confidential.
6. Nurses provide impartial, honest and accurate information in relation to nursing care and healthcare products.
7. Nurses support the health, wellbeing and informed decision making of people requiring or receiving care.
8. Nurses promote and preserve the trust and privilege inherent in the relationship between nurses and people receiving care.
9. Nurses maintain and build on the community's trust and confidence in the nursing profession.
10. Nurses practise nursing reflectively and ethically.

CULTURALLY COMPETENT NURSING

The primary focus of nursing care is the person and how they respond to their environment and experiences or situations related to health or illness. These experiences are given shape and personal meaning by **culture**—the socially inherited characteristics of a human group. The healthcare system encompasses many people (staff and patients) who are culturally diverse. This diversity includes differences in country of origin, health beliefs, sexual orientation, race, socioeconomic level and age.

Culture influences us all in our work, home and social lives. We therefore need to understand what the term 'culture' means. Rosenjack-Burcham (2002) defines culture as 'a learned world viewpoint or paradigm shared by a population or group and transmitted socially. It influences values, beliefs, customs and behaviours, and is reflected in the language, dress, food, materials and social interactions of a group' (p. 7). In Leininger's seminal work (1991) culture is described as 'the learned and transmitted values, beliefs and practices . . . the blueprint for living, remaining healthy, or for dying' (p. 36). Culture is primarily learned in our family or community life and can be shared with others. Our own culture can be experienced by us in an unconscious way and can change over time. Culture is therefore different from ethnicity, which is determined at birth. Interacting across cultures requires us to be aware of our own culture and requires an understanding of and skill in interpersonal and group communication.

Increasing cultural and ethnic diversity in most regions of the world over the past 40 years has made provision of culturally competent care essential for nurses and other health professionals (Everson et al., 2015). However, studies indicate that people from non-English-speaking backgrounds experience twice as many adverse health events as English-speaking people (Divi et al., 2007), with misunderstandings, miscommunication and culturally unsafe care by health professionals

frequently reported (Johnstone & Kanitsaki, 2008). Many factors account for culturally unsafe care, including lack of awareness, skills and empathy, as well as ethnocentrism (people's belief that their own cultural group's beliefs and values are the only acceptable ones) and prejudice.

People of every culture have the right to have their cultural values known, respected and addressed appropriately in nursing and other healthcare services (Leininger, 1991). To provide nursing care that is culturally competent, nurses must develop sensitivity to personal fundamental values about health and illness; must accept the existence of differing values; and must be respectful of, interested in, and empathetic towards people from different cultures, without being judgmental. **Cultural competence** is essential to quality care. According to Betancourt et al. (2003) cultural competence 'entails understanding the importance of social and cultural influences on patients' health beliefs and behaviours, considering how these factors interact at multiple levels of the health care delivery system, and devising interventions that take these issues into account' (p. 294).

A related concept, **cultural safety**, is 'The effective nursing practice of a person or family from another culture, as determined by that person or family' (Nursing Council of New Zealand (NCNZ), 2012, p. 32). Unsafe cultural practice comprises any action that 'diminishes, demeans or disempowers the cultural identity and wellbeing of an individual' (NCNZ, 2012, pp. 32–33).

Cultural competence and cultural safety allow nurses to connect with and understand people receiving care as well as their families and friends, their community and the profession of nursing. Through communication nurses are offered an opportunity to understand people's experience of health and illness at a personal level rather than simply at the theoretical or biomedical level. Effective communication helps to foster an environment in which culturally safe care is negotiated and delivered.

The NMBA *Code of Ethics for Nurses in Australia (2008)* (NMBA, 2013a) states that Registered Nurses:

- accept individuals/groups to whom care is provided regardless of race, culture, religion, age, gender, sexual preference, or physical or mental state
- ensure that personal values and attitudes are not imposed on others
- maintain an effective process of care when confronted by differing values, beliefs and biases.

Standard 2 of the NMBA *National Standards for Practice* (2016) refers to therapeutic relationships and indicates that Registered Nurses must 'establish, sustain and conclude therapeutic relationships in a way that is respectful and acknowledges the dignity, culture, values and beliefs and rights of a person'.

While developing a growing appreciation of the various cultural groups you come into contact with in your many nursing roles is essential, developing an appreciation and understanding of the history and culture of Aboriginal and Torres Strait Islander people (Australia's First People) is fundamental to the development of professional nurses and to nursing practice which is experienced as culturally safe. Standard 1 of the NMBA *National Standards for Practice* (2016) relates to critical thinking and analysis, and Element 1.3 advocates that Registered Nurses 'Respect peoples' culture and experiences as a core part of person-centred and evidence-based practice, which includes recognising the role of family and community that underpin Aboriginal and Torres Strait Islander cultures and health'.

In order to be effective in delivering appropriate care to Aboriginal and Torres Strait Islander people nurses need:

- awareness of important Aboriginal and Torres Strait Islander issues such as cultural differences, and specific aspects of Indigenous history and its impact on Indigenous peoples in contemporary Australian society
- the skills to interact and communicate sensitively and effectively with Indigenous peoples
- the motivation to interact successfully with Indigenous peoples in order to improve access, service delivery and patient outcomes (Farrelly & Lumby, 2009).

Undertaking this journey into the history and culture of Indigenous Australians is likely to challenge your understanding of your own culture and how your cultural values impact on the way you provide nursing care to all people.

In the chapters that follow the cultural implications of the various clinical situations are discussed and expanded upon, and you will be presented with opportunities to apply and contextualise your learning about cultural safety.

LEGAL AND ETHICAL DILEMMAS IN NURSING

A **dilemma** is a choice between two unpleasant, ethically troubling alternatives. Nurses face dilemmas almost daily—so many, in fact, that a complete discussion of them is impossible here. However, many commonly experienced dilemmas involve confidentiality, human rights and issues of dying and death. The nurse must use ethical and legal guidelines to make decisions about moral actions when providing care in these and many other situations.

The rights of each individual can result in dilemmas for nurses in the clinical setting. For example, the right to privacy and confidentiality may create a dilemma if it conflicts with the nurse's right to information that may affect their personal safety. The right to refuse treatment (including surgery, medication, nutrition and hydration) is an example of people's rights that can cause nursing dilemmas. The situation, the alternatives and the potential consequences of refusal must be carefully explored with the person.

The issues surrounding dying and death have become increasingly topical as advances in technology extend the lives of people with chronic debilitating illness and major trauma. These changes have altered concepts of living and dying, resulting in ethical dilemmas regarding quality of life and death with dignity versus technological preservation of life. Additionally, difficulties in establishing competence to make informed decisions about withholding and withdrawing treatment, and use of narcotic analgesia at the end of life, are some issues that nurses will encounter in their practice.

ROLES OF THE NURSE IN MEDICAL–SURGICAL NURSING PRACTICE

Healthcare today is a vast and complex system. It reflects changes in society, changes in the populations requiring nursing care and a philosophical shift towards health promotion rather than illness care. The roles of the medical–surgical nurse have broadened and expanded in response to these changes. Medical–surgical nurses are not only caregivers but also educators, advocates, leaders and managers, and researchers. The nurse assumes these various roles to promote and maintain health, to prevent illness and to facilitate coping with disability or death for people in a range of healthcare settings.

The nurse as caregiver

Nurses have always been caregivers. However, the activities carried out within the caregiver role have changed tremendously in the 21st century. From 1900 to the 1960s, the nurse was almost always female and was regarded primarily as the person who gave personal care and carried out doctors' orders. This dependent role has changed as a result of the increased education of nurses, research into and the development of nursing knowledge, a strong evidence base and the recognition that nurses are autonomous and well-informed professionals.

The caregiver role for the nurse today is both independent and collaborative. Nurses independently make assessments and plan and implement patient care, based on nursing knowledge and skills. Nurses must also collaborate with other members of the interprofessional healthcare team to implement and evaluate care (see Figure 1.3).

In providing comprehensive and person-centred care the nurse uses critical thinking skills to analyse and synthesise knowledge from the arts, the sciences, and nursing research and theory. The science (knowledge base) of nursing is translated into the art of nursing through caring. Caring is the means by which the nurse is connected with and concerned for the person who is the recipient of care. Thus, the nurse as caregiver is knowledgeable, skilled and empathetic. Nursing care must address not only the physical needs but also the psychosocial, cultural, spiritual and environmental needs of each person and their family. Considering all aspects of a person's being ensures a holistic approach to nursing (Sharoff, 2006). Subsumed within the concept of 'holistic healthcare' is the concept of caring for the mind, body and spirit.

FIGURE 1.3 ■ The healthcare team discusses the individualised plan of care and outcomes

The nurse as educator

The nurse's role as educator is becoming increasingly important for several reasons. There is much greater emphasis on health promotion and illness prevention; hospital stays are becoming shorter; and the number of people with chronic illnesses in our society is increasing. Early discharge of people from the hospital setting to the home means that family caregivers must learn how to perform complex skills. All these factors make the educator role essential to maintaining the person's health and wellbeing.

The framework for the role of educator is the teaching–learning process. Within this framework the nurse assesses learning needs, plans and implements teaching methods to meet those needs, and evaluates the effectiveness of the teaching. To be effective educators nurses need effective interpersonal skills and familiarity with adult learning principles (see Figure 1.4).

A major component of the educator role today is discharge planning. Discharge planning, which begins on admission to a healthcare setting, is a systematic method of preparing the person and their family for departure from the healthcare facility and for maintaining continuity of care after they leave the setting. Discharge planning also involves making referrals, identifying community and personal resources, and arranging for necessary equipment and supplies for home care.

The nurse as advocate

The person entering the healthcare system may not always be prepared to make independent decisions. However, nurses need to be aware that today's healthcare consumer is better educated

FIGURE 1.4 ■ The nurse's role as educator is an essential component of care. As part of the discharge planning process, the nurse is responsible for teaching for self-care at home

about options for care, and may have very definite opinions. The nurse as patient advocate actively promotes the patient's right to autonomy and free choice. The nurse as advocate speaks for the person, mediates between the person and other people, and/or protects the person's right to self-determination. The goals of the nurse as advocate are to:

- assess the need for advocacy
- communicate with other healthcare team members
- provide teaching to the person and family
- assist and support decision making
- serve as a change agent in the healthcare system
- participate in health policy formulation.

The nurse must practise advocacy while maintaining the belief that people have the right to choose treatment options, based on information about the results of accepting or rejecting the treatment, without coercion. The nurse must also accept and respect the decisions of the person, even though they may differ from the decisions the nurse would make.

The nurse as leader and manager

All nurses are leaders and managers. They practise leadership and they manage time, people, resources and the environment in which they provide care. Nurses carry out these roles by directing, delegating and coordinating nursing activities. Nurses must be knowledgeable about how and when to delegate, as well as the legal requirements of delegation. Nurses also evaluate the quality of care provided.

Models of care delivery

Nurses are leaders and managers of patient care within a variety of models of care delivery. Models of care may include:

- task-oriented nursing
- team nursing
- patient allocation or total patient care
- primary nursing
- case management.

Task-oriented nursing refers to a model in which nurses undertake specific tasks related to nursing care across a group of people. Some examples of task allocation may be when a nurse undertakes to shower all people in a ward; another nurse may undertake the medications for the same group of people. In this model of care delivery, nursing care relates to sets of activities that are performed by nurses for people.

Team nursing is a model that 'teams' experienced permanent nurses with less experienced or casual staff to achieve nursing goals using a group approach. A team may consist of a Registered Nurse, an Enrolled Nurse and an Assistant in Nursing. The Registered Nurse is the team leader. The team leader is responsible for making assignments and has overall responsibility for patient care by team members. All team members work together, each performing the activities for which they are best prepared.

Patient allocation models were developed because nurses recognised the need for total patient care. The implementation of these types of models results in nurses getting to know the whole person, rather than people being cared for as a series of tasks. A nurse will be allocated to their patients (the number is dependent on factors such as patient need, staff mix and ward policies) and undertake all nursing care for the allocated person/people.

Primary nursing allows the nurse to provide individualised direct care to a small number of people during their entire inpatient stay. This model was developed to reduce the fragmentation of care experienced by the person and to facilitate continuity of care. In primary nursing the nurse provides care; communicates with the person, families and other healthcare providers; and carries out discharge planning.

Case management focuses on management of a caseload (group) of patients. The purpose of case management is to maximise positive outcomes and contain costs. The nurse who is case manager is usually a clinical specialist, and the caseload consists of people with similar healthcare needs. As case manager the nurse makes appropriate referrals to other healthcare providers and manages the quality of care provided, including accuracy, timeliness and cost. The case manager is also in contact with patients after discharge, ensuring continuity of care and health maintenance.

The model of care delivery implemented on a ward will depend on a range of factors, including the degree of innovation and commitment by the persons involved. Some models work better when there are sufficient numbers of highly qualified staff (RNs) to deliver care; others may focus on supporting less experienced staff using a team approach.

Delegation

Delegation is carried out when the nurse assigns appropriate work activities to other members of the healthcare team. When the nurse delegates nursing care activities to another person, that person is authorised to act in the place of the nurse, although the nurse retains the accountability for the activities performed. Delegation skills are becoming increasingly important in healthcare as facilities restructure and implement cost containment measures. Delegation depends on knowing one's own scope of practice and that of the person to whom one plans to delegate.

Nurses' **scope of practice** refers to the roles, functions, responsibilities, activities and decision-making capacity that they are educated, competent and authorised to perform. One's scope of practice is influenced by the wider environment, the specific setting, legislation, policy, education, standards and the health needs of the population. Registered Nurses have a key role in the coordination and supervision of others who assist them in the provision of care to people. A decision-making template developed by the ANMC (2007) provides guidance not only for individual practice decisions by Registered Nurses but also for decisions about if, and when, it is appropriate to delegate aspects of patient care to others.

Evaluating outcomes of nursing care

CLINICAL PATHWAYS A **clinical pathway** is a plan designed to provide healthcare, often within a multidisciplinary team. Such pathways are generally developed for specific diagnoses—usually high-volume, high-risk and high-cost case types—with the collaboration of members of the healthcare

team. This patient care management tool describes how resources will be used to achieve predetermined outcomes. It also establishes the sequence of multidisciplinary interventions, including education, discharge planning, consultations, medication administration, diagnostics, therapeutics and treatments.

The goals of clinical pathways are to:

- achieve realistic, expected person and family outcomes
- promote professional and collaborative practice and care
- ensure continuity of care
- guarantee appropriate use of resources
- reduce costs and length of stay
- provide the framework for continuous improvement.

Clinical pathways are often used in conjunction with case management models and/or quality improvement efforts. The overall goal is to design pathways that facilitate a reproducible standard of care for specific patient populations and improve the quality and proficiency of that care.

The healthcare facility determines the process for developing a clinical pathway. Information imperative to the development of any clinical pathway includes literature reviews, chart reviews and expert opinion. A typical approach is to first identify high-cost, high-volume and high-risk case types for the agency. Next, a multidisciplinary team develops a consensus around the management of the case type and a clinical pathway. The pathway is then piloted with a designated group of people, and revised based on the number and types of variances. The goal is to develop a pathway that best meets the needs of people in the particular practice setting.

When people do not achieve expected outcomes, variances (deviations from the established plan) from the clinical pathways are recorded and studied by the multidisciplinary team. In many facilities, clinical pathways are designed so that interventions and variances can be easily documented. Most documentation systems require a check-off when interventions are performed or variances occur.

In many facilities, clinical pathways are replacing traditional nursing care plans. The advantages of clinical pathways are that they are outcome driven and provide a timeline to achieve specified goals. Additionally, clinical pathways provide opportunities for healthcare workers to collaborate and establish dynamic plans of care that consider all of the people's needs. Although initially developed for acute hospitalisations, clinical pathways are now being developed to manage people in the home, outpatients and those in long-term settings.

Clinical governance

Clinical governance is defined as a systematic and integrated approach that improves quality and safety and results in optimal patient outcomes (Office of Safety and Quality in Health Care, 2001). Health jurisdictions in Australia have embraced clinical governance by attempting to hold healthcare providers accountable for the quality and safety of the care they deliver. Clinical governance places the responsibility for the quality of care jointly on organisations and on individuals within organisations. As a leader and manager within a healthcare organisation, the nurse has an important role in promoting continuous quality improvement through governance structures such as:

- clinical risk management
- clinical quality and safety frameworks
- consumer participation
- clinical effectiveness
- clinical audit
- evidence-based practice
- credentialling/professional development
- research and development.

The medical–surgical nurse is well placed to contribute to the evaluation of the quality of clinical practice through peer review, clinical audit and external accreditation processes.

The nurse as researcher

Nurses have always identified problems in patient care. Although they have developed interventions to meet specific needs, the activities often have not always been conducted within a scientific framework or communicated to other nurses through nursing literature. To develop the science of nursing, nursing knowledge is established through clinical research and then published so that the findings can be used by all nurses to provide evidence-based person-centred care. This means that all nurses must consider the researcher role as integral to nursing practice.

Over the past decade there has been much more attention placed on the importance of evidence-based healthcare and nurses are expected to use the best clinical evidence available to inform their patient care decisions. Evidence from rigorous

LINKS TO NATIONAL PATIENT SAFETY STANDARDS

NSQHS Standard 1:
Governance for Safety and Quality in Health Service Organisations

Standard 1 of the National Safety and Quality Health Service Standards (NSQHSS) specifies that:

- There are integrated systems of governance to manage patient safety and quality risks.
- Care provided by the clinical workforce is guided by current best practice.
- All members of the clinical workforce have the appropriate qualifications and skills to provide safe high-quality healthcare.
- Patient safety and quality incidents are recognised, reported and analysed so as to improve safety systems.
- Patient's rights are respected and participation in their care supported.

Source: © Australian Commission on Safety and Quality in Health Care.

studies constitutes the best type of evidence to underpin nurses' decisions and actions. Nursing care that is based on high-quality research evidence is more likely to be cost effective and result in positive patient outcomes (Joanna Briggs Institute, 2013).

Summaries of relevant nursing research are included in almost all of the nursing care chapters of this textbook. After the summary and discussion of each study, a critical thinking section specifically related to the findings of the study encourages students to apply the findings in the clinical setting.

CHAPTER HIGHLIGHTS

- Safe and effective nursing care focuses on the provision of person-centred care, working in interprofessional teams, using evidence-based practice and working within legal and ethical frameworks.
- The nursing process is an approach used by nurses to provide care to promote wellness, maintain health, restore health or facilitate coping with disability or death. The five steps of the nursing process are assessment, diagnosis, planning, implementation and evaluation.
- Clinical reasoning is a dynamic process in which nurses collect cues, process this information, come to an understanding of the situation (or patient's problem), plan and implement care, evaluate outcomes, and reflect on and learn from the process. The questioning of assumptions and the avoidance of clinical reasoning errors are central to this process.
- The clinical practice of nurses is guided by codes of conduct, codes of ethics and standards of practice.
- Nurses function as caregivers, educators, advocates, leaders and managers, and researchers to promote and maintain health, prevent illness and facilitate coping with disability or death for the adult person.

CONCEPT CHECK

1 The Nursing and Midwifery Board of Australia (NMBA) has developed a set of standards for practice. What is the primary purpose of these standards?
1 to make all nurses equal
2 to promote safe and effective nursing care
3 to reduce the number of legal actions
4 to provide a set of ethical guidelines

2 What does the nurse use in the clinical setting to make clinical judgments and decisions?
1 nursing process
2 standards of care
3 clinical reasoning skills
4 all of the above

3 Which of the following statements is true of outcomes developed during the planning phase of the nursing process?
1 Outcomes are mutually established by the person and the nurse.
2 Outcomes are mutually established by the nurse and the doctor.
3 Outcomes are mandated by institutional policies and standards.
4 Outcomes are written by the person receiving care and their family members.

4 The steps of the nursing process are used when providing care. From the list below, select the order in which the steps are most often used.
1 diagnosis
2 assessment
3 evaluation
4 implementation
5 planning

5 When nurses discuss the 'science of nursing', what does this phrase mean?
1 clinical competency
2 holistic care
3 evidence-based practice
4 practice component

6 What role does the nurse demonstrate when appraising health information?
1 advocate
2 caregiver
3 researcher
4 educator

7 What goal is a component of the nurse's role as advocate?
1 assisting and supporting the person in their decision making
2 conducting research about the effects of exercise
3 delegating responsibilities for care to others
4 performing range-of-motion exercises

8 A nurse assigns appropriate work activities to other members of her team. What role is being illustrated?
1 advocate
2 leader/manager
3 researcher
4 caregiver

9 A method of establishing a standard of care and evaluating outcomes of that standard involves:
1 writing a dress-code policy for a healthcare agency
2 creating a clinical pathway for a specific type of person
3 establishing clinical governance approaches
4 implementing a new procedure to change dressings

10 A Registered Nurse delegates vital signs assessment to an Assistant in Nursing. Who is accountable for the assessment findings?
1 the Assistant in Nursing
2 the person receiving care
3 the nurse
4 the doctor

CHAPTER 2

HEALTH AND ILLNESS IN ADULTS

AMANDA WILSON, TRACY LEVETT-JONES

KEY TERMS

LEARNING OUTCOMES

- Define health, including the concepts of the illness–wellness continuum and high-level wellness.
- Explain what determinants of health are and how they influence health, disease and illness.
- Discuss the nurse's role in promoting healthy lifestyles and preventing illness and injury.
- Describe the different behaviours and needs of people with acute and chronic illness.
- Describe the primary, secondary and tertiary levels of illness prevention.
- Compare and contrast the physical status, changes in health, assessment guidelines and healthy behaviours of the young adult, middle adult and older adult.
- Explain the definitions, functions and developmental stages and tasks of the family.

CLINICAL COMPETENCIES

- Include knowledge of developmental levels and of activities to promote, restore and maintain health when planning and implementing care for adults.
- Include family members in teaching to promote and maintain health of the adult.

DEFINING HEALTH

The Constitution of the World Health Organization (WHO) defines **health** as 'a state of complete physical, mental, and social well-being, and not merely the absence of disease or infirmity' (WHO, 1948, p. 1). This definition is fundamental to contemporary healthcare perspectives and can be expanded to encompass the various levels of health people experience throughout their life. However, the concept of health is subjective and reflects an individual's perspective of quality of life. For example, someone with a terminal diagnosis can still enjoy life and feel 'well'—however, their definition of health will differ radically from that of a person without that diagnosis. These factors, which greatly influence nursing care, are reflected in the **illness–wellness continuum** and the concept of high-level wellness.

The illness–wellness continuum

The illness–wellness continuum represents health as a dynamic process, with high-level wellness at one extreme of the continuum and death at the opposite extreme (see Figure 2.1). During our lifetime we would place ourselves in different locations on this continuum. The continuum of health and illness was expanded to include the concept of high-level wellness, with 'good health' differentiated from 'wellness' in the following way:

> *Good health can exist as a relatively passive state of freedom from illness in which the individual is at peace with his environment . . . Wellness is an integrated method of functioning, which is oriented toward maximising the potential of which the individual is capable, within the environment where he is functioning.* (Dunn 1959, p. 4)

The philosophy of **holistic healthcare** involves the concept that person-centred care considers all facets of an individual including physical, psychosocial, cultural, spiritual and intellectual. Similarly, the elements of wellness include self-perception, environment, culture and spiritual values. To promote, maintain or restore health, both the nurse and the person receiving care need to recognise and address this framework of wellness factors.

DETERMINANTS OF HEALTH

Australia has a population of approximately 24 million people (Australian Bureau of Statistics (ABS), 2015). Australians today are living 25 years longer than their great-grandparents who were born a century ago. Females can now expect to live to 84 years and men 80 years (Australian Institute of Health and Welfare (AIHW), 2015a). There are many factors that affect health and wellness. These factors are referred to as **determinants of health** and they can influence good health or be risk factors for poor health. The following sections describe some of the major determinants of health and their impact.

Genetic make-up

Genetic make-up is a 'grab bag' of inherited features from generations of family members and provides a blueprint for health throughout life. Genetic make-up determines eye colour, and affects personality, temperament and intellectual potential; it also makes us susceptible to developing hereditary conditions. Cystic fibrosis (CF), haemophilia, type 2 diabetes, hypercholesterolaemia (elevated levels of cholesterol in the blood) and some types of cancer are examples of genetic diseases and disorders. Research into genetic make-up is providing insights into ways to diagnose, treat and even prevent these conditions. Research has also shown how quickly genetic structure changes and how our health choices can influence the genetic health of our children.

Cognitive abilities and educational level

Cognitive abilities are developed in childhood, which is why school education is considered an important determinant of health. Our level of cognitive development affects our perceptions of health and illness and may also affect health practices. Educational levels affect our ability to understand and follow guidelines for health—this is called health literacy. If a person cannot read well, written materials such as brochures or handouts on health behaviours and resources are of little value. In Australia educational levels are lower in rural and remote areas compared with major cities, with very remote areas having the lowest levels of school completion.

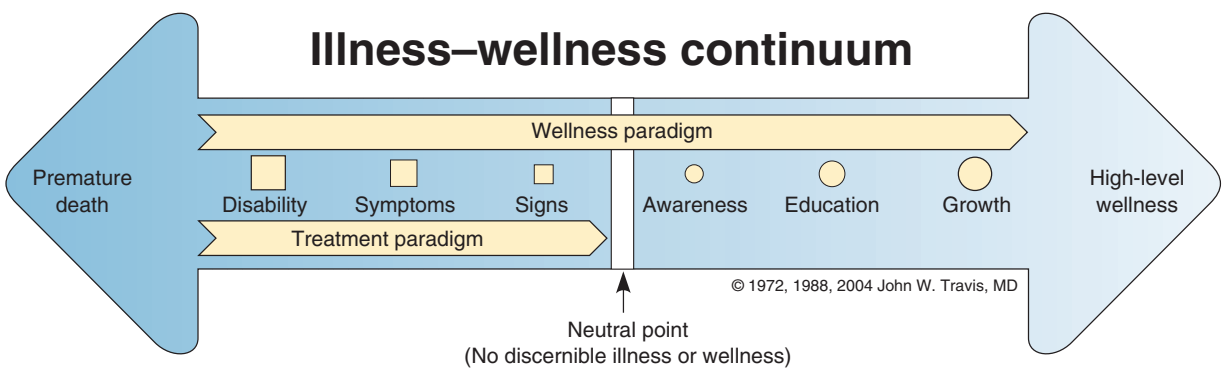

FIGURE 2.1 ■ The illness–wellness continuum

Race, ethnicity and cultural background

Ethnicity and cultural background influence health values and behaviours, lifestyle and illness behaviours. Every culture defines health and illness uniquely and every culture has different health beliefs and practices. Certain diseases occur at different rates in some races and ethnic groups. For example, the blood disease beta thalassaemia is a genetic disease that occurs more often in people of Italian or Greek descent. For this reason it is also known as Mediterranean anaemia.

Indigenous health

Nursing care of Aboriginal and Torres Strait Islander people is covered in Chapter 52. Many Aboriginal and Torres Strait Islander people experience disability and reduced quality of life due to poor health and many die earlier than the general Australian population. They also experience high rates of chronic disease, such as diabetes and heart disease, at much younger ages. Indigenous Australians are hospitalised for renal failure at 14 times the rate of other Australians and the rate of hospitalisation for endocrine, nutritional and metabolic diseases, including diabetes, is three times that of the rest of Australia (AIHW, 2015b). Aboriginal and Torres Strait Islander people suffer a higher burden of emotional distress and mental illness than that experienced by the wider community. The major contributing factors to these problems include persistent social and economic disadvantages, limited access to healthcare and low levels of nutrition.

A major national initiative called *Close the Gap* was developed at the 2008 Indigenous Health Summit. This initiative included a Statement of Intent between the Australian Government and Indigenous peoples of Australia 'to work together to achieve equality in health status and life expectancy between Aboriginal and Torres Strait Islander peoples and non-Indigenous Australians by the year 2030' (Australian Human Rights Commission, 2008). *Close the Gap* aims to reduce Indigenous disadvantage in terms of life expectancy, child mortality, access to early childhood education, educational achievement and employment outcomes.

Age, gender and developmental level

Age, gender and developmental level are factors in health and illness. Chronic conditions vary with age. Asthma and hay fever are common in the younger age groups, whereas arthritis and hypertensive diseases are more prevalent conditions for those aged 55 years and over. Some diseases occur only in one gender; for example, prostate cancer in men and cervical cancer in women. The older adult is more likely to experience chronic illnesses and is more at risk of serious illness or death from infectious diseases such as influenza and pneumonia.

Lifestyle and environment

The way we live directly impacts on our health. What we eat and how much, alcohol and smoking rates, use of illegal drugs, exercise patterns, stress, grief and happiness all contribute to our health and wellbeing. Too much food can result in obesity, diabetes and hypertension. Smoking causes cancers and respiratory diseases as well as contributing to heart disease and stroke. Lack of exercise is linked to multiple health problems including cardiovascular problems and mental health issues.

The environment you live and work in also impacts on your health. Occupational exposure to toxic substances, such as asbestos or coal dust, increases the risk of pulmonary disorders. Air, water and food pollution increase the risk of respiratory disorders, infectious diseases and cancers. Environmental temperature variations can result in hypothermia or hyperthermia, especially in the older adult. The World Health Organization specifies that everyone should have access to clean air and water and good-quality food.

Socioeconomic background

Socioeconomic status is mainly linked to income or wealth and has a major impact on health status. Socially and economically disadvantaged Australians are more likely to have shorter lives, higher levels of disease and lower use of preventive healthcare than those who are better off. This population tends to smoke more, exercise less, weigh more and eat less fresh food and more processed food high in fat and sugar. These are all risk factors for chronic health conditions including respiratory diseases, cancers and endocrine and cardiovascular diseases. The socioeconomic disadvantage experienced by Aboriginal and Torres Strait Islander people makes them more vulnerable to health risk factors such as smoking, alcohol misuse and domestic violence (AIHW, 2015b).

Geographical area

The geographical area in which a person lives influences their health status as access to healthcare services varies greatly between regional, rural and remote areas of Australia. For example, healthcare services in rural and remote areas can be affected by factors such as larger catchment areas, smaller populations, and fewer general and specialist medical professionals. Rural and remote area residents also have different patterns of service use. For these reasons, they generally have poorer health than people living in major cities, with higher levels of mortality, disease and health risk factors. For example, the prevalence of chronic conditions such as asthma, lung disease, cancer and arthritis in people living in rural and remote areas is more common than in people living in metropolitan areas (AIHW, 2008). Residents of the more inaccessible regions of Australia are generally disadvantaged in their educational and employment opportunities, income and access to goods and services. In some areas they also have less access to basic necessities such as fresh fruit and vegetables.

Compared with those in major urban centres, Australians living in rural and remote areas generally have less access to primary healthcare services and staff, more driving risks (such as poorer road conditions and longer travelling times), longer patient transport times and jobs with higher risks, such as primary production and mining. Preventable cancers—for example, those associated with sun exposure (melanoma) or smoking (lung, head and neck, and lip) and those detectable through screening (cervix)—have significantly higher incidence rates in rural and remote areas. Higher rates of morbidity and mortality in rural and remote areas are also partly influenced by the larger proportion of Indigenous Australians living in these areas (AIHW, 2015b).

PROMOTION OF HEALTH AND PREVENTION OF ILLNESS AND INJURY

For many years, the emphasis in nursing was on the care of acutely ill people in the hospital setting. Changes in society and healthcare have seen this emphasis shift towards preventive and community-based care. Although the primary focus of this chapter is not community health nursing, the importance of the nurse's role in health protection and promotion, as well as teaching illness prevention behaviours, is an essential component of medical–surgical nursing. Community nursing is discussed more fully in Chapter 51. Nurses promote health by teaching activities that maintain wellness, providing information about the characteristics and consequences of diseases when risk factors have been identified, and by supplying specific information about decreasing risk factors (Pender, Parsons & Murdaugh, 2006).

Programs such as the 'Immunise Australia Program' provide widespread immunisation against a large number of communicable diseases (see Table 2.1). This initiative aims to increase national immunisation rates by funding free vaccination programs, administering the Australian Childhood Immunisation register and providing information about immunisation to the general public and health professionals (Department of Health, 2015a). Nurses play an integral role in educating the public about the effectiveness of immunisation to save lives and prevent serious illness (Department of Health, 2015b). The occupational nature of healthcare workers, including nursing students, places them at risk of acquiring vaccine-preventable diseases, and health department policies generally require students and non-immune workers to be immunised.

Nurses are well placed to provide 'education and management to truncate an anticipated rising tide of CVD (cardiovascular disease) in Australia' (Carrington et al., 2009, p. 684). One of the aims of the National Health and Medical Research Council's Australian Dietary Guidelines (2013) is to reduce the risk of chronic diseases, and nurses are an integral part of the interprofessional team responsible for protecting and promoting wellness through healthy eating.

Healthy living

Practices that are known to promote health and wellness include the following:

- exercising moderately and regularly
- getting enough sleep
- limiting alcohol consumption to a moderate amount
- stopping smoking.

ACUTE AND CHRONIC ILLNESS

The National Health Priority Areas initiative is an Australian program in which all the state and territory governments work together with health experts, including clinicians, researchers, organisations and consumers, to reduce the national burden of illness (AIHW, 2015c). This initiative uses evidence-based strategies from prevention through to treatment, management and maintenance to target health areas which impose high social and financial costs on Australian society. There are nine National Health Priority Areas:

1. arthritis
2. asthma
3. cancer
4. cardiovascular disease
5. dementia
6. diabetes
7. injury
8. mental health
9. obesity.

TABLE 2.1 National Immunisation Program Schedule (NIPS)—Special Groups

AGE	VACCINE
6 months and over	• Influenza (people with medical conditions placing them at risk of serious complications of influenza)
12–18 months	• Pneumococcal conjugate (13vPCV) (Aboriginal and Torres Strait Islander people living in high-risk areas—Queensland, Northern Territory, Western Australia and South Australia)
12–24 months	• Hepatitis A (Aboriginal and Torres Strait Islander people in high-risk areas—Queensland, Northern Territory, Western Australia and South Australia)
12 months	• Pneumococcal conjugate (13vPCV) (Individuals who are medically at risk)
6 months to less than 5 years	• Influenza (Aboriginal and Torres Strait Islander people)
4 years	• Pneumococcal polysaccharide (23vPPV) (Individuals who are medically at risk)
15 years and over	• Influenza (Aboriginal and Torres Strait Islander people) • Pneumococcal polysaccharide (23vPPV) (Aboriginal and Torres Strait Islander people who are medically at risk)
50 years and over	• Pneumococcal polysaccharide (23vPPV) (Aboriginal and Torres Strait Islander people)
Pregnant women (at any stage of pregnancy)	• Influenza
65 years and over	• Influenza • Pneumococcal polysaccharide (23vPPV)

BOX 2.1 The most common diseases and injuries of the Australian population

Cancer is the leading cause of disease burden, followed by cardiovascular disease, then mental disorders. There has been a decline in death rates from heart attacks since 2008.

Myocardial infarction (heart attack) rates are falling and survival rates are improving. Survival rates are improving for cancer overall. However, asthma has become more common among children and young adults and the rate of type 2 diabetes has doubled in the past two decades. Diabetes is the main cause of end-stage kidney disease and the number of people treated for this disease has tripled in the past 25 years (AIHW 2014a).

BOX 2.2 Incidence and prevalence

- *Incidence* refers to the number of new cases of an illness, disease or event occurring during a given period. Example: The number of new cases of diabetes diagnosed in 2016.
- *Prevalence* is the number of cases of a disease that exist at any given time. This includes new cases, ongoing cases and people who died during this period. Example: The total number of people who had diabetes in 2016.

See Box 2.1 for an overview of the most common diseases and injuries of the Australian population. Box 2.2 discusses incidence and prevalence.

Disease and illness

Disease and illness are terms that are often used interchangeably, but they do have different meanings. In general, nursing is concerned with illness, whereas medicine is concerned with disease.

Disease

Disease (literally meaning 'without ease') is a medical term describing alterations in the structure and function of the body or mind. Diseases usually have mechanical, biological or normative causes. Mechanical causes of disease result in damage to the structure of the body and are the result of trauma or extremes of temperature. Biological causes of disease impact on body function and can result from a variety of reasons including the normal ageing process. Normative causes are psychological but involve a mind–body interaction, so physical manifestations occur in response to the psychological disturbance.

The causes of many diseases are still unknown but common causes include:

- genetic defects
- foetal exposure to viruses, chemicals or drugs
- biological agents or toxins (including viruses, bacteria, fungi, protozoa and helminths)
- physical agents such as temperature extremes, radiation and electricity
- chemical agents such as alcohol, drugs, strong acids or bases, and heavy metals
- generalised response of tissues to injury or irritation
- changes in antibody productions, resulting in allergies or hypersensitivities
- faulty metabolic processes where production of hormones or enzymes is above or below normal.

Diseases may be classified as acute or chronic, infectious (communicable), congenital, degenerative, functional, malignant, psychosomatic, idiopathic or iatrogenic. These classifications are defined in Table 2.2. In all diseases, alterations in structure or function cause signs and symptoms (manifestations). These warning signs often prompt a person to seek health advice.

Symptoms are subjective in that the person perceives them: 'I feel nauseous and have a headache'. Signs are objective in that they can be seen and measured; for example, bleeding, vomiting, diarrhoea, limitation of movement, swelling. Pain (a subjective symptom) is the most common reason people seek healthcare.

Chronic diseases cause the greatest health problems in the world today, and the number of people with chronic diseases is rising steadily as people live longer and more populations are impacted by lifestyle, behaviour and environmental factors.

- Chronic diseases are a major health problem in all developed countries, accounting for a high proportion of deaths, disability and illness. Yet many of these diseases are preventable, or their onset can be delayed, by relatively simple measures. A summary of the characteristics of chronic diseases according to AIHW (2015d) is:
  - complex causality
  - multiple risk factors

TABLE 2.2 Disease classifications and definitions

CLASSIFICATION	DEFINITION
Acute	Rapid onset, lasts a relatively short time and is self-limiting.
Chronic	Has one or more of the following: (1) is ongoing or permanent, (2) leaves permanent disability, (3) causes irreversible pathophysiology, (4) requires rehabilitation, (5) requires a long period of care.
Communicable	Can spread from one person to another.
Congenital	Existing at or before birth.
Degenerative	Resulting from deterioration or impairment of organs or tissues.
Functional	Affects function or performance but does not have manifestations of organic illness.
Malignant	Tends to become worse and cause death.
Psychosomatic	A psychological disease causing physiological symptoms.
Idiopathic	Unknown cause.
Iatrogenic	Unintended or unnecessary harm or suffering arising from healthcare management.

- long latency periods
- a prolonged course of illness
- functional impairment or disability.

Over 75% of Australians have at least one chronic condition and as people age they are more likely to have one or more chronic conditions (ABS, 2009).

Chronic diseases range from mild to severe, and are usually characterised by periods of remission and exacerbation. During periods of remission the person may be symptom free; however, in periods of exacerbation, the symptoms reappear. Each person with a chronic disease has a unique set of responses and needs. The response of the person to the disease is influenced by the following factors:

- where in their life cycle the disease occurs
- the type and degree of limitations imposed by the disease
- the visibility of impairment or disfigurement
- the pathophysiology causing the disease
- the relationship between the impairment and functioning in social roles
- pain and fear.

These factors are highly complex. They are interrelated within each person, resulting in individualised behaviours and needs. Because there are so many different chronic diseases, and because every person will have a unique response, it is difficult to generalise about needs. However, most people with a chronic disease will need to:

- live as normally as possible—symptoms and treatment can make the person feel alienated, lonely and different
- adapt activities of daily living and self-care
- grieve the loss of physical function and structure, income, status, roles and dignity
- comply with a treatment plan
- maintain a positive self-concept and a sense of hope
- maintain a feeling of being in control
- confront the inevitability of death (Miller, 2000).

Some people with chronic disease successfully meet health-related needs whereas others do not. Nursing interventions for the person with a chronic disease focus on education and support to promote independent functioning, reduce healthcare costs and improve quality of life.

Illness

Illness is the response a person has to a disease. This response is highly individualised, because the person responds with their own perceptions of the disease as well as those of others. The concept of illness combines pathophysiological changes and psychological effects of these and the impact on the individual's roles, relationships and values, and cultural and spiritual beliefs. A person may have a disease but not see themselves as ill or they may validate feelings of illness through the comments of others: 'You look pale, do you feel OK?'.

An **acute illness** occurs rapidly, lasts for a relatively short time and is usually self-limiting (it will resolve itself). The condition may respond to self-treatment or to medical–surgical intervention. People with uncomplicated acute illnesses usually have full recovery and return to normal pre-illness functioning.

Illness behaviours are the way people cope with the changes caused by a disease. Illness behaviours are highly individualised and are influenced by age, gender, family values, economic status, culture, educational level and mental status. The concept of a sequence of illness behaviour was first defined in 1972 (Suchman, 1972):

1. *Experiencing symptoms.* The first stage of an acute illness is when someone experiences signs or symptoms that alert them to a change in their health. The most significant example is pain but other signals of illness include bleeding (haemorrhage), swelling (oedema), fever (pyrexia) or difficulty with breathing (dyspnoea). If the signs and symptoms are mild or are familiar (coughing and nasal congestion), the person will often self-medicate. It is only if the symptoms are prolonged or become more severe that the person moves to the second-stage illness behaviour. Most people would not define this stage to be an illness as they consider it a normal part of the fluctuating status of health: 'It's nothing, just a sniffle'.
2. *Assuming the sick role.* At this stage the individual accepts that their symptoms are proof of illness. They may seek external health advice and take steps to rest by not attending work or school. They may cautiously admit to illness: 'I am feeling a bit unwell'. Self-preoccupation is characteristic of this stage, so the person focuses on changes in function and ability caused by the illness. As the illness resolves, the individual resumes normal activities and may retrospectively admit to illness: 'I was feeling sick but I'm much better now'. However, if the signs and symptoms persist or become worse, the person moves to the next stage by seeking medical care.
3. *Seeking medical care.* In our society, a general practitioner or other healthcare provider usually provides the initial validation of illness. People who believe they are ill, or are encouraged to contact a healthcare provider, seek help in finding out the cause of the illness (diagnosis), how long it will last (prognosis) and the best way of treating it. If the diagnosis requires interventions, the person moves to the next stage. If the diagnosis does not require support, the person may return to normal functioning or, if dissatisfied with this answer, may seek validation from a different healthcare provider.
4. *Assuming a dependent role.* At this stage the person accepts the diagnosis, trajectory and planned treatment of the illness. As the severity of the illness increases, so does their dependent role. During this stage the person may enter a hospital for treatment and care. How an individual responds to care depends on many factors: severity of the illness, anxiety or fear about the outcome, loss of roles, their support systems available, their reaction to stress and their previous experiences with illness care.
5. *Recovery and rehabilitation.* The final stage of acute illness is recovery and rehabilitation. Institutional healthcare sees recovery begin in the hospital but completed at home. This process means education for the person and continuity of care as a major goal for nursing. The shift in settings means nursing care continues outside the hospital in community

settings and the home. The person now relinquishes their dependent role and resumes normal roles and responsibilities. The experience and knowledge gained during treatment and care may place the person on a higher level of wellness after recovery is complete. Recovery time is flexible as the severity of the illness and the method of treatment will affect this, as will the person's compliance and motivation.

ILLNESS PREVENTION

Prevention includes any measures that limit the progression of an illness at any point of its course. Three levels of illness prevention were first defined in 1965. Each level of prevention occurs at a distinct point in the development of a disease process and requires specific nursing interventions (Edelman & Mandle, 2006):

1. *Primary level of prevention.* Generalised health promotion activities as well as specific actions that prevent or delay a disease occurring, including:
   - protecting against environmental risks, such as air and water pollution
   - eating nutritious foods
   - protecting against industrial hazards
   - wearing seat belts and helmets
   - sex counselling and practising safe sex
   - being immunised
   - genetic screenings
   - not smoking and reducing alcohol intake.
2. *Secondary level of prevention.* Interventions around early diagnosis and treatment if an illness is already present. Stopping or slowing the pathological process and helping the person to return to health as soon as possible. These include:
   - screenings for diseases such as hypertension, diabetes and glaucoma
   - physical examinations and diagnostic tests for cancer
   - specific treatments; for example, the treatment of streptococcal infections of the throat will prevent secondary infections of the heart and/or kidneys.
3. *Tertiary level of prevention.* Stopping the disease process and rehabilitating the person back to their normal place in society. Tertiary prevention measures include:
   - medical or surgical treatment for an illness
   - specific rehabilitation programs for cardiovascular problems, head injuries and strokes
   - work training programs following illness or injury
   - educating the public to employ rehabilitated people to the fullest possible extent.

STAGES OF ADULTHOOD

The adult years of life can be divided into three major stages: the young adult (18 to 40 years), the middle adult (40 to 65 years) and the older adult (over 65 years). Adult developmental markers are not as clearly delineated as in the infant or child; however, specific changes do occur with ageing in intellectual, psychosocial and spiritual development, along with physical structures and functions.

The developmental theories specific to the adult, with related stages and tasks, are listed in Table 2.3. Applying a

TABLE 2.3 Theories of adult development

	THEORIST	AGE	TASK
Psychosocial development	Erikson	18–25	Identity versus role confusion • Establishing an intimate relationship with another person • Committing to work and relationships
		25–65	Generativity versus stagnation • Accepting one's own life as creative and productive • Having concern for others
		65–death	Integrity versus despair • Accepting worth of one's own life • Accepting inevitability of death
Spiritual development	Fowler	After 18	• Having a high degree of self-consciousness • Constructing one's own spiritual system
		After 30	• Being aware of truth from a variety of viewpoints
	Westerhoff	Young adult	Searching faith • Acquiring a cognitive and an affective faith through questioning one's own faith
		Middle–older adult	Owned faith • Putting faith into action and standing up for beliefs
Moral development	Kohlberg	Adult	Postconventional level Social contract/legalistic orientation • Defining morality in terms of personal principles • Adhering to laws that protect the welfare and rights of others Universal–ethical principles • Internalising universal moral principles • Respecting others; believing that relationships are based on mutual trust

TABLE 2.3 Theories of adult development (continued)

	THEORIST	AGE	TASK
Developmental tasks	Havighurst	18–35	• Selecting and learning to live with a mate • Starting a family and rearing children • Managing a home • Starting an occupation • Taking on civic responsibility • Finding a congenial social group
		35–60	• Achieving community and social responsibility • Establishing and maintaining an economic standard of living • Assisting teenage children in becoming responsible and happy adults • Developing relaxation-time activities • Relating to one's spouse as a person • Accepting and adjusting to the physiological changes of middle age • Adjusting to ageing parents
		60 and over	• Meeting community and social obligations • Establishing an affiliation with one's own age group • Establishing satisfactory physical living arrangements • Adjusting to decreasing physical strength, health, retirement, reduced income, death of spouse

variety of developmental theories is important to the holistic care of the adult as nurses perform assessments, implement care and provide teaching.

The young adult

In Australia, an adult is considered to be aged 18 years or over. A 'young adult' is someone aged between 18 and 25 years. A young adult is typically at the peak of physical development with all body systems functioning at maximum efficiency. During the thirties, normal physiological changes begin to occur. Table 2.4 gives a comparison of physical status for young adults during their twenties and thirties.

Risks for alterations in health

The young adult is at risk of accidents, sexually transmitted infections, substance abuse, and physical or psychosocial stressors. These risk factors may be interrelated.

INJURIES Injury is the leading cause of death, morbidity and permanent disability for Australians aged under 45 and a major source of healthcare costs. Injury causes a range of physical, cognitive and psychological disabilities that seriously affect the quality of life of individuals and their families. Factors that increase the risk of injury are age, gender, alcohol use, place of residence, ethnicity, socioeconomic status and occupation. Suicide is the leading cause of death in Australian young adults (24–44 years) followed by accidental poisoning, motor vehicle accidents, coronary heart disease and breast cancer (AIHW, 2012).

SEXUALLY TRANSMITTED INFECTIONS Sexually transmitted infections include chlamydia, genital herpes, human papillomavirus (HPV), gonorrhoea, syphilis and HIV/AIDS. Young adults who are sexually active with a variety of partners and who do not use protection such as condoms are at

TABLE 2.4 Physical status and changes in the young adult years

ASSESSMENT	20s	30s
Skin	Smooth and even	Wrinkles begin to appear
Hair	Slightly oily, shiny Balding may begin	Greying may begin Balding may begin
Vision	Snellen 20/20	Some loss of visual acuity and accommodation
Musculoskeletal	Strong, coordinated	Some loss of strength and muscle mass
Cardiovascular	Maximum cardiac output	Slight decline in cardiac output
Functional	60–90 beats/min Mean BP: 120/80	60–90 beats/min Mean BP: 120/80
Respiratory	Rate: 12–20 Full vital capacity	Rate: 12–20 Decline in vital capacity

greatest risk of these diseases. Nursing care of people with sexually transmitted infections is discussed in Chapter 49.

SUBSTANCE ABUSE The 2013 *National Drug Strategy Household Survey* found that two in five Australians smoked tobacco, drank alcohol at risky levels or used an illicit drug in 2013. However, rates of alcohol and smoking use had declined since 2010 and illicit drug use had remained stable. Misuse of prescribed medication had increased (AIHW, 2014b).

Alcohol and tobacco are the drugs most commonly used by Australians, with people starting to smoke tobacco at around 16 years. With the exception of marijuana/cannabis, the proportion of the population who have used illicit drugs at some time in their life is relatively low. However, tobacco, alcohol and illicit drug use contributes to significant illness and disease, injury, workplace concerns, violence, crime and breakdowns in families and relationships in Australia.

The most commonly reported illicit drugs used are marijuana/cannabis, followed by ecstasy, painkillers/analgesics used for non-medical purposes, and meth/amphetamine (AIHW, 2014b). Although alcohol abuse occurs at all ages, it is greater in the twenties than any other decade of life. Alcohol contributes to motor vehicle accidents and physical violence, and damages the developing foetus in pregnant women. It can cause liver disease and nutritional deficits. Nursing care of people with substance abuse issues is discussed in Chapter 5.

PHYSICAL AND PSYCHOSOCIAL STRESSORS

Physical stressors that increase the risk of illness in young adults include environmental pollutants and work-related risks such as falls, electrical hazards, mechanical injuries or exposure to toxins or infectious agents. Other physical stressors include exposure to the sun and ingestion of chemical substances such as caffeine, alcohol and nicotine.

Many different and individualised psychosocial stressors may affect young adults, including the pressure to make choices regarding education, occupation, relationships, independence and lifestyle. The young adult without adequate education or job skills may face unemployment, poverty and homelessness. Divorce is another psychological stressor that often results in loneliness, feelings of failure, financial difficulties, domestic violence and child abuse. In 2013, the divorce rate in Australia was two per 1000 people. The average time from marriage to divorce was 12 years and the median age at divorce was 45 years for men and 42 years for women (ABS, 2014).

Assessment guidelines

The following guidelines are useful in assessing the achievement of significant developmental tasks in the young adult. Does the young adult:

- feel independent from parents?
- have a realistic self-concept?
- like themselves and the direction in which their life is going?
- interact well with family?
- cope with the stresses of constant change and growth?
- have well-established bonds with significant others, such as marriage partners or close friends?
- have a meaningful social life?
- have a career or occupation?
- demonstrate emotional, social and economic responsibility for their own life?
- have a set of values that guide behaviour?
- have a healthy lifestyle?

Physical assessment of the young adult includes height and weight, blood pressure and vision. During the health history, the nurse should ask specific questions about substance use, sexual activity and concerns, exercise, eating habits, menstrual history and patterns, coping mechanisms, any familial chronic illnesses and family changes.

See Figure 2.2 and Table 2.5 for the most recent available overview of the burden of disease and Disability Adjusted Life Year (DALYs) in 15–44 year olds in Australia.

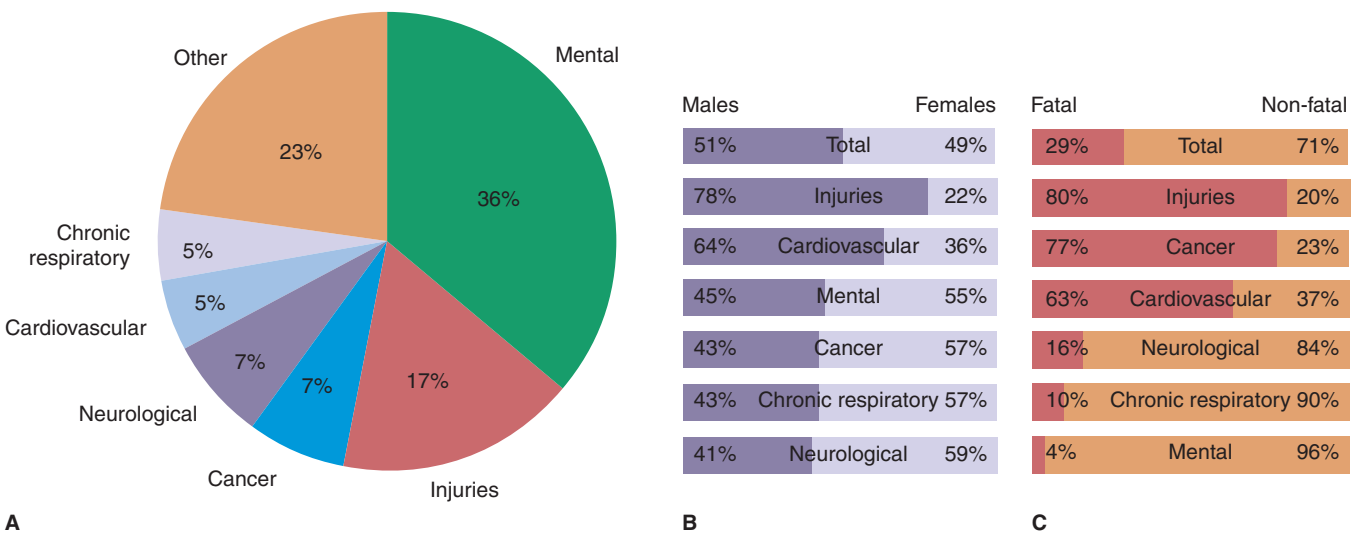

FIGURE 2.2 ■ Burden of disease disability adjusted life years (DALYs) in 15–44 year olds by broad cause group expressed as: *A,* proportions (rounded) of total, *B,* proportions by sex, and *C,* proportions due to fatal and non-fatal outcomes, Australia, 2003

Promoting healthy behaviours in the young adult

Health information for the young adult is primarily provided in community settings including:

- Health-related courses and seminars at community colleges and universities provide information on exercise, alcohol and drug abuse, smoking cessation, mental health and sexual health.
- Workplace programs emphasise blood pressure monitoring, exercise, smoking cessation, nutrition guidelines and stress reduction activities.
- Community programs provide information on media, support groups, and risk factors for disease and injury.

The middle adult

Many physical status and function changes take place between ages 40 and 65. Table 2.6 lists the physical changes that normally occur in the middle years.

Risks for alterations in health

The middle adult is at risk of obesity, cardiovascular disease, cancer, substance abuse, and physical and psychosocial stressors. These factors may be interrelated.

OBESITY The middle adult often has a problem maintaining a healthy weight. Weight gain at this age is the result of consuming the same number of kilojoules/calories while physical activity decreases and basal metabolic rate falls. Obesity affects all major organ systems, increasing the risk of atherosclerosis, hypertension, elevated cholesterol and triglyceride levels, and diabetes. Obesity is also associated with heart disease, osteoarthritis and gallbladder disease.

CARDIOVASCULAR DISEASE The major risk factors, especially for coronary artery disease, include age, male gender, physical inactivity, cigarette smoking, hypertension,

TABLE 2.6 Physical changes in the middle adult years

ASSESSMENT	CHANGES
Skin	• Decreased turgor, moisture and subcutaneous fat result in wrinkles. • Fat is deposited in the abdominal and hip areas.
Hair	• Loss of melanin in hair shaft causes greying. • Hairline recedes in males and sometimes females.
Sensory	• Visual acuity for near vision decreases (presbyopia) during the 40s. • Auditory acuity for high-frequency sounds decreases (presbycusis), more commonly in men. • Sense of taste diminishes.
Musculoskeletal	• Skeletal muscle mass decreases by about age 60. • Thinning of intervertebral discs results in loss of height (about 2.5 cm). • Postmenopausal women may have loss of calcium and develop osteoporosis.
Cardiovascular	• Blood vessels lose elasticity. • Systolic blood pressure may increase.
Respiratory	• Loss of vital capacity (about 1L from age 20 to 60) occurs.
Gastrointestinal	• Large intestine gradually loses muscle tone; constipation may result. • Gastric secretions are decreased.
Genitourinary	• Hormonal changes: menopause, women (↓ oestrogen); andropause, men (↓ testosterone).
Endocrine	• Gradual decrease in glucose tolerance.

elevated blood cholesterol levels and diabetes. Other contributing factors include obesity, stress and lack of exercise. The middle adult is also at risk of peripheral vascular, cerebrovascular and cardiovascular disease.

CANCER Cancer is the leading cause of death and illness in Australia, closely followed by cardiovascular disease (Begg et al., 2007). The five most common cancers in Australia are prostate, colorectal, breast, melanoma and lung cancer. One in every two Australian males and one in every three Australian females will be diagnosed with cancer before age 85 (AIHW, 2014a). The AIHW *Australia's Health 2014* report shows that:

- 4 million women participated in Breast Screen Australia between 2011 and 2012.
- 3.7 million women participated in the National Cervical Screening Program between 2011 and 2012.
- 35% of over 2 million people invited to participate in the National Bowel Cancer Screening Program between 2011 and 2012 returned a completed bowel cancer screening kit for analysis.

Nursing care of the person with cancer is discussed in Chapter 13.

SUBSTANCE ABUSE Although middle adults use a variety of substances, the most commonly abused are alcohol, nicotine and prescription drugs. Excess alcohol use in the middle adult contributes to an increased risk of liver cancer, cirrhosis, pancreatitis, hyperlipidaemia and anaemia. Alcoholism also increases the risk of accidental injury or death and disrupts careers and relationships. Tobacco smoking increases the risk of cancers of the larynx, lung, mouth, pharynx, bladder, pancreas, oesophagus and kidney, as well as chronic obstructive pulmonary disease and cardiovascular disorders.

PHYSICAL AND PSYCHOSOCIAL STRESSORS The middle adult years are ones of change and transition, frequently resulting in stress. Both men and women must adapt to changes and declines in physical appearance and function and accept their own mortality. The age for first-time parents has risen substantially in the past few decades, and children are living at home longer, usually due to financial reasons. The middle adult becomes part of what has been called 'the sandwich generation' (Miller, 1981), caring simultaneously for children and ageing parents. Both men and women may make career changes, and approaching retirement becomes a reality. Divorce in the middle years is also a major emotional, social and financial stressor.

Assessment guidelines

The following guidelines are useful in assessing the achievement of significant developmental tasks in the middle adult. Does the middle adult:

- accept the ageing body?
- feel comfortable with and respect themselves?
- enjoy some new freedom to be independent?
- accept changes in family roles?
- enjoy success and satisfaction from work and/or family roles?
- interact well and share companionable activities with a partner?
- expand or renew previous interests?
- pursue charitable and altruistic activities?
- consider plans for retirement?
- have a meaningful philosophy of life?
- follow health promotion practices?

Physical assessment of the middle adult includes all body systems, including blood pressure, vision and hearing. Monitoring for risks and possible cancer symptoms is essential. The nurse should ask specific questions about food intake and exercise habits, substance abuse, sexual concerns, changes in the reproductive system, coping mechanisms and family history of chronic illnesses.

See Figure 2.3 and Table 2.7 for an overview of the burden of disease (DALYs) in 45–64 year olds in Australia.

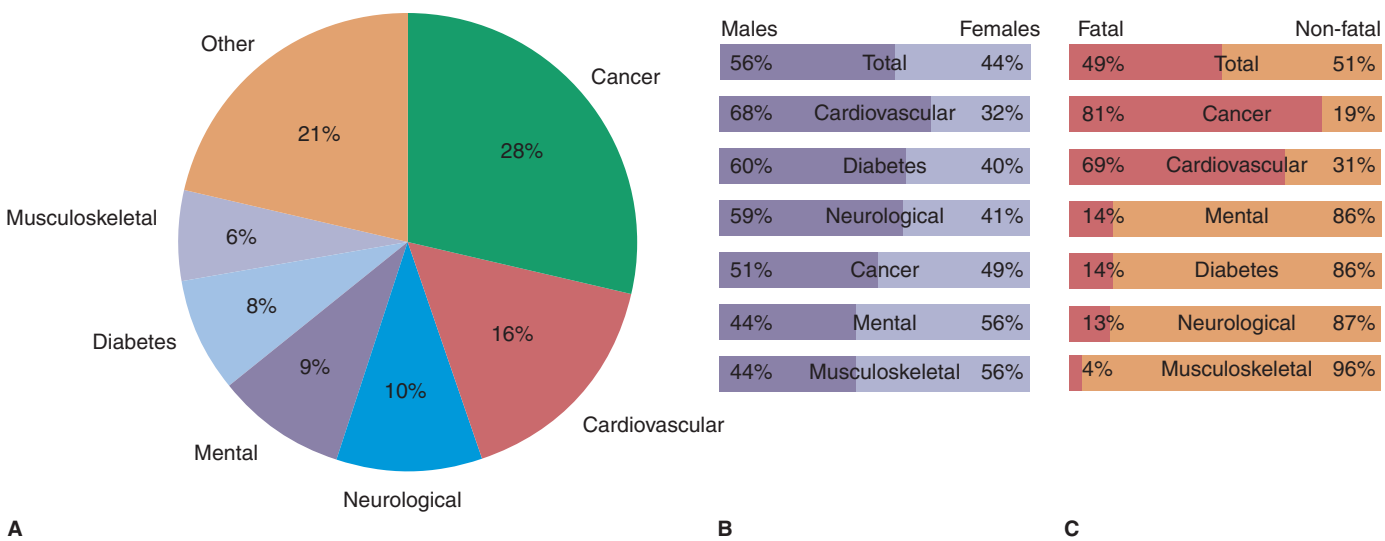

FIGURE 2.3 ■ Burden of disease (DALYs) in 45–64 year olds by broad-cause disease group expressed as: *A,* proportions (rounded) of total, *B,* proportions by sex, and *C,* proportions due to fatal and non-fatal outcomes, Australia, 2003

Promoting healthy behaviours in the middle adult

Health information for the middle adult can be provided in a variety of community settings, including outpatient clinics, occupational health clinics and private practice. Examples are as follows:

- Specific programs emphasise accepting responsibility for one's own health. This type of teaching can be through seminars or on a one-to-one basis, and includes information specific to individuals with an identified need, such as smokers, women who have re-entered the workforce or men nearing retirement.
- Community and employment agencies provide information about safety hazards in the home, workplace and community.
- There are many community resources available including programs offered at alcohol/drug abuse treatment centres, clinics and health centres, counselling services, crisis intervention centres, intimate partner violence programs, and health education and promotion agencies (e.g. the Association of Relatives and Friends of the Mentally Ill, Red Cross Australia, the Cancer Council Australia, the Heart Foundation of Australia and Diabetes Australia).

The older adult

The older adult period begins at age 65, but it can be further divided into three periods: the young-old (ages 65 to 74), the middle-old (ages 75 to 84) and the old-old (age 85 and over). With increasing age a number of normal physiological changes occur (see Table 2.8).

Improving older people's health is an Australian national research priority. One area of special interest is adopting a healthy lifestyle at older ages because its benefits include the prevention of disease and functional decline, extended longevity and enhanced quality of life (WHO, 2002).

The increase in numbers of older adults has important implications for nursing. People needing healthcare in all settings will be older, requiring nursing interventions and teaching specifically designed to meet needs that differ from those of young and middle adults. Although older person nursing is a nursing specialty area, it is also an integral component of medical–surgical nursing (see Figure 2.4).

Risks for alterations in health

The older adult is at risk of alterations in health from a variety of causes. Most older adults have one chronic health problem, while many have multiple illnesses (co-morbidities). Ischaemic heart disease (coronary heart disease) and cerebrovascular diseases (notably stroke) are the two leading causes of death, accounting for about 30% of all deaths among older Australian men and women. Like the middle adult, the older adult is at risk of decreased health from obesity and a sedentary lifestyle. Other risk factors specific to this age group include accidental injuries, pharmacological effects, and physical and psychosocial stress.

INJURIES Injuries in the older adult cause many problems: illness, financial burdens, hospitalisation, self-care deficits, loss of independence and even death. The risk of injury is increased by the normal physiological changes that accompany ageing,

FIGURE 2.4 ■ The older adult population is increasing more rapidly than any other age group, making nursing of older adults an integral component of medical–surgical nursing practice

TABLE 2.8 Physical changes in the older adult years

ASSESSMENT	CHANGES
Skin	• Decreased turgor and sebaceous gland activity result in dry, wrinkled skin. Melanocytes cluster, causing 'age spots' or 'liver spots'.
Hair and nails	• Scalp, axillary and pubic hair thins; nose and ear hair thickens. Women may develop facial hair. • Nails grow more slowly; may become thick and brittle.
Sensory	• Visual field narrows, and depth perception is distorted. • Pupils are smaller, reducing night vision. • Lenses yellow and become opaque, resulting in distortion of green, blue and violet tones, and increased sensitivity to glare. • Production of tears decreases. • Sense of smell, taste and thirst decreases. • Age-related hearing loss progresses, involving middle- and low-frequency sounds. • Threshold for pain and touch increases. • Alterations in proprioception (sense of physical position) may occur.
Musculoskeletal	• Loss of overall mass, strength and movement of muscles occurs; tremors may occur. • Loss of bone structure and deterioration of cartilage in joints results in increased risk of fractures and limitation of range of motion.
Cardiovascular	• Systolic blood pressure rises. • Cardiac output decreases. • Peripheral resistance increases, and capillary walls thicken.
Respiratory	• Continued loss of vital capacity occurs as the lungs become less elastic and more rigid. • Anteroposterior chest diameter increases; kyphosis. • Although blood carbon dioxide levels remain relatively constant, blood oxygen levels decrease by 10–15%.
Gastrointestinal	• Production of saliva decreases, and decreased number of taste buds decrease accurate receptors for salt and sweet. • Gag reflex is decreased, and stomach motility and emptying are reduced. • Both large and small intestines have some atrophy, with decreased peristalsis. • The liver decreases in weight and storage capacity; gallstones increase; pancreatic enzymes decrease.
Genitourinary	• Kidneys lose mass and the glomerular filtration rate is reduced (by nearly 50% from young adulthood to old age). • Bladder capacity decreases and the micturition reflex is delayed. Urinary retention is more common. • Women may have stress incontinence; men may have an enlarged prostate gland. • Reproductive changes in men occur: – Testosterone decreases. – Sperm count decreases. – Testes become smaller. – Length of time to achieve an erection increases; erection is less full. • Reproductive changes in women occur: – Oestrogen levels decrease. – Breast tissue decreases. – Vagina, uterus, ovaries and urethra atrophy. – Vaginal lubrication decreases. – Vaginal secretions become alkaline.
Endocrine	• Pituitary gland loses weight and vascularity. • Thyroid gland becomes more fibrous and plasma decreases. • Pancreas releases insulin more slowly; increased blood glucose levels are common. • Adrenal glands produce less cortisol.

pathophysiological alterations in health, environmental hazards and lack of support systems. The two major causes of injury in the older adult are falls and motor vehicle accidents. Of these, falls with resultant hip fractures are the most significant in terms of long-term disability and death.

PHARMACOLOGICAL EFFECTS Medications are commonly used by older Australians to treat and manage illness and health conditions and include prescription pharmaceuticals, over-the-counter medications, vitamins and minerals and, increasingly, illegal drugs. The level of use of pharmaceuticals generally increases with age. The rate of prescribed medication use for Australians aged 65 years and over is about 100 per 100 general practitioner encounters, which means, on average, that every time a person in this age group sees a doctor, they are prescribed medication (AIHW 2007, p. 31).

A number of risk factors predispose the older adult to experiencing drug toxicity. Age-related changes in tissue and organ structure and function alter the absorption of both oral and parenteral medications. Low nutritional levels and decreased liver

FOCUS ON CULTURAL DIVERSITY Diversity in older Australian adults

- Australians aged 65 years and over have one of the highest life expectancies in the world.
- More than 50% of all older people in Australia are aged 65–74 years. About 30% are the middle-old and 12% are the old-old.
- By 2036, the number of Australians aged 65 years and over is expected to more than double, from 2.7 million to 6.3 million, and will represent 24% of the total population.
- Older Australians are active contributors to family and community life.
- Most older people live in their own homes—only 6% live in non-private dwellings, which include aged care homes and hospitals.
- Australian women of all cultural backgrounds tend to live longer than the men.
- The life expectancy gap between Indigenous and non-Indigenous Australians, and the very low proportion of the Indigenous population aged 65 years and over, means the 'older Indigenous' population is considered to include people aged 50 years and over.
- Most older Australians born in non-English countries come from Italy, Greece, Germany, the Netherlands and China.

Source: Data from Australian Institute of Health and Welfare (2007). *Older Australia at a glance.*

function may alter drug metabolism. The ageing kidney may not excrete drugs at the normal clearance rate. Self-administration of both prescribed and non-prescribed medications presents risks for error from confusion, forgetfulness or misreading the directions. The older adult may take several drugs at once, placing them at risk of drug–drug interaction or an adverse drug event. These events are responsible for high rates of hospital admissions and mortality in older Australians (Morgan, 2009).

PHYSICAL AND PSYCHOSOCIAL STRESSORS The older adult is exposed to the same environmental hazards as the young and middle adult, but the accumulation of years of exposure may now appear; for example, skin cancer from many years of sun exposure and hearing loss due to long-term noise pollution. Older adults (especially males) are at increased risk of respiratory disorders as a result of smoking, or from such pollutants as coal or asbestos dust. Living conditions and economic constraints may prevent the older adult from having necessary heating and cooling, contributing to thermal-related illnesses and even death. Mistreatment of older people (elder abuse) and neglect further increases the risk of injury or illness.

Psychosocial stressors for the older adult include the illness or death of a spouse, decreased or limited income, retirement, isolation from friends and family because of lack of transportation or distance, return to the home of a child or relocation to an aged care facility. A further stressor may be role loss or reversal; for example, when the wife becomes the caretaker of her chronically ill husband.

Assessment guidelines

The following guidelines are useful in assessing the achievement of significant developmental tasks in the older adult. Does the older adult:

- adjust to the physiological changes of ageing?
- manage retirement years in a satisfying manner?
- have satisfactory living arrangements and income to meet changing needs?
- participate in social and leisure activities?
- have a social network of friends and support people?
- view life as worthwhile?
- have high self-esteem?
- have the abilities to care for self or to secure appropriate help?
- gain support from a value system or spiritual philosophy?
- adapt lifestyle to their diminishing energy and ability?
- accept and adjust to their own death and that of significant others?

Physical assessment of the older adult includes a careful examination of all body systems. When taking a health history, the nurse should ask specific questions about dietary patterns; elimination; exercise and rest; use of alcohol, nicotine, over-the-counter medications, and prescription and non-prescription drugs; sexual concerns; financial concerns; and support systems.

See Figure 2.5 and Table 2.9 for an overview of the burden of disease (DALYs) in 65–74 year olds in Australia.

Promoting healthy behaviours in the older adult

Older adults derive the same benefits from health teaching as young adults and middle adults and should never be viewed as being 'too old' for healthy living practices. However, nurses need to structure teaching activities to meet age-related physiological changes, such as using large print. Health education for the older adult is provided in hospitals, aged care facilities, retirement villages, outpatient clinics, senior citizen centres and other community settings. Examples are as follows:

- Educational seminars teach about accident prevention in the home, in cars and when using public transport.
- Health screenings that are specifically aimed at the older adult.
- Community programs provide immunisation for influenza and pneumonia.
- Literature gives information about financial assistance for healthcare, crisis hotlines, community services and resources (described earlier for the middle adult), transportation and nutrition.

THE CONCEPT OF FAMILY

Although some people are totally alone in the world, most have one or more other people who are significant in their lives. These significant others may be related or bonded to the person by birth, adoption, marriage or friendship. Although not always meeting traditional definitions, people (or even pets) significant to the person are considered the person's family. The nurse

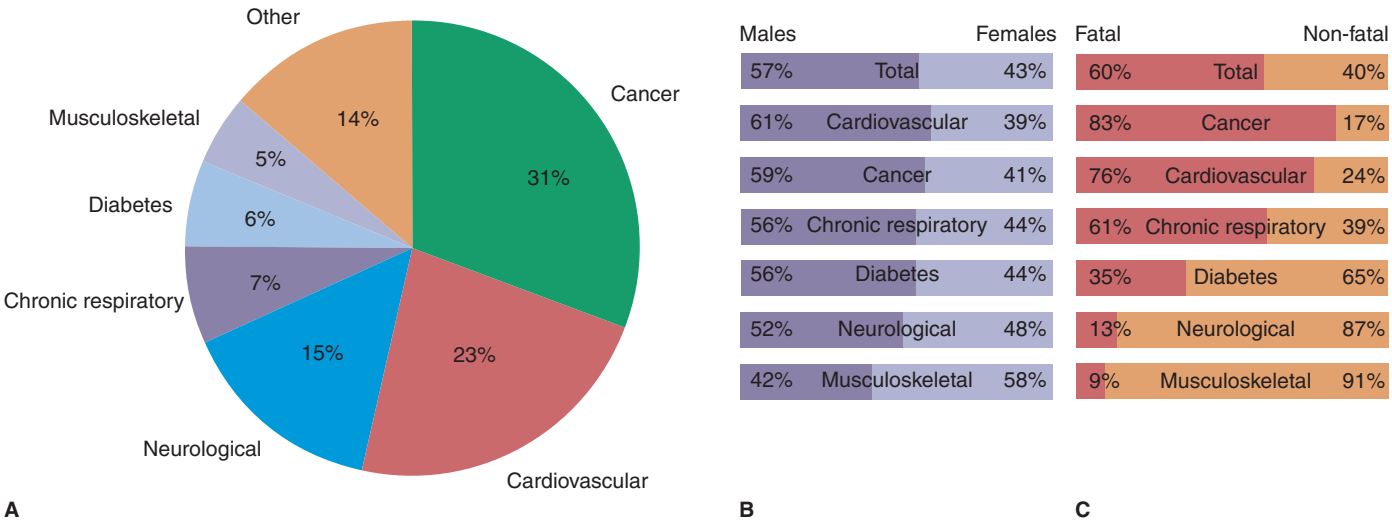

FIGURE 2.5 ■ Burden (DALYs) in 65–74 year olds by broad cause group expressed as: *A*, proportions (rounded) of total, *B*, proportions by sex, and *C*, proportions due to fatal and non-fatal outcomes, Australia, 2003

RANK	MALES	DALYs	% OF TOTAL	FEMALES	DALYs	% OF TOTAL
1	Ischaemic heart disease	37 860	15.5	Ischaemic heart disease	21 052	11.4
2	Lung cancer	19 258	7.9	Type 2 diabetes	11 517	6.2
3	Type 2 diabetes	14 203	5.8	Breast cancer	10 445	5.7
4	Prostate cancer	11 950	4.9	Dementia	10 236	5.5
5	Adult-onset hearing loss	11 920	4.9	Lung cancer	9 937	5.4
6	COPD	11 693	4.8	Stroke	9 635	5.2
7	Stroke	10 938	4.5	COPD	8 855	4.8
8	Colorectal cancer	10 531	4.3	Colorectal cancer	7 513	4.1
9	Dementia	7 872	3.2	Osteoarthritis	6 088	3.3
10	Parkinson's disease	3 958	1.6	Adult-onset hearing loss	5 834	3.2

should always include the family as an integral component of care in all healthcare settings.

Definitions and functions of the family

What is a **family**? The definitions of a family are changing as society changes. According to one definition, a family is a unit of people related by marriage, birth or adoption (Duvall, 1977). A more comprehensive definition is that a family is composed of two or more people who are emotionally involved with each other. In a global society, it may not be possible for family members to live in close proximity, but they can remain emotionally involved.

Although every family is unique, all families have certain structural and functional features in common. Family structure (family roles and relationships) and family function (interactions among family members and with the community) provide the following:

- *Interdependence.* The behaviours and level of development of individual family members constantly influence and are influenced by the behaviours and level of development of all other members of the family.
- *Maintaining boundaries.* The family creates boundaries that guide its members, providing a distinct and unique family culture. This culture, in turn, provides values.
- *Adapting to change.* The family changes as new members are added, current members leave and the development of each member progresses.
- *Performing family tasks.* Essential tasks maintain the stability and continuity of the family. These tasks include physical maintenance of the home and the people in the home, the production and socialisation of family members and the maintenance of the psychological wellbeing of members.

Family developmental stages and tasks

The family, like the individual, has developmental stages and tasks. Each stage brings change, requiring adaptation, and each new stage also presents family-related risk factors for

alterations in health. The nurse must consider the person's needs both at a specific developmental stage and within a family with specific developmental tasks. Family developmental stages and developmental tasks are described next. Related risk factors and health problems for each stage are listed in Table 2.10.

The couple

The developmental tasks of the couple include adjusting to living together, establishing a mutually satisfying relationship, relating to relatives and deciding whether to have children (for those of child-bearing age).

Family with infants and preschoolers

The family with infants or preschoolers must adjust to having and supporting the needs of more than two members. Other developmental tasks of the family at this stage include developing an attachment between parents and children, adjusting to the economic costs of having more members, coping with energy depletion and lack of privacy, and

TABLE 2.10 Family-related risk factors for alterations in health

STAGE	RISK FACTORS	HEALTH PROBLEMS
Couple or family with infants and preschoolers	• Lack of knowledge about family planning, contraception, sexual and marital roles • Inadequate antenatal care • Altered nutrition: inadequate nutrition, overweight, underweight • Smoking, alcohol/drug abuse • First pregnancy before age 16 or after age 35 • Low socioeconomic status • Lack of knowledge about child health and safety • Rubella, syphilis, gonorrhoea, HIV/AIDS	• Premature pregnancy • Low-birth-weight infant Birth defects • Injury to infant or child Accidents
Family with school-age children	• Unsafe home environment • Working parents with inappropriate or inadequate resources for child care • Low socioeconomic status • Child abuse or neglect • Multiple, closely spaced children • Repeated infections, accidents and hospitalisations • Unrecognised and unattended health problems • Poor or inappropriate nutrition • Toxic substances in the home	• Behaviour problems • Speech and vision problems • Learning disabilities • Communicable diseases • Physical abuse • Cancer • Developmental delay • Obesity, underweight
Family with adolescents and young adults	• Family values of aggressiveness and competition • Lifestyle and behaviour leading to chronic illness (substance abuse, inadequate diet) • Lack of problem-solving skills • Conflicts between parent and children	• Violent death and injury • Alcohol/drug abuse • Unwanted pregnancy • Suicide • Sexually transmitted infections • Domestic abuse
Family with middle adults	• High-cholesterol diet • Overweight • Hypertension • Smoking, alcohol abuse • Physical inactivity • Personality patterns related to stress • Exposure to environment: sunlight, radiation, asbestos, water or air pollution • Depression	• Cardiovascular disease (coronary artery • disease and cerebral vascular disease) • Cancer • Accidents • Suicide • Mental illness
Family with older adults	• Age • Depression • Drug interactions • Chronic illness • Death of spouse • Reduced income • Poor nutrition • Lack of exercise • Past environment and lifestyle	• Impaired vision and hearing • Hypertension • Acute illness • Chronic illness • Infectious diseases (influenza, pneumonia) • Injuries from burns and falls • Depression • Alcohol abuse

carrying out activities that enhance the growth and development of the children.

Family with school-age children

The family with school-age children has the developmental tasks of adjusting to the expanded world of children in school and encouraging educational achievement. A further task is promoting joint decision making between children and parents.

Family with adolescents and young adults

The developmental tasks of the family with adolescents and young adults focus on transition. While providing a supportive home base and maintaining open communications, parents must balance freedom with responsibility and release adult children as they seek independence.

Family with middle adults

The family with middle adults (in which the parents are middle aged and children are no longer at home) has the developmental tasks of maintaining ties with older and younger generations and planning for retirement. If the family consists of just the middle-aged couple, they have the developmental tasks of re-establishing their relationship as a couple and possibly taking on the role of grandparents.

Family with older adults

The older adult family has the developmental tasks of adjusting to retirement, adjusting to ageing and coping with the loss of a spouse. If a spouse dies, further tasks include adjusting to living alone and perhaps selling the family home.

The family of the person with a chronic illness

The person with a chronic illness may be hospitalised for diagnosis and treatment of acute exacerbations, but their care is primarily provided at home. Chronic illness in a family member is a major stressor that causes changes in family structure and function and performing family developmental tasks.

Many factors affect family responses to chronic illness and these responses in turn affect the person's response to and perception of the illness. Factors influencing response to chronic illness include personal, social and economic resources as well as the nature and course of the disease and the demands of the illness as perceived by family members.

Support for the family is essential. The following information should be considered when performing any family assessment and developing a plan of care:

- cohesiveness and communication patterns within the family
- family interactions that support self-care
- friends and relatives available to help
- family values and beliefs about health and illness
- cultural and spiritual beliefs
- developmental level of the person and family.

It is important to remember that standardised teaching plans may not be effective. People with chronic illnesses and their families should be given the freedom to choose appropriate literature, self-help or support groups, and interactions with others who have the same illness.

CHAPTER HIGHLIGHTS

- Health is an ever-changing state affected by genetic make-up, cognitive abilities, education, ethnicity, cultural background, age, gender, developmental level, lifestyle, environment, socioeconomic background and geographical area.
- The emphasis of nursing has shifted from acute care in the hospital setting to preventive community-based care. An essential component of medical–surgical nursing is teaching health behaviours that promote and maintain functional health status.
- Illnesses may be acute or chronic and behaviours of illness follow a sequence of experiencing symptoms, assuming the sick role, seeking medical help, assuming a dependent role, recovery and rehabilitation.
- Young adults are at risk of alterations in health from injury, sexually transmitted infections, substance abuse, workplace exposure to pollutants, sun exposure and psychological stressors.
- Middle adults are at risk of alterations in health from obesity, cardiovascular disease, cancer, substance abuse, and the stresses of change and transition.
- Older adults are at risk of alterations in health from chronic illnesses, injuries, drug toxicities, and changes in income and marital status.
- The family is an integral component in planning and implementing nursing care for the adult.

CONCEPT CHECK

1 Which definition best describes wellness?
1. a complete absence of disease
2. depends on the number of chronic illnesses
3. never having to take medications
4. gaining the best potential functioning of an individual

2 Many different factors affect the health of an individual. Which of the following are included? (Select all that apply.)
1. genetic make-up
2. cognitive abilities
3. height
4. age
5. ethnicity

3 Which of the following diseases has a genetic basis?
1. tuberculosis
2. cystic fibrosis
3. appendicitis
4. indigestion

4 Primary levels of prevention are general health promotion actions that prevent or delay the occurrence of a disease. Which of the following is a primary preventive activity?
1. practising safer sex
2. screening for hypertension
3. breast self-examination
4. having surgery

5 You call your tutor to say you have the 'flu' and will not be in class. What level of illness behaviour are you demonstrating?
1 experiencing symptoms
2 assuming the sick role
3 seeking medical care
4 assuming a dependent role

6 Your nephew was born with a heart defect. How would this disorder be classified?
1 an acute illness
2 a malignant illness
3 an iatrogenic illness
4 a congenital illness

7 Of the following descriptors, which is specific to a chronic illness?
1 occurs rapidly
2 lasts for a long time
3 is self-limiting
4 lasts for a short time

8 Mr Jones, age 50, is 15 kg overweight, smokes and rarely exercises. As a middle adult these factors increase his risk of disorders of which body system?
1 cardiovascular
2 renal
3 gastrointestinal
4 nervous

9 You are asked to present a health-related program at the local senior citizen centre. What would be an appropriate topic?
1 the hazards of substance abuse
2 accident prevention in the home
3 family roles and tasks
4 treating acute illness

10 Which of the following developmental tasks are part of the life of a family with older adults if a spouse dies? (Select all that apply.)
1 coping with lack of privacy
2 planning for retirement
3 adjusting to ageing
4 coping with loss
5 relating to family

UNIT 2

ALTERATIONS IN PATTERNS OF HEALTH

CHAPTER 3

NURSING CARE OF PEOPLE HAVING SURGERY

ASHLEY KABLE, NATALIE GOVIND

LEARNING OUTCOMES

- Discuss the differences and similarities between outpatient and inpatient surgery.
- Describe legal requirements and responsibilities prior to surgery.
- Describe the various classifications and risk factors of surgical procedures.
- Identify diagnostic tests used during the perioperative period.
- Describe nursing implications for medications prescribed for the person having surgery.
- Describe appropriate nursing care for people having surgery in the preoperative, intraoperative and postoperative phases of surgery.
- Identify variations in perioperative care for the older adult.
- Describe principles of pain management specific to acute postoperative pain control.
- Apply the nursing process as a framework for providing individualised care for people undergoing surgery.

CLINICAL COMPETENCIES

- Assess the physiological health status of people having surgery to determine their ability to tolerate surgery and risks of complications.
- Assess the psychosocial health status of the person having surgery and their family.
- Ensure safety of the person having surgery within the operating theatre and throughout the postoperative period.
- Participate in education for the person and their family prior to anaesthesia and prior to discharge from the facility.
- Describe the sterile field in the operating theatre, practise infection control and take occupational health and safety precautions to prevent infections and minimise hazards.
- Physiologically monitor the person during surgery. As part of the interprofessional team, promote safe practice and rehabilitation of the person having surgery.
- Monitor and control the environment to prevent accidents or injury to the person having surgery and members of the healthcare team.
- Respect the person's rights, including privacy, at all times.

KEY TERMS

Surgery is an invasive medical procedure performed to diagnose or treat illness, injury or deformity. Although surgery is a medical treatment, the nurse assumes an active role in caring for the person before, during and after surgery. **Interprofessional care** and teamwork by nurses, surgeons, anaesthetists, pharmacists and allied health professionals can prevent complications and promote optimal recovery of the person having surgery.

Perioperative nursing is a specialised area of practice. It incorporates the three phases of the surgical experience: preoperative, intraoperative and postoperative. The **preoperative** phase begins when the decision for surgery is made and ends when the person having surgery is transferred to the operating room. The **intraoperative phase** begins with the person's entry into the operating room and ends with transfer to the post anaesthesia care unit (PACU), or recovery room. The **postoperative phase** begins with the person's arrival at the PACU and ends with their complete recovery from the surgical intervention.

CLASSIFICATIONS OF SURGICAL PROCEDURES

Surgical procedures can be classified according to purpose, risk factor and urgency (see Table 3.1). Based on this information, nursing care can be individualised to meet the needs of the person having surgery.

Although the perioperative nurse works in collaboration with other healthcare professionals to identify and meet the needs of the person having surgery, the perioperative nurse has the primary responsibility and accountability for nursing care of the person undergoing surgery.

SETTINGS FOR SURGERY

People having surgery may be inpatients or outpatients. The complexity of the surgery and the recovery and expected condition of the person following the surgery are the major differences. Sometimes outpatients (i.e. people intending to be discharged home immediately following surgery) are admitted to the hospital. Cataract removal with or without lens implants, hernia repairs, tubal ligations, vasectomies, dilation and curettage (D&C), haemorrhoidectomies and biopsies are commonly performed in outpatient surgeries.

Inpatient and outpatient surgeries are performed in the same operating suites in most hospitals. There are also **day surgery units/centres** (also called *ambulatory surgery*), which are not physically connected to a hospital. Perioperative nursing roles support people having surgery irrespective of whether surgeons practise in hospitals or in freestanding surgical facilities. Some outpatient surgeries are performed in surgeons' offices rather than surgical centres. The number of outpatient surgeries has grown rapidly in the past decade as part of the effort to contain the high costs of surgery. Moreover, increasingly complex surgeries on people with complicated medical problems are now commonly performed on an outpatient basis. This increase in number of procedures and acuity level of people having surgery presents challenges for the perioperative nurse, the person having surgery and their family.

Outpatient surgery potentially offers several advantages:

- decreased cost to the person having surgery and the hospital
- reduced risk of hospital-acquired infection
- less interruption to the person's and their family's routine
- possible reduction in time lost from work and/or other responsibilities
- less physiological stress for the person and their family.

TABLE 3.1 Classification of surgical procedures

	CLASSIFICATION	FUNCTION	EXAMPLES
Purpose	Diagnostic	Determine or confirm a diagnosis	Breast biopsy, bronchoscopy
	Ablative	Remove diseased tissue, organ or extremity	Appendectomy, amputation
	Constructive	Build tissue/organs that are absent (congenital anomalies)	Repair of cleft palate
	Reconstructive	Rebuild tissue/organ that has been damaged	Skin graft after a burn, total joint replacement
	Palliative	Alleviate symptoms of a disease (not curative)	Bowel resection in a person with terminal cancer
	Transplant	Replace organs/tissue to restore function	Heart, lung, liver, kidney transplant
Risk factor	Minor	Minimal physical assault with minimal risk	Removal of skin lesions, dilation and curettage (D&C), cataract extraction
	Major	Extensive physical assault and/or serious risk	Transplant, total joint replacement, cholecystectomy, colostomy, nephrectomy
Urgency	Elective	Suggested, though no foreseen ill effects if postponed	Cosmetic surgery, cataract surgery, bunionectomy
	Urgent	Necessary to be performed within 1 to 2 days	Heart bypass surgery, amputation resulting from gangrene, fractured hip
	Emergency	Performed immediately	Obstetric emergencies, bowel obstruction, ruptured aneurysm, life-threatening trauma

Outpatient surgery also presents some disadvantages:

- less time for the nurse to establish rapport with the person and their family
- less time for the nurse to assess, evaluate and teach the person and their family
- lack of opportunity for the nurse to assess for the risk of postoperative complications that may occur after discharge
- less time for adequate pain control before discharge.

Following outpatient surgery, the person is discharged after meeting the discharge criteria of the institution and demonstrating the following:

- normal vital signs
- ability to stand and begin to walk without dizziness or nausea
- minimal pain
- ability to urinate
- orientation to time and place
- understanding of postoperative instructions.

Many similarities exist between the nursing care of people admitted for inpatient and for outpatient surgery. Physical care is provided in much the same manner in the preoperative, intraoperative and postoperative phases of surgery. The major differences lie in the degree of teaching and emotional support that must be provided for people having outpatient surgical procedures and their families. In addition to the physiological insult of surgery, the person having outpatient surgery must cope with the stress of needing to learn a great deal of information in a short span of time. The nurse teaches the person and their family in both the preoperative and postoperative periods to enable the person to perform self-care following discharge and recognise the development of complications that require further clinical management. More extensive teaching and emotional support is necessary as people requiring more complex surgical procedures and experiencing more complicated health problems undergo outpatient surgery.

CONSIDERATION FOR PRACTICE

People having outpatient surgery should wear or bring clothing that will be easy to put on after surgery and accommodate any dressings or appliances. Despite fasting, people having outpatient surgery should bring any medications such as steroids, antibiotics, anticoagulants, antivirals, diuretics, oral contraceptives, hypotensives, cardiotonics, hypoglycaemics, asthma medications, seizure medications and analgesics, as well as any herbal preparations, that they regularly use. People having surgery should consult with the surgeon and anaesthetist before taking these medications, prior to and following surgery.

LEGAL REQUIREMENTS

It is the responsibility of the surgeon who performs the procedure to obtain the person's consent for the surgical procedure. The surgeon should discuss the procedure with the person and their family in language they can understand. **Informed consent** is disclosure of the risks associated with the intended procedure or operation to the person, and includes completion of a legal document required for certain diagnostic procedures or therapeutic measures, including surgery. The language of the document varies according to the statutory and common law of each state. This legal document protects the person undergoing surgery, the nurse, the surgeon and the healthcare facility.

Informed consent includes provision of the following information prior to a person signing a consent for medical procedure treatment form:

- need for the procedure in relation to the diagnoses
- description and purpose of the proposed procedure
- possible benefits and potential risks
- likelihood of a successful outcome
- alternative treatments or procedures available
- anticipated risks should the procedure not be performed
- surgeon's advice about what is needed
- the person's right to refuse treatment or withdraw consent.

The nurse may be present when the preceding information is provided. Later, the nurse can discuss the information with the person and their family, if necessary. If the person having surgery has questions or concerns that were not discussed or made clear, or if the nurse questions the person's understanding, the surgeon is responsible for supplying further information. Following a thorough discussion of the consent for operation or special procedures, the person having surgery voluntarily signs the form. Depending on various state and hospital policies, the nurse may also sign the form, indicating that the correct person is signing the form and that the person was alert and aware of what was being signed. In many circumstances the person having surgery is admitted to the surgical unit or day surgery with an already completed consent form.

PERIOPERATIVE RISK FACTORS

Prior to planning and implementing care for the person having surgery, the nurse must first assess their needs and the factors that may increase the risks associated with surgery. The type of surgical procedure directs the assessment and interventions planned by the nurse. However, a complete assessment is also necessary to identify *risk factors* and to determine the person's overall health status. Table 3.2 lists common risk factors for the person undergoing surgery and the related nursing interventions and implications. For example, when a person is admitted for surgery on the right knee, it should be of concern to the nurse if this person has diabetes, smokes 25 cigarettes per day, has numbness in the right foot and takes insulin. This information should be incorporated into a nursing care plan, using appropriate nursing diagnoses and interventions to meet all of the person's needs and to assist them towards full postoperative recovery.

Risks are associated with all surgical interventions. For example, transporting the person to and from the operating suite requires assessment of their need for supplementary oxygen, intravenous therapy, cardiac monitoring and safety issues pertaining to the means of transport. Many people enter the operating suite highly anxious and may benefit from medication to help them relax prior to administration of anaesthesia. This can be discussed with the anaesthetist. Chemicals, electrical equipment and environmental hazards in the surgical area have the potential to cause harm and must be monitored and maintained carefully.

TABLE 3.2 Nursing implications for surgical risk factors

FACTOR	ASSOCIATED RISK	NURSING IMPLICATIONS
Advanced age	Older adults have age-related changes that affect physiological, cognitive and psychosocial responses to the stress of surgery; decreased tolerance of general anaesthesia and postoperative medications; and delayed wound healing.	Selected nursing interventions are summarised in Table 3.6.
Obesity	The obese person is at increased risk of delayed wound healing, wound dehiscence, infection, pneumonia, atelectasis, thrombophlebitis, arrhythmias and heart failure.	Promote weight reduction if time permits. Monitor closely for wound, pulmonary and cardiovascular complications postoperatively. Encourage coughing, turning, and diaphragmatic breathing exercises and early ambulation.
Malnutrition	Reserves may not be sufficient to allow the body to respond satisfactorily to the physical assault of surgery; organ failure and shock may result. Increased metabolic demands may result in poor wound healing and infection.	With the surgeon and dietitian, promote weight gain by providing a well-balanced diet high in kilojoules, protein and vitamin C. Administer nutritional supplements and, if indicated, total parenteral nutrition intravenously, and tube feedings as prescribed. Daily weights and kilojoule counts also may be ordered.
Dehydration/ electrolyte imbalance	Depending on the degree of dehydration and/or type of electrolyte imbalance, cardiac arrhythmia or heart failure may occur. Liver and renal failure may also result.	Administer intravenous fluids as ordered. Monitor fluid input and output and weight. Monitor for evidence of fluid and electrolyte imbalance (see Chapter 9). Closely monitor fluid intake (oral and parenteral) to prevent circulatory overload.
Renal and liver dysfunction	The person with renal or liver dysfunction may poorly tolerate general anaesthesia, have fluid/electrolyte and acid–base imbalances, decreased metabolism and excretion of drugs, increased risk of haemorrhage, and delayed wound healing.	Monitor for fluid volume overload, intake and output, and response to medication. Evaluate closely for drug side effects and evidence of acidosis or alkalosis.
Cardiovascular disorders	Presence of cardiovascular disease increases the risk of haemorrhage and shock, hypotension, thrombophlebitis, pulmonary embolism, stroke (especially in the older person) and fluid volume overload.	Diligently monitor vital signs, especially pulse rate, regularity and rhythm, and general condition of the person. Assess skin colour. Assess for chest pain, lung congestion and peripheral oedema. Observe for signs of hypoxia, and administer oxygen as ordered. Early postoperative ambulation and leg exercises reduce the risk of vascular problems such as thrombophlebitis and pulmonary embolism.
Respiratory disorders	Respiratory complications such as bronchitis, atelectasis and pneumonia are some of the most common and serious postoperative complications. Respiratory depression from general anaesthesia and acid–base imbalance may also occur. People with pulmonary disease are more at risk of developing these complications.	Closely monitor respirations, pulse and breath sounds. Also assess for hypoxia, dyspnoea, lung congestion and chest pain. Encourage coughing, turning and diaphragmatic breathing exercises and early postoperative ambulation. Encourage the person to stop smoking or at least to reduce the number of cigarettes smoked.
Diabetes mellitus	Diabetes causes an increased risk of fluctuating blood glucose levels, which can lead to life-threatening hypoglycaemia or ketoacidosis. Diabetes also increases the risk of cardiovascular disease, delayed wound healing and wound infection.	Monitor the person closely for signs and symptoms of hypoglycaemia and hyperglycaemia. Monitor blood glucose levels every 4 hours or as ordered. Administer insulin if prescribed. Encourage intake of food at the designated meal and snack times.
Alcoholism	The person may be malnourished and experience alcohol withdrawal and delirium tremens. More general anaesthesia may be required. Haemorrhage and delayed wound healing can result from liver damage and poor nutritional status.	Monitor closely for signs of alcohol withdrawal and delirium tremens. Encourage well-balanced diet. Monitor for wound complications. Administer supplementary nutrients parenterally as ordered.

TABLE 3.2 Nursing implications for surgical risk factors (continued)

FACTOR	ASSOCIATED RISK	NURSING IMPLICATIONS
Nicotine use	Cigarette smokers are at increased risk of respiratory complications such as pneumonia, atelectasis and bronchitis because of increased mucous secretions and a decreased ability to expel them.	Ideally, the person having surgery should stop smoking. Be supportive of them, and monitor closely for respiratory difficulties. Coughing, turning and diaphragmatic breathing exercises with early ambulation are very important. Increase daily fluid intake to 2500–3000 mL (unless contraindicated) to help liquefy respiratory secretions to aid expectoration. A nicotine patch may help them to tolerate withdrawal during the postoperative period.
Adolescence	Diversity in age and physical, cognitive and psychological maturation makes preparation for surgery vary in content and inclusion of significant others. Increased need for control, privacy and peer interaction poses special challenges in the acute care setting.	Adapt assessment and interventions to the developmental level of individual people, involving them in preparation and care to the extent possible. Allow for regressive and independent behaviour, including rejection of adult support.
Medications	Anaesthesia interaction with some medications can cause respiratory difficulties, hypotension and circulatory collapse. Other medications can produce side effects that may increase surgical risk.	Inform the anaesthetist of all prescribed or over-the-counter medications.
Anticoagulants (including aspirin)	May cause intraoperative and postoperative haemorrhage.	Monitor for bleeding. Assess prothrombin time (PT value) and partial thromboplastin time (PTT value).
Diuretics (particularly thiazides)	May lead to fluid and electrolyte imbalances, producing altered cardiovascular response and respiratory depression.	Monitor fluid input and output and electrolytes. Assess cardiovascular and respiratory status.
Antihypertensives (particularly phenothiazines)	Increase the hypotensive effects of anaesthesia.	Closely monitor blood pressure.
Antidepressants (particularly monoamine oxidase inhibitors)	Increase the hypotensive effects of anaesthesia.	Closely monitor blood pressure.
Antibiotics (particularly the 'mycin' group)	May cause apnoea and respiratory paralysis.	Monitor respirations.
Herbal supplements	Some may prolong the effects of anaesthesia. Others may increase the risks of bleeding or raise blood pressure.	Inquire about the use of herbs or other dietary supplements. These should be discontinued at least 2 weeks before surgery.
Temperature variations	Deviations from normothermia, either hypothermia or hyperthermia, may cause infection, cardiac morbidity, myocardial ischaemia, surgical bleeding, skin damage or discomfort for the person having surgery.	Monitor core temperatures and prevent chilling or overheating. Use warmed fluids. Remove wet drapes and ensure the person is clean and dry immediately post surgery.

Unfortunately, there is a risk of performing the wrong surgery on the wrong person: including wrong site, wrong procedure and/or wrong person. In 2012, the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) (2012) issued a universal protocol mandating preoperatively: (1) verifying the procedure, (2) physically marking and initialling the site, and (3) taking a 'time out' before starting any procedure. The goal of the time out is to ensure the right procedure will be performed on the right person on the correct site with the necessary and correct healthcare professionals in attendance. A 'time out' is an intentional stoppage of the preparation for the operation, in the operating suite, before the person having surgery is anaesthetised. All participants are introduced and encouraged to ask any questions or express any concerns before the surgery is commenced to prevent adverse outcomes. The World Health Organization (WHO) and World Alliance for Patient Safety (2009) now recommends use of the Surgical Safety Checklist for this purpose. This checklist has been reported to significantly reduce surgical morbidity and mortality (de Vries et al., 2010), and a statement on the WHO Patient Safety (2009) webpage claims that half a million deaths per annum are potentially preventable if the checklist is implemented worldwide.

Another potential error is retained foreign bodies such as instruments, needles or sponges. To prevent accidental retention of foreign objects, standardised procedures for counting objects used in surgery must be consistently applied and

adhered to. Methodical wound exploration before closing the site, using x-ray-detectable materials in the wound, maintenance of optimal operating theatre environments to allow focused surgical performance and employing technological methods to ensure no unintended item remains are now the norm in surgical practice. Like wrong site injury, foreign body retainment is linked to poor communication among perioperative care providers and faulty processes of care in the operating theatre and perioperative period (Greenberg et al., 2007).

People having surgery may be using medications that increase the risk of complications associated with a surgical procedure, such as increasing the risk of bleeding. Over-the-counter medicines and herbal preparations, as well as prescription medications, may interact with drugs given during surgery, putting a person at increased risk (Collins, Oakey & Ramakrishnan, 2011; King et al., 2009). A complete history of the medications the person has been taking regularly is vital information. As part of the preoperative planning and teaching, early consideration of complementary and alternative medicine is also important. This information should be obtained in a non-judgmental manner, because a judgmental attitude could cause the person to withhold information.

Anticoagulant medications are frequently discontinued by the anaesthetist in the preoperative clinic prior to surgery to prevent excessive blood loss during surgery. These include aspirin and non-steroidal anti-inflammatory drugs. If laboratory tests of clotting/bleeding time, PT, PTT and INR (International Normalised Ratio) are elevated, the surgery may be cancelled. Guidelines for discontinuing use vary according to the particular medication; it is generally recommended that aspirin or products containing aspirin be discontinued 5 days or longer before surgery. Similarly, herbs or nutritional supplements that impair clotting should be discontinued 2 weeks prior to surgery (Collins, Oakey & Ramakrishnan, 2011; King et al., 2009). The most common self-prescribed medicines that may inhibit coagulation are vitamin E, garlic, ginkgo, ginseng, fish oil and chamomile. Many plants that contain coumarins have the potential to interact with warfarin and inhibit coagulation. Others inhibit platelet aggregation or prevent the conversion of fibrinogen to fibrin. All of these create a risk of bleeding.

People taking warfarin for the risk of blood clots due to atrial fibrillation will be counselled about the appropriate time to withdraw warfarin. If surgery is urgent due to trauma or sudden onset of morbidity, the impact of anticoagulants needs to be evaluated, with PT, PTT and INR results required before the operation and appropriate medication administered to promote clotting.

In addition to clotting impairment, excessive consumption of herbal medicines or dietary supplements can produce levels of chemicals that interact with conventional medications, exacerbating or impairing the intended effect (Collins, Oakey & Ramakrishnan, 2011). Anaesthetic drugs often decrease hepatic blood flow and interfere with the metabolism and elimination of medications. This increases the risk of adverse drug–herbal supplement interactions during surgery. Cardiovascular instability, impaired glucose control, increased metabolism of perioperative medication, and unpredictable response to anaesthesia are categories of adverse reactions of perioperative herbal use (King et al., 2009; Rowe & Baker, 2009).

In the perioperative period, hypothermia and hyperthermia are risks. Typically, surgical suites are maintained as cooler environments; however, research shows that normothermia (core body temperature in the range of 36.0˚C to 37.5˚C) in the person having surgery reduces the risk of infection, cardiac morbidity, myocardial ischaemia, surgical bleeding and personal discomfort (Burger & Fitzpatrick, 2009; Yang et al., 2012). Methods to minimise the risk of hypothermia include:

- Apply warm blankets on arrival in the surgical area and after sterile drapes are removed.
- Limit the amount of skin exposed during positioning and skin preparation.
- Limit the time of skin exposure between prepping and draping.
- Prevent surgical drapes from becoming wet.
- Adjust the room temperature for normothermia.
- Monitor the person's temperature to avoid overheating.
- Use heat-maintenance devices such as warming units, stockings, caps and leggings.
- Warm irrigation or infusion solutions as needed.
- Humidify the airway.
- Clean and dry the person immediately postoperatively.

An anaesthetised person loses heat intraoperatively and is unable to restore temperature through the normal mechanisms of shivering or muscle contractions (Burger & Fitzpatrick, 2009). Hyperthermia should also be avoided. Heating of fluids or use of heating units necessitates accurate measurement of the person's temperature. Body temperature is best evaluated through core temperature monitoring, which includes oesophageal or tympanic assessment.

Interpreting and responding to identified risk factors requires adequate clinical reasoning and interprofessional communication skills. It is important to bring concerns to the attention of the surgeon and/or anaesthetist prior to surgery, so that necessary modifications can be made for the person during the perioperative period.

CONSIDERATION FOR PRACTICE

Remind people with diabetes that the stress of surgery increases, rather than decreases, blood sugar. Coordinate insulin injections and/or hypoglycaemic medication with the person, surgeon and anaesthetist.

INTERPROFESSIONAL CARE

The person undergoing surgery receives care from a number of healthcare professionals. Surgeons, nurses, anaesthetists, anaesthetic technicians, venepuncturists, pathologists, x-ray technicians, physiotherapists and paramedical staff such as registration clerks and wardsmen/porters are often involved in securing the safety and health of people having surgery. Case managers, social workers and spiritual care providers are available based on the person's needs and preferences. This interprofessional approach focuses on maintaining the person in the best possible health status before, during and after surgery. For some major and frequently performed procedures, the interprofessional

team can develop and map a routine clinical process of recovery. This process is described in a document called a *clinical pathway* (or critical pathway, care path or map). These are multidisciplinary maps that document the various stages of recovery, and appropriate therapeutic responses by team members, in order to assist the person to arrive safely and successfully at the point of discharge. Any divergence from a stated pathway results in variances that must be carefully documented and appropriately managed by the interprofessional team.

Diagnostic tests

Thorough clinical preoperative assessments may be complemented by diagnostic tests if they are clinically indicated (Apfelbaum et al., 2012). Diagnostic tests performed prior to surgery provide baseline data or reveal problems that may place the person at additional risk during and after surgery. Because of the trend towards shortened hospital stays, many diagnostic studies and procedures are performed in a preadmission clinic (pre-op clinic) within a week prior to elective surgery as part of the preadmission assessment process.

Complete blood counts, electrolyte studies, coagulation studies and urinalysis are the most commonly performed preoperative laboratory tests. Table 3.3 discusses the significance and nursing implications of abnormal findings for these common tests. Additional diagnostic tests may be performed as the history and physical findings indicate. For example, if the person has a low haemoglobin and haematocrit, and significant blood loss during surgery is anticipated, then the surgeon may order a type and crossmatch of the person's blood for a possible transfusion.

In addition to laboratory tests, older people or those with risk factors related to heart and lung function typically have a chest x-ray. This radiological procedure provides baseline information about the size, shape and condition of the heart and lungs. Pulmonary complications such as lung disease, tuberculosis, calcification, infiltration or pneumonia may require that surgery be postponed to allow the person to undergo further evaluation or treatment. If findings are abnormal and the surgery cannot be postponed, information from the chest x-ray study can be used to determine the safest form of anaesthesia.

Another commonly performed preoperative diagnostic procedure is the electrocardiogram (ECG). This test is ordered routinely for people undergoing general anaesthesia (except for low-risk procedures) when they have cardiovascular disease or risk factors (Fleisher et al., 2014). The ECG provides data for the evaluation of either new or pre-existing cardiac conditions. The person's surgery may be cancelled or postponed if a life-threatening cardiac condition is discovered.

In addition to the chest x-ray study and ECG, other diagnostic tests may be performed preoperatively to gather further assessment data. For example, for people who have chronic obstructive pulmonary disease, lung function tests are often performed to determine the extent of respiratory dysfunction. This information guides the anaesthetist before and during surgery in choosing the type of anaesthetic to be used, and it guides the surgeon and nursing staff in the recovery phase.

The glomerular filtration rate is a rapid and useful indicator of renal function. A low serum creatinine is an indicator of good renal function, so the creatinine value must be confirmed in the urine; however, it is useful to know that normal values are lower in older adults due to decreased muscle mass. Older adults are especially susceptible to renal insufficiency, which puts them at risk of volume overload in the perioperative period and accumulation of metabolic by-products and medications dependent on renal clearance.

Pregnancy testing for women may also be useful prior to surgery, particularly for elective procedures.

TABLE 3.3 Laboratory tests for perioperative assessment

TEST	SIGNIFICANCE OF INCREASED VALUES	SIGNIFICANCE OF DECREASED VALUES	NURSING IMPLICATIONS
Haemoglobin (Hgb or Hb) and haematocrit (HCT)	Dehydration, excessive fluid plasma loss, polycythaemia vera	Fluid overload, excessive blood loss, anaemia	Monitor oxygenation, fluid input and output, and vital signs; assess for bleeding.
Glucose and haemoglobin-A (HbA1c)	Impaired glucose metabolism, stress or infection	Inadequate glucose intake in relation to insulin	If decreased, monitor for signs and symptoms of hypoglycaemia. Notify surgeon if < 48 mmol/mol or > 59 mmol/mol for diabetics and < 20 mmol/mol or > 42 mmol/mol for non-diabetics.
White blood cell (WBC) count	Infectious/inflammatory processes, leukaemia	Immune deficiencies	Monitor for signs of inflammation; monitor drainage, temperature and pulse. Use standard or transmission-based precautions.
Platelet count	Malignancies, polycythaemia vera	Clotting deficiency disorders, chemotherapy	If decreased, assess for bleeding at incision sites and drainage tubes, and assess for haematomas.
Carbon dioxide (CO_2)	Emphysema, chronic bronchitis, asthma, pneumonia, respiratory acidosis, vomiting, nasogastric (NG) suctioning	Metabolic acidosis, hyperventilation	Monitor respiratory status and arterial blood gases (ABGs).

(continued)

TABLE 3.3 Laboratory tests for perioperative assessment (continued)

TEST	SIGNIFICANCE OF INCREASED VALUES	SIGNIFICANCE OF DECREASED VALUES	NURSING IMPLICATIONS
Oxygen (O_2)	Can be excessive for exacerbated COPD patients or CO_2 retainers	May indicate respiratory depression associated with narcotic analgesia or physiological deterioration including haemorrhage	Monitor O_2 % using pulse oximetry and ABGs if respiratory status deteriorates.
Electrolytes:			
Potassium (K^+)	Kidney dysfunction, dehydration, suctioning	Side effects of diuretics, vomiting, NG suctioning	Monitor K^+ level, cardiac and neurological function, and preoperative diuretic therapy.
Sodium (Na^+)	Kidney dysfunction, normal saline-containing intravenous fluids	Side effects of diuretics, vomiting, NG suctioning	Monitor Na^+ level and fluid input and output; assess for peripheral oedema and effects of perioperative diuretic therapy.
Chloride (Cl^-)	Kidney dysfunction, dehydration, alkalosis	Side effects of diuretics, vomiting, NG suctioning	Monitor Cl^- level and fluid input and output; assess for peripheral oedema and perioperative diuretic therapy.
Prothrombin time (PT) and partial thromboplastin time (PTT)	Defect in mechanism for blood clotting, anticoagulant therapy (aspirin, heparin, warfarin), side effect of other drugs affecting clotting time	Hypercoagulability of the blood may lead to thrombus formation in the veins	If clotting time is elevated, monitor PT/PTT values. Assess for bleeding at incision site and drainage tubes and for haematomas. If clotting time is decreased, monitor for thrombus formation (pulmonary emboli, thrombophlebitis), and evaluate PT and PTT values.
Urinalysis	Varied	Varied	Used to detect abnormal substances (e.g. protein, glucose, red blood cells or bacteria) in the urine. Notify surgeon if abnormalities are detected.

Medications

The person having surgery receives medications before, during and after surgery to achieve specific therapeutic outcomes. Routine oral medications may be withheld during preoperative fasting periods, and the anaesthetist will normally specify medications that should be given, and those that should be withheld. People with diabetes require careful management of their medications during fasting so they don't experience extreme fluctuations in blood glucose levels and associated risks. The anaesthetist will often order pain medication, anticoagulants and antibiotics postoperatively if indicated. Generally, routine medication orders must be revised by the surgeon or anaesthetist when the person returns to the postsurgical care unit.

The person having surgery may be given preoperative medications 45 to 70 minutes before the scheduled surgery depending on medical orders. Any delay in administration should be reported promptly to the anaesthetist. Preoperative medications may also be given in the anaesthetic room to produce the desired effects.

An increasingly common strategy to prevent intense or lingering pain is the use of *pre-emptive analgesia*. Pre-emptive analgesia prevents sensitisation of the central and peripheral nervous system by painful stimuli, by blocking the pain pathways with local, regional or epidural analgesia prior to incision. Sensitisation to pain prolongs the painful experience; however, blocking the sensitisation throughout the perioperative period results in decreased pain in the postoperative period, shortened hospital stay, quicker return to self-care and decreased residual pain (Hariharan et al., 2009).

A combination of preoperative drugs may be ordered to achieve the desired outcomes with minimal side effects. Such outcomes include sedation, reducing anxiety, inducing amnesia to minimise unpleasant surgical memories, increasing comfort during preoperative procedures, reducing gastric acidity and volume, increasing gastric emptying, decreasing nausea and vomiting, and reducing the incidence of aspiration by drying oral and respiratory secretions.

Antibiotic prophylaxis is effective in the prevention of postoperative complications in many surgeries (Kwarteng, Ahluwalia & Osborne, 2008; Smaill & Gyte, 2010). In Australia, the Therapeutic Guidelines Limited (2014) publishes antibiotic guidelines and these are used to select the appropriate antibiotics, depending on the procedure to be performed. The timing of antibiotic prophylaxis is an important aspect of providing this preventive therapy (Kable, Gibberd & Spigelman, 2008a).

Thromboprophylaxis should also be provided for many procedures. People should be assessed to identify their risk factors for developing postoperative venous thrombosis. Deep vein thrombosis occurs in more than 20% of people who undergo major surgery, with an increased incidence following orthopaedic surgery (Joanna Briggs Institute (JBI), 2008). People having surgery who develop postoperative venous thrombus may complain of pain, tenderness, swelling, increased heat, changes to skin colouration or enlarged veins. Adverse outcomes may lead to pulmonary embolism, sudden death or post-thrombotic syndrome (JBI, 2008). Thromboprophylaxis includes pharmacological strategies such as the use of low molecular weight heparin (LMWH) preparations,

and a range of non-pharmacological strategies including thigh-length approved compression profile thromboembolic stockings, sequential compression devices and ambulation as soon as possible after surgery (JBI, 2008). The National Health and Medical Research Council (NHMRC) (2009) has published clinical practice guidelines for thromboprophylaxis in Australian hospitals.

Table 3.4 outlines some commonly prescribed preoperative medications.

Decisions made about which of the person's routine medications to administer prior to surgery when the person is required to be nil by mouth (NBM) are made in consultation with the surgeon and/or anaesthetist. Caution is required in relation to potential interactions between anaesthesia and medications and the effect on the person if drugs such as steroids, antiseizure medications and tranquillisers are discontinued abruptly. Generally, insulin is withheld when the person is NBM, but depending on the anticipated length of the surgery, the dosage may be adjusted for the previous evening as well as the morning of surgery. Under anaesthesia the signs and symptoms of hypoglycaemia (insulin reaction) are absent, so withholding insulin the morning of surgery when the person is NBM is advisable. Plasma glucose is monitored intermittently during surgery with the goal of maintaining a normal blood sugar level (see Table 3.2). People who ordinarily manage their diabetes mellitus with oral medications often experience hyperglycaemia perioperatively (Betts, Brink, Silink et al., 2009). It is common to manage hyperglycaemia with sliding-scale insulin. However, evidence-based practice now supports subcutaneous basal insulin administration for hyperglycaemic people to maintain glycaemia at 48–59 mmol/mol (previously measured in mmol/L in Australia) throughout the perioperative period. This practice is associated with better healing, fewer infections and shorter hospital stays (Betts et al., 2009).

Assessment of medications that the person normally uses is vital prior to anaesthesia. In addition to medications prescribed by a doctor, assessment should include over-the-counter preparations (including aspirin and illegal drugs) and herbal medications (see Table 3.2).

INTRAOPERATIVE MEDICATIONS **Anaesthesia** is used to produce unconsciousness, analgesia, reflex loss and muscle

TABLE 3.4 Preoperative medications

GENERIC	ACTION BY CATEGORY	NURSING IMPLICATIONS
Antibiotics	Prevent surgical site infections in orthopaedic and general surgeries and are associated with lower risk of mortality in elderly people	Correct timing is important for maximum effectiveness. Monitor people for reactions. Be aware of microbial resistance and responsible use of medicines.
Thromboprophylaxis: low molecular weight heparins (LMWHs)	Prevents formation of clots in the peripheral circulation which otherwise may result in deep venous thrombosis and possible emboli	Be aware of bruising and monitor bleeding.
Benzodiazepines (midazolam, diazepam, lorazepam)	Decrease anxiety and produce sedation to some extent. May induce amnesia	Monitor for respiratory depression, hypotension, drowsiness and lack of coordination.
Narcotic analgesics (morphine, fentanyl)	Decrease anxiety, provide analgesia	Monitor for respiratory depression and safety if ambulating. Anti-emetics may be needed.
Non-opioid analgesics	Provide mild to moderate analgesia. Single dose or 4-hourly administration over a short period. Sometimes referred to as NSAIDs, due to antipyretic and anti-inflammatory actions	Reassessment required if pain has not ceased. Assess for adverse effects. Cease 72 hours preoperatively and assess clotting times.
Antacids (sodium citrate)	Increase the pH and reduce volume of gastric fluid; used in people with gastro-oesophageal reflux disease and/or trauma	No significant factors in this setting.
H_2 receptor antagonists (cimetidine, famotidine, ranitidine)	Reduce gastric acid volume and concentration	Monitor for confusion and dizziness in older adults.
Gastric acid pump inhibitors (lansoprazole, pantoprazole, omeprazole)	Suppress gastric acid secretion	Monitor for dizziness and headache, rash or thirst.
Anti-emetics (metoclopramide, prochlorperazine, ondansetron)	Enhance gastric emptying. Often used with narcotic analgesics to alleviate side effects of nausea and vomiting	Monitor for sedation and extra-pyramidal reaction (involuntary movement, muscle tone changes and abnormal posture).
Anticholinergics (atropine sulfate, scopolamine)	Reduce oral and respiratory secretions to decrease risk of aspiration; decrease vomiting and laryngospasm	Monitor for confusion, restlessness and tachycardia. Prepare the person to expect a dry mouth.

relaxation during a surgical procedure. General anaesthesia produces these effects, whereas regional anaesthesia results in analgesia, reflex loss and muscle relaxation but does not cause the person to lose consciousness. An anaesthetist administers anaesthetics during the intraoperative phase of surgery.

General anaesthesia **General anaesthesia** is most commonly administered by inhalation and, to a lesser extent, by the intravenous route. It produces central nervous system depression. As a result, the person loses consciousness and does not perceive pain, skeletal muscles relax and reflexes diminish.

Advantages of general anaesthesia include rapid excretion of the anaesthetic agent and prompt reversal of its effects when desired. Additionally, general anaesthesia can be used with all age groups and any type of surgical procedure. It produces amnesia.

Disadvantages of general anaesthesia include risks associated with circulatory, respiratory, hepatic and renal side effects. People with serious respiratory or circulatory diseases, such as emphysema or congestive heart failure, are at greater risk of complications. People with renal or hepatic disease cannot metabolise and eliminate anaesthetics safely.

General anaesthesia is provided with inhalation agents or total intravenous anaesthesia (TIVA), also known as neuroleptanalgesia. People with a history of malignant hyperthermia (MH) avoid inhalational agents because they can trigger this complication (see Box 3.1). With the increase in ambulatory and minimally invasive surgeries, anaesthetics that enable shorter recovery phases are used, allowing a *fast-tracking* approach with a rapid recovery phase, and people who are managed this way will often bypass the PACU.

General anaesthesia comprises three distinct phases: induction, maintenance and emergence. During the induction phase, the person receives the anaesthetic agent intravenously or by inhalation. During this phase, airway patency is achieved and maintained with either endotracheal intubation or alternative devices including the laryngeal mask airway (LMA), oesophageal–tracheal Combitube, or lighted stylet or wand. These alternative methods of airway maintenance do not require direct visualisation of the vocal cords for placement, as is required for the endotracheal tube, but still maintain adequate ventilation. Intubation can be difficult with some people, and these alternative devices are an option to avoid other more invasive airway alternatives such as creation of a surgical airway with a cricothyroidotomy or tracheostomy.

The next phase of general anaesthesia is maintenance. During this period, the person is positioned, the skin is prepared and surgery is performed. The anaesthetist maintains the required depth of anaesthesia while constantly monitoring physiological parameters such as heart rate, blood pressure, respiratory rate, temperature, and oxygen and carbon dioxide levels. The final phase of anaesthesia is the person's emergence from this altered physiological state. As the anaesthetic agents are withdrawn or the effects reversed pharmacologically, the person begins to awaken. The endotracheal tube or laryngeal mask is removed (extubated) once the person is able to re-establish voluntary breathing. It is critical to ensure airway patency during this period, because extubation may cause bronchospasm or laryngospasm.

Regional anaesthesia **Regional anaesthesia** is a type of local anaesthesia in which medication instilled around the nerves blocks transmission of nerve impulses in a particular area. Regional anaesthesia produces analgesia, relaxation and reduced reflexes. The person is awake and conscious during the surgical procedure but does not perceive pain. Regional anaesthesia may be classified in several ways:

- Local nerve infiltration is achieved by injecting lignocaine around a local nerve to depress nerve sensation over a limited area of the body. This technique may be used when a skin or muscle biopsy is obtained or when a small wound is sutured.

BOX 3.1 Malignant hyperthermia

Malignant hyperthermia (MH) is a rare but serious reaction to volatile inhalational anaesthetic gases and succinylcholine, a depolarising neuromuscular blocker. The person who suffers this reaction manifests the following signs and symptoms: unexplained rise in end-tidal carbon dioxide that does not respond to ventilation, hyperthermia, tachypnoea, tachycardia and sustained skeletal muscle contraction. If unchecked the condition can progress to hyperkalaemia, myoglobinuria, disseminated intravascular coagulation, congestive heart failure, bowel ischaemia and compartment syndrome in the limbs. Dantrolene sodium is the drug that inhibits the muscular pathology and prevents death.

Because the condition is inherited, susceptibility testing is available but the testing is expensive and the most accurate test involves an invasive procedure. The 'gold standard' involves biopsy of thigh skeletal muscle tissue to determine sensitivity to caffeine and halothane (CHCT). Genetic testing is not as sensitive and reliable as CHCT but will be improved with the discovery of more causative mutations. People with muscle myopathies such as muscular dystrophy sometimes experience early signs of MH and respond well to dantrolene. The symptoms of MH may manifest with other pathologies, so it is important for people to know if they have a genetic susceptibility to MH, which could affect all members of their family.

MH can develop during an operation or when the person returns to the PACU. If the early symptoms of MH (e.g. escalating temperature, increased carbon dioxide production) are suspected, immediately administer 100% oxygen with a non-rebreather mask, stay with the person, ensure good IV access, and immediately call the anaesthetist who will order dantrolene which can be given as an IV bolus dose. Administration of dantrolene can be repeated until the signs and symptoms of MH diminish. Measures to decrease core body temperature should be started at once and continued until core temperature is 36.0°C. A urinary catheter should be placed to monitor urine output. Blood samples are taken and sent to pathology for testing. Blood gases should measure pH; and sodium bicarbonate is given to correct metabolic acidosis. Insulin may be ordered to decrease serum potassium. These people require critical care and are transferred to the intensive care unit for continued monitoring and doses of dantrolene every 4–6 hours.

- Nerve blocks are accomplished by injecting an anaesthetic agent at the nerve trunk to produce a lack of sensation over a specific area, such as an extremity.
- Epidural blocks are local anaesthetic agents injected into the epidural space, outside the dura mater of the spinal cord. This type of intraspinal anaesthesia provides effective pain relief for surgeries for people of all ages, with less risk of adverse effects than general anaesthesia. It is indicated for surgeries of the arms and shoulders, thorax, abdomen, pelvis and lower extremities. The epidural catheter is often left in place for pain relief in the postoperative period.
- Spinal anaesthesia is administered similarly to epidural except the anaesthetic medication is infused in a single injection. Spinal anaesthesia is effective for approximately 90 minutes. Surgeries of the lower abdomen, perineum and lower extremities are likely to use this type of regional anaesthesia. Any leakage of cerebrospinal fluid (CSF) into the epidural space may cause reduced CSF pressure and postoperative headaches. Treatment for this headache may include hydration, caffeine, analgesics or administration of an epidural blood patch. Hypotension is common with epidural and spinal anaesthesia. Monitor BP and, if critical hypotension occurs, alert the anaesthetist and expect to increase intravenous fluids and administer vasoactive medications.

CONSIDERATION FOR PRACTICE

The addition of adrenaline to lignocaine suppresses bleeding around the surgical site. Care must be taken to ensure that plain lignocaine is only ever used for end digit surgery (i.e. fingers, toes, tip of nose) to ensure that tissues remain perfused.

Conscious sedation An increasing number of surgical and diagnostic procedures are being performed using **conscious sedation**. This type of anaesthesia provides analgesia, amnesia and moderate sedation. The pharmacological effects are produced by administering a combination of intravenous medications with opioids (such as morphine sulfate and fentanyl) and/or sedatives (such as diazepam and midazolam). During conscious sedation the person is able to independently maintain an open airway. This allows them to respond to verbal and physical stimulation. Supervision by the surgeon or anaesthetist is always required, and staff must be prepared to initiate rescue if sedation becomes too deep. This type of sedation is increasingly being used in ambulatory care for procedures such as colonoscopy and cataract surgery.

Assessment prior to conscious sedation includes evaluating the person's physical status. People with compromised circulation or airway, a history of sleep apnoea or snoring, a history of problems with anaesthesia or analgesia, or medications that would potentially interact with conscious analgesia medications require more careful assessment. People who will be managed with conscious sedation should be appropriately fasted with a patent IV line in situ, and baseline vital signs are assessed and recorded prior to administration of the sedative. Equipment to rescue the person should be available if sedation becomes too deep. Monitor oxygen saturation, blood pressure, pulse, breathing and level of consciousness throughout the procedure.

Common adverse side effects include venous thrombosis, phlebitis, local irritation, confusion, drowsiness, hypotension and apnoea. Reversal agents (naloxone hydrochloride) are used as needed to enhance the safety of conscious sedation.

POSTOPERATIVE MEDICATIONS Management of acute postoperative pain by medication improves with greater understanding of pain physiology and the development of better methods to deliver adequate pain medication. For more information on pain management, see the 'Nursing care' section later in this chapter on managing acute postoperative pain, and also see Chapter 8.

Established, persistent, severe pain is more difficult to treat than recently commenced pain. Therefore, postoperative analgesics should be administered at regular intervals around the clock to maintain a therapeutic blood level. Administering analgesics on an 'as needed' (prn) basis lowers this therapeutic level and delays in medication administration further increase pain intensity. Therefore, regular rather than prn administration of analgesics is recommended in the first 36 to 48 hours postoperatively. People using patient-controlled analgesia (PCA) or patient-controlled epidural analgesia (PCEA) in the postoperative period need to be taught the importance of using the allowed dosages regularly to prevent increasing pain levels.

CONSIDERATION FOR PRACTICE

Nurses are responsible for assessing the pain level of people having surgery and administering pain medication. Work collaboratively with surgeons, anaesthetists and the pain team and people in the postoperative period to schedule postoperative analgesics, rather than rely on prn administration orders.

Non-steroidal anti-inflammatory drugs (NSAIDs) can be used to treat mild to moderate postoperative pain. This category of drugs should be given soon after surgery (orally, parenterally or rectally) along with opioids unless contraindicated. Although NSAIDs may not be sufficient to control pain completely, they allow lower doses of opioid analgesics and, therefore, fewer side effects. NSAIDs can usually be given safely to older people, but observe closely for side effects, particularly gastric and renal toxicity and bleeding. Be aware that NSAIDS are not comparable and their actions and side effects vary substantially, thus they cannot be used interchangeably.

Opioid analgesics, such as morphine, are considered to be most effective for managing moderate to severe postoperative pain. Opioid dosage requirements vary greatly from one person to another, so the dosage must be individually tailored. Later in the postoperative recovery period, opioid analgesics (oral or intramuscular) may be given prn. In this way, pain relief can be maintained while the potential for drug side effects is decreased.

Contrary to the belief of some healthcare professionals, physical dependence and tolerance to opioid analgesics is uncommon in short-term postoperative use. Additionally, opioid analgesics, when used to treat acute pain, rarely lead to psychological dependence and addiction. Acute pain can be appropriately treated initially with opioids, and subsequently with paracetamol as healing progresses. Management of

chronic or persistent pain, in contrast, evolves from paracetamol to opioids as tolerance develops or the condition worsens. The opioid-naive person will tolerate and achieve analgesia with a lower dose of opioid than the person who is opioid tolerant and uses opioids for persistent pain.

In the immediate postoperative period, older people benefit from the same protocol for morphine titration as younger people. Intravenous morphine may be initiated at a slightly reduced dose and then titrated to the same protocol as younger people. Morphine-related adverse effects such as nausea, vomiting, respiratory depression, urinary retention, pruritus and allergy or sedation are similar among age groups. However, older adults may require fewer opioids than younger people in the later postoperative period. PCEA may be more effective for older adults and is associated with earlier improved mental status and bowel activity (Rutledge, Caple & Pravikoff, 2011). Older people tend to be more sensitive to the analgesic effects of opioids, experiencing a higher peak effect with a longer duration of pain control.

Surgical environment

MEMBERS OF THE SURGICAL TEAM The intraoperative environment is complex and requires members of the surgical team to function as a coordinated unit. The surgeon, surgical assistant(s), perioperative nurse surgeon's assistant, anaesthetist, anaesthetic nurse or technician, instrument nurse (scrub) (see Figure 3.1) and circulating nurse (scout) constitute the main surgical team. Each member provides specialised skills and is essential to the successful outcome of the surgery. Risks to members of the surgical team from blood-borne pathogens or injury are minimised when the surgical team is well organised and prepared.

FIGURE 3.1 ■ An instrument nurse in the operating room

Source: ©Tom Tracy Photography/Alamy.

The surgeon is the medical officer who performs the operative procedure. As head of the surgical team, the surgeon is responsible for all medical actions and judgments.

The surgical assistant works closely with the surgeon in performing the operation. The number of assistants varies according to the complexity of the procedure. The assistant may be another surgeon, a nurse or other trained personnel. The assistant performs such duties as exposing the operative site, retracting nearby tissue, sponging and/or suctioning the wound, ligating bleeding vessels and suturing or helping suture the surgical wound.

The anaesthetist evaluates the person preoperatively, administers the anaesthesia and other required medications, transfuses blood or other blood products, infuses intravenous fluids, continuously monitors the person's physiological status, alerts the surgeon to developing problems and treats them as they arise, and supervises the person's recovery in the PACU.

The **circulating nurse** is a highly experienced nurse who coordinates and manages a wide range of activities before, during and after the surgical procedure. For example, the circulating nurse oversees the physical aspects of the operating room itself, including the equipment. The circulating nurse also assists with transferring and positioning the person, prepares the person's skin, ensures that no break in aseptic technique occurs, and records the surgical count of all accountable items, including sharps, sponges and instruments (ACORN, 2012). The handling of surgical instruments and associated accountable items must also comply with relevant state department of health policy directives. The circulating nurse assists all other team members, including the anaesthetist. Thorough documentation in the surgical area is essential, and the circulating nurse is responsible for documenting intraoperative nursing activities, medications, blood administration, placement of drains and catheters and length of the procedure. The circulating nurse also formulates a care plan based on physiological and psychosocial assessments of the person. Finally, the circulating nurse is at all times an advocate for the safety and well-being of the person having surgery.

The role of the **instrument nurse** primarily involves technical skills, manual dexterity and in-depth knowledge of the anatomical and mechanical aspects of a particular surgery. The instrument nurse handles sutures, instruments and other equipment immediately adjacent to the sterile field. The registered nurse ensures appropriate delegation and supervision of staff and participates in the surgical count (Australian College of Operating Room Nurses (ACORN), 2012).

The role of nurses in surgery continues to evolve to improve the care of people having surgery. Although not participating in the surgical procedure, PACU (recovery) nurses are part of the surgical team and are responsible for assessing, monitoring and implementing care of people during the recovery period from anaesthesia. In recent years, nurses have begun to specialise within the already specialised field of perioperative nursing and PACU nurses are now highly specialised care providers. Within the perioperative unit, specialty surgical teams are developing in response to the demands of increasingly complex technical surgeries. For example, a designated open heart surgical team may be responsible for all open cardiac cases and not be routinely involved with other procedures. The use of specialty

TRANSLATIONTO PRACTICE Evidence-based practice: assisting older adults to communicate postoperative pain

Nurses rely heavily on people's assessments of the pain they are experiencing. Pain is a subjective experience—a symptom rather than a sign. Rating of pain intensity by the person who has had surgery is the gold standard for knowing when to provide an intervention to decrease pain, and it is considered more accurate than nurses' evaluations of behavioural manifestations of pain. Older people who believe that healthcare providers know how to manage their pain are at risk of inadequately treated pain.

McDonald and colleagues (2005) used a program for coaching older adults about postoperative pain communication and management. In this study, older adults preparing for single-knee replacement surgery attended a preoperative joint replacement class where they learned about recovering from the surgery and pain management. Forty participants older than age 65 were randomly assigned either to the regular class, which included pain management information, or an intervention class, which included both information on pain management and skills to effectively communicate about pain.

Those in the communication skills class were taught to enhance pain communication with several strategies consistent with communication accommodation theory (CAT). CAT holds that people adjust their communication based on their own needs and the perceived behaviour of others. Skills to enhance communication include evaluating whether the other person (the nurse) has understood the message being given about pain, and is willing to include the person as a team member in controlling the pain. Language to describe pain intensity, location and sensation is modelled. People who have had surgery must report their pain because they are the experts about their own pain experience.

The groups were post-tested on postoperative days 1 and 2 and on days 1 and 7 after discharge, using the Brief Pain Inventory Short Form (BPI-SF). This instrument consists of 15 questions that measure pain severity, extent of interference with activities and pain relief in response to treatment. The group that received the communication skill information had significantly less pain interference with activity and greater pain relief with treatments on postoperative day 1 than the comparison group. On postoperative day 2, pain interference was similar for both groups and pain relief with treatment was greater for the comparison group. Pain severity scores were similar for both groups on postoperative days 1 and 2. There was no significant difference between the two groups in the post-discharge measures of any pain dimension.

IMPLICATIONS FOR NURSING

Findings from this study highlight the importance of coaching older adults to report their pain experience candidly, particularly in the immediate postoperative period. Establishing trust between the nurse and the person receiving care is critical to relieving pain. Coaching older people to describe their pain location, intensity and sensation gives them permission to communicate in a manner with which they may feel uncomfortable at first. Coaching is necessary to dispel myths about professional expertise and to allow personal control and independence so that they are willing to ask for pain medications. Exploring with older people their perception of pain, as well as the significance it has for recovery from illness, are necessary elements in providing adequate pain relief and restoring health.

CRITICAL THINKING IN PERSON-CENTRED CARE

1. What physiological changes make pain management more difficult for an 80-year-old person following surgery than for a 30-year-old person?
2. An older person says: 'I deserved this pain, so I don't want to take anything to make it better.' What would be your response and why?
3. An Indigenous Australian man, aged 67, replies that 'Something doesn't feel right' when asked to rate his pain on a scale of 0 to 10. His pulse is increased and he is protective of his abdominal incision. What could you ask or do to accurately assess his pain?
4. If your grandfather or grandmother were having surgery tomorrow, what would you like them to be taught about pain management?
5. An independent, 85-year-old woman has a PCA pump for analgesia following major surgery. She continuously presses the pump button, but continues to complain of severe pain. What do you do now?
6. A female non-English-speaking Somalian refugee appears to be in pain following labiaplasty. What are the cultural issues associated with labiaplasty for these women? Would it be appropriate to ask her husband to act as a translator? How can you arrange an interpreter to assist this woman to communicate with you, so you can provide adequate pain relief for her?

surgical teams allows nurses to become highly skilled in a particular range of procedures and communications impacting on the care of people having surgery.

SURGICAL ATTIRE Strict dress codes are necessary to provide infection control within the operating theatre, to reduce cross-contamination between the surgery department and other hospital units or departments, and to promote the health and safety of people having surgery. Based on research and recommendations by hospital infection control authorities, guidelines for attire differ among surgical facilities. Following institutional guidelines, all personnel in the surgical department must be in proper surgical attire. The design and composition of the surgical attire minimises bacterial shedding, thus reducing wound contamination. The area in the surgical department is divided into *unrestricted*, *semi-restricted* and *restricted zones*. The unrestricted zones permit access by those in hospital uniforms or street clothes. These areas may also allow limited access for communicating with operating room personnel and handover of people having surgery.

CONSIDERATION FOR PRACTICE

Objects on the sterile drape are considered sterile. Remain a minimum of 30 cm away from draped tables and sterile fields to avoid contamination if you are not attired in sterile gown and gloves.

The semi-restricted zones require scrub attire, including a scrub suit, shoe covers and a cap or hood (see Figure 3.2). Hallways, work areas and storage areas are considered semi-restricted. Scrub attire is covered with sterile gowns in the restricted areas only if the person is 'scrubbed in' for the surgery. Only fabrics that are woven or disposable and will not harbour bacteria are allowed and all items of apparel must be covered by appropriate fabric. Nails that are chipped, varnished or artificial are not worn in surgery or anywhere the nurse will have direct contact with people at high risk. These nails are associated with glove tears and even after careful handwashing can harbour potential pathogens.

CONSIDERATION FOR PRACTICE

Staff in operating theatres must be knowledgeable about the nature of hazards within the perioperative environment. Hazards include a class A electrical area due to the quantity and type of equipment (including electrosurgical equipment) used in this environment; anaesthetic gases and other chemicals such as formaldehyde and fumes from bone cement and chemical sterilising agents, and surgical plume (smoke from electrosurgical and laser equipment); latex; sharps, including needle-stick injuries; laser and x-ray exposure; assembly and transport of theatre equipment; and biological hazards, including potential for exposure to blood and body fluids and possible sero-conversion for blood-borne viruses, including Creutzfeldt-Jakob disease (CJD).

Restricted zones are within operating rooms. Personnel wear masks, sterile gowns and gloves in addition to appropriate scrub attire if they are participating at the operating table. The outer sterile covering is changed between procedures or when it becomes soiled or wet.

FIGURE 3.2 ■ Surgical attire. Scrub attire includes scrub suit, shoe covers, and cap or hood to cover hair. Sterile attire includes scrub suit, shoe covers, and cap or hood, plus gown, gloves and mask

Source: ©Tyler Olson/Fotolia.com.

THE SURGICAL SCRUB The surgical scrub is performed to render hands and arms as clean as possible in preparation for a procedure. All personnel who participate directly in the procedure must perform a surgical scrub with an approved antimicrobial solution. Skin cannot be rendered sterile, but it can be considered 'surgically clean' following the scrub. The purposes of the surgical scrub are to:

- remove dirt, skin oils and transient microorganisms from hands and forearms
- increase safety for people having surgery by reducing microorganisms on surgical personnel
- leave an antimicrobial residue on the skin to inhibit growth of microbes for several hours.

Following the 3- to 5-minute surgical scrub (ACORN, 2012), hands and arms are dried with sterile towels.

Preparation of the person having surgery

Although much preparation has taken place prior to the transfer of the person to the surgical department, additional activities such as clipping of hair or shaving and positioning may be performed. The skin preparation, which usually includes cleansing the area with a prescribed antimicrobial agent, may have been performed either by the person or by nursing personnel before the transfer to the surgical department. Additional skin cleansing is performed in the surgical department to further decrease microorganisms on the skin and thereby reduce the possibility of wound infection.

The surgeon also may order preoperative hair removal to reduce surgical site infection; however, there is insufficient evidence to show that preoperative hair removal results in fewer surgical site infections than not removing the hair (JBI, 2007). The skin may be shaved or clipped in and around the proposed incision area (see Figure 3.3). Shaving may be completed preoperatively; however, it is best performed on the day of surgery (JBI, 2007) and is often performed within the operating theatre suite. The use of both clipping and depilatory creams results in fewer surgical site infections than shaving with a razor (JBI, 2007). The extent of hair removal for surgery varies. Generally, the area of hair removal is wider than the planned incision because of the possibility of unexpected extension of the incision. Disposable, sterile supplies are used, in accordance with aseptic techniques. However, the benefit of shaving the incisional site requires further research (JBI, 2007). Physical trauma to the shaved area can weaken the normal barrier that provides a defence against organisms, thus increasing the chance of wound infection. An altered body image also may result from the psychological trauma of a surgical shave, particularly if the shave involves the head or groin area.

Preparing the person for surgery also includes **positioning** them on the operating table. Figure 3.4 shows frequently used positions and describes corresponding surgical procedures and possible adverse effects. Positioning exposes the operative site in conjunction with access for anaesthesia administration. Careful and correct positioning is imperative to prevent injury to the person. Pressure, rubbing and/or shearing forces can cause injury to the tissue over bony prominences. If positioning causes normal joint range of motion to be exceeded, injury to muscles

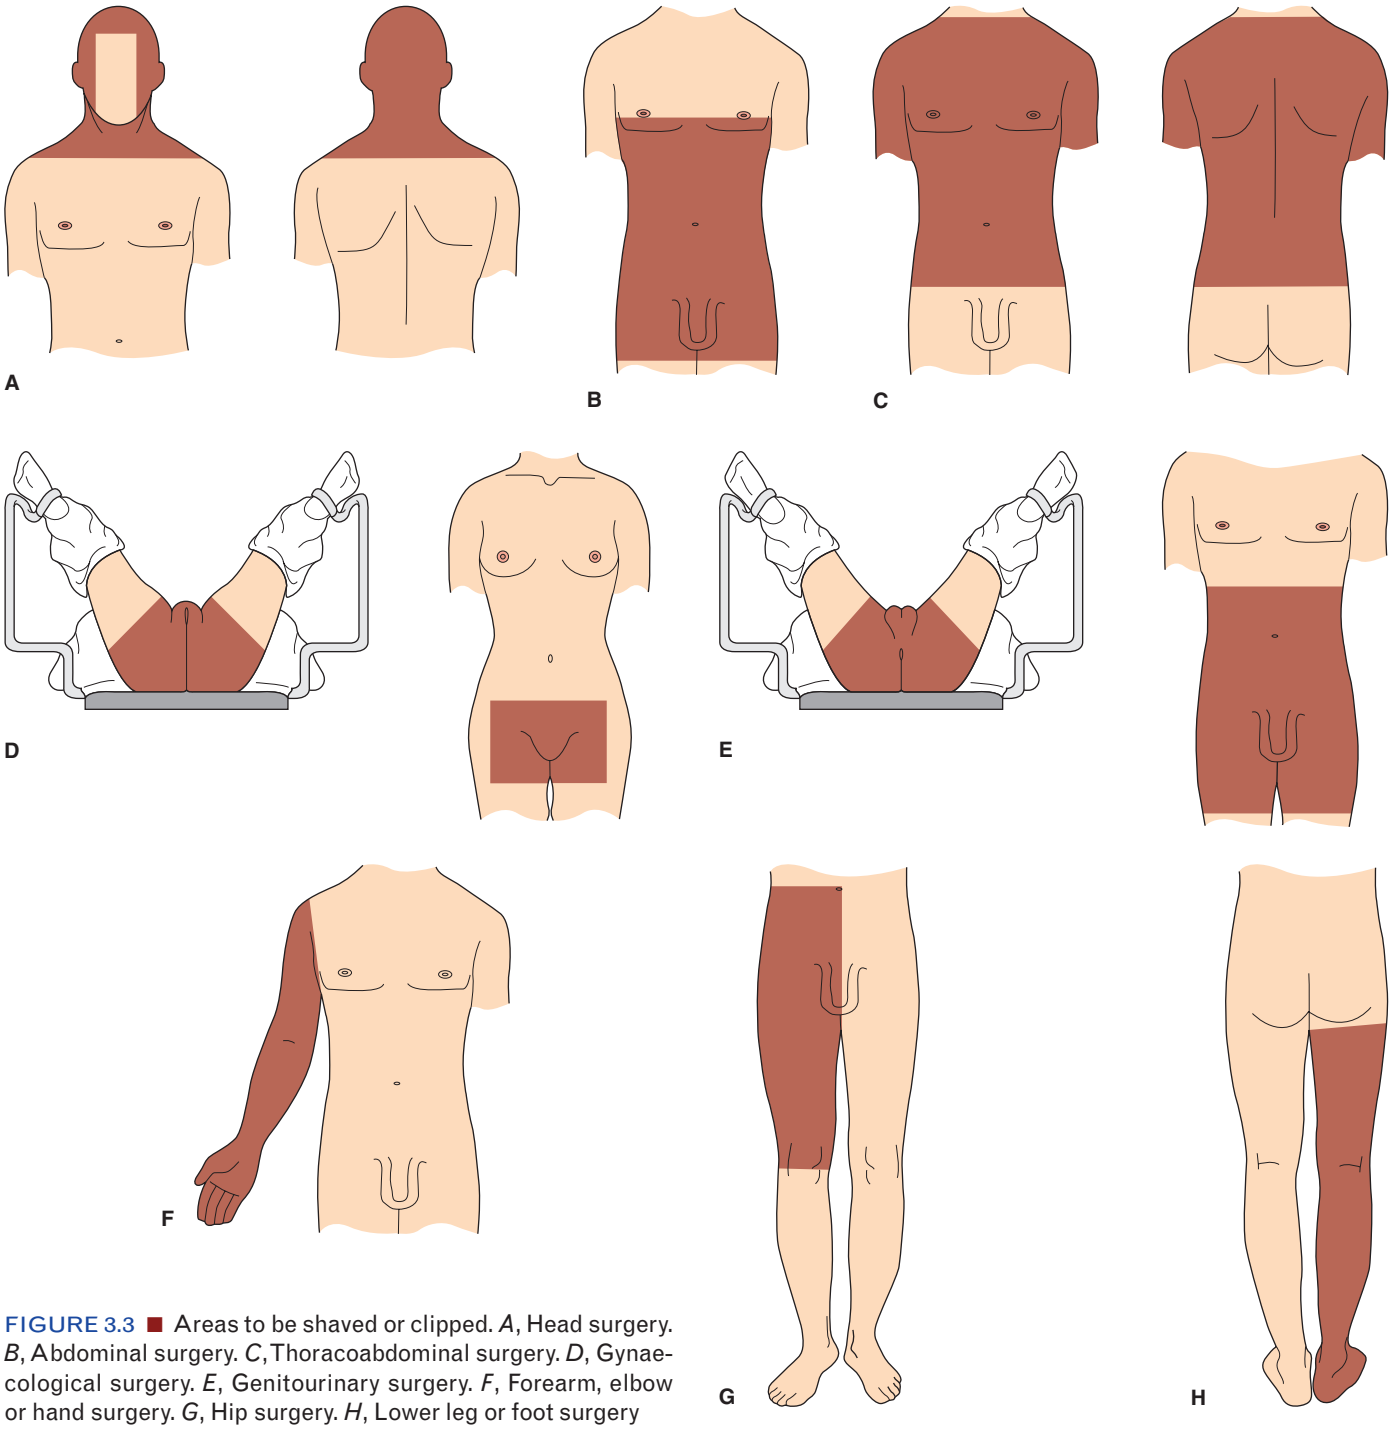

FIGURE 3.3 ■ Areas to be shaved or clipped. *A*, Head surgery. *B*, Abdominal surgery. *C*, Thoracoabdominal surgery. *D*, Gynaecological surgery. *E*, Genitourinary surgery. *F*, Forearm, elbow or hand surgery. *G*, Hip surgery. *H*, Lower leg or foot surgery

and joints can occur. Improper positioning also can lead to sensory and motor dysfunction, resulting in nerve damage. Pressure on peripheral blood vessels can decrease venous return to the heart and negatively affect the person's blood pressure. Additionally, oxygenation of the blood can be decreased if the person is not properly positioned to promote lung expansion.

As the anaesthetised person cannot respond to discomfort, it is the surgical team's responsibility to position them not only for the best surgical advantage but also for their safety and comfort. The circulating nurse refers to hospital policy, the surgeon's preference and the person's health history to ensure optimal positioning, and continuously assesses them during the intraoperative period.

INTRAOPERATIVE AWARENESS Prior to induction of anaesthesia, the circulating nurse establishes rapport with the person to assess their psychological status. After anaesthetic medications have been given, the person may appear oblivious to the surroundings; however, recall of intraoperative events has been reported. Although most people do not consciously

Position and use	Possible adverse effects and nursing interventions
(a) The *dorsal recumbent (*or *supine*) *position* is used for many abdominal surgeries (e.g. colostomy and herniorrhaphy), as well as for some thoracic surgeries (e.g. open heart surgery) and some surgeries on the extremities. 	This position may cause excessive pressure on posterior bony prominences, such as the back of the head, scapulae, sacrum and heels. Pad these areas with soft materials. To avoid compression of blood vessels and sluggish circulation, ensure that the knees are not flexed. Use trochanter rolls or other padding to avoid internal or external rotation of the hips and shoulders.
(b) The *semisitting position* is used for surgeries on the thyroid and neck areas. 	This position can lead to postural hypotension and venous pooling in the legs. It may promote skin breakdown on the buttocks. Sciatic nerve injury is possible. Assess for hypotension. Ensure that knees are not sharply flexed. Use soft padding to prevent nerve compression.
(c) The *prone position* is used for spinal fusions and removal of haemorrhoids. 	This position causes pressure on the face, knees, thighs, anterior ankles and toes. Pad bony prominences, and support the feet under the ankles. To promote optimum respiratory function, raise the person's chest and abdomen, and support with padding. Corneal abrasion could occur if the eyes are not closed or are insufficiently padded.
(d) The *lateral chest position* is used for some thoracic surgeries, as well as hip replacements. 	This position may cause excessive pressure on the bony prominences on the side on which the person is positioned. Ensure adequate padding and support, especially of the downside arm. The weight of the upper leg may cause peroneal nerve injury on the downside leg. Both legs must therefore be padded.
(e) The *lithotomy position* is used for gynaecological, perineal or rectal surgeries. 	This position causes an 18% decrease (from a standing position) in vital capacity of the lungs. Monitor respirations, and assess for hypoxia and dyspnoea. The lithotomy position can lead to joint damage, peroneal nerve damage and damage to peripheral blood vessels. To avoid injury, ensure adequate padding, and manipulate both legs into the stirrups simultaneously.
(f) The *jackknife position* is used for proctological surgeries, such as removal of haemorrhoids, and for some spinal surgeries. 	This position causes a 12% decrease (from a standing position) in vital capacity of the lungs. Monitor respirations, and assess for hypoxia and dyspnoea. In this position, the greatest pressure is felt at the bends in the table. Therefore, the person is supported with pads at the groin and knees, as well as at the ankles. Padding of the chest and knees helps prevent skin breakdown. Padding and proper positioning help prevent pressure on the ear, the neck, and the nerves of the upper arm.

FIGURE 3.4 ■ Common surgical positions

remember what happened or what was said, psychological trauma can result. Because loss of consciousness is gradual, conversations during surgery should be professional.

SPECIAL CONSIDERATIONS FOR THE OLDER ADULT Surgeries that last longer than two hours are associated with an increased risk of complications in older adults (Kable et al., 2008b). Because of cardiovascular and tissue changes that result from ageing, the older adult is more prone to hypotension, hypothermia and hypoxaemia resulting from anaesthesia and the cool temperature in the operating room.

Positioning may also cause complications in the older adult. Intraoperative positioning of arthritic joints can cause postoperative joint pain unrelated to the operative site. Extended duration of surgery may increase the chance of pressure areas. The older person is at increased risk of developing pressure areas because of decreased subcutaneous fat tissue and reduced peripheral circulation.

Finally, the older adult often has some degree of hearing and/or visual impairment. These impairments combined with a strange environment can make the operating room a frightening, disorienting place. By effectively communicating with the person, the nurse can provide support and reassurance to minimise these factors. To decrease confusion and assist in communication, hearing aids and glasses should be used when appropriate and possible.

Nutrition

Wound healing after surgery depends on adequate nutritional intake. During the immediate postoperative phase, dietary intake is often withheld until evidence of peristalsis is determined and the person can tolerate liquids without nausea and vomiting. While intravenous fluids maintain hydration and electrolyte balance, they do not provide nutrition. Some people believe that intravenous fluids are the same as intravenous 'feeding', but this is a myth. Unless balanced nutrition through gastrointestinal intake can be re-established within 3–4 days, parenteral hyperalimentation is critical for homeostasis and wound healing.

- Protein, kilojoules and vitamins are needed for wound healing and recovery from surgery.
- Low-fat, high-fibre diets are important for chronic cardiovascular fitness, but are contraindicated in the wound healing phase following surgery.
- Failure to use the gastrointestinal tract for more than 4–5 days allows the intestinal mucosa to atrophy, putting the person at risk of gastrointestinal tract haemorrhage and infection.

Fluid administered through peripheral veins must be isotonic, or only moderately hypertonic, to prevent sclerosing the small peripheral veins. Solutions of 10% dextrose are tolerable peripherally for a short time but do not provide adequate kilojoules for healing and maintenance. To provide adequate nutrition for people who have extended recovery periods without eating after surgery, central vein access must be established and parenteral nutrition administered. Education and counselling to support adequate nutritional intake should be ongoing throughout the preoperative and postoperative period.

Nursing care

The following section will discuss nursing care in each of the three phases of surgery. A case study at the end of the section follows one person through the postoperative experience, bringing this information together. Perioperative nursing diagnoses are provided in Table 3.5 to assist in identifying the needs of the person having surgery. This is not an exhaustive list, but it can serve as a guide in identifying possible nursing diagnoses.

TABLE 3.5 Examples of perioperative nursing diagnoses

PREOPERATIVE	INTRAOPERATIVE	POSTOPERATIVE
• Deficient knowledge	• Deficient knowledge	• Deficient knowledge
• Anxiety	• Anxiety	• Pain
• Fear	• Fear	• Ineffective breathing pattern
• Decisional conflict	• Ineffective airway clearance	• Ineffective airway clearance
• Ineffective coping	• Risk of aspiration	• Impaired skin integrity
• Ineffective sexuality patterns	• Decreased cardiac output	• Imbalanced nutrition
• Disturbed sleep pattern	• Hypothermia	• Ineffective sexuality patterns
• Disturbed thought processes	• Risk of infection	• Disturbed sleep pattern
• Interrupted family processes	• Disturbed thought processes	• Fatigue
• Spiritual distress	• Impaired gas exchange	• Urinary retention
	• Impaired urinary elimination	• Impaired urinary elimination
	• Deficient fluid volume	• Impaired adjustment
	• Excess fluid volume	• Disturbed body image
	• Impaired communication: verbal	• Impaired mobility: physical
		• Risk of activity intolerance
		• Risk of injury
		• Ineffective health maintenance
		• Deficient diversional activity
		• Social isolation
		• Spiritual distress

Preoperative nursing care

Each person's response to planned surgery varies greatly. When planning and implementing nursing care, consider individual psychological and physical differences, the type of surgery and the circumstances surrounding the need for surgery. A comprehensive nursing assessment is needed to determine the most appropriate care for each person undergoing surgery.

Before planning and implementing care for the person having surgery, gather assessment information by taking a nursing history and performing a physical examination. Use this information to establish baseline data, identify physical needs, determine teaching needs and psychological support for the person and their family, and prioritise nursing care. The type of surgical procedure directs the assessment and intervention planned by the nurse.

Surgery is a significant and stressful event. Regardless of the nature of the surgery (whether major or minor), the person and their family will be anxious. Some people seek care from a spiritual provider during this time. The degree of anxiety they will feel is not necessarily proportional to the magnitude of the surgical procedure. For example, a person scheduled to have a biopsy to rule out cancer, which is considered minor surgery, may be more anxious than a person undergoing gallbladder removal, which is considered major surgery.

The nurse's ability to listen actively to both verbal and non-verbal messages is imperative to establishing a trusting relationship with the person and their family. Therapeutic communication can help the person identify fears and concerns. The nurse can then plan nursing interventions and supportive care to reduce their anxiety level and assist them to cope successfully with the stressors encountered during the perioperative period.

Preoperative teaching

Teaching people is an essential nursing responsibility in the preoperative period. Education and emotional support have a positive effect on people's physical and psychological well-being, both before and after surgery. Previous research has determined that people who received preoperative education experienced less pain and anxiety, fewer complications, earlier discharge and increased satisfaction with their care, and returned to normal activities sooner. Positive outcomes may be attributed in part to the sense of control the person gains through the education they and their family receive.

Teaching should begin as soon as the person learns of the upcoming surgery. Teaching may begin in the surgeon's office or at the time of preadmission testing and assessment. Although education continues during postoperative care, most teaching is done before surgery because pain and the effects of anaesthesia can greatly diminish the person's ability to learn.

The amount of information desired varies for each individual. Therefore, the nurse should assess the person's need for and readiness to accept information. The teaching will be directed in part by the particular surgical procedure that is being performed and by the type of anaesthesia. The information in Box 3.2 is relevant to most people undergoing major surgery.

In addition to teaching the person and their family about measures that will decrease the risk of complications, provide other preoperative information to prepare them for surgery. This information should include the following:

- diagnostic tests—reasons and preparations
- arrival time for surgery
- preparations for surgery including: bowel preparation, skin preparation, indwelling catheter or bladder elimination, start of intravenous infusion, preoperative medication, handling of personal effects (rings, watch, money)
- sedative/hypnotic medication to be taken the night before surgery to promote rest and sleep
- education about whether to take medications on the morning of the surgery
- informed consent
- expected timetable for surgery and the recovery room
- method to inform family of progress throughout surgery
- transfer to the surgery department
- location of the surgical waiting room
- transfer to recovery room
- anticipated postoperative routine and devices or equipment (drains, tubes, equipment for IV infusions, oxygen or humidifying mask, dressings, splints, casts)
- plans for postoperative pain control
- if/when to commence fasting.

Be aware that dehydration, hypovolaemia and hypoglycaemia are recognised side effects of fasting. Thirst, worry and hunger are also reported by people having surgery and may be related to fasting. Fasting does not ensure that the stomach will be empty or that the gastric contents will be less acidic.

CONSIDERATION FOR PRACTICE

People about to undergo surgery may experience unnecessarily long preoperative fasts due to changes in surgery schedules and delays. How will this influence your management of people who are elderly, have diabetes mellitus or who may miss important medications as a result of these delays?

Preoperative preparation of people having surgery

A preoperative surgical checklist serves as a guide for preparing the person for surgery in most institutions. Complete the checklist before the person is transported to surgery. Nursing responsibilities on the day of surgery are as follows:

- Assist with bathing, grooming and changing into the operating room gown.
- Ensure that the person takes nothing by mouth. Provide additional teaching and reinforce prior teaching.
- Remove nail polish, lipstick and make-up to facilitate circulatory assessment during and after surgery.
- Ensure that identification and allergy bands are correct, legible and secure.
- Remove hair pins and jewellery; a wedding ring may be worn if it is taped to the finger.
- Complete skin or bowel preparation as ordered.
- Insert an indwelling catheter, intravenous line or nasogastric tube if ordered.
- Remove prostheses such as artificial eyes and contact lenses, and store them in a safe place. Note that

BOX 3.2 Preoperative teaching for people having surgery

Diaphragmatic breathing exercise

Diaphragmatic (abdominal) breathing exercises are taught to the person who is at risk of developing pulmonary complications, such as atelectasis or pneumonia. Risk factors for pulmonary complications include general anaesthesia, abdominal or thoracic surgery, history of smoking, chronic lung disease, obesity and advanced age.

In diaphragmatic breathing, the person inspires deeply while allowing the abdomen to expand outwards. On expiration, the abdomen contracts inwards as air from the lungs is expelled.

1. Explain to the person that the diaphragm is a muscle that makes up the floor of the thoracic cavity and assists in breathing. The purpose of diaphragmatic breathing is to promote lung expansion and ventilation and enhance blood oxygenation.
2. Position the person in a high or semi-Fowler's position (see figure below right).
3. Ask the person to place their hands lightly on their abdomen.
4. Instruct the person to breathe in deeply through their nose, allowing their chest and abdomen to expand.
5. Instruct the person to hold their breath for a count of five.
6. Tell the person to exhale completely through pursed (puckered) lips, allowing their chest and abdomen to deflate.
7. Instruct the person to repeat the exercise 5 times consecutively.

Encourage them to perform diaphragmatic breathing exercises every 1–2 waking hours, pre and postoperatively.

Coughing exercise

Coughing exercises are also taught to the person who is at risk of developing pulmonary complications. The purpose of coughing is to loosen, mobilise and remove pulmonary secretions. Splinting the incision decreases the physical and psychological discomfort associated with coughing.

1. Assist the person in following steps 1 to 4 for diaphragmatic breathing.
2. Ask them to splint the incision with hands or pillow (see figure below).
3. Tell them to take 3 deep breaths and then cough forcefully.
4. Instruct the person to repeat the exercise 5 times consecutively every 2 hours while awake, taking short rest periods between coughs, if necessary.
5. Provide fluids as appropriate following exercise.

Diaphragmatic breathing exercise

Splinting abdomen while coughing

(continued)

BOX 3.2 Preoperative teaching for people having surgery (continued)

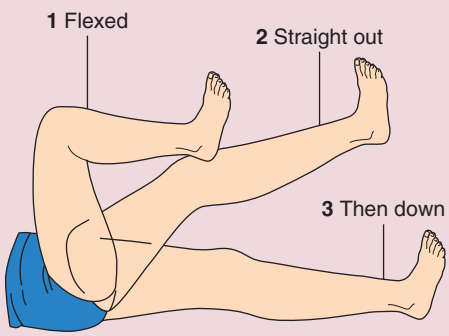
Leg, ankle and foot exercises

Leg exercises are taught to people who are at risk of developing thrombophlebitis (inflammation of a vein, which is associated with the formation of blood clots). Risk factors for developing thrombophlebitis include decreased mobility preoperatively and/or postoperatively, a history of difficulties with peripheral circulation, and cardiovascular, pelvic or lower extremity surgeries.

The purpose of leg exercises is to promote venous blood return from the extremities. As the leg muscles contract and relax, blood is pumped back to the heart, promoting cardiac output and reducing venous stasis. These exercises also maintain muscle tone and range of motion, which facilitate early ambulation.

Teach the person to perform the following exercises while lying in bed:

1. Muscle pumping exercise: contract and relax calf and thigh muscles at least 10 times consecutively.
2. Leg exercises:
   a. Bend the knee and raise it towards the chest (see figure below).
   b. Straighten out leg and hold for a few seconds before lowering the leg back to the bed.
   c. Repeat exercise 5 times consecutively prior to alternating to the other foot.
3. Ankle and foot exercises:
   a. Rotate both ankles by making complete circles, first to the right and then to the left (see figure below).
   b. Repeat 5 times and then relax.
   c. With feet together, point toes towards the head and then to the foot of the bed (see figure below).
   d. Repeat this pumping action 10 times and then relax.



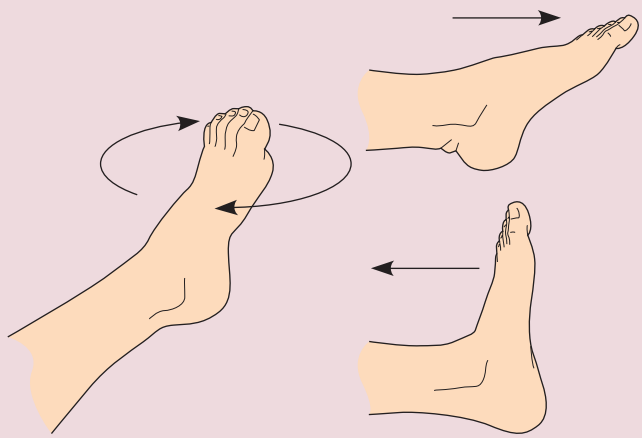
Leg exercises

Encourage the person to perform leg, ankle and foot exercises every 1–2 hours while awake, depending on their needs and ambulatory status.

Turning in bed

The person who is at risk of circulatory, respiratory or gastrointestinal dysfunction following surgery is taught to turn in bed. Although this may be a simple task prior to surgery, after surgery (particularly after abdominal surgery) they may find it a difficult procedure. To make the procedure more comfortable, they may need to splint the incision by using the hand placed on a small pillow or blanket. Additionally, they should be taught that analgesics can be given to ease postoperative discomfort involved with turning. Encourage them to turn every 2 hours while awake.

1. Tell them to grasp the side rail towards the direction to be turned, to rest the opposite foot on the mattress and to bend the knee.
2. Instruct them to roll over in one smooth motion by pulling on the side rail while pushing off with the bent knee.
3. Pillows may need to be positioned behind their back to help them maintain a side-lying position. Older people may also need padding over pressure points between the knees and ankles to decrease the chance of decubitus ulcer formation from pressure.



Ankle and foot exercises

the anaesthetist may request that dentures are worn to theatre and removed immediately prior to anaesthesia.

- Leave a hearing aid in place if the person cannot hear without it and notify the operating theatre nurse.
- Verify that the informed consent has been signed prior to administering preoperative medications.
- Weigh the person and record height and weight in the chart (for correct dosage of anaesthesia).
- Verify that all ordered diagnostic test reports are in the chart.
- Instruct the person to empty their bladder immediately before the preoperative medication is administered (unless an indwelling catheter is in place).
- Administer preoperative medication as scheduled (refer to 'Medications' earlier in the chapter and Table 3.4).
- Ensure the safety of the person once the medication has been given by placing them on bed rest with raised side rails and by placing the call switch within reach.
- Assess and record vital signs.
- Provide ongoing supportive care to the person and their family.
- Document all preoperative care in the appropriate location, such as the preoperative surgical checklist, the medication record and the narrative preoperative nursing notes.
- Verify with the surgical personnel the person's identity, and verify that all their information is documented appropriately.

- Assist with transfer from the bed to the theatre trolley if required.
- Prepare the person's room for postoperative care, including making the surgical bed and ensuring that the anticipated supplies and equipment are in the room.

Intraoperative nursing care

The intraoperative phase of surgery begins when the person enters the operating room and ends when they are transferred to the post anaesthesia care unit (PACU). Nursing care in this phase focuses on keeping them and the environment safe and providing physiological monitoring and psychological support.

Hazards associated with surgery can be minimised for people by use of a surgical safety checklist. The WHO (2009) has formed the World Alliance for Patient Safety that has developed a 'Safe Surgery Saves Lives' initiative. This program has produced a Surgical Safety Checklist that has been adopted in many countries including Australia.

A multisite study was conducted to evaluate the effectiveness of introducing this checklist and reported significant reductions in morbidity and mortality as a result of its implementation (Haynes et al., 2009). The checklist includes three phases: Sign in, Time out and Sign out, and requires all members of the surgical (and anaesthetic) team to contribute at critical junctures: before anaesthesia is administered, immediately before the incision and before the person is transported from the operating theatre. The implementation in Australia of a shorter version of this safe surgery protocol has been reported in a study by Healy, and compliance with this protocol is increasing (Healy, 2012).

LINKS TO NATIONAL PATIENT SAFETY STANDARDS

NSQHS Standard 5:
Patient Identification and Procedure Matching

'The intention of this standard is to correctly identify all patients whenever care is provided and correctly match patients to their intended treatment.' (ACSQHC, 2011, p. 40)

Implementing this standard is achieved by the establishment of explicit systems and processes that ensure routine use of at least three approved patient identifiers when providing care, therapy or services, and during transfer of care.

Caring for individuals having surgery will often require multiple occasions when routine checking of patient identification and procedure matching must be undertaken, and often involves several team members checking these details together. Some examples include during the process of documenting informed consent for the surgical procedure, during use of the preoperative surgical checklist in the ward before the person is transported to the operating theatre, during the transfer of care between ward staff and operating theatre staff, at the time when the person is checked into the anaesthetic room, during the use of the Surgical Safety Checklist in the operating theatre (in particular to check the correct operative site), during transfer to the PACU, and during transfer to the ward after surgery. In addition, this standard will apply to occasions of medication administration, infusion of intravenous fluids and blood products, and diagnostic testing. When these checks are conducted it is important that they are correctly documented. The documentation of these checking processes protects clinicians from making errors such as undertaking an incorrect procedure or at an incorrect surgical site, and reduces the risk of adverse events for people having surgery.

Postoperative nursing care

Immediate postoperative care

Immediate postoperative care begins when the person has been transferred from the operating room to the PACU. The PACU nurse is part of the surgical team and monitors the person's vital signs and surgical site to determine the response to the surgical procedure and to detect significant changes. Assessing mental status and level of consciousness is another ongoing nursing responsibility, and the person may require repeated orientation to time, place and person. Emotional support also is essential, because the person is in a vulnerable and dependent position. Assessing and evaluating hydration status by monitoring intake and output is crucial to detecting cardiovascular or renal complications. In addition, the PACU nurse assesses the person's pain level. Careful administration of analgesics provides comfort without compounding the potential side effects from the anaesthesia.

Care when the person is stable

When awake and after being stabilised, the person is transferred to their hospital room. The PACU nurse communicates information about the person's condition and postoperative orders to the ward/unit nurse prior to their arrival. This prepares the ward/unit nurse for additional problems or needed equipment (see Box 3.3).

Immediate and continuing assessment is essential to detect and/or prevent complications. In documenting assessment findings, the nurse completes a flow record of the individual person's situation. Baseline data are obtained, documented and

BOX 3.3 Patient handover from the PACU nurse to the ward nurse

The quality of the patient handover from the PACU nurse to the ward nurse is a critical factor in patient safety. A systematic review by Wong, Yee and Turner (2008) identified that poor handover can result in discontinuity of care, the provision of inadequate or inaccurate care, adverse patient outcomes and legal claims of malpractice. A well-known definition of handover is 'the transfer of professional responsibility and accountability for some or all aspects of care for a patient, or group of patients, to another person or professional group on a temporary or permanent basis' (Australian Medical Association, 2007, p. 8). Because of the potential risk of patient harm, clinical handover is one of the Australian Commission on Quality and Safety in Healthcare's National Standards.

LINKS TO NATIONAL PATIENT SAFETY STANDARDS

NSQHS Standard 6: Clinical Handover

Safe and effective clinical handover processes require standardised approaches that are fit for purpose and appropriate to the clinical context in which handover occurs. Attention to high-quality clinical handover enhances patient safety as critical information is more likely to be transferred and acted upon (ACSQHC, 2011).

Source: © Australian Commission on Safety and Quality in Health Care.

compared with preoperative data. A postoperative head-to-toe assessment includes, but may not be limited to, the following:

- general appearance
- vital signs
- level of consciousness
- emotional status
- skin colour and temperature
- discomfort/pain
- nausea/vomiting
- type of intravenous fluids and flow rate
- dressing site
- drainage on the dressing and/or bed linen
- urinary output (catheter or ability to urinate)
- ability to move all extremities.

The hospital policy or surgeon's orders dictate the frequency of follow-up assessments. After major surgery, the nurse generally assesses the person every 15 minutes during the first hour and, if they are stable, every 30 minutes for the next 2 hours, and then every hour during the subsequent 4 hours. Assessments are then carried out every 4 hours, subject to change according to the person's condition and the protocol for the particular surgical procedure. It is critical to inform the surgeon immediately if the assessment reveals any signs of impending shock or other life-threatening changes.

After carrying out the initial assessment and ensuring the person's safety by raising the side rails and placing the call switch within reach, the nurse reviews the surgeon's postoperative orders. These orders guide the nurse in the care of the postoperative person. For example, the orders specify activity level, diet, medications for pain and nausea, antibiotics, continuation of preoperative medications, frequency of vital sign assessments, administration of intravenous fluids, and laboratory tests such as haemoglobin and potassium level. In most institutions, orders written prior to surgery must be reordered following surgery because the person's condition is presumed to have changed.

Nursing care of common postoperative complications

Several factors place the person at risk of postoperative complications and adverse events (Kable, Gibberd & Spigelman, 2009). Nursing care before, during and after surgery is aimed at preventing and/or minimising the effects of these complications.

Preoperative care and teaching to decrease postoperative complications have been discussed previously. The following section addresses postoperative cardiovascular, respiratory and wound complications, and problems associated with elimination.

Cardiovascular complications

Common postoperative cardiovascular complications include shock, haemorrhage, deep venous thrombosis and pulmonary embolism.

SHOCK Shock is a life-threatening postoperative complication. It results from an insufficient blood flow to vital organs, an inability to use oxygen and nutrients, or the inability to rid tissues of waste material. Hypovolaemic shock, the most common type in the postoperative period, results from a decrease in circulating fluid volume. Decreased fluid volume develops with blood or plasma loss or, less commonly, from severe prolonged vomiting or diarrhoea. Symptoms vary according to the severity of the shock; the greater the loss of fluid volume, the more severe the symptoms. Chapter 10 provides a detailed discussion of nursing care of people with various types of shock.

HAEMORRHAGE Haemorrhage is an excessive loss of blood. A concealed haemorrhage occurs internally from a blood vessel that is no longer sutured or cauterised, or from a drainage tube that has eroded a blood vessel. An obvious haemorrhage occurs externally from a dislodged or ill-formed clot at the wound. Haemorrhage also may result from abnormalities in the blood's ability to clot; these abnormalities may result from a pathological condition, or they may be a side effect of medications.

Haemorrhage from a venous source oozes out quickly and is dark red, whereas an arterial haemorrhage is characterised by bright red spurts of blood pulsating with each heartbeat. Whether the haemorrhage is from a venous or an arterial source, hypovolaemic shock will occur if sufficient blood is lost from the circulation.

Common assessment findings with haemorrhage depend on the amount and rate of blood loss. Restlessness and anxiety are observed in the early stage of haemorrhage. Obvious bleeding will be present if the haemorrhage is external. The person will have symptoms characteristic of shock, such as hypotension and tachycardia (weak, thready pulse).

Care of the person who is haemorrhaging centres around stopping the bleeding and replenishing the circulating blood volume. Nursing care includes providing care for shock and one or more of the following:

- applying one or more sterile gauze pads and a firm pressure dressing to the area
- applying pressure with gloved hands (may be necessary for severe external bleeding)
- preparing the person and their family for emergency surgery (in severe situations when bleeding cannot be stopped).

DEEP VENOUS THROMBOSIS Deep venous thrombosis (DVT) is the formation of a thrombus (blood clot) in association with inflammation in deep veins. This complication most often occurs in the lower extremities of the person postoperatively. It may result from the combination of several factors, including trauma during surgery, pressure applied under the knees, sluggish blood flow during and after surgery and reduced mobility. People with a high risk of developing DVT include those who are over age 40 and who:

- have undergone orthopaedic surgery to lower extremities; urological, gynaecological or obstetric surgeries; or neurosurgery
- have a history of varicose veins
- have a history of thrombophlebitis or pulmonary emboli
- are obese
- have an infection
- have a malignancy.

Common assessment findings reveal pain or cramping in the involved calf or thigh. Redness, tenderness, warmth, discolouration of the skin and oedema (JBI, 2008) of the entire extremity may occur along with a slightly elevated temperature. The person may have a positive Homans' sign (pain in the calf on dorsiflexion of the affected foot). Suspected DVT can be confirmed by duplex Doppler scans; however, it is important to remember that many venous thrombi are asymptomatic.

Nursing care of the person with DVT focuses on preventing a portion of the clot from dislodging and becoming an embolus (travelling blood clot) circulating to the heart, brain or lungs; preventing other clots from forming; and supporting the person's own physiological mechanism for dissolving clots. Nursing care includes the following measures:

- Administer anticoagulants and analgesics as prescribed. (NSAIDs are not usually given in combination with anticoagulants, because doing so increases the anticoagulant effects.)
- Monitor pathology results for clotting times.
- Apply thigh-high graduated compression stockings or devices to stimulate venous return.
- Ensure that the affected area is not rubbed or massaged.
- Record bilateral calf or thigh circumferences every shift.
- Teach and support the person and their family about self-management.
- Assess colour and temperature of the involved extremity every shift.

PULMONARY EMBOLISM A pulmonary embolism is a dislodged blood clot or other substance that lodges in a pulmonary artery. For the postoperative person with DVT, the threat that a portion of the thrombus may dislodge from the vein wall and travel to the lung, heart or brain is a constant concern. Early detection of this potentially life-threatening complication depends on the nurse's astute, continuing assessment of the person postoperatively.

Common assessment findings of the person experiencing a pulmonary embolism include mild to moderate dyspnoea, chest pain, diaphoresis, anxiety, restlessness, rapid respirations and pulse, arrhythmias, cough and cyanosis. The severity of the symptoms is determined by the degree of pulmonary vascular blockage. Sudden death can occur if a major pulmonary artery becomes completely blocked.

Stabilising respiratory and cardiovascular functioning while preventing the formation of additional emboli is of utmost importance in the care of the person with a pulmonary embolism. Nursing care includes the following measures:

- Immediately notify the surgeon and/or anaesthetist.
- Frequently assess and record general condition and vital signs.
- Maintain the person on bed rest, and keep the head of the bed elevated.
- Provide oxygen as ordered and monitor pulse oximetry.
- Administer prescribed intravenous fluids to maintain fluid balance while preventing fluid overload.
- Administer prescribed anticoagulants.
- Maintain comfort by administering analgesics and sedatives. (Use caution to prevent respiratory depression.)
- Provide supportive measures for the person and their family.

Refer to Chapter 34 for a detailed discussion of pulmonary embolism.

Respiratory complications

Common postoperative respiratory complications include pneumonia and atelectasis.

PNEUMONIA Pneumonia is an inflammation of lung tissue. Inflammation is caused either by a microbial infection or by a foreign substance in the lung, which leads to an infection. Numerous factors may be involved in the development of pneumonia, including aspiration infection, retained pulmonary secretions, failure to cough deeply and impaired cough reflex, and decreased mobility.

Common assessment findings of the person with postoperative pneumonia are as follows:

- high fever
- rapid pulse and respirations
- chills (may be present initially)

- productive cough (may be present depending on the type of pneumonia)
- dyspnoea
- hypoxia
- chest pain
- pulmonary crackles and wheezes.

Treating the pulmonary infection, supporting the person's respiratory efforts, promoting lung expansion, and preventing the organisms' spread are the goals in the care of the person with pneumonia. Nursing care includes the following measures:

- Obtain sputum specimens for culture and sensitivity testing.
- Position the person with the head of the bed elevated.
- Encourage the person to turn, cough and perform deep-breathing exercises at least every 2 hours.
- Assist with incentive spirometry, intermittent positive pressure breathing (IPPB) and/or nebuliser treatments as ordered.
- Ambulate the person as their condition permits and as prescribed.
- Administer oxygen as ordered.
- Assess vital signs, breath sounds and general condition.
- Maintain hydration so that pulmonary secretions are easier for the person to expectorate.
- Administer antibiotics, expectorants, antipyretics and analgesics as ordered.
- Provide or assist with frequent oral hygiene.
- Prevent the spread of microorganisms by teaching proper disposal of tissues, covering mouth when coughing, and good handwashing technique.
- Provide supportive measures for the person and their family.

Chapter 34 provides a detailed discussion of pneumonia.

ATELECTASIS Atelectasis is an incomplete expansion or collapse of lung tissue resulting in inadequate ventilation and retention of pulmonary secretions. Common assessment findings include dyspnoea, hypoxia, diminished breath sounds over the affected area, anxiety, restlessness, crackles and cyanosis.

Promoting lung expansion and systemic oxygenation of tissues is a goal in the care of the person with atelectasis. Nursing care includes these tasks:

- Position the person with the head of bed elevated.
- Administer oxygen as prescribed.
- Encourage coughing, turning and deep breathing every 2 hours.
- Ambulate the person as their condition permits and as prescribed.
- Assist with incentive spirometry or other pulmonary exercises, such as inflating a balloon, as ordered.
- Administer analgesics as prescribed.
- Promote hydration.
- Provide supportive measures to the person and their family.

Wound complications

Discussion of the complications associated with surgical wounds follows an overview of wound healing, wound drainage and nursing care of wounds.

Wounds heal by either *primary*, *secondary* or *tertiary* intention (see Figure 3.5). Healing by primary intention takes place when the wound is uncomplicated and clean and has sustained little tissue loss. The edges of the incision are well approximated

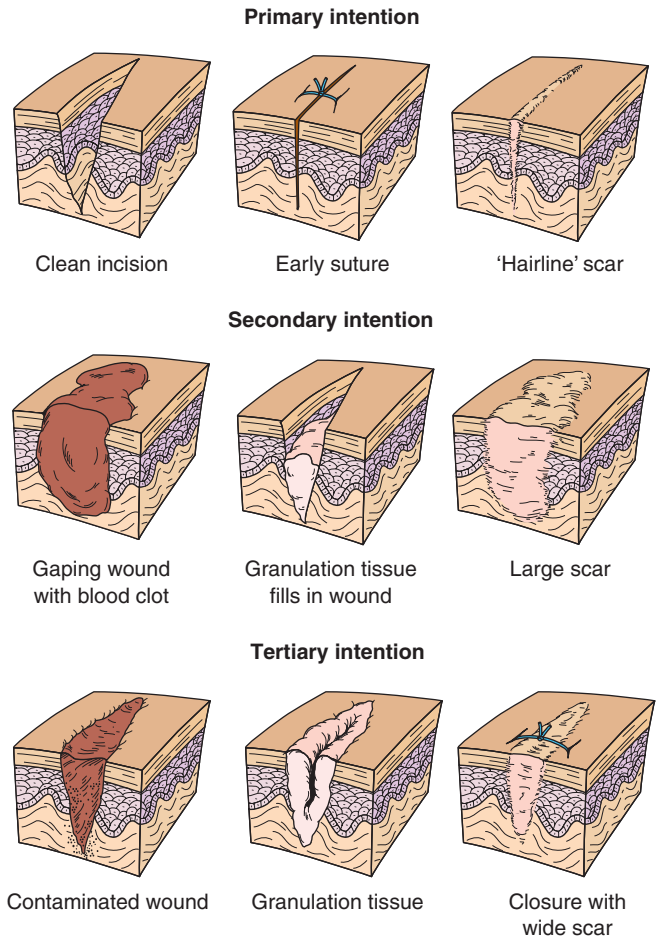

FIGURE 3.5 ■ Wound healing by primary, secondary and tertiary intention

(joined) with sutures, staples or glue for drain holes or superficial wounds. This type of surgical incision heals quickly and very little scarring is expected.

Secondary intention refers to the healing that occurs when the wound is large, gaping and irregular. Tissue loss prevents wound edges from approximating; therefore, granulation fills in the wound. This type of wound takes longer to heal, is more prone to infection, and develops more scar tissue.

If enough time passes before a wound is sutured, healing by tertiary intention occurs. Infection is more likely to take place. Because the wound edges are not approximated, tissue is regenerated by the granulation process. Closure of the wound results in a wide scar.

From the time the surgical incision is made until the wound is completely healed, all wounds progress through four stages of healing. However, healing time varies according to many factors, such as age, nutritional status, smoking, general health, and the type and location of the wound. Box 3.4 provides a summary of the stages of wound healing.

Wound drainage (exudate) results from the inflammatory process in the first two stages of wound healing. The drainage is from the rich blood supply that surrounds the wound tissue and is composed of escaped fluid and cells. The drainage is described as serous, sanguineous or purulent.

BOX 3.4 Stages of wound healing

- *Stage I: from surgery through to day 2.* Inflammatory process occurs to prepare the surrounding tissue for healing. Blood vessels constrict, and clotting occurs. Vasodilation and increased capillary permeability follows, bringing plasma, white blood cells and fibroplastin to the wound site. Epithelial cells begin to form and re-establish blood flow in the wound tissue. A mild temperature elevation is normal.
- *Stage II: day 3 through to day 14 following surgery.* Fewer white blood cells are present. Collagen tissue forms in the wound tissue. Granulation tissue, red with a rich blood supply, is established.
- *Stage III: day 15 to week 6 following surgery.* Collagen fibres continue to strengthen the wound. As the blood supply decreases, the scar tissue appears pink and somewhat raised.
- *Stage IV: several months to a year following surgery.* As the wound tissue constricts, the scar becomes flat, smaller and white.

- Serous drainage contains mostly the clear serous portion of the blood. The drainage appears clear or slightly yellow and is thin in consistency.
- Sanguineous drainage contains a combination of serum and red blood cells and has a thick, reddish appearance. This is the most common type of drainage from a non-complicated surgical wound.
- Purulent drainage is composed of white blood cells, tissue debris and bacteria. Purulent drainage is the result of infection and tends to be of a thicker consistency, with various colours specific to the type of organism. It also may have an unpleasant odour.

Box 3.5 describes and illustrates various types of wound drainage devices. These devices decrease pressure in the wound area by removing excess fluid, which promotes healing and decreases complications.

Nursing care of the person with a postoperative surgical wound focuses on prevention and monitoring for wound complications. The nurse assumes a leading role in supporting the wound healing process, providing emotional support to the person and teaching them wound care.

BOX 3.5 Wound drainage devices

A Penrose drain, used for passive wound drainage, promotes healing from the inside to the outside (see *Figure A* below). The use of the drain decreases the chance of abscess formation. The safety pin in the Penrose drain prevents the exposed end from slipping down into the wound, and facilitates x-ray detection if necessary. Wound care focuses on cleaning around the drain with a prescribed solution, such as sterile normal saline, and replacing the pre-cut gauze dressing as necessary to keep the surrounding skin dry and encourage further drainage. An absorbent dressing is placed over the drain and gauze (not shown).

Wound suction devices promote drainage of fluid from the incision site, decreasing pressure on healing tissues and reducing abscess formation. Shown are the Jackson-Pratt and Bellovac wound suction devices (see *Figures B* and *C* below).

The frequency with which the nurse empties the device depends on the time elapsed since surgery, type of surgery, amount of drainage and hospital policy. For example, immediately after surgery the nurse may empty the device every hour. With time, as drainage decreases, the device is emptied every 2 to 4 hours (per hospital policy). Amount, colour, consistency and odour of drainage are documented.

Usually, the drain is removed on the second to fourth day after surgery. Removal causes minor discomfort. The drain site is cleaned and a sterile dressing is applied.

Source: C © Wellspect Healthcare and Dentsply IH Pty Ltd (Australia).

Common assessment findings of an infected wound include pain; purulent, odorous discharge and redness; warmth; tenderness; and oedema around the edges of the incision. Additionally, the person may have a fever, chills and increased respiratory and pulse rates. Nursing care includes the following measures:

- Follow the Australian Wound Management Association's *Standards for Wound Management* (2011).
- Observe aseptic technique during dressing changes and handling of tubes and drains, including the 'Five Moments for Hand Hygiene' approach as recommended in Australia by Hand Hygiene Australia (ACSQHC, n.d.).
- Assess vital signs, especially temperature.
- Evaluate the characteristics of wound discharge (colour, odour and amount).
- Assess the condition of the incision (approximation of the edges, sutures, staples or drains).
- Clean, irrigate and pack the wound in the prescribed manner. Sterile normal saline is often prescribed.
- Maintain the person's hydration and nutritional status.
- Swab the wound for a microbial culture prior to beginning antibiotic therapy (if indicated).
- Administer antibiotics and antipyretics as prescribed.

Dehiscence is a separation in the layers of the incisional wound (see Figure 3.6A). Treatment depends on the extent of wound disruption. If the dehiscence is extensive, the incision must be resutured in surgery. **Evisceration** is the protrusion of body organs from a wound dehiscence (see Figure 3.6B). These serious complications may result from delayed wound healing or may occur immediately following surgery. They also may occur after forceful straining (coughing, sneezing or vomiting).

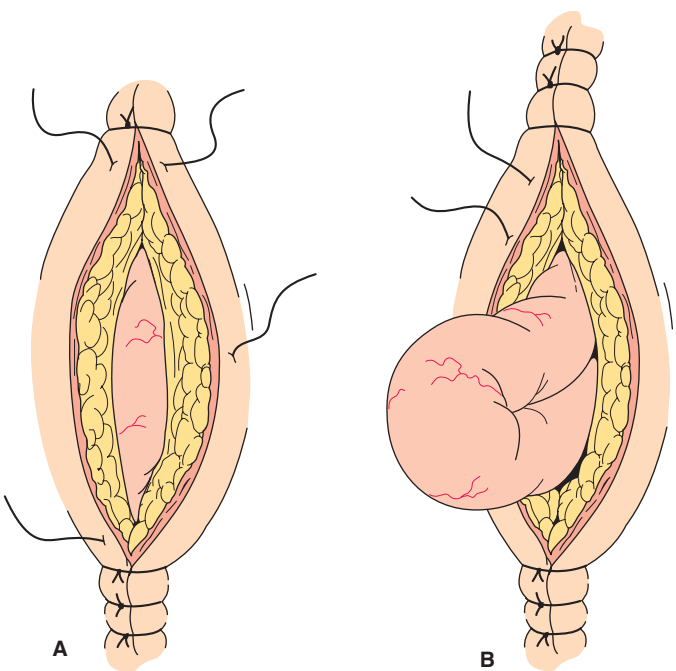

FIGURE 3.6 ■ Wound complications. *A*, Dehiscence is a disruption in the incision resulting in a separation of the layers of the wound. *B*, Evisceration is a protrusion of a body organ through a surgical incision

When dehiscence occurs, immediately cover the wound with a sterile dressing moistened with normal saline. Emergency surgery is performed to repair these conditions.

The nurse or medical officer may remove sutures or staples after the wound has healed sufficiently (usually 5 to 10 days after surgery). Removal is performed using aseptic technique. Additional support may be provided to the incision by applying strips of tape (or Steri-Strips) as directed by institutional policy or by the medical officer.

Complications associated with elimination

Common postoperative complications associated with elimination include urinary retention and altered bowel elimination. The inability to urinate with urinary retention may occur postoperatively as a result of the recumbent position, effects of anaesthesia and narcotics, inactivity, altered fluid balance, nervous tension or surgical manipulation in the pelvic area. Nursing care centres on promoting normal urinary elimination and includes the following measures:

- Assess for bladder distension if the person has not voided within 7 to 8 hours after surgery or is urinating small amounts frequently. Ultrasound assessment is often used for this purpose.
- Assess the amount of urine in the bladder with a portable ultrasound scanner. This non-invasive procedure provides information to prevent unnecessary catheterisation and decreases the potential for urinary tract infections and urethral trauma from repeated catheterisations.
- Monitor intake and output.
- Maintain intravenous infusion if fluids are prescribed.
- Increase daily oral fluid intake to 2500 to 3000 mL if the person's condition permits.
- Insert an intermittent or indwelling catheter if ordered.
- Promote normal urinary elimination by:
  a. Assisting and providing privacy when the person uses a bedpan.
  b. Helping the person to use the bedside commode or walk to the bathroom.
  c. Assisting males to stand to void.
  d. Pouring a measured amount of warm water over the perineal area (if urination occurs, subtract the amount of water from the total amount for an accurate output measurement).

Bowel elimination frequently is altered after abdominal or pelvic surgery and sometimes after other surgeries. Return to normal gastrointestinal function may be delayed by general anaesthesia, narcotic analgesia, decreased mobility or altered fluid and food intake during the perioperative period.

Nursing care centres on the return of normal bowel function and includes the following measures:

- Assess for the return of normal peristalsis:
  a. Auscultate bowel sounds every 8 hours while the person is awake.
  b. Assess the abdomen for distension. (A distended abdomen with absent or high-pitched bowel sounds may indicate paralytic ileus.)
  c. Determine whether the person is passing flatus.
  d. Monitor for passage of stool, including amount and consistency.

- Encourage early ambulation within prescribed limits.
- Facilitate a daily fluid intake of 2500 to 3000 mL (unless contraindicated).
- Provide privacy when the person is using the bedpan, bedside commode or bathroom.

If no bowel movement has occurred within 3 to 4 days after surgery, an aperient, suppository or an enema may be prescribed.

Special considerations for older adults

Physiological, cognitive and psychosocial changes associated with the ageing process place the older adult at increased risk of postoperative complications. These age-related changes with selected nursing interventions are summarised in Table 3.6. With an increasing population of older adults, particularly the very old, the nurse must be aware of these normal changes and modify nursing care accordingly in an effort to provide safe, supportive care.

Managing acute postoperative pain

Pain is expected after surgery (Layzell, 2008). It is neither realistic nor practical to eliminate postoperative pain completely. Nevertheless, the person having surgery should receive substantial relief from and control of this discomfort. Controlling postoperative pain not only promotes comfort but also facilitates coughing, turning, deep-breathing exercises, earlier ambulation and decreased length of hospitalisation, resulting in fewer postoperative complications and therefore reducing healthcare costs. Despite the apparent benefits and methods of effective pain control and improved understanding of pain physiology, many people do not receive adequate pain relief or control postoperatively.

TABLE 3.6 Nursing interventions for older people having surgery

SYSTEM	AGE-RELATED CHANGES	NURSING INTERVENTIONS
Body composition	Change in weight and fat distribution and hydration	Provide for warmth and frequent turning. Assess for dehydration and fluid imbalance. Provide comfort measures when NBM.
Integument	Diminished integrity secondary to loss of subcutaneous fat and decreased oil production and elasticity	Provide careful preoperative preparation, including hair removal, to avoid trauma. Position carefully to prevent pressure ulcers.
Sensory–perceptual	Decline in vision and hearing ability	Compensate for sensory deficits: speak low, not loud; minimise noise in environment; provide adequate room light; stay within the person's field of vision when speaking; encourage them to wear their hearing aid to the operating room.
Respiratory	Decreased efficiency of cough reflex and decreased aeration of lung fields. Reduced pulmonary functional reserve and lung function, with increased risk of infection and bronchospasm with airway obstruction	Maintain airway with positioning, provide oxygen as needed, maintain hydration and mobility. Teach and encourage coughing and diaphragmatic breathing exercises preoperatively and encourage smoking cessation. Constantly monitor lung sounds and respiratory status.
Cardiovascular	Less efficient, decreased cardiac reserve and adaptation to stress. Risk of arrhythmias and extreme blood pressure changes.	Monitor for hypotension and shock. Assess for thrombus formation, cardiac arrhythmias, peripheral pulses and oedema.
Gastrointestinal	Decline in gastric motility, risk of altered drug absorption, GORD, maldigestion and bowel elimination problems	Encourage intake of adequate fluids, nutritious meals, soft diet. Assist with feeding; monitor bowel function. Encourage mobility.
Genitourinary	Decreased renal function reserve, risk of nephrotoxic injury and adverse reactions to medications, risk of volume overload, dehydration and other electrolyte imbalances; loss of bladder control and urinary tract infections. Risk for falls.	Monitor fluid input and output and electrolyte levels. Assess for drug side effects. Assist with voiding as needed.
Musculoskeletal	Stiffness of joints; decrease in strength; brittleness of bones, intervertebral disc degeneration and joint erosion. Risk for falls.	Carefully position on operating table with bony prominences well padded to prevent pressure sores. Move carefully and gently. Provide effective pain management. Encourage mobilisation postoperatively. Prevent falls.
Cognition and nervous system	Decreased reaction time and reflexes and slow motor skills, deficits in balance and coordination, slowed cognitive processing; risk of delirium and altered mental status while in hospital. Risk for falls.	Provide ample time for making decisions. Implement safety measures. Talk to people respectfully as an adult. Orient frequently. Monitor for postoperative delirium. Provide effective pain management. Prevent falls.

Sources: C. M. Smith & V.T. Cotter (2012). *Age Related Changes in Health. Evidence-Based Geriatric Nursing Protocols for Best Practice* (4th ed.). New York: Springer Publishing Company; LLC. R. Griffiths, F. Beech, A. Brown, J. Dhesi, I. Foo, J. Goodall, W. Harrop-Griffiths, J. Jameson, N. Love, K. Pappenheim & S. White (2014). Guidelines: Peri-operative care of the elderly 2014. *Anaesthesia*, *69*(Suppl. 1), 81–98.

Managing acute postoperative pain is an important nursing role before, during and after surgery. Successful pain management involves the cooperative efforts of the person, anaesthetist and nurse (Layzell, 2008; McMain, 2010. The American Society of Anesthesiologists (2012) suggests six specific institutional policies for perioperative pain management. These include education and training for healthcare providers, monitoring of individual outcomes, documentation of monitoring activities, monitoring of outcomes at an institutional level, 24-hour availability of anaesthetists providing perioperative pain management and use of a dedicated Acute Pain Service. Preoperatively, the person should learn how much pain to anticipate and what methods are available to control pain. After discussing options with the person having surgery, healthcare providers must respect their personal preferences.

Postoperative medications were discussed earlier in the chapter. Various non-pharmacological approaches to pain management can also be used alone or in combination to control acute postoperative pain (ANZ College of Anaesthetists and Faculty of Pain Medicine, 2010). Music, distraction and imagery techniques and acupuncture can decrease mild pain and anxiety. Additional information on pain management techniques is found in Chapter 8.

The person's input and participation in assessing pain and pain relief is essential to a successful pain control regimen. For example, the person can rate the pain on a scale of 0 to 10 (where 0 signifies no pain and 10 signifies unbearable pain). Assess and document pain at scheduled intervals to determine the degree of pain control, to observe for drug side effects, and to assess the need for changes in the dosage and/or frequency of medication administration. When a range of dosage is ordered, carefully titrate opioid dosages based on individual assessments of need and response to therapy.

Community-based care

The postoperative phase does not end until the person has recovered completely from the surgical intervention. Thus the nurse plays a vital role as they near discharge. People who have surgery are usually discharged within a few days, and many complications can develop after discharge. As people prepare to recuperate at home, the nurse provides information and support to help them successfully meet self-care demands. All aspects of teaching should be accompanied by written guidelines, directions and information. This is particularly helpful when a large amount of unfamiliar, detailed information is presented. Because the hospital stay is often brief, an organised, coordinated effort to educate the person and their family should be made. Teaching needs vary, but the most common needs include:

- Wound care. Teaching is more effective if the nurse first demonstrates and explains the procedure for the person and their family or other caregiver. They should then participate in the care. To evaluate the effectiveness of the teaching, ask them to demonstrate the procedure in return. Ideally, teaching is carried out over several days, evaluated and periodically reinforced.
- Signs and symptoms of a wound infection. The person should be able to determine what is normal and what should be reported to their doctor.
- Method and frequency of taking own temperature.
- Limitations or restrictions that may be imposed on such activities as lifting, driving, bathing, sexual activity and other physical activities.
- Control of pain. If analgesics are prescribed, instruct the person in the dosage, frequency, purpose, common side effects and other side effects to report to the surgeon. Reinforce the use of relaxation, distraction, imagery or other pain control techniques that they have found useful in controlling their postoperative pain.
- Signs and symptoms of DVT and preventative strategies.
- Recommended strategies for rehabilitation and follow-up.

NURSING CARE PLAN A person having surgery

Martha Overbeck is a 74-year-old widow of German descent who lives alone in a retirement complex. She is active there, as well as in the Lutheran Church. She has been in good health and is independent, but she has become progressively less active as a result of arthritic pain and stiffness. Mrs Overbeck has degenerative joint changes that have particularly affected her right hip. On the recommendation of her surgeon and following a discussion with her friends, Mrs Overbeck has been admitted to the hospital for an elective right total hip arthroplasty. Her surgery has been scheduled for 8 am the following day.

Mrs Eva Jackson, a close friend and neighbour, accompanies Mrs Overbeck to the hospital. Mrs Overbeck explains that her friend will help in her home and assist her with the wound care and prescribed exercises.

ASSESSMENT

Gloria Nobis, RN, is assigned to Mrs Overbeck's care on return from surgery. Ms Nobis performs a complete physical assessment and determines that Mrs Overbeck is drowsy but oriented. Her skin is pale and slightly cool. Mrs Overbeck states that she is cold and requests additional covers. Ms Nobis places a warmed cotton blanket next to Mrs Overbeck's body, adds another blanket to her covers, and adjusts the room's thermostat to increase the room temperature. Mrs Overbeck states that she is in no pain and would like to sleep. She has even, unlaboured respirations and stable vital signs compared with preoperative readings.

Mrs Overbeck is NBM. An intravenous solution of dextrose and saline is infusing at 100 mL/h per infusion pump. No redness or oedema is noted at the infusion site. Ms Nobis notes that the antibiotic cephalothin is to be administered intravenously. Mrs Overbeck has a large secured dressing (Primapore) over her right upper lateral thigh and hip with no indications of ooze from the wound. Tubing protrudes from the distal end of the dressing and is attached to a passive suctioning device (Bellovac). Ms Nobis observes 50 mL of dark red drainage from the suctioning device and records the amount and characteristics on a wound assessment chart. Mrs Overbeck has an indwelling catheter in place with 250 mL of clear, light amber urine in the dependent gravity drainage bag.

NURSING CARE PLAN A person having surgery (continued)

When assessing Mrs Overbeck's lower extremities, Ms Nobis finds her feet slightly cool and pale with rapid capillary refill time bilaterally. Dorsalis pedis and posterior tibial pulses are strong and equal bilaterally. Ms Nobis notes slight pitting oedema in the right foot and ankle compared with the left extremity. She also notes sensation and ability to move both feet and toes, without numbness or tingling (paraesthesia).

Ms Nobis records these findings on the postoperative record. After ensuring that Mrs Overbeck is safely positioned and can reach her call switch, Ms Nobis gives Mrs Overbeck's friend a progress report. They then go into Mrs Overbeck's room.

DIAGNOSES

Ms Nobis makes the following postoperative nursing diagnoses for Mrs Overbeck.

- *Potential for infection:* right hip wound infection related to disruption of normal skin integrity by the surgical incision manifested by elevated temperature, redness, swelling, local pain, wound breakdown and wound exudate containing pus.
- *Injury* related to potential dislocation of right hip prosthesis secondary to hip arthroplasty manifested by acute severe pain, abnormal limb alignment and inability to mobilise.
- *Acute pain*, related to right hip incision and positioning of arthritic joints during surgery manifested by a high rating of pain on a pain scale, tachycardia, elevated blood pressure, dilated pupils, paleness, sweating, vasoconstriction, limited ability to move limb, restlessness, anxiety and shallow breathing.

PLANNING

Ms Nobis plans to use a clinical pathway to actively implement nursing strategies that will monitor the recovery of Mrs Overbeck, use evidence-based guidelines to prevent the development of potential postoperative complications, support her recovery and promote her comfort and progress during recovery. This will require using the clinical reasoning process to determine appropriate therapeutic responses, including the recognition of any indications of deterioration in physiological status. It will also include postoperative teaching to develop independence and motivate sustained self-management during hospitalisation and after discharge.

Expected outcomes

The expected outcomes established in the plan of care specify that Mrs Overbeck will:

- Regain skin integrity of the right hip incision without experiencing signs or symptoms of infection.
- Demonstrate (along with Mrs Jackson) proper aseptic technique while performing the dressing change.
- Verbalise signs and symptoms of infection to be reported to her surgeon.
- Describe measures to be taken to prevent dislocation of right hip prosthesis.
- Report control of pain at incision and in arthritic joints.
- Remain afebrile.

IMPLEMENTATION

Ms Nobis develops a care plan that includes the following interventions to assist Mrs Overbeck during her postoperative recovery.

- Provide prophylactic measures to minimise the risk of postoperative venous thromboembolism, including administration of low molecular weight heparin as ordered, early mobilisation, checking the correct application of graduated compression stockings, and/or sequential compression devices, assisting with exercises and monitoring Mrs Overbeck for potential manifestations of DVT.
- Use aseptic technique while changing dressing.
- Monitor temperature and pulse every 4 hours to assess for elevation.
- Assess wound every 8 hours for purulent drainage and odour. Assess edges of wound for approximation, oedema, redness or inflammation in excess of expected inflammatory response.
- Teach Mrs Overbeck and Mrs Jackson how to use aseptic technique while assessing the wound and performing the dressing change.
- Teach Mrs Overbeck and Mrs Jackson the signs and symptoms of infection and when to report findings to the surgeon.
- Review and discuss with Mrs Overbeck the written materials on hip arthroplasty.
- Convey empathetic understanding of Mrs Overbeck's incisional and arthritic joint pain.
- Provide analgesia every 4 hours (or as ordered) to maintain a therapeutic blood level.

EVALUATION

Throughout Mrs Overbeck's hospitalisation, Ms Nobis works with Mrs Overbeck and Mrs Jackson to ensure that Mrs Overbeck can care for herself after discharge from the hospital. Five days after her surgery, Mrs Overbeck is discharged with a well-approximated incision with no indications of an infection. Prior to discharge, Ms Nobis is confident that with Mrs Jackson's help, Mrs Overbeck can properly assess the incision. With minimal help, Mrs Overbeck is able to replace the dressing using aseptic technique. She can state the signs and symptoms of an infection, take her own oral temperature, and describe preventive measures to decrease the chances of dislocating her prosthetic hip. Because of her reduced mobility the past 5 days, Mrs Overbeck says she can tell the arthritis in her 'old bones' is 'acting up'. She reports a lessening of pain in her right hip following surgery and a pain that is different to her arthritic pain as experienced pre-surgery. Mrs Overbeck tells Ms Nobis she will be back the following winter to have her left hip replaced.

(continued)

NURSING CARE PLAN A person having surgery (continued)

CRITICAL THINKING IN THE NURSING PROCESS

1 Describe risk factors for Mrs Overbeck's safety; what changes in her home environment would you suggest to promote safety until she recovers more fully?
2 Why is Mrs Overbeck placed on the antibiotic cephalothin although she has no indications of an infection? What teaching would you do?
3 Mrs Overbeck's clotting time is slightly elevated as a result of an ordered anticoagulant. Why would this medication be ordered? Consider the person's age and the area of surgery.
4 Mrs Overbeck is 13.6 kg above her ideal weight and has osteoarthritis. Develop a care plan for the nursing diagnosis *Health Maintenance Problems* related to intake in excess of metabolic requirements and limited mobility.

REFLECTION ON THE NURSING PROCESS

1 Using the critical thinking process, identify what you have learned from this case study that you will apply to your clinical practice in the future.
2 Consider this learning in relation to the Nursing and Midwifery Board of Australia (NMBA) (2013) *National Competency Standards for the Registered Nurse (2006)*.
3 What teaching aids would be helpful to educate people recovering from hip arthroplasty surgery, during the postoperative period?

CHAPTER HIGHLIGHTS

- Surgery takes place in traditional and non-traditional settings with increasing use of minimally invasive procedures that expedite discharge, facilitate healing and increase satisfaction for people having surgery.
- Surgery is an invasive procedure, and legal guidelines must be followed to protect the person having surgery and the healthcare providers. The surgical team includes surgeons, anaesthetists, nurses and anaesthetic technicians; all are responsible for the safety of the person and the progression of the surgery.
- The focus on safety during surgery continues to increase, with attention directed to preventing wrong site/wrong patient operations occurring. Procedures are established to verify that the right person will have the correct surgery. A team approach to safety works best; each member of the team must feel accountable for the results of the surgery and entitled to share observations and concerns as the procedure progresses.
- Inpatients who have surgery have relatively short stays, which are best achieved by early ambulation, pain control and proper nutrition. Providing information for self-care is challenging with the shortened stays and rate of admissions and discharges. From the time of entry to the surgical setting, the person's discharge must be planned and prepared.
- Teaching people prior to and following surgery empowers them to achieve successful recovery, discharge and rehabilitation. Most of the care people receive during healing is provided either by themselves or a caregiver outside the healthcare environment. People having surgery and their families need to know appropriate assessments and interventions to monitor the healing process.
- Pain management is offered prior to, during and after surgery with methods designed to give the best therapeutic response. While acute pain related to the surgery occurs many people also experience persistent pain that affects their response to pain management therapies.
- Behaviours characteristic of older adults and ethnically diverse populations increase the need for individualised care. Assessment of physical and emotional status can be more difficult when people have hearing or visual impairments or when individuals speak and understand a foreign language. Surgery can be frightening to people and their families and they need reassurance and interventions to decrease pain, relieve anxiety and promote healing.
- Operating room and post anaesthesia nursing care are professional specialties that require unique orientation and education. These professionals make careful assessments of the risks each person faces and make plans to ensure safe, successful surgical outcomes. Special attention is focused on early recognition and treatment of postoperative complications associated with cardiopulmonary function, respiratory function, wound healing, elimination and pain.

CONCEPT CHECK

1 The nurse's primary responsibility relating to informed consent is:
1 defining the risks and benefits of the surgery
2 checking that the person's signature appears on the consent form and that the form is accurately completed
3 discussing alternative therapies with the person
4 advising the person and their family about what is needed for the diagnosis

2 Obtaining a preoperative blood pressure measurement serves the following purpose:
1 fulfils a legal requirement
2 provides information for the amount of anaesthetic required
3 prevents atelectasis
4 provides a baseline to compare with postoperative blood pressure levels

3 Non-steroidal anti-inflammatory drugs are given in the postoperative period to:
1 stimulate appetite
2 increase amnesia
3 potentiate analgesia
4 improve renal function

4 Discharge planning for a person following general surgery will include dietary management guidelines. Specifically, the person will eat a diet:
1 low in cholesterol, high in fat
2 high in protein, moderate in kilojoules
3 low in fat, high in fibre
4 without dairy products, but otherwise regular

5 In the immediate postoperative period for knee surgery, assessment distal to the site includes:
1 urinary pH
2 rebound tenderness
3 Chvostek's sign
4 neurovascular assessment

6 In the postoperative period, medications the person is prescribed prior to surgery must be:
1 continued after surgery
2 decreased by half for 36 hours
3 ordered anew prior to administration
4 withheld until evidence of anaesthesia is absent

7 The person with diabetes mellitus who is NBM prior to surgery:
1 has no risk of hyperglycaemia
2 should receive sliding-scale insulin prescriptions
3 will benefit from hypoglycaemia during anaesthesia
4 will fail to manifest signs of hypoglycaemia under anaesthesia

8 Acute pain management medications in the immediate postoperative period generally:
1 progress from NSAIDs to opioids
2 should include pre-emptive and multimodal analgesia
3 should be prn to promote control
4 induce a strong sedative effect to decrease the risk of nausea

9 Lengthy operative procedures can put the older person at risk of:
1 memory loss due to blood loss
2 hearing loss due to extended anaesthesia
3 weight loss due to lack of nutritional intake
4 pressure sores and joint pain from operative positioning

10 Hypothermia in the perioperative period:
1 decreases cardiac ischaemia
2 reduces the risk of wound infection
3 increases comfort and analgesia
4 requires interventions to prevent and relieve

CHAPTER 4

NURSING CARE OF PEOPLE EXPERIENCING LOSS, GRIEF AND DEATH

PAMELA VAN DER RIET, VICTORIA PITT, GREG BLYTON

LEARNING OUTCOMES

- Differentiate the difference between loss, grief and mourning.
- Compare and contrast the theories of loss and grief.
- Explain factors affecting responses to loss.
- Describe person-centred care and the role of the nurse in end-of-life care.
- Discuss legal and ethical issues in end-of-life care.
- Describe palliative care philosophy and activities of a hospice.

CLINICAL COMPETENCIES

- Identify physiological changes in the dying person.
- Provide nursing interventions to promote a comfortable death.
- Provide person-centred care for individuals and families experiencing loss, grief or death.

KEY TERMS

LOSS, GRIEF AND MOURNING

Loss may be defined as an actual or potential situation in which a valued object, person, relationship, body part or emotion that was formerly present is lost or changed and can no longer be seen, felt, heard, known or experienced. A loss may be temporary or permanent, complete or partial, objectively verifiable or perceived, physical or symbolic. Only the person who experiences the loss can determine the meaning of the loss. Individuals experiencing health changes because of an eventually fatal condition may also feel a loss of trust in their body; this is particularly so for individuals diagnosed with cancer. Although the importance of loss varies for each person, people most commonly fear the losses listed in Box 4.1.

Loss always results in change. The stress associated with the loss may be the precipitating factor leading to physiological or psychological change in the person or family. The effective or ineffective resolution of feelings surrounding the loss determines the person's ability to deal with the resulting changes.

An **eventually fatal condition** is defined as:

> *any illness where it is expected that death will be a direct consequence of the specified illness. This definition is inclusive of illnesses of both a malignant and non-malignant nature. An eventually fatal condition might be expected to shorten an individual's life. This differs from chronic illness where, even though there may be significant impact on the person's abilities and quality of life, there is likely to be a less direct relationship between the illness and the person's death.* (Adapted from Palliative Care Australia, 2005, p. 11)

Grief is the emotional response to loss and its accompanying changes. Grief as a response to loss is a normal and an inevitable dimension of the human experience. The loss of a job, a role (e.g. the loss of the role of spouse, as occurs in divorce), a goal, body integrity, a loved one, or the impending loss of one's own life may trigger grief. Loss is also integral to death. Although death is a critical penultimate loss, losses that occur in any phase of the life cycle may produce grief responses as intensely painful as those observed in the death experience.

Grieving may be thought of as the internal process the person uses to work through the response to loss. **Mourning** describes the actions or expressions of the bereaved, including the symbols, clothing and ceremonies that make up the outward manifestations of grief. Both grieving and mourning are healthy responses to loss because they ultimately lead the person to invest energy in new relationships and to develop positive self-regard.

BOX 4.1 Types of losses

- Death
- Health
- Body part
- Social status
- Lifestyle
- Relationship (i.e. through breakup or divorce)
- Reproductive function
- Sexual function

A commonly used definition of **death** is an irreversible cessation of circulatory and respiratory functions or irreversible cessation of all functions of the entire brain, including the brainstem. With the current life support systems available, the most often used criterion for determining death is whole-brain death (permanent irreversible cessation of the functioning of all areas of the brain). The criteria for brain death are listed in Chapter 10.

Although death is an inevitable part of life, the acknowledgement of death as part of the process of an eventually fatal condition is often immensely difficult for the person and their loved ones. Death may be accidental (such as from trauma), intentional (suicide) or come at the end of a long and painful struggle with an eventually fatal condition such as cancer or motor neuron disease.

THEORIES OF LOSS AND GRIEF

Nurses often care for individuals exhibiting responses typical of various stages of the grieving process. Highly individual in quality and duration, the grief process may range from discomforting to debilitating, and it may last a day or a lifetime, depending on what the loss means to the person experiencing it. Although each person experiences loss in a different manner, knowledge of some of the major theories of loss and grief can give the nurse a framework for holistic, person-centred care of the individual and family anticipating or experiencing a loss. Table 4.1 summarises the theories discussed.

Freud: psychoanalytic theory

Freud (1917/1957) discussed grief and mourning as reactions to loss. Freud described the process of mourning as one in which the person gradually withdraws attachment from the lost object or person. He observed that with normal grieving,

TABLE 4.1 Summary of theories of loss

THEORIST	DYNAMICS
Freud (1917/1957)	Grief and mourning are reactions to loss. Grieving is the inner labour of mourning a loss. Inability to grieve a loss results in depression.
Bowlby (1973, 1980)	The successful grieving process initiated by a loss or separation during childhood ends with feelings of emancipation from the lost person or object.
Engel (1964)	After the person perceives and evaluates the loss, they adapt to it. Shock and disbelief, developing awareness and restitution occur during the first year following the loss; in the months following, the person puts the lost relationship into perspective.
Kübler-Ross (1969)	Five stages define the response to loss: denial, anger, bargaining, depression and acceptance. Stages are not necessarily sequential.
Caplan (1990)	Periods of psychological crisis are precipitated by hazardous circumstances; successful resolution of grief involves feelings of hope and engaging in activities of ordinary living.

this withdrawal of attachment is followed by a readiness to make new attachments. In comparing melancholia (prolonged gloominess, depression) with the 'normal' emotions of grief and its expression in mourning, Freud observed that the 'work of mourning' is a non-pathological condition that reaches a state of completion after a period of inner labour.

Bowlby: protest, despair and detachment

Bowlby (1973, 1980) believed that the grieving process initiated by a loss or separation from a loved object or person successfully ends when the grieving person experiences feelings of emancipation from the lost object or person. He divided the grieving process into three phases and identified behaviour characteristics of each phase.

1. *Protest*. The protest phase is marked by a lack of acceptance of the loss. All energy is directed towards protesting the loss. The person experiences feelings of anger towards self and others, and feelings of ambivalence towards the lost object or person. Crying and angry behaviour characterise this phase.
2. *Despair*. The person's behaviour becomes disorganised. Despair mounts as efforts to deny the loss compete with acceptance of permanent loss. Crying and sadness, coupled with a desire for the lost object or person to return, result in disorganised thoughts as the person recognises the reality of the loss.
3. *Detachment*. As the person realises the permanence of the loss and gradually relinquishes attachment to the lost object, a reinvestment of energy occurs. Both the positive and negative aspects of the relationship are remembered. Expressions of hopefulness and readiness to move forward are characteristic of this phase.

Engel: acute grief, restitution and long-term grief

Engel (1964) related the grief process to other methods of coping with stress: after the person perceives and evaluates the loss (the stressful event), they adapt to it. Engel's recognition of the impact of cognitive factors on the grieving process is an important contribution to an understanding of grieving.

Engel described three main stages in the grief process: an acute stage, a restitution stage and a long-term stage. The acute stage is initiated by shock and disbelief and is manifested by denial, which may help the person to cope with their overwhelming pain. As the shock and disbelief begin to fade, the loss becomes a reality, and pain, anguish, anger, guilt and blame surface. Culturally patterned behaviour, such as maintaining a stoic pose in public or weeping openly, characterise this phase.

The acute stage is followed by a stage of restitution, in which the mourning is institutionalised. Friends and family gather to support the grieving person through rituals dictated by the culture. The mourner continues to feel a painful void and is preoccupied with thoughts of the loss. The bereaved may join a support group or seek other social support for coping with the loss. This stage lasts until the point at which the bereaved begins to come to terms with the loss and their interest in people and activities is renewed.

Kübler-Ross: stages of coping with loss

Kübler-Ross's (1969) research on death and dying provided a framework for gaining insight about the stages of coping with an impending or actual loss. According to Kübler-Ross, not all people dealing with a loss go through these stages, and those who do may not experience the stages in the sequence described. In identifying the stages of death and dying, Kübler-Ross (1978) repeatedly stressed the danger of prematurely labelling a 'stage' and emphasised that her goal was to describe her observations of how people come to terms with situations of loss.

Some or all of the following reactions may occur during the grieving process and may reappear as the person experiences the loss:

- *Denial*. A person may react with shock and disbelief after receiving word of an actual or potential loss. After receiving a life-limiting diagnosis, notification of a death or other serious loss, people may make such statements as 'This can't be happening to me' or 'This can't be true'.
- *Anger*. In the anger stage, the person resists the loss. The anger is often directed towards family and healthcare providers in the biomedical model.
- *Bargaining*. The bargaining stage serves as an attempt to postpone the reality of the loss. The person makes a secret bargain with a higher power, expressing a willingness to do anything to postpone the loss or change the prognosis.
- *Depression*. The person enters a stage of depression as the full impact of the actual or perceived loss is realised. The person prepares for the impending loss by working through the struggle of separation. While grieving over 'what cannot be', the person may either talk freely about the loss or withdraw from others.
- *Acceptance*. The person begins to come to terms with the loss and resumes activities with an air of hopefulness for the future. Some dying people, but not all, reach a stage of acceptance in which they may appear to be almost devoid of emotion. The struggle is past, and the emotional pain is gone.

Caplan: stress and loss

Caplan's (1990) theory of stress and its relationship to loss is useful in understanding the grief process. He expanded the focus of the grief process to include not only bereavement but also other episodes of stress that people experience, such as the stress that can result from surgery or childbirth. Caplan described three factors that influence the person's ability to deal with a loss:

1. the psychic pain of the broken bond and the agony of coming to terms with the loss
2. living without the assets and guidance of the lost person or resource
3. the reduced cognitive and problem-solving effectiveness associated with the distressing emotional arousal.

He believed these factors might cause distress for a year or more following the loss.

Caplan described the process of building new attachments to replace those that have been lost. This process involves two elements: a feeling of hope and the assumption of regular activity as a form of participating in ordinary living.

FACTORS AFFECTING RESPONSES TO LOSS

A variety of factors affect a person's responses to loss. These include age, social support, families, cultural and spiritual practices, and rituals of mourning.

Age

The understanding of and reaction to loss is influenced by the age of the person experiencing the loss. In general, as people experience life transitions, their ability to understand and accept the losses associated with the transitions increases. From the age of three years, the development of the concept of death as a loss proceeds rapidly. However, from the toddler to older adolescents, individuals may experience difficulties expressing their emotional responses. Therefore, it is important for the nurse to encourage the family and carers to assist the child to understand that the source of their response may be their reaction to the grief or loss (Crowe, 2004).

Social support

Grieving is painful and lonely. One's social support system is important because of its potentially positive influence on the successful resolution of grief. Some losses may lead to social isolation, placing the individual at high risk of dysfunctional grief reactions. Characteristic factors that can interfere with successful grieving include the following:

- perceived inability to share the loss
- lack of social recognition of the loss
- ambivalent relationships prior to the loss
- extreme traumatic circumstances of the loss.

The relocation of work or home, a relationship breakdown or even the death of a pet can cause a person to feel extremely isolated, yet the person experiencing these types of losses does not ordinarily receive the same social support offered to the person mourning the death of a loved one. A woman having an abortion or giving up a child for adoption seldom receives the same social support as a mother who has lost a child at birth. It is especially important, therefore, for the nurse *not* to place a value on the individual's loss when assessing the need for support.

The painful nature of grief can cause the individual to withdraw from a previously established social support system, thereby increasing the feelings of loneliness caused by the loss. A recently widowed woman, for example, may refuse invitations involving married couples with whom she had socialised while her husband was alive. The individual's needs for social interaction, however, remain similar to those established before the loss.

Families

A well-functioning family usually rallies after the initial shock and disbelief and provides support for each other during all phases of the grieving process. After a loss, the functional family is able to shift roles, levels of responsibility and ways of communicating.

The family may have negative as well as positive effects. For example, the dying person may request that someone the family perceives as an outsider be near, and the family may respond with anger to the perceived 'intrusion'. Similarly, certain family members may express hurt feelings or anger if the individual is unresponsive to other family members. Well-meaning family members also may try to shield the individual from the pain of grieving. It is rare for the family and the dying person to experience anger, denial and acceptance in unison. While one member is in denial, another may be angry because 'not enough is being done'.

Cultural and spiritual practices

Spirituality is at the core of human existence, integrating and transcending the physical, emotional, intellectual and social dimensions (Reed, 1996). It involves a person's beliefs and values and cannot be viewed in isolation from their culture and background (Abbas & Panjwani, 2008). When confronted by a life-limiting illness, people often ask questions of themselves, and others, as to what their life has meant, why this illness has affected them and what will happen to them when they die. Spirituality can provide structure to a person's experience, giving a sense of coherence, and can assist with coping and providing feelings of wellbeing (Rumbold, 2003; Vivat, 2008).

Many individuals have beliefs about their life, including principles and values that they have lived by, their personal philosophy and the goals they have pursued in life. These beliefs may be questioned as the individual responds to actual or perceived losses experienced in their life. If unresolved, these concerns and perceptions can lead to spiritual or existential distress, causing a sense of hopelessness, anxiety and depression. When spiritual distress is resolved, people can die more peacefully.

For some people, spirituality is about religion, while for others it is about making sense of their existence. Spirituality is a way of being and often involves multiple practices/multiple forms of understanding experiences; it is, therefore, not necessarily the same for everyone. Abbs' fluid description captures the discursive context of spirituality:

> *. . . an intrinsic part of human existence—it can be experienced in particular moments of relationship, of heightened perception, and of high creativity; in states of trance, self transcendence and spontaneous enthusiasm, as in those unexpected moments of timelessness when the sheer miracle of consciousness quietly reveals itself. It can also be located in moments of acute personal crises and near breakdown; in moments of abandonment and anxiety.* (Abbs, 1995, p. 28)

Furthermore, Abbas and Panjwani (2008) point out that failure to provide spiritual care means failure to provide holistic care. The care of a dying person needs to consider more than attention to physical needs; it must also take into account a holistic approach involving a spiritual dimension of care (Abbas & Panjwani, 2008; Amoah, 2011; Penman, Oliver & Harrington, 2013; Puchalski, 2012). van der Riet (1999), in her research

FIGURE 4.1 ■ Nurses play an important role in caring for people who are experiencing an eventually fatal condition

involving the ways in which people undergoing treatment for cancer experienced massage and visualisation, found that people may not use the term 'spirituality'; however, they may use metaphors of spirituality to mean peace, centredness, comfort, healing, wellbeing, intimacy and reconnection with their bodies. Some of these metaphors included 'floating on a cloud' and 'I felt at one'. For them, spirituality involved an awareness of their bodies as new and no longer diseased with cancer.

Nurses play an important role in caring for people who are experiencing an eventually fatal condition (see Figure 4.1), as it is often difficult for them to maintain hope and a sense that their lives have had meaning. Spirituality is an important part of nursing practice. To assist with the person's spiritual needs, nurses can help them, through sensitive and empathetic responding, to accept the uncertainty that comes with their illness and possible death. Respect for the cultural and spiritual beliefs and practices of people and their families are paramount in caring for dying people. Context and environment are both an important part of a person's experience of spirituality (Billock, 2009). People who are religious need opportunities for prayer, devotions and religious rituals. Those without religious beliefs may find solace and achieve a sense of spirituality from meditation, guided imagery, music or art.

It is essential that the nurse has the ability to reflect on their own practice and actions that support the spirituality of the people they care for. For the nurse the concept of spirituality may be captured by the sense of seeing people at peace, or expressing that they feel balanced and connected again. Spirituality also encapsulates the sense of the nurse connecting with a person and having an understanding of their suffering and of being privileged to see their courage and strength. It could be sharing an intimate moment with a person.

Rituals of mourning

Through participation in ceremonies such as baptisms, confirmations and weddings, people joyously celebrate progression to a new stage of life and loss of a former way of being. The funeral ceremony may serve many purposes in meeting the needs of the bereaved, as people gather to share their loss. Through the funeral preparation and ceremony, people symbolically express triumph over death and deny the fear of death. Culture is the primary factor that dictates the rituals of mourning. It is important for health professionals to understand and respect the diversity that exists in our society in relation to grief and loss. The following section is intended to guide health professionals in developing an understanding of the diverse cultures within our society.

Death and dying in Indigenous Australian culture

There are no set rules that define how Indigenous Australians react to the loss of a loved one. However, many of the customs observed during funerals in the past are still evident in contemporary Indigenous society. The health professional should take into account the impact of colonisation when addressing the needs of Indigenous Australians. Christianity, assimilation and other values and beliefs adopted from colonial society have affected how Indigenous Australians now treat death and dying. Indigenous Australian culture is an evolving social phenomenon bringing change and diversity.

LINKS TO NATIONAL PATIENT SAFETY STANDARDS

NSQHS Standard 2:
Partnering with Consumers

'The intention of this standard is to create a health service that is responsive to patient, carer and consumer input and needs.' (ACSQHC, 2011, p. 22)

Implementation of this standard is ensured through strong governance structures that reflect the importance of the cultural diversity of a population. Partnering with consumers supports the active participation of all groups in the evaluation and improvement of an organisation, especially those groups who may not always participate in providing feedback.

Patients who are dying and their grieving families are extremely vulnerable and need to feel safe and supported by compassionate and professional care. Culturally competent partnerships between health systems, services, patients, families, carers and consumers are important in ensuring a sense of dignity and safety in the vulnerable state of grief and loss. Systems that support consumers as partners in planning, designing and evaluating care will strengthen the delivery of culturally competent care, ensuring that with ongoing support patients and their families will adapt to loss.

The following information reflects some of the history, customs and values of Indigenous Australians during times of grief, bereavement and funerals, and suggests avenues of understanding and approach for health professionals providing care for Indigenous Australians.

POST-TRAUMATIC STRESS SYNDROME Colonisation has had a major transgenerational impact on the psyche of many Indigenous Australians. The clashes between Indigenous Australians and Europeans included massacres, poisoning, dispossession, displacement and alienation, and there were many deaths and funerals (Reynolds, 1989). The socio-historical impact on contemporary Indigenous Australians should be considered when dealing with issues of death and dying.

GRIEF AND BEREAVEMENT FOR INDIGENOUS AUSTRALIANS The perspectives that were too often portrayed in the pages of Australian colonial ethnography texts ignored some of the fundamental issues that are critical to the provision of adequate support and comfort to Indigenous people experiencing grief and bereavement following the loss of loved ones. There are commonalities in the ways in which different Indigenous groups cope with death, but these were not explored in these texts and need to be addressed.

- *Grief counselling*. The family, extended family and friends gather around the deceased person as a collective group. This practice allows the grieving party space, connection and, most importantly, an opportunity to provide support to each other in a time of grief, loss and crisis. This support operates as a mechanism whereby the members of the group perform the roles of grief counsellor, bereavement counsellor and priest, therefore facilitating the healing process.
- *Barriers*. One of the major problems that confront Indigenous people and health professionals can sometimes be found in the rigid hospital policies that are embedded in administrative bureaucracy. In the event that a person dies in hospital, there may be policies that restrict visitation. For example, in some hospitals restrictions may apply that allow no more than two or three people to be with the deceased body at any one time and there may also be policies that only permit visitors between certain hours. These rules are impediments to the essence of healing in Indigenous Australian culture. They stop critical connections, respect and space, and deny the opportunity for the enactment of the healing process. Large numbers of Indigenous people faced with institutional barriers to this healing process may end up gathering inside and outside hospital areas where they can group together.
- *Space*. Indigenous people need sufficient space to gather together to facilitate the grieving and bereavement process where they can offer each other support, respect and counselling (see Figure 4.2).
- *Respect*. Health professionals should listen and understand the importance of this connection with regard to the grieving and healing process.
- *Time*. The grieving and bereavement process may take days or even weeks. It is important to respect this process and to provide space for this length of time. For example, in the early 20th century if an Indigenous woman lost and buried her child she grieved at the gravesite until new grass began shooting where her child was buried. During this period of around two weeks other members of the community brought food and water to support the grieving mother.
- *Cultural safety*. Health professionals create a culturally safe environment through awareness and consideration of the Indigenous person's cultural identity and acknowledgement of their difference within a Western-orientated healthcare system. The Nursing Council of New Zealand (2002, p. 9) defines unsafe cultural practice as any actions that 'diminish, demean or disempower the cultural identity of an individual'. Listening in a non-judgmental way to Indigenous people is a critical skill in acquiring cultural safety. As a nurse, culturally safe practice means you need to be able to recognise and understand the dynamics of cultural, personal and professional power (Richardson & Carryer, 2005).

Notifying the designated Indigenous liaison coordinator attached to the hospital about the death is critical, as this is often a link to the deceased person and their family.

The following quote provides some insight into the meaning of death, and the connection to the land, for the Indigenous person: 'Tree the same as me, When he get old he'll die. He'll be dead and burn. He'll leave his ashes behind. Tree becomes earth.' (Neidjie, 1985).

The important thing for health professionals to understand when dealing with death and dying is to treat people as they find them and to be mindful that there will be diversity and cultural variance which may be contrary to their own practices and beliefs. If Indigenous Australians are able to facilitate their own healing mechanisms and engage in mutual respect, connection and group support, then these practices will often minimise the need for ongoing support or bereavement counselling.

FIGURE 4.2 ■ Indigenous Australians need sufficient space to gather together to facilitate the grieving and bereavement process where they can offer each other support, respect and counselling

Cultural diversity in the care of individuals with an eventually fatal condition

The 'Focus on Cultural Diversity' box below provides some insights into the practices of major cultural groups present in Australia. This is not a prescription for dealing with individuals within these cultures with an eventually fatal condition, but rather a guide. Rituals and practices within society are fluid and diverse and are affected by changes within the society, and community and family groups. Nurses should focus on the individual and provide respect and care in response to their particular needs.

END-OF-LIFE CARE

Providing quality care to individuals at the **end-of-life** (the final weeks of life when death is imminent) is a priority of the Australian Government. In 2000 the National Palliative Care Program was established and has since funded many initiatives that aim to improve both access to and quality of palliative care services across all Australian states and territories (Department of Health and Ageing, 2009). These initiatives are supported by Palliative Care Australia (2005), which has published *Standards for Providing Quality Palliative Care for All Australians*. Selected standards are:

- Care, decision making and care planning are each based on a respect for the uniqueness of the person, their caregiver/s and family. Their needs and wishes are acknowledged and guide decision making and care planning.
- Ongoing and comprehensive assessment and care planning are undertaken to meet the needs and wishes of the person, their caregiver/s and family.
- Care is coordinated to minimise the burden on the person, their caregiver/s and family.
- The primary caregiver/s is/are provided with information, support and guidance about their role according to their needs and wishes.
- The unique needs of dying people are considered, their comfort maximised and their dignity preserved.
- Staff and volunteers reflect on practice, and initiate and maintain effective self-care strategies (Palliative Care Australia, 2005).

FOCUS ON CULTURAL DIVERSITY Cultural aspects of eventually fatal condition care

Culture	Nursing interventions
Arabic	Arabic-speaking people tend to come from the Middle East and north-east Africa and follow the Muslim culture. In Muslim culture the body of the deceased is handled as little as possible, and preferably by those of the same sex and from a Muslim culture. The body of the deceased should be handed over as soon as possible to the Muslim community so washing and burial rituals can be undertaken.
Chinese	Ensure the head of the family is present when illness is discussed. The person may not want to discuss approaching death. Special amulets or cloths may be brought from home. Family members may prefer to bathe the body after death.
Greek	In the past, the family would control information related to an individual's eventually fatal condition and not provide the person with that information. However, this approach has changed over time, although the family is still significantly involved in care and decision making. Home is a significant place and is the preferred care environment. Nurses should offer to contact the family priest who may give communion, rather than 'last rites', as this has a more positive connotation.
Italian	The family is usually involved when an eventually fatal condition is discussed and may wish to shelter the person from discussions of diagnosis and prognosis. Home is the preferred place for care. Prayer may be an important part of end-of-life care and it is important to offer attendance by a priest.
Korean	Ensure the eldest son in the family is involved in discussions concerning an individual's eventual fatal condition. The hospital tends to be the preferred place to die, especially if there are young children living at home. Many Koreans follow a Buddhist or Confucianist doctrine of religion. The family may have sought help from a herbal doctor called a '*Hanui*'. The body of the deceased is usually left overnight.
Polish	Family is a significant part of healthcare. However, not all individuals have family present in Australia. Home is the preferred place for care. However, hospital and hospice environments are accepted places for care. Many are involved in the Catholic Church, and respect for the church and a belief in God is a significant aspect of life.
Vietnamese	Ensure the head of the family is involved in discussions concerning an eventually fatal condition with the person. You may find that the entire family will make end-of-life decisions, often with assistance from spiritual leaders such as a priest or monk. Individuals often prefer to die at home. The family should have extra time with the body, and vocal expressions of grief are not uncommon. After the person has died, the family might request to open all the windows and outside doors of the room to allow the person's spirit to leave their body.

Nursing considerations for end-of-life care

Nurses care for the dying person in many environments, including general and acute hospital settings such as intensive care and emergency departments, residential aged care facilities, hospices and the home. (See 'Translation to practice: Evidence-based practice for end-of-life care' for research on intensive care nurses' experiences with end-of-life care.) Regardless of the setting, the individual's wishes about death should be respected.

Legal and ethical issues

Decision making and consent are issues that are often debated strongly when considering end-of-life care. The legal and ethical issues surrounding advance directives, enduring power of attorney, do-not-resuscitate (DNR) directives, euthanasia and quality of life are especially important to nurses in upholding each person's specific care requests. Types of advance directives are shown in Box 4.2.

Settings for end-of-life care

Settings and services for the provision of end-of-life care range from residential aged care facilities, hospitals and hospices to the person's own home. **Palliative care** is a term used within Australia to describe a philosophy of care provided for individuals at the end-of-life or with an eventually fatal condition. In the literature, the term '**hospice care**' may be used to refer to the philosophy of care; however, in Australia, the term 'hospice' more often refers to a setting where palliative care is provided. The philosophy of palliative care is outlined in this section, followed by a brief description of the settings in which this philosophy may be integrated into care.

Philosophy of palliative care

Palliative care is a philosophy of care, rather than a program of care. It is holistic, comprehensive and coordinated care for individuals with an eventually fatal condition, provided where possible in a setting of the person's choice (Department of Health and Ageing, 2000). Palliative care reaffirms the right of every person and family to fully participate in the final stages of life. Palliative care is provided by nurses, doctors, allied health professionals and volunteers. It is based on a philosophy of dying being a normal part of living, and on ensuring the individual is provided with comfort and dignity, encompassing physical, psychological, social, emotional and spiritual aspects of the dying experience (Department of Health and Ageing, 2000). The philosophy of palliative care may be provided in any setting, including those outlined below.

HOME/RESIDENTIAL AGED CARE FACILITY/ COMMUNITY LIVING An individual often prefers to die at their permanent living environment, which may include a private home or residential aged care facility. Community or hospital/hospice outreach program-based nurses working within the palliative care philosophy are usually the main care providers for individuals in this setting. It is essential that care provided to individuals in this setting includes ongoing comprehensive assessment involving the person, the family and the support services that are available, including general medical and palliative care specialist teams.

BOX 4.2 Types of advance directives

Advance directives, sometimes referred to as 'living wills', are legal documents that allow a person to plan healthcare or provide insights into treatment preferences in the event of incapacity. Advance directives may be formally written legal documents, including living wills or enduring powers of attorney, or informal orally communicated requests expressed to loved ones, carers or health professionals. Advocating for the person's treatment preferences is an aspect of care that many nurses will face, and the nurse must always ensure that the person is aware of the preferences stated in their directives and that they remain current. The legislation across Australia concerning advance directives varies, so it is essential that the nurse is aware of the approach taken by the state or territory in which they are practising.

Advanced care planning has evolved in the face of limitations associated with advance directives. An advanced care plan should support the advance directive, in that it further develops documented communications of the person's preferences as to future care and/or the withdrawal of care and treatment.

An **enduring power of attorney** is a document that can delegate the authority to make health, financial and/or legal decisions on a person's behalf. It must be in writing and must state that the designated person is authorised to make healthcare decisions.

A **do-not-resuscitate (DNR) directive** or *not for resuscitation (NFR) order* is written by the doctor for the individual for whom it is believed that cardiopulmonary resuscitation (CPR) would be of no benefit. This order is usually based on the wishes of the individual and family that no CPR be performed for respiratory or cardiac arrest. However, this directive does not extend to all treatment and care, and the nurse must ensure that other treatments should be offered and discussed with the person if applicable. The nurse must ensure that current, clear verbal and written communication of the directive is established within the multidisciplinary team, the person and the family.

Euthanasia (from the Greek for painless, easy, gentle or good death) is now a commonly used term to signify a killing prompted by humanitarian motives. There are many arguments and ethical debates for and against euthanasia, and nurses have often found themselves at the centre of the debate. As a result, nurses have pushed for the development of appropriate guidelines and procedures for DNR directives. Within Australia it is illegal to assist in an individual's suicide or to perform euthanasia.

TRANSLATION TO PRACTICE Evidence-based practice for end-of-life care

End-of-life care is emerging as a major issue in Australia. In a submission to the National Health and Hospitals Reform Commission, Palliative Care Australia has rightly pointed out that end-of-life care is everyone's affair. Further to its submission, many people in acute care are not receiving adequate end-of-life care. Good palliative care at the end of life should be consistent across all settings and for all people with a life-limiting illness. Sadly this is not the case.

Although many individuals die in hospital, little research has been done about deaths in acute care settings, such as intensive care (ICU), coronary care and critical care units. Although people are admitted to ICUs to gain access to advanced life-saving technologies, it is a reality that some die in these settings (Kirchhoff et al., 2000). Most nurses working in ICU acknowledge that it is not the most desirable setting for providing end-of-life care for an individual and their family (Kirchhoff et al., 2000; Sorensen & Iedema, 2007). However, research is beginning to address ways that nurses and the nursing profession can move forward to improve end-of-life care in ICUs (Kirchhoff et al., 2000; Sorensen & Iedema, 2007; Truog et al., 2008).

IMPLICATIONS FOR NURSING

Kirchhoff et al. (2000) advocate that, regardless of the setting for end-of-life care, nurses need to ensure that individuals are as free from pain as possible, and that their comfort and dignity are maintained. In addition, family members should be given time to begin to accept the dying process. This may be facilitated by having the family member involved in care and providing the time and space for family rituals and saying goodbye. Sorensen and Iedema (2007) focus on the importance of patient advocacy in end-of-life care in ICU and encourage nurses working in ICU to develop end-of-life care knowledge and formal assessments and to engage in open discussions with a multidisciplinary approach to advocate for the most appropriate care for the individual.

CRITICAL THINKING IN PERSON-CENTRED CARE

1. What environmental differences are present in an ICU that might make quality end-of-life care more difficult for nurses?
2. The family of a person in the ICU says to you, 'My son is going to die, isn't he?' What would you need to know before responding? How would you respond?
3. A person in the ICU who previously had been improving suddenly dies. Staff are saddened and several are in tears. A more experienced nurse says, 'Oh, you just have to go on. There's nothing else to do.' Do you agree? Why or why not?

Inquiry into Palliative Care in Australia—Submission to the Australian Senate Standing Committee on Community Affairs. Deakin West, ACT: Author.

HOSPICE/INPATIENT PALLIATIVE CARE BED The hospice setting is not restricted to the end of life, and is often used earlier in the disease experience. Individuals may seek admission to a hospice for assessment, symptom management, respite or care at the end of life. The hospice environment may be separate from or connected to a hospital setting and is focused on the relief of physical, emotional and spiritual distress for individuals who have an eventually fatal condition. Its goal is to prevent and relieve suffering by early assessment and treatment of pain and other physical, psychosocial and spiritual needs to improve the person's quality of life.

The team providing care to individuals in this setting has a well-defined palliative care philosophy and usually includes doctors, nurses, allied health professionals (including social workers, occupational therapists and dietitians), pastoral care, community liaison nurses and volunteers. If it is the individual's wish to return to their home environment, this is supported by the team with continued assessment and involvement of a community outreach hospice/palliative care team. The expected outcomes of care are directed by interventions to manage current manifestations of the illness and to prevent new manifestations from occurring.

ACUTE HOSPITAL SETTING Individuals with an eventually fatal condition who are receiving palliative care are often nursed within acute care settings. It is a significant factor of the National Palliative Care Strategy (Department of Health and Ageing, 2010) that nurses acknowledge that individuals with an eventually fatal condition often move between hospice/palliative environments and the acute care setting. In recognition of this, nurses need to develop further knowledge of the palliative care philosophy in order to facilitate and support person's individual care needs.

Symptom management in the dying person

Death is a highly individualised process and may occur rapidly or slowly. Physiological changes are a part of the dying process. Although each person responds differently, certain manifestations are common in the dying process, regardless of the trauma or disease process that is causing death. The discussion that follows includes treatments and related nursing care.

Pain

Pain is a common problem for individuals at the end of life. It is acknowledged that about two-thirds of people with cancer will experience pain that requires intervention (Quigley, 2005). Pain is what individuals often say they fear the most. Pain is a subjective experience influenced by the person's

emotions, previous experiences with pain, and family and culture. Unfortunately, pain may be under-treated at the end of life because doctors and nurses fear they will cause addiction, respiratory depression or sedation (Quigley, 2005). There is also the concern that the use of adequate pain relief may be seen as contributing to euthanasia rather than a person's comfort. However, nearly all pain at the end of life can be managed without causing addiction or respiratory depression. It is of utmost importance to keep the individual comfortable through general comfort measures (see Box 4.3) and by administering prescribed medications for pain, neuropathic pain (which is rarely relieved by opioids), seizures and/or anxiety. Thse pathophysiology, treatment and nursing care of people experiencing pain are fully described in Chapter 8.

CONSIDERATION FOR PRACTICE

There is no maximum allowable dose at end of life for opioids such as morphine sulfate; the dose should be increased by the palliative care medical specialist/doctor to whatever is necessary to relieve pain. Pethidine is not useful for chronic pain because it has a short half-life and a toxic metabolite that can cause irritability and seizures (Tierney, McPhee & Papadakis, 2004).

BOX 4.3 Providing comfort for the person nearing death

- Maintain clean skin and bed linens.
- Use a slide sheet to turn the person as often as required to keep them comfortable.
- Position the person to promote comfort and protect bony areas with padding. Reposition the person and raise the head of the bed if fluids accumulate in the upper airways and back of the throat.
- Use incontinence pads or insert an indwelling catheter (only if ordered) for urinary incontinence.
- Use gentle massage to reduce anxiety, improve circulation and shift oedema.
- Provide small, frequent sips of fluids or ice chips.
- Provide oral care, using a soft moist brush or moistened swabs. Do not use glycerine swabs as they dry the mouth out.
- Clean secretions from the eyes and nose.
- Administer prescribed pain medications as needed to maintain comfort.

Dyspnoea

Dyspnoea is the symptom of breathlessness. Although it may be experienced by some individuals with lung disease throughout their illness trajectory, it becomes more common as death nears. Dyspnoea is a subjective experience, and individuals often report feelings of suffocation, shortness of breath or tightness in the chest, which increase their anxiety and distress.

As death nears, respirations often become fast or slow, shallow and laboured. The person may have apnoea or Cheyne-Stokes respirations (regular periods of deep, rapid breathing followed by no breaths for 5 to 30 seconds). Secretions often gather at the back of the throat, which may cause an audible sound as the person breathes through them (Nuccio & Nuccio, 2009). This can be very distressing for family members and they should be reassured that these symptoms are normal for a person close to death. Fluid may accumulate in the lungs causing rales and rhonchi, especially in people who are well hydrated and are having difficulty swallowing or coughing. These sounds are not usually distressing for the person, but they may be treated by changing their position, and administering oxygen and opioids (to improve respirations and decrease anxiety). Anticholergic drugs provided early in care, prior to the build-up of secretions, can be helpful for people at the end of life (Nuccio & Nuccio, 2009).

Note that oxygen and suctioning are only temporary measures (especially with suctioning) and may even be traumatic for the person. Nursing care that may improve respiration includes keeping the head of the bed elevated and regular position changes. Morphine is the medication of choice for palliative treatment of dyspnoea. For individuals experiencing dyspnoea earlier in their illness, the breeze from a fan may provide some benefit.

Nausea, anorexia and dehydration

Typically, people at the end stage of life will be drinking and eating very little, if at all. This reduction in food and fluid intake may occur for a number of reasons, including symptoms of nausea and vomiting, dysphagia (difficulty swallowing) or as a result of fatigue. It may also be related to a reduced level of consciousness or a bowel obstruction, or simply anorexia (the absence of appetite) (van der Riet, 2009).

Nausea, with or without vomiting, is a common problem experienced by dying people. Nausea and vomiting may be caused by reduced gastric emptying, constipation, bowel obstruction, a side effect of morphine, uraemia or hypercalcaemia. The following list includes anti-emetic medications that may be used for nausea and vomiting at the end stage of life: prochlorperazine (Phenergan) or odansetron (Zofran), metoclopramide (Maxalon), levomepramazine, methotrimeprazine (Nozinan), cyclizine and haloperidol (Serenace). As with all medications, those used as anti-emetics may cause further complications or compound present health issues, such as increased constipation or drowsiness. It is essential that the nurse conduct a comprehensive assessment prior to and following the initiation of any medication regimens ordered.

Anorexia is another issue faced by many at the end of life. However, anorexia may be a protective mechanism by the body. The breakdown of body fats results in ketosis, which leads to a sense of wellbeing and helps decrease pain. This is one reason that parenteral or enteral feeding is not advocated at the end of life as it does not improve symptoms or prolong life, and may actually cause discomfort (Good et al., 2011).

Anorexia and a decrease in food and fluid intake are normal in the dying person; however, the family may view the practice of not enforcing fluids and food as 'giving up'. They may feel that their loved one is being abandoned if nurses and doctors are not intervening by providing intravenous fluids (van der Riet et al., 2008). All people at the end of life should be offered food and drink, but intravenous fluids are not routinely given (van der Riet, Brooks & Ashby, 2006).

Dehydration in the person nearing death primarily causes discomfort from dry mouth and thirst. The person should be given small sips of water, or an atomiser can be used to spray the inside of the mouth. Mouth care should be provided at least every 2 hours and more often if the person is breathing through their mouth. Good mouth care should involve moistening swabs with water (not glycerine swabs, as they dry mucous membranes), an oral gel or oral spray. It is important to avoid any drying agents such as lollies (sugar-free are fine), coffee and high-sugar drinks. When cleaning the person's teeth, there is no need to rinse the toothpaste. Mouthwashes may be used if tolerated and might include the following: salt and soda bicarbonate, Difflam and chlorhexidine.

Families need to be aware that dehydration is less of a problem than over-hydration. Forcing fluids or initiating intravenous fluids for hydration may in turn have adverse affects such as pulmonary oedema (increased fluid in the lungs), peripheral oedema, ascites, excessive wound or fistula drainage, and increased gastrointestinal secretions leading to vomiting.

CONSIDERATION FOR PRACTICE

Intravenous tubing may affect communication and physical contact between an individual who is dying and their loved ones. In a study by van der Riet et al. (2008), nurses reported that having tubes or lines in place, such as intravenous lines, affected the intimacy and the relationship between family members and the person.

Altered levels of consciousness

Neurological dysfunction may result from any or all of the following: decreased cerebral perfusion, hypoxaemia, metabolic acidosis, sepsis, an accumulation of toxins from liver and renal failure, the effects of medications and disease-related factors. These changes may result in a decreased level of consciousness or agitated delirium (Bush et al., 2014). People with terminal delirium may be confused, restless or agitated. Moaning, groaning and grimacing often accompany the agitation and may be misinterpreted as pain. The level of consciousness often decreases to the point where the person cannot be aroused. Although decreased consciousness and agitation are both normal states at the end of life, they are very distressing to the individual's family.

If possible, treatment for confusion or agitation is based on its cause—for example, pain or dyspnoea. Other medications include low doses of neuroleptics, tranquillisers or anti-anxiety medications. A person near death often has altered cerebral function, so the nurse must stand near the bedside and speak clearly. Hearing is believed to be the last sense a dying person loses, so the nurse should never whisper or engage in conversation with the family as if the person were not there.

Hypotension

As death nears, cardiac output decreases, as does intravascular blood volume. As a result, blood pressure gradually decreases and the pulse is often rapid and irregular. The extremities are cooler, and cyanosis is present in nail beds, skin and lips. The skin on the legs and in dependent areas may become mottled in colour. Renal perfusion decreases and the kidneys cease to function. Urinary output is scanty.

Complementary therapies: their use in end-of-life care

Complementary therapy is a broad term that recognises the link between the individual's mind, body and soul as fundamental to their health and wellbeing (Harris, Nagy & Vardaxis, 2006). Individuals may investigate complementary therapies and trial or extensively use therapies that are not prescribed by a medical practitioner.

Complementary therapies at the end of life have the potential to promote relaxation and comfort. The most frequently used complementary therapies for people requiring palliative care include aromatherapy, meditation, visualisation and massage (van der Riet, 2011). Nowadays in a hospital setting it is not uncommon to see some family members or carers practising therapies such as Reiki or therapeutic touch on a dying person. Reiki has been described as an art in which the practitioner transfers life energy between the practitioner and person in a compassionate way to bring balance, strength and harmony to both body and mind (Bossi, Ott & DeCristofare, 2008). For dying patients Reiki has the benefit of an improved sense of wellbeing and a positive sense of spiritual renewal (Viliotti, 2013). Throughout the increasing trajectory of an illness it is important for the nurse to adequately assess, inform, educate and support the person through the process of investigation, trial and use of these therapies. Complementary therapies may contribute to a nurse's self-care strategies, especially modalities such as yoga and meditation.

Support for the person and family

As the person's condition deteriorates, the nurse's knowledge of the person and family guides the care provided. It may be necessary to provide opportunities for individuals to express personal preferences about where they want to die and about funeral and burial arrangements. If the family feels that this is morbid, the nurse may explain that it helps the person to keep a sense of control as they approach death.

People who are dying need the opportunity to say goodbye to others. The nurse encourages and supports the person and family as they terminate relationships as a necessary part of the grief process. The nurse acknowledges that termination is painful and, if the person or family desires, stays with them during this time. Family members are often afraid to be present at the moment of death, yet dying alone is the greatest fear expressed by people at end of life.

Death

The nurse may also fear being present at the moment of the person's death. Research indicates that nurses and other health professionals frequently have difficulty in dealing with death and dying (Mallory, 2003; Melo & Oliver, 2011) In fact, Kübler-Ross (1969) noted that the nurse's fear of death frequently interferes with their ability to provide support for the dying person and family. Thoughts such as 'Please, God, don't let him die on my shift' are common, and they express the nurse's emotional turmoil in dealing with the task. Nurses who have worked through their own feelings about death and dying with effective self-care strategies are more at ease in assisting the dying person towards a peaceful death.

After the death, the nurse should be attentive to the needs of the family and significant others and acknowledge that grief reactions and needs vary for individuals. The nurse should allow the bereaved to express their sorrow, anger or guilt, which may help them resolve their grief. By accepting variations in the expression of grief, the nurse supports the family's grief reactions and helps prevent dysfunctional grieving. Dysfunctional grieving is an extended and unsuccessful resolution of grief.

Resolution of grief begins with acceptance of the loss. The nurse can encourage this by respecting the bereaved person's needs by maintaining open, honest dialogue and by providing the family with the opportunity to view, touch, hold, wash, kiss or visit with the person's body as long as is needed. As family members realise the finality of the death, they are often comforted by the presence of the nurse who cared for the person during the final days. Open and honest communication can ensure that the nurse is aware if their presence is required or not.

Care after a person dies

The nurse documents the time of death (which is required for the death certificate and all official records), notifies the doctor and notifies and supports the family. Once a person dies it is important that all infusion pumps and pressure mattresses are turned off. Experiencing machine alarms or noticing a deceased loved one's body move (from the rise and fall of a pressure mattress) can cause unnecessary distress for the bereaved person.

If the person dies at home, death must be pronounced before the body is removed from the home. Jewellery may be removed from the deceased and given to the family unless they ask that it be left on. Nurses should document the removal of valuables or jewellery and record who takes possession of the items, especially if the death occurs in a hospital or residential aged care facility. All tubing may be removed from the deceased unless otherwise indicated, such as in cases requiring a coroner's inquest. The body of the deceased is kept in place until the family is ready and gives permission for the body to be removed; this may be minutes, hours or days.

Acknowledgement of death in a hospital setting

Part of the philosophy of palliative care is the acknowledgement that death is a normal part of the life cycle. However, in hospitals or residential aged care facility settings, a person's death is not always acknowledged or discussed with the other residents of the facility/setting. Nurses in acute settings must acknowledge that a person may witness the death of another person and may need an opportunity to share their experience and express their feelings. There is a changing culture in Australian residential aged care facilities, where the deceased person's life may be celebrated with the other residents, allowing them to gain closure and acknowledgement of the death of a fellow resident.

Nurses' grief

The nurse who has developed a close relationship with the person who has died may experience strong feelings of grief. Sharing grief with the family after the death of a loved one helps both the nurse and family to cope with their feelings about the loss. Taking time to grieve after the person's death provides a release that can help prevent 'blunting' of feelings, a problem often experienced by nurses who care for individuals with an eventually fatal condition.

CONSIDERATION FOR PRACTICE

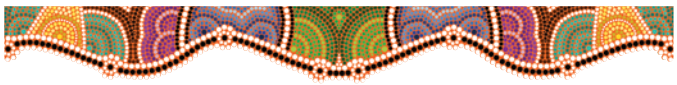
Crying with families, at one time considered unprofessional, is now recognised as simply an expression of empathy and caring.

Nurses working with individuals who are critically ill or have an eventually fatal condition should be aware that witnessing a person's death and the family's grief may reactivate feelings about some unresolved grief in their own lives. In these cases, nurses may need to reflect on their responses to their own losses. Also, nurses who work with individuals who are dying need support from peers and other professionals to work through the often overwhelming feelings that result from dealing with death, grief and loss.

INTERPROFESSIONAL CARE

Interventions for loss and grief may be planned and implemented by any or all members of the healthcare team. Nurses and social workers provide interventions to help individuals or families adapt to a loss. They also make referrals to mental health professionals (grief counsellors, social services), support groups, chaplains/pastoral care or legal agencies.

Grieving individuals may enter the healthcare system with significant somatic symptoms. Somatic symptoms are physical symptoms caused by the distress of grief. In some cases, the symptoms of grief and loss are overlooked until the person reaches a crisis state requiring psychiatric medical intervention. Collaborative care by the doctor and the nurse early in the normal grieving process can help the person achieve an early and effective resolution of grief and avoid physical or psychiatric health problems.



Nursing care

Nurses practising in all types of settings care for individuals who are in various stages of the grieving process. Like pain, grief is highly individual. The grief process may range from uncomfortable to debilitating, and it may last for a day or a lifetime, depending on what the loss means to the person experiencing it. The following section provides nurses with insights into the assessment and exploration of grief and loss for individuals for whom they care. It is acknowledged that this information is not exhaustive. Nurses should always maintain open communication with the person, significant others and multidisciplinary team; this will ensure individualised assessment and enquiry that has the person's needs as the main focus.

Health promotion

In planning a grief assessment of an individual, acknowledgement that the experience of loss can be associated with a range of factors is essential. It is also important that the nurse considers the individual's response, which may vary greatly from others' responses. In an era of short acute care hospitalisation, nurses may feel that an elaborate grief assessment is impossible or, at the least, impractical. However, research and clinical experience suggest that individuals who delay the grieving process after a loss are prone to have health problems that may last a lifetime.

Assessment

Grief reactions are personal and individual. However, knowledge of the expected physical reactions to loss provides the nurse with a basis for identifying reactions that require further assessment. To assess the extent of somatic distress—that is, physical symptoms caused by distress—the nurse observes for changes in sensory processes and asks questions about the individual's sleeping and eating patterns, activities of daily living, general health status and pain.

Physical assessment

Individuals may experience one or more predictable somatic symptoms as they become aware of a loss. Gastrointestinal symptoms occur frequently and may include indigestion, nausea or vomiting, anorexia, weight gain or loss, constipation or diarrhoea. The shock and disbelief that accompany a loss may cause shortness of breath, a choking sensation, hyperventilation or loss of strength. Some individuals also report insomnia, preoccupation with sleep, fatigue and decreased or increased activity level.

Crying and sadness are observed during normal grief states. Crying may make the individual feel exhausted and interfere with carrying out activities of daily living. However, a person who is unable to cry may have difficulty completing the mourning process. If the person does not express feelings of grief, somatic symptoms may increase. If a person is experiencing pain, it is imperative that their concerns be assessed, especially if the person has cancer or another painful illness. Knowledge of pain theories and pain assessment can help the nurse assess the need for pain medication (see Chapter 8).

Reactions to loss are not always obvious. For example, in individuals who experience an illness following a serious loss, assessment may reveal somatic complaints related to the grief state as well as the illness. When a person who has been healthy begins to develop patterns of increased illness, the nurse should be aware that this may signal dysfunctional grieving. This is especially common in the loss and grieving associated with a change in body image. In addition to making a physical assessment, assess the person's perception of the alteration in body image. The loss of a body part, weight gain or loss, and scars from surgery or trauma can be difficult for the person to accept. Some individuals may grieve hair loss that accompanies chemotherapy used in cancer treatment.

Spiritual assessment

Spiritual beliefs and practices greatly influence people's reaction to loss, and it is important for nurses to use sensitivity and skill when assessing a person's spiritual needs. Nurses need to establish rapport and trust with the person before they assess their spirituality. Nurses do not have a right to ask deeply personal questions about spirituality unless they have established trust and a connection with the person. The word 'spirituality' is loaded and can have many different interpretations. As Johnson (2005) and Roy (2011) remind us, spirituality has an elusive and perplexing quality. Some people might find the word 'spiritual' quite confronting because of possible judgments and may use metaphors such as 'peace' to describe their sense of spirituality.

Assessing the person's spiritual life and its significance to the person and family helps identify spiritual support systems. However, assessment needs to be explored within the context of the individual and their culture. Areas that might be explored include beliefs and meaning, experience and emotion, ritual and practice, courage and hope (Swinton, 2006).

Psychosocial assessment

When working through the grief process, individuals can be overwhelmed by the fears associated with the loss and the changes it will produce. Individuals diagnosed with cancer can also experience a lack of trust in their body, especially if their diagnosis was not prompted by specific symptoms. The individual responding to an actual or perceived loss commonly expresses anxiety (fear of the unknown). An extreme level of anxiety can threaten the individual's wellbeing. Assessment includes helping individuals openly acknowledge their fears. Some individuals may fear the feelings they experience while proceeding through the grief process more than the loss itself. The most common fear expressed by individuals facing a loss is that of losing self-control.

Focusing on the meaning of the loss to the person is more important than attempting to place the person in a sequence or phase of grief. The degree of caring and sensitivity shown when asking questions that consider the meaning of the loss influences the amount of information the person will be willing to reveal. Asking questions such as 'Why do you feel this way?' or 'What does this loss mean to you?' is less helpful than making a statement such as 'This must be difficult for you.'

MEETING INDIVIDUALISED NEEDS Teaching suggestions for individuals experiencing a loss

- Encourage both children and adults to discuss expected or impending loss and to express their feelings.
- Encourage problem-solving skills: define what possible changes and problems may be related to the predicted loss, develop potential strategies for dealing with problems, list pros and cons of each strategy and decide which strategies might be most useful to try first to solve potential problems associated with loss.
- Talk to individuals and families about how to support a person who is dealing with an impending loss.
- Explain what to expect with a loss: sadness, fear, rejection, anger, guilt, loneliness.
- Develop strategies for goal setting and future-orientated planning.
- Discuss signs of grief resolution:
  - Individuals and families need to understand that the acute stage of grief has no set timeline and, as discussed previously, grief reactions may vary for each individual.
  - Explain that 'triggers' such as photographs, events, songs or memories and especially the anniversary of the loss may potentially cause painful 'waves' of grief.

The latter more effectively conveys empathy and a genuine interest in hearing how the person feels about the loss.

Awareness of the altered sensorium observed during the stage of shock and disbelief provides parameters for assessment. The nurse may note in the individual feelings of numbness, unreality, emotional distance, intense preoccupation with the loss, helplessness, loneliness and disorganisation. As awareness of the loss begins to develop, preoccupation with the person who has died or the object that has been lost may increase, and self-accusation and ambivalence towards the person or object may follow.

Exploring grief

Anticipatory grieving, chronic sorrow and **death anxiety** are issues that individuals experiencing loss and grief, as well as the person who is nearing death, may experience. Nurses may find that the following information will assist in the assessment and exploration of anticipatory grieving, chronic sorrow and death anxiety.

Anticipatory grieving

Anticipatory grieving is a combination of intellectual and emotional responses and behaviours by which people adjust their self-concept in the face of a potential loss. Anticipatory grieving may be a response to one's own future death; to potential loss of body parts or functions; to potential loss of a significant person, animal or possession; or to potential loss of a social role. Nursing enquiries are designed to assist with grief resolution.

- Assess for factors causing or contributing to the grief. Ask about support systems, how many losses have occurred, relationship with the lost person, significance of the body part and previous experiences with loss and grief. *Grief and mourning occur when a person experiences any type of loss.*
- Use open-ended questions to encourage the person to share concerns and the possible effect on the family. *Grief resolution cannot occur until the individual acknowledges the loss.*
- Promote a trusting nurse–patient relationship: allow enough time for communications; speak clearly, simply and concisely; listen; be honest in responses to questions; do not give unrealistic hope; offer support; and demonstrate respect for the person's age, culture, religion, ethnicity and values. *An effective nurse–patient relationship begins with acceptance of the individual's feelings, attitude and values related to the loss. If the person is ready to talk, listening and being present are the most appropriate interventions.*
- Discuss with the person and their family the stages of grief. *This helps them to be aware of their emotions in each stage and reassures them that their reactions are normal.*
- Provide time for decision making. *In periods of stress, people may need extra time to make informed decisions.*
- Provide information about appropriate resources, including support from family, friends and support groups, community resources and legal/financial aids. *Support from others decreases feelings of loneliness and isolation and facilitates grief work.*

Chronic sorrow

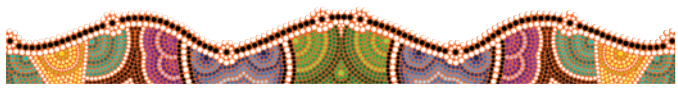
Chronic sorrow is a cyclical, recurring and potentially progressive pattern of pervasive sadness experienced in response to continual loss, throughout the trajectory of an illness or disability. It is triggered by situations that bring to mind the person's losses, disappointments or fears. It may be experienced by a person, parent or caregiver, or a person with a chronic illness or a disability.

- Explain the difference between chronic sorrow and chronic grieving. *Grieving is time limited and ends in adaptation to the loss. Chronic sorrow may vary in intensity, but it persists as long as the person with the disability or chronic sorrow condition lives.*
- Encourage verbalisation of feelings about the loss and about the personal relevance of changes to hopes for the future. *Expressing feelings is normal and necessary to decrease the emotional pain.*
- Help identify triggers that intensify the sorrow, such as birthdays, anniversaries and holidays. *When triggers have been identified, role-playing may make the events less painful.*
- Refer to appropriate community support groups. *Participating in support groups with others experiencing grief is helpful in coping with loss.*
- *Encourage use of personal, family, significant other and spiritual support systems to facilitate coping with loss.*

Death anxiety

Death anxiety is worry or fear related to death or dying. It may be present in individuals who have an acute life-threatening illness, who have an eventually fatal condition, who have experienced the death of a family member or friend, or who have experienced multiple deaths in the same family.

- Explore the person's knowledge of the situation. For example, ask, 'What has your doctor told you about your condition?' *This informs you of the person's knowledge base about the condition and about their ability to make informed decisions.*
- Ask them to identify their specific fears about death. *This provides data about any unrealistic expectations or misperceptions.*
- Ask the person to identify needed help. *This determines whether available resources are adequate.*
- Encourage independence and control in decisions about treatment and care. *This promotes self-esteem, decreases feelings of powerlessness and allows the person to retain dignity in dying.*
- Facilitate access to culturally appropriate spiritual rituals and practices. *This provides spiritual comfort.*
- Explain advance directives and assist with them if necessary. *Advance directives help ensure that the individual's wishes for end-of-life care are carried out.*
- Encourage life review and reminiscence. *Life review is self-affirming.*
- Encourage activities that may bring comfort such as listening to music, aromatherapy, massage or relaxation exercises. *These activities decrease anxiety.*
- Suggest keeping a journal or leaving a written legacy. *A written document provides continuing support to others after death.*



NURSING CARE PLAN A person experiencing loss and grief

Mrs Sandra Bell is an 87-year-old widow recently admitted to a residential aged care facility following her husband Allan's death 12 months ago. Mr Bell had suffered from dementia, and his wife was his carer until 2 years prior to his death when he had been admitted to a dementia unit of the local rural hospital. Mrs Bell visited her husband regularly even when he could no longer recognise her. She has lived all her life in a country town and had established a strong network of friends through membership of the golf club and local services club. However, her social contacts with friends have diminished because of their poor health. Mrs Bell has a daughter and son who both live in the city. Although they keep in regular contact by telephone, they are only able to visit on special family occasions.

Knowing the strain of maintaining a home and losing contact with close friends, Mrs Bell's family felt it would be best for her to move to the city to be closer to her children and grandchildren. Mrs Bell sold her home and entered a residential aged care facility in the city, to be closer to her family.

After several visits, Mrs Bell's daughter notices that her mother has become less social, not wanting to mix with the other residents or participate in community activities, and is more and more upset about her situation. Mrs Bell complains that the other residents are unfriendly and that she misses her home and friends. She does not like the community dining room and says that her back and hips are painful. Mrs Bell also tells her daughter she is not sleeping and is constipated. Her daughter speaks to the nurse and is told that her mother is very quiet, does not mix well with the other residents, seems resentful when approached by the staff and does not volunteer that she is unwell. The nurse reports to Mrs Bell that during her admission to the aged care facility her medical tests showed arthritis but no other pathological disorder.

ASSESSMENT

On assessment, Mrs Bell says, 'I'm a sick woman and no one will listen to me! I can't walk, I'm so weak, my head hurts and I'm always sick in my stomach. I haven't had a bowel movement in a week and I never sleep more than three hours a night.' Physical assessment findings include swollen knees and ankles, with limited mobility of the lower extremities.

DIAGNOSES

- *Grieving* related to death of husband, lost contact with friends, and recent move from a country town to a residential aged care facility in the city.
- *Disturbed sleep pattern* related to grieving.
- *Constipation* related to inactivity.

PLANNING

- A multidisciplinary team planning meeting was organised by the Nursing Unit Manager (NUM) to review and identify Mrs Bell's issues. The following diagnoses were identified, along with expected outcomes, implementation and evaluation.

Expected outcomes

- Engage in normal grief work: work through grief process, discuss reality of losses, use non-destructive coping mechanisms, and discuss positive and negative aspects of the loss.
- Experience adequate and restful sleep.
- Have a bowel movement with soft formed stools at least every other day.

IMPLEMENTATION

- Promote trust: show empathy and caring, demonstrate respect for her culture and values, offer support and reassurance, be honest and engage in active listening.
- Assist in identifying her feelings: anger, fear, loneliness, guilt, isolation.
- Explore previous losses and the ways in which she has coped.
- Encourage review of her relationship with her deceased husband.
- Reinforce expressions of behaviours associated with normal grieving.
- Encourage participation in usual spiritual practices.
- Encourage participation in a grief group that meets at the facility.
- Consult with the physical and recreational therapist to help the nursing staff provide afternoon activities tailored to Mrs Bell's interests.
- Provide measures that assist in bowel evacuation: Encourage exercise as tolerated, including walks. Offer

(continued)

NURSING CARE PLAN A person experiencing loss and grief (continued)

fluids foods that stimulate bowel movement (e.g. fresh fruit). Offer privacy: close the door, ensuring that the buzzer is within reach and do not interrupt.
- Provide measures to assist sleep (e.g. offer warm milk drink with honey, chamomile tea, quiet environment). Offer gentle back massage, use of aromatherapy oils such as lavender.
- Administer a mild laxative and/or stool softener, if necessary, but discontinue as soon as possible.

EVALUATION

After 4 weeks at the residential aged care facility, Mrs Bell states, 'I don't feel any better, but I know I have to accept my situation.' Although Mrs Bell says she doesn't feel better, she is walking the length of the hall, sleeping better and having regular bowel movements. She is also less withdrawn and has openly discussed her feelings related to her husband's death and the loss of her social contacts. She has attended the grief group once and has attended pastoral care services on Sunday for the past 2 weeks. Her children visit her each Saturday and take her in a wheelchair to the shopping centre.

CRITICAL THINKING QUESTIONS

1. What common physical manifestations of grief did Mrs Bell experience?
2. Outline what you have learned from Mrs Bell's case study/story.
3. What communication strategies and education would you use if Mrs Bell told you she does not want any help and that she just wants to be left alone to die?

REFLECTION ON THE NURSING PRACTICE

1. How would you respond to Mrs Bell if she says to you, 'Please help me die'?
2. How might you broach the topic of advance directives with a person? Do you feel comfortable about talking to people about advanced care planning?

CHAPTER HIGHLIGHTS

- Grief is the emotional response to a loss, experienced by a person as grieving. Bereavement, a form of depression accompanied by anxiety, is a common response to loss of a loved one by death. Death, although inevitable, is an immensely difficult loss.
- There are many different theories of how individuals respond to loss, and grief. These theories are useful when providing nursing care to individuals and their families.
- A person's response to loss is influenced by age, social support, family members, cultural and spiritual beliefs, and rituals of mourning. Nurses need to assess the way in which they respond to loss, to better care for people.
- Legal and ethical issues involved in end-of-life care include advance directives, advanced care planning, enduring power of attorney, do-not-resuscitate directives and euthanasia.
- Palliative care is a philosophy of care that supports a dignified and peaceful death when individuals and their families are faced with limited life expectancy. Palliative care is focused on the relief of physical, mental and spiritual distress for people with an eventually fatal condition.
- To provide knowledgeable and compassionate care at the end of life, nurses must recognise symptoms that may be present as the individual nears death, support the person and their family, provide care to the individual and family immediately after death, and resolve their own grief.
- Nursing care of individuals experiencing an actual or potential loss includes accurate individualised physical, spiritual and psychosocial assessment, and awareness of responses of anticipatory grieving, chronic sorrow and/or death anxiety.

CONCEPT CHECK

1 Which of the following statements best describes loss?
   1 It is determined by one's cultural values.
   2 It is largely dependent on support of family and friends.
   3 It can be determined only by the person who experiences it.
   4 It is the same as grief and mourning.

2 Kübler-Ross believed that one usually first responds to a situation of loss with:
   1 anger
   2 bargaining
   3 depression
   4 denial

3 What is an important factor in the successful resolution of grief?
   1 social isolation
   2 support systems
   3 triggers of grief
   4 loss acknowledgement

4 What is the primary factor that dictates the rituals of mourning?
   1 culture
   2 age
   3 gender
   4 religion

5 What document expresses a person's wishes in relation to the planning of treatment in the event of their inability to communicate their wishes because of an eventually fatal condition?
   1 enduring power of attorney
   2 advanced care planning
   3 do-not-resuscitate directive
   4 living will

6 Which of the following statements is true of a hospice?
   1 A hospice is a special place of care.
   2 A hospice care is a lifelong type of care.
   3 A hospice is a model of care rather than a place of care.
   4 A hospice is designed for individuals with serious chronic illness.

7 A person nearing death requests that no medication be given that would cause a loss of consciousness, including pain medication. What would a nurse do to provide the best end-of-life care in this situation?
   1 Give the medication; comfort is the highest priority.
   2 Give half the ordered dose to provide compassionate care.
   3 Discuss this with family members and follow their wishes.
   4 Respect the person's wishes and withhold pain medications.

8 Which of the senses is believed to be the last one lost as a person nears death?
1 hearing
2 vision
3 touch
4 smell

9 Which of the following statements best describes the treatment of pain at the end of life?
1 As an individual nears death, no pain is perceived and no medications are necessary.
2 It is important to withhold pain medications if the individual has respiratory changes.
3 There is no maximum allowable dose for opioids during end-of-life care.
4 Nurses should not administer opioids to the dying person.

10 A woman, recently widowed, tells the nurse, 'I just can't even get out of bed in the mornings anymore.' What response would be most helpful in resolving her grief?
1 'I don't know why you feel that way.'
2 'This must be a difficult time for you.'
3 'Why do you think you feel this way?'
4 'After you get up, you will feel better.'

CHAPTER 5

NURSING CARE OF PEOPLE WITH PROBLEMS OF SUBSTANCE MISUSE

ANNA TRELOAR, TERESA STONE

KEY TERMS

LEARNING OUTCOMES

- Distinguish between substance use disorders and substance-induced disorders.
- Explain risk factors associated with substance misuse.
- Classify major addictive substances and explain effects of addictive substances on physiological, cognitive, psychological and social wellbeing.
- Support interprofessional care in the provision of individualised care for people living with substance use problems, including diagnostic tests, emergency care for overdose and treatment of withdrawal.
- Develop awareness of current policy, both local and global, and future directions in relation to alcohol and drug use treatment and primary prevention measures.
- Recognise signs and symptoms of potential substance use disorders in co-workers and understand professional responsibilities in relation to this.

CLINICAL COMPETENCIES

- Assess health status of people living with substance use disorders.
- Monitor, document and report physical manifestations of substance abuse.
- Assess for signs of withdrawal and monitor for complications.
- Use evidence-based research to plan and implement nursing care for people experiencing withdrawal symptoms.
- Implement individualised nursing interventions for people living with substance use disorders.
- Provide skilled nursing care in a range of clinical settings during the period of substance withdrawal.
- Collaborate with other disciplines when caring for people with substance use disorders.
- Educate people about stress management, coping skills, nutrition, relapse prevention and healthy lifestyle choices.

Substance use, misuse and dependence are widespread in Australia today. There is a common belief that legal drugs do less damage than illegal drugs, but as you read this chapter you will see that this is not the case. People who misuse substances may believe that they cannot change their pattern of consumption; many people do not recognise that their use has become problematic or, if they do, do not know how to find help. Their families also may require assistance and education.

Consider this family:

Sue (39) is in the kitchen preparing the evening meal. She finds her job very stressful on top of family responsibilities. She takes a couple of pills from the packet on the shelf. She used to take alprazolam, but that's hard to get now. She makes do with what she can get from all the doctors she visits regularly, and with what friends give her.

Her husband Joe (43) is still in the pub. He works hard on the building site and doesn't see why he shouldn't relax at the end of the day. It's his shout. He is not sure how many schooners he has had tonight—same as other days most likely. But how many is that? He's often very late for dinner at home now, and there is not much cash in his wallet.

Joe's elder son, Dale (19), is just home from TAFE and wishing he had never ever been introduced to ice (crystal methamphetamine). He is behind in his course, he is running out of money, and lately he has had the strange feeling that people are looking at him and talking and laughing about him.

Upstairs in his room Joe's younger son, Milton (15), is rolling a joint (marijuana cigarette). He wants to be a pilot, or a soccer star, or play guitar in a band. He is in love with Rosie next door. But she doesn't know and wouldn't care anyway. There's nobody to talk to. Angrily, he lights up.

Nobody in this family realises that their substance use has become problematic, but all are misusing a drug—whether the drug is legal, illegal or a legal substance being illegally used.

SUBSTANCE-RELATED DISORDERS

Substance use and psychiatric diagnoses are categorised in the *Diagnostic and Statistical Manual of Mental Disorders* (5th ed.) (DSM-5-TM) published by the American Psychiatric Association (APA) (2013). The APA currently divides **substance-related disorders** into two groups: substance use disorders (e.g. alcohol use disorder, opioid use disorder) and substance-induced disorders (e.g. substance-induced delirium, substance-induced psychotic disorder). Physiological dependence, including tolerance and withdrawal, is a normal response to repeated doses of many prescribed medications including opioids, sedatives and stimulants; people should not be diagnosed with a substance use disorder solely on the basis of this (APA, 2013). Substance use disorders are seen as a pathological pattern of behaviours related to substance use (APA, 2013). Diagnostic criteria are described in more detail in Table 5.1.

A mild disorder is suggested by two or three of the points in Table 5.1, a moderate disorder by four or five, and a severe disorder by six or more.

APA's DSM-5-TM criteria (discussed in more depth in Chapter 50) deal with behavioural aspects and maladaptive patterns of substance use, emphasising the physical symptoms of **tolerance** and **withdrawal**. Tolerance occurs when the initial dose of a substance loses its effectiveness over time. As tolerance increases, higher and higher doses are needed to obtain the desired effect.

TABLE 5.1 Substance use disorders

1. Substance is taken in larger amounts or for longer periods than is intended.
2. Unsuccessful or persistent desire to cut down or control substance use.
3. More time occupied in getting, taking and recovering from the substance.
4. Intense craving.
5. Failure to fulfil important obligations.
6. Continued use of substance despite persistent problems.
7. Important activities given up or reduced because of use.
8. Continued use in hazardous situations.
9. Continued use despite knowledge of physical or psychological problems caused by use.
10. Presence of tolerance to the drug.
11. Presence of withdrawal symptoms.

Source: Adapted from American Psychiatric Association (2013). *Diagnostic and statistical manual of mental disorders* (5th ed.) (DSM-5-TM). Washington, DC: Author.

Ceasing to take a drug on which a person is physically dependent can produce **withdrawal symptoms** within hours—an uncomfortable state lasting several days, manifested by a range of signs and symptoms depending on which drug is involved.

In any 12-month period, 5.1% of Australians aged 16–85 years suffer a substance use disorder, men at twice the rate of women (7.0% compared with 3.3%). Higher rates prevail in lower age groups. Alcohol use disorders are more prevalent than all other substances (Australian Bureau of Statistics, 2008).

Substance use problems frequently coexist with other physical and mental health conditions such as anxiety and depressive disorders. More than 90% of people who commit suicide have a depressive or substance abuse disorder (National Institute of Mental Health, 2004). The human tendency to seek pleasure and avoid stress and pain is partially responsible for substance abuse. Currently available data suggest that ethanol increases opioid neurotransmission, this activation being part of the mechanism responsible for its reinforcing effect (Oswald & Wand, 2004). Most studies have focused on the role of dopamine D1 and D2 receptors in sustaining the addictive nature of drugs, but recently the dopamine D3 receptor has also appeared to be involved in drug-seeking behaviour (Heidbreder et al., 2004). Alcohol also binds directly to the receptors for acetylcholine, serotonin and gamma-aminobutyric acid (GABA) and the NMDA (*N*-methyl-D-aspartate) receptors for glutamate (Dubuc, 2002). The following link will show you in detail how drugs and alcohol interact: http://thebrain.mcgill.ca/flash/i/i_03/i_03_m/i_03_m_par/i_03_m_par_alcool.html#drogues.

The reinforcing properties of alcohol and other drugs can create a pleasurable experience, and reduce the intensity of an unpleasant one.

Dependence on psychoactive substances is a chronic relapsing brain disease. Repeated use of psychoactive substances tends to hijack the reward centre of the brain, which has strong neuronal pathways to the prefrontal regions that regulate behaviour, decision making and inhibition control. Neuroadaptation associated with **substance dependence** triggers strong urges and cravings to use drugs, thus contributing to the relapsing nature of the condition: stress, withdrawal symptoms and

drug cues can all be triggers to relapse. These neurophysiological aspects of substance dependence currently form an area of intense research interest (Baler & Volkow, 2006).

Substance craving may be heightened by the **kindling** effect—long-term changes in brain neurotransmission occurring after repeated detoxifications which increase neuron sensitivity, and are believed to intensify obsessive thoughts or cravings. Eventually the brain responds spontaneously in a dysfunctional manner even when the substance is no longer used (Breese, Overstreet & Knapp, 2005). This phenomenon may explain the tendency for subsequent episodes of withdrawal to worsen progressively.

Co-occurring disorders refers to substance abuse or dependence and a psychiatric disorder coexisting in one individual, a condition also described as co-morbidity, **dual diagnosis** or dual disorder. Increasing numbers of people experience co-morbid mental health and drug and alcohol problems and disorders, which adds complexity to assessment, diagnosis, treatment and recovery, and is known to increase the risk of relapse (Government Department of Human Services, Victoria, 2007), and of HIV infection, medical complications and premature death (NSW Health, 2008b). A recent large-scale study of Australians living with psychosis found that alcohol and illicit drug use was very common (51% were diagnosed with alcohol dependence, 51% with cannabis misuse or dependence, and 32% with other illicit misuse or dependence), and that there has been a substantial increase in substance use among Australians living with psychosis since the last large-scale study in 1997–1998 (Moore et al., 2012). One disorder can be an indication of another: alcohol dependence and major depression commonly occur together. Gilman and Abraham (2001) suggested that each of these illnesses poses a significant risk of development of the other within 12 months; a depressed person may use alcohol in self-medication, and an alcohol-dependent person may become depressed. Virgo et al. (2001) found that those dually diagnosed were more likely to be younger, male, in less stable accommodation, unemployed, and to have more than one psychiatric diagnosis and personality disorder. They tended also to have more crises and to pose greater risk to themselves and others. (Table 5.2 lists terminology associated with substance abuse.)

TABLE 5.2 Terminology associated with substance abuse

TERM	DEFINITION
Abstinence	Voluntarily refraining from drugs or alcohol
Addiction	A disease process characterised by the continued use of a specific chemical substance despite physical, psychological or social harm (formerly used interchangeably with substance dependence; dependence is the preferred term)
Co-dependence	Maladaptive behaviour by a partner of a person misusing substances tending to perpetuate the alcohol or drug dependence
Co-occurring disorders	Concurrent diagnosis of a substance use disorder and a psychiatric disorder. One can precede and cause the other, as in the relationship between alcoholism and depression
Cross-tolerance	Tolerance of one drug confers tolerance of another
Delirium tremens	A medical emergency usually occurring 3 to 5 days after the start of alcohol withdrawal and lasting 2 to 3 days; characterised by paranoia, disorientation, delusions, visual hallucinations, elevated vital signs, vomiting, diarrhoea and diaphoresis
Detoxification	The process of helping an addicted individual safely through withdrawal
Dual diagnosis	The coexistence of substance abuse/dependence and a psychiatric disorder in one individual (used interchangeably with dual disorder and co-occurring disorders)
Harm reduction	A strategy recommended by NSW Health (2008b) which emphasises the use of realistic and practical approaches to harm reduction, focusing on reducing the negative effects of drug and alcohol use
Kindling	Brain sensitisation to events such as stress, trauma or the effects of substance use
Korsakoff's psychosis	Secondary dementia caused by thiamine (B_1) deficiency which may be associated with chronic alcoholism; characterised by progressive cognitive deterioration, confabulation, peripheral neuropathy and myopathy
Physical dependence	A state in which withdrawal syndrome will occur if drug use is discontinued
Polysubstance abuse	Simultaneous use of many substances
Problematic drug and alcohol use	Patterns of drug and alcohol use warranting intervention (NSW Health, 2008b)
Psychological dependence	An intensive subjective need for a particular psychoactive drug
Risk factor	Any attribute, characteristic or exposure that increases the likelihood of developing a disease or condition; may include behavioural, environmental, biomedical or genetic factors.
Tolerance	State in which a particular dose elicits a smaller response than formerly. With increased tolerance, higher and higher doses are needed to obtain the desired response
Wernicke's encephalopathy	Caused by thiamine (B_1) deficiency, characterised by nystagmus, ptosis, ataxia, confusion, coma and possible death; thiamine deficiency is common in chronic alcoholism
Withdrawal syndrome	Constellation of signs and symptoms occurring in physically dependent individuals when they discontinue drug use

RISK FACTORS

Various **risk factors** help explain why one person becomes addicted while another does not. Genetic, biological, psychological and sociocultural factors can influence dependence on or abuse of a substance.

- *Genetic factors* include an apparent hereditary factor, especially with alcohol use and dependence. Up to 50% of vulnerability to addiction can be attributed to genetic factors (Dick & Agrawa, 2008). Women generally drink less alcohol than men do, and are less likely to have characteristics associated with heavy drinking such as aggressiveness, drinking to reduce distress and antisocial tendencies (Nolen-Hoeksema, 2004); however, women are more vulnerable than males to the acute and long-term effects of alcohol abuse.
- *Biological factors* were first identified by Jellinek (1946) in his disease model of alcoholism; he hypothesised that addiction to alcohol might have a biochemical basis and noted specific phases of the disease. Expanding on Jellinek's early work, researchers have implicated low levels of dopamine and serotonin in the development of alcohol dependence (Czermak et al., 2004; Nellissery et al., 2003). Dopamine and dopamine receptor sites are intricately involved in the complex workings between the nervous system and substances of abuse; an impact of any drug on the biochemical mechanism of the brain must occur at a receptor site or at a number of them (see Figure 5.1).

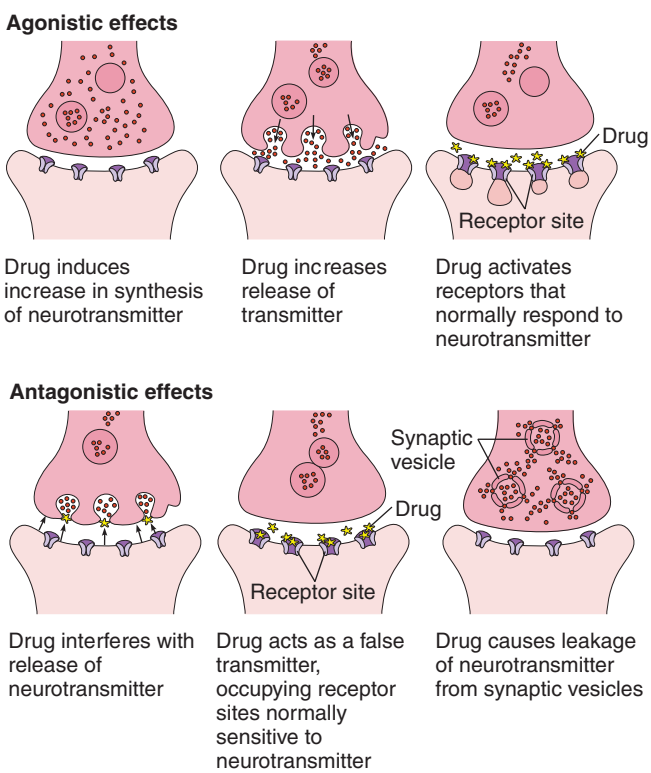

FIGURE 5.1 ■ Action of abusive substances at brain receptor sites

Most substances of abuse either mimic or block the brain's most important neurotransmitters at their respective receptor sites; for example, heroin and other opioids mimic natural opiate-like neurotransmitters such as endorphins, encephalins and dynorphins. In contrast, cocaine and other stimulants block the re-uptake of dopamine, serotonin and norepinephrine (noradrenaline) (Stuart & Laraia, 2005).

- *Psychological factors* attempt to explain substance abuse through a combination of psychoanalytical, behavioural and family system theories. Psychoanalytical theorists may view substance abuse as a fixation at the oral stage of development, whereas behavioural theorists see addiction as a learned, maladaptive behaviour. Family system theory focuses on the pattern of family relationships through several generations. Although no addictive personality type has been identified, substance-dependent people seem to exhibit several common factors: many substance abusers have experienced sexual or physical abuse in childhood and, as a result, have low self-esteem and difficulty in expressing emotions; higher levels of distress have been associated in young adults with hazardous or harmful alcohol or illicit drug consumption (Australian Institute of Health and Welfare (AIHW), 2014; Caldwell et al., 2002). A link also exists between substance abuse and psychological disorders such as depression, anxiety, and antisocial and dependent personalities; substance users who are depressed or anxious are less likely to embrace treatment for drug or alcohol dependence. The habit of using a substance becomes a form of self-medication to cope with day-to-day problems, and over time develops into dependence.
- *Sociocultural factors* may influence individuals' decisions as to when and how they use which substances. Environmental factors, including socioeconomic disadvantage and peer group pressure as well as cultural norms about drug and alcohol, influence patterns of use (de Crespigny et al., 2003). Little firm evidence concerning culturally and linguistically diverse people living in Australia indicates any variables associated with problematic drug and alcohol use (NSW Health, 2008b). Compared with other ethnic groups, Asians report the lowest prevalence of family history of alcoholism (Ebberhart et al., 2003). While Indigenous Australians have been shown to be less likely than the non-Indigenous to consume alcohol, those who do are more likely to drink at risky and high-risk levels, and are therefore more likely to experience the adverse physical and social effects of heavy alcohol consumption (Ministerial Council on Drug Strategy, 2006).

Many factors contribute to substance use and to the risk of substance abuse and dependence; no single element can cause one individual to develop a pattern of drug use while another does not. Some people experiment, some use recreationally, and a few become dependent. Risk factors can only help identify those who are most vulnerable. Thorough assessment is necessary in order to understand the whole person and plan appropriate interventions.

Substance users come from all ages and social, economic and cultural groups, with no particular personality styles or traits. Young people by nature are often risk takers, their

FOCUS ON CULTURAL DIVERSITY Substance use and special groups

Ethnic identity plays a unique role in substance use; adolescents in particular are influenced by cultural norms and practices, in addition to other environmental and biological factors. Positive ethnic identity (i.e. strong affiliation, attachment and pride) may 'protect' adolescents and help them form resistant behaviours (Marsiglia et al., 2004). However, introduction to and immersion in Australian culture may contribute to the initiation and maintenance of drug and alcohol abuse (NSW Health, 2008b).

High levels of problematic drug and alcohol use among Indigenous Australians are both the cause and effect of much suffering (Ministerial Council on Drug Strategy, 2006, p. 2), and are linked to the effects of dispossession and dislocation from traditional lands. Indigenous Australians are at increased risk of violence, depression, anxiety, attempted suicide, poor nutrition and medical complications (NSW Health, 2008b). In order to develop a culturally appropriate treatment plan, nurses need to consider the community and to consult with the person living with substance use disorder, the family, senior community members and specialist Indigenous health workers. Factors identified as contributing to the success of drug and alcohol health interventions include Indigenous community control, clearly defined management structures and procedures, trained staff and effective staff development programs, multi-strategy and collaborative approaches, adequate funding, and clearly defined, realistic objectives for provision of appropriate services to meet community needs (Gray, Saggers & Sputore, 2000).

In New Zealand, Kypri (2003) observed different patterns of drinking among Maori and non-Maori people: while similar total volumes of alcohol were consumed, non-Maori drank more frequently but, on average, 40% less alcohol per drinking occasion. The alcohol-related mortality of Maori is four times that of non-Maori, and years of life lost due to alcohol more than double (Ministry of Agriculture and Forestry, 2005).

Critical thinking in person-centred care

1 You are a school nurse in a community with a large population of Indigenous people. Alcohol consumption and binge drinking among the high school students are an increasing problem, and the head teacher has asked you for ideas to deal with it. How would you respond?
2 You are caring in the emergency department for a 23-year-old Asian female, brought in by her boyfriend. He tells you they had been at a party where she consumed alcohol for the first time. She is weak, her face is flushed and she is vomiting violently. What would you do?

experimental or social drug use arising in response to a desire to test social boundaries and cultural norms as part of their path to independence and adulthood. The majority mature out of this stage of their lives and become responsible and productive adults, but the age of initiation into alcohol or other drug use has emerged as a risk factor for developing a substance use disorder (King et al., 2013).

A variety of factors can lead to continued problematic use of alcohol and/or other drugs, resulting in substance abuse and substance dependence; these include a history of abuse or trauma, and mental health problems such as antisocial personality disorder, depression, anxiety disorders, low self-esteem and social anxiety. Alarmingly, prescription medication misuse is on the rise (AIHW, 2015).

ADDICTIVE SUBSTANCES AND THEIR EFFECTS

Caffeine

Caffeine is a central nervous system stimulant, which increases the heart rate and acts as a diuretic. Although commonly consumed daily in soft drinks, energy drinks, coffee, tea, chocolate, guarana, and some prescription and over-the-counter medicines, an excessive amount can cause negative physiological effects, especially cardiac-related risks. Approximately 300 mg per day is safe for most people, but more than 600 mg is considered excessive and is not recommended; it may cause insomnia, anxiety, depression and stomach upsets (Kneisl & Trigoboff, 2013; NSW Health, 2007). An average cup of instant coffee may contain 60–100 mg of caffeine; an espresso coffee, 90–200 mg; tea, 30–100 mg; cola drinks, 30–50 mg per 250 mL serve; and chocolate, 20–60 mg per 200 g bar (NSW Health, 2007).

People with a history of cardiac disease are advised to reduce caffeine intake or eliminate it altogether: large quantities can cause higher total cholesterol levels. Abrupt withdrawal is likely to cause headaches, irritability and generalised feelings of tiredness in a caffeine-addicted person.

Nicotine

Nicotine is found in tobacco (cigarettes and cigars) and enters the system via the lungs and oral mucous membranes; in low doses it stimulates nicotinic receptors in the brain to release noradrenaline and adrenaline, causing vasoconstriction. As a result, the heart rate accelerates and the force of ventricular contractions increases. Gastrointestinal (GI) effects include an increase in gastric acid secretion, tone and motility of GI smooth muscle, and promotion of vomiting. Nicotine acts on the central nervous system (CNS) as a stimulant, binding to acetylcholine receptors in the brain and causing the release of dopamine and noradrenaline. Initially, nicotine increases respiration, mental alertness and cognitive ability, but eventually it depresses these responses (Kneisl & Trigoboff, 2013).

The difficulty of quitting smoking is thought to be caused by dopamine release, which in turn reinforces the addictive craving for more. Nicotine in cigarettes has a half-life of 1 to 4 hours, so withdrawal symptoms become evident within a few hours after the last cigarette; withdrawal peaks during days 2 and 3, and tends to resolve at about 2 to 4 weeks. According

to DSM-5-TM (APA, 2013), nicotine withdrawal can be diagnosed if four or more of the following symptoms are present within the first 24 hours of nicotine reduction or cessation:

- depressed mood
- insomnia
- irritability, frustration or anger
- anxiety
- difficulty concentrating
- restlessness
- increased appetite.

Cessation can pose a problem for hospitalised smokers now that health facilities are smoke-free (see Table 5.3).

Tobacco smoking is the single most preventable cause of ill health and death, being a major risk factor for coronary heart disease, stroke, peripheral vascular disease, cancer and a variety of other diseases and conditions. However, smoking rates in Australia are falling (AIHW, 2014). Almost one-third of persistent smokers have reduced their daily consumption, and one-quarter tried unsuccessfully to give up the habit. Rates were higher in remote areas and for those of the lowest socioeconomic status. People who have never smoked (10.6 million) and ex-smokers (4.4 million) far exceed the number of smokers (3.3 million) aged 14 years and older. The age group 12–17 years was the only one in which girls were more likely than boys to smoke daily (3.2% versus 1.8%) (AIHW, 2011).

For women, unique health concerns arise: second-hand effects from smoking have been demonstrated, especially on the foetus during pregnancy, leading to increased risks such as low birth weight, spontaneous abortion, perinatal mortality and sudden infant death.

Cannabis

Cannabis is the general name given to the psychoactive substances found in the marijuana plant, *cannabis sativa*, the main active constituent being delta-9-tetra-hydrocannabinol (THC). The psychoactive properties are mostly of a CNS depressant nature; in high doses hallucinogenic properties can occur, affecting some of the senses—for example, distortion of lights, sounds and music—but full hallucinations are rare (NSW Health, 2008a).

TABLE 5.3 Guide for the management of nicotine-dependent inpatients

1. IDENTIFY EVERY TOBACCO USER ON ADMISSION

Use Substance Use History form, or include smoking status on existing admission forms
Ex-smokers—encourage continuing abstinence
Daily/occasional smokers—follow steps 2 to 5

2. MANAGE INPATIENT NICOTINE DEPENDENCE

Inform people of the policy for smoking in your facility and specify contra-indications to their treatment regimen if they leave the ward/facility to smoke
Discuss options for management of nicotine dependence while in hospital, such as:

- abstinence
- abstinence supported by nicotine replacement therapy (NRT), unless contra-indicated
- smoking offsite in outdoor designated areas, if available

If a person has a history of mental health problems, consult treating clinician—adjustment of medications may be necessary.

3. PRESCRIBE NICOTINE THERAPY

Arrange prescriptions for NRT (with the person's consent)
Record:

- type (patch/inhaler/gum) and dose on medication chart
- 'Nicotine dependent' in person's notes

4. MONITOR PERSON'S WITHDRAWAL SYMPTOMS

If a person is still experiencing withdrawal symptoms:

- review NRT dose/product (person may benefit from combination therapy)

5. DISCHARGE

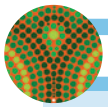
Ask all smokers: 'Do you plan to smoke when you go home?'
'Yes.'

- Encourage future quit attempt: 'The best thing you can do for your health is to stop smoking. When you're ready, phone the Quitline or talk to your doctor.'

'No.'

- Arrange 3-day post-discharge NRT
- Include treatment summary in discharge plan
- Advise person to seek cessation support from GP/pharmacist/Quitline 137 848
- Provide brochures on smoking cessation.

Source: Adapted from NSW Health (2015). *Managing nicotine dependence: A guide for NSW Health staff.* Reproduced with the permission of NSW Health.



TRANSLATION TO PRACTICE Evidence-based practice for smoking cessation in hospital

Despite its well-publicised deleterious health effects, and legally restricted access to cigarettes, tobacco was still responsible for the greatest disease burden in Australia in 2003 (7.8% of the total burden) (AIHW, 2007). Smoking has been banned from shops, malls, hospitals, office buildings and restaurants. Admission to hospital provides an excellent opportunity for nurses to assist people to stop smoking. It may be easier to quit in an environment where smoking is restricted or prohibited, and those facing the risks associated with surgery may be more open to cessation efforts.

In a review of the literature Rigotti et al. (2005) found that high-intensity behavioural interventions which included at least 1 month of follow-up contact were effective in helping people in hospital care to quit smoking; healthcare professionals, especially nurses, can be very effective in smoking cessation efforts, and evidence-based brief intervention guidelines are available (NSW Health, 2005).

Silagy et al. (2005) found that nicotine replacement therapy (NRT), available as chewing gum, skin patches, inhalers and lozenges, increases the likelihood of success in quitting smoking, with or without additional counselling; its purpose is to reduce symptoms of withdrawal from tobacco products by replacing nicotine in the blood. Rice and Stead (2005) were of the same opinion and stressed the potential benefits of nursing interventions. Effective strategies, which nurses should incorporate as part of their standard practice, include asking people about their tobacco use, counselling those who want to quit, encouraging and reinforcing cessation efforts, and early follow-up with those who succeed.

CRITICAL THINKING IN PERSON-CENTRED CARE

1. You are caring for a 55-year-old man, recently hospitalised for acute angina, who wants information about the best way to stop smoking. What would you do?
2. Why do you think nurses and other healthcare professionals should (or should not) quit smoking?
3. A 12-year-old girl in your care tells you she has occasionally smoked cigarettes and believes it increases her popularity among older friends. She admits knowing smoking is supposed to be bad for you but doesn't see the harm in a few cigarettes every day. How would you respond?

THC activates specific cannabinoid receptors in the brain. Evidence indicates effects similar to those of opioids and cocaine, producing a pleasurable sensation, probably through release of endogenous opioids and then dopamine (Kneisl & Trigoboff, 2013). Adverse effects include paranoia, increased appetite, anxiety, depression and sedation. Cannabis can cause drug-induced psychosis (but usually only in people with a genetic predisposition or susceptibility); this can be difficult to distinguish from other psychotic illnesses, such as schizophrenia. Marijuana use can also trigger relapse in people living with schizophrenia. Drug-induced psychoses tend to resolve relatively quickly (within a week) with cessation of drug use (NSW Health, 2008a).

Marijuana/cannabis is the illicit drug most used across all Australian age groups with about 1.9 million people having used the drug in the previous 12 months, an increase from 1.6 million in 2007 (AIHW, 2011). A World Health Organization (WHO) study found cannabis use in the United States and New Zealand (both 42%) to be far higher than in any other country surveyed (Degenhardt et al., 2008).

Cannabis withdrawal is marked by three or more of the following:

- sleep disturbance (insomnia and vivid dreams)
- reduced appetite or weight loss
- irritability, anger or aggression
- anxiety or nervousness
- restlessness
- depressed mood
- at least one of abdominal pain, shakiness, sweating, fever, chills or headaches (APA, 2013).

The major part of the management approach for cannabis withdrawal should be supportive counselling, provision of accurate information about signs and symptoms, and relapse prevention planning. Medications may be appropriate for some people; most commonly prescribed are benzodiazepines, to be used with discretion and in the short term.

Alcohol

Worldwide, an astonishing 3.3 million people died in 2012 (5.9% of all deaths) from the harmful use of alcohol (WHO, 2014). **Alcohol** is a CNS depressant and acts on the main inhibitory neurotransmitter, GABA. It is the most commonly used drug in Australia and New Zealand because of its broad social acceptance and entrenchment in cultural norms; however, it can cause a wide range of harm (Shield, Parry & Rehm, 2013).

In 2010, most people aged 14 years or more (80.5%) had consumed a full serve of alcohol (AIHW, 2011) and in 2011–2012 nearly one in five adults drank more than two standard drinks per day, men being three times as likely as females to drink at risky levels (AIHW, 2014). The main psychoactive ingredient in alcohol is ethyl alcohol, which contributes to changes in mood, thinking and behaviour.

Alcohol is rapidly absorbed from the small bowel (about 80%) and stomach (about 20%). It reaches the brain within 5 minutes of ingestion, with blood plasma concentrations peaking at between 30 and 90 minutes. Alcohol readily crosses the blood–brain barrier and placenta; 95% is metabolised by the liver into carbon dioxide and water, and 1–5% is excreted unchanged in saliva, urine, faeces and sweat (National Centre for Education and Training on Addiction (NCETA), 2004). Generally, one standard alcoholic drink takes approximately 1 hour to metabolise; low doses induce a decrease in inhibitions, a feeling of comfort and relaxation, flushing of the skin, and mild impairment of thinking and judgment. With rising blood alcohol levels, speech becomes slurred and is accompanied by increasing loss of motor control, including development of ataxia. At higher levels

memory is affected, with potential for blackouts; the person becomes stuporous and unable to be aroused, and coma and death can occur (NSW Health, 2008a). Blood alcohol levels (BALs) are highly predictive of CNS effects: euphoria, reduced inhibitions, impaired judgment and increased confidence are seen at 0.05%; toxic levels in excess of 0.5% can cause coma, respiratory depression, peripheral collapse and death (Kneisl & Trigoboff, 2013).

The 2010 National Drug Strategy Household Survey (AIHW, 2011) showed that one in five Australians aged 14 or older, far more males than females, were consuming alcohol at a level that put them at risk of short- or long-term harm from drinking.

Moderate use of certain types of alcohol can have positive physiological effects in reducing coronary artery disease and protecting against stroke, but in excess it can diminish the ability to function and lead ultimately to life-threatening conditions. Alcohol abuse can cause severe neurological and psychiatric disorders, and damage to the liver can progress from fatty liver to other diseases such as hepatitis; chronic alcoholism is the major cause of fatal cirrhosis. Damaging effects on many other systems include myocardial disease, erosive gastritis, acute and chronic pancreatitis, sexual dysfunction and an increased risk of breast cancer.

Malnutrition, another serious complication, can result in neurological impairments; in particular, thiamine (B_1) deficiency is thought to cause the severe cognitive impairment which is a principal feature of **Wernicke's encephalopathy** and **Korsakoff's psychosis** observed in people with chronic alcohol dependence (Stuart & Laraia, 2005). Sometimes considered to be two distinctive disorders, these are actually different phases of the same disease, commonly called Wernicke–Korsakoff syndrome: Wernicke's encephalopathy indicates the 'acute' stage of the illness and Korsakoff's psychosis indicates the 'chronic' stage.

Although alcohol is a CNS depressant, it actually disrupts and alters the sleep cycle, decreasing sleep quality, intensifying obstructive apnoea and reducing total sleeping time. Heavy drinkers have a higher mortality rate and many fatalities result from alcohol-related accidents.

Chronic consumption of alcohol produces tolerance. Cross-tolerance occurs when alcohol and other CNS depressants such as benzodiazepines and opioids are used in combination; taken together they have a mutually enhancing effect, thereby increasing the possibility of respiratory depression and death (Australian Government Department of Health and Ageing, 2009).

WITHDRAWAL Abrupt withdrawal of alcohol causes overexcitation of the brain because previously inhibited receptors are no longer inhibited (Carlson et al., 2012); this manifests clinically as anxiety, tachycardia, hypertension, diaphoresis, nausea, vomiting, tremors, sleeplessness and irritability.

The onset of alcohol withdrawal usually occurs 6–24 hours after the last drink. Heavily dependent people can begin to develop signs and symptoms of withdrawal even before the blood alcohol level reaches zero. Consumption of other CNS depressants—for example, benzodiazepines—may delay the emergence of the syndrome.

Mild withdrawal syndrome episodes generally settle after 24–48 hours, and the majority of uncomplicated cases within 72 hours; occasionally, more severe cases may continue for up to 10 days (NSW Health, 2008a).

Complicated alcohol withdrawal carries a significant risk of further morbidity and is potentially life threatening. Proper assessment and monitoring procedures, in combination with early and adequate institution of the necessary medical treatment, should prevent the development of complicated withdrawal syndrome in a hospital setting.

Withdrawal scales provide an objective method of assessing a person at risk, and the course of the syndrome. The most validated and widely used scale is the Clinical Institute Withdrawal Assessment for Alcohol—revised version (CIWA-AR) (Sullivan et al., 1989).

- Withdrawal scales do not diagnose withdrawal; they monitor the severity of the range of signs and symptoms of those experiencing or at risk of developing alcohol withdrawal.
- Start the monitoring as soon as possible after admission to hospital.
- Re-evaluate regularly.
- Explain why monitoring is necessary and what might be expected.
- Report promptly any changes in the person's condition.
- Don't assume that the condition is just alcohol withdrawal; assess for other potential factors and if concerned seek further advice.
- Supportive care alone is often effective in minor alcohol withdrawal.

Risk factors for severe alcohol withdrawal include:

- previous episodes of alcohol withdrawal
- previous seizures during withdrawal
- history of delirium tremens
- CIWA-AR score above 10
- advanced age
- co-morbidities
- detectable blood alcohol level on admission
- high daily intake of alcohol
- abnormal liver function
- prior benzodiazepine use
- male sex
- previous blackouts
- concomitant use of CNS depressants or illicit substances (Carlson et al., 2012; Maldonado et al., 2014).

TREATMENT

- Early and adequate pharmacological intervention can prevent development of a complicated alcohol withdrawal syndrome carrying significant risk of added morbidity.
- Caution is required in treating elderly or respiratorily compromised people.
- Diazepam, a long-acting benzodiazepine, is widely recognised as the pharmaceutical agent of choice. Contraindications to diazepam include respiratory failure, significant liver impairment, and possible head injury or cerebrovascular accident. In these situations, specialist consultation is essential (NSW Health, 2008c).

Best practice principles of nursing care for treatment are outlined in Box 5.1.

Screening in primary care settings, such as general practices, community health centres and multipurpose health facilities, for identification of people drinking at risky or harmful

BOX 5.1 Principles of nursing care in relation to alcohol

- Routinely take an alcohol use history from all admissions.
- Consider the possibility of alcohol withdrawal if clinical symptoms are occurring in a patient, as some patients may minimise how much alcohol they consume when initially asked.
- Identify those at risk of alcohol withdrawal (for men, daily consumption of 80–100 grams or 8–10 standard drinks, and for women 80 grams or 8 standard drinks).
- Monitor those at risk by means of an alcohol withdrawal scale.
- Start monitoring for alcohol withdrawal as soon as possible; if the person is intoxicated on admission, as soon as the BAL goes below 0.10%.
- Seek medical advice and, if treatment for withdrawal is indicated, commence it early.
- Clearly explain all aspects of care.
- Provide a quiet, softly lit, pleasant environment.
- Give thiamine.
- Monitor hydration.

levels, or who may be dependent, is a useful initiative; early intervention prevents delay until irreparable health damage or psychosocial consequences have occurred (Australian Government Department of Health and Ageing, 2009). A range of validated screening instruments/questionnaires available for use includes the AUDIT, the MAST and the CAGE.

Biological markers useful in assessing alcohol consumption include serum GGT (gamma-glutamyl transferase), AST (aspartate aminotransferase), ALT (alanine aminotransferase), HDL-cholesterol, uric acid, mean corpuscular volume and carbohydrate-deficient transferrin (CDT). Serum GGT, a liver enzyme, is the most useful of the current available tests (Australian Government Department of Health and Ageing, 2009).

Benzodiazepines

Benzodiazepines, minor tranquillisers belonging to the sedative–hypnotic group of drugs, have a CNS depressant effect through action at the GABA receptor sites. Widely prescribed for sedation such as premedication for hospital procedures for their muscle relaxant and amnestic properties, for relief of anxiety (anxiolytic) and as anticonvulsants, benzodiazepines also negatively affect some areas of performance, including memory, motor skills and reaction times (NCETA, 2004), and have been linked to increased falls in the elderly. Often referred to as 'benzos', they are also widely used for illicit or non-prescribed purposes. Benzodiazepines were first marketed in 1959 as a safe alternative to barbiturates, and in the 1970s and 1980s became the most commonly prescribed class of drugs. With increasing doses the level of sedation progresses, extending to unconsciousness. The respiratory depression caused by benzodiazepines is minimal, but combination with other **central nervous system depressants** (e.g. alcohol and opioids) may have life-threatening consequences.

WITHDRAWAL The rate of developing dependence varies: after 3 to 12 months' usage, 10% to 20% of users will become dependent, rising to 20% to 45% when duration of use exceeds 12 months. Heavy users can experience such medical complications of withdrawal as seizures, hallucinations and delirium if dosage is reduced too rapidly; gradual reduction is therefore recommended (NSW Health, 2008c). Depending on the half-life of the particular benzodiazepine, onset of withdrawal occurs 2 to 5 days after stopping or significantly reducing the usual intake; the peak is usually reached on days 7 to 10, and most signs and symptoms usually abate by the end of the second or third week (NSW Health, 2008c). Table 5.4 gives the absorption rates and half-lives of common benzodiazepines.

CONSIDERATION FOR PRACTICE

People in hospital for other reasons may undergo withdrawal from regular, long-term use of even low doses of benzodiazepines—particularly the elderly, who may develop delirium.

- Usage even at low doses should not be stopped abruptly because of the risk, particularly for the sick and the elderly, of precipitating withdrawal.
- Routinely take a history of benzodiazepine use at admission, or as soon as practicable.
- Heavy users or polydrug users should be stabilised before admission on a long-acting preparation (preferably diazepam) at a dose about 40–50% of their regular intake (or 80 mg/day, whichever is lower) (NSW Health, 2008c).
- A hospital admission, during an acute illness, may not be the appropriate time to undertake an elective withdrawal; this may best be managed in an outpatient setting.

Psychostimulants

Psychostimulants, or CNS stimulants, comprising a diverse group of natural and synthetic drugs with a wide range of actions and effects, include:

- amphetamine-type substances, including amphetamine, methamphetamine and dexamphetamine (speed, crystal, crystal meth, ice)
- synthetic amphetamine derivatives, such as methylenedioxymethamphetamine (MDMA—ecstasy), paramethoxyamphetamine (PMA), methylenedioxy-amphetamine (MDA)
- methylphenidates—Ritalin®
- cocaine
- phentermine (Duramine®) and diethylpropion (Tenuate®), prescribed appetite suppressants
- ephedrine and pseudoephedrine, contained in various prescribed cold and flu preparations (adapted from Hulse, White & Cape, 2002).

Psychostimulants are structurally related to the naturally occurring neurotransmitters dopamine, serotonin, adrenaline and noradrenaline. CNS or psychoactive effects include euphoria, increased alertness, increased talkativeness, sense of wellbeing, increased energy and confidence, improved mental and physical performance, loss of appetite and insomnia. Physiological effects include increased blood pressure, tachycardia or irregular heartbeat and increased temperature (Hulse et al., 2002).

TABLE 5.4 Absorption rates, half-lives and equivalent daily doses of common benzodiazepines*

GENERIC NAME	TRADE NAME	TIME TO PEAK CONCENTRATION	ELIMINATION HALF-LIFE†	EQUIVALENT DOSE‡
Diazepam	Antenex Ducene Ranzepam Valium Valpam	30–90 min	Biphasic: rapid phase half-life, 3 hours; elimination half-life, 20–48 hours	5 mg
Alprazolam	Alprax Xanax Kalma	1 hour	6–25 hours	0.5–1.0 mg
Bromazepam	Lexotan	0.5–4 hours	20 hours	3–6 mg
Clobazam	Frisium	1–4 hours	17–49 hours	10 mg
Clonazepam	Paxam Rivotril	2–3 hours	22–54 hours	0.5 mg
Flunitrazepam	Hypnodorm	1–2 hours	20–30 hours	1–2 mg
Lorazepam	Ativan	2 hours	12–16 hours	1 mg
Nitrazepam	Alodorm Mogadon	2 hours	16–48 hours	2.5–5 mg
Oxazepam	Alepam Murelax Serepax	2–3 hours	4–15 hours	15–30 mg
Temazepam	Euhypnos Normison Temaze Temtabs	30–60 min after tablets, 2 hours after capsules	5–15 hours	10–20 mg
Triazolam	Halcion	1–3 hours	Biphasic: rapid phase half-life, 2.5–3.5 hours; elimination half-life, 6–9 hours	0.25 mg
Zolpidem (not a benzodiazepine)	Stilnox	0.5–3 hours	2.5 hours	Not known

* Based on manufacturer's product information.

† Elimination half-life: time for the plasma drug concentration to decrease by 50%.

‡ Equivalent dose: approximate dose equivalent to diazepam 5 mg.

Amphetamines, MDMA (ecstasy) and cocaine are types of psychostimulants more commonly available in Australia.

Amphetamines

The term **'amphetamine'** includes three types: amphetamine, dexamphetamine and methamphetamine and it is available in five forms:

1. *Powder* ('speed', 'goey', 'whiz'): texture ranges from fine to crystallised or coarse powder, coloured white, yellow, brown, orange or pink. Powder is usually snorted or injected but is sometimes mixed in drinks.
2. *Pills*: methamphetamine often appears in pill form, frequently sold as MDMA (ecstasy); manufacturers may mix it with ketamine or gamma hydroxybutyrate (GHB) to produce MDMA-like hallucinogens (McKetin, McLaren & Kelly, 2005).
3. *Base* ('paste', 'pure', 'wax'): oily, waxy or pasty substance with a sticky, damp or gluggy texture. Usually swallowed, smoked or snorted, but may require mixing with a dry powder; can be injected if heated, but has the potential to damage veins.
4. *Liquid* ('ox blood'): high-purity freebase, more pure than speed and normally swallowed or smoked.
5. *Crystal methamphetamine* ('crystal', 'crystal meth', 'ice'): appears as crystals or coarse crystalline powder, white or translucent in colour. The most pure and potent form of methamphetamine, it is usually smoked in a glass pipe or injected, but can be snorted or swallowed. Ice use in Australia, as a proportion of stimulant use, has more than doubled from 22% in 2010 to 50% in 2013 (AIHW, 2015).

MDMA

MDMA (methylene-dioxymethamphetamine), known as 'ecstasy', 'eccies', 'dingers', appears most often in tablet form, but it can be crushed then snorted, and occasionally injected.

Cocaine

Extracted from the coca leaf and imported into Australia, **cocaine** is a white, odourless, crystalline powder and is snorted, injected or swallowed. Crack cocaine, which is smoked, has been reported in Australia but is rare. Cocaine is less available and more expensive than amphetamines.

Stimulant drugs are used by a diverse group of people from a wide variety of socio-demographic backgrounds. Long-distance transport drivers and shift workers use them for their wakefulness-promoting effects, nightclub and dance/music festival patrons for increased energy, and others for potential weight loss, sexual enhancement, and to self-medicate otherwise untreated attention deficit and hyperactivity disorders. The range of users extends from younger age groups experimenting with drugs to polydrug users and long-term injectors.

Drug users will often present to hospitals and other health-care facilities for matters unrelated to their drug use, which they may be reluctant to disclose. It is important to note that they may not regard their drug use as a problem, so it is necessary to take a good history and interact in a non-judgmental way.

Psychostimulant intoxication

Because of burgeoning use in Australia, presentations to general hospital emergency departments and psychiatric emergency centres by people experiencing methamphetamine intoxication have increased; symptoms include agitation, aggression, paranoia, bruxism (teeth grinding and jaw clenching), psychosis and confusion. The primary goal of treatment is to ensure person and staff safety. Sedation is the principal method, the main medications employed being benzodiazepines, anti-psychotics, and even short-acting anaesthetic agents.

WITHDRAWAL Psychostimulant drug withdrawal is not a medically dangerous condition, and generally involves a self-limiting 2- to 5-day period of lethargy, dysphoria, irritability, anxiety, somnolence and increased appetite. The extent of signs and symptoms and the duration of the withdrawal syndrome will be influenced by which drug is involved, the dose, duration of use, and health and personality of the user. Withdrawal typically occurs in three phases, as illustrated in Table 5.5.

TREATMENT Treatment is mostly supportive: understanding, patience, encouragement and positive affirmation. Medical treatment might involve judicious short-term use of benzodiazepines to alleviate some of the anxiety and agitation and help with disturbed sleep. If protracted low mood or more severe depression exists or psychotic features do not resolve within a couple of days, further assessment will be required. Medical complications, usually resulting from injecting drug use, may need further investigation and treatment. A primary aim of health services contact is to educate people about the risks of continued use, discuss harm minimisation options, offer referral or arrange engagement in some sort of relapse prevention support. The medical and psychiatric complications of stimulant use are listed in Table 5.6.

TABLE 5.5 Phases of psychostimulant withdrawal

PHASE	TIME SINCE LAST STIMULANT USE	COMMON SIGNS AND SYMPTOMS
Crash	*Amphetamines:* typically commences 12–24 hours after last amphetamine use, and subsides by days 2–4. *Cocaine:* occurs within hours of last use, with short duration (up to 48 hours). Some people do not report a significant crash on stopping cocaine.	Exhaustion, fatigue Sleep disturbances (typically increased sleep, although insomnia or restless sleep may occur) Mood disturbances—typically flat mood or dysphoria: may be associated with anxiety or agitation Low cravings Generalised aches and pains
Withdrawal	*Amphetamines:* typically commences 2–4 days after last use, peaks in severity over 7–10 days, and then subsides over 2–4 weeks. *Cocaine:* typically commences 1–2 days after last use, peaks in severity over 4–7 days, then subsides over 1–2 weeks.	Strong cravings Fluctuating mood and energy levels, alternating between irritability, restlessness, anxiety and agitation Fatigue, lacking energy, anhedonia Disturbed sleep, including vivid dreams, insomnia General aches and pains, headaches Muscle tension Increased appetite Poor concentration and attention Disturbances of thought (e.g. paranoid ideation, strange beliefs) and perception (misperceptions, hallucinations) can re-emerge during withdrawal phase after having been masked during crash
Extinction	Weeks to months	Gradual resumption of normal mood with episodic fluctuations in mood and energy levels, alternating between irritability, restlessness, anxiety, agitation and fatigue Fatigue, lacking energy and anhedonia Episodic cravings Disturbed sleep

TABLE 5.6 Medical and psychiatric complications of stimulant use

SYSTEM	COMPLICATIONS
Cardiovascular	Arrhythmias: tachycardia, bradycardia, ventricular tachycardia. Hypertension: may lead to cerebrovascular accidents. Spasm of arteries: leading to myocardial infarcts or cerebrovascular accidents. (Myocardial infarcts can occur during first weeks of withdrawal.) Cardiomyopathy and congestive heart failure.
Neurological	Seizures: clonic convulsions. Cerebrovascular accident: including brain haemorrhages, infarcts and ischaemic episodes. Neuropsychological changes: deficits in attention, concentration, memory and new learning skills. Movement disorders: e.g. tics, disturbed gait, stereotyped repetitive movements, choreiform movements.
Psychiatric	May mimic any psychiatric disorder. More commonly: • depression, with changes in mood and affect, sleep, activity • paranoia, ranging from hypervigilance to paranoid psychosis • anxiety and aggression, ranging from irritability and agitation to panic attacks or violence (more common in amphetamine and methamphetamine users) • delirium, with clouding of consciousness, disorientation, confusion • psychosis, characterised by paranoia and anxiety, impaired reality testing with loss of insight and delusions (e.g. ideas of reference, persecutory delusions) and perceptual disturbances (including misperceptions and visual, auditory or tactile (formication) hallucinations).
Respiratory	Smoking of cocaine and amphetamines can result in chronic lung damage (including pneumonia, pulmonary oedema, bronchitis).
Sexuality	Short-term stimulant use is often associated with increased sexual drive and performance. However, chronic use can lead to difficulties achieving orgasm, altered menstruation (oligomenorrhea, amenorrhoea) and galactorrhoea in women, and reduced libido, impotence and gynaecomastia in men.
Hyperpyrexia	Extremely elevated body temperature, which can contribute to seizures, cardiac arrhythmias and death. Rhabdomyolysis can also occur, resulting in acute renal and hepatic failure, disseminated intravascular coagulation and death.
Pregnancy	Stimulant use during pregnancy is associated with higher rates of obstetric complications (spontaneous abortion, miscarriage and placental abruption), and harm to the foetus.
Other	Weight loss (chronic loss of appetite and increased metabolism). Skin lesions and abscesses, due to adulterants, particularly in injectors.

Source: NSW Health (2008c). *Drug and alcohol withdrawal: Clinical practice guidelines: NSW.* Sydney: NSW Health. © New South Wales Ministry of Health for and on behalf of the Crown in right of the State of New South Wales.

Although over the past decade the number of psychostimulant users in Australia and worldwide has increased, not many specialist treatment programs are available; withdrawal management and follow-up support are the mainstays of treatment. Interventions such as relapse prevention counselling, including coping with cravings and learning refusal skills (Lee et al., 2007), self-help groups and harm-reduction programs should be encouraged. Motivational interviewing and cognitive behavioural therapy are the most empirically supported approaches to drug counselling, and a validated counselling manual has been developed for regular amphetamine users (Baker et al., 2003).

Opioids

Opioids such as morphine (Kapanol, Anamorph, MS Contin), pethidine, codeine, methadone (Physeptone, Biodone), hydromorphone (Dilaudid, Jurnista) buprenorphine (Subutex, Suboxone), oxycodone (Oxycontin, Endone), fentanyl, and heroin (diacetylmorphine) are narcotic analgesics. While opioids have many therapeutic uses, they also have abuse potential. Heroin has historically been the primary illicitly used opioid, but over the past decade its availability in Australia (and worldwide) has fluctuated, and abuse of pharmaceutical opioids has significantly increased. Narcotic analgesics are a pain reliever derived from natural or synthetic opioids; interacting with the endogenous opioid receptors, they produce a depressant effect on the CNS causing drowsiness, reduced pain perception and euphoria, the last effect being highly reinforcing.

Prolonged use of opioid drugs leads to the development of tolerance—progressing to euphoria, respiratory depression, analgesia and nausea—and physical dependence. Tolerance to the analgesic effects of opioids manifests itself in lowering the pain threshold: apparently mild pain may be perceived as more severe, which may inadvertently be misinterpreted by the treating nurse as drug-seeking behaviour rather than inadequately relieved pain.

Withdrawal

Unlike alcohol withdrawal, the syndrome associated with cessation of opioid use is not medically serious except in pregnant women. Opioid withdrawal is potentially life threatening for the foetus, as is withdrawal precipitated by naltrexone (an

opioid antagonist). Opioid withdrawal can be viewed as a flu-like syndrome with major and minor symptoms:

Minor

- restlessness/agitation
- lacrimation
- rhinorrhoea
- perspiration/hot and cold flushes
- yawning
- insomnia
- mydriasis (dilated pupils)
- piloerection (goose flesh).

Major

- muscle aches
- joint pain/back pain/pain in long bones
- abdominal cramps
- nausea and vomiting
- diarrhoea
- drug-seeking behaviour.

Psychological/emotional aspects

- emotional and teary
- scattered thoughts
- drug cravings.

Treatment

Opioid-dependent people are often admitted to hospitals and develop unplanned withdrawal. While the syndrome is not medically dangerous, the symptoms can cause considerable discomfort and may lead to resumption of use to avoid or abate the symptoms. Early discharge and thus poor intervention outcomes are probable results.

An opioid withdrawal scale is helpful in monitoring the progress of the syndrome (Wesson & Ling, 2003). Another method of assessment is that withdrawal signs and symptoms will usually begin around the time of the user's expected next dose. The short half-life of heroin produces onset at 6 to 24 hours after last use, and duration is 5 to 10 days. Withdrawal from methadone, which has a longer half-life, occurs 24 to 48 hours after the last dose and lasts for 10 to 20 days.

The requirement in Australia is for a medical practitioner to seek specific approval to prescribe or supply a drug of addiction (listed in Schedule 8 of the Poisons Standard by the Australian Government Department of Health Therapeutic Goods Administration, 2015) to anyone who is known to be, or suspected of being, a drug-dependent person. This does not apply in hospital settings, where these drugs may, without approval, be prescribed for such people for up to 14 days. The policy provides for the management of opioid-dependent people who have been admitted to a hospital (public or private), whether or not they are on an opioid substitution program.

Methadone maintenance is the recommended treatment for pregnant women who are opioid dependent, and breastfeeding is encouraged; linking with specialist antenatal services is also important (NSW Health, 2008a). If anyone on an opioid substitution program is admitted to a hospital, the program should be continued unless medically contra-indicated. Details of the type of substitution medication, current dose, when last administered, and whether any 'take-away' doses have been dispensed all need to be confirmed with the person's prescriber, clinic, dispensing pharmacy, or the relevant state regulatory body, and the prescriber, clinic or pharmacy must be notified on discharge.

People who have been treated for opioid withdrawal should be advised of the increased risk of overdose if they resume using, because they have lost their tolerance; even lesser amounts than those previously used could result in overdose.

Treatment services suitable for an opioid-dependent person include detoxification, residential rehabilitation, outpatient counselling, opioid substitution treatment with methadone or buprenorphine, 12-step self-help programs and naltrexone maintenance. Because of the unique pharmaceutical properties of buprenorphine, which is the principal treatment, specialist advice is recommended for the management of opioid withdrawal undertaken in a general hospital setting. Different types of treatment are more or less appropriate at different stages of dependence; referring the person to a specialist drug and alcohol treatment service may be appropriate to aid exploration of these options.

Hallucinogens

Hallucinogens work on the brain to cause hallucinations, which can affect any of the senses—visual (sight), auditory (hearing), olfactory (smell), gustatory (taste) and tactile (touch)—and distort thoughts and moods. Sometimes called 'psychedelic drugs', they include naturally occurring and synthetic (man-made) compounds.

Hallucinogenic drugs include:

- d-lysergic acid diethylamide (LSD)—'trips', 'acid'
- psilocybin—'magic mushrooms'
- anticholinergics—datura or angel's trumpet
- dimethyltryptamine (DMT)
- phenethylamines—mescaline
- phencyclidine (PCP)—angel dust.

Some drugs, such as cannabis and ecstasy, can cause hallucinogen-like effects in high doses; normally taken orally, on an irregular basis.

Harm (especially behavioural and psychiatric consequences) is more likely to arise from acute drug effects than regular or dependent patterns of use. They are typically used experimentally, occasionally or irregularly, so withdrawal treatment is not required; few people present to treatment centres because of hallucinogen use.

Immediate effects can include:

- disturbances of the senses (sight, hearing, touch, taste or smell); these can be full hallucinations (i.e. have no basis in reality) or illusions (i.e. distortions of reality)
- a sense of increased clarity or sharpness
- altered perceptions (space becomes distorted, changed sense of time)
- changed and intense thoughts
- emotional swings
- dizziness
- weakness
- numbness
- nausea
- dilated pupils
- raised blood pressure, pulse and body temperature
- tremor
- ataxia

- agitation
- anxiety/panic attacks
- psychosis.

Death from overdose of hallucinogens is rare.

One of the few known long-term effects of hallucinogen use is 'flashbacks'—times when feelings similar to those caused by the drug arise intermittently some days, weeks or years after last use. Flashbacks can be precipitated by other drug use, stress, anxiety and fatigue. Other effects include difficulties with memory and concentration, and precipitation or worsening of mental health problems (NSW Health, 2008b).

Treatment

Management of hallucinogen intoxication involves ensuring the safety of the person and others; disturbed thinking and moods may result in agitation and erratic behaviour. Helpful interpersonal techniques include reality orientation, reassurance, and a calm and confident manner. Medical management of acute reaction to hallucinogen ingestion usually includes administration of benzodiazepines, clonidine and antipsychotic medications (Hulse, White & Cape, 2002).

Solvents

Solvents produce a CNS depressant effect: they comprise a range of products producing vapours to be inhaled through the nose or mouth, which may cause feelings of intoxication and lead to an altered state of consciousness. They can be sprayed into a plastic bag ('bagging') or soaked on a cloth or sleeve ('huffing'), or inhaled directly from the container or a drink bottle ('sniffing'). They include gases (e.g. nitrous oxide) and highly volatile compounds or mixtures (petrol, chrome-based paints, glues, aerosol spray cans, butane gas and paint thinners).

Solvents are rapidly absorbed from the lungs, so small amounts quickly take effect. Brain damage or 'sudden sniffing death' can occur the first, tenth or hundredth time of use; another peril is the wide assortment of organic solvents available to and potentially inhaled by young children.

Effects usually clear within a few hours. A sustained effect can be achieved by repeated use; high doses can result in coma and death. Toxicity varies greatly, depending on the substance. Generally, signs include cardiac arrhythmia, hypoxia and neurological impairment. Solvent and alcohol intoxication are similar; short-term effects include euphoria, excitation, disinhibition, slurred speech, ataxia, drowsiness, dizziness, nausea, vomiting, headaches, disorientation and sensory distortions.

Withdrawal

Withdrawal symptoms are not common, and are generally mild:

- anxiety
- depression
- anorexia
- irritation
- tremors
- headache
- nausea
- dizziness.

Confusion and hallucinations can occur after chronic solvent use (NSW Health, 2008b).

OTHER DRUGS

Ketamine

Ketamine (ketamine hydrochloride) is a CNS depressant, best described as a dissociative anaesthetic agent. It is one of the newer drugs to migrate into the illicit-drug-using world, and was developed in the 1970s as a medical anaesthetic for both humans and animals. Illicitly, ketamine can be used as the primary drug, but is also mixed with drugs such as methamphetamine and ecstasy to mimic or supplement their effects. It is pharmaceutically produced in liquid form, but converted to powder and tablet forms for illicit purposes. Commonly swallowed, snorted, smoked or injected, it has a rapid onset but short duration of action (1–6 hours). The half-life is 3 hours (Hulse, White & Cape, 2002) and it can be 24 to 48 hours before the user feels completely 'normal' again.

Ketamine's effects appear to be subjective, depending on the user and the setting. Rarely in Australia do people need treatment because of ketamine, which tends to be used experimentally or socially. Whether it will become a bigger problem is not clear.

At low doses ketamine can produce a state that has some stimulant effects and other sedating effects resembling alcohol intoxication.

At higher doses the effects can include:

- drowsiness
- increased perception
- apathy
- dissociative 'out of body' sensations (flying or floating, detachment from the immediate environment, near-death experiences)
- feelings of paralysis
- analgesia or a reduced response to pain
- hallucinations
- disorganised thoughts
- personality changes
- euphoria
- convulsions
- confusion and disorientation
- risk of respiratory failure
- loss of consciousness.

Larger doses can induce emesis, seizures and respiratory depression. Doses of 1 gram or more can cause death. Ketamine is extremely dangerous when combined with other CNS depressants such as alcohol, benzodiazepines or GHB because of the potentiating effects, whereby each drug increases the effect of the other drug.

Effects of longer-term use can include:

- weight loss and anorexia
- possible memory and concentration difficulties
- mental health disturbances (e.g. anxiety)
- development of tolerance
- possible dependence.

Withdrawal

A withdrawal syndrome involving fear, tremors, facial twitches and craving can occur after cessation of long-term daily use (NSW Health, 2008c).

Gamma hydroxybutyrate (GHB)

Gamma hydroxybutyrate is another CNS depressant and, although it has some mixed properties, it is essentially a dissociative anaesthetic agent; another of the newer drugs diverted to illicit use. Occurring naturally in the brain, GHB was first manufactured and studied in the 1960s, and used in several countries as a general anaesthetic. However, it was withdrawn from use in most countries, including Australia, because of unwanted side effects such as vomiting and seizures.

GHB has a narrow dosage range between stages of a therapeutic effect, the desired effect if used illicitly, and overdose. Like most drugs, it can have a potentiating effect in combination with drugs of the same or similar class. GHB comes in the form of liquid, capsules, powder or crystals.

The effects of GHB are experienced usually within 15 minutes of use, and last for approximately 3 hours.

Effects of lower amounts may include:

- a sense of wellbeing
- relaxation
- drowsiness
- induced sleep
- nausea
- increased confidence, reduced inhibitions
- dizziness
- headache
- increased sociability
- enhanced sense of touch.

There is a narrow threshold between the desired effect and coma. Effects of an overdose can include:

- confusion
- agitation
- extreme drowsiness/grogginess
- hallucinations
- difficulty focusing eyes
- vomiting
- stiffening of muscles
- impaired movement and speech
- convulsions
- unconsciousness/abrupt short-term coma
- respiratory collapse
- amnesia (afterwards)
- death.

GHB is a difficult substance to detect or measure in body fluids and no rapid assay urine test is available. Obtaining verbal drug use history is the best method for assessing recent GHB use.

Withdrawal

Abrupt cessation may cause a user who has developed tolerance to and dependence on GHB to suffer withdrawal symptoms, which usually start about 12 hours after the last dose and can continue for approximately 2 weeks (NCETA, 2004).

Withdrawal symptoms may include:

- confusion/delirium
- agitation
- anxiety
- paranoia
- tremor
- diaphoresis
- muscle cramps
- hallucinations
- tachycardia
- disturbed sleeping patterns
- bowel and bladder incontinence.

Management of GHB withdrawal may require use of both short- and long-acting benzodiazepines. Some users may require further sedation with a short-acting anaesthetic agent (e.g. propofol) (NSW Health, 2008c).

New psychoactive substances

The National Drug and Alcohol Research Centre at the University of NSW reports regularly on new psychoactive substances (NPSs) such as synthetic cannabis. Patients may not know exactly what they have taken; nurses need to be aware of NPSs.

INTERPROFESSIONAL CARE

Successful treatment of substance abuse and dependence requires the skills of an interprofessional team specialising in the psychiatric aspects of such disorders, in effective clinical partnership with professionals working in other settings (NSW Health, 2008b).

Psychosocial interventions for which there is the strongest evidence and professional consensus include assessment and brief intervention, motivational interviewing, cognitive behaviour therapy, psychodynamic therapy, dialectical behaviour therapy, self-help approaches and continuing care (NSW Health, 2008b). Therapies may include detoxification, pharmacotherapy, drug antagonists, drug agonists, anti-craving medication, aversion agents, group and/or individual psychotherapy, psychotropic medications, cognitive–behavioural strategies, family counselling and self-help groups.

Substance users can be treated in either inpatient or outpatient settings. Substance overdose can be a life-threatening condition requiring emergency hospitalisation for medical stabilisation before implementation of any of the recommended interventions. Several diagnostic tests provide valuable information about the person's physical condition and set the course for treatment.

Diagnostic tests

Blood and urine are the body fluids most often tested for drug content; saliva, perspiration and hair also may be tested. A breathalyser provides the simplest method of detecting blood alcohol content; more invasive procedures such as serum drug levels to treat drug overdoses or complications are useful in the emergency department and other hospital settings. Urine drug screens (UDS) may be a rapid assay test via 'dip-stick' products, or sent away for laboratory analysis; UDS is non-invasive, and is the preferred method for detecting substances in the body. Companies often require a precautionary UDS of prospective employees, some amateur and professional athletes have to submit to random drug testing, and determination of drug use arises in the legal system in connection with criminal activity and family court proceedings. The period in which drugs can be found in blood and urine varies according to dosage and the metabolic properties of the drug; traces may disappear within 24

hours, or still be detectable 30 days later. The psychoactive substance found in marijuana, THC, is stored in fatty tissues (especially the brain and reproductive system), and can be detected in the body for up to 6 weeks (Kneisl & Trigoboff, 2013).

Knowledge of the blood alcohol level is helpful in ascertaining levels of intoxication and tolerance, and whether recent drinking has been accurately reported. At 0.10% (after five to six drinks in 1 to 2 hours), voluntary motor action becomes clumsy, and reaction time is impaired to a degree that varies with gender, weight and food ingestion. Intoxication will occur more rapidly in small women drinking alcohol on an empty stomach than in large males who have eaten a full meal. At 0.20% (after 10 to 12 drinks in 2 to 4 hours), function of the motor area in the brain is depressed, causing staggering and ataxia (Kneisl & Trigoboff, 2013). A level above 0.10% without associated behavioural symptoms indicates the presence of tolerance; high tolerance is a sign of physical dependence.

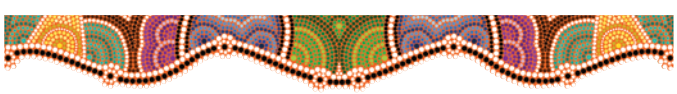
Assessing for withdrawal symptoms is important when the BAL is high and the person shows significant tolerance: medication for treatment of withdrawal from alcohol is usually not started until the BAL is below a set norm (usually 0.10%) unless withdrawal symptoms become severe. BAL may be repeated several times, several hours apart, to assess the body's metabolism of alcohol and determine when it is safe to administer medication to minimise the withdrawal symptoms.

Emergency care for overdose

People who have overdosed on any substance constitute a serious medical emergency. They may become severely sedated and difficult to arouse, requiring determined efforts to maintain wakefulness, but stupor and coma may nevertheless occur. Respiratory depression may require mechanical ventilation, while a seizure is another serious complication needing emergency treatment. Methamphetamine overdose can cause psychosis, arrhythmias, stroke and cerebral haemorrhage (Lee et al., 2007).

Cases of intentional overdose necessitate constant monitoring for further signs of suicidal ideation—never leave an actively suicidal person alone.

It is important not to assume the level of sedation to be due solely to intoxication if there is any possibility of a concomitant or contributing factor; conditions which can mimic aspects of intoxication include post-ictal states, hypoglycaemia, head injury, hepatic failure, stroke and other cerebrovascular events, infection, respiratory failure and hypoxia (NCETA, 2004).



Nursing care

Nurses and midwives will encounter people with problems of substance misuse in all healthcare settings—hospital emergency departments, medical and surgical units, mental health, inpatient wards, outpatient clinics, maternity wards, home visiting, community health departments, pain clinics, ambulatory care centres and in specific drug and alcohol treatment programs.

Substance users are a diverse group of people with differing needs and backgrounds; they are often subject to discrimination and prejudices similar to those directed at other minority groups, which can effect further marginalisation. These negative attitudes are often formed and fuelled by fear, ignorance and inaccurate information. If judged in a negative manner by nurses and other healthcare workers, drug users are likely to be less comfortable in accessing healthcare, thereby potentially worsening their condition and prognosis. Nurses need to view drug and alcohol misuse as a health problem, not a moral one. Forming a therapeutic relationship and delivering person-centred care will increase the likelihood of useful health interventions; nurses command a high level of community support and trust, and are therefore in an ideal position to positively influence outcomes for people with these health problems (NCETA, 2004).

Drug and alcohol use assessment

Drug and alcohol use assessment should be a routine part of everyone's care. It comprises a comprehensive history of use of all types of drugs: route of administration; frequency, amount and duration of use, and the time and amount of last dose; likelihood of substance intoxication; potential risk of withdrawal; possible mental health co-morbidities; physical and psychosocial issues; child protection concerns; and harm minimisation strategies.

Nursing interventions

A substantial body of evidence confirms the effectiveness of interventions and benefits of treatment that nurses can provide for people presenting with substance use problems: screening, assessment, provision of information and advice, opportunistic interventions and withdrawal management; counselling, including motivational interviewing and relapse prevention; referral to clinicians with specialist skills in drug and alcohol; and follow-up monitoring and care coordination. These interventions have been shown to be effective in specialist and non-specialist settings.

Opportunistic intervention

'Opportunistic intervention' describes taking advantage of an opening or chance to discuss a health-related concern which might not be the primary reason for presentation to the health facility: essentially, dealing with problems of substance use at a critical time for the person admitted. For example, opportunistically during routine contacts (perhaps at needle and syringe exchanges), staff should provide all drug users with information and advice about reducing exposure to blood-borne viruses, including reduction of sexual and injection risk behaviours (National Institute for Health and Clinical Excellence, 2007). A discussion about consumption of alcohol above the recommended safe levels with a person admitted to a gastroenterology ward for a bleeding gastric ulcer is another example.

Key strategies include interacting with people in a non-judgmental way, clearly identifying the link between their substance use and the negative health or lifestyle consequences; providing information; and offering further assistance or referral.

Opportunistic interventions need not be extensive, and can be executed in as little as 5 minutes. Australian research (Heather et al., 1996) has shown that brief counselling provided on a general hospital medical ward directed at men's heavy drinking

resulted in reduction of their alcohol consumption after discharge. Pregnancy and the perinatal phase are appropriate times to discuss drug and/or alcohol problems and ascertain whether further assistance or treatment might be beneficial. While opportunistic interventions can be undertaken at any stage of substance using, they are most appropriate in the earlier stages. Heavily substance-dependent people, people with co-morbid mental health issues, or those who feel powerless to change should be referred for specialist treatment (NSW Health, 2008b).

Psychosocial interventions

Conveying respect and providing non-judgmental care are the basis of all psychological interventions. The efficacy of several psychosocial interventions has been proven by research: these include motivational interviewing, problem solving, goal setting and relapse prevention (including identifying triggers and distinguishing a lapse from a relapse), which are briefly outlined here.

Stages of change model

The stages of change model can assist nurses both to understand and to build a rapport with people, and is the basis for many of the psychological approaches employed. DiClemente (2005) posits the five stages of change summarised in Table 5.7: precontemplation, contemplation, preparation, action and maintenance. Research has shown this model underpins all types of change related to behaviours such as smoking, drinking and using drugs. Relapse also is seen as a part of the circle—it is normal for people to 'travel around' the circle before reaching a stable change.

Motivational interviewing

This therapeutic approach is intended as a means for clinicians to help people to work towards change, and to deal with their fluctuation between opposing behaviours and thoughts (Miller & Rollnick, 1991). It uses an approach that matches the current stage of change and assists movement through the stages towards successful sustained change (Miller, 1995); it replaces previous direct and often confrontational approaches. Box 5.2 explains the principles of this approach.

Problem solving

The ability to respond effectively to problems is associated with improved treatment outcomes (NCETA Consortium, 2004). Nurses should support the development of problem-solving skills, including techniques such as problem analysis, verbal instruction, written information and skill rehearsal.

Goal setting

Goal setting gives people a direction, and provides a standard by which progress can be reviewed together with evidence of improvement. Goals should be practical, realistic and linked with

TABLE 5.7 Stages of change model

STAGE	DESCRIPTION	STRATEGIES AND CONSIDERATIONS
Precontemplation	The person is unaware, or barely aware, that there is a problem; the cons of giving up outweigh the pros, and there is no intent to change substance using in the foreseeable future. There may also be a lack of hope because of previous failures.	Prescriptive advice can be counterproductive, creating resistance, and arousing a range of defence mechanisms which prevent people from hearing/understanding the need for change. Provide information and feedback to raise problem awareness and the possibility of change, and raise doubt to increase the perception of the risks and problems of their current behaviour.
Contemplation	The existence of a problem is acknowledged, and the person may exhibit visible signs of distress. At this stage people are open to information and education, are contemplating change but are not quite ready, and are considering the positives and negatives of giving up.	Using the person's language and goals, examine the reasons for both changing and not changing, and tip the balance in favour of change.
Preparation	The person is beginning to set goals and make plans, and strategies are developed.	Suggest choices and probe the person's thinking about options.
Action	Behavioural change has clearly begun, and significant efforts have been made to stop using alcohol or drugs. The action stage on average lasts 6 months.	Give support to take steps towards change. Raise awareness of the psychological, cognitive, behavioural and emotional events which can work against best efforts, and plan strategies to overcome potential triggers.
Relapse	Alcohol or drugs are used again.	Treat this as a learning opportunity—a chance to ascertain which strategies and which part of the plan did not work. Help the person to identify and use strategies to prevent relapse, but to prepare for and expect it. Urge them not to give up, and to continue on the wheel of change.
Maintenance	Continued abstention from alcohol or drugs, and intent to sustain and strengthen improvements made. It can take a few years to feel 'secure'.

BOX 5.2 Principles of motivational interviewing

1. Express empathy
Understanding the cycle of change can help the nurse to empathise, communicate a sense of respect, and give direction to intervention strategies (Miller, 1995); an empathic therapeutic style is associated with greater long-term behaviour change.

2. Develop discrepancy
Motivation for change occurs when people perceive a discrepancy between where they are and where they want to be. The object of this approach is to enhance and focus attention on such discrepancies with regard to alcohol and drug use (Miller, 1995); at this stage the nurse may discuss concerns about the person's current level of use, what is positive about such use and what is causing problems (NSW Health, 2008b).

3. Roll with resistance and avoid argumentation
New perspectives may be raised but not imposed: arguing is counterproductive and can create defensiveness. The simplest response to resistance is non-resistance; repeating the person's statement in a neutral form acknowledges and validates it, and can elicit an opposite reaction.

4. Support self-efficacy
Self-efficacy is the belief that one can adopt a behaviour or accomplish a particular task; it is important because belief in the possibility of change is an effective motivator. The nurse facilitates informed choice of goal and method of treatment, and communicates confidence and optimism (NCETA Consortium, 2004).

treatment plans derived directly from results of assessment and person-centred collaboration; the plans should contain strategies for achieving these goals and, where appropriate, include parents, partners, families and friends (Marsh & Willis, 2007).

Relapse prevention

Relapse prevention and management encompass cognitive behavioural strategies which provide people with the skills and confidence to avoid or to deal with any setbacks; thus nurses should explore their triggers with them—what situations, moods, thoughts or events might lead to a high risk of relapse (Marsh & Willis, 2007).

Health promotion and global policy on primary prevention measures for substance abuse

Member states of the United Nations General Assembly, increasingly concerned about threats posed by the world drug problem, have called for the elimination or significant reduction of drug supply and demand by 2019 (United Nations Office on Drugs and Crime, 2012). Controversially others, citing the failure of the so-called 'war on drugs' and its effects on the murder rate ('Eight of the world's most violent countries are in Latin America or the Caribbean, the source of most of the world's cocaine and heroin'), have called for an end to prohibition (*Economist*, 2012). Supporters of this viewpoint note that because the trade is illegal the 'multi-billion dollar profits' go to criminal entities; this gives them enormous power and in some cases funds terrorism (*Economist*, 2012).

The World Health Organization (2010), acknowledging the desirability of global measures to reduce alcohol misuse and recognising its links with socioeconomic status, has drawn up a list of areas for action. These include drink-driving policies and countermeasures, the availability, marketing and pricing of alcoholic beverages, and reducing the negative consequences of drinking and alcohol intoxication.

Health promotion

Health promotion efforts are aimed at preventing drug use among children and adolescents and reducing the risks among adults. Teenagers are a vulnerable population, often succumbing to peer pressure; therefore, adolescence is the most common phase for the first experience with drugs (Stuart & Laraia, 2005). Healthy lifestyles, parental support, stress management, good nutrition and information about ways to cope with peer pressure are important topics for the nurse to cover in school prevention programs.

Nurses should advise adults about the physiological or physical effects of substances on the body, and provide information about healthy coping mechanisms and relaxation and stress reduction techniques to decrease the risks of substance abuse.

Harm minimisation is the key philosophy and basis for government policy in the management of drug- and alcohol-related issues. This philosophy accepts that drug and alcohol use exists, is likely to continue, and is widespread across all levels of the Australian and international communities; it does not preclude abstinence and is interrelated with harm (demand and supply) reduction. Harm minimisation describes reducing the impact of drug- and/or alcohol-related harm to individuals and the community through a range of cost-effective public health policies, strategies and practices. Because of their numbers, roles, knowledge and skills, nurses and midwives are particularly well placed to identify risks of harm associated with drug and alcohol use, and can apply a range of harm reduction strategies and interventions (NSW Health, 2008c).

Assessment

A comprehensive approach to the assessment of substance use is essential to ensure adequate and appropriate intervention. Three important areas to assess are people's history of substance use, their medical and psychiatric history, and the presence of psychosocial concerns.

Ask questions in a non-threatening, matter-of-fact manner, as if you are having a casual conversation. Questions can be phrased so as not to imply judgment or disapproval: for example, a non-threatening question such as, 'How much alcohol do you drink?' is preferable to the judgmental question, 'You don't drink too much alcohol, do you?' Open-ended questions that elicit more than a simple 'yes' or 'no' answer help to determine the direction of future counselling. Examples of open-ended questions are

BOX 5.3 Examples of open-ended questions for assessment

- On average, how many days per week do you drink alcohol or use drugs?
- On a typical day when you use drugs or alcohol, how many hits or drinks do you have?
- What is the greatest number of drinks you have had at any one time during the past month?
- What drug(s) did you take before coming to the hospital or clinic?
- How long have you been using the substances?
- How often and how much do you usually use?
- What kind of problems has substance use caused for you, your family, friends, finances and health?

provided in Box 5.3. Use of therapeutic communication techniques helps to establish trust prior to the assessment process.

A diverse range of medications is available for use in the management of substance abuse or dependence and substance withdrawal (see Table 5.8). The most appropriate medication for use in any particular situation will depend on which substance has been abused, the level of use, whether the treatment is for withdrawal management or as relapse prevention, and the physical and mental health of the person.

History of past substance use

A thorough substance use history is necessary to ascertain the possibility of tolerance, physical dependence, or withdrawal syndrome; the following questions are helpful in eliciting a pattern of substance use behaviour:

- How many substances have been used simultaneously (**polysubstance abuse**—simultaneous use of many substances)?
- When was the first use of the substance(s), and thereafter how often and how much?
- Is there a history of blackouts, delirium or seizures?
- Is there a history of withdrawal syndrome, overdoses and complications from previous substance use?
- Has the person ever been treated in an alcohol or drug abuse clinic?
- Has the person ever been arrested for driving under the influence, or charged with any criminal offence committed while using drugs or alcohol?
- Is there a family history of drug or alcohol use?

Medical and psychiatric history

A personal medical history is an essential area for assessment, and should include the existence of any concomitant physical or mental conditions (e.g. HIV, hepatitis, cirrhosis, oesophageal varices, pancreatitis, gastritis, Wernicke–Korsakoff syndrome, depression or anxiety). Ask about prescribed and

NURSING CARE OF THE OLDER ADULT Alcohol use disorders in the older adult

Alcohol use disorders in older people are common and are associated with considerable morbidity and numerous physical problems. Alcohol abuse affects alertness, judgment, coordination and reaction time, increasing the risk of falls and injuries, which can rob older people of their independence. Alcohol negatively interacts with the natural ageing process to increase the risk of hypertension, cardiac arrhythmias, cancers, gastrointestinal problems, cognitive deficits, bone loss and emotional challenges, most notably depression (Stevenson, 2005). Older adults (especially women) are also more likely to use prescription or over-the-counter medicines, which can be harmful when mixed with alcohol and/or illicit drugs (Lantz, 2005; Simoni-Wastila & Strickler, 2004).

Although substance abuse and dependence are not as common in the elderly, they are under-detected and misdiagnosed for a number of reasons: people in this age group are less likely to disclose their problems, and screening and diagnostic instruments may not uncover misuse (O'Connell & Chin, 2009). Substance abuse problems can also be difficult to detect because many of the symptoms (e.g. insomnia, depression, loss of memory, anxiety, musculo-skeletal pain) may be confused with conditions commonly seen in the elderly (Lantz, 2005), and may be thought of as 'part of the ageing process'. Alcohol and drug abuse can also make other medical problems hard to diagnose—for example, by dulling a pain sensation that might warn of a heart attack.

Clinical staff may view alcohol use disorders as being understandable in the context of poor health and changing life circumstances—this can lead to therapeutic pessimism when confronted with such problems (O'Connell & Chin, 2009). However, the absolute number of elderly people with substance use disorders is increasing in proportion with the ageing population (Blow & Barry, 2014): by 2020 the number in need of substance abuse treatment is predicted to increase from 1.7 million in 2001 to 4.4 million (Gfroerer et al., 2003). Therefore, health services need to improve provision of age-appropriate screening, treatment methods and services (O'Connell & Chin, 2009). Because depression and alcohol abuse are the disorders most frequently found in completed suicides, it is important that nurses routinely screen older adults for both substance abuse and mental disorders.

CRITICAL THINKING IN PERSON-CENTRED CARE

1. You are caring for an 85-year-old man who tells you that his wife died 6 months ago, and he drinks only to dull the pain of her loss. How would you respond?
2. What do you think is the reason for the frequent failure of nurses and other healthcare professionals to recognise and treat substance abuse problems in older adults?
3. You are caring for an older adult who denies that alcohol has become a serious problem, even after three episodes of hospitalisation in 6 months because of accidents, falls and blackouts. What would you do?

TABLE 5.8 Drugs used in the treatment of substance withdrawal/abuse

DRUG	DOSE	PURPOSE
BENZODIAZEPINES		
1. Midazolam	Individualised, IMI, IV	Diminishes anxiety and has anticonvulsant qualities to provide safe withdrawal. May be ordered q4h or prn to manage adverse effects from withdrawal, then dose is tapered to zero.
2. Diazepam (Valium)	4–120 mg/day	
3. Oxazepam (Serepax)	30–120 mg/day	
4. Lorazepam (Ativan)	2–6 mg/day	
VITAMINS		
1. Thiamine (vitamin B_1)	100 mg/day	Prevents Wernicke's encephalopathy
2. Folic acid	1 mg/day	Corrects vitamin deficiency caused by heavy long-term alcohol abuse
3. Multivitamins	1 tab/cap daily	
ANTICONVULSANTS		
1. Phenytoin (Dilantin)	Individualised as per bodyweight	Seizure prophylaxis
2. Magnesium sulfate	1 g q6h	Reduces post-withdrawal seizures
ABSTINENCE MEDICATIONS		
1. Disulfiram (Antabuse)	250 mg/day	Prevents breakdown of alcohol
2. Naltrexone (ReVia)	50 mg/day	Diminishes cravings for alcohol and opioids
3. Acamprosate (Campral)	133.3–199.8 mg/day	Decreases alcohol craving
ANTIDEPRESSANTS		
1. Fluoxetine (Prozac)	20–80 mg/day	Enhances and stabilises mood and diminishes anxiety
2. Sertraline (Zoloft)	50–200 mg/day	Enhances and stabilises mood and diminishes anxiety
SYMPTOMATIC TREATMENT FOR INDIVIDUAL WITHDRAWAL SYMPTOMS		
Metoclopramide (Maxolon)	30 mg/day	Nausea and vomiting
Prochlorperazine (Stemetil)	10–30 mg/day	Nausea and vomiting
Paracetamol	Up to 4 g/day	Headache, generalised aches and pains
Ibuprofen (or other non-steroidal anti-inflammatory agents)	Up to 1.6 g/day	Headache, generalised aches and pains
Kaomagma		Diarrhoea
Hyoscine butylbromide (Buscopan)	80 mg/day	GIT spasm
OPIOID AGONISTS		
Methadone	Individualised	Opioid substitution agent for maintenance treatment
Buprenorphine	Individualised	Opioid substitution agent for maintenance treatment or opioid withdrawal management
Buprenorphine-naloxone	Individual dosage up to 32 mg/day	Opioid substitution agent for maintenance treatment

GIT = gastrointestinal tract; IMI = intramuscular injection; IV = intravenous; q4h (q6h) = every 4 (6) hours; prn = as needed.

over-the-counter medications as well as any allergies or sensitivity to drugs. Also significant is the current mental status, and a brief overview is required:

- Is there a history of abuse (physical or sexual) or family violence?
- Any history of suicide attempts?
- Current suicidal or homicidal ideation?

PSYCHOSOCIAL ISSUES Information about the person's level of stress and other psychosocial concerns can assist in the assessment of substance use problems:

- Has substance use affected the person's ability to hold a job?
- Has substance use affected relationships with spouse, family, friends or co-workers?
- How does the person usually cope with stress?
- Does the person have a support system that helps in times of need?
- How does the person spend leisure time?

SCREENING TOOLS Several screening tools are available which may help the nurse to determine the degree of severity of substance abuse or dependence (see Figure 5.2). These provide a non-judgmental, brief and easy method to ascertain patterns of substance abuse behaviours:

- The Alcohol Use Disorders Identification Test (AUDIT), the 10-question tool most commonly used in Australia for screening for excessive drinking, was developed by the

Brief MAST **Scoring Yes to 3 or more indicates alcoholism**

1. Do you feel you are a normal drinker?
2. Do friends or relatives think you are a normal drinker?
3. Have you ever attended a meeting of Alcoholics Anonymous?
4. Have you ever been in trouble at work because of drinking?
5. Have you ever lost friends or girlfriends/boyfriends because of drinking?
6. Have you ever neglected your obligations, your family, or your work for 2 or more days in a row because of your drinking?
7. Have you ever had delirium tremens (DTs), severe shaking, or heard voices or seen things that were not there after heavy drinking?
8. Have you ever gone to anyone for help about your drinking?
9. Have you ever been in a hospital because of your drinking?
10. Have you ever been arrested for drunken driving or other drunken behaviour?

B-DAST **The following questions concern information about your involvement with drugs *not including alcoholic beverages* during the past 12 months.**

In the statements, 'drug abuse' refers to (1) the use of prescribed or over-the-counter drugs in excess of the directions and (2) any non-medical use of drugs. The various classes of drugs may include cannabis, solvents, anti-anxiety drugs, sedative-hypnotics, cocaine, stimulants, hallucinogens, and narcotics. Remember *do not include alcoholic beverages*.

Have you used drugs other than those required for medical purposes?	Yes ___	No ___
Do you abuse more than one drug at a time?	Yes ___	No ___
Are you always able to stop using drugs when you want to?	Yes ___	No ___
Have you had 'blackouts' or 'flashbacks' as a result of drug use?	Yes ___	No ___
Do you ever feel bad about your drug abuse?	Yes ___	No ___
Does your spouse (or parents) ever complain about your involvement with drugs?	Yes ___	No ___
Have you neglected your family because of your use of drugs?	Yes ___	No ___
Have you engaged in illegal activities in order to obtain drugs?	Yes ___	No ___
Have you ever experienced withdrawal symptoms (felt sick) when you stopped taking drugs?	Yes ___	No ___
Have you had medical problems as a result of your drug use (e.g. memory loss, hepatitis, convulsions, bleeding, etc.)?	Yes ___	No ___

Scoring: one positive response warrants further evaluation.

FIGURE 5.2 ■ Screening tools for alcohol and drug abuse

Sources: Adapted from The brief MAST: A shortened version of the Michigan Alcohol Screening Test by A. D. Porkorny, B. A. Miller & H. B. Kaplan (1972). *American Journal of Psychiatry*, *129*, 342–345. Copyright 1972 by the American Psychiatric Association; and *Brief Drug Abuse Screening Test* (B-DAST) (p. 363) by H. A. Skinner (1982). Langford Lance, England: Elsevier Science Ltd. Copyright 1982.

World Health Organization. Particularly suitable for primary healthcare settings, it has been used in several different countries with diverse cultural groups. A score of 8 to 10 is associated with harmful or hazardous drinking. As a general guide, a score of 13 or more is likely to indicate alcohol dependence.

- Other screening tools, less often used in Australia, include the MAST and the CAGE.

WITHDRAWAL ASSESSMENT TOOLS Nurses working in medical–surgical, mental health and special substance abuse units routinely care for people experiencing acute alcohol or opiate withdrawal. Several assessment tools are available to determine the severity of withdrawal symptoms and indicate the need for pharmacological treatment to manage them; for example:

- The Clinical Institute Withdrawal Assessment of Alcohol—Revised (CIWA-Ar) (Sullivan et al., 1989) (see Figure 5.3) is used widely in clinical and research settings for initial assessment and ongoing monitoring of alcohol withdrawal signs and symptoms. The CIWA-Ar scale is a validated 10-item assessment tool to monitor and help guide treatment for people undergoing alcohol withdrawal. It screens for several symptoms (e.g. high blood pressure, rapid pulse, tremors, anxiety, agitation, hallucinations and sweating); the resulting score directs administration of benzodiazepines or other drugs to relieve associated symptoms of withdrawal and prevent seizures. A score of 8 points or fewer corresponds with mild withdrawal symptoms; 9 to 15 points indicate moderate withdrawal; 15 or greater denote severe withdrawal and an increased risk of delirium tremens and seizures.
- The Clinical Opiate Withdrawal Scale (COWS) (Wesson & Ling, 2003) rates 11 common signs or symptoms of opiate withdrawal. The total score assesses the intensity

Clinical Institute Withdrawal Assessment of Alcohol Scale, Revised (CIWA-Ar)

Patient:_____ **Date:** _____ **Time:** _____ (24 hour clock, midnight = 00:00)

Pulse or heart rate, taken for one minute:_____ **Blood pressure:**_____

NAUSEA AND VOMITING -- Ask 'Do you feel sick to your stomach? Have you vomited?' Observation.
0 no nausea and no vomiting
1 mild nausea with no vomiting
2
3
4 intermittent nausea with dry heaves
5
6
7 constant nausea, frequent dry heaves and vomiting

TACTILE DISTURBANCES -- Ask 'Have you any itching, pins and needles sensations, any burning, any numbness, or do you feel bugs crawling on or under your skin?' Observation.
0 none
1 very mild itching, pins and needles, burning or numbness
2 mild itching, pins and needles, burning or numbness
3 moderate itching, pins and needles, burning or numbness
4 moderately severe hallucinations
5 severe hallucinations
6 extremely severe hallucinations
7 continuous hallucinations

TREMOR -- Arms extended and fingers spread apart. Observation.
0 no tremor
1 not visible, but can be felt fingertip to fingertip
2
3
4 moderate, with patient's arms extended
5
6
7 severe, even with arms not extended

AUDITORY DISTURBANCES -- Ask 'Are you more aware of sounds around you? Are they harsh? Do they frighten you? Are you hearing anything that is disturbing to you? Are you hearing things you know are not there?' Observation.
0 not present
1 very mild harshness or ability to frighten
2 mild harshness or ability to frighten
3 moderate harshness or ability to frighten
4 moderately severe hallucinations
5 severe hallucinations
6 extremely severe hallucinations
7 continuous hallucinations

PAROXYSMAL SWEATS -- Observation.
0 no sweat visible
1 barely perceptible sweating, palms moist
2
3
4 beads of sweat obvious on forehead
5
6
7 drenching sweats

VISUAL DISTURBANCES -- Ask 'Does the light appear to be too bright? Is its color different? Does it hurt your eyes? Are you seeing anything that is disturbing to you? Are you seeing things you know are not there?' Observation.
0 not present
1 very mild sensitivity
2 mild sensitivity
3 moderate sensitivity
4 moderately severe hallucinations
5 severe hallucinations
6 extremely severe hallucinations
7 continuous hallucinations

ANXIETY -- Ask 'Do you feel nervous?' Observation.
0 no anxiety, at ease
1 mildly anxious
2
3
4 moderately anxious, or guarded, so anxiety is inferred
5
6
7 equivalent to acute panic states as seen in severe delirium or acute schizophrenic reactions

HEADACHE, FULLNESS IN HEAD -- Ask 'Does your head feel different? Does it feel like there is a band around your head?' Do not rate for dizziness or lightheadedness. Otherwise, rate severity.
0 not present
1 very mild
2 mild
3 moderate
4 moderately severe
5 severe
6 very severe
7 extremely severe

AGITATION -- Observation.
0 normal activity
1 somewhat more than normal activity
2
3
4 moderately fidgety and restless
5
6
7 paces back and forth during most of the interview, or constantly thrashes about

ORIENTATION AND CLOUDING OF SENSORIUM -- Ask 'What day is this? Where are you? Who am I?'
0 oriented and can do serial additions
1 cannot do serial additions or is uncertain about date
2 disoriented for date by no more than 2 calendar days
3 disoriented for date by more than 2 calendar days
4 disoriented for place/or person

Total **CIWA-Ar** Score _____
Rater's Initials _____
Maximum Possible Score 67

*The **CIWA-Ar** is not* copyrighted and may be reproduced freely. This assessment for monitoring withdrawal symptoms requires approximately 5 minutes to administer. The maximum score is 67 (see instrument). Patients scoring less than 10 do not usually need additional medication for withdrawal.

Sullivan, J.T.; Sykora, K.; Schneiderman, J.; Naranjo, C.A.; and Sellers, E.M. Assessment of alcohol withdrawal: The revised Clinical Institute Withdrawal Assessment for Alcohol scale (**CIWA-Ar**). *British Journal of Addiction* 84:1353-1357, 1989.

FIGURE 5.3 ■ Assessment tool for alcohol withdrawal

Source: From Assessment of alcohol withdrawal: The revised Clinical Institute Withdrawal Assessment for Alcohol scale (CIWA-Ar) by J.T. Sullivan, K. Sykora, J. Schneiderman, C. A. Naranjo & E. M. Sellers (1989). *British Journal of Addiction*, *84*, 1353–1357.

of opiate withdrawal and determines the extent of physical dependence on opioids: a score of 12 or less indicates mild symptoms or none; 13 or more, moderate to severe.

Nursing interventions

Primary nursing diagnoses and interventions for people with substance abuse problems are listed below, together with implications for nursing care in acute and home care settings. See the 'Nursing care plan' box for more information about withdrawal from alcohol.

Risk of injury and risk of violence

- Assess level of disorientation to determine specific risks to safety. *Knowledge of level of cognitive functioning is essential to the development of an appropriate plan of care.*
- Obtain a drug history as well as urine and blood samples for laboratory analysis of substance content. *Subjective history is often not accurate and knowledge regarding substance use is important for accurate assessment.*
- Place the person in a quiet, private room to decrease excessive stimuli, but do not leave alone if excessive hyperactivity or suicidal ideation is present. *Excessive stimuli increase agitation.*
- Frequently orient the person to reality and the environment, ensuring that potentially harmful objects are stored out of reach. *People's disorientation and confusion may cause harm to themselves or others.*
- Monitor vital signs every 15 minutes until stable, and assess for signs of intoxication or withdrawal. *The most reliable information about withdrawal symptoms is vital signs; they provide information about the need for medication during detoxification.*

Ineffective denial

- Be genuine, honest and respectful. Keep all promises and convey an attitude of acceptance. *The development of a non-judgmental, therapeutic relationship is essential to gain trust.*
- Identify maladaptive behaviours or situations that have occurred in the person's life and discuss how the use of substances might have been a contributing factor. *The first step in combating denial is for the person to recognise the relationship between substance use and personal problems.*
- Encourage participation in therapeutic group activities such as co-occurring disorder or Alcoholics Anonymous (AA) meetings with people who are having or have had similar problems. *Peer feedback is often more accepted than feedback from authority figures.*

Ineffective coping

- Establish a trusting relationship. *Trust is essential to the therapeutic relationship*.
- Set limits on so-called manipulative behaviour and maintain consistency in responses. It is more helpful to think of this behaviour as care-eliciting to avoid the judgmental overtones of the word 'manipulative'. *The person may not be able to set their own limits, and needs to begin to accept responsibility without being manipulative.*
- Encourage the person to verbalise feelings, fears or anxieties, and make observations or statements acknowledging their validity. *Verbalisation of feelings helps to develop insight into behaviours and long-standing problems.*
- Explore methods of dealing with stressful situations other than resorting to substance use. Provide encouragement for changing to a healthier lifestyle. *Teach healthy coping mechanisms (e.g. physical exercise, progressive muscle relaxation, deep-breathing exercises, meditation and mindfulness).*

Imbalanced nutrition: less than body requirements

- Administer prescribed vitamins and dietary supplements. *Vitamin B_1 is necessary to prevent complications from chronic alcoholism such as Wernicke's syndrome.*
- Monitor pathology results (e.g. total albumin, complete blood count, urinalysis, electrolytes and liver enzymes) and report significant changes. *Pathology results provide necessary information to determine the extent of malnourishment.*
- Collaborate with the dietitian to determine the number of kilojoules needed for adequate nutrition and realistic weight gain. Document intake, output and kilojoule count. Weigh daily if condition warrants. *Weight loss or gain is significant assessment information for development of an appropriate plan of care.*
- Emphasise the importance of a balanced diet and relate this to the physical effects of malnutrition on body systems.

Chronic or situational low self-esteem

- Spend time with the person and convey an attitude of acceptance. Encourage the person to accept responsibility for their own behaviours and feelings. *An attitude of acceptance enhances self-worth.*
- Encourage the person to focus on strengths and accomplishments rather than weaknesses and failures. *Minimise attention to negative ruminations.*
- Encourage participation in therapeutic group activities and offer recognition and positive feedback for actual achievements. *Success and recognition increase self-esteem.*
- Teach assertiveness techniques and effective communication techniques such as using 'I feel' rather than 'You make me feel' statements. *Previous patterns of communication may have been aggressive and accusatory, causing barriers to interpersonal relationships.*

Deficient knowledge

- Assess level of knowledge and readiness to learn the effects of drugs and alcohol on the body. *Baseline assessment is required to develop appropriate teaching material.*
- Develop a teaching plan that includes measurable objectives. Include significant others, if possible. *Lifestyle changes often affect all family members.*

- Begin with simple concepts and progress to more complex issues. Use interactive teaching strategies and written materials at the appropriate educational level. Include information on physiological effects of substances, the propensity for physical and psychological dependence, and the risks to a foetus if pregnant. *Active participation and handouts enhance retention of important concepts.*

Disturbed sensory perceptions

- Observe for withdrawal symptoms and watch closely for seizures. Monitor vital signs. Provide adequate nutrition and hydration. *These actions provide supportive physical care during detoxification.*
- Frequently assess level of orientation. Orient and reassure if hallucinations, delusions or illusions are being experienced.

NURSING CARE PLAN A person experiencing withdrawal from alcohol

George Russell, aged 58, fell at home and broke his right wrist. His wife took him to the emergency department (ED) where an open reduction internal fixation (ORIF) was performed. Extensive anaesthesia was required so he was admitted to the postoperative unit for observation.

He has a ruddy complexion and looks older than his stated age. He discloses that he lost his factory job two years ago and did only odd jobs until being hired last week by a local assembly plant. His father was recovering from alcoholism and his 30-year-old son has in the past been treated for alcohol misuse. Mr Russell believes alcoholism runs in the family, but feels that his drinking is under control; however, he cannot remember the events leading up to his fall, or how he might have broken his wrist.

ASSESSMENT

During the nursing assessment, Mr Russell is hesitant in providing information and refuses to make eye contact. The ED nurse had detected alcohol on his breath, and a pre-surgery assessment had registered his blood alcohol level as 0.40%. His vital signs are within the upper limits of normal, but he is confused and disoriented, with slurred speech and a slight tremor of the hands; he is 1.83 m tall and weighs 63 kg; his total albumin is 2.9 mg and he has elevated liver enzymes. His wife says that he rarely eats the meals she prepares; he is usually drinking and has no appetite for food.

DIAGNOSES

- *Ineffective individual coping* related to possible hereditary factor and personal vulnerability.
- *Risk of injury* related to aggressive behaviour, unsteady gait and impaired motor responses.
- *Ineffective denial* related to inability to recognise maladaptive behaviours caused by substance use.
- *Imbalanced nutrition*: *less than body requirements* related to anorexia manifested by decreased weight and low serum protein levels.

PLANNING

- Establish trusting relationship with Mr Russell and spend time with him discussing his feelings, fears and anxieties.
- Consult with a doctor regarding a schedule for medications during detoxification.
- Consult with a dietitian to determine a suitable diet to provide adequate nutrition and realistic weight gain. Consult with doctor to begin vitamin B_1 (thiamine) and dietary supplements.

Expected outcomes

- He will identify three adaptive coping mechanisms he can use as alternatives to alcohol in response to stress.
- He will verbalise the negative effects of alcohol and agree to seek professional help with his drinking.
- He will be free of injury as evidenced by steady gait and absence of subsequent falls.
- He will gain 0.45 kg per week without evidence of increased fluid retention. Serum albumin levels will return to normal range.

IMPLEMENTATION

- Observe for signs of withdrawal syndrome; medicate according to regimen. Provide softly lit, comfortable, supportive, safe environment.
- Document intake and output.
- Explain the effects of alcohol abuse on the body and emphasise that prognosis is closely associated with abstinence.
- Teach three relaxation techniques that Mr Russell feels are useful.
- Provide information about self-help groups and, if he is receptive, a list of meeting times and phone numbers.

EVALUATION

Mr Russell was discharged from the postoperative unit without complications. He successfully underwent detoxification and contacted the Employee Assistance Program at his new place of employment. He was on medical leave while his wrist completely healed, and now attends Alcoholics Anonymous meetings 5 days a week. He reports that he enjoys taking long walks with his wife in the warm weather, and his appetite has returned. He has gained 2 kg in the past 6 weeks and feels physically better than he has in many years.

CRITICAL THINKING IN THE NURSING PROCESS

1. Explain why it would be important during the initial nursing assessment to include questions about Mr Russell's medication history and his use of additional medications.
2. Mr Russell asks you to explain the risks of taking disulfiram (Antabuse). What should you tell him?
3. Develop a care plan for Mr Russell for the identified problem of *Imbalanced nutrition: less than body requirements*. Why is this necessary?

REFLECTION ON THE NURSING PROCESS

1. Mr Russell tells you he believes that alcoholism 'runs in the family'. What response do you make?
2. Mrs Russell tells you she noticed that her husband increased his alcohol consumption after his father, to whom he was very close, died suddenly. She asks, 'Could it have been the grief?'. What can you say to her?

- Explain all interventions before approaching a person withdrawing from alcohol. Avoid loud noises and talk softly. Decrease external stimuli by dimming lights. *Excessive stimuli increase agitation.*
- Administer prn medications according to detoxification schedule. *Benzodiazepines help to minimise the discomfort of the withdrawal symptoms.*

Disturbed thought processes

- Use simple, step-by-step instructions and face-to-face interaction when communicating. *A person withdrawing from alcohol may be confused or disoriented.*
- Express reasonable doubt if the person relays suspicious or paranoid beliefs. Reinforce accurate perception of people or situations. *It is important to communicate that you do not share the false belief as reality, without devaluing the emotional experience of the person.*
- Do not argue with delusions or hallucinations. Convey acceptance that the person believes a situation to be true (their perception), but that the nurse does not see or hear what is not there. *Arguing or denying the belief serves no useful purpose, because delusions are not eliminated.*
- Talk to a person withdrawing from alcohol about real events and real people. Respond to feelings and reassure them that they are safe from harm. Discussions that focus on the delusions may aggravate the condition. *Verbalisation of feelings in a non-threatening environment may help develop insight.*

Community-based care

The community provides many options for treating substance abuse, comprising a mixture of individual, group and family therapy. Specific treatment options include outpatient drug and alcohol counselling through facilities such as community health centres, outpatient detoxification, outreach services, day programs, youth-specific services and self-help groups: for example, Alcoholics Anonymous and Narcotics Anonymous. Community-based care allows people to deal with problems relating to such matters as relationships or parenting, employment, and training and education while still receiving support for substance use recovery. The range of options will depend on the particular mix of services available in each locality.

Teaching the substance user and family covers:

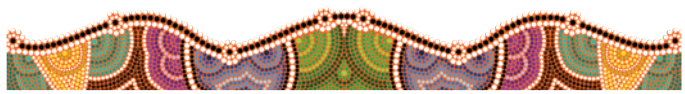
- the negative effects of substance abuse, including physical and psychological complications
- the signs of relapse, and the importance of after-care programs and self-help groups in preventing it
- information about specific medications that help to reduce the craving for alcohol (naltrexone) and maintain abstinence (disulfiram [Antabuse]), including the potential side effects, possible drug interactions, and any special precautions to be taken (e.g. avoiding over-the-counter medications such as cough syrup, which may have alcohol content)
- ways to manage stress, including techniques such as progressive muscle relaxation, abdominal breathing, mindfulness, meditation and effective coping skills.

In addition, suggest the following resources:

- Alcoholics Anonymous, Narcotics Anonymous and other self-help groups
- employee assistance programs
- individual, group and/or family counselling
- community rehabilitation programs.

CONSIDERATION FOR PRACTICE

People are at highest risk of relapse within the first few months after stopping the abused substance. Intense triggers and cravings are a normal, although difficult, feature of the earlier stages of recovery. An acronym which can assist in recognising behaviours that lead to relapse is HALT: hungry, angry, lonely and tired. Nurses should emphasise the importance in preventing relapse of a balanced diet, adequate sleep, healthy recreation activities and a caring support system.



IMPAIRED NURSES

Healthcare providers are as susceptible as anyone else to developing substance abuse; by the very nature of their roles, dentists, pharmacists, physicians and nurses are at higher risk than other professionals because of their high degree of accessibility to opioids (Trinkoff et al., 2000). One study exploring family history of alcohol and drug use in healthcare professionals found that nurses reported a higher prevalence of alcoholism than did dentists and physicians (Kenna & Wood, 2005). No significant differences, however, were found in healthcare professionals' drinking levels. Nurses experience many pressures in the workplace and have easy access to drugs; two factors—stronger religious practices and treatment for depressive symptoms—were associated with reduced substance abuse. Substance abuse and dependence can lead to impaired professional practice; nurses must act responsibly when co-workers display signs of substance abuse. Warning signs of impaired nurses in the workplace are listed in Table 5.9.

Impairment panels

The rules of the Nursing and Midwifery Board of Australia and the Nursing Council of New Zealand ensure that nurses and midwives whose ability to practise is impaired, due to factors such as mental or physical illness, or alcohol or drug use, are brought to the attention of the regulating body and assisted to overcome their problems before those problems develop to such an extent that the public are placed at risk. Programs generally provide a confidential and non-disciplinary alternative for handling impairment and the opportunity for nurses to agree to conditions being placed on their registration to enable them to continue to practise (Nurses and Midwives Board NSW, 2009).

TABLE 5.9 Warning signs of impaired nurses in the workplace

AT-RISK SITUATIONS	OBSERVABLE WARNING SIGNS
Easy access to prescription drugs	Inaccurate narcotic counts or frequent missing drugs People complain of ineffective pain control, deny receiving pain medication Excessive 'wasting' of drugs Volunteering to give medications to people Frequent trips to the bathroom
Role strain	Frequent tardiness or absenteeism, especially before and after scheduled days off Haphazard or inaccurate documentation Errors of judgment in nursing care Unorganised, erratic behaviour; unkempt appearance
Depression	Irritability, inability to focus or concentrate Abrupt mood swings Isolating self, taking long breaks Apathetic, depressed, lethargic Unexplained absences from assigned unit
Signs of alcohol or drug use	Smell of alcohol on breath Excessive use of perfumes, mouthwash or mints Slurred speech, flushed face, reddened eyes, unsteady gait
Signs of withdrawal	Tremors, restlessness, sweating Watery eyes, runny nose, stomach aches

CHAPTER HIGHLIGHTS

- Substance misuse is the unsanctioned use of any chemical despite adverse effects on the individual's physical, psychological, interpersonal or social health.
- Substance dependence occurs when control over the chemical substance is lost and the individual must use increasing amounts to produce the desired effect (tolerance), and must use the substance to avoid or relieve uncomfortable symptoms (withdrawal).
- Combinations of genetic, biological, psychological and sociocultural factors contribute to substance misuse or dependence. Addictive behaviour has been linked to biochemical changes in dopamine and serotonin brain levels, as well as heredity, ethnic differences and peer pressure. Thorough assessment of individual risk factors is necessary in order to plan and deliver appropriate nursing interventions.
- Adolescents are particularly influenced by society and peers to use substances: predominantly tobacco, alcohol and illicit drugs. A positive ethnic identity and family environment act as 'protective' deterrents for substance use.
- Substance misusers have common characteristics including risk-taking behaviour, low tolerance for frustration or pain, compulsive preoccupation with the substance, anxiety, anger and low self-esteem. Stress management, anger control, social support and counselling are helpful management strategies.
- While alcohol is the most commonly used and misused substance, polysubstance misuse frequently occurs: substances such as marijuana, cocaine and methamphetamine are often used in conjunction with alcohol. Prescription anti-anxiety agents have been misused in the past, and there is a growing trend towards prescription narcotic analgesic abuse.
- Nurses are susceptible to substance misuse because of pressures in the workplace and easy access to drugs. In order to avoid impaired professional practice, nurses need to assess their response to stress and seek early treatment for depressive symptoms.

CONCEPT CHECK

1 In which stage of change are people not considering a change in their drinking or drug-taking behaviour and frequently described as being 'in denial'?
   1 contemplation
   2 precontemplation
   3 preparation
   4 relapse

2 Which of the following are the *most* appropriate questions to ask in interviewing a person who you suspect has been abusing alcohol?
   1 'Typically, on how many days a week do you drink alcohol?'
   2 'Have you been drinking lately?'
   3 'You don't drink too much alcohol, do you?'
   4 'Has your drinking caused a lot of problems in your personal relationships?'

3 What is the rationale behind ordering thiamine (vitamin B_1) for a person with a history of chronic alcoholism?
1 to prevent acute pancreatitis
2 to prevent cirrhosis of the liver
3 to prevent hepatic encephalopathy
4 to prevent Wernicke's encephalopathy

4 Which of the following substances present the highest medical danger during withdrawal?
1 CNS stimulants and amphetamines
2 opioids and marijuana
3 alcohol and benzodiazepines
4 amphetamines and hallucinogens

5 What is the rationale for prescribing disulfiram (Antabuse) for someone with alcohol abuse problems?
1 to decrease the discomfort of withdrawal symptoms
2 to decrease the pleasant, reinforcing effects of alcohol
3 to prevent the breakdown of alcohol, thereby inhibiting impulsive drinking
4 to block the signs and symptoms of alcohol withdrawal

6 Which of the following is NOT a warning sign of substance abuse by a nurse?
1 impaired motor coordination, slurred speech, bloodshot eyes
2 unkempt appearance, disorganised, erratic behaviour
3 patients consistently report effective pain control
4 frequent absenteeism or tardiness, unexplained absences from the unit

7 Which of the following statements is FALSE?
1 Smoking is the leading known cause of preventable death and disease among women.
2 Smoking rates for women have steadily declined since the 1950s.
3 Women who smoke during pregnancy have a higher risk of spontaneous abortions.
4 Women who smoke have an increased risk of stroke and heart disease.

8 Which statement illustrates an understanding of quality use of prescribed benzodiazepines?
1 'I can take as many as I need to feel better.'
2 'It's okay to give some to my daughter if she is stressing about exams.'
3 'My new pills must be safe because my GP prescribed them.'
4 'I know why my pills were prescribed, how they work, possible side-effects and how to take them correctly.'

9 Which of the following is a realistic goal for people with a substance abuse problem?
1 They will identify ways to deal with stressful situations instead of resorting to substance use.
2 They will refrain from using substances until craving for the substance has been eliminated.
3 They will focus on negative aspects of past behaviours and interpersonal relationships.
4 They will be able to use alcohol or drugs in moderation.

10 All of the following are TRUE except:
1 People may use or abuse alcohol and other drugs because of an underlying and undiagnosed mental health problem.
2 Many drugs both legal and illegal can cause symptoms which suggest mental illness.
3 People who have become dependent on substances cannot ever change their behaviour.
4 MAST, B-DAST, COWS, AUDIT, CAGE and CIWA-Ar are all assessment tools used in alcohol and other drug work.

CHAPTER 6

NURSING CARE OF PEOPLE IN THE EMERGENCY DEPARTMENT OR EXPERIENCING DISASTERS

JOY LYNEHAM, JULIA MORPHET

LEARNING OUTCOMES

- Outline the role of the emergency department within the Australian healthcare system.
- Discuss the aims and purpose of the triage system.
- Outline the range of assessments conducted in the emergency department, including primary and secondary survey.
- Outline the processes of disaster planning, response and mitigation.
- Explain the scope of nursing practice in the emergency department.
- Define the meaning, types and classifications of disasters.
- Describe the common types of injuries or symptoms that are associated with a disaster.
- Identify ways that nurses are able to provide care to people with special considerations during a disaster.

CLINICAL COMPETENCIES

- Demonstrate a structured approach to assessment using a primary/secondary survey.
- Assess health status of people who have experienced unexpected health breakdown.
- Use evidence-based research to plan and implement nursing care for people with injuries suffered as a result of a disaster.
- Using assessment skills, determine priority nursing diagnoses, and implement and evaluate individualised nursing interventions for people experiencing disasters.
- Provide skilled nursing care to treat disaster-related injuries.
- Integrate interprofessional care with an understanding of local, state and federal systems of disaster response.
- Evaluate and revise plan of care and interventions based on the person's condition, environmental factors and resources to promote, maintain or restore functional health status to people who have sustained injuries.

KEY TERMS

The emergency department (ED) is a common pathway for admission to hospital. Accidents, sudden illness and exacerbation of chronic conditions are just a few of the reasons people present to an ED. The ED is unique in the hospital setting as, in reality, there are no limits on the type and number of patient presentations. People being cared for in the ED are usually considered unstable until they have a definite diagnosis.

Although all nurses will be expected to care for victims of disasters, whether they work in acute care settings, ambulatory sites, long-term care facilities or at home in their communities, the ED is usually where people experiencing disasters receive initial care. There is no way to know where or when a disaster may strike. Because of this, nurses must be prepared to assist individuals, families, friends, healthcare workers, first responders and communities in their recovery from disastrous events.

There are a number of basic competencies that nurses should be cognisant of related to disaster preparedness and management of people in the ED. This chapter provides an introduction to the concepts important to understanding the role and function of emergency nurses, both within the ED setting and in the disaster setting.

EMERGENCY NURSING IN AUSTRALIA

The ED is a unique and unpredictable practice setting, defined as 'a dedicated area in a hospital that is organised and administered to provide a high standard of emergency care to those in the community who perceive the need for or are in need of acute or urgent care including hospital admission' (Australian College for Emergency Medicine (ACEM), 2009, p. 2). In Australia and New Zealand, all residents are entitled to present to public hospital EDs for free emergency healthcare, and 40% of all hospital admissions come through the ED (Department of Health (Vic.), 2011).

The provision of quality emergency nursing care requires an extensive knowledge of body systems, disease processes, age groups, specialty populations, health promotion and education. Emergency nurses must be able to apply their knowledge and skills to care for people of all ages and populations, with a diversity of undiagnosed illnesses and injuries and a multitude of different presentations in clinical areas ranging from minor injury clinics through to the resuscitation cubicles and triage (College of Emergency Nursing (CENA), 2009; 2013).

Emergency nurses must also be skilled at assessment, triage, emergency preparedness, resuscitation and crisis intervention (CENA, 2013). The busy and variable nature of the ED means that communication and teamwork are also essential emergency nursing skills.

Communication

Emergency nurses play a fundamental role in the assessment, management and disposition (transfer to a hospital ward or discharge home) of people within the ED. Effective assessment and management of people in the ED is reliant on clear communication. **Communication** is the exchange of information between two or more people, groups or entities. It involves verbal and written exchanges, as well as body language, attitude and tone (Nadzam, 2009). Emergency nurses need to communicate with people in the ED and their families, nursing colleagues, and medical allied health and support staff. Appropriate communication facilitates safe and timely interventions, and appropriate dispatch of people from the ED to hospital wards or the community.

Visits to the ED are usually episodic and often distressing. Emergency nurses can support people by providing them with information and explanations regarding processes, health conditions and plans of care. Clear communication also allows the emergency nurse to provide education for the person on health promotion, illness prevention and access to relevant community services. 'Effective communication, which is timely, accurate, complete, unambiguous, and understood by the recipient, reduces errors and results in improved patient safety' (Victorian Quality Council, 2010, p. 3), as well as increasing patient satisfaction (Saunders, 2005). However, when effective communication is absent, care of the person is compromised: it has been reported that 20% of sentinel events in Australia were the result of communication failures (Victorian Quality Council, 2010), and that poor communication can increase ED length of stay (Sprivulis et al., 2006).

Communication between emergency nurses and other health professionals must be based on current, concise and timely information. The emergency nurse should be able to distinguish between urgent and non-urgent problems, and convey this information clearly. Emergency nurses should ensure they have assessed the person and read their notes, and should have the person's health history available when communicating with other members of the healthcare team (Curtis et al., 2009).

ISBAR (Identify, Situation, Background, Assessment, Request) is a tool that is used to help provide standardised structure to verbal communication both in the ED and in other clinical contexts to ensure timely, relevant and structured clinical handover, in line with the National Safety and Quality Health Service Standards (Australian Commission on Safety and Quality in Healthcare (ACSQH), 2012). ISBAR helps to prioritise information for both the transmitter (speaker) and the receiver. It decreases the chance of forgetting relevant information and helps to decrease assumptions by making the purpose of the communication obvious at the outset (Marshall et al., 2009). Table 6.1 provides examples of information that should be communicated within each step of the tool.

The triage system in the emergency department

In 2013–2014 there were 9.2 million presentations to Australian public hospital EDs (Australian Institute of Health and Welfare (AIHW), 2014, p.11), and 609 000 presentations to New Zealand EDs in 2011–2012 (New Zealand Ministry of Health, 2013). In light of the number and variety of people presenting to Australasian emergency departments, it is important that there are both appropriately skilled staff to care for people, and a system in place to prioritise care and ensure the most effective utilisation of resources.

Triage is the process by which all people presenting to an ED for care are assessed and their care prioritised according to

TABLE 6.1 ISBAR

	SEQUENCE	INFORMATION TO BE COMMUNICATED
I	Identify	Identify yourself—name, position, location. Identify the person you are speaking about.
S	Situation	Explain WHY you are calling. Provide the person's age, gender, current status (stable, unstable).
B	Background	Give the relevant details such as presenting problems and clinical history. Include aspects of history, examination, investigations and management where relevant.
A	Assessment	Outline your assessment of the person. State what you think is going on. Give your interpretation of the situation. Don't leave the receiver to guess what you are thinking—tell them. Stating the obvious is helpful here.
R	Request	State what you want from them. Be clear about what you are requesting (e.g. review, transfer) and how urgently your request should be addressed.

Source: Adapted from S. Marshall et al. (2009). The teaching of a structured tool improves the clarity and content of interprofessional clinical communication. *Quality and Safety in Health Care*, *18*, 137–140.

actual or potential severity of illness or injury; it is the first point of clinical contact for every person who presents to the ED in need of healthcare (ACEM, 2012; CENA, 2012). In Australasia, triage is a nursing responsibility, and ACEM guidelines indicate that EDs must have 'a nurse at triage . . . at all times' (2009, p. 2). The triage nurse must perform a rapid assessment on each person who presents to the ED, and, commensurate with their findings, allocate each person a triage category based on the Australasian Triage Scale (ATS) (ACEM, 2012; CENA, 2009). The ATS is a five-level priority scale which determines the time and sequence in which people receive care (CENA, 2012). As illustrated in Table 6.2, each triage category equates to a maximum time a person can wait before being reviewed by a medical officer. As such, the ATS categories indicate the level of clinical urgency for each person (ACEM, 2012), and ensure that resources are allocated according to need, resulting in the most critically ill people receiving the greatest resource allocation. ATS categories should be applied in response to the question: 'This patient should wait for medical assessment and treatment no longer than . . . [e.g. 10 minutes if an ATS category 2]' (ACEM, 2000, p. 1).

Triage is an autonomous role which should be undertaken by an experienced and appropriately prepared emergency nurse (CENA, 2009). The triage nurse has many responsibilities, including patient assessment and allocation of an ATS category, initiation of nursing interventions to improve patient outcomes (e.g. first aid), reassessment and management of people in the waiting room, and provision of education to people in the ED and their family members (CENA, 2009).

Triage decisions clearly affect a person's safety in determining the order in which people are seen. The Emergency Triage Education Kit (ETEK) was developed by the Australian government to provide consistent education to triage nurses (Department of Health and Ageing, 2007), thereby supporting consistency in triage decision making. Consistency in triage decision making means that a person should receive the same triage category regardless of the ED to which they present, or how busy the ED is when they arrive. Importantly, triage consistency ensures the appropriate utilisation of finite ED resources and optimal service delivery (CENA, 2009).

TABLE 6.2 Australasian Triage Scale

ATS CATEGORY	TREATMENT ACUITY (MAXIMUM WAITING TIME)	PERFORMANCE INDICATOR THRESHOLD
ATS 1	Immediate	100%
ATS 2	10 minutes	80%
ATS 3	30 minutes	75%
ATS 4	60 minutes	70%
ATS 5	120 minutes	70%

Disaster triage

Civilian disasters also require a triage system to support the allocation of resources: however, this triage system is quite different from the ATS. While the ATS aims to ensure that the sickest people receive the most resources, disaster triage aims to 'do the most for the most' (Mackway-Jones, 2011, p. 91). In disaster settings, decisions are made to allocate resources only to those who are likely to survive, rather than allocate valuable resources such as blood products or a surgeon's time on those unlikely to survive. In disaster triage, the focus is not what is best for individuals, but what is best for the community.

As resources are often limited, disaster triage relies upon the use of colours to reflect triage categories. Table 6.3 illustrates the disaster triage system used in Australasia.

Patient assessment in the emergency department

Primary survey

As people presenting to the ED are largely an undiagnosed population, assessment is focused on recognition of symptoms rather than disease processes. Assessment in emergency nursing is systematic,

TABLE 6.3 Disaster triage system, by category

TRIAGE CATEGORY	LEVEL OF URGENCY	DESCRIPTION	COLOUR
T1	Immediate priority	Casualties who require immediate life-saving procedures	Red
T2	Urgent priority	Casualties who require surgical or medical intervention within 2–4 hours	Yellow
T3	Delayed priority	Less serious cases whose treatment can safely be delayed beyond 4 hours	Green
T4	Expectant priority	Casualties whose condition is so severe that they cannot survive despite the best available care and whose treatment would divert medical resources from salvageable people who may then be compromised	Blue
Dead	N/A	Deceased casualties	White or black

Source: Adapted from K. Mackway-Jones (ed.) (2011). *Emergency triage*, (Ch. 15). Manchester: Wiley-Blackwell.

and is guided by the *primary survey*, *secondary survey* and a *focused assessment*. The National Safety and Quality Health Service Standards identify the importance of recognition and response to clinical deterioration (ACSQH, 2012). Failure to identify that a person is deteriorating can have serious consequences, and this structured approach to assessment reduces the risk that signs or symptoms of illness are missed. The **primary survey** identifies life-threatening illnesses or conditions, and follows the ABCDE mnemonic (see Table 6.4) (Higginson, Jones & Davies, 2011). The ABCDE mnemonic is designed to aid the nurse in identifying actual or potential threats to airway, breathing, circulation, disability (i.e. neurological status) and exposure. Life-threatening illness or injury must be treated prior to continuing with the assessment (Resuscitation Council (UK), 2005). For example, if the airway is not patent, the nurse should intervene to ensure airway patency before moving on to assess breathing. It is also important that these findings are reported to senior nursing and medical staff.

Airway assessment is the first step in the primary survey. The ED nurse will assess the airway for patency. Common causes of airway obstruction include foreign bodies, vomit or the person's tongue (Higginson, Jones, & Davies, 2010). Signs of obstructed airway include audible stridor, gurgling, wheezing or snoring (Higginson et al., 2011), a hoarse voice or drooling. If a person is talking, it can be concluded that their airway is patent. If a person has an obstructed airway, the nurse should call for help, then intervene by performing a head tilt/chin lift or jaw thrust (Australian Resuscitation Council, 2010). The head tilt/chin lift can move the tongue from the pharynx, thus opening the airway (Higginson et al., 2011).

TABLE 6.4 Primary survey mnemonic

PRIMARY SURVEY MNEMONIC		EXAMPLES OF DOCUMENTATION
A	Airway	Patent/stridor/drooling etc.
B	Breathing	Respiration rate, work of breathing, SpO_2
C	Circulation	Heart rate, strength and regularity, blood pressure, skin colour and temperature
D	Disability	Glasgow Coma Scale, temperature, blood sugar level
E	Exposure	Head to toe identifying abnormalities

If cervical injury is suspected, a jaw lift is preferred, as there is less risk of cervical spine movement (Higginson et al., 2011). The use of suction can also remove many obstructions if performed correctly (Higginson et al., 2011).

When the airway is patent, the nurse can assess breathing. This will include looking and feeling for rise and fall of the chest, and listening for air entry. The ED nurse will observe the work of breathing, including the use of accessory muscles during respiration, patient positioning, respiratory rate and chest symmetry. If the person is breathing, the ED nurse may decide to initiate some oxygen therapy (Higginson et al., 2011) (e.g. to improve oxygenation in response to observed increased work of breathing or tachypnoea), before moving on to assess circulation.

Assessing circulation entails feeling for rate, strength and regularity of pulse, checking blood pressure, and looking for sources of uncontrolled haemorrhage. If circulation is intact, the ED nurse can assess for disability. This includes assessment of neurological status using the Glasgow Coma Scale (GCS) (see Chapter 40 for a description of the GCS), and assessment of pain. Pain can be assessed using a numerical rating scale (e.g. 0–10) or a visual analogue scale (horizontal or vertical lines on a continuum of increasing pain). Refer to Chapter 8 for more information about pain assessment.

In the person with a GCS less than 13 (or two points less than their normal), the emergency nurse may also measure the person's blood glucose level (BGL). Alterations to BGL can affect neurological status, with some people presenting unconscious or with signs similar to those of a stroke. The nurse can check for exposure by removing the person's clothing and performing a thorough examination. If appropriate, the nurse may insert a urinary catheter to facilitate measuring response to fluid resuscitation. The primary survey is completed with an assessment of temperature and the initiation of treatments to minimise hypothermia.

Secondary survey

After the primary survey is complete, and any life-threatening findings addressed, the secondary survey can commence. The **secondary survey** is a brief but thorough head-to-toe examination which aims to detect all signs and symptoms of illness or injury, with an emphasis on the need for continued reassessment of the person and evaluation of their response to interventions (CENA, 2011). The head-to-toe examination should include visual inspection, palpation and auscultation of the person's

anterior and posterior body surfaces, looking for abnormalities. Many actions occur simultaneously during the assessment and, while performing the head-to-toe physical assessment, the emergency nurse should also be gathering the person's health history.

Focused assessment

Following the primary and secondary survey, the emergency nurse should undertake a focused assessment of the body system or region of concern, as identified by the signs and symptoms or mechanism of injury (Curtis et al., 2009). The **focused assessment** should help to identify specific issues and guide treatment. For example, a person who presents with a painful wrist following a fall would be assessed for threats to ABCDE, have a secondary assessment, including collection of health history, followed by a focused assessment of the distal limb (Curtis et al., 2009). A mental health assessment may be undertaken as part of the focused assessment if relevant (see Chapter 50).

Once the person has been thoroughly assessed, any concerns—sometimes referred to as 'red flags' (Curtis et al., 2009)—must be identified, reported (using ISBAR) and documented. Abnormal vital signs, symptoms of a time-critical illness (e.g. acute myocardial infarction (AMI), stroke or envenomation), or a high-risk medical history (e.g. renal failure in a person with confusion), are all concerns which may be of threat to the person's life or limb.

HEALTH HISTORY The health history can be collected by asking questions of the person admitted to the ED and their carer/next of kin during the physical assessment. The health history should include the presenting problem and associated symptoms, the mechanism of injury (i.e. how the injury occurred), if relevant, current treatment for the presenting problem, relevant past medical and surgical history, medications, known allergies, immunisation status, family history and a social history (CENA, 2011; Curtis et al., 2009).

INVESTIGATIONS Investigations assist in diagnosis of illness and injury, and subsequent development of a definitive plan of care for the person. Investigations can assist in the identification of people who are sick or have complex needs. It is important that emergency nurses understand the rationale for ordering specific investigations and the significance of each result, so that they understand the rationale for further management of the person. Many EDs in Australia and internationally (Innes et al., 2015) have introduced protocols to allow emergency nurses to initiate investigations such as ordering pathology and distal limb x-rays. Nurse-initiated investigations have been shown to reduce length of stay in the ED (Innes et al., 2015).

REASSESSMENT Following each intervention, an important responsibility of the emergency nurse is the reassessment of the person (Curtis et al., 2009). The purpose of reassessment is two-fold: (i) to ascertain if the intervention was effective, and (ii) to establish if there are any undesired effects from the intervention. For example, a person who is hypotensive may be given a fluid bolus to improve blood pressure. Following the fluid bolus, the emergency nurse should reassess the person's heart rate and blood pressure to determine whether the intervention has achieved its purpose. The emergency nurse should also consider the undesired effect of a fluid bolus in some people (fluid overload), and assess for signs of this (i.e. assess work of breathing and listen to breath sounds).

DOCUMENTATION It is important in all areas of healthcare provision that each person's assessment findings and interventions are documented, and this is also true in the ED. Australasian EDs are moving towards a paperless environment, and for many emergency nurses documentation from triage through to discharge is all computer-based. In the ED, nursing documentation will include the person's health history, nursing assessment and vital signs, interventions (including drugs and fluids administered), reassessment, and reporting of findings (CENA, 2011).

The scope of nursing practice in the emergency department

The scope of practice for Australasian emergency nurses is broad and highly specialised. Unlike nurses in most ward settings, emergency nurses care for people across the lifespan, delivering newborns, managing unwell children and adults, and providing end-of-life care. The problems that people may present with also vary, from those with minor injuries to the critically ill. As a result, Australasian emergency nurses need to have excellent critical thinking and clinical reasoning skills, as well as an extensive clinical skill set. Emergency nurses need to consolidate the person's health history with assessment findings to determine appropriate nursing interventions and the degree of urgency with which interventions must occur.

Emergency nursing skills in Australasian EDs include the ability to provide simple first aid at triage; insert IV cannulae and draw blood; select and apply appropriate wound dressings; apply plaster backslabs and splints to support injured limbs; close simple wounds using sutures; and provide appropriate oxygen delivery to people who are short of breath. As well as these clinical skills, emergency nurses have many advanced practice roles, including the collection and systematic interpretation of 12-lead electrocardiograms, haemodynamic monitoring and management of the intubated person. Emergency nurses require a practical understanding of ventilation, with studies revealing that Australian emergency nurses are responsible for the initial and ongoing selection of ventilator settings using both non-invasive positive pressure ventilation and mechanical ventilation (Rose & Gerdtz, 2009a; 2009b), for both adult and paediatric patients.

As they are likely to care for people with a variety of illnesses, it is essential that emergency nurses possess considerable pharmacological knowledge. Pain is the most common presenting complaint in the ED, and many Australian EDs have introduced policies allowing emergency nurses to initiate oral analgesia (Shaban et al., 2012), including Schedule 8 drugs, for people in pain.

Nurses have a central role in the timely discharge of people from the ED. Consistent triage decisions, nurse-initiated analgesia, timely assessment, nurse-initiated investigations, and recognition and reporting of abnormal findings all contribute to a rapid ED journey and achieving the national throughput targets. Communication of each person's requirements and plans of

care facilitates the timely allocation of a hospital ward bed, or the arrival of family to transport the person home.

Emergency Nurse Practitioners

Many Australian EDs also have Nurse Practitioners working in the ED team. Nurse Practitioners have completed formal education beyond that of the Registered Nurse, allowing them to work in an advanced practice role, making independent and collaborative decisions about people's healthcare needs. The scope of the Nurse Practitioner includes ordering investigations, diagnosis of illness, prescribing medications and referral of people to specialists as required (CENA, 2006; Middleton et al., 2011; Nursing and Midwifery Board of Australia (NMBA), 2014).

People with unique needs in the emergency department

Emergency departments cater for a broad range of people, all with unique healthcare needs. However, some groups are recognised as collectively having specific needs that impact on clinical presentation, resource allocation, clinician experience and education requirements, and their equipment and environmental needs. These groups include those in the community who are more vulnerable, such as children, the elderly, people with an aural or visual impairment, people with a mental illness and victims of violence. Other people with unique needs include obstetric patients, Aboriginal and Torres Strait Islander and Maori people, and people who are culturally and linguistically diverse. Emergency nurses are encouraged to consider the unique health needs of all people presenting to the ED and to address each person's needs in a culturally safe way.

DISASTER NURSING

Definition

The World Health Organization (2015a) defines a **disaster** as:

1. A serious disruption of the functioning of a community or a society causing widespread human, material, economic or environmental losses which exceed the ability of the affected community or society to cope using its own resources (International Strategy for Disaster Reduction (ISDR)).
2. [A] Situation or event, which overwhelms local capacity, necessitating a request to national or international level for external assistance (Center for Research on the Epidemiology of Disasters (CRED)).
3. A term describing an event that can be defined spatially and geographically, but that demands observation to produce evidence. It implies the interaction of an external stressor with a human community and it carries the implicit concept of non-manageability. The term is used in the entire range of risk-reduction activities, but it is possibly the least appropriate for response.

For a disaster to be declared, CRED (2015) states that at least one of the following must be fulfilled:

- ten or more people reported killed
- one hundred or more people reported affected
- declaration of a state of emergency
- call for international assistance.

Emergency Management Australia's *Emergency Glossary* (1998) states that in Australia a disaster is recorded when at least one of the following occurs:

- three or more deaths
- 20 injuries or illnesses
- significant damage to property, infrastructure, agriculture or the environment; or disruption to essential services, commerce or industry at an estimated total cost of A$10 million or more at the time the event occurred.

Types of disasters

In the past, disasters were simply categorised as **natural** or **man-made** (technological), accidental or intentional. As there are more events than fit these definitions, the categories for disasters have been significantly expanded (see Table 6.5). Acts of terrorism are not contained within the new classification.

TABLE 6.5 Classification of disasters

DISASTER GROUP	SUBGROUP	MAIN TYPE
Natural	Geophysical	Earthquake
		Mass movement
		Volcanic activity
	Meteorological	Extreme temperature
		Fog
		Storm
	Hydrological	Flood
		Landslide
		Wave action
	Climatological	Drought
		Glacial lake outburst
		Wildfire
	Biological	Epidemic
		Insect infestation
		Animal accident
	Extraterrestrial	Impact
		Space weather
Technological	Industrial accident	Chemical spill
		Collapse
		Explosion
		Fire
		Gas leak
		Poisoning
		Radiation
		Other
	Transport accident	Air
		Road
		Rail
		Water
	Miscellaneous accident	Collapse
		Explosion
		Fire
		Other

Source: EM-DAT (2015c).

In recent history the Asia–Pacific basin has been affected by a number of significant natural disasters, resulting in 119 disaster events, 6050 deaths and 79.6 million people affected. In Australia in 2015 the Western Australian wildfire (see Figure 6.1) and the New South Wales storm event (see Figure 6.2) resulted in significant losses. The storm resulted in three deaths and 5890 people affected and the wildfires resulted in one death, 450 people affected and 29 homes lost (EM-DAT, 2015b).

Disasters can be unintentional, such as a campfire that has been left unattended and creates a massive bushfire. This is an example of an accidental man-made disaster. Intentional disasters occur when harm and/or destruction is the primary aim of the perpetrators. Most disasters result in the destruction of property, loss of life and/or injury to person.

The potential for a disaster exists at any time when hazardous materials are involved as, by their nature, they pose a potential risk to life, health or property if they are released, due to their chemical, biological or physical nature. The hazard exists during any stage of use, from the production and storage of these substances to their transportation, use or disposal. Hazardous materials are often involved in acts of terrorism.

Terrorism

Terrorism is not a modern concept; the earliest recorded acts of terrorism are seen throughout the New Testament of the Holy Bible where the Zealots of Judea waged a campaign against the Romans to free Judea from foreign rule. In Australia **terrorism**. is defined in the Commonwealth *Criminal Code Act 1995*, Part 5.3, Division 100:

> *Terrorist act means an action or threat of action where:*
>
> *a. The action is done or the threat is made with the intention of advancing a political, religious or ideological cause; and*
> *b. The action is done or the threat is made with the intention of:*
> *i. Coercing, or influencing by intimidation, the government of the Commonwealth or a State, Territory or foreign country, or of part of a State, Territory or foreign country; or*
> *ii. Intimidating the public or a section of the public.*
>
> *A terrorist group commits acts of violence to:*
>
> - *produce widespread fear*
> - *obtain worldwide, national or local recognition for their cause by attracting the attention of the media*
> - *harass, weaken or embarrass government security forces so that the government overreacts and appears repressive*
> - *steal or extort money and equipment, especially weapons and ammunition vital to the operation of their group*
> - *destroy facilities or disrupt lines of communication in order to create doubt that the government can provide for and protect its citizens*
> - *discourage foreign investments, tourism or assistance programs that can affect the target country's economy and support of the government in power*
> - *influence governmental decisions, legislation or other critical decisions*
> - *free prisoners*
> - *satisfy vengeance*
> - *turn the tide in a guerrilla war by forcing government security forces to concentrate their efforts in urban areas. This allows the terrorist group to establish itself among the local populace in rural areas.* (Terrorism Research, 2012, para. 5)

Terrorists use both conventional (e.g. bombs, guns) and non-conventional (e.g. chemical, biological and nuclear) means to achieve their end. A terrorist strike is not usually predictable. Government counter-terrorism efforts use surveillance with the aim of preventing or minimising danger to the public; however, there have been situations when surveillance information was not analysed correctly or not passed on to the relevant authorities. Surveillance relates to the collection and analysis of data to determine a change or significant trend in a group (Bradt, Bartley, Hibble, & Varshney, 2015). The goal of the surveillance system is to determine the status of the public's health and detect any sudden change in that status.

Healthcare providers have become a necessary component of terrorism surveillance, especially with biologically based agents. A disaster preparedness plan that outlines the protocol and procedures to be taken with a suspected bioterrorism attack, as well as the response to mass casualty incidents,

should be established in every healthcare facility. Most countries have a central or federal disaster plan; for example, COMDISPLAN 2014 (Australia) and National Civil Defence Emergency Management Plan Order 2015 (New Zealand).

Common disaster-related injuries and related symptoms

Natural disasters

Tsunami can bring water waves travelling more than 800 kph and *cyclones* have winds of up to 200 kph and flooding rains. Most deaths from tsunami and cyclones occur as a result of drowning, collapsed buildings or flying debris which becomes lethal in high winds (Queensland Disaster Management, 2012).

Thunderstorms bring the risk of a lightning strike. The short duration of a lightning strike results in a very short flow of current internally, despite the high voltage of lightning. However, the longer the duration of contact with high-voltage current, the greater the potential for tissue destruction. The greatest conductors of electrical current in the body are the nerves, muscles and blood vessels, which have a high electrolyte and water content. High resistors to electric current are bones, tendons and fat, due to their tendency to heat up and coagulate instead of transmitting current. Much of the energy current may be dissipated at the skin surface, resulting in significant surface burns (Talley & O'Connor, 2013; Thomson & Howard, 2013).

Floods, most commonly caused by heavy rainfall in Australia, can spread over thousands of square kilometres causing injury and destruction. Most flood-related deaths result when people attempt to drive, walk, swim or play in flood waters as the depth and current are easily misjudged.

Bushfires (or wildfires) are a common occurrence in Australia and, with a combination of high temperatures, high winds and dry but plentiful vegetation, can be lethal. The warning system includes a 'Catastrophic alert' category (Code Red) (Australian Government Bureau of Meteorology, 2015). Fire-related injuries include burns, smoke inhalation and toxic fume poisoning, the last being the most common.

Earthquakes have a high incidence of mortality and morbidity due to the multiple injury modalities, as seen in Christchurch in February 2011. The most common health effects experienced by victims of earthquakes include stress-related symptoms; wounds; bone, joint and muscle injuries; burns from explosions; clean-up injuries; gastrointestinal and respiratory problems; aggravation of chronic illnesses; obstetric complications; and death (Lu-Ping et al., 2012). Countries such as New Zealand and Japan are prone to earthquakes as they are situated on the boundaries of two constantly moving tectonic plates which move, causing frequent quakes. The incidence of earthquakes in Australia is low, as it is sitting on a single tectonic plate.

Technological injuries

Explosive or blast injuries are the result of explosive munitions, often involving car or package bombs. Care for people injured by blast injuries typically focuses on abdominal and lung injuries, penetrating wounds, traumatic amputations and burns. The level of injury depends on how close the victim was to the epicentre of the blast. More complex are injuries from dirty bombs, which contain a conventional explosive packed with radioactive waste by-products. When detonated, deadly radioactive particles are released into the environment, spreading in the wind like a dust cloud. In this way, dirty bombs reach far wider areas than the initial explosion (Gaillard, Regenstreif & Fanton, 2014) and cause long-term effects as a result of radiation exposure changing cellular DNA. These changes can result in either cell/organ death or malignant changes within an organ.

Thermal burns are the most common mechanism resulting in injury and death associated with nuclear detonation. Thermal burn injuries can be severe and are treated like any other burn. Radiation suppresses the immune system, so special care must be taken to reduce the potential infection often associated with full-thickness burns (Christensen et al., 2014). More information on burn care can be found in Chapter 16.

DISASTER PLANNING, RESPONSE AND MITIGATION

Disaster planning and risk reduction in Australia is informed by the World Health Organization (WHO) Sendai Framework for Disaster Risk Reduction 2015–2030, the outcomes of which are stated as:

> *The substantial reduction of disaster risk and losses in lives, livelihoods and health and in the economic, physical, social, cultural and environmental assets of persons, businesses, communities and countries.* (WHO, 2015b, p. 12)

Disaster preparedness has been a priority issue for the Australian government. There are federal and state disaster plans which involve defence forces, public health services, State Emergency Services, police, and fire and ambulance services. The main federal coordinating bodies are the Emergency Management Australia (EMA) and the Australian Disaster Information Network (ADIN). There are disaster plans in each Australian state and the Commonwealth Government Disaster Response Plan (COMDISPLAN) (Emergency Management Australia (EMA), 2014) is the framework for states and territories to request Commonwealth assistance arising from any type of emergency.

EMA has created detailed manuals containing information about emergency management, such as *Aspects of Chemical, Biological and Radiological Hazards* (EMA, 2000) and *Flood Preparedness* (Australian Attorney-General's Department, 2009). These guides are a resource for individuals and families to form a disaster plan.

In addition, the handbook *Disaster Health* (Australian Emergency Management Institute, 2011) is another invaluable source for Australasian nurses.

Stages and phases of a disaster

Warfield (2015) outlines the *goals of disaster management* as follows:

1. Reduce, or avoid, losses from hazards.
2. Assure prompt assistance to victims.
3. Achieve rapid and effective recovery.

There are four disaster management phases to achieve the above goals. The length of each phase greatly depends on the severity of the disaster.

1. *Mitigation*: reducing the effects of disaster
2. *Preparedness*: preparing and planning a response in advance
3. *Response*: putting the plans into action so that hazards are minimised and the needs of the victims met
4. *Recovery*: restoration of the community to a pre-disaster functional level.

Mitigation occurs when actions are taken that eliminate or reduce the chance of a disaster happening or reduce the effects of an unavoidable disaster. Information such as countermeasures and emergency risk are critical for mitigation to be successful. Appropriate building codes, vulnerability analyses and public education all contribute to mitigation.

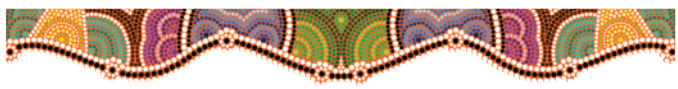
Preparedness is having a comprehensive disaster plan in place that coordinates the efforts of public and private organisations such as the State Emergency Services, the military and all levels of government. Each organisation has specific roles and is able to mobilise quickly and effectively. This level of readiness enables a community to respond to any emergency situation.

The plan will be based on familiarity with possible disaster agents based on previous experiences, as well as experiences of others from various regions and countries. It is imperative that all people and agencies who may be involved in the disaster response be involved in the planning. In this way, information is shared and representatives from each agency explain and offer their respective resources and expertise and note deficiencies in the plan. Planning committees will exist on all levels—federal, regional, state, local and individual agency. Nurses participate in this facet of disaster planning by having a nurse representative on the planning committee at least at the agency level.

Response to disasters happens in the emergency stage and after the disaster event has occurred. The purpose of the emergency response is to act to maintain life, maintain health and evaluate and respond to the psychological needs of the affected community. The community has been rapidly assessed for damage, and the types and extent of injuries suffered, as well as the immediate needs of the community, have been determined. Hospital disaster planners must plan for the possibility that the next disaster may involve the hospital. The hospital's response may include the evacuation of people receiving care as well as relocating and operating from an independent facility. Surge capacity is the healthcare system's ability to rapidly expand beyond normal services to meet the increased demand for qualified personnel, medical care and public health in the event of a large-scale disaster. The aims of the Australian Government Department of Health and Ageing (2011) *National Health Emergency Response Arrangements* (2011) are to:

- outline the strategic authorities, responsibilities, arrangements and the mechanisms that enable a coordinated national health sector response to emergencies of national consequence;
- inform and guide a coordinated Australian health sector response to, and recovery from, emergencies of national consequence; and
- provide a strategic planning framework for guidance to the future revisions of existing health sector emergency plans.

Recovery is the final phase and, as the word implies, it is the period when the emergency is under control and the community starts to rebuild. In this phase the resources established in the disaster plan may be put into action. The recovery depends on the ability of the resources to meet the needs of the community affected. In many disasters the available resources need to be supplemented by government and aid agencies. There is no distinct point at which immediate relief changes into recovery and then into long-term sustainable development. There is no set period for the recovery phase; this phase depends on the type of disaster. It can take years for a community to recover; some never return to their pre disaster state.



Nursing care

The role of the nurse in a disaster

Disaster nursing is a relatively new discipline internationally; however, it should be remembered that nurses have been on the front line of wars and disasters for over a century. The International Red Cross has deployed nurses to conflict zones since 1919. The World Association for Disaster and Emergency Medicine (WADEM), an international multidisciplinary organisation, established a nursing chapter in 2004. The role of nurses in a disaster situation in Australia is not clearly defined but depends greatly on a number of variables, including the nature of the disaster; the number of victims and severity of injuries; the location of the disaster and of the nurse; and the availability of supplies, rescue and command personnel, and other necessary resources. The nurse must be able to perform under stressful conditions but will not be expected to endanger self, other nurses or other rescuers. It is important to remember that during a disaster access to normal services such as transport, communication, interpreters, food and water, and even medical care is going to be disrupted and at times not available. In addition, your colleagues may not react or respond to the disaster as you might expect.

The emergency nurse may be involved in first-line response (i.e. attending the disaster site) or be responsible for individuals attending the ED for stabilisation. All Australian hospitals have a disaster plan and increasingly these are put to the test.

Nurses may have to assume expanded roles in making decisions for the most appropriate treatment of casualties. Discussions should take place among doctors, nurses and policy makers regarding the necessity of nurses' expanded roles in crisis situations. Additionally, healthcare personnel should receive specialised training in order to be safe and competent practitioners of the expanded duties. This training must be practised and updated and those participating in the training

BOX 6.1 Key triage points to remember in mass casualty management

- Use a triage system that is easy to learn, easy to implement in stressful conditions and does not require advanced diagnostic skills yet allows for basic interventions.
- Use the Incident Management System on every incident and wear personnel identification vests.
- Get accurate preliminary and final headcounts and relay this information to the incident commander.
- Use some type of visual colour-coded identification system to indicate each person's priority.
- Do not fall into the trap of using your time by providing one-to-one care.
- Re-triage individuals frequently, at the incident, on arrival at the treatment area and periodically thereafter.
- Make certain the 'walking-wounded' are gathered and treated.
- Pre-plan for potential incidents that may occur.
- Be aware that emergency responders may be potential targets.
- Practise, practise, practise.

Source: Adapted from Prehospital triage by M.R. Streger (1998) in *Emergency Medical Services, 21*(6), 23–27, 45.

must be tracked and notified of additional requirements as necessary. Nurses take on a variety of roles based on their expertise and the needs of the victims. Nurses will be expected to follow the emergency preparedness plans outlined in their communities and in their agencies of employment. It is critical that nurses work within their scope of practice, as victims of a disaster will present with a variety of individualised needs including anxiety, impaired verbal communication, ineffective or impaired coping, fear, post-trauma syndrome, powerlessness, injury and trauma.

Mass casualty management

During a disaster, nurses may be expected to triage victims. The nature of triage can change depending on the type of disaster and the number of victims; however, the system described in Table 6.3 is initially used. When the number of casualties is around 100, then **reverse triage** may be instigated; that is, those with the best chance of survival are transported first (Lerner et al., 2015). Many emergency personnel will share the difficulty of making these decisions at disaster sites when the first inclination might be to rescue the most severely injured. Box 6.1 shows key triage points to remember.

Isolation and personal protective equipment

People suspected of having a highly contagious disease, such as H2N2 influenza, will need to be isolated to prevent spread of the disease to others. Airborne protection can be achieved with negative-pressure ventilation. All people entering the room should wear personal respiratory protective devices capable of filtering submicron particles. Decontamination of the air may be achieved through ventilation and supplemented by ultraviolet light (Heymann, 2004).

Gas masks are used in a broad range of military, industrial and emergency situations to protect the user from hazardous dust, gas or other aerosols. Biological contaminants that are spread through aerosolised droplets create a threat to those not wearing personal protective equipment (PPE). A gas mask may be considered a high-performance respirator and is usually equipped with both eye protection and air supply protection or treatment. Protective clothing is made to guard against mild irritants and even serious lethal materials. Some protective suits are disposable, intended for one use only. Others are durable, multilayered fabrics that are completely impermeable and are reusable. Each state disaster plan has issued guidelines to inform healthcare workers and first responders about the correct level of PPE for various situations (Australian Radiation Protection and Nuclear Safety Agency, 2014).

The recommendations by the US Environmental Protection Agency (EPA) (2015) for personal protection clothing are listed in Box 6.2.

In addition to the isolation of individuals, special air handling systems are used in the isolation rooms to prevent the spread of the contaminated droplets into the general hospital air vents. Many hospitals have the capability to shut off airflow in contaminated areas to prevent the spread of contaminants to other 'clean' areas of the hospital. The heating, ventilation, air conditioning and refrigeration (HVAC) systems are closely monitored and can be shut down in designated areas to avoid air intake from the outside as well, especially in cases of outdoor environmental contamination.

Recording victim data

Each health area has a trauma sheet to record data about victims of disasters. The categories on the data sheet include demographics, circumstances of the injury, injury conditions, and disposition and details of the conditions. The completion of this form will be initiated by the triage nurse and completed by the nurse who implements the treatment or transfers the injured person to another unit/department.

Psychosocial needs

The importance of mental health services for victims, the public, first responders and healthcare workers cannot be overstated in both emergency and disaster situations. People react to disasters in a variety of ways, both physically and behaviourally. Their reactions depend on the severity of their injuries, real and perceived threat and their proximity to the area of direct impact. The closer the person is to the area of impact and the longer the exposure, the greater the likelihood of a more severe reaction to the event.

BOX 6.2 EPA levels of protective clothing

Level A protection is required when the greatest potential for exposure to hazards exists and when the greatest level of skin, respiratory and eye protection is required. Examples of Level A clothing and equipment include:

- positive-pressure, full-face-piece self-contained breathing apparatus (SCBA) or positive-pressure supplied-air respirator with escape SCBA
- totally encapsulated chemical- and vapour-protective suit
- inner and outer chemical-resistant gloves
- disposable protective suit, gloves and boots.

Level B protection is required under circumstances requiring the highest level of respiratory protection, with lesser level of skin protection. Examples of Level B protection include:

- positive-pressure, full-face-piece self-contained breathing apparatus (SCBA) or positive-pressure supplied-air respirator with escape SCBA
- inner and outer chemical-resistant gloves
- face shield
- hooded chemical-resistant clothing
- coveralls
- outer chemical-resistant boots.

Level C protection is required when the concentration and type of airborne substances is known and the criteria for using air-purifying respirators is met. Typical Level C equipment includes:

- full-face air-purifying respirators
- inner and outer chemical-resistant gloves
- hard hat
- escape mask
- disposable chemical-resistant outer boots.

Level D protection is the minimum protection required. Level D protection may be sufficient when no contaminants are present or work operations preclude splashes, immersion or the potential for unexpected inhalation or contact with hazardous levels of chemicals. Appropriate Level D protective equipment may include:

- gloves
- coveralls
- safety glasses
- face shield
- chemical-resistant, steel-toe boots or shoes.

Source: US Environmental Protection Agency (EPA) (2015). *Personal Protection Clothing.* www2.epa.gov/emergency-response/personal-protective-equipment.

Table 6.6 summarises the normal initial responses aimed at survival (Murray, Zentner & Yakimo, 2008; Selye, 1965; 1980; Wilson & Raphael, 2013).

Special considerations

Disasters are not selective in their victims; anyone in the target zone will be affected: young, old impaired or healthy. As in most emergency situations the very young and old are likely to be more vulnerable. Issues such as limited mobility and access to resources can impact on the younger and older person's ability to react to the crisis. The notion of community becomes important. Community knowledge, such as knowing where older people or young families live in your area, can help first responders to assist these victims and evacuate them to safety. When injured, the older person may have fewer physiological reserves due to the ageing process, and their chances of full recovery are reduced in accordance with the amount of time it takes to be rescued. The very young are dependent for all basic needs and have limited physiological reserves. If separated from their carer they risk further harm. Therefore, restoring a carer's role is critical.

TABLE 6.6 Responses to stress: General Adaptation Syndrome (GAS) and levels of anxiety

GAS STAGE	PHYSICAL RESPONSE	BEHAVIOURS RELATED TO ANXIETY
Alarm stage	Pupils dilate; blurred vision. Hearing sharper or diminished.	Misinterpret stimuli. Confusion. Poor concentration. Selective inattention. Need for assistance.
Severe anxiety or panic	Stronger, faster heart rate and respirations. Palpitations, arrhythmias, elevated blood pressure.	Feeling of impending doom. Terror. Fearful. Agitation Irritability. Demanding. Impulsive. Paraesthesias.
	Muscle tone increased. Headaches.	Muscle tension. Excitable, restless movements. Tremors. Rigidity. Weakness.
	Basal metabolism rate increased. Body temperature elevated. Perspiration. Altered glucose, protein and lipid metabolism. Increased startle response.	Insomnia. Urgency of speech and movement. Fatigue. Dehydration. Weight loss. Appetite changes. Smooth muscle of gastrointestinal and urinary tracts less motile, interfering with digestion and elimination of wastes.
	Hypoglycaemia from glycogenolysis due to high energy demands.	Blood glucose increase. Appetite changes. Dehydration. Fatigue. Poor concentration.
	Increased blood clotting and suppressed immune response if stage persists.	Blood stasis; thrombus formation. Resistance to infection and disease reduced.

Source: Based on K. S. Quigley (2010). General adaptation syndrome. *Corsini Encyclopedia of Psychology*, 1.

Each age group will have unique reactions to a disaster. Teenagers may take unnecessary risks such as crossing a flooding river—these behaviours result in an increase in the death and injury toll.

PEOPLE WITH MOBILITY AND SENSORY DEFICITS The Australian Institute of Health and Welfare estimates that one in four Australians has some form of activity limitation due to a chronic condition. Many people require the use of assistive technology devices to accommodate mobility and other impairments. Careful planning must be in place in order to provide necessary support to this group during and after a disaster. Volunteers or staff can assist with relocation to a safe room or shelter when required; however, relocation can be problematic when access to this group of people is limited by the disaster. These individuals or their caregivers must provide input to service personnel to determine what kind of support services would be necessary in an emergency or disaster.

NON-ENGLISH-SPEAKING PEOPLE Providing information in a variety of languages is not unusual in Australian culture; however, information regarding actions to be taken during a disaster is often provided in English only. In addition, one cannot assume that people are literate in their own language. It is ideal to obtain the assistance of an interpreter who can translate information for those who don't speak English. Communication aids can be prepared in advance of disasters to be used during emergencies. The use of visual aids is very helpful.

IMMUNOCOMPROMISED PEOPLE The immunocompromised population is at greater risk of complications and death than the general population. Bottled water should be ready so the immunocompromised person can avoid drinking water of questionable purity. It is safest for this population of individuals to consume processed or tinned foods if they can be heated to the proper temperatures.

SPIRITUAL CONSIDERATIONS Religion tends to be a source of comfort for those who are experiencing the threat of loss of life, property or way of living. Churches, mosques, synagogues and religious leaders become active in supporting their congregations in times of disaster. Religious leaders should be actively involved in community planning for disaster preparedness, especially if certain religious considerations should be strictly followed where possible. In times of uncertainty many individuals turn to their religion for answers and support. Access to normal spiritual activities and support may be interrupted and in some cases it falls to the nurse to provide spiritual care. The nurse does not need to believe in the same way the victim does; however, assisting them to carry out a religious ritual will assist in that person's recovery or journey to death.

Community-based care

Nurses are invaluable in disaster relief efforts, whether they are answering questions from their neighbours regarding the water supply in their communities or assisting in complex care using their advanced practice knowledge in a hospital.

Nurses have a responsibility to the public to maintain competence in nursing practice and to be cognisant of evolving threats to the public's health. Nurses must learn about anticipated and unexpected disasters, as well as their vital roles in emergency preparedness and response. Nurses will play a role in disaster response whether they work in acute care settings, long-term care, ambulatory care or in the community or at home.

Teaching about disaster preparedness and appropriate actions is important in all communities. The Australian government has become more active in educating the public at all stages of a disaster, as seen in the guides mentioned earlier. Disaster preparedness and response procedures should be practised on a regular basis prior to an emergency. A multitude of communication means are available through technological support systems, such as internal phones and handheld communication devices. Written and visual cue boards are often more useful because they are not reliant on power. However, these methods of communication have been challenged by recent disasters in Japan and the Black Saturday fires in Victoria, but when services are limited adaptation will occur.

NURSING CARE PLAN A person with spinal injuries from being blown off a roof during a storm

Michael Vaughan, a 29-year-old carpenter, is married to Jacqui, 27; they have an 18-month-old daughter Grace. The couple has just purchased an older house in the city that needs a great deal of work. Michael is fit and well and cannot remember the last time he needed to have medical assistance. During a heavy rainstorm with high winds, the roof started leaking. To protect his house Michael climbed onto the roof to seal the leak. He did not secure himself on the roof and a gust of wind blew him to the ground, a fall of approximately 6 metres. He was transported to hospital by ambulance on a spine board with a (hard) cervical collar fitted. At the hospital's ED he was given a triage category of 2 because of the potential spinal injuries and height of his fall.

ASSESSMENT

Lisa Smith, RN, obtains a nursing assessment, as follows:

Primary survey

D(anger): Michael's cervical spine is secured and the spinal board is maintaining spinal alignment

R(esponse): Michael is alert and oriented to his surroundings

NURSING CARE PLAN A person with spinal injuries from being blown off a roof during a storm (continued)

A(irway): Michael is able to talk articulately and without distress—airway patent
B(reathing): Michael has equal air entry on both sides, chest rising is equal, R 26, SaO_2 96% on room air
C(irculation): Michael is pink and well perfused. All major pulses present, strong and equal. Right dorsalis pedis pulse is weak and thready. Capillary return is < 2 secs except on the right leg below the knee. HR 122, BP 110/60
D(isability): GCS 15. Non-visual pain scale 8

Secondary survey

Head: Conscious and alert, no lacerations on head—Cx collar in place.
Torso: Multiple bruises appearing on the right side, no tenderness over liver, spleen, kidneys, bowel sounds present and normal, no evidence of deformity to the chest cavity. Back examination by medical staff (log rolled) shows bruising on right side, no palpable deformity of spine or spinous processes.
Limbs: Arms normal in appearance and range of motion, no pain on palpation, no deformity seen. Bruising on right shoulder. Left leg and foot normal with no deformity or pain. Right leg is pale, cool, reduced sensation to touch, unable to move without severe pain.

Michael does not accept that he needed to take precautions when attempting to fix the roof or that calling the SES may have been a better option.

Focused assessment (spine and right leg)

X-rays rule out any spinal injury or concerns about the cervical spine.

Examination of the right leg shows bruising on anterior surface. Slight deformity 10° laterally. Gentle palpation reveals disruption mid-shaft tibia and fibula.

A peripheral IV is initiated with continuous fluids, and IV antibiotics are ordered every 8 hours. Michael is now fasting.

DIAGNOSES

- *Acute pain* related to right leg injury evidenced by pain score of 8.
- *Impaired circulation* to right leg related to displaced and separated fracture mid-shaft tibia and fibula evidenced by changes in colour, warmth, sensation and movement (CWSM).
- *Risk of hypovolaemia* due to internal haemorrhage related to leg fractures.

Expected outcomes

- Pain relieved within 15 minutes with narcotic IVI.
- Return of circulation to right lower leg—surgical intervention required.
- Mobility restored—surgical intervention required.
- Remains normovolaemic.
- Skin remains intact.
- Michael understands his role in this situation and does not take any further risks.

PLANNING

- Monitor Michael's heart rate and rhythm, blood pressure and respiratory rate every half hour.
- Arrange orthopaedic review for management of fractured tibia and fibula.
- Assess Michael's signs and symptoms of pain and administer pain relief as required and prescribed.
- Observe for internal bleeding.
- Maintain hydration: monitor intake and output.
- Inspect posterior skin every 4 hours, document skin condition, report changes.
- Arrange education in regard to home safety.

Expected outcomes

- Pain relieved within 15 minutes with narcotic IVI.
- Return of circulation to right lower leg—surgical intervention required.
- Mobility restored—surgical intervention required.
- Remains normovolaemic.
- Skin remains intact.
- Michael understands his role in this situation and does not take any further risks.

IMPLEMENTATION

- Assess and record Michael's heart rate and rhythm, blood pressure and respiratory rate every half hour.
- Administer IVI narcotics as per pain score and medication orders.
- Monitor and record pain scores every 30 minutes.
- Prepare Michael for surgery.
- Monitor CWSM every 15 minutes until surgery then 30/60 for 4 hours, 1/24 for 24 hours.
- Post-operative rehabilitation to restore pre-incident mobility.
- Provide education in regard to home safety.

EVALUATION

Michael was transferred to surgery for internal fixation of right tibia and fibula. He was admitted to the orthopaedic unit for 7 days then discharged home in a POP cast and non-weight-bearing on crutches.

CRITICAL THINKING IN THE NURSING PROCESS

1. Explain Michael's initial observations in relation to his pain and injury.
2. What post-surgical observations would indicate neurovascular compromise and what are the appropriate nursing interventions?
3. What are the major physiological considerations for Michael?
4. What could impede healing in Michael's situation?

REFLECTION ON THE NURSING PROCESS

1. Outline what you have learned from this case study.
2. How will you apply the systematic assessment process described in this case study in your future nursing practice?
3. What cues were important for the critical decision making?
4. How did you determine priority?

CHAPTER HIGHLIGHTS

- Triage in the ED is the process of sorting people using medical acuity as its basis.
- Emergency assessment consists of three stages: primary assessment, secondary assessment and a focused assessment.
- ED nursing interventions are focused on stabilisation and disposition.
- Disasters require extraordinary efforts beyond those needed to respond to everyday emergencies.
- Reverse triage is used in mass casualty events instead of traditional triage in order to do the greatest good for the greatest number.
- Nurses will be actively engaged in assessing the physical as well as the mental needs of victims, their families, first responders and other healthcare personnel.
- Nurses are actively involved in disaster mitigation, planning and response efforts by learning and practising their communities' and agencies' disaster preparedness systems.

CONCEPT CHECK

1 The primary aim of the Australasian Triage Scale is to:
   1 ensure appropriate allocation of funding to the ED
   2 ensure that ED care is delivered according to time of arrival to the ED
   3 ensure that ED care is delivered according to clinical need
   4 prevent ED overcrowding

2 The primary function of the ED triage nurse is to:
   1 provide first aid to people presenting to the ED
   2 ensure that ED care is delivered according to time of arrival to the ED
   3 assess and prioritise patient care
   4 provide education and redirect people to appropriate community services

3 During the primary assessment of a collapsed victim, the nurse determines that the person has a patent airway. The next assessment the nurse makes includes:
   1 the level of consciousness
   2 observation for external bleeding
   3 the status of the person's respiration
   4 the rate and character of carotid or femoral pulses

4 A man is brought into the ED via ambulance following a high-speed motor vehicle accident. He is unconscious, and bleeding profusely from the arm. In planning care for this man, the nurse gives the highest priority to the goal of:
   1 maintaining the person's airway
   2 assisting the person's breathing
   3 controlling the bleeding
   4 maintaining the person's fluid volume

5 The key difference between emergencies and disasters is that:
   1 emergencies are controlled
   2 disasters result from man-made errors
   3 emergencies can typically be handled by available emergency services
   4 disasters typically involve the local emergency services and no other agencies

6 The purpose of reverse triage is to:
   1 save scarce resources for future use
   2 test first responders on their triage classification categories
   3 save those people who are in the most critical condition
   4 do the greatest good for the greatest number with limited resources

7 Which of the following is true about personal protective equipment (PPE)?
   1 PPE protects by creating a barrier against hazards
   2 eye, face, head, foot and hand protection are addressed in PPE programs
   3 PPE should reduce the likelihood of occupational injury and/or illness
   4 healthcare workers do not need to wear PPE if they follow strict handwashing protocol and universal precautions

8 The goals of disaster management are:
   1 preparedness, response and recovery
   2 mitigation, response and recovery
   3 reduce hazards, prompt assistance, effective recovery
   4 mitigation, reduce hazards, prompt assistance, effective recovery

UNIT 2 BUILDING CLINICAL COMPETENCE

Alterations in patterns of health

CLINICAL SCENARIO

You have been assigned to care for the following four people for the 0700 shift in an emergency department (ED). Significant data obtained during report are as follows:

- Peter Black is a 46-year-old who was admitted to the ED 2 hours ago after being thrown 20 metres during a cyclone. When last taken, his vital signs were T 37.6°C, P 86, R 24 and BP 140/86. He had multiple abrasions and lacerations that were sutured in the emergency room. He is now complaining of numbness in both legs.
- Alice Jones is a 19-year-old woman with a history of asthma. She has not been using her preventer, and came to the ED 4 hours ago complaining of shortness of breath. She has been having salbutamol nebulisers every 30 minutes. Her vital signs are T 37.2°C, P 90, R 26, BP 134/88, SpO_2 95% on room air.
- John Linner, aged 67, was brought in by his family 3 hours ago. He is in the terminal stages of colon cancer, and the family are no longer able to care for him at home. Vital signs are T 36°C, P 54, R 10, BP 88/68. The family is requesting that a nurse check on Mr Linner because they feel that death is imminent.
- Paul Gregs, aged 47, was brought in by police after he was seen standing in the middle of the road directing traffic. He has a history of alcohol abuse, and on admission his alcohol level was 0.45. Current vital signs are T 36.7°C, P 110, R 30, BP 168/94. He is confused, agitated and diaphoretic.

Critical thinking questions

1 In what order would you review these people after handover?

1.
2.
3.
4.

2 What top two priority nursing diagnoses would you choose for each of the people presented above? Can you explain, if asked, the rationale for your choices?

	Priority Nursing Diagnosis #1	Priority Nursing Diagnosis #2
Peter Black		
Alice Jones		
John Linner		
Paul Gregs		

3 After assessing Mr Black, which nursing intervention should the nurse perform first?

1. Call the doctor to report the numbness in his legs.
2. Have Mr Black perform active exercises to prevent thrombosis in his legs.
3. Ambulate Mr Black in the hall to promote circulation to his legs.
4. Medicate Mr Black for pain so he can move his legs better.

4 Outline the elements of the primary and secondary survey, and describe how you would apply them in relation to Peter Black.

5 What are the changes that occur in the airway with asthma?

1. Oedema, bronchoconstriction, increased mucus production
2. Oedema, bronchoconstriction, decreased mucus production
3. Oedema, bronchodilation, decreased mucus production
4. Oedema, bronchodilation, increased mucus production

6 Describe the focused respiratory assessment you would undertake on Alice Jones.

7 Prioritise four nursing interventions for Alice Jones.

1.
2.
3.
4.

8 With a history of alcoholism for 5 years, what is a priority nursing intervention in the plan of care for Mr Gregs?

1. Identify maladaptive behaviours that may contribute to the alcoholism.
2. Encourage participation in therapeutic group activities.
3. Teach the effects of alcohol on the body.
4. Use a respectful, non-judgmental approach to gain trust.

9 A prescription for naltrexone is given to Mr Gregs. He voices understanding of how to take the medication when he states:

1. 'I must avoid all forms of alcohol and narcotics while taking this medication.'
2. 'It is all right to take over-the-counter cold medications if I catch a cold.'
3. 'This medication will keep me from having withdrawal symptoms.'
4. 'I can get physically ill if I drink alcohol while taking this medication.'

10 When Mr Gregs was admitted to the ED, which laboratory studies would you expect to have taken? (Select all that apply.)

1. bilirubin
2. serum electrolytes
3. ALK
4. complete blood cell count
5. AST
6. WCC

11 To prepare the family for Mr Linner's death, the nurse institutes the following interventions:

1. Teach the stages of coping with the loss of their family member.
2. Explain the physical symptoms they may see as death approaches.
3. Discuss funeral and burial arrangements with the family.
4. Refer family to appropriate support groups to assist in dealing with death.

12 When preparing for the role the nurse will play in disaster relief, the nurse must first:

1. be able to apply basic first aid skills
2. be aware of decontamination procedures
3. serve on disaster preparedness committees
4. know how to take care of himself or herself

CASE STUDY

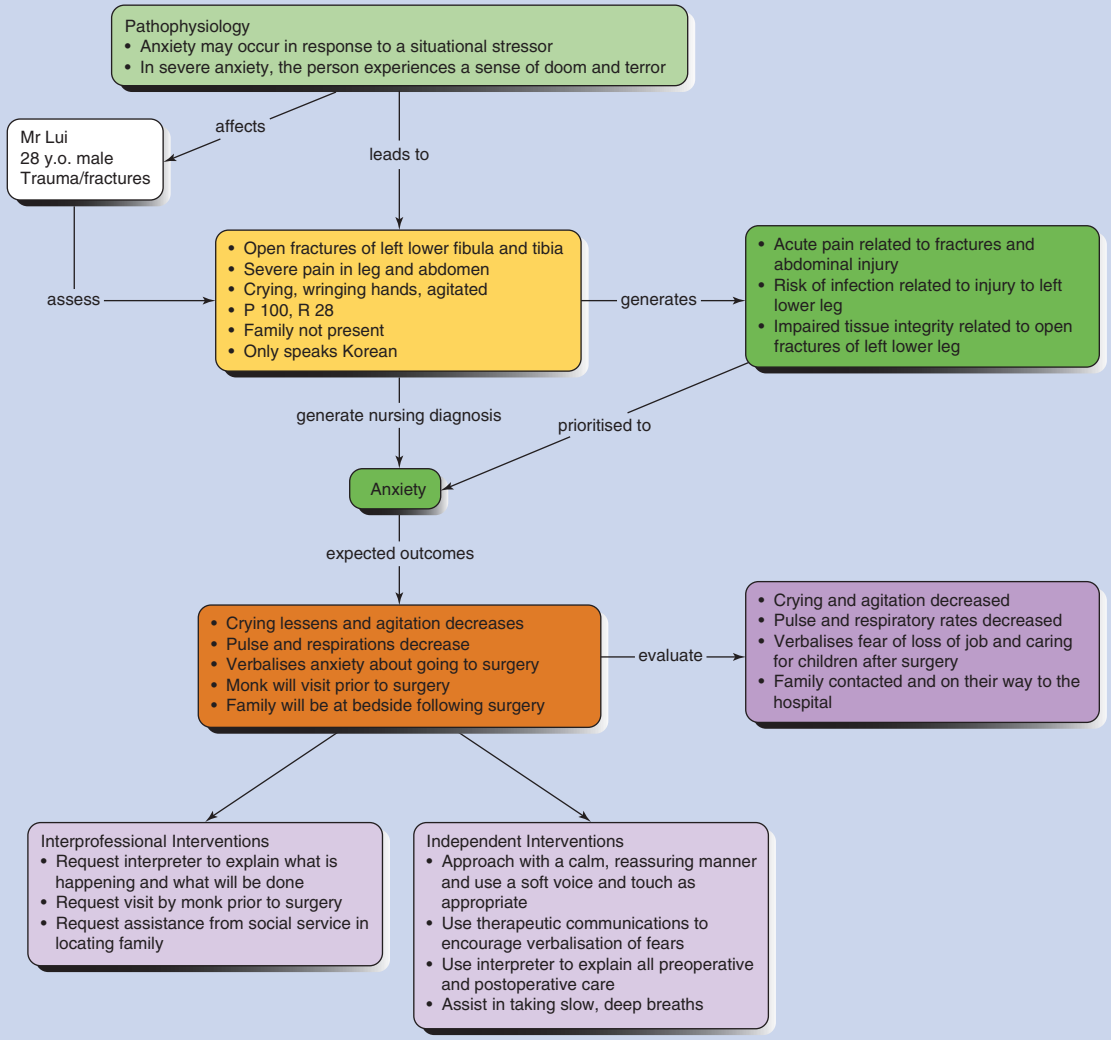
Mr Kim Lui is admitted to the emergency department with open left fractures of the tibia and fibula, left upper quadrant pain and reddened areas across the left shoulder, neck and chest. According to the paramedics, he was involved in a multiple-car crash on a freeway. On initial assessment he is found to be a non-English-speaking Korean, 28 years of age, is 1.8 m in height and weighs 54 kg. His vital signs areT 37°C, P 100, R 28 and shallow, BP 150/86. He indicates his pain scale level as 9 out of 10, even after being medicated with morphine in the ambulance.

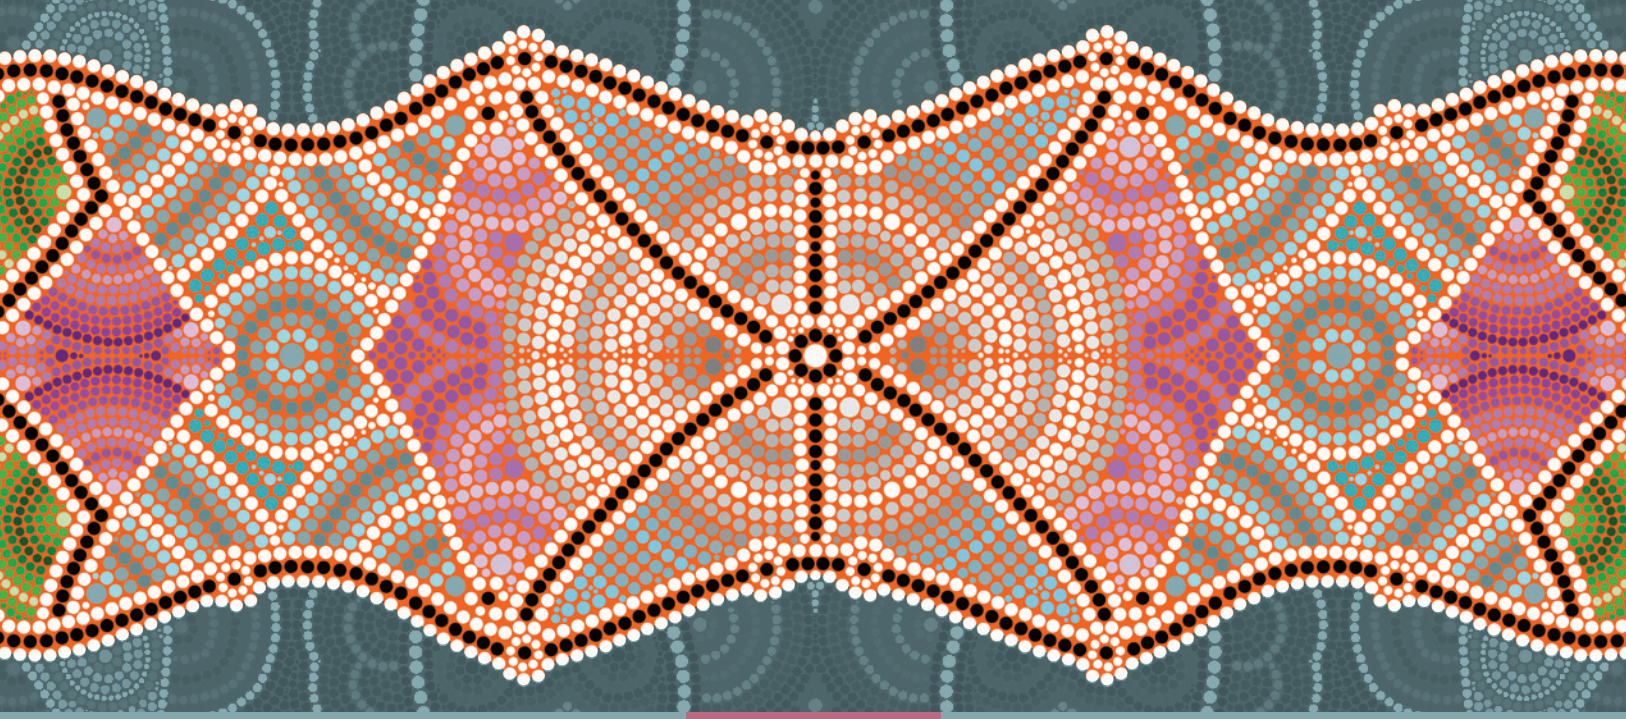
After chest, abdominal and leg x-rays, Mr Lui is diagnosed with crushing injury and comminuted fractures of the left tibia and fibula, a haematoma on his spleen and bruising across the shoulder, neck and chest due to the seat belt. With the use of a translator, the doctor explains that he will have to have surgery to repair his fractures.

Blood is taken for the following pathology tests: full blood count (FBC) with differential, electrolytes, prothrombin time (PT), partial thromboplastin time (PTT) and blood gases. A urine specimen is sent to the laboratory for a urinalysis. Preoperative preparation is completed. The nurse tries to answer any questions Mr Lui has regarding the surgery and what will happen in the postoperative period. The nurse attempts to contact family members and a monk to see Mr Lui before he goes to surgery. At the ordered time, the nurse administers prescribed preoperative medication and Mr Lui is sent to the operating room.

Due to difficulty understanding the English language, pain and the need for surgery, Mr Lui is very anxious. The nursing diagnosis of *Anxiety* is appropriate for guiding preoperative nursing care. Anxiety is an uneasy feeling of not knowing what is going to happen. The pathophysiology of anxiety is anticipation of danger or a threat to health status that leads to a 'fight-or-flight' response from the sympathetic nervous system. Manifestations of anxiety are restlessness, tachycardia, rapid breathing, facial flushing, increased perspiration, weakness, tremors, and impaired attention and concentration. Complications of anxiety are nausea, vomiting, diarrhoea, loss of appetite, insomnia, immobility and powerlessness that can lead to panic or phobias.

Based on Mr Lui's medical diagnosis and treatment plan, anxiety is identified as the priority nursing diagnosis at this time.





UNIT 3

PATHOPHYSIOLOGY AND PATTERNS OF HEALTH

CHAPTER 7

GENETIC IMPLICATIONS OF ADULT HEALTH NURSING

KAMAREE BERRY

KEY TERMS

LEARNING OUTCOMES

- Discuss the role of genetic concepts in health promotion and health maintenance.
- Apply knowledge of the principles of genetic transmission and risk factors for genetic disorders to nursing practice.
- Describe the significance of providing education about genetics and counselling follow-up in an ethically justifiable manner.
- Identify the implications of genetic advances for nursing practice with particular attention to spiritual, cultural, ethical, legal and social issues.
- Identify the significance of recent advances in human genetics in terms of healthcare delivery.

CLINICAL COMPETENCIES

- Integrate genetic physical assessment and the use of a pedigree family history into nursing care according to the NMBA professional standards (2016) required of the RN.
- Identify people or families with actual or potential genetic problems and initiate referrals to appropriate professionals according to the relevant nurses' scope of practice and NMBA professional standards (2016) for the RN.
- Prepare people and their families for a genetic evaluation and facilitate the genetic counselling process according to the relevant nurses' scope of practice.
- Integrate genetic concepts into education for people and their families.

OVERVIEW OF GENETICS AND GENOMICS

Increasingly nurses and midwives encounter people with conditions related to genetics and thus they need the knowledge, skills and attitudes to effectively care for these people in culturally safe and ethically justifiable ways. The completion of the Human Genome Project (HGP) (see Box 7.1) has accelerated the incorporation of genetics into mainstream medical, midwifery and nursing practice. The HGP changed not only the way disease treatment is approached but, more importantly, how nurses and midwives look at health promotion and health maintenance. Thanks to the HGP we now have a much better idea of the contribution of genetics to illness and wellness, targeted drug therapy (**pharmacogenetics**) and the development of genetic tests that identify those at risk of specific illnesses. We know now that most illnesses have a genetic component. We know that myocardial infarction, some forms of cancer, mental illness and diabetes, as well as addiction and Alzheimer's disease are all caused by the interaction between at least one gene and complex environmental and social factors.

The explosion of knowledge about genetics and genomics brings significant nursing, medical, ethical and legal concerns, which all health professionals must consider. With the ability to predict the risk of developing many conditions comes a better understanding of how genetic and environmental and lifestyle factors interact to produce disease. In addition, we have the capacity to tailor treatments based on an understanding of the genetic basis of disease in the individual, and in all likelihood this will reduce the burden of these conditions on society and individuals. For example, population-based screening for colorectal cancer guidelines recommends that screening begin at age 50. It is now possible to adjust the guidelines to take into account genomic risk factors such as having a first-degree relative (parent, sibling or child) who developed cancer at a younger age, or people with multiple affected first-degree relatives so that screening begins at an earlier age.

People and populations are increasingly offered predictive tests and carrier tests to determine if they are at risk of conditions such as Alzheimer's disease (AD), which is a major cause of disability in the older adult. Most AD cases are late in onset and are undoubtedly influenced by a combination of genetic and environmental factors. Inheritance plays a role in approximately 80% of cases (Rao, Degnan & Levy, 2014) and has a risk association with the APOE 4 allele. The social and ethical implications of this knowledge are enormous. Would you want to know if you are at risk of Alzheimer's disease? Would you tell your life insurer? If you knew that you are at a genetic risk of heart disease, would you be more likely to change your lifestyle? Should testing for Alzheimer's disease or Down syndrome be compulsory? If the tests are 'positive', should an affected foetus be aborted by state order because of the financial costs of lifelong care? These questions show the financial price we pay as individuals and members of society for information about our future health risks, as well as the social consequences, including unfair discrimination with regard to life insurance and employment.

DNA is at the centre of the state of our health (see Figure 7.1). We know that wellness and good health are associated with properly structured and functioning genes. If they are not functioning properly, ill health or an increased risk of disease can result. This includes not only the well-known genetic disorders and problems, but also complex conditions such as heart disease, stroke, diabetes and several kinds of cancer. The knowledge gained from human genome research has and will have a profound impact on the prevention, diagnosis, prediction and treatment of genetic disorders and complex diseases.

BOX 7.1 Human Genome Project

The Human Genome Project (HGP) is one of the great accomplishments in medical history. Funded in the United States by the National Institutes of Health and the Department of Energy in 1990, the mission of the now completed HGP was to map the complexities of chromosomes and the genes within them, and how they affect human health.

The ultimate goal was to sequence the human genome and identify all human genes. The completion of a high-quality reference sequence was announced in April 2003, marking 50 years since the publication in the journal *Nature* of the letter by James Watson and Francis Crick describing DNA's double-helix structure. Information obtained through the sequencing of the human genome has had a tremendous impact on finding the genes associated with human illness and health. Now that the HGP has been completed, research is being directed towards understanding the complex functions of cellular regulation, human variation, and the interplay of genes and environment, and how all the cell organelles, genes and proteins work together in life's functions (USDOE Genome Programs, 2008).

INTEGRATING GENETICS AND GENOMICS INTO NURSING PRACTICE

Genetics generally focuses on one gene, whereas **genomics** involves multiple genes as well as interacting factors such as environmental conditions and cultural and social influences, all of which affect the 'expression' or triggering of individual or groups of genes. Genetics and genomics have revolutionised how people perceive themselves, as well as their health status and their health potential. Therefore, nurses and midwives must integrate new genetic knowledge into practice. In 2012, the American Nurses Association (ANA) and International Society of Nurses in Genetics (ISONG) published the *Statement on the Scope and Standards of Genetics Clinical Nursing Practice* defining 38 competencies under seven major categories (ANA/ISONG, 2012): (1) risk assessment and interpretation, (2) genetic education, counselling, testing and results interpretation, (3) clinical management, (4) ethical, legal and social implications, (5) professional role, (6) leadership, and (7) research.

Kirk, Tonkin and Skirton (2011) published, for the National Genetics Education and Development Centre in the UK, a wide-ranging review and revised competence-based framework, including learning outcomes and practice indicators for nurses and midwives. While the Australian standards for the RN (Nursing and Midwifery Board of Australia (NMBA), 2010) do not specifically refer to genetics, Standard 5.1 states that nurses 'use a

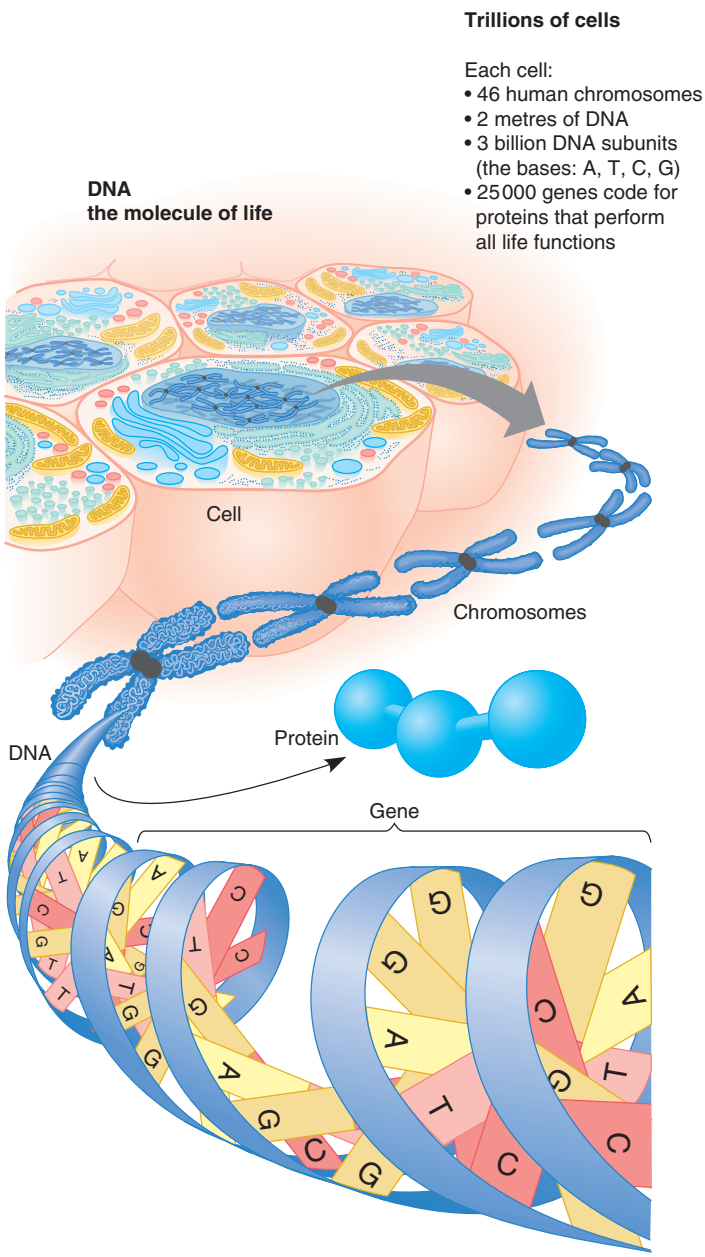


FIGURE 7.1 ■ Each cell nucleus throughout the body contains the genes, DNA and chromosomes that make up the majority of an individual's genome. The remaining portion of the human genome is in the mitochondria

relevant evidence-based assessment framework to collect data about the physical, socio-cultural and mental health of the individual/group' which of course would include a family history. Therefore, both the UK and US frameworks and competency standards have relevance for Australian nurses and midwives.

FOUNDATIONS OF GENETICS

Nurses need to have foundational knowledge of the cell, DNA, cell division, chromosomes and genes in order to deliver competent care and to enable people requiring assessment, support and referral to fully benefit from advances in genetics (see Box 7.2).

BOX 7.2 Using the people-first approach

Nurses must incorporate a 'people-first' philosophy and use genetic terminology that is sensitive to the maintenance of an individual's positive self-image. This can be accomplished by using terms such as 'unaltered' or 'wild-type' gene instead of 'normal' gene and 'altered gene'; 'altered, disease-producing gene' or 'gene alteration' instead of the terms 'mutated' or 'abnormal' gene when communicating genetic concerns.

wild-type = normal = expected = unaltered

versus

mutated = abnormal = defective = unexpected = altered

The cell is the basic unit of life and the working unit of all living systems. Life starts as a single cell, but the developed human body is made up of trillions of cells. These cells share common features, such as a nucleus that contains 46 chromosomes and organelles such as mitochondria. There are many different types of 'specialised' cells that function differently depending on their location. For example, pancreatic cells have a very different function from that of nerve cells.

All human cells, except mature red blood cells, contain a complete set of deoxyribonucleic acid (DNA) molecules. DNA molecules consist of long sequences of nucleotides or bases represented by the letters A, G, T and C. The order of these bases gives the exact instructions for the functioning of that particular cell. Writing the correct order of the bases using the above abbreviations represents the sequence of the bases in DNA. The entire DNA in a human cell is referred to as the **human genome**, or the complete set of inheritance for an individual. The human genome includes the DNA in the cell nucleus as well as the DNA found in the mitochondria, which will be discussed later in this section. Each person's genome is unique. Identical (monozygotic) twins are the exception because they develop from only one fertilised ovum and share identical DNA.

The cell nucleus contains about 183 cm of DNA that is tightly wound and packaged into 23 pairs of **chromosomes**, making a complete set of 46 chromosomes. The structure and number of chromosomes can be shown by a karyotype, or picture, of an individual's chromosomes (see Figure 7.2). There are two copies of each chromosome. One copy, or half of the complete set of these 46 chromosomes, is inherited from the mother and the other copy, or the other half of the 46 chromosomes, is inherited from the father. For example, an individual will have two of chromosome 1, one inherited from her mother and one inherited from her father. These two copies or pairs of inherited chromosomes are called **homologous chromosomes**. Chromosomes are numbered according to size, with chromosome 1 being the largest and chromosome 22 being the smallest. The first 22 pairs of chromosomes, known as **autosomes**, are alike in males and females. The 23rd pair, the **sex chromosomes**, determines an individual's gender. A female has two copies of the X chromosomes (one copy inherited from each parent) and a male has one X chromosome (inherited from his mother) and one Y chromosome (inherited from his father).

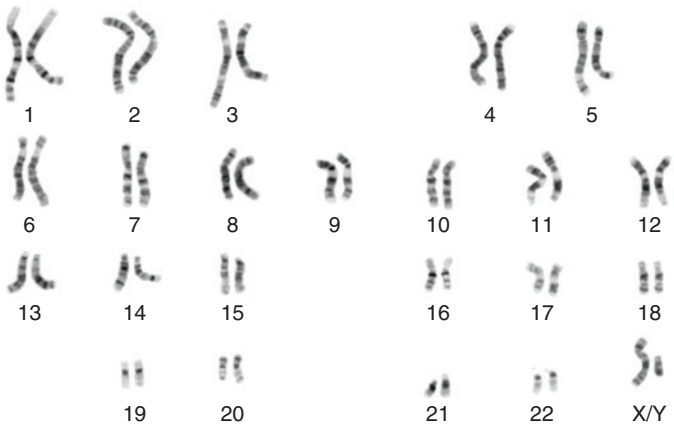

FIGURE 7.2 ■ A karyotype is a picture of an individual's chromosomes. It shows the chromosomal structure and number of the 22 pairs of autosomes and the sex chromosomes

Cell division

Mitosis and meiosis are the two types of cell division in human cells. **Mitosis** is the process of making new cells and takes place in the **somatic**, or tissue, **cells** of the body. Cell division through mitosis heals wounds and replaces cells lost daily on skin surfaces and in the lining of gastrointestinal and respiratory tracts. In addition, mitosis is responsible for development. The mitotic activity of the zygote and its daughter cells is the foundation for a human's growth and development. The zygote undergoes mitosis to form a multicellular embryo, then foetus, then infant. Cell division through mitosis results in two cells, called *daughter cells,* that are genetically identical to the original cell, or *mother cell*, and each other.

Meiosis is also known as the reduction division of the cell. Meiosis occurs only in the sex cells of the testes and ovaries and results in the formation of the sperm and oocyte (gametes). Meiosis is very similar to mitosis in that it is a form of cell division; however, through a series of complex mechanisms, the amount of genetic material is reduced by half (23 chromosomes). This is very important because when the two sex cells combine during fertilisation, the total number of chromosomes (46) is present in the offspring's cells. The purpose of meiosis is to produce gametes, to reduce the number of chromosomes by half and to make new combinations of genetic material from crossing over and independent assortment processes, which allow diversity in the human population.

Chromosomal alterations

Alterations in chromosomes often occur during cell division (meiosis or mitosis) and are classified as either alterations in the number of chromosomes or structural alterations. They involve either part of or the whole chromosome. The clinical consequences of number and structural changes in the chromosomes in an individual vary depending on the amount and type of DNA affected by the alterations.

Alterations in chromosome number

An increase or decrease in chromosomal numbers can occur during meiosis or mitosis (see Box 7.3). Alterations often occur during meiosis because meiosis is a highly specific and complex process and each new daughter cell must contain exactly one chromosome from each homologous pair of chromosomes. During meiosis, the paired chromosomes may fail to separate, resulting in daughter cells with either two copies or no copies of that chromosome. This is known as **nondisjunction**.

Nondisjunction creates an egg or sperm cell with either two copies or no copies of a particular chromosome. When these egg or sperm cells are fertilised by a normal gamete that contains 23 copies of all of the chromosomes, a zygote that is monosomic (one member of the chromosome pair is missing) or trisomic (having three chromosomes instead of the usual two) results. These circumstances produce such conditions as Turner's syndrome (**monosomy**) or Down syndrome (**trisomy** 21). As you have already read, normally each cell has 23 pairs of chromosomes, making a total of 46 chromosomes. One of these pairs, the sex chromosomes, determines the gender of the foetus (46XY for a boy and 46XX for a girl). In **Turner's syndrome** (affects about 1:2000 girls) there will usually be only one X chromosome or portion of one missing in all or some of the cells. The reason for this total or partial loss of the chromosome usually cannot be found, but the loss occurs soon after conception. Sometimes there may be abnormalities in the X chromosome in only some cells in the body. This is referred to as mosaic Turner's syndrome and there may be few or no symptoms and fertility may not be affected. Parents need to be reassured that there was nothing either parent could have done to prevent this from happening; it is a biological accident for which no one is responsible. Girls with Turner's syndrome are at risk of impairments in the cognitive, behavioural and social domains—learning disabilities, particularly with regard to spatial perception, visual–motor integration, mathematics, memory, the ability to formulate goals and plan action sequences to attain them, and attention span. To complicate matters, a female with 45X Turner's syndrome may manifest an X-linked recessive disorder, such as haemophilia, because she has only one X chromosome.

The missing genes cause significant problems for the girl, but the main ones are:

- short stature (average height: 143 cm)
- lack of secondary sexual characteristics (failure to develop at puberty)
- infertility.

BOX 7.3 Variations in chromosomal number

Aneuploidy—the condition when extra or missing chromosomes exist; if there is an addition or deletion of chromosome number and the individual lives, physical abnormalities and/or mental retardation are common.

Monosomy—the loss of a single chromosome from a pair; i.e. Turner's syndrome (45XO).

Trisomy—the gain of a single chromosome, making a total of three copies of a certain chromosome; i.e. trisomy 21 or Down syndrome.

Euploidy—the presence of the normal number of 46 chromosomes.

Polyploidy—the condition when more than two pairs of all the chromosomes are present.

Klinefelter's syndrome, also known as the XXY condition, describes males who have an extra X chromosome in most of their cells. Klinefelter's syndrome is named after Dr Henry Klinefelter. Boys with Klinefelter's syndrome are born with at least one extra X chromosome (47 chromosomes in each cell, rather than the normal number of 46). Klinefelter's syndrome is also called 47XXY syndrome. It is thought to be caused by an error within the fertilised egg or the dividing cells as the baby develops. The presence of the Y chromosome ensures male sexual characteristics but, because the testicles are underdeveloped, there may not be enough testosterone production. This is why the penis and testicles are smaller than average, and why most men with Klinefelter's syndrome are infertile. Some researchers suspect that advanced maternal age may be a risk factor.

Down syndrome is named after Dr John Langdon Down who first identified the syndrome in 1866. Trisomy 21 (Down syndrome) is caused by an extra copy of chromosome 21. An obsolete term that should never be used to describe someone with Down syndrome is *mongolism*. The extra chromosome causes certain physical characteristics and affects intellectual development. In Australia, about 95% of all pregnant women consent to have a screening test to determine if the foetus is at risk of Down syndrome. About 1:20 (5%) women will be notified that the foetus is at increased risk. Only further testing will show which babies do have the problem. It is important to remember that even if the test shows that the baby is at low risk of Down syndrome the child may be born with other complications. Testing does NOT ensure the 'perfect baby'. Down syndrome occurs in all races and cultures. Approximately 1 in every 800 babies is born with Down syndrome. However, the actual rate is probably much higher than this because many women will choose to terminate their pregnancy.

Alterations in chromosome structure

Alterations in chromosome structure include inversions, deletions and duplications, and translocations. In a chromosomal inversion a segment of a chromosome is reversed, changing the DNA sequence for that portion of the chromosome. It occurs when a chromosome breaks in two places and the piece between the breaks turns upside down and reattaches within the same chromosome. The clinical consequences of an inversion depend on how much chromosomal material is involved, where the inversion occurs and what type of inversion is present.

A chromosomal alteration that includes a missing (deletion) or additional (duplication) whole chromosome or segment of a chromosome is an unbalanced rearrangement. An unbalanced rearrangement can result in missing genes, confusing directions from the genes, or too much gene product, which often results in a condition that is not compatible with life, or in altered physical and/or mental development. An example is cri du chat syndrome (intellectual disability, crying that sounds like a cat mewing and low-set ears). Cri du chat syndrome is an abnormality resulting in the deletion of a large part of the short arm of chromosome 5. **Translocation** (chromosomal reshuffling) occurs when a segment of a chromosome transfers or moves and attaches itself to another chromosome. An example is the reciprocal translocation that is found in 95% of people with chronic myelogenous leukaemia (CML). The contributing translocation occurs between chromosomes 9 and 22. The translocation results in a shortened chromosome 22, an observation first described by Nowell and Hungerford in 1960 and subsequently termed the Philadelphia (Ph1) chromosome after the city where it was discovered. The translocation (two chromosomes break, then parts from each chromosome switch places) relocates an oncogene called Abl from the long arm of chromosome 9 to the long arm of chromosome 22. As a result, a new, abnormal gene called BCR produces Bcr-Abl tyrosine kinase, an abnormal protein that causes too many stem cells to develop into white blood cells (granulocytes or blasts). The exact cause of CML is unknown, though it is now known how the disease develops from genetic changes in myeloid cells.

Unlike the translocation responsible for Down syndrome, which occurs in the germ cells, the translocation responsible for CML occurs in somatic cells and therefore is not inheritable (National Cancer Institute, 2009; Nussbaum et al., 2007). Thus environmental factors account for only a small number of CML cases and so family history does not appear to play a role in the development of CML.

Genes

Nurses must also have knowledge of genes—what they are, the role genes play in homeostasis, as well as the consequences of gene alterations. How these gene alterations are inherited is also important for nursing and midwifery interventions and teaching the person who is at risk of, or who has, a known gene (DNA-based) condition. Knowledge of the function and inheritance of genes is implicit in health promotion as well as health maintenance of the person and their family.

A **gene** is a small portion (segment) of the nucleotide (base) sequence of a chromosome DNA molecule that can be identified as having a particular function or characteristic. These segments of DNA within each gene have specific directions for the functioning of the gene. This specific sequence of nucleotides (the genes and the variations therein) is referred to as the individual's **genotype**. Each chromosome contains numerous genes arranged in a linear order. Researchers currently believe there are about 20 000 to 30 000 genes in the human genome (Jameson & Kopp, 2012; Lister Hill National Center for Biomedical Communications, 2014). The number of genes present on each chromosome varies. Chromosome 1 is the largest chromosome and has the largest number of genes, with 2968. The Y chromosome has the smallest number of genes, with 231 (Human Genome Project (HGP), 2008a).

All genes come in pairs because chromosomes come in pairs. The only exception to all genes being paired are the genes on the sex chromosomes (X and Y) present in males. All genes have a specific location on a specific chromosome. This is known as the **genetic locus**. For example, one of the many genes located on chromosome 19 is a gene for eye colour. There may be slight variations or different forms of a gene—for instance, green versus blue eye colour—and these different forms or versions of genes are called **alleles**. When an individual has two identical forms (alleles) of a gene, they are said to be **homozygous** (homo = same). If an individual has two different forms (alleles) of the gene, they are said to be **heterozygous** (hetero = different). Genes can be described as *altered* or *mutated*, when a change has taken place, or *expressed*, when the gene has an impact on the outward

appearance of an individual and/or the functioning of cells. The observable, outward expression of an individual's entire physical, biochemical and physiological make-up, as determined by their genotype (alleles) and environmental factors, is referred to as **phenotype**. Phenotype may be expressed or observed as curly or straight hair or the presentation of signs and symptoms of a disease.

Function and distribution of genes

Although the function of more than 50% of the genes in the human genome is still unknown, we do know that about 2% of the genes give directions to parts of the cell for how to make proteins, what type of proteins to make and how much of a protein to make (HGP, 2008a). These protein-directing genes are very important to life and functioning as a human being because proteins are very specialised and perform a variety of functions within the cell. These functions include transmitting messages between cells, fighting infection, directing genes to turn 'on' or 'off' and forming structures, as well as sensing light, taste and smell (Jegalian, 2000). Some gene activities change from moment to moment in response to tens of thousands of intra- and extracellular environmental signals (USDOE Genome Programs, 2008). An example of this is the feedback mechanism that stimulates a cell to produce insulin after eating a candy bar. After eating, a gene on chromosome 11 directs pancreatic cells to produce, modify and secrete insulin. Although the gene for producing insulin is present in all nucleated cells of the body, it is only functional in insulin-secreting pancreatic cells (Guttmacher et al., 2004).

Mitochondrial genes

Chromosomes in the cell nucleus are not the only site where genes reside. Several dozen that are involved in energy metabolism are located in the cell mitochondria (the 'powerhouse' of the cell). **Mitochondria** are concerned with energy production and metabolism. Some cells contain more mitochondria than others, but each mitochondrion contains its own copies of DNA, identified as mitochondrial DNA (mtDNA). Because ova have many mitochondria and sperm do not (most mitochondria are located in the tail of the sperm that detaches after fertilisation), mtDNA is primarily inherited from the mother. Therefore, mitochondrial genes and any diseases due to DNA alterations on those genes are transmitted through the mother in a matrilineal pattern. This pattern of inheritance is very different from the pattern of inheritance of genes found in the nucleus of the cell (Guttmacher et al., 2004). Thus, an affected female will pass the mtDNA mutation to all of her children; however, an affected male will not pass the mtDNA mutation to any of his children (John et al., 2010; Nussbaum et al., 2007). Signs and symptoms of conditions occurring as a result of mitochondrial gene alterations primarily involve high-energy tissues and organs such as skeletal muscles, liver, kidney, brain and nerve cells, ears, eyes, endocrine system and heart muscle. Symptoms develop over years as unhealthy or dying cells are not replaced. Hypertrophic cardiomyopathy, heart block, seizures and deafness are also associated with mtDNA gene alterations (John et al., 2010; Nussbaum et al., 2007). An Italian research team has found that chronic kidney disease (CKD) is possibly linked to oxidative stress caused by dysregulation of the genes that control mitochondria (Granata et al., 2009).

Gene alterations and disease

A protein will malfunction and in many cases cause disease if any kind of alteration (mutation or change) is present in the order of the DNA sequence within a gene. These gene alterations can be inherited from one or either parent or they can be acquired. *Mutations* inherited from a parent (hereditary mutations) are also known as *germline mutations* because the mutation exists in the reproductive sperm or ova of the parent. Consequently, the DNA in every cell of that offspring will have the gene alteration and also can be inherited from generation to generation.

The second kind of gene alteration is an *acquired mutation* or *somatic mutation*. These alterations occur in the DNA of cells of the individual throughout their life. They can result from errors during cell division (mitosis) or from environmental influences such as radiation or toxins (National Institutes of Health (NIH) and National Cancer Institute (NCI), 1995).

Today, we know that gene alterations are responsible for approximately 6000 hereditary diseases. However, different gene alterations within a particular gene can result in a wide variety of signs and symptoms. Since it occurs in one of the first 22 pairs of chromosomes, the cystic fibrosis (CF) defect is autosomal. It is not sex-linked, so the disease can occur in either gender. For example, the CFTR gene for cystic fibrosis is a very large gene located on chromosome 7. More than 1500 different mutations of this gene have been reported to cause cystic fibrosis (Ferraguti et al., 2011). The area of the CFTR gene that controls mucus production can have more than 300 different gene alterations, resulting in a variety of symptoms ranging from mild, to severe, or no symptoms at all (NIH/NCI, 1995). Gene alterations, not the genes themselves, cause genetic diseases and conditions. Since CF is a recessive trait, an affected individual must receive two defective genes in order to be born with CF. As with all chromosome pairs, one is inherited from the mother and one is inherited from the father. This means that both parents must carry the cystic fibrosis trait or have CF themselves in order to have a child with CF. People who are carriers have only one defective gene. They will not have CF and will not have any symptoms. On average about 1 in 25 Australians and New Zealanders are genetic carriers for CF but they are more likely to be a carrier if they are of Northern European descent (including the UK). If both parents are carriers there is a 1 in 4 chance that each parent will pass on their defective gene, meaning their baby will also have CF. Interestingly, other factors probably influence the course of CF. For example, changes in genes other than CFTR might explain why some people with the disease are more severely affected than others. So far none of these factors have been identified.

All babies in Australia are screened for CF shortly after birth:

- Genetic testing may be available to determine if a person is a carrier of the faulty CFTR gene. The screening test may be offered pre-pregnancy and in pregnancy when there is a family history of CF or a blood relative is a genetic carrier for CF.
- Genetic screening may also be available as part of pre-pregnancy planning for those people with a high chance of being a genetic carrier for CF based on their family history. The screening will only pick up those who are carriers of one of the more common changes in the CFTR gene.

Other situations where gene alterations cause illness and disease are through gene interaction with the environment. These genes and conditions are referred to as multifactorial (Jegalian, 2000). Alterations in regulatory genes may also occur. Regulatory genes play a part in maintaining homeostasis or normal functioning. A regulatory gene mutation might lead to the loss of expression of a gene, to unexpected expression in a tissue in which it is usually silent, or a change in the time when a gene is usually expressed. An example of a regulatory gene mutation associated with disease includes the insulin gene region that increases the risk of type 1 diabetes (Guttmacher et al., 2004). Researchers have identified a gene, KIAA0350, that increases the risk of getting type 1 diabetes (insulin-dependent diabetes) (Hakonarson et al., 2007). This finding does not mean that researchers know how to prevent diabetes in those who have these genetic mutations. Diabetes is a complex disorder and the risk of developing it is known to be affected by environmental factors and at least four other genes.

Gene alterations that decrease risk of disease

Although it is common to associate gene mutations with disease, it is important to remember that gene mutations can also be helpful and decrease the risk of disease. Gene alterations and genetic variations may also have a protective role in the expression of diseases. A common example is the protective value of the gene alteration that causes sickle cell disease. Those individuals with this gene alteration have protection against malaria. Another, less common example of a 'protective' gene alteration is the one on the receptor gene named CCR5. This mutation consists of a deletion within the DNA sequence. Persons who are homozygous for the CCR5 mutation (have two copies of the altered gene) are almost completely resistant to infection with HIV type I, and those who are heterozygous for the deletion (have one copy of the altered gene) progress much more slowly from the stage of HIV infection to AIDS (Guttmacher et al., 2004). As genomic research continues, more and more of these types of beneficial gene alterations will be identified.

Single nucleotide polymorphisms

Single nucleotide polymorphisms, or SNPs ('snips'), are one-letter (base pair) variations in the DNA sequence that occur in more than 1% of the population. In all people, 99.9% of the DNA is identical; SNPs are responsible for differences among individuals. **Polymorphisms** are DNA sequences that have many forms but give the genetic 'directions' for the same thing. Most of these differences have no effect on the individual. Some cause subtle differences in numerous characteristics in appearance such as widow's peak, tongue rolling and attached ear lobes. Other SNPs, however, affect an individual's risk of certain diseases and have a major impact on how the individual responds to environmental factors such as toxins, microbes and medications. Biological markers are important for the construction of chromosome maps and are easily tracked, stable segments of DNA. Scientists are mapping these areas of SNPs in order to move to the next step of identifying the multiple genes that are associated with diseases that are not caused by single-gene alterations—those complex diseases caused by multiple genes such as cancer, cardiovascular disease, some forms of mental illness and diabetes (HGP, 2008c; Jegalian, 2000). More recently, an international collaboration has linked common SNPs on chromosome 5 to five different types of cancer while at the same time conferring protection against melanoma. Of note, four of the five cancers have a strong environmental contribution to risk (smoking for lung and bladder cancer, UV light for skin cancer, and HPV infection for cervical cancers) (Stefanson & Thorunn Rafnar, 2009).

PRINCIPLES OF INHERITANCE

Knowledge of inheritance allows nurses and midwives not only to offer and reinforce genetic information to people and their families, but also to assist them in managing their care and in making reproductive decisions. The basic underlying principles of inheritance that health professionals can apply to inheritance risk assessment and teaching include: (1) all genes are paired, (2) only one gene of each pair is transmitted (passed on) to an offspring, and (3) one copy of each gene in the offspring comes from the mother and the other copy comes from the father. Understanding the Mendelian patterns of inheritance is made easier by relating these principles.

Mendelian patterns of inheritance

Conditions that are caused by a mutation or alteration of a single gene are known as *monogenic* or *single-gene disorders*. There are more than 6000 known single-gene disorders occurring in about 1 in 200 births (HGP, 2008a). The most common gene alterations that result in genetic disorders are categorised into Mendelian inheritance patterns because they are predictably passed on from generation to generation following Mendel's laws of inheritance. These single-gene mutations follow an autosomal dominant, autosomal recessive, **X-linked recessive** or **X-linked dominant** inheritance pattern. The first three of these patterns are the most common. Modes of transmission or inheritance for thousands of conditions resulting from monogenic alterations have been identified (*Online Mendelian inheritance in man*, 2003).

Recessive versus dominant disorders

The distinction between recessive and dominant phenotypes or disease presence (expression) lies in the amount of gene product (usually proteins) from the unaltered (**wild-type** or normal) **gene**. When the individual is heterozygous (has one unaltered gene and one altered gene), the altered gene as well as the disease is classified as recessive if half of the product produced from the unaltered gene is enough to maintain homeostasis and perform the expected function. Therefore, two altered genes must be present to cause a diseased state. If the altered gene causes disease even though the unaltered gene is producing the gene product, then the altered gene as well as the disease is classified as dominant (Nussbaum et al., 2007).

Autosomal dominant conditions

Autosomal dominant (AD) conditions are the result of an altered gene on any of the 22 autosomes or non-sex chromosomes (see Figure 7.3). More than half of the known Mendelian

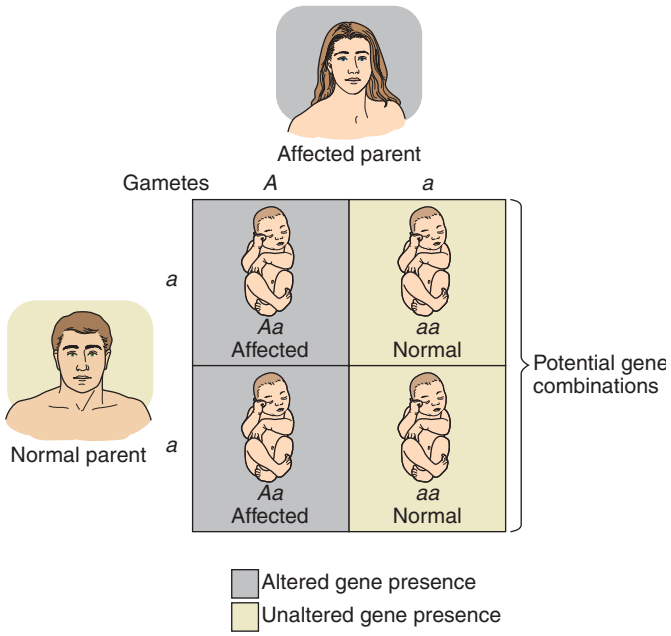

FIGURE 7.3 ■ This Punnett square shows potential gene combinations (genotypes) and resulting phenotypes of children from parent genotypes with an autosomal dominant altered gene. Phenotypes are expressed (affected) when a male or female has one copy of the gene alteration

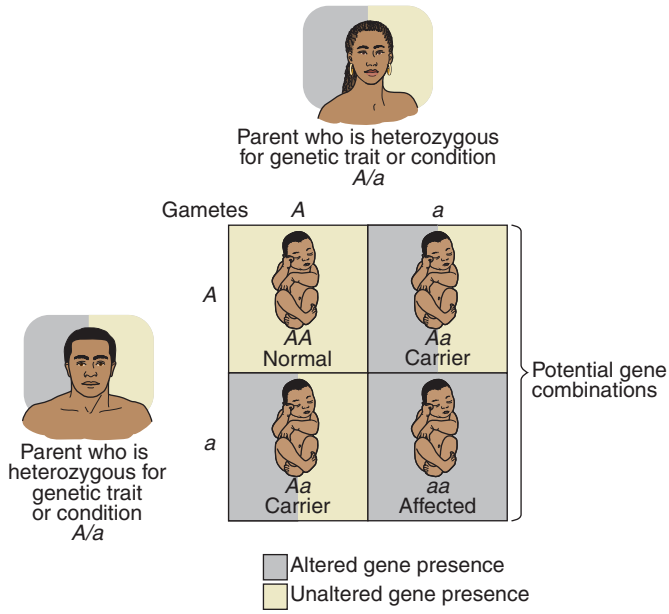

FIGURE 7.4 ■ This Punnett square shows potential gene combinations (genotypes) and resulting phenotypes of children from parent genotypes with an autosomal recessive altered gene. Phenotypes are expressed (affected) when a male or female has two copies of the gene alteration

conditions are autosomal dominant. In AD conditions, disease occurs in spite of the fact that there exists one unaltered or normal gene. Also, homozygous dominant conditions are generally much more severe than heterozygous dominant conditions and are often lethal. Because homozygous dominant conditions are usually lethal and would result from *both parents being affected*, the nurse or midwife should consider an individual exhibiting an autosomal dominant condition as heterozygous. See Box 7.4 for characteristics of an AD pattern of inheritance.

BOX 7.4 Autosomal dominant Mendelian inheritance characteristics

(*Examples:* neurofibromatosis, breast and ovarian cancer, autosomal dominant polycystic kidney disease, Marfan's syndrome, Huntington's disease, familial hypercholesterolaemia.)

When the health professional gathers a family history, they should assess for any of the following characteristics of autosomal dominant inheritance:

1. Both males and females are affected.
2. Males and females are usually affected in equal numbers.
3. An affected child will have an affected parent and/or all generations will have an affected individual (appearing as a vertical pattern of affected individuals on the family pedigree).
4. Unaffected children of an affected parent will have unaffected offspring.
5. A significant proportion of isolated cases are due to a new mutation.

Autosomal recessive conditions

A gene or genetic condition is considered recessive when two copies of altered genes are needed to express the condition—for example, cystic fibrosis. Autosomal recessive (AR) conditions are the result of an altered gene on any of the 22 autosomes or non-sex chromosomes (see Figure 7.4). An individual with a recessive condition has inherited one altered gene from their mother and one from their father. In most cases, neither of the parents is affected and, therefore, each of the parents must have a single gene alteration on one chromosome of a pair and the normal, wild-type or unaltered form of the gene on the other chromosome. These parents would be known as **carriers** of the condition and they do not usually exhibit any signs and symptoms of the condition. Because the gene alteration occurs on a non-sex chromosome, both males and females have an equal chance of inheriting the altered gene from their parent. Generally, conditions that are autosomal recessive are more severe and have an earlier onset than conditions with other patterns of inheritance. Most inborn errors in metabolism or metabolic conditions are autosomal recessive. Many are enzyme defects and the functioning of the unaltered gene is sufficient to provide normal functioning in the person who is heterozygous or the carrier of one copy of the altered gene (Lashley, 2005). See Box 7.5 for characteristics of an AR pattern of inheritance.

X-linked recessive conditions

X-linked conditions are the result of an altered gene on the X chromosome. Unlike the autosomes, the sex chromosome, X, is unevenly distributed to males and females. The female has two X chromosomes and the male has only one. Thus, the family history and pattern of inheritance has a characteristic distribution pattern among the males and females in the family (see Figure 7.5).

BOX 7.5 Autosomal recessive Mendelian inheritance characteristics

(*Examples*: haemochromatosis type 1, cystic fibrosis, phenylketonuria, sickle cell anaemia.)

When the health professional gathers a family history, they should assess for any of the following characteristics of autosomal recessive inheritance:

1. Both males and females are affected.
2. Males and females are usually affected in equal numbers.
3. An affected child will have an unaffected parent but may have affected siblings (appearing as a horizontal pattern of affected individuals on the family pedigree).
4. The condition may appear to skip a generation.
5. The parents of the affected child may be consanguineous (close blood relatives).
6. The family may be descendants of a certain ethnic group that is known to have a more frequent occurrence of a certain genetic condition.

Because the male has only one copy of any gene on the X chromosome, it becomes the only copy available to give direction for those particular functions of these genes regardless of whether it is considered dominant or recessive in the female. Thus, if any of these genes are altered, an unaltered counterpart is not present to 'override' the altered functioning gene.

The consequences of the altered gene on an X chromosome will be expressed in all males. Females, on the other hand, will have two copies and the unaltered gene generally compensates for the altered gene, making the female a carrier. The male receives his X chromosome from his mother and his Y chromosome from his father. The female offspring receives an X chromosome from each of her parents. Thus, all affected males will pass on the altered X chromosome to all of his daughters who will be carriers of the altered gene. A male can never transmit an altered gene on the X chromosome to his sons because the male will transmit only the Y chromosome to his sons. Because of these transmission patterns, the most commonly occurring transmission of an X-linked condition is through a female who is a carrier of an altered gene. See Box 7.6 for characteristics of an X-linked recessive pattern of inheritance.

X-linked dominant conditions

X-linked dominant conditions also exist but are very rare. The inheritance pattern for X-linked inheritance differs from autosomal inheritance only because the X chromosome has no homologous chromosome in the male; the male has an X and a Y chromosome. For an X-linked dominant disorder, if the father carries the abnormal X gene, all of his daughters will inherit the disease but no sons will have the disease. If the mother carries the abnormal X gene, 50% of all her children (daughters and sons) will inherit the disease tendency. The other children inherit the normal copy of the chromosome. If a male is affected, the condition is severe and often lethal.

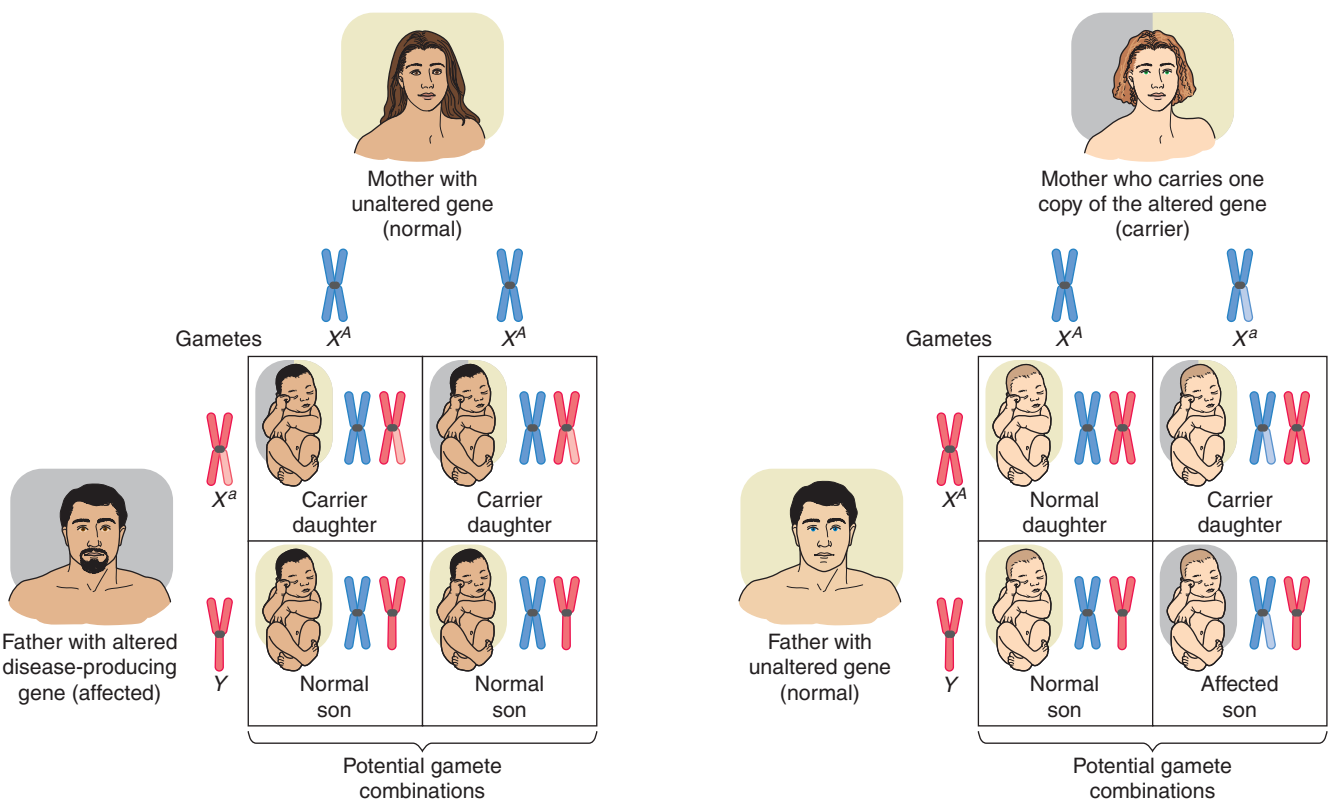

FIGURE 7.5 ■ These Punnett squares show potential gene combinations (genotypes) and resulting phenotypes of children from different parent genotypes with an X-linked recessive altered gene. Phenotypes are expressed (affected) in a male with only one copy of the gene alteration and in a female with two copies of the altered gene

BOX 7.6 X-linked recessive Mendelian inheritance characteristics

(*Examples:* haemophilia A; Duchenne muscular dystrophy.)
When gathering a family history, the health professional should assess for any of the following characteristics of X-linked recessive inheritance:

1. More males will be affected than females; rarely seen in females.
2. An affected male will have all carrier daughters.
3. There is no male-to-male inheritance.
4. Affected males are related by carrier females.
5. Females may report varying milder symptoms of the condition.
6. A new sporadic case could be due to a new mutation.

A family history of multiple male miscarriages may be a sign of an X-linked dominant condition. X-linked dominant diseases are very uncommon, but some inherited forms of rickets are transmitted in this manner. Very few genes have been discovered on the Y chromosome.

Variability in classic Mendelian patterns of inheritance

Along with understanding the classic Mendelian inheritance patterns, several other concepts are also important for families to understand when health professionals are assisting people with, or at risk of inheriting, a genetic disorder. These include the following exceptions or variations to the traditional Mendelian patterns of inheritance.

Penetrance

Penetrance is the probability that a gene will be expressed phenotypically. It is an 'all or none' concept, in that either the gene will be expressed (even if mildly expressed) or it will not be expressed at all. Penetrance can be measured in the following way. In a certain group of individuals with the same genotype, what percentage of them will exhibit at least some signs and/or symptoms of the condition? If the number is less than 100%, then that condition is said to show reduced penetrance. For example, the gene alterations that cause achondroplasia exhibit 100% penetrance and all individuals with one copy of the gene alteration will exhibit signs and symptoms of the disease (Daly et al., 2010; Nussbaum et al., 2007).

New mutation

When there is no previous history of a condition, including even subtle signs and symptoms of the disease in any other immediate or distant family member, the disease may be caused by a spontaneous new mutation. This case is usually called *de novo* mutation. New mutations of a gene are most frequently seen in autosomal dominant conditions because one copy of an altered gene is all that is necessary to elicit a state of altered health. Autosomal dominant diseases known to have high mutation rates include neurofibromatosis, achondroplasia (dwarfism) and Marfan's syndrome. New mutations are also possible in autosomal recessive diseases, although rarely expressed because two altered genes are necessary for signs and symptoms to appear. Finally, new mutations are often seen in X-linked recessive disorders, such as haemophilia A, since a male with just one altered gene will demonstrate the disease.

Anticipation

Anticipation is said to occur when successive generations of a family exhibit more severe signs and symptoms of certain diseases and the disease often has an earlier onset. An example is myotonic dystrophy type 1, an autosomal dominant condition characterised by a range of signs and symptoms including myotonia, muscle weakness, cataracts and cardiac arrhythmias. The congenital form is severe, causing intellectual disability, and may be life threatening. Most children with this congenital form of myotonic dystrophy have a mildly affected mother who may not even be aware she has the disease (Nussbaum et al., 2007). The severity of the condition, as well as the age of onset, is determined by the number of trinucleotide repeats. Trinucleotide repeats are short DNA sequences such as the CTG base sequence of the gene DMPK that are repeated to more than 2000 times, resulting in alterations in the protein products produced by the gene and varying signs and symptoms.

Variable expressivity

Expressivity is used to describe the severity of the **gene expression** of the phenotype. When people with the same genetic make-up (genotype) exhibit signs and/or symptoms with varying degrees of severity the phenotype is described as *achondroplasia* exhibit 100% penetrance (Nussbaum et al., 2007).

Neurofibromatosis type 1 (NF1) is a common autosomal dominant disorder which displays considerable inter- and intra-familial variability in phenotypic expression. Although neurofibromatosis has 100% penetrance, variable expressivity can occur within family members with each family member exhibiting a variety of signs and/or symptoms.

Multifactorial (polygenic or complex) disorders

Many birth defects such as cleft lip and palate, as well as many adult-onset conditions such as cancer, mental illnesses, asthma, diabetes, obesity, heart disease and Alzheimer's disease, have a multifactorial cause. **Multifactorial** conditions occur as a result of several gene (polygenic) variations, lifestyle and environmental influences that work together. The polygenic concept is illustrated with the multiple genes involved in an individual's susceptibility for breast cancer. These genes have been identified on chromosomes 6, 11, 13, 14, 15, 17 and 22. Exactly which genes interrelate and how many environmental influences are enough to cause the presentation of many of the common complex diseases or conditions is not known. It is now known that the birth defect spina bifida is caused by the action of several genes, but its prevalence also depends on the amount of folate in the diet. Hypertension is influenced by a number of genes, but also by obesity. The precise causes of multiple sclerosis (MS) are largely unknown. MS is most likely a multifactorial condition involving interaction between genetic, lifestyle and environmental factors. It is well documented that MS also runs in some

families. There are probably a number of genes that cause susceptibility to MS as well as affecting the severity and progression of the disease. The major contributing genes for many common complex conditions have now been identified.

Multifactorial conditions accumulate in families, but these conditions do not follow the characteristic Mendelian pattern of inheritance seen with single-gene conditions. Inheritable recurrence risks vary in multifactorial conditions. With information gathered from a family history, basic occurrence risks can be assessed for an individual. For instance, premature death in a first-degree relative, two affected first-degree relatives, and two second-degree maternal or paternal relatives with at least one individual having premature onset of the disease are all considered high inheritance risks. Moderate risks include an individual having a first-degree relative with late or unknown disease onset or two second-degree relatives from the same lineage with late or unknown disease onset. An individual having no affected relatives or a negative family history, or only one affected second-degree relative from one or both sides of the pedigree, is considered average or general population risk (Scheuner et al., 1997).

Recurrence risks refer to whether or not a condition will occur again in subsequent pregnancies. Because a Mendelian pattern is not present, statistical percentages can be used to represent the chance that parents have a condition that will occur in another child. The risk of recurrence is higher when more than one family member is affected. The recurrence risk after the first affected child is 4%, whereas the recurrence risk after a second affected child increases to 10%. It is also known that the recurrence risk increases with an increase in severity of the defect.

INTERPROFESSIONAL CARE

Many health professionals work together in the screening, diagnosis, identification, prediction and treatment of genetic disorders. The goals of collaborative care are early diagnosis through testing and assessment, prediction and development of an effective treatment plan, psychosocial support to enhance decision making and coping, and referral to a genetic specialist as needed.

Genetic testing

Genetic testing may be used for a person's clinical management, for making personal decisions or for assisting in reproductive choices. A genetic test is very different from other types of clinical tests. Genetic tests involve the analysis of DNA, RNA, chromosomes and serum levels of specific enzymes or metabolites. Enzymes and metabolites are part of the protein products that genes produce. DNA, RNA and/or chromosomes are unique for each individual and the results have personal, social, financial and legal implications. Some genetic tests are diagnostic, while others are predictive or inform the individual of an increased risk of acquiring a disease or condition. A 'positive' genetic test may indicate that an asymptomatic individual will develop a genetic condition, but a prediction of the onset or severity of the condition cannot be made.

Complications also arise in a person's understanding because a negative test result cannot guarantee that the disease or condition might not develop in the future, often because environmental influences cannot be measured or controlled. Also, the genetic test may have only been able to detect the most common gene mutations and not all of the disease-producing gene alterations are known or available for inclusion in clinical testing. People may learn that they will develop a genetic condition such as Huntington's disease, for which there is no treatment. People may find out through genetic testing that they are a carrier and they have unknowingly passed the altered disease-producing gene on to their children.

Finally, the implications of genetic test results are far reaching. While confidentiality and autonomy for the individuals are always foremost for the nurse, the implications for the person's children, grandchildren, siblings and other extended family members who share a percentage of the same genes can be life altering. This information may be very confusing and very different from how they have perceived healthcare in the past and how they perceived the implications of a simple 'blood test'.

TYPES OF GENETIC TESTS Nurses and midwives should understand that genetic tests can be classified into two categories: screening and diagnostic. A positive screening genetic test result notifies the person of an increased risk or probability but must always be confirmed by diagnostic testing. Screening genetic tests are most commonly completed in prenatal, newborn and carrier circumstances. In contrast, a diagnostic test can definitively validate or eliminate a genetic disorder in the symptomatic person and then direct clinical management. Box 7.7 lists some of the positive and negative aspects of genetic testing.

BOX 7.7 Positive and negative outcomes related to genetic testing

Benefits of genetic testing

Provides for:

- Early screening and preventive measures
- Future planning and life preparation
- Lifestyle adaptations
- Decreased confusion and anxiety
- Psychological stress relief
- Reproductive choices
- Informed extended family members
- Early medical and/or surgical intervention
- Cost of medical follow-up reduced (if negative result).

Possible negative outcomes of genetic testing

- Survivor guilt
- Loss of identity
- No treatment may exist
- Employability and insurability affected
- Confusion about accessing healthcare and resources
- Risk of invasion of confidentiality and privacy
- Social stigmatisation.

Source: Data from Secretary's Advisory Committee on Genetic Testing (SACGT), *National Institutes of Health, 2000.*

Several categories of genetic tests included as subcategories of screening and diagnostic genetic tests follow:

- *Newborn screening*. In Australia, the Guthrie test is offered to mothers of all newborn infants and provides a means to identify children who have an increased risk of developing more than 30 genetic diseases such as phenylketonuria, CF and hypothyroidism. Some researchers are lobbying for newborns to be tested for fragile X syndrome, which is the most common cause of inherited intellectual disability, even though in Australia it affects only about 1 in 3600 males and between 1 in 4000 and 1 in 6000 females. The syndrome is caused by a genetic abnormality on the X chromosome, where a single sequence of three DNA base pairs is repeated many times, with devastating consequences.
- *Carrier testing* is completed on asymptomatic individuals who may be carriers of one copy of a gene alteration that can be transmitted to future children in an autosomal recessive or X-linked pattern of inheritance. This may be part of a couple's premarriage or preconception planning if they belong to a particular ethnic group with known risks of developing genetic disorders such as sickle cell anaemia and haemophilia. It may be necessary to determine the exact gene mutation from an affected family member prior to carrier testing. This is often completed through lineage analysis. In Australia, the haemoglobinopathies are the only group of conditions for which population screening is widely offered and which is government funded. The thalassaemias are the most common single gene disorders in the world's population and are a common cause of hereditary anaemia. Recent immigration to Australia, especially from South-East Asia, has introduced large numbers of people from areas where alpha-thalassaemia is common. Screening programs, particularly antenatal testing, are used to detect the carrier state for alpha-thalassaemia as well as the Hb variants in the homozygous form, or in combination with alpha-thalassaemia, which may cause severe disease. In some Australian states there are also population screening programs for cystic fibrosis and autosomal recessive conditions more common in Ashkenazi (Eastern European) Jewish individuals; this screening is generally offered on a user-pays basis.
- *Preimplantation genetic diagnosis (PGD).* Parents with a family history of a serious or fatal genetic condition now have the option of combining IVF and genetic testing, in a technique known as preimplantation genetic diagnosis (PGD). Couples using PGD first need to use IVF procedures to generate embryos. A single cell can then be removed from the early embryo without damaging it. This cell can be tested to see if it carries the genetic defect that causes the condition. Only embryos that do not carry the defective gene are implanted in the mother. Some couples have used PGD on embryos to determine if they can provide a bone marrow transplant for a sick sibling. The bone marrow cells for the sick sibling are taken from the umbilical cord blood of the new baby. Using this process of tissue typing, these babies are sometimes called 'saviour siblings', as they have the potential to save their brother or sister's life.
- Regulations regarding this use of PGD testing vary from country to country. In Australia, some states have PGD regulations and others do not. (See www.nscc.edu.au/public-education_what-cells_cord.aspx for a discussion of the social and ethical implications of this form of genetic testing.)
- *Predictive genetic testing* is usually made available to the asymptomatic individual and includes both predispositional and presymptomatic testing. A positive predispositional testing result will indicate there is an increased risk that the individual might eventually develop the disease. Common examples include breast cancer and hereditary non-polyposis colorectal cancer. A presymptomatic test is performed when development of the disease is certain if the gene alteration is present. The Australian Breast Cancer Network (2013) position statement explains that an extensive family history of breast cancer is a known predictive risk factor for the disease. A strong family history can indicate an inherited predisposition through the presence of a germline mutation in genes associated with breast cancer. A germline mutation is a mutation that occurs in the genetic material of the egg or sperm and can be passed on at conception. Inherited gene mutations account for 5% to 10% of all breast cancer. Some research suggests that BRCA1 and BRCA2 are tumour suppressor genes; that is, genes whose loss of function can lead to neoplastic growth. However, other studies point to the role of BRCA1 and BRCA2 in DNA repair, where inadequate repair may cause additional mutations and ultimately cancer.
- The estimated frequency of BRCA1 or BRCA2 gene mutation carriers in the general population is 1 per 1000 people. The frequency in specific population groups has also been estimated: for those of Ashkenazi Jewish descent, the rate of BRCA1 or BRCA2 gene mutation carriers is 1 per 50 to 100 people.
- Women with inherited mutations in genes such as BRCA1 and BRCA2 have a potentially high risk of developing breast cancer and for developing the disease at an earlier age. Those carrying mutations are also at increased risk of cancers of the ovary and fallopian tube (and perhaps other cancers). It is important to note that the risk of developing breast cancer never reaches 100%, which means that those with inherited gene mutations have a genetic predisposition to the disease but are not certain to develop it.
- Predictive genetic testing is medically indicated when the seriousness and mortality of the disease can be reduced with knowledge of the gene alteration. Life planning and lifestyle choices can be influenced by predictive testing. In Australia, premiums for private health insurance are not based on risk assessment according to the individual's present or past health or their family history. Premiums for life insurance products, which include cover for life, disability and trauma, and business and bank loans, are calculated according to the present and past health of the applicant and any genetic information, including their family history or any genetic test result (underwritten). The Investment and Financial Services Association Ltd (IFSA) has a policy on genetic testing and life insurance which states that no applicant will be required to undergo a predictive genetic test. Under Australian law, an application for a life insurance product is required to disclose any health or genetic information known to the applicant (Otlowski et al., 2007).
- Other uses of genetic testing include organ transplantation tissue typing and pharmacogenetic testing, which involves

predicting or studying the person's response to particular medications (Javitt, Stanley & Hudson, 2004). Predictive tests and carrier tests are now being offered to determine if people are at risk of conditions such as Alzheimer's disease (AD). The precise causation of AD is not fully understood. However, some cases of early-onset AD are caused by a number of genetic mutations on chromosomes 21, 14 and 1. Scientists have recently discovered that the mutations seen in early-onset AD are not involved in this form of disease. Dozens of studies have confirmed that the APOE-D4 allele increases the risk of developing AD. In September 2009, researchers identified three genes (CLU, PICALM and CR1) that significantly increase the risk of someone developing AD. Three of the genes have roles in protecting the brain from damage. Changes in the genes may remove this protection or may even turn them into 'killers' (van Es & van den Berg (2009).

DIAGNOSING CHROMOSOMAL ALTERATIONS Microscopic examination of chromosomes through a karyotype can reveal chromosomal alterations such as chromosomal additions, deletions, gross breaks, and rearrangements or rejoinings (translocations) (USDOE Genome Programs, 2008). Among other things, these chromosomal alterations are responsible for many forms of cancer and, more importantly, particular tumour types. Chromosomal diagnostic examination can be accomplished with a simple blood sample and skin or buccal cell sampling. A karyotype is completed in a cytogenetics laboratory. Chromosomes can be identified by their size and unique light and dark banding patterns. The pairs of autosomal chromosomes are arranged from 1 to 22 according to each chromosome's size, unique banding patterns and centromere position. The sex chromosomes complete the picture, with the X chromosome(s) first, then the Y chromosome (if present). The karyotype shows all of the chromosome pairs lined up and positioned on a piece of paper, allowing for visual chromosomal analysis. (See Figure 7.2 earlier in this chapter.) The final report contains numerical data that includes the total number of chromosomes present. If there is an additional or deleted chromosome, it is identified with a plus (+) or minus (–) symbol. For example, the male individual with 47, XY, +18 has 47 chromosomes (instead of the expected number of 46) that include an additional chromosome 18. Guidelines for writing results of karyotyping are determined by the International System of Human Cytogenetic Nomenclature (ISCN). These guidelines allow for use of a standardised universal language by cytogenetic laboratories and in medical publications.

DIAGNOSING GENE ALTERATIONS With the rapidly expanding advances in technology and the identification of genes in the human genome, the availability of genetic, DNA (gene)-based tests has grown tremendously. Currently, more than 1000 genetic tests are available with more becoming available each day (USDOE Genome Programs, 2008). **DNA-based tests** involve new, sophisticated technology that permits the examination of the DNA itself. Genetic testing that is DNA-based can be obtained from blood, bone marrow, amniotic fluid, fibroblast cells of the skin, or buccal cells from the mouth. Genetic testing includes different types of DNA-based tests. The appropriate genetic tests may be testing for a specific mutation. This would be used if a family member was known to have a genetic condition and could therefore be tested for that particular gene alteration. Another way to examine DNA is by running a panel of mutations. This is done when there are a specific number of identified genes that the majority of individuals with a genetic condition have—for instance, a panel of the three mutations on the BRCA1 gene that are common in the Ashkenazi Jewish population. A third type of DNA-based test is a complete gene sequence (GeneTests, 2004).

Quality and accuracy of genetic tests

Genetic nurses have expressed concerns that genetic tests are becoming available too quickly, with no regulation of the companies that are offering genetic tests. The quality, accuracy and reliability of genetic test results are not measured against any common standard. Individuals often make hard and irrevocable life-altering decisions after receiving test results, so accuracy and reliability are essential. Also, in most cases, minimal or no education is provided for the individual who is undergoing testing; nor is there any quality counselling or follow-up after the results are given to the individual. Genetic tests are often offered by laboratories before the tests have been proven safe, effective and practical. Because the majority of genetic conditions are rare, there is often only one laboratory offering the genetic test that is needed. Recently, concerns have been voiced about 'direct-to-consumer' genetic testing. Genetic tests are being offered at 'walk-in' locations and also via the internet. Individuals can receive results of genetic tests in private without a physician's order and fear of discrimination, but also without education or knowledge of the implications of the test results.

Concerns also exist related to test validity, test sensitivity and specificity, the quality of the laboratory performing the test, and the competence of the person's healthcare provider to interpret the test results. **Test sensitivity** refers to how specifically the test identifies (positive test result) individuals who are affected and/or who have the disease phenotype. A test with a high degree of sensitivity has very few false negatives and many true positives. **Test specificity** refers to how specifically the test does not identify (negative test result) individuals who are unaffected or do not have the disease phenotype. A test with a high degree of specificity has very few false positives (SACGT, 2000). The laboratory selected for the genetic test should have a CLIA88 (Clinical Laboratories Improvement Amendments of 1988) certification (Javitt, Stanley & Hudson, 2004).

Nursing care

The role of the nurse in genetic testing

With knowledge of available genetic tests and the many implications related to genetic testing, the nurse can assist people as they weigh choices regarding genetic testing. As consumers of multimedia, people often have unreliable sources for information related to genetic testing. They may form many misconceptions about the types of genetic tests available and what information these different types of genetic tests are able and not able to provide. Nurses involved in education about genetic testing must include education for the individual and the

family. Communication with the person about genetic testing should include an assessment of the positive and negative outcomes of the test. Are there existing treatments for the condition being tested? Psychological issues should also be emphasised. Who will be affected by the test results? Will the test results be shared with extended family members?

The nurse is responsible for alerting people to their right to make an informed decision prior to any genetic testing, with consideration of the special circumstances arising from the family, culture and community life. All genetic testing should be voluntary and it is the nurse's responsibility to ensure that the consent process includes discussion of the risks and benefits of the test, including any physical harm as well as potential psychological and societal injury by stigmatisation, discrimination and emotional stress (Beskow et al., 2001; International Society of Nurses in Genetics, 2005).

Above all, nurses have a responsibility to fully educate people about the multiple issues related to genetic testing. People should engage in genetic testing with full knowledge and confidentiality, and autonomously. Informed consent may be given verbally, although some laboratories require written consent. Prior to the testing, the people should have an idea of the probability of a positive or negative result, if one can be determined by the person's or family history (GeneTests, 2004). To deliver the expected standard of care, it is imperative that the nurse includes these issues when developing an educational plan for the person anticipating the use of genetic testing and as part of the informed consent process.

Ensuring confidentiality and privacy for genetic testing

Although confidentiality and privacy are integral parts of delivery of care for all nurses, this issue is of even more concern as it relates to genetic information. Results of genetic tests can be far reaching and can affect employment and insurance options. Will the results affect the person's ability to obtain and/or maintain insurance coverage? Can an employer refuse to hire or promote an individual because of genetic testing results? Can genetic information be released to the courts, the armed forces, schools or adoption agencies? Would a person with a known gene alteration for Huntington's disease be offered a scholarship to the best university? There is debate over whether genetic privacy is different from medical privacy. Nurses should inform people of their rights and responsibilities regarding who will have access to the genetic test results. Those providing the genetic tests must provide the person with assurance that the results will be handled confidentially and that there will be no access to the genetic information by a third party without written permission of the individual being tested.

Results of genetic tests should only be communicated directly to the individual who gave the consent. No outside governmental, employment or insurance organisations should ever have access to genetic test results without the written permission of individuals. People should confirm how they will receive the test results. They should ask who will have access to the test results and what will happen to the DNA sample after the test is completed. In the majority of cases, results of genetic tests should not be shared with extended family members without written permission. Healthcare providers are legally liable to maintain that confidence. Exceptions to the individual's privacy may be made only when the individual refuses to inform extended family members when a very high probability of irreversible harm exists for an extended family member, and informing the family member can prevent the harm (Badzek et al., 2013; National Human Genome Research Institute, 2008). Every effort should be made to educate the individual about the benefits of informing extended family members if applicable. Genetic testing should ideally be accompanied by pre-test and post-test counselling by genetic specialists or by another knowledgeable healthcare provider.

Psychosocial issues

Although family and individual anxiety may be decreased with a negative test result, potential problems do exist and the nurse or midwife must be prepared to address them. Concerns about carrier status may interfere with development of intimacy and interpersonal relationships. Non-paternity may be revealed through genetic testing. For example, the parents of a child born with an autosomal recessive condition will be considered carriers of the altered gene the majority of the time. To counsel the parents about future pregnancies, the parents would be tested to confirm their genotype and non-paternity may become an issue. A positive test result may lead to feelings of unworthiness, confusion, anger, depression and self-image disturbance. Survivor guilt may affect adults with negative results if their siblings are positive. The individual carrying a gene alteration for a late-onset disease may have an increased tendency for risky behaviours and may choose not to be a positive member of society. Relatives of an individual affected with a genetic disorder may be very frightened when they realise what their own future might be (SACGT, 2000). The individual who has inherited an altered disease-producing gene may foster deep resentment towards the parent who carries the altered gene. Parents and older generations may feel tremendous guilt for passing the altered gene to their children and grandchildren (Wertz, Famos & Reilly, 1994).

Economic issues

The nurse should consider the cost of genetic tests, which can range from hundreds to thousands of dollars, depending on the size of the gene being tested. In Australia, many of the tests are sent to overseas organisations for analysis.

Genetic tests differ from routine medical tests in many ways. The risks and benefits of genetic testing are numerous and complicated. Nurses have an obligation to maintain their knowledge regarding genetic testing, to advocate for the person, and to maintain ethical standards of care. Above all, nurses and midwives must be able to recognise the limits of their expertise and how to refer a person to genetic specialists and additional resources.

Assessment

Health promotion and health maintenance

Health promotion and health maintenance of the person are viewed as the foundations of all nursing and midwifery care. However, most individuals do not know their complete genetic make-up. Some know they carry an altered gene that causes a specific disease, but the majority of individuals do not know with certainty what their future health status will be. With no

sure knowledge of genetic make-up or whether a certain alteration in health status will occur (e.g. heart disease), healthy lifestyles are not always a priority. Imagine, then, if people knew their statistical risks for developing or inheriting disease by having complete access to the types of genes in their cells? Health promotion and health maintenance teaching and nursing interventions would be based on specific genes. The nurse could provide important, life-saving nutritional information to people based on their specific risks, and each individual then might be more inclined to maintain a proper diet, give up their sedentary lifestyle, increase exercise and decrease fast-food intake. Personal lifestyle choices would become more personal and monitoring health might take on a new meaning.

With knowledge of genetic conditions, the nurse can ensure health teaching and early detection of complications from genetic conditions with emphasis on primary and secondary care interventions. For example:

- A woman with a strong family history and/or mutations in the BRCA1 and BRCA2 tumour suppressor genes should begin monthly self breast exams and have screening clinical breast exams and mammographies at an earlier age than the general population.
- A man with a strong family history and/or mutations in the BRCA1 and BRCA2 tumour suppressor genes should report any mass, tenderness or swelling in the breast tissue and maintain early screening for prostate cancer.
- Aggressive colonoscopy screening every 1 to 2 years beginning at age 25 is important for the individual with a positive family history and/or mutations in the MLH1/MSH2 gene, which increases the risk of hereditary nonpolyposis colorectal cancer.

People receiving early intervention and health-promotion-focused care can live longer and with a much better quality of life than those who do not. The nurse must be able to identify both community-based and genetic-based resources that are available to assist the person with strategies to support both health promotion and health maintenance activities.

By simply integrating into practice the genetic aspects of assessment, observation and history gathering, the nurse can improve the standard of care delivered and have a very positive impact on the person. The nurse does not need to be a genetic expert, but with heightened awareness, appropriate inquiries and referrals to genetic specialists can be completed.

Health history

Nurses can improve the standard of nursing care and have a positive impact on people by integrating genetic concepts into their existing practice of inspection, observation and history gathering. Nurses should be able to recognise genetic features of physical assessment, basic patterns of inheritance and predisposition to development of disease. As health professionals integrate genetic concepts into their delivery of care, appropriate inquiries and referrals to genetic specialists can be completed.

Although family history has long been a part of nursing assessments, the relative importance of this assessment piece has recently increased as our knowledge of the interaction of genes and the environment has expanded. In phenotypically 'healthy' individuals, an accurate and complete family history can identify a single-gene (Mendelian) disorder or a mitochondrial, multifactorial or chromosomal inheritance pattern as well as guide the prevention, diagnosis and treatment of common complex diseases such as cardiovascular disease and cancer. A family history illustrates the interaction of genes and the environment for an individual and consequently provides a basis for individualised disease prevention (Guttmacher et al., 2004). Although an individual's inheritance risks from their own genotype are non-modifiable, knowledge of an individual's increased risk of chronic disease can influence lifestyle choices, clinical management, and sometimes risk reduction and prevention of the disease. Knowledge of a family history can also guide diagnostic workups and clinical treatment (Guttmacher et al., 2004).

Pedigrees

A nurse should know how to take a family history, record the history in a pedigree and think 'genetically'. A pedigree is a pictorial representation or diagram of the medical history of a family. Multiple symbols are utilised to present this picture (see Figure 7.6) and the finished pedigree presents a family's medical data and biological relationship information at a glance (see Figure 7.7). A pedigree provides the nurse, genetic counsellor or geneticist with a clear, visual representation of relationships of affected individuals to the immediate and extended family. It can identify other individuals in the family who might benefit from a genetic consultation. It can also

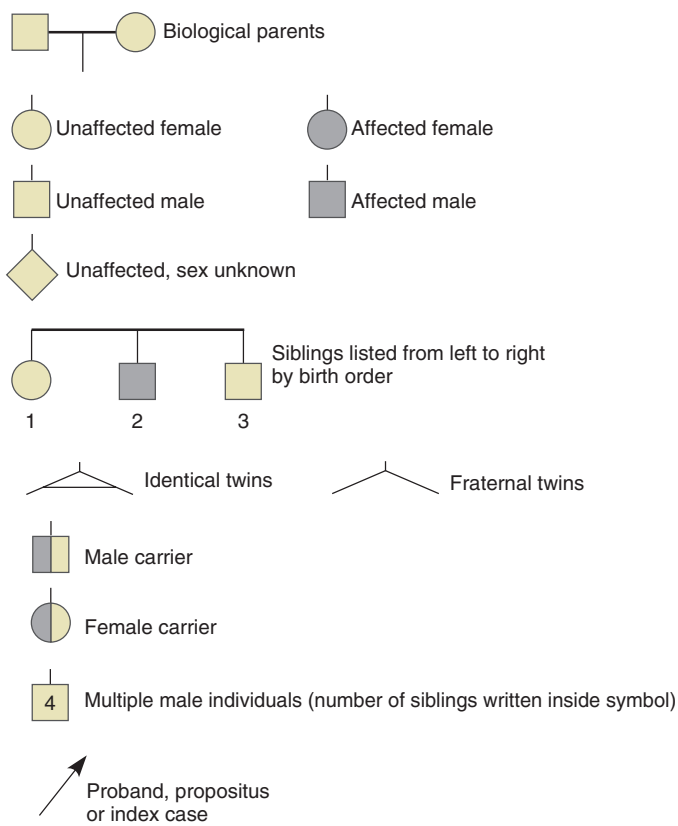

FIGURE 7.6 ■ Selected standardised symbols for use in drawing a pedigree

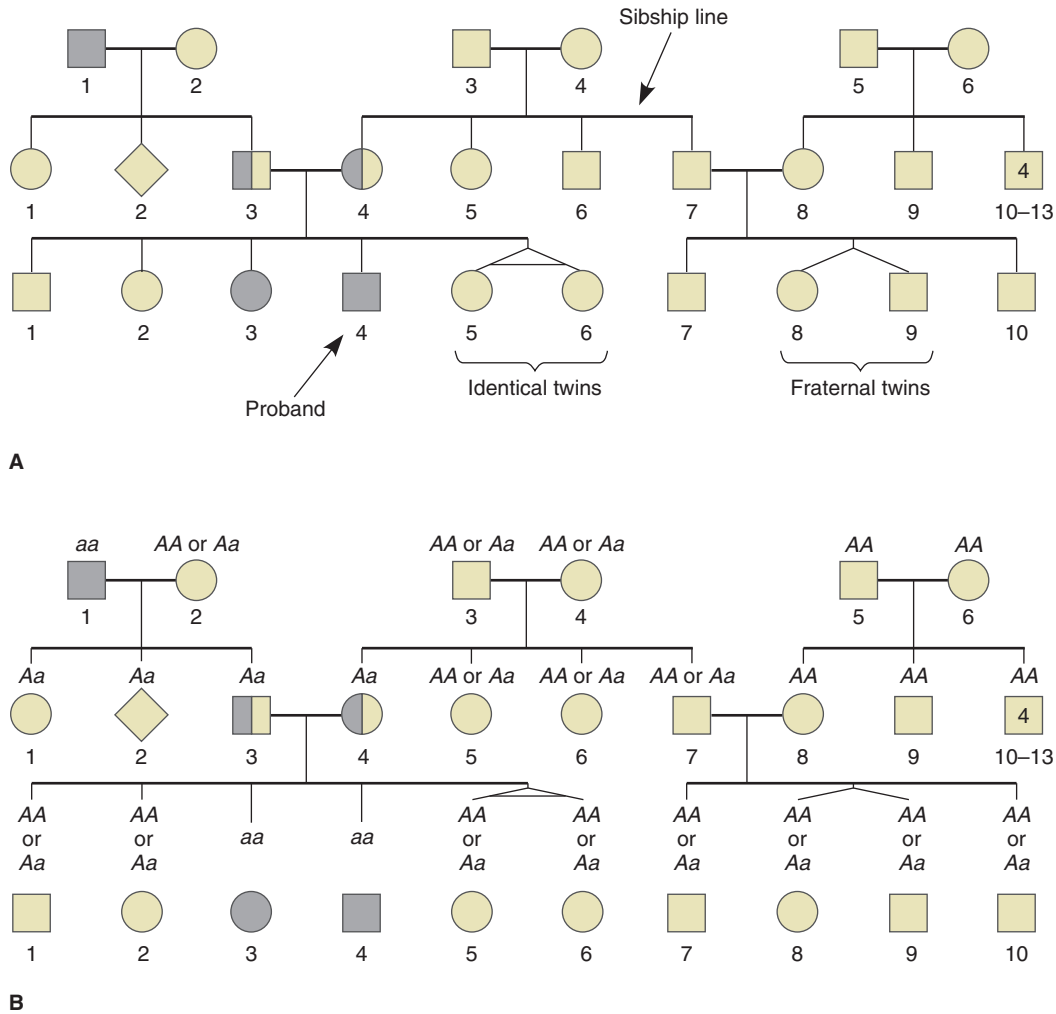

FIGURE 7.7 ■ Sample three-generation pedigree. *A*, A representative pedigree for a single character or genetic condition through three generations. *B*, The most probable genotypes of each individual in the pedigree for an autosomal recessive condition, represented by AA, Aa, or aa

identify a single-gene alteration pattern of inheritance or a cluster of multifactorial conditions, and a referral and/or reproductive risk teaching for the individual and family can result. A family's learning can be enhanced by the visual teaching contribution a pedigree can provide and which may also clarify any inheritance misunderstandings or misconceptions. Box 7.8 lists steps for creating a family pedigree. If correctly and fully completed, a pedigree allows all healthcare professionals working with the individual or family to quickly see what history and background information has been collected (see Box 7.9).

It is important to gather a three-generation family pedigree even if the nurse believes this is a first occasion of the condition within a family (see Figure 7.7). A condition without any identifiable inheritance pattern on the pedigree may be due to a new mutation or variable expressivity. Throughout the process of gathering family history assessment data, the nurse must remember family confidentiality at all times: all information related to a pedigree is confidential information. The history may reveal sensitive details that include infertility problems, elective termination of pregnancies or non-paternity. This information may not even be known by a current partner or immediate and extended family members. Other sensitive issues include pregnancies conceived by technology, a history of suicides, drug or alcohol abuse, and same-sex relationships. Box 7.10 lists ethical implications of genetic information.

Challenges inherent in recalling the family history include the person's inability to remember any conditions that may have been surgically repaired and then forgotten, or reporting conditions that may have been attributed incorrectly to other causes. Also, the family history may contain information previously unknown to extended family members. Reproductive decisions may have been made that were against the family's religious or cultural beliefs. Both immediate and extended

BOX 7.8 Steps in drawing a pedigree

I. How to:
   1. Work in pencil.
      a. Family historians often remember additional relatives and details only after questioning is almost completed.

II. Organisation:
   1. Begin recording data in the middle of the sheet of paper.
      a. Allow enough room for both the maternal and paternal sides of the family.
   2. Use only standard pedigree symbols.
      a. For example, males are represented by squares and females by a circle.
   3. The male individual in a couple is placed on the left of the relationship line and the paternal side of the family also goes on the left-hand side of the paper.

III. Determining family relationships:
   1. The clinician should determine the relationships within the family by asking questions such as:
      - Do you have a partner or are you married?
      - How many biological brothers and sisters do you have?
      - How many children do you have?
      - Do all the children have the same biological father?
      - Do all the children share the same mother and father?
   2. Referral to 'the baby's father or mother' can be helpful until a relationship or marriage is established between the parents.
   3. Referral to a 'union' if marriage does not exist can also help communication.
   4. Determine if each individual is married, has children, signs and symptoms, etc., before continuing on to the next individual.
   5. Always ask if there is any chance the mother could be related to the father or if any other parents in the family are blood relatives.
      - To determine consanguinity.

IV. Who should or should not be included:
   1. To ensure accuracy, the pedigree should include the parents, offspring, siblings, aunts, uncles, grandparents and first cousins of the individual seeking counselling.
   2. Detailed information about the spouses of the proband's family can be omitted unless there is a history of some kind of disorder or condition. The proband is the first clinically affected family member diagnosed with a genetic disorder. For example, a baby born with Down syndrome may be the proband.
   3. Eliminating persons or any information that do not contribute any valuable information can help keep the pedigree small and more manageable.

V. Recording the family history:
   1. Determine the approximate size of the family.
   2. Record the family's ethnic background at the top of the page.
   3. The initial drawing should begin with the proband, or the person who is affected with the genetic condition.
      a. This is usually the reason someone is seeking a genetic referral.
   4. The proband is marked with an arrow on the pedigree.
   5. Draw and mark the symbols for the brothers and sisters of the proband. Draw the relationship line, the line of descent, marriage or union line, and symbols for the parents of the proband.
      a. Repeat this step for any children of the proband or children of the proband's brothers and sisters.
   6. Children resulting from a mating (siblings) should be recorded in descending order of their birth, with the oldest sibling on the left.
   7. Continue with symbols for all immediate relatives drawn previously and then draw and mark symbols for paternal grandparents and indicated relatives followed by the same for the maternal grandparents and relatives.
   8. A legend key should contain all of the correct symbols for each indicated disease.
   9. Record the age of onset of common and complex diseases and/or conditions such as coronary heart disease; diabetes mellitus; hypertension; colon, breast, ovarian or endometrial cancer; and stroke.
   10. The pedigree should include at least three generations.
      a. Generations are symbolised by Roman numerals along the left-hand side of the paper with the first generation marker, I, at the top.
      b. Each person in the generation should follow an imaginary horizontal line from left to right.
   11. The names of each individual (maiden names in case of married women) and their dates of birth should be included along with half-siblings, pregnancy losses, stillbirths, previous marriages and adopted children.

VI. Other:
   1. Consanguinity may be suspected if the historian repeatedly gives the same last name on both sides of the family.
      a. Consanguinity can be confirmed by asking if any relatives in the family have ever had a child together.

VII. Completing the pedigree:
   1. When completed, the pedigree should be dated and signed with the name, credentials and position of the person drawing it.

Source: Data from *The practical guide to the genetic family history* by R. L. Bennett (1999). New York: Wiley-Liss.

BOX 7.9 Specific facts and health information to include in a pedigree

- Age/birth date or year of birth
- Age of death (year, if known)
- Cause of death
- Age at diagnosis
- Full siblings versus half- or step-siblings
- Pregnancy with gestational age (last menstrual period (LMP)) or estimated date of delivery (EDD)
- Infertility versus no children by choice
- Pregnancy complications with gestational ages noted (e.g. 6 wks, 32 wks)
- Miscarriage (spontaneous abortion (SAB))
- Stillbirth (SB)
- Pregnancy termination (TOP)
- Relevant health information (e.g. height and weight)
- Affected/unaffected status—define shading of symbols in a legend key
- Ethnic background
- Consanguinity
- Date pedigree taken or updated
- Name of person who took pedigree and credentials
- Key or legend

family members may be unaware of these 'family skeletons' and the person may be very reluctant to reveal this information (Bennett, 1999; Bowers, 2002).

Genetic physical assessment

An assessment of newborns and children with a genetics focus on minor and major anomalies is essential. A minor anomaly or malformation is an unusual or morphological feature that in itself is of no serious medical or cosmetic concern to the individual or family. A major anomaly is a serious structural defect at birth that may interfere with normal functioning of body systems and may lead to a lifelong disability or even an early death (Aase, 1992).

Some children grow into adults whose physical features may or may not have been recognised as potential links to genetic conditions. Anomalies that exist after a person is beyond expected developmental and cognitive milestones may go unnoticed, but they may still be important. The nurse can pick up cues to genetic problems by inspecting the person and other family members. If practical, nurses should ask to look at family photographs and examine them for common dysmorphic features and family traits. Subjective assessment data can also be valuable. A person's complaints of fatigue and joint pain may indicate the onset of hereditary haemochromatosis. A physical assessment that includes a genetics focus is important for nurses when caring for people of any age. An undiagnosed genetic condition may also have implications for reproductive decisions the person makes. However, genetic assessments and genetic referrals are important throughout the lifespan.

Nursing diagnosis and interventions

Nurses are responsible for comprehensively delivering the correct standard of care to people, but at the same time being aware of the limitations of their own knowledge and expertise. In addition to the continuous integration of genetic aspects into nurses' assessments of family history and physical assessment, nurses and midwives are also responsible for carrying out interventions that include initiating referrals to genetic specialists and delivering care to the individual or family in any of the following ways. Nursing diagnoses to consider include:

- *Anticipatory grieving*
- *Anxiety*
- *Disturbed body image*
- *Ineffective coping*
- *Decisional conflict*
- *Interrupted family processes*
- *Ineffective health maintenance*
- *Deficient knowledge*
- *Powerlessness*
- *Spiritual distress*.

Genetic referrals and counselling

After gathering assessment data that incorporates genetic concepts, the nurse and/or midwife is able to initiate a referral to genetic specialists if there are indicators for a genetic referral (see Box 7.11). The nurse and/or midwife should provide the person with information about the advantages of a referral to genetic specialists and the disadvantages of not following through with the referral. The nurse should inform the person that a genetic referral can provide information and answer many questions they may have concerning genetic health. Questions regarding the conditions, inheritance, availability of treatment, as well as economic, insurance and future implications, can be addressed.

People who are concerned about genetic disease may benefit from a genetic consultation whether or not genetic testing is available for that condition. Many people seek information and coping strategies as much as they do test results. Referral of a person with a suspected genetic problem to a geneticist or genetic clinic is an expected nursing responsibility in the same way as are referrals to a dietitian or a social worker. When in doubt, the nurse should contact a genetic counsellor or geneticist to discuss concerns.

PREPARATION FOR GENETIC REFERRALS AND GENETIC COUNSELLING Not knowing what to expect from a genetic referral is common, and fear of the unknown may cause anxiety for the person. To facilitate the referral to a genetic specialist, the clinical nurse should educate the person so that they know what to expect during as well as after a genetic evaluation.

Usually, before the first genetic evaluation visit the person will be contacted to provide a detailed medical and family history and to make an appointment for genetic consultation. The person should be prepared to give as exact a family history as possible so that a detailed three-generation pedigree can be constructed. The person should be informed that a genetic consultation usually lasts several hours. During the appointment, a genetic clinical nurse, genetic counsellor and/or physician will perform an initial interview, and a geneticist will examine the person in order to establish an accurate

BOX 7.10 Ethical implications of genetic information

Clinicians must consider the enormity of the ethical issues facing all families who have knowledge of their genetic make-up. The ethical issues a nurse may have to discuss with the person are numerous. A few of the issues are listed below.

Access to information

- Who should have access to personal genetic information and how will it be used?
- Do insurers, employers, courts, police force, schools, universities, adoption agencies and the armed forces have a right to access this information?

Self-perception

- How does personal genetic information affect an individual's perception of self?
- How does personal genetic information affect society's perceptions of that individual?
- How does personal genetic information affect an individual's cultural identity?
- How is self-identity and self-worth affected by a confirmed genetic risk or condition?

Family roles and relationships

- Should an individual be tested for an autosomal dominant condition if the siblings and/or parents are opposed to knowing if they, themselves, have the altered gene?
- Should potential mates have genetic information?
- Should two people with increased genetic risk be prohibited from having children?
- Should a child be tested?
- Should the father be told if genetic testing and/or genetic counselling reveals non-paternity?
- Should adoption records contain a complete genetic history of the biological parents?
- Is there an obligation to tell other family members if an altered gene that demands a change in lifestyle (nutrition, exercise, smoking, etc.) is diagnosed?
- Is there an obligation to tell other family members if an altered gene that causes early debilitation and/or death is diagnosed?

Informed consent

- Are all individuals receiving true informed consent and do they understand all of the consequences of agreeing to even a simple blood test in the doctor's office that may reveal a diagnosis or increased risk of a genetic condition?

Health and life insurance

- Should insurance companies have access to genetic test results?
- Should medical insurance costs be higher for persons with a known gene disease-producing alteration?
- Should medical insurance costs be higher for persons with a known increased risk of disease because of any gene alteration?
- Should medical insurance costs be higher for persons with known increased risk of disease because of any gene alteration if they make unhealthy lifestyle choices and do nothing to lower their risk?
- Should the individual be covered by medical insurance at all?
- Should individuals pay higher costs if they have children?
- Should individuals be required to have a large life insurance policy to financially protect their families?

Financial

- Should the child be eligible for government grants or any scholarship money?
- Should society be expected to financially support children through government programs or private insurance?
- What is the motivation to save money for the future?

Employment

- Should an employer have access to an individual's genetic profile?
- Should a young adult be hired even though they will burden the company with multiple sick days, higher insurance financial support, etc.?
- Should the individual receive promotional opportunities and increased job responsibilities if the employer knows there will be a large number of lost work days?
- Will the individual's productivity be affected by the genetic condition?

diagnosis. Tests may be ordered. These may include chromosome (cytogenetic) analysis, DNA-based testing, x-rays, biopsy, biochemical tests and linkage studies (Lashley, 2005). After the exam and the completion of any applicable testing, the geneticist and/or genetic counsellor will discuss the findings with the person and make recommendations. The discussion will include the natural history of the condition, the inheritance patterns, the current preventive or treatment options, and the risks to the person and/or family. The visit will also include opportunities for questions and answers, as well as the assessment and evaluation of the person's understanding. It is typical for the information retention of a person facing a new genetic diagnosis to be very low. This makes it imperative for the clinician to take advantage of opportunities to reinforce genetic concepts at a later time when the person is ready.

As the visit concludes, the person can expect appropriate referrals to be made, discussion of available services or research studies, and possible scheduling of a follow-up visit. A summary of the information is usually sent to the person, and their healthcare provider will receive a report if requested by the person.

Genetic healthcare providers present the person with information to promote informed decisions. They are also sensitive to the importance of protecting the individual's autonomy. A challenge during any visit to a genetic

BOX 7.11 Adult indicators for a referral to a genetic specialist

Adult history assessment data

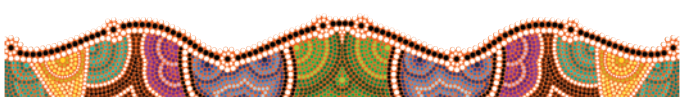
- Several closely related individuals affected with the same or related conditions:
  - Breast and ovarian cancer
  - Colon and endometrial cancer
  - Diabetes
  - Hypertension
  - Coronary heart disease
  - Thyroid cancer
  - Colon polyps
- A common disorder with earlier age of onset than typical (increase concern if it occurs in more than one family member):
  - Breast cancer: < 45–50 years of age or premenopausal
  - Colon cancer: < 45–50 years of age
  - Prostate cancer: < 45–60 years of age
  - Vision loss: < 55 years of age
  - Hearing loss: < 50–60 years of age
  - Dementia: < 60 years of age
  - Heart disease: < 40–60 years of age
  - Stroke: < 60 years of age
- A sudden or unexpected death in someone who 'seemed' healthy:
  - Renal disease
  - Asthma
  - Suicides

An individual with:

- Two or more conditions
- A medical condition and dysmorphic features
- Developmental delay with dysmorphic features and/or physical birth anomalies
- Learning disabilities
- Behavioural problems
- Unexplained:
  - Movement disorders
  - Seizures
  - Hypotonia
  - Ataxia
  - Infertility
- Disproportionate tall or short stature
- Proportionate short stature with dysmorphic features
- Atypical sexual development
- Premature ovarian failure

Source: American Medical Association (2004). *Family medical history in disease prevention.* Retrieved from www.ama-assn.org/resources/doc/genetics/family_history02.pdf. American Medical Association. Copyright 2005.

specialist is providing non-directive counselling. People should be permitted to make decisions that are not influenced by any biases or values from the nurse, counsellor or geneticist. Many people are accustomed to practitioners and nurses providing direction and guidance in their decision making so they may be very uncomfortable with the non-directional approach of the nurse. They may believe that the nurse or healthcare provider is withholding very bad news. The nurse should discuss the positives and negatives of each decision and present as many options as possible through the use of therapeutic listening and communication skills (Cunniff, 2001).



EDUCATION

The nurse and/or midwife must be aware of available genetic resources and participate in educating the person on genetic disorders as well as health promotion and prevention. Informing people of what to expect from a genetic referral, as well as clarifying and/or reinforcing information obtained during a genetic referral or from genetic test results, is also important.

Prior to teaching, the clinician assesses the person's cultural and religious beliefs. Are the gene alterations viewed as uncontrollable and believed to be occurring secondary to cultural belief, such as a stranger looking at the person? Or, are the gene alterations considered a 'punishment'? A person's readiness to learn can be influenced by cultural or religious beliefs and values. Obtaining educational materials in the person's native language will also help facilitate the teaching–learning experience.

The clinician must be aware of common inheritance misconceptions such as a person's belief that, with a 25% recurrence risk, after one child is affected, the next three children will be unaffected, or with a 50% recurrence risk, every other child will be affected. The recurrence risk *for each pregnancy* should be continually stressed by the nurse. People often believe that a family member has inherited the genetic condition because they look like or 'take after' a relative with a genetic condition. When new gene alterations or mutations are discussed, people will often exhibit surprise because no one else in the family has the condition, so they perceive that the trait or condition cannot possibly be inherited (Bennett, 1999). Helping people to understand these genetic concepts is fundamental to delivering the required standard of genetic nursing care.

Psychosocial care

To meet the person's psychosocial needs, the nurse should identify the person's expectations and needs, as well as their cultural and spiritual values and belief system. From where does the person receive strength? Denial of the genetic diagnosis is common and nurses must be aware of the person's state of acceptance. Individuals often will not believe that a chronic genetic condition exists. Nurses must also provide care to help alleviate any anxiety and/or guilt in the person. Anxiety about the unknown is common when awaiting diagnosis or test results, but individuals also experience anxiety from not understanding the future implications of a confirmed genetic disease. Guilt may be associated with knowledge of the existence of a genetic condition in a family. The nurse must support people as they contemplate telling extended family members, friends and neighbours about a confirmed diagnosis. People often do not want to tell extended family members until they are ready. The nurse should encourage open discussion and the expression of fears and concerns. Feelings of guilt and shame are very common as a person deals with the loss of the expectation and dream of a healthy, productive life. Reinforce that genetic alterations are caused by changes within a gene and not by superstitions related to sin or other cultural beliefs. However, it is important to remember that everyone has superstitions or beliefs and the nurse must remain non-judgmental. As mothers, fathers, siblings and extended family members provide continuous care for the person with a genetic condition, depression can result. Depression also can occur in the individual with the chronic condition. The clinician must maintain awareness of the possibility of depression and be proactive in obtaining support for the individual or family.

The nurse also is responsible for assessing the person's coping mechanisms as well as available family, spiritual, cultural and community support systems. Genetic conditions can cause a permanent strain on family dynamics and relationships. The counsellor may need to help the person reaffirm their own self-worth and value (Lashley, 2005). If seen in an academic setting, people may feel they are part of a 'production line' even though they are present for a very private problem (Cunniff, 2001). It is important to be sensitive to these perceptions, provide open communication and encourage discussion of feelings. Growth and development, and meeting adult developmental milestones, can be altered by actual or potential genetic disorders. Especially unique is the potential or actual inheritance of a late-onset condition such as Huntington's disease. The person with this altered gene may not meet any of the developmental tasks in moving through adulthood. Should the person get married, attend university, save money or worry about future? The nurse must identify the impact of genetic knowledge on activities of daily living but also on movement through developmental milestones. Both individual and family strengths need to be identified.

Working in collaboration with the other members of the healthcare team, nurses can refer the person to a support group. However, it is important to have the person's permission if the nurse is providing their name and contact information to a support group.

Another key role for the team is to help people with the often difficult task of communicating genetic information such as inheritance patterns to extended family members. Cultural values of autonomy and privacy are affected when a person must consider whether to communicate genetic information to extended family members who may also carry the altered gene. The history of a genetic alteration that may or may not cause disease can be extensive within a family, affecting multiple family members. Family members often have difficulty understanding that some genetic conditions have variable expressivity. Members of the extended family often are shocked and feel a profound sense of guilt that they are the one who has carried the gene alteration that caused their loved one to have a genetic condition.

Careful self-assessment of feelings is essential for every member of the team. Nurses play an important role in advocating for people and support their decisions even if the decisions contradict their own ideals and morals. Coping with genetic revelations and making genetic-related treatment decisions are difficult activities for everyone. Team members must remember that people will need resources and support and also help in gathering information about reproductive options.

Evaluation

Expected outcomes of delivering healthcare with a genetic focus include:

- The person will make informed and voluntary decisions related to genetic health issues.
- The person will accurately identify:
  - basic genetic concepts and simple inheritance risk probabilities
  - what to expect from a genetic referral
  - the influence of genetic factors in health promotion and health maintenance
  - differences between medical and genetic tests
  - social, legal and ethical issues related to genetic testing.

VISIONS FOR THE FUTURE

Nurses are often the primary caregivers to whom people turn for information, guidance and clarification of ideas. Their role is essential not only in providing direct nursing care but as a member of the community. As more information about the genetic revolution becomes available to consumers—in areas such as pharmacogenomics, gene transfer, ethics, genetic engineering and stem cell research—the role of nurses not only remains vital but will also grow enormously. Clinicians should remain educated, informed, knowledgeable and ready to discuss trends and changes with individuals and their families.

CHAPTER HIGHLIGHTS

- Nurses and midwives are responsible for basic genetic knowledge and for delivering the expected standard of genetic nursing care.
- When cell division does not occur as expected, chromosomal alterations on the autosomes or sex chromosomes can result.
- Chromosomal alterations can be seen in a human karyotype.
- Protein-directing genes are very important to life and functioning as a human being because proteins are very specialised and perform a variety of functions within the cell.
- Different forms of genes are alleles.
- A person may be identified as heterozygous or homozygous for a single gene.
- Some gene alterations cause disease and some are protective from disease.
- Mitochondrial gene alterations are inherited from the mother and primarily involve high-energy organs such as skeletal muscles, brain and heart muscle.
- Multifactorial inheritance does not follow Mendelian inheritance patterns.
- Genetic healthcare providers present the person and their family with information to promote informed decisions.
- Many types of genetic tests are available and they differ from routine medical tests.
- All genetic tests have special considerations related to social, financial, ethical and legal implications.
- Basic genetic nursing care involves family risk assessment through a detailed family history, drawing a three-generation pedigree and integrating genetic concepts into a physical assessment.
- Care should be taken in initiating a referral to a genetic specialist.
- Knowledge of the principles of inheritance allows the clinician not only to offer and reinforce genetic information to individuals and their families, but also to assist them in managing their care and in making reproductive decisions.
- Genetic concepts can be applied to health promotion and health maintenance.
- The nurse must be aware of the social, ethical, cultural and spiritual issues related to the delivery of healthcare.

CONCEPT CHECK

1 A person you are caring for is discussing the inheritance of an autosomal dominant trait. He has the condition and his wife does not. They have one child without the condition. The nurse would be correct in explaining to the person that he is most likely which genotype?
1 FF
2 Ff
3 ff
4 X_fY

2 A male diagnosed with Fabry disease is admitted to the unit. Which statement made by the person would indicate to the nurse that he understands Mendelian inheritance concepts? 'I have the disease because . . .' (Select all that apply.)
1 'my mother had Fabry disease and my father did not'
2 'my father's mother had Fabry disease'
3 'my grandmother's brother had Fabry disease'
4 'my father has Fabry disease'

3 The nurse is providing information regarding genetic testing to a couple who believe they are carriers of an autosomal recessive gene alteration. Which statement is appropriate?
1 'If both of you are carriers, all of your sons will be affected and all of your daughters will be carriers.'
2 'Chromosomal studies will reveal if you are actually a carrier.'
3 'Newborn screening will reveal if your child is affected.'
4 'During the genetic evaluation, you will be asked to provide at least a three-generation family history.'

4 The nurse knows that which assessment data obtained during a family history may suggest a genetic condition or inherited susceptibility to a common disease? (Select all that apply.)
1 breast cancer at age 33
2 a sibling who died unexpectedly while playing basketball at age 66
3 colon polyps in four third-degree relatives
4 a brother's unexplained infertility

5 When analysing a family pedigree, the nurse/midwife notes the pedigree demonstrates that successive generations contain affected individuals, both males and females are affected, and there is no father-to-offspring inheritance. What is the most likely pattern of inheritance?
1 autosomal dominant
2 autosomal recessive
3 X-linked recessive
4 multifactorial
5 mitochondrial

6 When developing a teaching plan, which statement is a correct rationale regarding the health promotion and health maintenance benefits from an assessment of family history? (Select all that apply.)
1 Clinical treatment options can be more focused.
2 Prophylactic treatments can be started early.
3 Specific diet, exercise regimen and genotype can be determined.
4 Single-gene alteration can be diagnosed.

7 The nurse is recording a family pedigree. Which would be correct to include in drawing the pedigree?
1 Detailed information is important for all persons recorded on the pedigree.
2 The maternal side of the family should be placed on the left of the page.
3 The proband is marked with an arrow and a 'P'.
4 Two generations should be recorded and labelled with Roman numerals.

8 The clinician would consider which assessment finding(s) as minor anomalies? (Select all that apply.)
1 café au lait spots
2 ear pits
3 atrial septal defect (ASD)
4 hypertelorism

9 Which are appropriate concepts for the clinician to include when developing a teaching plan for the individual prior to genetic testing? (Select all that apply.)
1 Predispositional genetic tests are medically indicated when the seriousness and mortality of the disease can be reduced with knowledge of the gene alteration.
2 To meet quality assurance, laboratories should hold a CLIA88 certification.
3 A mutation panel contains the most common gene alterations, but may not include all of the disease-causing mutations.
4 Family members affected by genetic test results have a legal right to the test results.

10 The person asks the nurse if a genetic referral is necessary. Which information would be appropriate for the nurse to provide? Most likely genetic specialists will: (Select all that apply.)
1 provide direction for important decision making
2 complete chromosomal studies
3 ask to see photographs of relatives
4 provide information about the natural history of the condition

CHAPTER 8

NURSING CARE OF PEOPLE IN PAIN

ADAM BURSTON, FLORAIDH CORFEE

KEY TERMS

LEARNING OUTCOMES

- Describe the neurophysiology and theories of pain.
- Compare and contrast definitions and characteristics of acute and chronic pain.
- Discuss factors affecting individualised responses to pain.
- Clarify myths and misconceptions about pain.
- Introduce interprofessional care for the person in pain, and discuss pharmacological and non-pharmacological treatment alternatives.
- Describe a framework for providing individualised nursing care for the person experiencing pain.

CLINICAL COMPETENCIES

- Assess pain intensity; quality; location; pattern; intensifiers; nullifiers; side effects of analgesics; effect on physical, psychological and social function, and on mood; and support for managing pain.
- Determine the person's desire and preference for pain management.
- Intervene with pharmacological and non-pharmacological methodologies. Administer medications knowledgeably and safely.
- Teach the person, their family and significant others about effective pain control.
- Evaluate effectiveness of pain relief; retreat or adjust doses of medication; and intervene as necessary.
- Revise plan of care according to the person's response to interventions and need for control.

The International Association for the Study of Pain (IASP) defines pain as 'an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage' (ANZCA, 2010). Pain is a subjective response, not always measureable or observable, to both physical and psychological stressors which all people experience at some point during their lives. Although pain is usually experienced as uncomfortable and unwelcome, it also serves a protective role, and may warn of potential health-threatening conditions. For this reason, pain needs to be assessed and considered an essential vital sign.

Each individual pain event is a distinct personal experience. It is influenced by physiological, cognitive, psychological, sociocultural and spiritual factors. Pain is the symptom most associated with describing oneself as ill, and it is the most common reason for seeking healthcare (Merskey, 2014).

However, the inability to communicate pain does not imply the person does not need suitable pain-relieving treatment. The clinician must be vigilant in the assessment and management of any person's pain (ANZCA, 2010). Linguistic and cultural familiarity do not guarantee effective communication of the complexities of pain (Hadjistavropoulos et al., 2011).

NEUROPHYSIOLOGY AND THEORIES OF PAIN

Neurophysiology

The peripheral nervous system is composed of two types of neurons: sensory and motor. Pain is perceived through the sensory neurons and responded to through the motor neurons. Connections or synapses occur within the spinal cord and again within the central nervous system (CNS), where cognitive analysis of the painful stimulus leads to a response.

Nerve receptors of pain are called **nociceptors** (see Figure 8.1). These are the nerve receptors that are sensitive to pain (noxious stimuli) and give an immediate response when stimulated. They are located at the ends of small afferent neurons and are woven throughout all tissues of the body, except the brain. Nociceptors are especially numerous in the skin and muscles. Pain occurs when biological, mechanical, thermal, electrical or chemical factors stimulate nociceptor activity to the spinal cord. The intensity and duration of the stimuli determines the sensation.

Reactions are caused either by persistent mechanical, chemical or thermal stimuli that create a cascade of chemical mediators which can act directly on the cell or via a messenger system

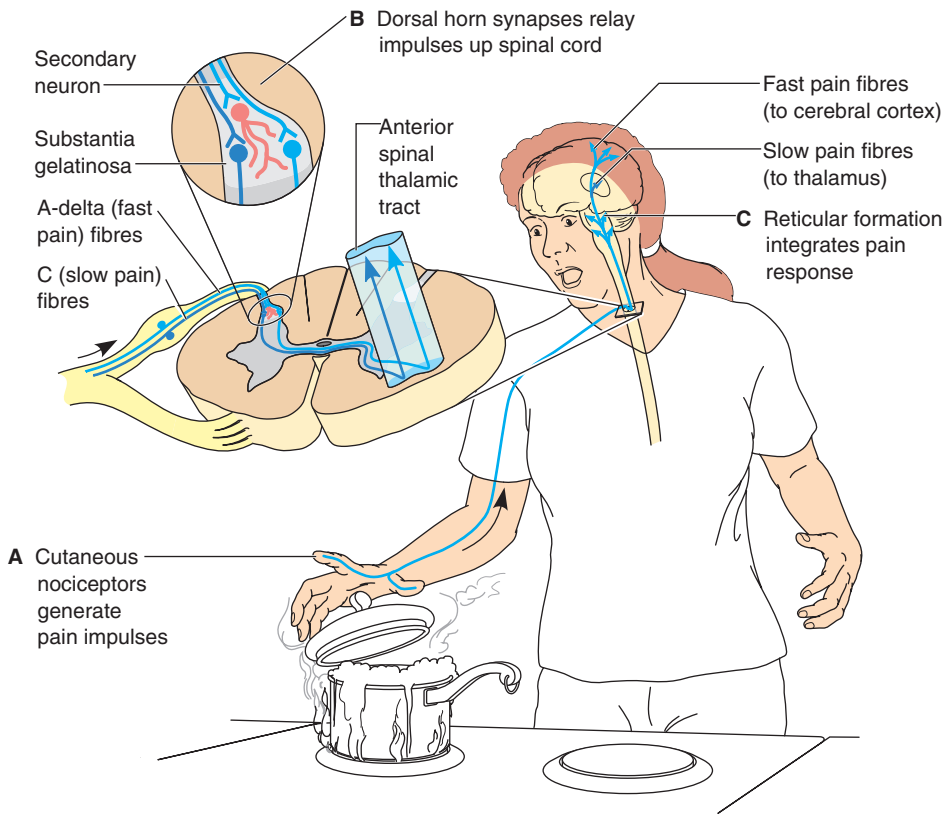

FIGURE 8.1 ■ *A*, Cutaneous nociceptors generate pain impulses that travel via A-delta and C fibres to the spinal cord's dorsal horn. *B*, Secondary neurons in the dorsal horn pass impulses across the spinal cord to the anterior spinothalamic tract. *C*, Slow pain impulses ascend to the thalamus, while fast pain impulses ascend to the cerebral cortex. The reticular formation in the brainstem integrates the emotional, cognitive and autonomic responses to pain

to activate **nociception**. Bradykinin, a polypeptide element of the kinin protein system, is a pain-producing chemical; other biochemical sources of pain include prostaglandins, substance P, histamine, leukotriene B, hydrogen ions and serotonin (ANZCA, 2010; Crisp, Taylor, Douglas & Rebeiro, 2012). These biochemicals are thought to bind to nociceptors in response to noxious stimuli, causing the nociceptors to initiate pain impulses.

Ascending pain pathways

The ascending pathways of pain are illustrated in Figure 8.1 and are summarised as follows:

1. Pain is perceived by the nociceptors in the periphery of the body—for example, in the skin or viscera. Cutaneous pain is transmitted through two types of nerve fibres that transmit signals:
   - A-delta fibres are medium-diameter, myelinated and respond primarily to high-intensity mechanical or heat stimuli, causing sharp, stabbing-like pain.
   - Smaller C nerve fibres are small-diameter, unmyelinated, and respond to lower-intensity thermal, chemical or mechanical cold stimuli, resulting in a dull and aching type of pain. The pain from deep body structures (such as muscles and viscera) is primarily transmitted by C fibres and is commonly associated with persistent pain.

   Both A-delta and C fibres are involved in most injuries. For example, if a person bangs their elbow, A-delta fibres transmit this pain stimulus within 0.1 second. The person feels this pain as a sharp, localised, smarting sensation. One or more seconds after the blow, the person experiences a duller, aching, diffuse sensation of pain impulses carried by the C fibres.
2. Second-order sensory neurons transmit the impulses from the afferent neurons (A-delta fibres and C fibres) through the dorsal horn of the spinal cord, where they synapse in the substantia gelatinosa. This first synapse is important for modulation input in the CNS. The impulses then cross over to the anterior and lateral spinothalamic tracts.
3. The impulses of the second-order neurons ascend via the anterior and lateral spinothalamic tracts and pass through the medulla and midbrain to the thalamus.
4. In the thalamus and cerebral cortex, the pain impulses are perceived, described, localised and interpreted, and a response is formulated. A noxious impulse becomes pain when the sensation reaches conscious levels and is perceived and evaluated by the person experiencing the sensation.

Some pain impulses ascend along the paleospinothalamic tract in the medial section of the spinal cord. These impulses enter the reticular formation and the limbic systems, which integrate emotional and cognitive responses to pain. Interconnections in the autonomic nervous system may also cause an autonomic response to the pain. In addition, deep nociceptors often converge on the same spinal neuron, resulting in pain that is experienced in a part of the body other than its origin.

Inhibitory mechanisms

Efferent fibres run from the reticular formation and midbrain to the substantia gelatinosa in the dorsal horns of the spinal cord. Along these fibres, pain may be inhibited or modulated. The analgesia system is a group of midbrain neurons that transmits impulses to the pons and medulla, which in turn stimulate a pain inhibitory centre in the dorsal horns of the spinal cord. The exact nature of this inhibitory mechanism is unknown.

The most clearly defined chemical inhibitory mechanism is fuelled by endorphins (endogenous morphines) which are naturally occurring opioid peptides present in neurons in the brain, spinal cord and gastrointestinal tract. Endorphins in the brain are released in response to afferent noxious stimuli, whereas endorphins in the spinal cord are released in response to efferent impulses. Endorphins work by binding with opiate receptors on the neurons to inhibit pain impulse transmission (see Figure 8.2).

Pain theories

Several theories attempt to explain the response to pain and the diversity of human experiences with pain. Specificity and pattern theories describe nerve impulses of varying intensity terminating in pain centres in the forebrain. These theories provide explanations of the neurophysiological basis of pain.

The gate-control theory

In 1965, Melzack and Wall postulated the gate-control theory (Perl, 2011). A gating mechanism exists at the spinal cord level where nerve transmission may be blocked by competing

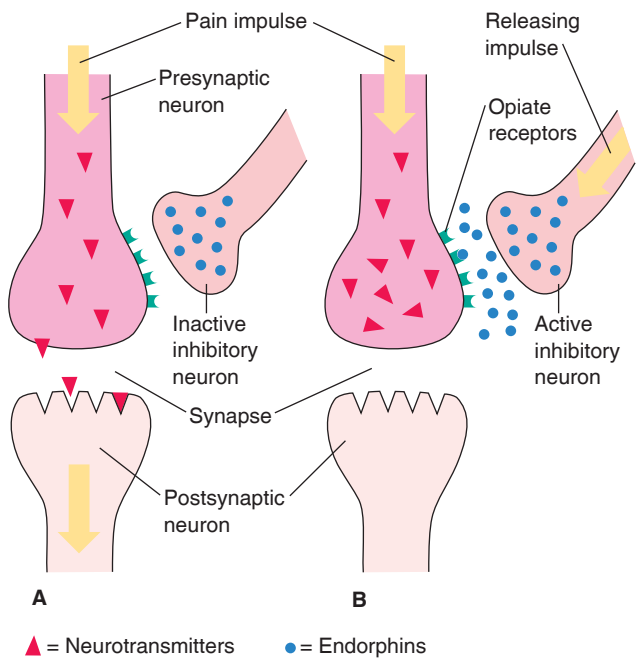

FIGURE 8.2 ■ *A*, Pain impulse causes presynaptic neuron to release burst of neurotransmitters across synapse. These bind to postsynaptic neuron and propagate impulse. *B*, Inhibitory neuron releases endorphins, which bind to presynaptic opiate receptors. Neuro-transmitter release is inhibited and pain impulse is interrupted

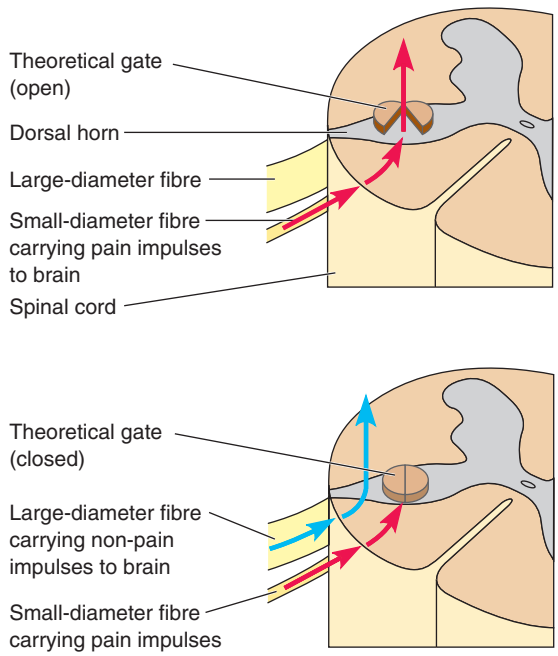

FIGURE 8.3 ■ The spinal cord component of the gate-control theory. Pain transmission by small-diameter fibres is blocked when large-diameter fibres carrying touch impulses dominate, closing the gate in the substantia gelatinosa

impulses. This explains the ability of even low-intensity stimulation such as light brushing of the skin to successfully block the experience of pain. Pain perception results from the interaction of two systems: the substantia gelatinosa in the dorsal horns of the spinal cord (see Figure 8.3), which regulates impulses entering or leaving the spinal cord; and an inhibitory system within the brainstem.

A-delta and C fibres in the spinal cord carry fast and slow pain impulses, while large-diameter A-beta fibres carry impulses for tactile stimulation from the skin. In the substantia gelatinosa, these impulses encounter a 'gate' thought to be opened and closed by the domination of either the large-diameter or the small-diameter fibres. If impulses along the small-diameter pain fibres outnumber impulses along the large-diameter touch fibres, the gate is open, and pain impulses travel unimpeded to the brain. If impulses from the touch fibres predominate, they will close the gate, and the pain impulses will be 'turned away' at the gate. This explains why light stimulation such as massaging a stubbed toe can reduce the intensity and duration of the pain.

The second system described by gate-control theory is the inhibitory system located in the brainstem. It is believed that cells in the midbrain, activated by a variety of stimuli such as opiates, psychological factors, or even simply the presence of pain itself, signal receptors in the medulla which in turn stimulate nerve fibres in the spinal cord to block the transmission of impulses from pain fibres. Ongoing research demonstrates that the control and modulation of pain is much more complex than the description supplied by gate-control theory, which served as a basis for further research about pain-modulating systems. Ongoing theory development of the neuromatrix integrates cultural, genetic, attention, expectation, personality and stress factors with basic neurophysiological function (Perl, 2011). This neuromatrix is particularly useful to understand chronic pain and phantom limb pain, considering there is no defined relationship between tissue injury and the pain experience.

Central sensitisation

Another pain theory that is quite significant in clinical terms describes the effect of sensitising the central and peripheral nervous system to painful stimuli. Central sensitisation manifests as pain hypersensitivity. This theory suggests painful signals create a cascade of changes in the nervous system, which in turn increase the responsiveness of the peripheral and central neurons. These changes, in turn, amplify light touch and pressure, causing enhanced after sensations, increased temporal summation and response to future signals (IASP, 2010). Studies of infants undergoing painful procedures show that those who received analgesia experienced reduced sensitivity to future painful events, while those who did not receive analgesia experienced greater sensitivity (Shen & El-Chaar, 2015). Sensitisation occurs from nociceptive barrage as well as inflammation following an injury or incision. In adults this theory indicates the value of preventing sensitisation as well as treating perceived pain with multimodal pain therapy.

DEFINITIONS AND CHARACTERISTICS OF PAIN

Acute pain

Acute pain has a sudden onset, is usually temporary, is localised and is the common, everyday pain that most people know. Pain that lasts for less than 3 months and has an identified cause is classified as acute pain (Hague & Shenker, 2014). The onset is usually immediate, most often resulting from tissue injury from trauma, surgery or inflammation. The pain is often sharp and localised, although it may radiate. Acute pain warns of actual or potential injury to tissues. As a stressor, it initiates the fight-or-flight autonomic stress response. Characteristic physical responses include tachycardia, rapid and shallow respirations, increased blood pressure, dilated pupils, sweating, pallor and alterations to blood sugar levels. The three major types of acute pain are as follows:

1. *Somatic pain* arises from nerve receptors originating in the skin or close to the surface of the body. Somatic pain may be either sharp and well localised, or dull and diffuse. It is often accompanied by nausea and vomiting.
2. *Visceral pain* arises from body organs, and is dull and poorly localised because of the low number of nociceptors. The viscera are sensitive to stretching, inflammation and ischaemia, but relatively insensitive to cutting and temperature extremes. Visceral pain is associated with nausea and vomiting, hypotension and restlessness. It often radiates or is referred, that is perceived at a location other than that of the painful stimulus. It may be described as cramping, intermittent pain or colicky pain.

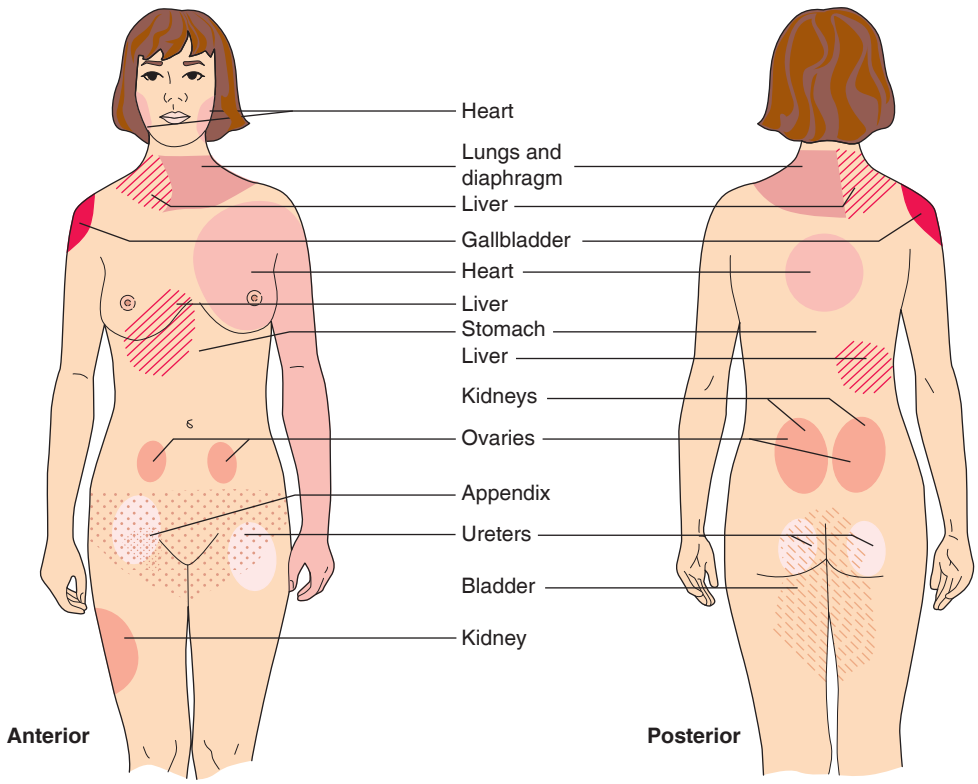

FIGURE 8.4 ■ Referred pain is the result of the convergence of sensory nerves from certain areas of the body before they enter the brain for interpretation. For example, a toothache may be felt in the ear, pain from inflammation of the diaphragm may be felt in the shoulder, and pain from ischaemia of the heart muscle (angina) may be felt in the left arm

3. *Referred pain* is perceived in an area distant from the site of the stimuli and commonly occurs with visceral pain. Visceral fibres synapse at the level of the spinal cord, close to fibres innervating other subcutaneous tissue areas of the body (see Figure 8.4). Pain in a spinal nerve may be felt over the skin in any body area innervated by sensory neurons that share that same spinal nerve route. Body areas defined by spinal nerve routes are called dermatomes (see Chapter 40).

Persistent (chronic) pain

Persistent (chronic) pain is ongoing and prolonged pain. It is not always associated with an identifiable cause but often arises from an acute situation such as post trauma, herpes zoster, acute back pain and postoperative surgical pain.

Predictive factors for chronic post-surgical pain include preoperative, intraoperative and postoperative factors:

- Preoperative considerations include pain, moderate to severe lasting for more than one month, repeat surgery, psychological vulnerability (e.g. catastrophising), preoperative anxiety.
- Intraoperative considerations include a surgical approach with risk of nerve damage.
- Postoperative factors include pain (acute, moderate to severe), radiation to the area, depression, neuroticism and anxiety (adapted from ANZCA, 2010, p. 11).

Neurological changes that can occur with persistent pain are changes in perception. Physical changes that result are loss of muscle mass, deconditioning, postural changes, alterations in appetite and weight, constipation and sleep disturbances. Persistent pain is complex and is poorly understood. It is suggested that when persistent pain is present it can develop to an individual disease process because of the secondary changes that occur in the body (Cousins, 2012).

The 'persistent (chronic) pain syndrome' refers to the unspecific behaviours that can occur with persistent pain. Often a cycle of persistent pain and disability causes physical deconditioning, drug tolerance, reduced activity, passive treatments, distorted beliefs and social stresses such as financial pressures, altered gender roles and the destruction of intimate relationships. From a psychological perspective the person with persistent pain experiences anxiety, anger, hopelessness and frustration, which can result in the person becoming depressed, withdrawn and irritable (Hill, 2014). Although persistent pain may range from mild to severe, its unrelenting presence often results in the pain itself becoming a pathological process requiring intervention.

Breakthrough pain

Breakthrough and incident pain relates to how pain progresses through time. **Breakthrough pain** occurs between doses of analgesia; it can be prevented by giving breakthrough analgesia more

frequently, increasing the dose of the analgesia, or increasing the slow (continuous) release medication. **Incident pain** occurs when procedures, dressings or activity increase the pain experience. Incident pain can often be predicted and analgesia should be available and given prior to the activity commencing.

Neuropathic pain

Neuropathic pain may be acute or chronic resulting from injury or disease that affects the peripheral or central nervous systems. Acute neuropathic pain may result from lesions or entrapment of nerves (Brown et al., 2015; Taverner, 2014). Neuropathic pain can be caused by numerous factors such as trauma, surgery, inflammation, toxicity, and immunological and vascular changes affecting either the central nervous or the peripheral nervous systems of the body. Examples of neuropathic pain arising from the CNS are post-stroke pain and spinal cord injury. Peripheral causes of neuropathic pain are diabetic neuropathy, HIV-related neuropathies and tumours invading the nerve area and surgery.

Common surgeries that have a higher incidence postoperatively of persistent neuropathic pain are amputation (phantom limb pain), thoracotomy, mastectomy, hernia repair and cholecystectomy (ANZCA, 2010). The person with neuropathic pain will often state their pain is burning, shooting or electric; they might comment on numbness in and around the area or the sensation of pins and needles. Diagnosis is usually made with a detailed history, personal description and pain assessment.

- *Complex regional pain syndrome* (*CRPS*) is neuropathic pain that results from nerve damage from either major or minor trauma (Marinus et al., 2011). CRPS is recognised as a persistent pain condition in which functional restoration by constant rehabilitation is the main goal (Pollard, 2013). Common features of CRPS are continuous, severe pain (usually burning or electric), trophic changes (hair and nails alter in growth), vasospasm changes (vasodilation causing the limb to become hot, red and swollen, followed by vasoconstriction) and limb immobility causing muscle wasting. It is common for CRPS to develop from minor injuries and research suggests that the pathophysiology is characterised by an 'aberrant host response to tissue injury' (Marinus et al., 2011, p. 637).
- *Neuralgias* are painful conditions that result from damage to a peripheral nerve caused by infection or disease. Postherpetic neuralgia (following shingles) is an example occurring in 50% of those who are over 50 years and 75% of those who are over 75 years. Trigeminal neuralgia can occur as an acute exacerbation of neuropathic pain. Most causes are idiopathic and the main treatment is with carbamazapine (ANZCA, 2010).

Phantom pain

Phantom pain is a common condition among amputees. Phantom pain commonly resembles pre-injury pain (if it was present) and is exacerbated by stump problems, ill-fitting prostheses and back pain. Phantom pain also occurs in other parts of the body after surgical removal (e.g. mastectomy, tongue). Phantom pain is *not* phantom sensation which resolves over time as the sensation retreats into the stump and is a contributory mechanism to phantom pain development (ANZCA, 2010).

Central pain

Central pain is related to a lesion in the brain or spinal cord that may spontaneously produce a high-frequency burst of impulses from the ascending spinothalamocortical pathways; their relays or end stations in the brain or spinal cord create a sensation of pain. A vascular lesion, tumour, trauma or inflammation may also cause central pain. Thalamic pain is most common, severe, spontaneous and often continuous. Hyperaesthesia (an abnormal sensitivity to touch, pain or other sensory stimuli) may occur on the side of the body opposite the lesion in the thalamus. The perception of body position and movement may also be lost.

Cancer (palliative) pain

Cancer (palliative) pain is a common condition of those with advanced cancer. Cancer pain is often persistent, arising from a number of factors (e.g. the disease process, the prescribed treatment, resultant disability and subsequent co-morbidity problems). Cancer pain can be a challenge to manage as curative opportunities have been ceased and death is inevitable. Cancer pain is often a mixture of nociceptive and neuropathic, having acute and persistent features with problems of breakthrough and incident pain.

FACTORS AFFECTING RESPONSES TO PAIN

Physical response to pain involves specific and often predictable neurological changes. In fact, everyone has the same pain *threshold* and perceives pain stimuli at the same stimulus intensity. For example, heat is perceived as painful at 44ºC to 46ºC, the range at which it begins to damage tissue. What varies is *tolerance*, which is based on perception of, and reaction to, pain. When a person is described as highly sensitive to pain, this is a reference to their **pain tolerance**, which is the amount of pain a person can endure before outwardly responding to it. The ability to tolerate pain may be decreased by repeated episodes of pain, fatigue, anger, anxiety and sleep deprivation. The use of such practices such as heat/cold, position, relaxation, distraction, hypnosis, spiritual practices, medications and alcohol may increase pain tolerance. The individualised response to pain is shaped by multiple and interacting factors, including sociocultural influences, emotional status, past experiences with pain, the source and meaning of the pain, the person's knowledge base and their age.

Sociocultural influences

The findings of research so far suggest that cultural influences should be an important consideration when assessing and treating pain. A person's response to pain is strongly influenced by family, community and culture. Sociocultural influences affect the way in which a person tolerates pain, interprets the meaning of pain, and reacts verbally and non-verbally to the pain. For example, if a person has a cultural background where males should not cry and must tolerate pain stoically, rather than expressing his discomfort a male person may appear withdrawn and refuse pain medication. On the other hand, when open and intense emotional expression is culturally acceptable, a person may demonstrate their discomfort clearly and be comfortable requesting pain medication.

Cultural standards also influence an individual regarding how much pain to tolerate, what types of pain to report, who to report the pain to, and what kind of treatment to seek. For example, a person from a Western culture may value 'being a good patient', which may cause them to avoid 'complaining' about their pain, whereas a person from another culture may value seeking information about pain, which may cause them to discuss their pain often and in detail. However, behaviours vary greatly within a culture and from generation to generation. The nurse should approach each person as an individual, observing them carefully, taking the time to ask questions, and avoiding making assumptions.

The nurse also brings with them a set of personal sociocultural values, beliefs and experiences about pain. If these values, beliefs and experiences differ from those of the person, the assessment and management of pain may be based on the values of the nurse rather than on the needs of the person. It is not uncommon to hear staff compare their own personal experiences of pain with the person receiving care (e.g. 'When I had my appendix removed I had two paracetamol and I was fine; this person doesn't need a PCA [patient-controlled analgesia] machine.').

Psychological status

The person's psychological status influences the perception of pain. Remember the IASP's definition of pain as a *sensory and emotional experience*; therefore, how an individual feels psychologically and emotionally will influence their response to pain. Pain sensations may be blocked by intense concentration (e.g. during sports activities) or may be increased by anxiety or fear. Pain is often increased when it occurs in conjunction with other illnesses or physical discomforts such as nausea or vomiting. The presence or absence of support people or caregivers who genuinely care about pain management may alter emotional status and the perception of pain.

Anxiety and depression may increase the perception of pain, and pain may in turn cause anxiety. Depression is clearly linked to pain and is generally associated with higher pain intensity (ANZCA, 2010). In addition, the muscle tension commonly found with anxiety can create its own source of pain. This association explains why non-pharmacological interventions such as relaxation or guided imagery are helpful in relieving or decreasing pain. Fatigue, lack of sleep and depression also are related to pain experiences. Pain interferes with a person's ability to fall asleep and stay asleep, and thus induces fatigue. In turn, fatigue can lower pain tolerance.

Past experiences with pain

Previous experiences with pain are likely to influence the person's response to a current pain episode. If supportive adults responded to childhood experiences with pain appropriately, the adult usually will have a healthy attitude to pain. If, however, the person's pain was responded to with exaggerated emotions or neglectful indifference, that person's future responses to pain may be exaggerated or denied.

The responses of healthcare providers to the person in pain can influence their response during the next pain episode. If providers respond to pain with effective strategies and a caring attitude, the person will remain more comfortable during any subsequent pain episode, and anxiety will be avoided. If, however, the pain is not adequately relieved, or if the person feels that empathetic care was not given, anxiety about the next pain episode sets up the person for a more complex and therefore more painful event.

Source and meaning

The meaning associated with the pain influences the experience of pain. For example, the pain of labour to deliver a baby is experienced differently from the pain following removal of a major organ for cancer. Because pain is the major signal for health problems, it is strongly linked to all associated meanings of health problems, such as disability, loss of role and death. For this reason, it is important to explain the aetiology and prognosis of pain to the person receiving care.

Knowledge

A lack of understanding of the source, outcome and meaning of pain can contribute negatively to the pain experience. The nurse needs to assess the person's readiness to learn, use methods of teaching that are effective for the person and family, and evaluate learning carefully. Teaching must include the process of the pain, its predictable course (if possible), and the proposed plan of care. In addition, nurses should discuss strategies for managing pain and encourage the person to communicate preferences for pain relief. Involving the patient's significant others regarding the presence of pain and how they can help promote effective relief assist in a holistic approach to pain management.

Age

Age influences a person's perception and expression of pain, and of the physical changes that will influence drug requirements (see Table 8.1). Dangerous misconceptions exist regarding the management of pain in older adults.

TABLE 8.1 Physical changes related to ageing and their influence on drug requirements

PHYSICAL CHANGE	EFFECT	OUTCOME
Cardiac output	Drug concentrations after bolus	Require smaller bolus dose
Muscle mass	Change in drug distribution	Potential for unwanted side effects
Liver function	Influences drug elimination	Drug accumulation
Renal function	Influences drug excretion	Drug accumulation
Cerebral blood flow	Alters response to analgesia	Unwanted and unexpected side effects can occur

Sources: Australian and New Zealand College of Anaesthetists and Faculty of Pain Medicine (2010). *Acute pain management: Scientific evidence* (3rd ed.). Melbourne: Australian and New Zealand College of Anaesthetists; Prowse, M. (2005). Postoperative pain in older people: A review of the literature. *Journal of Clinical Nursing, 16,* 84–97.

Misconceptions regarding ageing

Denny and Guido (2012) suggest there are several myths about the older adult and the process of ageing.

1. *Pain is expected in the older adult.* While the occurrence of pain is common in the older adult, it is often not recognised, or is undertreated (Tracy & Morrison, 2013); however, it is still an indicator of an underlying clinical issue. Often believing that pain is a part of growing older, the person may ignore pain or self-medicate with over-the-counter medications. Individuals in this age group may fail to acknowledge pain, believing that it is inevitable or fearing dependency if they alarm their loved ones (Gammons & Caswell, 2014).
2. *Pain perception decreases with age.* Age does not change the perception of acute pain. There is no evidence that nociception is altered by age. Stotts et al. (2007) investigated procedural pain in the hospitalised adult, and found that the younger group (18–64 years) and the older group (65+ years) experienced the same amount of procedural pain during wound care, wound drain removal, tracheal suctioning, turning, femoral sheath removal and central line insertion. However, it was interesting to note that the procedural *distress* was greater in the younger than the older patient (Stotts et al., 2007).
3. *When older adults report pain, they are attention seeking.* This is highly unlikely. Do not forget that some older people suffer mute myocardial infarction and experience painless peritonitis, pancreatitis and cholecystitis (Tracy & Morrison, 2013). The elderly are at a greater risk of mortality and morbidity if pain is not relieved.
4. *Opiates are dangerous in older adults.* When opiates are prescribed the factors identified in Table 8.1 need to be considered.
5. *Opiate use causes addiction in older adults.* Older adults may hesitate to ask for pain medicine because they fear addiction and loss of independence (Brown et al., 2015).

FAST FACTS

- Older people have the highest rate of illness and surgical procedures associated with pain; they also have the highest rate of complications associated with surgical interventions.
- Persistent pain is common in older adults. For those over 70 years of age, 50% of those living in the community and 80% of those in residential care suffer persistent pain.
- Musculoskeletal pain affecting major joints and back, or neuropathic pain from diabetic neuropathy and post-herpetic neuralgia have an increased prevalence in the ageing population.
- Concurrent illnesses are common in the elderly, making clinical presentation complex and sometimes difficult.
- Age and cognitive impairment enhance the risk of poor pain control which will influence the individual's quality of life.

Sources: Australian and New Zealand College of Anaesthetists and Faculty of Pain Medicine (2010). *Acute pain management: Scientific evidence* (3rd ed.). Melbourne: Australian and New Zealand College of Anaesthetists; Prowse, M. (2005). Postoperative pain in older people: A review of the literature. *Journal of Clinical Nursing*, *16*, 84–97.

Pain assessment in older adults may be difficult when the person is cognitively impaired and has difficulty communicating descriptions of pain. When discussing pain with the elderly person it is often better to use the terms they use when self-reporting pain, such as 'aching' or 'soreness'. However, some adults with cognitive impairments are able to describe current, usual or worse pain when a standardised pain scale is used, such as the verbal descriptor of 'mild, moderate or severe'.

A study of pain and associated behavioural and psychiatric symptoms of 2282 aged care residents was undertaken by Tosato et al. (2012). The study showed pain resulted in significant and positively associated socially inappropriate behaviours such as wandering, resistance to care, abnormal thought processes and delusions. Treatment of pain needs to be an integral component of behavioural management in the aged care resident with dementia. Predictive pain tools such as the Abbey scale need to be utilised and others developed to accurately record the pain of the non-verbal person (Ersek, Polissar & Neradilek, 2011; Liu, Briggs & Closs, 2010).

Delirium in the person who is acutely ill or has dementia (occurring in approximately 30% of adults over the age of 85) is a barrier to assessing pain (Alzheimer's Australia, 2015). Recommended methods for pain assessment include: (1) behavioural observations for which no tool has been validated; (2) documenting baseline behaviours and activity patterns and monitoring changes that might indicate the need for further pain assessment; and (3) conducting an empirical analgesia trial.

Pain in the paediatric population

'Children must be assumed to experience pain from birth onwards' (American Medical Association, 2010). In the past, infants and young children have been assumed to have a lack of pain sensation; however, it is now known that due to a more robust inflammatory response and lack of central inhibitory influence, their response to pain may be greater than that of adults.

Olmstead, Scott and Austin (2010) assert pain is often undermanaged in children due to:

- lack of assessment and reassessment of pain
- misunderstanding of how to quantify a subjective experience
- lack of knowledge in pain treatment
- the notion that addressing pain in children takes too much time
- fear of adverse effects of analgesic medications, including respiratory depression and addiction.

It is recommended that health professionals should anticipate painful experiences and monitor the condition of the child, and provide adequate information about what to expect and appropriate measures to reduce the distress to children and parents (Kozlowski & Monitto, 2013).

Optimal pain control can be achieved using a range of techniques. These may range from deep sedation or anaesthesia to cognitive behavioural strategies such as imagery and relaxation (see page 165). Whatever strategy is used, a quiet environment with calm parents and clear and confident instruction will assist the paediatric person experiencing pain (Truba & Hoyle, 2014).

Pain and cultural diversity

Research into pain and cultural diversity is needed to produce and refine multilingual pain-scoring charts. The nurse must try to be familiar with ethnic and cultural diversity in pain expression and management, and respect cultural differences. Pain behaviours are not an objective indicator of the amount of pain present for any individual person. An accurate history is needed and the use of a professional interpreter rather than family members is preferable to ensure accurate translation.

Patient-controlled analgesia devices may be used to provide efficient and effective analgesia (ANZCA, 2010). Nurses may underestimate the pain of those from a different cultural background or having a different language. In an American study, Asian patients received 24% lower doses of analgesics postoperatively than Caucasian people; however, both groups used similar amounts of opioid analgesia when using a PCA (Brown et al., 2015). A thorough explanation of the PCA is needed, through an interpreter, to ensure this concept is understood and this form of analgesia is utilised.

Pain and Indigenous Australians

Significant disparities exist between the life expectancy at birth of the general Australian population and that of Aboriginal and Torres Strait Islander Australians.

> *In 2005–2007, life expectancy at birth for Aboriginal and Torres Strait Islander males was 67.2 years, 11.5 years less than that for non-Indigenous males (78.7 years). For Aboriginal and Torres Strait Islander females, life expectancy at birth was 9.7 years less than for non-Indigenous females (72.9 years and 82.6 years respectively). The lower life expectancy for Aboriginal and Torres Strait Islander Australians can be attributed to a higher infant mortality rate, and a higher incidence of diseases such as diabetes mellitus, respiratory disorders, ear disease, eye disorders and some cancers, among Aboriginal and Torres Strait Islander peoples.* (Australian Bureau of Statistics, 2010)

Indigenous Australians are therefore considered to be a high-risk group in relation to healthcare. Variations in pain behaviours, verbal and non-verbal communication, and the accuracy of standard pain assessment tools have been identified as specific challenges (Fenwick, 2006). A culturally safe assessment of the person is required, with sensitivity to pain tolerance, language barriers and tendencies to display a stoic attitude to pain demonstrated. Where possible, nurses should use interpreters, Indigenous health workers or liaison officers. Note that, like other high-risk patient groups, Indigenous Australians often have multiple co-morbidities, which may influence the types of analgesics that may be prescribed.

MYTHS AND MISCONCEPTIONS ABOUT PAIN

Myths and misconceptions about pain and its management are common in both healthcare providers and the general population. Some of the most common misconceptions are:

- *Pain is a result, not a cause.* According to the traditional view of pain, it is only a symptom of a condition. However, it is now recognised that unrelieved or poorly relieved pain sets up further responses such as central sensitisation, amplifying pain sensations and delaying rehabilitation.
- *Persistent pain is really a masked form of depression.* Serotonin plays a chemical role in pain transmission and is also the major modulator of depression. Therefore, pain and depression are chemically related, not mutually exclusive. It is common to find them coexisting.
- *Opioid medication is too risky to be used to treat persistent pain.* This common misconception often deprives the person experiencing pain of the most effective source of pain relief. It is true that other methods should be tried first; however, if they prove ineffective, opioids should be considered as an appropriate alternative.
- *It is best to wait until the person has pain before giving medication.* It is now widely accepted that anticipating pain has a noticeable effect on the amount of pain a person experiences. Offering pain relief before a pain event is well on its way can lessen the pain. Remember that agony is harder to manage.
- *Many people lie about the existence or severity of their pain.* The most reliable source of pain severity is the person's score, as they will rarely lie about their pain.
- *Postoperative pain is best treated with intramuscular injections.* The most commonly used postoperative pain relief for many years was morphine or pethidine given intramuscularly. However, both have adverse effects, such as late-onset respiratory depression, they are painful to give and they can irritate the tissues (causing tissue abscess). Pethidine is short acting and also produces norpethidine, a CNS stimulant that can cause seizures. Most experts now do not recommend pethidine to manage postoperative pain (Cohen & Schecter, 2005).
- *Pain relief interferes with diagnosis*. Pain is the single most common reason that people present to an emergency department (ED).
- A common misconception is that analgesia given prior to medical assessment will mask the pathology and therefore diagnosis. In the case of abdominal pain, research shows that pain relief will not interfere with the diagnostic process in adults and children (ANZCA, 2010). Despite a prevailing attitude that pain management is an essential part of quality medical care, pain management in the ED is difficult because of the short-term associations with the person, increased vigilance against drug abuse and the myth that diagnosis is impaired by pain relief. Nevertheless, 60% of people presenting to Australian EDs with abdominal pain are satisfied with their analgesia on discharge (ANZCA, 2010).

INTERPROFESSIONAL CARE AND PHARMACOLOGICAL/NON-PHARMACOLOGICAL TREATMENT ALTERNATIVES

Effective analgesia relief results from collaboration among healthcare providers, particularly nurses, as it is the nursing staff that most closely cares for the person 24 hours a day, especially in an acute situation. For those with more persistent pain problems, there are pain clinics staffed by teams of healthcare professionals who use a multidisciplinary approach to manage persistent pain. Therapies may include traditional pharmacological agents as well

as psychotherapy, biofeedback, hypnosis, acupuncture, massage and other treatments. Hospices for palliation provide a multifaceted approach to pain management (see Chapter 4).

Non-pharmacological strategies to manage pain

KNOWLEDGE AND INFORMATION Knowledge and information will assist the person in managing their pain. Give direct, clear, concise information that the person understands, but do not make them more anxious and distressed. A clear, concise plan of action that has been discussed with the person will assist in effective pain management.

RELAXATION Relaxation involves learning activities that deeply relax the body and mind. Relaxation distracts the person, lessens the effects of stress from pain, increases pain tolerance, increases the effectiveness of other analgesic measures and increases perception of pain control. In addition, by teaching the person relaxation techniques, the nurse acknowledges the person's pain and provides reassurance that the person will receive help in managing the pain (Rejeh et al., 2013). Examples of relaxation activities include:

- *Diaphragmatic breathing* can relax muscles, improve oxygen levels and provide a feeling of release from tension. The technique for diaphragmatic breathing is described and illustrated in Chapter 3.
- *Progressive muscle relaxation* may be used alone or in conjunction with deep breathing to help manage pain. The person should be taught to tighten one group of muscles (such as those of the face), hold the tension for a few seconds, and then relax the muscle group completely. The person should repeat these actions for all parts of the body.
- *Guided imagery*, also called *creative visualisation*, is the use of the imaginative power of the mind to create a scene or sensory experience that relaxes the muscles and moves the attention of the mind away from the pain experience. To use guided imagery, the person must be able to concentrate, use their imagination and follow directions. The nurse can facilitate this technique by asking the person for some descriptions of what they find most relaxing. The nurse then speaks to the person in a calming, soothing voice about those places or situations. Audio recordings are available to assist with guided imagery.
- *Meditation* is a process whereby the person empties the mind of all sensory data and, typically, concentrates on a single object, word or idea. This activity produces a deeply relaxed state in which oxygen consumption decreases, muscles relax and endorphins are produced. At its deepest level, the meditative state may resemble a trance. Many books and CD/DVD recordings are available commercially.

DISTRACTION Distraction involves the redirection of the person's attention away from the pain and on to something that the person finds more pleasant. Examples of distracting activities are practising focused breathing, and listening to or doing some form of rhythmic activity to music. For example, the person using recorded music for distraction may sing along with the song, or tap out the rhythm with their fingers or foot. Full participation in the music is key to analgesia.

Distraction may also involve the individual participating in an activity that promotes pleasure and stimulates laughter, as laughing for 20 minutes or more is known to produce an increase in endorphins that may continue to give pain relief even after the person stops laughing.

BIOFEEDBACK Biofeedback is an electronic method of measuring physiological responses, such as brain waves, muscle contraction and skin temperature, and then 'feeding' this information back to the person. Most biofeedback units consist of electrodes placed on the skin and an amplification unit that transforms data into visual cues, such as coloured lights. The person thus learns to recognise stress-related responses and to replace them with relaxation responses. Eventually, the person learns to repeat independently those actions that produce the desired brain wave effect.

Relaxation helps avoid the anxiety that often accompanies and complicates pain. Additionally, biofeedback gives the person a measure of control over the response to pain.

HYPNOSIS Hypnosis is a trance state in which the mind becomes extremely suggestible. To achieve hypnosis, the person sits or lies down in a dimly lit, quiet room. The therapist suggests that the person relax and fix attention on an object. The therapist then repeats, in a calming, soothing voice, simple phrases such as instructions to relax and listen to the therapist's voice. Eventually the person hears only the therapist's voice; during this state, the therapist may then make suggestions to encourage pain relief.

Manual therapies

PHYSIOTHERAPY Physiotherapy can offer a range of pain management strategies—for example, graded reactivation programs, therapeutic ultrasound and exercises to increase strength and flexibility to promote pre-injury functional status.

MASSAGE Massage has been shown to assist in post-surgical abdominal pain and thoracic surgery. Pain scores are not necessarily lowered, but there is a reduction in the unpleasantness of pain (ANZCA, 2010).

HEAT AND COLD THERAPY Heat and cold therapy are commonly used as strategies to relieve pain; however, evidence regarding their effectiveness is inconsistent.

ACUPUNCTURE Acupuncture is an ancient Chinese system involving the stimulation of certain specific points on the body to enhance the flow of vital energy (chi) along pathways called meridians. Acupuncture points can be stimulated by the insertion and withdrawing of needles, the application of heat, massage, laser, electrical stimulation or a combination of these methods. Only care providers with special training can use this method. Acupuncture is becoming a more widely accepted therapy, especially for the treatment of pain.

TRANSCUTANEOUS ELECTRICAL NERVE STIMULATION A transcutaneous electrical nerve stimulation (TENS) unit consists of a low-voltage transmitter connected by wires to electrodes placed by the person as directed by the physical therapist (see Figure 8.5). The person experiences a gentle tapping or vibrating sensation over the electrodes. The person can adjust the voltage to achieve maximum pain relief. It is believed that TENS electrodes stimulate the large-diameter A-delta fibres activating inhibitory networks in the dorsal horn, which reduces the nociceptive transmission of the C fibres.

FIGURE 8.5 ■ The TENS unit is believed to assist in pain management in the ways described in the gate-control theory. Electrodes that deliver low-voltage electrical stimuli are placed directly on the person over painful areas

Source: © Rob Byron/Shutterstock.com.

A TENS unit is most commonly used to relieve persistent benign pain. Thorough education is essential, including an explanation of the manufacturer's directions, instructions on where to place the electrodes and the importance of placing the electrodes on clean, unbroken skin. The clinical use of TENS has been extensively studied (Johnson, 2014). TENS offers several advantages: avoidance of drug side effects, person control and good interaction with other therapies. Disadvantages are its cost and the need for initial expert training. When choosing a TENS machine make sure it is portable, has adjustable amplitude, can be managed by the user and has built-in output short-circuit protection. TENS should not be used by people with cardiac pacemakers and implanted defibrillators.

HYPERBARIC OXYGEN THERAPY This therapy is defined as the intermittent inhalation of 100% oxygen in a hyperbaric chamber at a pressure higher than 1 absolute atmosphere (1 ATA = 760 mmHg, the normal atmospheric pressure at sea level) (Yildez, Uzun & Kiralp, 2006).

This method is increasingly being tried and researched to manage neuropathic pain as well as headaches, cancer pain and postoperative pain. Initial animal studies relating to inflammation pain have been positive with hyperbaric oxygen therapy successfully relieving neuropathic pain for an extended period (Thompson et al., 2010).

Pharmacological strategies for managing pain

MEDICATION Medications are the most common approach to pain management. A variety of drugs with many kinds of delivery systems are available. These drugs include simple analgesics, non-steroidal anti-inflammatory drugs (NSAIDs), opioids, antidepressants and local anaesthetic agents. In addition to administering the prescribed medications, the nurse may act independently in choosing the dosage and timing. The nurse is also responsible for assessing the side effects of the medications, evaluating their effectiveness, and providing education. The nurse's roles in pain relief are those of advocate, educator and direct caregiver.

The World Health Organization (WHO) 'ladder of analgesia' effectively guides the use of medications (WHO, 1986/1990) (see Figure 8.6). Analgesics are used progressively until pain is reduced or relieved, reflecting the interactive nature of these types of medications. Initially a simple analgesic (e.g. paracetamol) is used. A person will then progress to NSAIDs and then

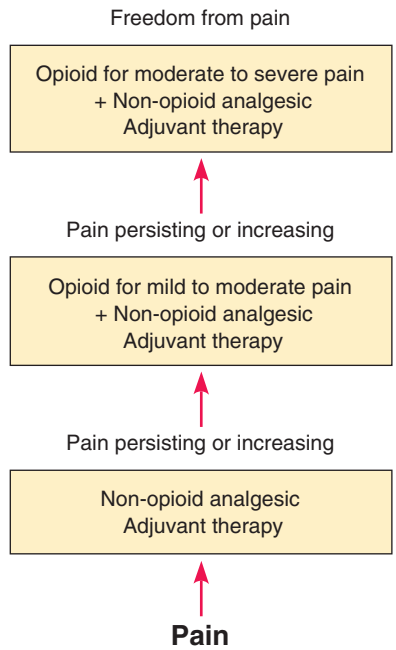

FIGURE 8.6 ■ The WHO analgesic ladder illustrates the process for selection of analgesic medications for pain management

LINKS TO NATIONAL PATIENT SAFETY STANDARDS

NSQHS Standard 4:
Medication Safety

'This standard is concerned with the systems and strategies to ensure clinicians safely prescribe, dispense and administer appropriate medicines to informed patients.' (Australian Commission on Safety and Quality in Healthcare (ACSQHC), 2011, p. 3)

Medication safety is supported by a range of initiatives across the interprofessional teams, including the implementation of a National Inpatient Medication Chart (NIMC), safe labelling practice, quality education and training, and accurate reconciliation and administration of medications (ACSQHC, 2011). Nurses play an integral role in the safe administration of medicines to an informed patient.

BOX 8.1 Terms associated with pain medications (usually opioids)

- **Addiction**: a disease characterised by aberrant drug-seeking behaviour that includes compulsive use of a substance, cravings and loss of control despite the negative biopsychosocial consequences.
- *Substance abuse disorder*: the use of any chemical substance for other than a medical purpose that causes a disintegration of the person and their life commitments.
- *Physical drug dependence*: a physiological need for a substance, that results in physical withdrawal symptoms if it is not supplied or the amount is reduced suddenly. Common withdrawal symptoms include agitation, insomnia, yawning, tachycardia, sneezing and diarrhoea.
- *Psychological drug dependence*: a psychological need for a substance. If the substance is not supplied, psychological withdrawal symptoms occur, including anxiety and irritability.
- *Drug tolerance*: the process by which the body requires a progressively greater amount of a drug to achieve the same results.
- *Equianalgesic*: having the same analgesic effect when administered to the same individual. Drug dosages are equianalgesic if they have the same effect as morphine sulfate 10 mg administered parenterally.
- *Pseudoaddiction*: behaviours resembling drug seeking; often as a result of receiving inadequate analgesia.

to opioid medications. Box 8.1 describes terms associated with pain medication.

Simple analgesics Simple **analgesics** such as paracetamol produce analgesia and reduce fever. The exact mechanism of action is uncertain, but it is used to treat mild to moderate pain. It is absorbed rapidly in the small intestine after oral administration, having an effect in approximately 30 minutes. Paracetamol can be given rectally, though absorption is erratic; there is also an intravenous preparation giving analgesia in approximately 10 minutes. Paracetamol should be given with caution to children, and those who are underweight or have liver or renal dysfunction.

NSAIDs NSAIDs (non-steroidal anti-inflammatory drugs) act on peripheral nerve endings and minimise pain by interfering with prostaglandin synthesis. These medications provide analgesic effects by reducing inflammation and by perhaps blocking the generation of noxious impulses. Examples include aspirin, diclofenac and ibuprofen. The NSAIDs have anti-inflammatory, analgesic and antipyretic actions. NSAIDs are useful (providing renal function is adequate) for mild to moderate pain and continue to be effective when combined with opioids for moderate to severe pain. The cyclooxygenase-2 (COX-2) selective NSAIDs (celecoxib, parecoxib) are newer formulations; although less harmful to gastric mucosa, their usage has been questioned because of cardiac-associated adverse reactions and care must always be taken when prescribing regarding the person's renal function.

NSAIDs have minimal side effects if used on a short-term basis, but side effects can and do occur when used over a long period for persistent pain problems.

Tramadol Tramadol is a centrally acting synthetic analgesic that is used for moderate to severe pain. Tramadol has a three-way action, having some opioid activity and also inhibiting the re-uptake of noradrenaline and serotonin. Because it is not completely an opioid, tramadol has been classed as a Schedule 4 medication. Its analgesic effect is comparable to that of codeine. It can be used for moderate to severe pain, though it is not as powerful as morphine. Tramadol is contraindicated in those with epilepsy, as seizures have been reported, but it causes less respiratory depression, gastric stasis and constipation than the opioids (Martinez, Guichard & Fletcher, 2015). Tramadol is available in oral (immediate and slow release) and intravenous preparations.

Opioids Opioids are derivatives of the opium plant. ('Opioid' is the preferred term as 'narcotic' has negative connotations.) These medications (and their synthetic forms) are the pharmacological treatment of choice for moderate to severe pain. Examples are morphine, codeine and fentanyl. Opioid analgesics produce analgesia by binding to opioid receptors both within and outside the CNS. A common myth among healthcare professionals is that using opioids for analgesia poses a real threat of addiction. When opioids are used as recommended, there is little to no risk of addiction (see Box 8.2). Nursing implications for opioids are found in the 'Medication administration' box below.

A summary of the common opioids, their preparations and the brand names available in Australia is shown in Table 8.2, and general adverse effects of opioids are listed in Box 8.3.

ADJUVANTS There are a number of drugs that are often used in pain management that assist with analgesia or control specific symptoms. These drugs are often referred to as the adjuvants or co-analgesics.

Antidepressants Antidepressants within the tricyclic chemical group act on the production and retention of serotonin in the CNS, thus inhibiting pain sensation. They also promote normal sleeping patterns, further alleviating the suffering of the person in pain. They are useful with neuropathic pain. Common drugs used in this class are amitriptyline, nortriptyline and doxepin.

Anticonvulsant medications Anticonvulsant medications such as gabapentin (Neurontin), pregabalin (Lyrica) and carbamazepine (Tegretol) are useful with neuropathic pain, including phantom limb pain, shingles (herpes zoster), migraine headaches and diabetic neuropathic pain. These drugs reduce pain and sleep disruption. Although these drugs are primarily used to treat epilepsy (seizures), they are also used to treat nerve pain conditions. Clinical studies have shown many anticonvulsant drugs to be effective.

Ketamine Ketamine is a dissociative anaesthetic and has the action of being an NMDA (N-methyl-D-asparate) antagonist. Tissue damage that causes continual nociception or neuropathic

BOX 8.2 Pain management and drug abuse history

The person with a substance abuse disorder often experiences sub-therapeutic dosing of opioid medications for pain. When providers suspect or learn of drug abuse, they tend to order lower doses than they would for a person of similar age and weight. Despite significant data showing very little addiction as the result of treating pain with adequate pain relief, prescribers still tend to under-treat pain in the person with a substance abuse disorder. When the person with a substance abuse disorder has an acute injury they usually need greater doses of pain medication because of the tolerance they have developed from repeated exposure to opioids and other drugs. The person with chronic cancer or non-cancer pain can display opioid tolerance due to perioperative opioid administration, particularly opioids of high potency (ANZCA, 2010).

Cook, Sefcik & Stetina (2004) reported on a study comparing analgesic prescribing practices for those in acute pain with a history of drug abuse with those in acute pain who had not abused drugs. It was found that prescribing practices were significantly different for the two groups. All were prescribed the same selection of medication and dosages; however, those with a history of drug abuse were prescribed significantly more non-opioid analgesics. Furthermore, there was no significant difference in the dosages prescribed for the two groups, despite the risk of greater tolerance to opiates by the heroin-addicted person. The prescribers did not take into account heroin-dependent tolerance to opioid medications and the increased need for analgesia among those with a history of drug abuse. It was also pointed out that opioid analgesics were rationed in an effort to wean the person from their addiction. This indicates how uninformed the prescribers were regarding the needs of a heroin-dependent person and their increased tolerance to opioids. The findings of this study have been supported by more recent research by Blay et al. (2012) who looked at pain management practices with patients who had a history of substance abuse, in the Australian context.

During the acute stress of injury or infection, withholding pain medication is an added stressor. Nurses attempting to advocate for the comfort needs of an addicted person may encounter resistance around this issue. This creates a potential ethical as well as a professional dilemma. Therefore, where possible, use a pain service to assist in a person's analgesic management.

Providing analgesics for a person with pain who has a history of or ongoing substance abuse is challenging. It is important to communicate clearly all information about medications and accessibility to the providers. Giving appropriate analgesic relief will help prevent the person sourcing medications illegally. Dose escalation may be monitored with careful assessment and random urine screens if requested by medical staff.

When the person is discharged from hospital care, consideration must be taken to exposing the community to opioid medications. If diversion of the drug or inappropriate use of the prescribed medication is suspected, then opioids can be prescribed with restrictions (e.g. collecting limited amounts at one time, or only after review by a medical practitioner). Detoxification is a matter for the person to determine when they are over their crisis.

TABLE 8.2 Common opioids available in Australia

OPIOID	PREPARATION	BRAND NAME
Morphine	Oral syrup (immediate release)	Ordine
	Oral tablet (immediate release)	Anamorph/Severdol
	Oral tablet/capsule (sustained release)	MSContin/Kapanol
	Injection (immediate release)	Morphine sulfate/Tartrate
Oxycodone	Oral tablet/capsule/elixir (immediate release)	Endone, Oxycodone, OxyNorm
		Oxycontin
	Oral tablet (sustained release)	Prolodone
	Suppository (absorption uncertain)	Oxycodone
	Injection (immediate release)	
Fentanyl	Lozenge (immediate release)	Atiq
	Transdermal patch (sustained release)	Durogesic
	Injection (immediate release)	Sublimaze
Hydromorphone	Oral liquid/tablet/injection (immediate release)	Dilaudid
	Oral (sustained release)	Junista
Methadone (absorption independently variable)	Oral syrup	Physeptone syrup/Biodone Forte
	Oral tablets	Physeptone
	Injection	Physeptone
Codeine	Oral tablet/linctus (immediate release)	Codeine phosphate
Pethidine	Injection (immediate release)	Pethidine

BOX 8.3 General adverse effects of opioids

Neurological symptoms are often dose-dependent, and may include sedation, dysphoria, confusion, dizziness, mental cloudiness, euphoria, miosis, muscle rigidity and seizures. It is usually advised that people do not drive, work heavy machinery or make critical decisions when initially taking these medications.

Respiratory symptoms are often dose-related, and may include cough suppression, respiratory depression, bronchospasm and asthma.

Cardiovascular symptoms may include bradycardia, hypotension and vasodilation.

Gastrointestinal symptoms may include nausea, vomiting, constipation, loss of appetite and biliary colic.

Dermatological symptoms may include itch, sweating, flushing and rash.

Urinary symptoms may include urinary retention, and changes in bladder and sphincter tone.

Neuroendocrine symptoms tend to develop after long-term use.They include a reduction in some hypothalamic-releasing hormones, which affects the gonads, adrenal cortex and endorphins.

Opioid rotation is common, especially for persistent pain as different opioids act on different receptors. Therefore, often a specialist will rotate the person on to a different opioid in the hope of producing more effective pain relief at a reduced dose. Sometimes equianalgesic tables are used to aid this rotation process, but these must be used with caution as each individual has different tolerances and preferences.

pain activates NMDA which subsequently produces sensitisation of the central nervous system. Low-dose ketamine calms down this NMDA reaction, and is used clinically for the person with persistent pain, opioid tolerance, substance abuse issues or a neuropathic pain state.

Nitrous oxide Nitrous oxide is useful for women in labour and for some dressings and procedures that are painful. Despite its analgesic and sedative effects, it has minimal cardiovascular or respiratory depressive effects. Neurological and bone marrow problems can develop with regular use, so relevant system testing should occur at regular intervals. To help prevent neurological problems, methionine, folic or folinic acid, and vitamin B12 should be prescribed (ANZCA, 2010).

Local anaesthetics Local anaesthetics block the initiation and transmission of nerve impulses in a local area, thus also blocking pain sensations. Common examples of these drugs are lignocaine, bupivacaine and ropivacaine.

Local anaesthetics can be delivered by a variety of methods—for example, a single-shot nerve injection, as wound infiltration, or via topical application. All have been shown to aid analgesia. Delivery can also be made directly to the sheath of a nerve through a peripheral nerve catheter offering a continuous nerve blockade when the catheter is connected to an ongoing local anaesthetic infusion. When this latter method is used, staff must be competent in the delivery system and the hospital should have standard protocols and policies to manage this technique. Side effects can occur from receiving local anaesthetics, such as trauma to the anaesthetised area and local anaesthetic toxicity from accidental intravascular injection.

Bisphosphonates Bisphosphonates are medications that target malignant tumours growing in bone. Referred to as osseous metastases, these expanding, painful tumours impair function. Bisphosphonates stabilise bone, slowing or preventing the development of tumours, and have a pain-relieving benefit which exceeds that of steroids and NSAIDs. Disodium pamidronate (Aredia) is effective with breast cancer metastases and multiple myeloma. A newer generation bisphosphonate, zoledronic acid (Aclasta), is useful with bony metastases secondary to lung, prostate, renal cell and other solid tumours (Mathew & Brufsky, 2015).

Radiopharmaceuticals Radiopharmaceuticals are unsealed substances produced in a nuclear reactor that emit a beta particle or an electron. The radioactivity is particularly damaging to malignant cells and is a safe and effective treatment for bony metastases. Radiopharmaceuticals are particularly useful in the management of those with prostate cancer and painful osteoblastic metastases confirmed on bone scan. This treatment coupled with external beam radiation therapy (EBRT) has been shown to provide symptomatic relief in 80% of this group (Goyal & Antonarakis, 2012). Negative effects may include severe renal dysfunction or severe bone marrow depression.

Treatments may be given intravenously or orally. Care of the person treated with radiopharmaceuticals must follow radiation precautions, disposing of all body fluids quickly and thoroughly. Urine excretion is essentially completed in the first 6 hours.

Duration of action

Each pharmacological agent has a unique absorption and duration of action. Remember that no drug will have a totally predictable course of action, because each person absorbs, metabolises and excretes medications at different dosage levels. The only way to obtain reliable data about the effectiveness of the medication for the individual person is to assess how that person responds. Therefore, the best choice is to individualise the dosing schedule.

There are two major descriptors of dosing schedules. The first type is for medications prescribed ‘on a regular basis’, such as paracetamol, NSAIDs and slow-release opioid preparations. These medications are usually given regularly if the person experiences constant pain predictably during a 24-hour period. The second type of dosing schedule is ‘on an as-needed basis’ (prn)—meaning *pro re nata* (Latin for ‘as circumstances may require’)—whereby immediate-release opioid medications are commonly used. Note that prn medication should be administered:

- as soon as the pain begins or prior to onset
- when increased pain is anticipated, such as when an activity is planned (e.g. a dressing), or when the regular prescribed medication does not cover all the pain. This is often the case in treating cancer pain as breakthrough medications may be required.

Giving analgesics before the pain occurs or increases gives the person confidence in the certainty of pain relief and thereby

MEDICATION ADMINISTRATION Opioid analgesics

Opioid analgesics are used to treat severe pain. The drugs in this category include morphine, codeine, opium derivatives, and synthetic substances. Morphine and codeine are pure chemical substances isolated from opium. These drugs decrease the awareness of the sensation of pain by binding to opiate receptors in the brain and spinal cord. It is also believed that they diminish the transmission of pain impulses by altering cell membrane permeability to sodium and by affecting the release of neurotransmitters for efferent nerves sensitive to noxious stimuli. People can develop a tolerance to opioids and they cause psychological and physical dependence. For the person who has had an acute painful assault and is now requiring slow-release preparations in the short term, ensure that there is a strategy to decrease their opioid consumption. For example, the person is given a written reduction plan to follow, a written reduction regimen is sent to their general practitioner, or the person is sent to a specialised pain medicine clinic to assist with opioid reduction.

NURSING RESPONSIBILITIES

- Opioids are regulated by individual state laws; the nurse and witness must record the date, time, person's name, type and amount of the drug used, and sign the entry in the Schedule 8 book (commonly known as the DD—Dangerous Drugs—Book). A witness must check the drug is given to the correct person. If the drug is disposed of after it is signed out, this must be recorded and witnessed in the Schedule 8 book.
- Keep an opioid antagonist, such as naloxone, immediately available to treat respiratory depression.
- Assess allergies or adverse effects from any opioids previously experienced by the person.
- Pethidine is associated with CNS toxicity and thus involves significant risk; use is discouraged.
- Assess for any respiratory disease, such as asthma or sleep apnoea, that might increase the risk of respiratory depression.
- Assess the characteristics of the pain and the effectiveness of drugs that have been previously used to treat pain.
- Take and record baseline vital signs before administering the drug.
- Administer the drugs following established guidelines.
- Monitor vital signs, level of consciousness, papillary response, nausea, bowel function, urinary function and analgesic effectiveness.
- Use non-invasive methods of pain management and multimodal analgesics in conjunction with opioid medications.
- Provide for person safety.

HEALTH EDUCATION FOR THE PERSON WITH PAIN, THEIR FAMILY AND SIGNIFICANT OTHERS

- The use of opioids to treat severe pain is unlikely to cause addiction.
- Do not drink alcohol.
- Do not take over-the-counter medications unless approved by the healthcare provider.
- Increase intake of fluids and fibre in the diet to prevent constipation.
- The drugs often cause dizziness, drowsiness and impaired thinking; use caution when driving or making critical decisions.

avoids some of the untoward effects of pain. The benefits of a preventive approach can be summarised as follows:

- The person may spend less time in pain.
- Frequent analgesic administration may allow for smaller doses and less analgesic administration.
- Smaller doses will in turn mean fewer side effects.
- The person's fear and anxiety about the return of pain will decrease.
- The person will probably be more physically active and avoid the difficulties caused by immobility.
- The swift and effective management of acute pain can prevent persistent pain states occurring.

The side effects of a drug can become difficult to manage if the dosage is too high, and the person may suffer unnecessary pain because of reluctance to endure side effects. The best formula for adequate dosage is a balance between effective analgesia and minimal side effects. Within prescribed limits, the nurse can choose the most appropriate dose according to the person's response. It is also the role of the nurse to inform the physician and request a review of their analgesics if the prescribed dosage does not meet the person's needs.

Routes of administration

ORAL ROUTE The oral route is the simplest route for both person and nurse. Special nursing care is still required, because some medications must be given with food, some are irritating to the gastrointestinal system, and some people may have trouble swallowing pills. Liquids, elixirs, capsules, soluble preparations and slow-release formulations are available for special applications.

RECTAL ROUTE The rectal route is helpful for those who are unable to swallow; however, absorption is unpredictable. The rectal route is contraindicated in those with diarrhoea, those with neutropenia and those who have had rectal surgery.

TRANSDERMAL MEDICATION The **transdermal** or 'patch' form of medication is increasingly being used because it is simple, painless and delivers a continuous level of medication (see Figure 8.7). Transdermal medications are easy to store and apply. Reapplication depends on the type of patch used (every 72 hours for fentanyl patches or 7 days for buprenorphine). Additional short-acting medication is often needed for breakthrough pain. Over-dosage can occur; therefore, it is important to start with a low-dose patch and **titrate** (which means to increase or decrease the dose in small increments) to the effective level. Again, these patches are good for those who are not eating or drinking; however, for those who sweat profusely or have a fever or inflammation of the skin, expect an increased absorption rate. Exercise and use of electric blankets or heating pads may also accelerate absorption of the medication and cause respiratory depression. (Deaths have occurred in the United States because of this problem.)

FIGURE 8.7 ■ The transdermal patch administers medication in predictable doses

To apply a medication transdermally, apply to a hairless area of skin that is not irritated or broken. The area of skin needs to be cleaned and then the patch applied. Apply the patch immediately upon opening the package, and ensure that the contact is complete, especially around the edges. The effectiveness of a patch is dependent on its absorption, and the next patch should always be applied to a different site. When first applying a transdermal medication, expect 12 to 24 hours (for fentanyl) and up to 3 days (for buprenorphine) until a therapeutic level is absorbed; also, when discontinuing expect a similar decline in level because of the medication reservoir in the skin. If the person complains of severe light-headedness, is pale, sweaty and weak, the medical officer needs to be informed immediately and the patch removed.

INTRAMUSCULAR INJECTION Intramuscular injection was once the most popular route for pain medication administration. Its disadvantages include uneven absorption from the muscle (resulting in delayed respiratory depression), discomfort on administration, and the time needed to prepare and administer the medication. It is also recognised that the quality of analgesia is inferior to that of intravenous patient-controlled analgesia.

INTRAVENOUS ROUTE The intravenous (IV) route provides the most rapid onset, usually ranging from 1 to 15 minutes. Medication can be given by drip, bolus or person-controlled analgesia (PCA)—a pump with a control mechanism that affords the person self-management of pain (see Figure 8.8). The advantages of PCA are dose precision, timeliness and convenience. The person does not have to wait for a nurse to assess the need for pain medication, then procure and deliver the analgesia (Hicks, Hernandez & Wanzer, 2012). Respiratory depression and sedation are minimised when plasma levels of opioids are steady (Lehne, 2012). Several drugs are available for this route. The disadvantages are the nursing care needed for any intravenous line, the potential for infection, the cost of disposable supplies and ensuring that only the actual patient presses the PCA button. For this reason the PCA method of administration requires careful education coupled with close and attentive monitoring.

SUBCUTANEOUS ROUTE The subcutaneous (SC) route is accepted; its disadvantages are similar to those of the intramuscular route.

EPIDURAL ROUTE The epidural route is invasive and requires more extensive nursing care, but may provide better analgesia and postoperative recovery than intravenous delivery. When opioids are inserted into the epidural space they are usually combined with local anaesthetics. This mixture can be given as an infusion or as a 'top-up'. When this combination of drugs is used the person experiences better analgesia, earlier bowel recovery, earlier mobility and a shorter length of hospital stay than with the intravenous route (ANZCA, 2010). See below for nursing implications for the person receiving epidural analgesia.

INTRATHECAL ROUTE The intrathecal route places drugs (usually opioids, local anaesthetics or both) into the cerebrospinal fluid. When medication is inserted into the intrathecal space it is usually as a single injection, and much smaller doses are required compared to the epidural route.

REGIONAL ANALGESIA Regional analgesia is commonly known as 'a nerve block'. Nerve blocks use local anaesthetics (sometimes in combination with a steroidal drug, depending on

FIGURE 8.8 ■ PCA units allow the person to self-manage severe pain. The units may be portable or mounted on intravenous poles

the situation) injected by a physician into or near a nerve, usually in an area between the nociceptor and the dorsal root. In the postoperative situation, nerve blocks can be either a single-shot injection or run as a continuous peripheral nerve block infusion (CPNB). When a CPNB is ordered, strict protocols, procedures and standards must be adhered to so as to ensure safety.

In the persistent-pain setting the procedure may be performed to determine the precise location of the source of the pain: pain relief indicates that the injection site is the source of the pain. Temporary nerve blocks may give the person enough relief to:

- develop a more hopeful attitude that pain relief is possible
- allow local procedures to be performed without causing discomfort
- exercise and move the affected part.

If the nerve block is successful, a permanent neurolytic agent can be used to give long-term analgesia.

SURGERY As an analgesic measure, surgery is usually performed only after all other methods have failed. Those who need this measure must understand possible risks such as reduced motor function or incontinences. Surgical procedures used to relieve pain are shown in Figure 8.9 and include the following:

- A *rhizotomy* is destruction of the dorsal spinal roots. It is most often performed to relieve back/neck pain. A rhizotomy can be performed by a spinal or neurosurgeon: the nerve fibres are surgically severed. Rhizotomies may also be performed by a pain specialist who injects a chemical, or uses a radiofrequency current or cryotherapy, to selectively destroy painful fibres. These types of rhizotomy are called percutaneous and usually offer temporary pain relief.
- A *sympathectomy* involves blocking the ganglia of sympathetic nerves, usually in the lumbar region, often with local anaesthetic or surgery. The sympathetic nerves play an important role in producing and transmitting the sensation of pain.
- A *cordotomy* is an incision into the anterolateral tracts of the spinal cord to interrupt the transmission of pain. Because it is difficult to isolate the nerves responsible for upper body pain, this surgery is most often performed for pain in the abdominal region and legs, including severe pain from terminal cancer. A percutaneous cordotomy produces lesions of the anterolateral surface of the spinal cord by means of a radiofrequency current.
- A *neurectomy* is the removal of a nerve. It is sometimes used for pain relief. A peripheral neurectomy is the severing of a nerve at any point distal to the spinal cord.

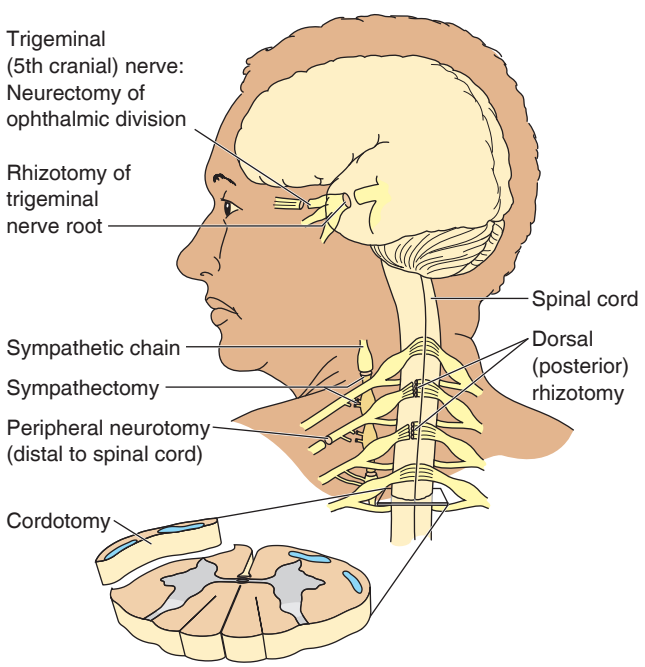

FIGURE 8.9 ■ Surgical procedures are used to treat severe pain that does not respond to other types of management. They include cordotomy, neurectomy, sympathectomy and rhizotomy

Nursing care

Assessment

Nursing assessment of the person with pain presents perhaps more of a challenge than almost any other type of illness or injury because of the subjectivity of pain and the effects it has on the individual.

A comprehensive approach to pain assessment is essential to ensure adequate and appropriate interventions. The five assessment areas are: (1) health history, (2) physiological response, (3) examination, (4) behavioural response, and (5) response to treatment.

1. Health history

Before commencing an in-depth assessment, discuss:

- The definition of the word 'pain' to ensure that the person and the provider are communicating on the same level. It is often helpful to use the person's own words when describing the pain. For example, the person may talk about discomfort as opposed to pain.
- Explain that the report of pain is important for promoting recovery, not just for achieving temporary comfort.
- Ask the person to establish a comfort-function goal. This is a level of pain that does not interfere with or prevent the performance of essential activities of recovery or living.

The person's history of the pain can be assessed by using the PQRST technique (Gregory, 2014):

- What precipitated (triggered, stimulated, makes it worse) the pain? What palliates (what makes it better, has anything relieved) the pain? What is the pattern of the pain?
- What are the quality and quantity of the pain? Is it sharp, stabbing, aching, burning, stinging, deep, crushing, vice-like, gnawing? A reliable indicator of the presence and degree of pain is the person's own statement about the pain. The McGill Pain Questionnaire is a useful tool in assessing the person's subjective experience of the pain. It asks the person to locate the pain, to describe the quality of the pain, to indicate how the pain changes with time and to rate the intensity of the pain (see Figure 8.10). Several tools are available to assess specific pain qualities (Hjermstad et al., 2011; Lin et al., 2011).

NURSING CARE PLAN A person receiving intraspinal analgesia

Intraspinal analgesia is used to manage acute postoperative, persistent and intractable cancer pain. The intraspinal route may be either intrathecal or epidural. Putting opioids into these spaces directly affects the opiate receptors in the dorsal horn of the spinal cord; the opioids are also absorbed systemically and affect the brain. This method provides complete pain relief but has some potentially dangerous side effects.

PROCEDURE

The physician places a needle and/or a catheter into the intrathecal or epidural space. Tubing may be attached to an infusion pump, and the prescribed medication is administered.

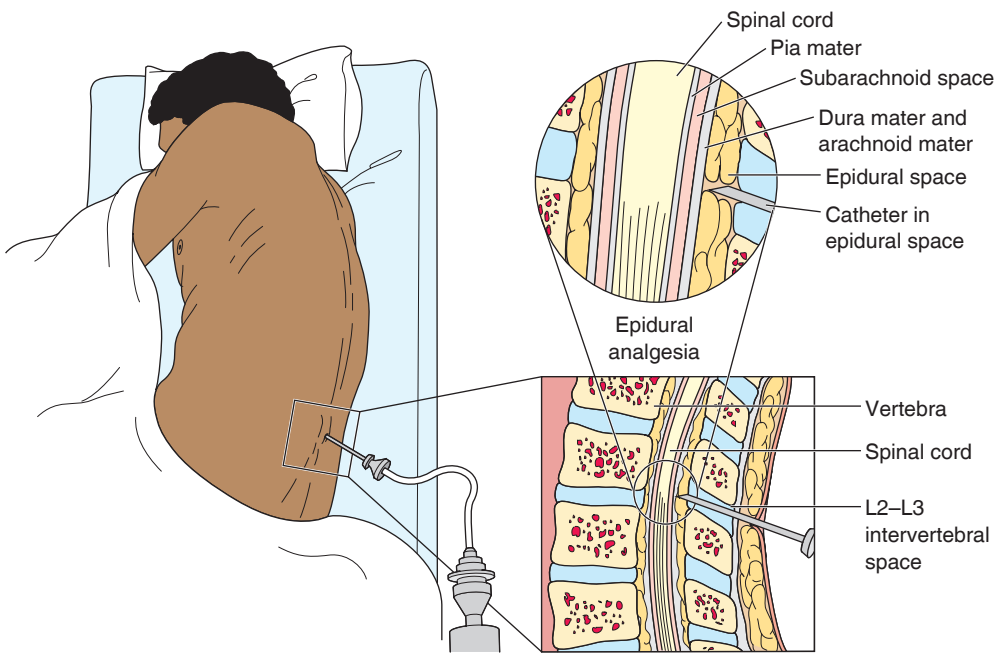
NURSING CARE

- Monitor vital signs closely. The exact methods will be determined by each individual hospital, but will most likely be similar to: monitor vital signs every 5 minutes for the first half-hour and then hourly for every hour for the first 24 hours. There is a risk of respiratory depression, which may not manifest itself for several hours.
- Ensure that naloxone, an opioid antagonist, is immediately available to reverse respiratory depression.
- Monitor the effectiveness of pain management.
- Monitor motor function (Bromage score) at least hourly in the first 6 hours post initial injection; if motor function has not returned after 3 hours, contact the anaesthetist immediately.
- Monitor fluid balance. Intraspinal opioids and local anaesthetics may alter the micturition reflex if the technique affects the lumbar dermatomes, causing urinary retention and necessitating the insertion of a urinary catheter.
- Use sterile technique to care for the catheter.

There are potential problems and contraindications when using intrathecal and epidural analgesia. For example:

- untrained staff
- refusal of treatment
- catheter placement issues (sepsis, infected injuries, spinal surgery or injury, catheter migration, disconnection or leakage at the site)
- hypovolaemia
- hypotension
- coagulation problems (including anticoagulant medications)
- potential for a dural puncture, epidural haematoma and abscess.

There are also several side effects of intrathecal and epidural analgesia, especially when opioids are used—for example, respiratory depression, sedation, nausea, vomiting, pruritis and urinary retention.



Placement of the catheter in the epidural space

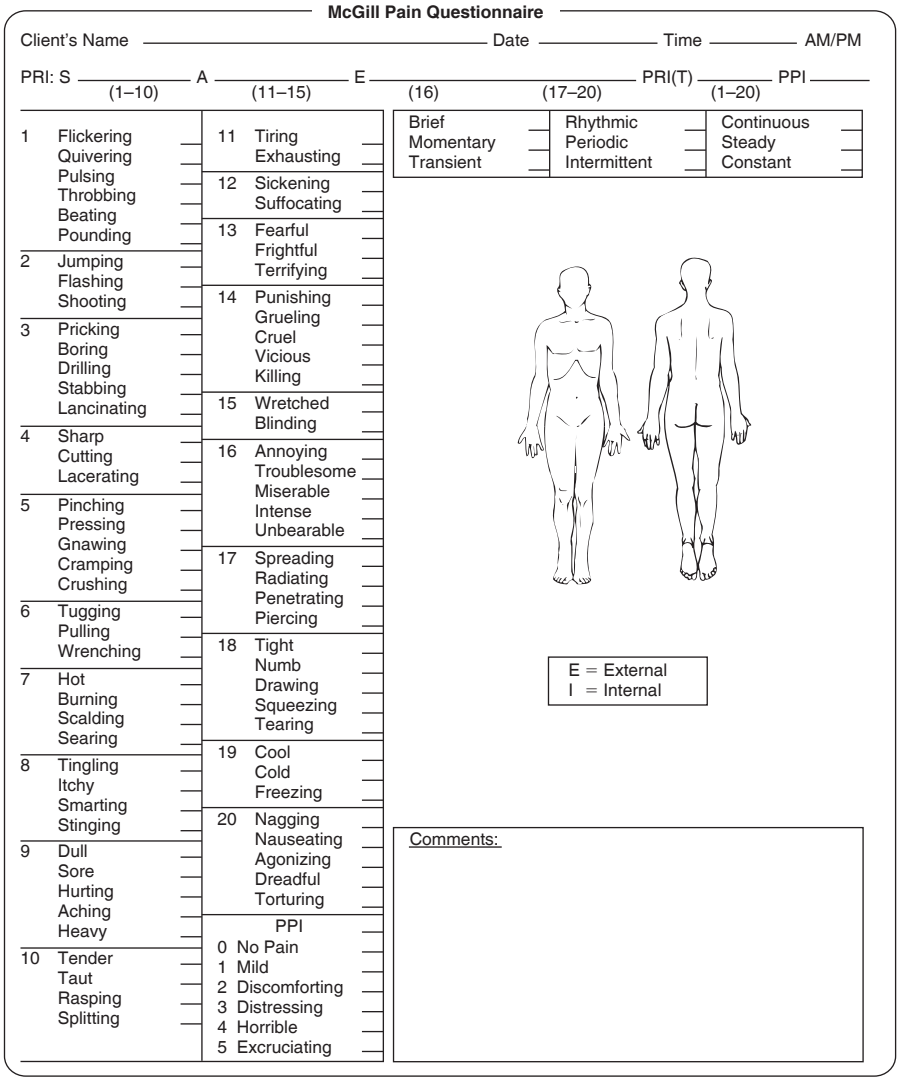


FIGURE 8.10 ■ The McGill Pain Questionnaire

Source: R. Melzack, (1975) The McGill Pain Questionnaire: Major properties and scoring methods. *Pain*, *1*(3), 277. © International Association for the Study of Pain.

- What is the region (location) of the pain? Does the pain radiate to other areas of the body?
- What is the severity of the pain? The most common method to assess the severity of pain is a pain rating scale. Several scales are illustrated in Figure 8.11.
- If you are caring for the person with an established persistent pain condition in an acute care setting, remember to ask what their normal pain score is when they are managing their life in the community. It is not unusual for those with a persistent pain condition to give higher pain scores.
- For the person who does not understand English or numerals, a scale using colours (e.g. light blue for no pain through to bright red for worst possible pain) or pictures may be helpful. Often pain assessment is made while a person is sedentary. In this state the person may experience less pain than when active and falsely estimate tolerable pain ratings. Provide guidelines for setting goals.
- What is the timing of the pain? When does it begin, how long does it last (continuous or intermittent), and how is it related to other events in the person's life?

The following nursing interventions will help the nurse assess for pain using a pain rating scale:

- Ensure consistent communication. Explain the specific pain rating scale used. If a word descriptor scale is used, verify that the person can read the language being used. If a numerical scale is used, be sure the person can count to 10. If the person is not able to report pain because of communication difficulties, intubation, emotional disturbances or cognitive impairments, monitor the manifestations of pain by taking vital signs, assessing skin temperature and moisture, observing pupils, observing facial expressions, position in bed, guarding of body parts and restlessness. Autonomic responses to pain may result in increased blood pressure, tachycardia, rapid respirations and perspiration and dilated pupils. Other responses to pain include grimacing, clenching the hands, muscle rigidity, guarding, restlessness and nausea. The person with chronic pain may have an unexpressive or tired face.
- Be sure the person is able to report pain. Researchers have found that nursing home residents with cognitive impairments can validly self-report pain (Chatterjee, 2012).

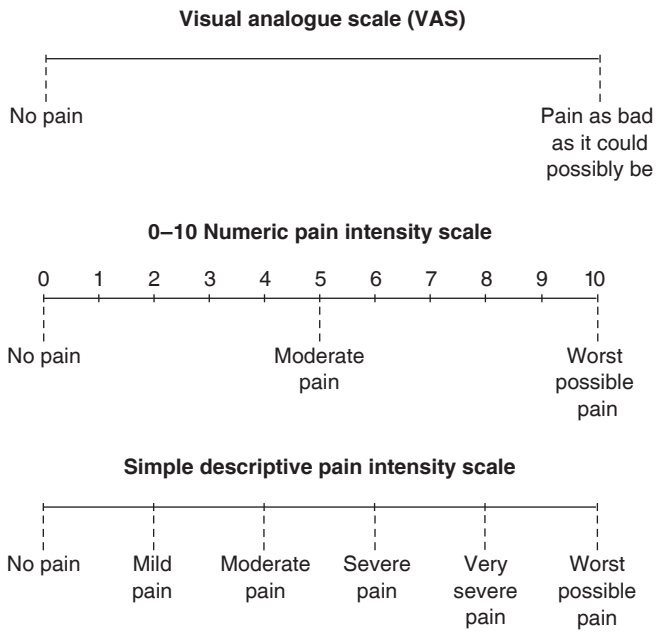

FIGURE 8.11 ■ Examples of commonly used pain scales

The following nursing interventions will help the nurse assess for pain using other measures:

- Look for indicators of pain, such as grimacing, restlessness, rubbing, stillness, verbal or non-verbal vocalisations, and holding on to an object tightly (Chatterjee, 2012).
- Pain has been shown to increase adverse behaviours such as wandering, carer resistance, socially inappropriate behaviours and delusional thoughts. Ensure pain is considered as part of the assessment of all aged care residents (Tosato et al., 2012).
- Ask a family member or caregiver, if they suspect the person has pain, to serve as a proxy pain rating.

2. Physiological response

When the body experiences acute pain, the stress response is initiated. This metabolic response releases neuroendocrine hormones systemically and a local release of cytokines at the injury site. Surgical stimuli that cause pain can influence the sympathetic efferent nerves, causing an increase in myocardial oxygen demand, influencing heart rate and blood pressure. Gastric motility is often reduced, so the potential for an ileus can develop. Injury/surgery to the upper abdominal or the thoracic area can cause difficulty in coughing, which can result in reduced functional residual capacity. If this persists, then ventilation perfusion problems can occur.

For those suffering with persistent pain, loss of muscle mass and physical deconditioning can occur. As these symptoms continue, movement restrictions develop, and insomnia, fatigue and a change in appetite may occur.

3. Examination

Examination of the person should include observation, auscultation, palpation and percussion of the sensitive areas. The physician will also undertake a physical assessment that does not cause any undue pain. Discuss the person's normal ability to perform activities of daily living and how this acute or chronic condition has affected this. Observe for pain behaviours and non-verbal clues such as facial expression and body language. Assess the effect the pain has on the person's sleep pattern. Note any pre-existing medical or pain conditions that could influence the person's current condition. Investigations ordered by the medical staff should assist in confirming clinical impressions.

4. Behavioural response

It is essential to assess the person's response to any treatment given for pain. If you give a medication for pain relief, go back and *assess* its effectiveness, especially with respect to functional abilities. The person's satisfaction must also be noted in response to their pain treatments, whether a treatment helped, had no effect on, or increased their pain. Meticulous documentation is critical as future pain regimens may be based on this.

5. Responses to treatment

Some behaviours are so typical of people in pain that the behaviours are referred to as pain behaviours. They include bracing or guarding the painful part, taking medication, crying, moaning, grimacing, withdrawing from activity and socialisation, becoming immobile, talking about pain, holding the painful area, breathing with increased effort, exhibiting a sad facial expression and being restless.

Behavioural responses to pain may or may not coincide with the person's report of pain and are not reliable cues to the pain experience. For example, one person may rate pain at an 8 on a 0–10 scale (where 0 = no pain and 10 = worst imaginable) while laughing or walking down the hall, while another may deny pain completely but be reluctant to move and grimace or moan. Denial of pain may be for a variety of reasons, including fear of injections, fear of drug addiction, misinterpretation of terms (the person may not think that aching, soreness or discomfort qualify as pain), or the belief that healthcare providers alone decide when a person is experiencing pain. Some may deny pain as part of an attempt to deny that there is something wrong with them. Others, by contrast, may think that 'as-needed' medications will be given only if their pain rating is high. Discrepancies between the person's report of pain and behavioural responses may be influenced by certain factors—for example, sociocultural factors, emotional state, knowledge, past experiences and age, and relaxation or distraction techniques.

SELF-MANAGEMENT OF PAIN The person's attempts to manage pain are useful additions to the assessment database. This information is individualised and specific to each person; it includes many factors such as culture, age and knowledge. Obtain detailed descriptions of actions the person or significant others used, and when and how these measures were applied, and how well they worked.

CONSIDERATION FOR PRACTICE

Do not assume that the older person or the person with a cognitive impairment is not having pain or is unable to identify its intensity.

Nursing diagnoses and interventions

Acute or persistent pain

Assess the characteristics of the pain by asking the person to:

- Point to the pain location, or mark the pain location on a figure drawing. *Pain location provides information about the aetiology of the pain and the type of pain being experienced.*
- Rate the intensity of the pain at rest and during movement by using a pain scale (1 to 10, with 10 being the worst pain ever experienced), a visual analogue scale (a scale on which pain is marked on a continuum from no pain to severe pain), or with word descriptors (such as the McGill Pain Questionnaire, and mild, moderate or severe). Use the same scale with each assessment. *The intensity of pain is a subjective experience. The perception of the intensity of pain is affected by the person's degree of concentration or distraction, state of consciousness and expectations.*
- Describe the quality of the pain. For example, say to the person: 'Describe what your pain feels like.' If necessary, provide word descriptors for the person to select from. *Descriptive terms provide insight into the nature and perception of the pain. In addition, the location and type of pain (e.g. acute versus persistent) affect the quality.*
- Describe the pattern of the pain, including time of onset, duration, persistence and times without pain. It is also important to ask whether the pain is worse at regular times of the day and whether it has any relationship to activity. *The pattern of pain provides clues about cause and location.*
- Describe any precipitating or relieving factors. *Precipitating factors include sleep deficits, anxiety, temperature extremes, excessive noise, anxiety, fear, depression and activity.*
- Describe the meaning of the pain, including its effects on lifestyle, self-concept, roles and relationships. *The person with acute pain may believe the pain is a normal response to injury, or that it signals serious illness and death. Pain is a stressor that may affect the person's ability to cope effectively. The person with persistent pain often has concerns about addiction to pain medication, costs, social interactions, sexual activities and relationships with significant others.*
- Monitor manifestations of pain by assessing skin temperature and moisture; observing pupils; observing facial expressions, position in bed and guarding of body parts; and noting restlessness. *Autonomic responses to pain may result in increased blood pressure, tachycardia, rapid respirations, perspiration and dilated pupils. Other responses to pain include grimacing, clenching the hands, muscle rigidity, guarding, restlessness and nausea. The person with persistent pain may have an unexpressive, flat affect with a tired facial appearance. (Remember, if the person has persistent pain, vital signs may not be increased.)*
- Communicate belief in the person's pain by verbally acknowledging the presence of the pain, listen carefully to the description of pain, and act to help the person manage the pain. *Because pain is a personal, subjective experience, the nurse must convey belief in the person's pain. By doing so, the nurse reduces the person's anxiety and thereby lessens their pain.* See the 'Translation to practice' box below.
- Provide optimal pain relief with prescribed analgesics, determining the preferred route of administration. Provide pain-relieving measures for severe pain on a regular around-the-clock basis or by self-administration (such as with a PCA pump). *The person is part of the decision-making process and can exert some control over the situation by choosing the administration route. Analgesics are usually most effective when they are administered before pain occurs or becomes severe. Around-the-clock administration has been proven to provide better pain management for both acute and persistent pain. Do not crush or break, or allow the person to chew, controlled-release oral preparations; a dose meant to be slowly absorbed that is absorbed rapidly may lead to a toxic overdose and death.*
- Evaluate and monitor the effects of analgesics and other pain-relieving measures and teach family members or significant others to be alert for adverse reactions to pain medications. Sedation, constipation, nausea and dizziness are common side effects. *Excessive sedation can progress to significant respiratory depression. Oxygen saturation should be checked regularly. Protocols will vary within your institution. Prevent falls that may result from sedation or dizziness. If the person has symptoms of excessive opioid dosage, antidotes are available. Naloxone is used for opioid overdose. Titrate naloxone slowly. Never push an entire dose all at once. Administer only enough naloxone to eliminate adverse effects such as respiratory depression or excessive sedation. If excessive naloxone is administered, the person may experience acute withdrawal and will have no pain relief. It may take considerable time to re-establish a therapeutic comfort level.*
- Determine the level of sedation the person will tolerate. *For those with persistent pain or cancer pain who need high doses of opioids, sedation may interfere with quality of life and neither the person nor the family want them to be sedated.* Several classes of drugs can be used to counteract sedation. They are usually given in the morning so that they will not interfere with night sleep. Amphetamines, especially methylphenidate (Ritalin), is the most commonly used; modafinil (Modavigil) has been used for several years; and donepezil (Aricept), which is used for the symptoms of Alzheimer's disease, reduces sedation and fatigue (Caraceni et al., 2012).
- Teach the person and family non-pharmacological methods of pain management, such as relaxation, distraction and cutaneous stimulation. *These techniques are especially useful when used in conjunction with pain medications and may also be useful in managing persistent pain.*
- Provide comfort measures, such as changing position, massage, oral care, skin care and changing bed linen. *Basic comfort measures for personal cleanliness, skin care and mobility promote physical and psychosocial wellbeing, lessening the perception of pain.*
- Provide person and family education, and make referrals if necessary to assist with coping, such as financial support services and home care. *The person (and family) with pain requires information about medications, non-invasive techniques for pain management and sources of assistance with home-based care. The person with acute*

TRANSLATIONTO PRACTICE Evidence-based practice for the person experiencing pain

Poor pain management is common. Despite having a wealth of evidence-based practice available there is a gap between research and clinical practice. Observational studies of pain management are valuable because they are time-sensitive. Relying on nurses' self-report of pain management introduces bias and loses currency. In a study by Manias, Bucknall & Botti (2005), nurses were observed in 2-hour periods. Examination of the collected observations by independent analysts revealed six categories of response to a person's pain. The pain was:

1. responded to effectively
2. prioritised as less important than completing medication administration, assessing vital signs, taking telephone calls or changing dressings
3. ignored because cues were missed
4. treated as part of the medication administration regimen and given or withheld according to schedule
5. prevented through comfort measures, medicating before pain was present or was going to occur as with dressing changes, teaching the importance of early communication about pain
6. was only addressed reactively, after the painful experience.

Because pain management is important, many hospitals employ acute, palliative and persistent pain services, with more attention being encouraged regarding listening to each person's self-reporting of pain. Communication among nurses, physicians and the person experiencing pain is key to pain relief. Knowledge of the pharmacodynamics and pharmacokinetics of analgesics needs to be taught and updated regularly. Environmental distractions and interruptions are associated with less attention to pain management. Few conditions have higher priority for the person than pain relief, but the study revealed that nurses accept pain as a normal component of the postoperative surgery experience. Administrators need to be aware that competing responsibilities affect nurses' ability to provide effective pain management. These responsibilities include documentation, admitting new people, and completing discharge education and arrangements. Pain management is an important component of professional nursing—nurses should be supported in their efforts to address pain with compassion and efficiency.

CRITICAL THINKING IN PERSON-CENTRED CARE

1 Reflect on your own experiences with pain. Evaluate how these experiences help or hinder your assessments and interventions for a person in pain.
2 You are caring for a young man who has multiple injuries from a motorcycle accident. He tells you his pain is so bad that he just wants to die. Describe and explain how you would respond, and why.
3 You are caring for an 80-year-old man with diabetes who has had his left foot amputated for gangrene. He is restless and moaning. Another nurse tells you to give only one-half of the ordered dose of opioids because 'he is old and there is a danger of respiratory depression'. Assess this nurse's suggested intervention and explain how you would handle this situation.
4 'Nurses tend to underestimate and under-medicate pain.' Discuss this statement using recent published research.

pain requires information about the expected course of pain resolution.

Community-based care

Educate the person, family and significant others regarding:

- specific drugs to be taken, including the frequency, potential side effects, possible drug interactions and any special precautions to be taken (such as taking with food or avoiding alcohol)
- how to take or administer the drugs (see Table 8.3)
- the importance of taking pain medications before the pain becomes severe
- an explanation that the risk of addiction to pain medications is very small when they are used appropriately for pain relief
- the importance of scheduling periods of rest and sleep.

In addition, suggest the following resources:

- pain clinics
- community support groups
- International Association for the Study of Pain (IASP)
- Australian Pain Society (APS)
- Cancer Council Australia.

TABLE 8.3 Providing long-term analgesia at home

ROUTE	DRUG	NURSING IMPLICATIONS
Oral	Oxycodone	Available in a slow-release formulation for 12-hour dosing (Oxycontin) and as fast-acting formulations (Oxynorm or Oxycodone elixir) for breakthrough pain.
Oral	Morphine	Formulated as slow-release particles in a capsule (Kapanol). If the person cannot swallow the capsule, it may be sprinkled over food or given by gastric tube. Morphine can also be given as a slow-release tablet (MsContin) or as immediate-release preparations either as a tablet (Anamorph) or capsule (Sevredol) or an elixir (Ordine).
Transdermal	Fentanyl	A patch absorbed slowly through the skin (Durogesic); allows 72-hour dose schedule. Takes up to 12 hours to achieve therapeutic level; when discontinued, therapeutic effect will decay slowly. A lozenge formulation fentanyl citrate (Actiq) absorbed through the buccal cavity can be used to treat breakthrough cancer pain in opioid-tolerant people.

NURSING CARE PLAN A person with persistent pain

Susan Akers, aged 37, is currently being seen at an outpatient clinic for persistent non-malignant pain. She works at a local paper factory. She has a 3-year history of neck and shoulder pain that usually is accompanied by headaches. She believes the pain is related to lifting objects at work, but it is now precipitated by activities of daily living. Susan is absent from work approximately three times a month and states that the absences are due to her pain and headaches. She has been seeking care in the local emergency department on an average of twice monthly for injections for pain. She does not regularly use medications but does take Panadeine Forte and Valium as needed (usually 3 or 4 times a day). Susan is divorced and has two children. She states that she has several friends in the area, but her parents and siblings live interstate.

ASSESSMENT

During the nursing history, Susan rates her pain during an acute episode as a 7 on a 1 to 10 scale. She states that lifting objects and moving her hands and arms above shoulder level causes sharp pain. The pain never really goes away, but it does decrease with upper extremity rest. She says that when she lifts a lot at work, she has difficulty sleeping that night. She takes two Panadeine Forte tablets every 4 hours when the pain is severe, but does not get complete relief. The medical officer diagnoses muscular pain.

DIAGNOSIS

- *Persistent pain* related to muscle inflammation resulting from repetitive movement and lifting of heavy objects manifested by pain on movement that lessens at rest and in response to analgesia.

PLANNING

After negotiating expected outcomes and intervention techniques, opioid analgesia and distraction techniques are to be used during the acute phase of management. Non-opioid analgesia is to be used after the acute phase and review of the work environment is to be undertaken.

Expected outcomes

- Return for follow-up visits with a journal of activities and pain experiences.
- After 3 to 5 days on regularly scheduled doses of pain medication, report a decrease in the level of pain from 7 to 3 or 4 on a 1 to 10 scale.
- Decreased number of absences from work.
- Modify activities at work and at home, especially when pain is intense.

IMPLEMENTATION

- Encourage discussion of pain and acknowledge belief in Susan's report of pain.
- Consult with a physician for a non-opioid analgesic with a minimum of side effects, and instruct in maintaining regular dosing schedules.
- For episodes of acute pain, take opioid analgesics as soon as the pain begins and every 4 hours, while continuing the dosage of non-opioid analgesic.
- Teach one relaxation technique that is personally useful.
- Explore distraction techniques such as listening to music, watching comedies or reading.
- Provide clinic phone number and instruct to call if pain is unrelieved with narcotic and non-opioid analgesics.

EVALUATION

Susan returns for scheduled follow-up visits with a completed journal of her activities and associated pain. She reports that taking oral opioid analgesics has relieved her pain and that within 3 weeks non-opioid analgesics have brought her pain under control. She also reports that her supervisor has reassigned her to a position that requires no lifting. She now rates her pain at 2 or 3 on a 1 to 10 scale. She has missed only 1 day of work in the last 3 months and reports that her children and friends have helped with her household tasks when she has requested they do so.

CRITICAL THINKING IN THE NURSING PROCESS

1. Describe three factors that support the statement 'Pain is a personal experience.'
2. Susan asks you how often she should take her pain medications. Do you tell her to (a) take them on a regular basis, or (b) wait until she experiences pain? Which action would you choose, and why?
3. Susan is at risk of constipation. Why, and what information would you provide?

REFLECTION ON THE NURSING PROCESS

1. What have you learned from the case study that you will apply to your clinical practice?
2. If someone is non-compliant with the negotiated care plan and returns to the pain clinic with continued discomfort, consider some of the reasons this non-compliance may have occurred.

CHAPTER HIGHLIGHTS

- Pain is perceived in the central nervous system. Opioids, and other analgesics, block the perception of pain; NSAIDs and most non-pharmacological interventions block or decrease the transmission of pain from the periphery to the CNS. Measures to block the sensitisation of pain-transmitting fibres are being used prior to painful procedures and incision in surgery.
- There are many types of pain, and treatment varies according to the type and combination of types. Acute pain usually decreases as healing progresses; persistent pain has acute exacerbations and compounds acute pain. Breakthrough pain is recognised as an increase in pain intensity that occurs when the peak and duration of medications are reached. Incident pain occurs in relation to a change or increase in activity. Central pain results from CNS lesions. Phantom pain occurs after amputation, seeming to originate in the missing body part.
- Ethnicity (genetics and culture) and gender impact on pain perception and behaviour. Behavioural assessment of pain intensity is less accurate than the person's report of pain intensity.

- Myths and misconceptions exist about pain and its management; the person's perceived cause of pain and the best self-care method to relieve pain provide pertinent assessment information.
- People respond to pain on the basis of their emotional state, past experiences with pain, and the meaning of the painful experience. The person with a malignant diagnosis may have an interpretation of pain that is significantly different from the person with benign disease.
- Older adults perceive pain as intensely as younger adults. The amount of opioids they may need is variable, as they may have difficulty metabolising or eliminating medications.
- Assertively assess pain in the older person. Older adults may hesitate to report pain for fear of losing independence or being considered a nuisance. Cognitive impairment following cardiovascular accident, dementia or delirium makes self-report of pain less available. Behavioural scales for assessing pain are useful when the person cannot give self-reports.
- Addiction is a neurophysiological disease. The person with addiction to opioids may need greater doses of opioids to control pain because of the tolerance they may have developed through usage.
- Emergency department physicians and nurses are constrained in the prescription of opioids by the risk of overmedicating the person who is drug-seeking and by the myth that pain management interferes with diagnosis.
- Pain management includes assessment, intervention and evaluation. It is important to verify that interventions have been effective. If not, interventions must be identified that bring pain down to a level of intensity with which the person feels satisfied.

CONCEPT CHECK

1 Your neighbour has had lower back pain for 9 months. How would this pain be categorised?
   1 acute pain
   2 persistent pain
   3 referred pain
   4 somatic pain

2 Which of the following statements is a misconception about pain?
   1 It is best to wait until a person has pain before giving medication.
   2 Anxiety can cause pain and pain can cause anxiety.
   3 Pethidine is no longer recommended for postoperative pain.
   4 The rationale for use of a TENS unit is supported by the gate-control theory.

3 You are taking a health history for a person who has taken a NSAID for several years. What would be an appropriate question to ask?
   1 'Do you understand what this drug could do to you?'
   2 'Have you ever vomited blood or had very dark stools?'
   3 'Do you know that you may become addicted to this drug?'
   4 'Have you noticed any problems with your breathing?'

4 You are replacing a transdermal pain medication. Where on the body would you place it?
   1 on one side of the buttocks
   2 below the navel, midline on the abdomen
   3 on the anterior thigh
   4 on the upper torso

5 Which of the following statements would be most useful in determining the quality of a person's pain?
   1 'Tell me where you hurt.'
   2 'Rate your pain on a scale of 0 to 10.'
   3 'Describe what your pain feels like.'
   4 'Tell me how this pain affects your sleep.'

6 The person has orders for intravenous patient-controlled analgesia (PCA). The following principles are true, except:
   1 basal doses are continuous
   2 overdose cannot occur
   3 a 10-minute lockout each hour allows six bolus doses
   4 unused bolus doses cannot accumulate

7 The most common side effects of opioid analgesics are:
   1 anuria, diplopia and cough
   2 constipation, nausea and sedation
   3 pruritus, constipation and hallucinations
   4 dysphagia, fever and gastritis

8 The preferred route of opioid administration for persistent pain is:
   1 transdermal
   2 oral
   3 intravenous
   4 rectal

9 The equivalent dose of an oral drug compared to the intravenous preparation of the same drug:
   1 is equal dosage
   2 is twice the intravenous dose
   3 varies according to the medication
   4 is one-half the intravenous dose

10 People treated for persistent pain may need additional pain management strategies for:
   1 breakthrough pain
   2 acute pain
   3 end-of-dose pain
   4 all of the above

CHAPTER 9

NURSING CARE OF PEOPLE WITH ALTERED FLUID, ELECTROLYTE AND ACID–BASE BALANCE

KAMAREE BERRY

KEY TERMS

LEARNING OUTCOMES

- Describe the functions and regulatory mechanisms that maintain water and electrolyte balance in the body.
- Compare and contrast the causes, effects and care of the person with fluid volume or electrolyte imbalance.
- Explain the pathophysiology and manifestations of imbalances of sodium, potassium, calcium, magnesium and phosphorus.
- Describe the causes and effects of acid–base imbalances.

CLINICAL COMPETENCIES

- Assess and monitor the person's fluid, electrolyte and acid–base balance.
- Administer fluids and medications knowledgeably and safely.
- Determine priority nursing diagnoses, based on assessment data, to select and implement individualised nursing interventions.
- Deliver pertinent information to the person and their family about diet and medications used to restore, promote and maintain fluid, electrolyte and acid–base balance.
- Integrate interprofessional care into care of a person with altered fluid, electrolyte and acid–base balance.

Changes in the normal distribution and composition of body fluids often occur in response to illness and trauma. These changes affect fluid balance of the intracellular and extracellular compartments of the body, the concentration of electrolytes within fluid compartments and the body's hydrogen ion concentration (pH). Normal physiological processes depend on a relatively stable state in the internal environment of the body. The fluid volume, electrolyte composition and pH of both intracellular and extracellular spaces must remain constant within a relatively narrow range to maintain health and life.

Homeostasis is the body's tendency to maintain a state of physiological balance in the presence of constantly changing conditions. Homeostasis is necessary if the body is to function optimally at a cellular level and as a total organism. Homeostasis depends on multiple factors in both the external and internal environments, such as available oxygen in the air and nutrients in food, as well as normal body temperature, respiration and digestive processes. The normal volume, composition, distribution and pH of body fluids reflect a state of homeostasis.

Changes in the normal volume of fluids, their composition, distribution, and relative acidity or alkalinity have the potential to disrupt most functional health patterns. Imbalances of fluids, electrolytes and pH affect the ability to maintain activities of daily living (the Activity–Exercise Pattern), think clearly (the Cognitive–Perceptual Pattern) and engage in self-care (the Health Perception–Health Management Pattern). Conversely, alterations in a number of health patterns affect the ability to maintain homeostasis. Alterations in the Nutritional–Metabolic Pattern affect the ability to consume adequate food and fluids. Disruptions of the Elimination Pattern may lead to retention or loss of excess amounts of fluids and electrolytes. Disrupted heart or respiratory function, which falls within the Activity–Exercise Pattern, has the potential to affect fluid, electrolyte and acid–base balance.

The goal in managing fluid, electrolyte and acid–base imbalances is to re-establish and maintain a normal balance. Nursing care includes identifying and assessing a person who is likely to develop imbalances, monitoring the person for early manifestations, and implementing collaborative and nursing interventions to prevent or correct imbalances. Effective nursing interventions require an understanding both of the multiple processes that maintain fluid, electrolyte and acid–base balance, and of the causes and treatment of imbalances that occur.

Mechanisms that maintain normal fluid and electrolyte balance are discussed first, followed by sections on fluid imbalances and electrolyte imbalances. Discussion of normal acid–base balance precedes discussion of acid–base imbalances. Case studies related to selected fluid, electrolyte and acid–base disorders are found throughout the chapter.

OVERVIEW OF NORMAL FLUID AND ELECTROLYTE BALANCE

Fluid and electrolyte balance in the body involves regulatory mechanisms that maintain the composition, distribution and movement of fluids and electrolytes. This section provides an overview of fluid and electrolyte balance in the body. It is followed by discussion of fluid volume and electrolyte balance disorders.

Body fluid composition

Body fluid is composed of water and various dissolved substances (solutes).

Water

Water is the primary component of body fluids. It functions in several ways to maintain normal cellular function. Water provides a medium for the transport and exchange of nutrients and other substances such as oxygen, carbon dioxide and metabolic wastes to and from cells; provides a medium for metabolic reactions within cells; assists in regulating body temperature through the evaporation of perspiration; provides form for body structure and acts as a shock absorber; provides insulation and acts as a lubricant.

Total body water constitutes about 60% of total body weight, but this amount varies with age, gender and the amount of body fat. Total body water decreases with ageing; in the older adult, body water may decrease to 45% to 50% of total body weight (Marieb & Hoehn, 2011). Adipose tissue contains comparatively little water. In the person who is obese, the proportion of water to total body weight is less than in the person of average weight; in a person who is very thin, the proportion of water to total body weight is greater than in the person of average weight. Adult females have a greater ratio of fat to lean tissue mass than adult males; therefore, they have a lower percentage of body water content.

To maintain normal fluid balance, body water intake and output should be approximately equal. The average fluid intake and output usually is about 2500 mL over a 24-hour period. Food and fluids consumed provide the majority of water gain; carbohydrate metabolism and other metabolic processes produce an additional small amount.

Urine production and excretion account for most water loss. The average daily urine output is 1200 to 1500 mL in adults. At least 400 mL of highly concentrated urine per day is required to excrete metabolic wastes produced by the body (Marieb & Hoehn, 2011). *Insensible* water loss (which normally cannot be measured) occurs through the skin, lungs and faeces. These losses, while normally small, can increase significantly during exercise, when environmental temperatures are high, and during illness that increases the respiratory rate, perspiration or gastrointestinal (GI) losses (particularly diarrhoea). Table 9.1 shows the sources of fluid gain and loss.

Electrolytes

Body fluids contain both water molecules and chemical compounds. These chemical compounds can either remain intact in solution or separate (dissociate) into discrete particles. **Electrolytes** are substances that dissociate in solution to form charged particles called ions. *Cations* are positively charged electrolytes; *anions* are negatively charged electrolytes. For example, sodium chloride (NaCl) in solution dissociates into a sodium ion, a cation carrying a positive charge (Na^+), and a chloride ion, an anion carrying a

TABLE 9.1 Balanced fluid gain and loss for an adult

	SOURCE	AMOUNT (mL)
Gain	Fluids taken orally	1200
	Water in food	1000
	Water as by-product of food metabolism	300
	↓	
	Total	**2500**
	↑	
Loss	Urine	1500
	Faeces	200
	Perspiration	300
	Respiration	500

negative charge (Cl^-). Electrolytes may be *univalent*, with only one unit of electrical charge, such as sodium (Na^+) and chloride (Cl^-); or they may be *divalent*, carrying two units of electrical charge, such as magnesium (Mg^{2+}) and phosphate (HPO_4^{2-}).

Electrolytes have many functions, including assisting in regulating water balance; regulating and maintaining acid–base balance; and contributing to enzyme reactions essential for neuromuscular activity.

The concentration of electrolytes in body fluids generally is measured in milliequivalents per litre of water (mEq/L). A *milliequivalent* is a measure of the chemical combining power of the ion. For example, 100 mEq of sodium (Na^+) can combine with 100 mEq of chloride (Cl^-) to form sodium chloride (NaCl). Sodium, potassium and chloride usually are measured in milliequivalents. In some cases, the amount of an electrolyte in body fluid may be measured by weight in milligrams per 100 mL (1 decilitre, dL) of water (mg/dL). Calcium, magnesium and phosphorus often are measured by weight in milligrams per decilitre. Other laboratories use the International System of Measurements, or SI units.

Body fluid distribution

Body fluid is classified by its location inside or outside cells. *Intracellular fluid* (ICF) is found within cells. It accounts for approximately 40% of total body weight (see Figure 9.1) and is essential for normal cell function, providing a medium for metabolic processes. *Extracellular fluid* (ECF) is located outside cells and accounts for approximately 20% of total body weight. ECF is classified by location:

- Interstitial fluid is located in the spaces between most of the cells of the body. It accounts for approximately 15% of total body weight.
- Intravascular fluid, called *plasma*, is contained within the arteries, veins and capillaries. It accounts for approximately 5% of total body weight.
- Transcellular fluid includes urine, digestive secretions and perspiration, as well as cerebrospinal, pleural, synovial, intraocular, gonadal and pericardial fluids.

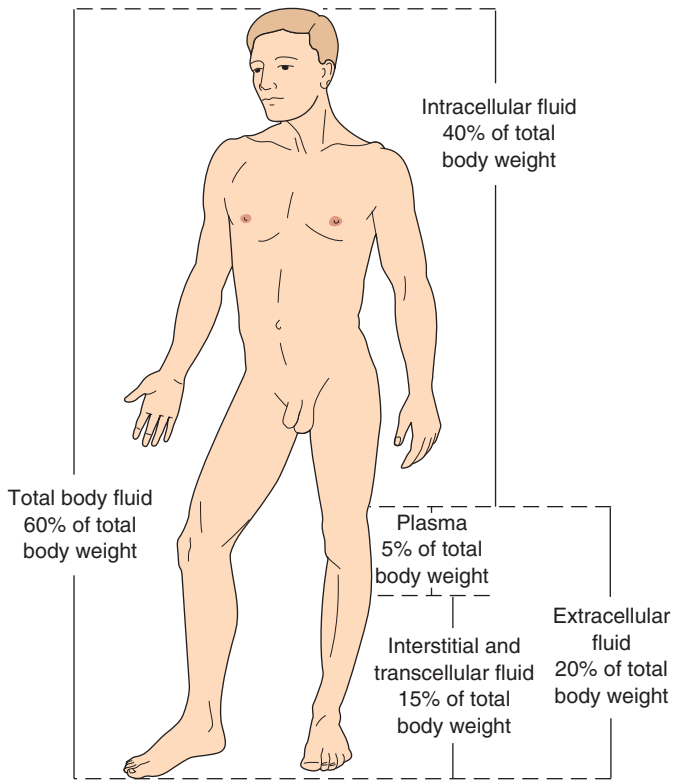

FIGURE 9.1 ■ The major fluid compartments of the body

A trace amount of water is found in bone, cartilage and other dense connective tissues; this water is not exchangeable with other body fluids.

ECF is the transport medium that carries oxygen and nutrients to, and waste products from, the cells. For example, plasma transports oxygen from the lungs and glucose from the digestive system to the tissues. These solutes diffuse through the capillary wall into the interstitial space and from there across the cell membrane into the cells. Waste products of metabolism (e.g. carbon dioxide and hydrogen ions) diffuse from the intracellular space into the interstitial space and from there into plasma via the capillary walls. Plasma then transports these waste products to the lungs and kidneys for elimination.

Although the overall concentration of solutes in ICF and ECF is nearly identical, the concentration of specific electrolytes differs significantly between these compartments, as shown in Figure 9.2. ICF contains high concentrations of potassium (K^+), magnesium (Mg^{2+}) and phosphate (PO_4^{2-}), as well as other solutes such as glucose and oxygen. Sodium (Na^+), chloride (Cl^-) and bicarbonate (HCO_3^-) are the principal extracellular electrolytes. The high sodium concentration in ECF is essential to regulating body fluid volume. The concentration of potassium in ECF is low. There is a minimal difference in electrolyte concentration between plasma and interstitial fluid. Normal values for electrolytes in plasma are shown in Table 9.2.

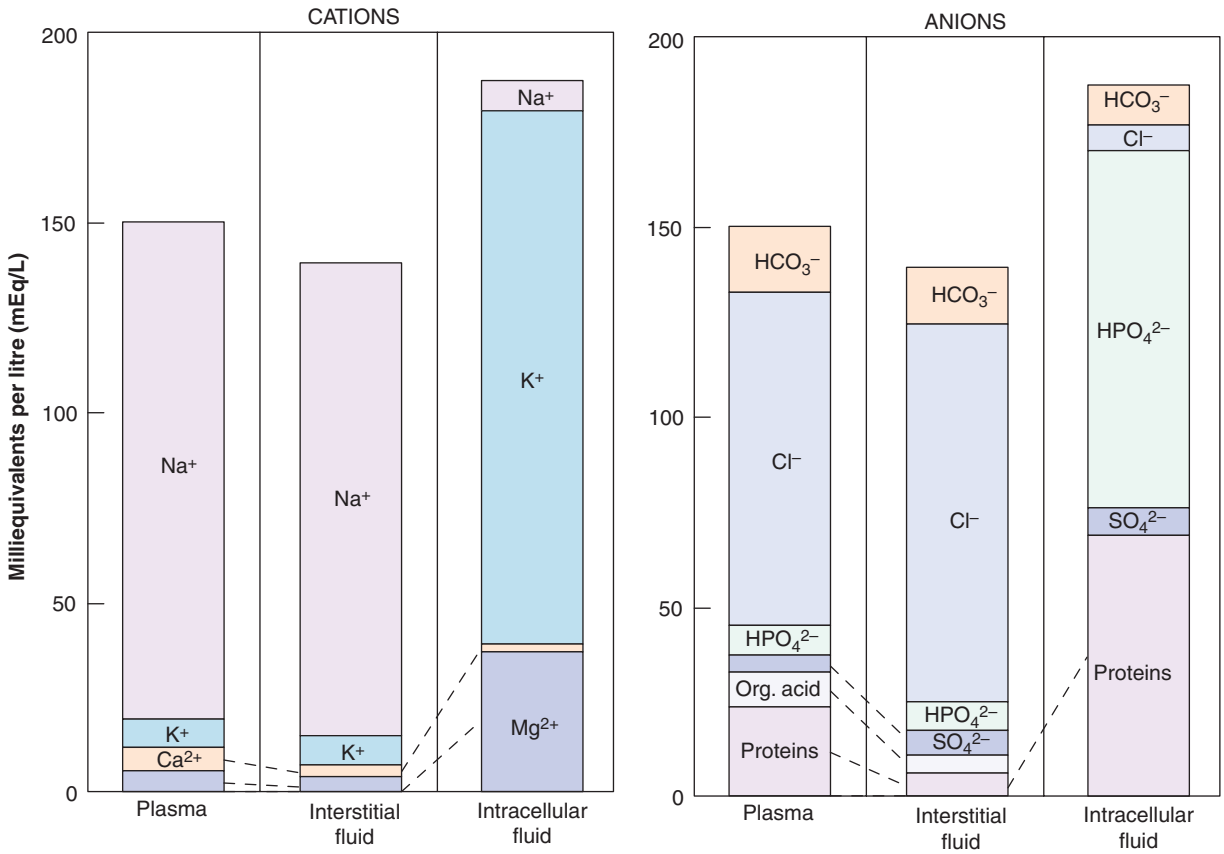

FIGURE 9.2 ■ Electrolyte composition (cations and anions) of body fluid compartments

The body fluid compartments are separated by several types of membranes:

- Cell membranes separate interstitial fluid from intracellular fluid.
- Capillary membranes separate plasma from interstitial fluid.
- Epithelial membranes separate transcellular fluid from interstitial fluid and plasma. These membranes include the mucosa of the stomach, intestines and gallbladder; the pleural, peritoneal and synovial membranes; and the tubules of the kidney.

A cell membrane consists of layers of lipid and protein molecules. The layering of these molecules controls the passage of fluid and solutes between the cell and interstitial fluid. The cell membrane is selectively permeable; that is, it allows the passage of water, oxygen, carbon dioxide and small water-soluble

TABLE 9.2 Normal values for electrolytes and serum osmolality

SERUM COMPONENT	VALUES	
ELECTROLYTES	CONVENTIONAL UNITS	SI UNITS
Sodium (Na^+)	135–145 mEq/L	135–145 mmol/L
Chloride (Cl^-)	95–105 mEq/L	95–105 mmol/L
Bicarbonate (HCO_3^-)	22–30 mEq/L	22–30 mmol/L
Calcium (Ca^{2+}) (total)	9–11 mg/dL	2.3–2.8 mmol/L
Potassium (K^+)	3.5–5.3 mEq/L	3.5–5.0 mmol/L
Phosphate/inorganic phosphorus (PO_4^{2-})	1.7–2.6 mEq/L (2.5–4.5 mg/dL)	0.8–1.5 mmol/L
Magnesium (Mg^{2+})	1.5–2.5 mg/dL (1.8–3.0 mEq/L)	0.8–1.3 mmol/L
Serum osmolality	280–300 mOsm/kg	275–295 mmol/kg

molecules, but bars proteins and other intracellular colloids. The capillary membrane separating the plasma from the interstitial space is made of squamous epithelial cells. Pores in the membrane allow solute molecules (such as glucose and sodium), dissolved gases and water to cross the membrane. Minute amounts of albumin and other proteins can also pass through the pores of a capillary membrane, but normally plasma proteins stay in the intravascular compartment.

Body fluid movement

Four chemical and physiological processes control the movement of fluid, electrolytes and other molecules across membranes between the intracellular and interstitial spaces and the interstitial space and plasma. These processes are osmosis, diffusion, filtration and active transport.

OSMOSIS The process by which water moves across a selectively permeable membrane from an area of lower solute concentration to an area of higher solute concentration is called **osmosis** (see Figure 9.3). A *selectively permeable membrane* allows water molecules to cross but is relatively impermeable to dissolved substances (solutes). Osmosis continues until the solute concentration on both sides of the membrane is equal. For example, if pure water and a sodium chloride solution are separated by a selectively permeable membrane, then water molecules will move across the membrane to the sodium chloride solution. Osmosis is the primary process that controls body fluid movement between the ICF and ECF compartments.

Osmolarity and osmolality The concentration of a solution may be expressed as the osmolarity or osmolality of the solution. *Osmolarity* refers to the quantity of solutes per litre of solution (by volume); it is reported in milliosmoles per litre (mOsm/L) in a solution. *Osmolality* refers to the quantity of solutes per kilogram of water (by weight); it is reported in milliosmoles per kilogram (mOsm/kg). Because osmotic activity in the body is regulated by the number of active particles (solutes) per kilogram of water, osmolality is used to describe the concentration of body fluids. The normal osmolality of both ICF and ECF ranges between 275 and 295 mOsm/kg. The osmolality of the ECF depends chiefly on sodium concentration. Serum osmolality may be estimated by doubling the serum sodium concentration (approximately 142 mEq/L). Glucose and urea contribute to the osmolality of ECF, although to a lesser extent than sodium.

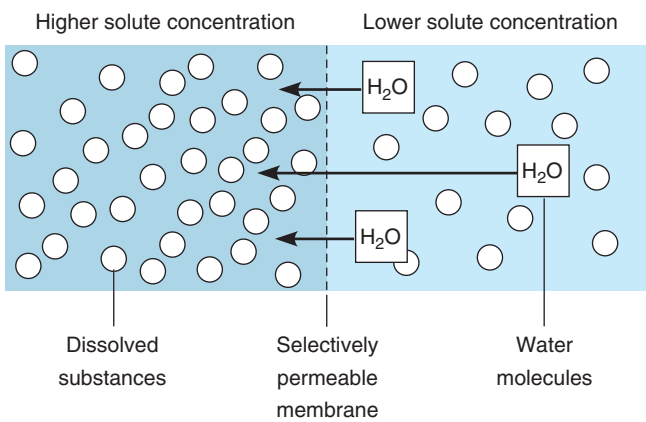

FIGURE 9.3 ■ Osmosis. Water molecules move through a selectively permeable membrane from an area of low solute concentration to an area of high solute concentration

Osmotic pressure and tonicity The power of a solution to draw water across a membrane is known as the *osmotic pressure* of the solution. The composition of interstitial fluid and intravascular plasma is essentially the same except for a higher concentration of proteins in the plasma. These proteins (especially albumin) exert colloid osmotic pressure (also called oncotic pressure), pulling fluid from the interstitial space into the intravascular compartment. Because the osmolality of intravascular and interstitial fluid is essentially identical, the osmotic activity of plasma proteins is important in maintaining fluid balance between the interstitial and intravascular spaces, helping to hold water within the vascular system.

Tonicity refers to the effect a solution's osmotic pressure has on water movement across the cell membrane of cells within that solution. *Isotonic* solutions have the same concentration of solutes as plasma. Cells placed in an isotonic solution will neither shrink nor swell because there is no net gain or loss of water within the cell and no change in cell volume (see Figure 9.4A). Normal saline (0.9% sodium chloride solution) is an example of an isotonic solution.

Hypertonic solutions have a greater concentration of solutes than plasma. In their presence, water is drawn out of a cell, causing it to shrink (see Figure 9.4B). A 3% sodium chloride solution is hypertonic. *Hypotonic* solutions (such as 0.45% sodium chloride) have a lower solute concentration than plasma (see Figure 9.4C). When red blood cells are placed in a hypotonic solution, water moves into the cells, causing them to swell and rupture (*haemolyse*).

The concepts of osmotic draw and tonicity are important in understanding the pathophysiological changes that occur with fluid and electrolyte imbalances, as well as treatment measures. For example, an increased sodium concentration of extracellular fluid pulls water from the ICF compartment into the ECF compartment, causing cells to shrink. In this case, administering a hypotonic intravenous solution to reduce the sodium concentration and osmolality of ECF will facilitate water movement back into the cells.

DIFFUSION The process by which solute molecules move from an area of high solute concentration to an area of low solute concentration to become evenly distributed is called **diffusion** (see Figure 9.5). The two types of diffusion are simple and facilitated diffusion. *Simple diffusion* occurs by the random movement of particles through a solution. Water, carbon dioxide, oxygen and solutes move between plasma and the interstitial space by simple diffusion through the capillary membrane. Water and solutes move into the cell by passing through protein channels or by dissolving in the lipid cell membrane. *Facilitated diffusion*, also

called carrier-mediated diffusion, allows large water-soluble molecules, such as glucose and amino acids, to diffuse across cell membranes. Proteins embedded in the cell membrane function as *carriers*, helping large molecules cross the membrane.

The rate of diffusion is influenced by a number of factors, such as the concentration of solute and the availability of carrier proteins in the cell membrane. The effect of both simple and facilitated diffusion is to establish equal concentrations of the molecules on both sides of a membrane.

FILTRATION The process by which water and dissolved substances (solutes) move from an area of high hydrostatic pressure to an area of low hydrostatic pressure is called **filtration**. This usually occurs across capillary membranes. *Hydrostatic*

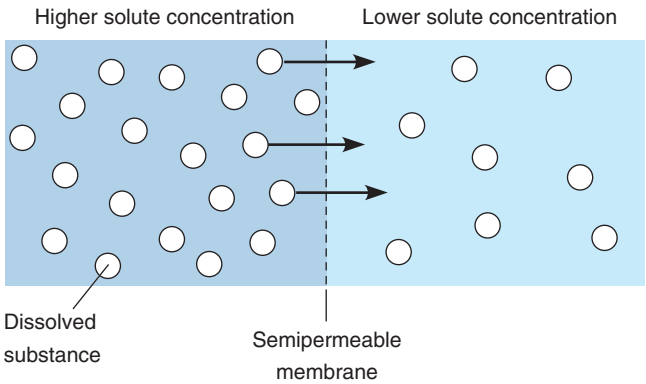

FIGURE 9.5 ■ Diffusion. Solute molecules move through a semipermeable membrane from an area of high solute concentration to an area of low solute concentration

pressure is created by the pumping action of the heart and gravity against the capillary wall. Filtration occurs in the glomerulus of the kidneys, as well as at the arterial end of capillaries.

A balance of hydrostatic (filtration) pressure and osmotic pressure regulates the movement of water between the intravascular and interstitial spaces in the capillary beds of the body. Hydrostatic pressure within the arterial end of the capillary pushes water into the interstitial space. Hydrostatic pressure within the interstitial space opposes this movement to some degree. At the venous end of the capillary, the osmotic force of plasma proteins draws fluid back into the capillary (see Figure 9.6).

ACTIVE TRANSPORT **Active transport** allows molecules to move across cell membranes and epithelial membranes against a concentration gradient. This movement requires energy (adenosine triphosphate, or ATP) and a carrier mechanism to maintain a higher concentration of a substance on one side of the membrane than on the other. The sodium–potassium pump is an important example of active transport (see Figure 9.7). High concentrations of potassium in intracellular fluids and of sodium in extracellular fluids are maintained because cells actively transport potassium from interstitial fluid (where the concentration of potassium is about 5 mEq/L) into intracellular fluid (where the potassium concentration is about 150 mEq/L).

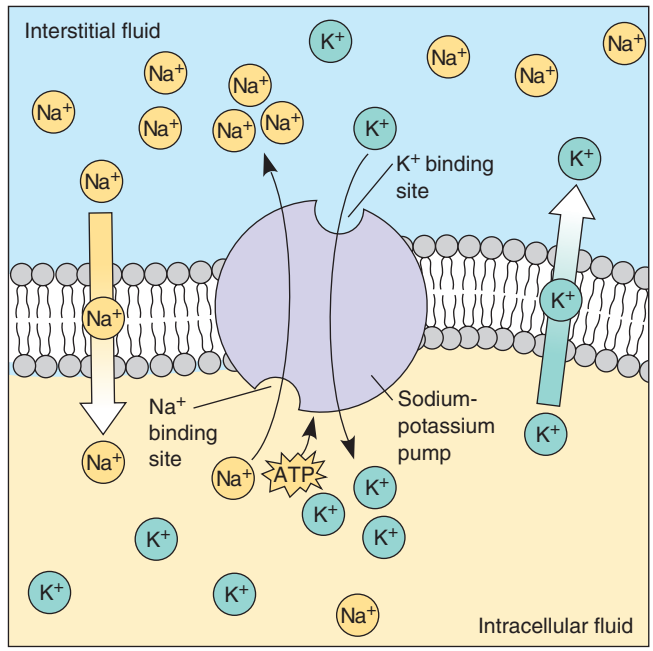

FIGURE 9.7 ■ The sodium–potassium pump. Sodium and potassium ions are moved across the cell membranes against their concentration gradients. This active transport process is fuelled by energy from ATP

Body fluid regulation

Homeostasis requires several regulatory mechanisms and processes to maintain the balance between fluid intake and excretion. These include thirst, the kidneys, the renin–angiotensin–aldosterone mechanism, antidiuretic hormone and atrial natriuretic peptide. These mechanisms affect the volume, distribution and composition of body fluids.

Thirst

Thirst is the primary regulator of water intake. Thirst plays an important role in maintaining fluid balance and preventing dehydration. The thirst centre, located in the brain, is stimulated when the blood volume drops because of water losses or when serum osmolality (solute concentration) increases (see Figure 9.8).

The thirst mechanism is highly effective in regulating extracellular sodium levels. Increased sodium in ECF increases

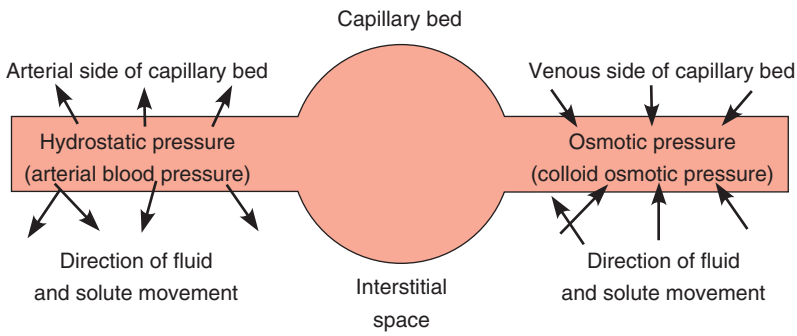

FIGURE 9.6 ■ Fluid balance between the intravascular and interstitial spaces is maintained in the capillary beds by a balance of filtration at the arterial end and osmotic draw at the venous end

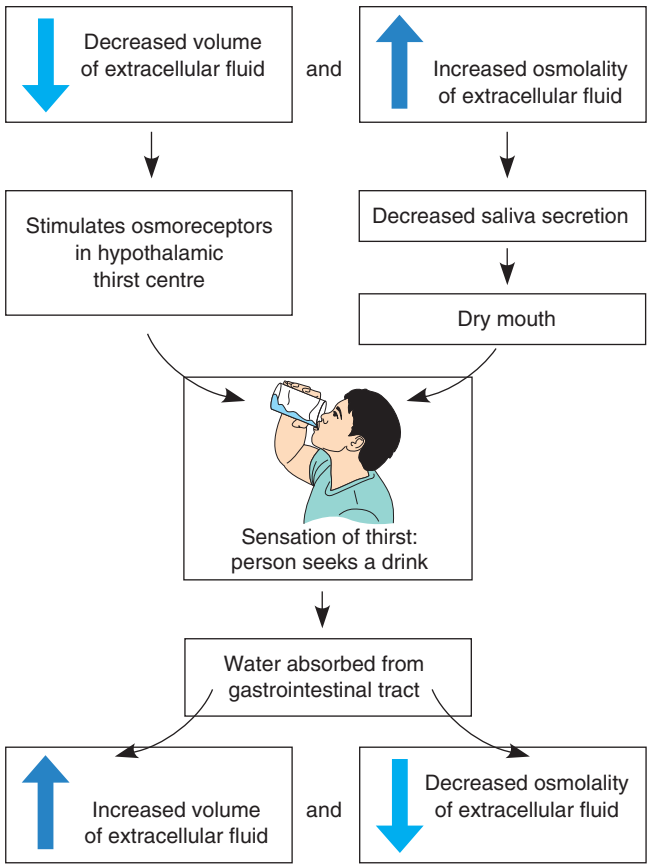

FIGURE 9.8 ■ Factors stimulating water intake through the thirst mechanism

serum osmolality, stimulating the thirst centre. Fluid intake in turn reduces the sodium concentration of ECF and lowers serum osmolality. Conversely, a drop in serum sodium and low serum osmolality inhibit the thirst centre.

CONSIDERATION FOR PRACTICE

The thirst mechanism declines with ageing, making older adults more vulnerable to dehydration and hyperosmolality (high serum osmolality). People with an altered level of consciousness or who are unable to respond to thirst are also at risk.

Kidneys

The kidneys are primarily responsible for regulating fluid volume and electrolyte balance in the body. They regulate the volume and osmolality of body fluids by controlling the excretion of water and electrolytes. In adults, about 170 L of plasma are filtered through the glomeruli every day. By selectively reabsorbing water and electrolytes, the kidneys maintain the volume and osmolality of body fluids. About 99% of the glomerular filtrate is reabsorbed, and only about 1500 mL of urine is produced over a 24-hour period.

Renin–angiotensin–aldosterone system

The renin–angiotensin–aldosterone system works to maintain intravascular fluid balance and blood pressure. A decrease in blood flow or blood pressure to the kidneys stimulates specialised receptors in the juxtaglomerular cells of the nephrons to produce renin, an enzyme. Renin converts angiotensinogen (a plasma protein) in the circulating blood into angiotensin I. Angiotensin I travels through the bloodstream to the lungs, where it is converted to angiotensin II by angiotensin-converting enzyme (ACE). Angiotensin II is a potent vasoconstrictor; it raises the blood pressure. It also stimulates the thirst mechanism to promote fluid intake and acts directly on the kidneys, causing them to retain sodium and water. Angiotensin II stimulates the adrenal cortex to release aldosterone. Aldosterone promotes sodium and water retention in the distal nephron of the kidney, restoring blood volume (see Figure 9.9).

Antidiuretic hormone

Antidiuretic hormone (ADH), released by the posterior pituitary gland, regulates water excretion from the kidneys. Osmoreceptors in the hypothalamus respond to increases in serum osmolality and decreases in blood volume, stimulating ADH production and release. ADH acts on the distal tubules of the kidney, making them more permeable to water and thus increasing water reabsorption. With increased water reabsorption, urine output falls, blood volume is restored and serum osmolality drops as the water dilutes body fluids (see Figure 9.10).

In addition to decreased blood volume and increased serum osmolality, increased amounts of ADH are released in response to stress, pain, surgery and anaesthesia, some medications such as morphine and barbiturates, and mechanical ventilation. Its

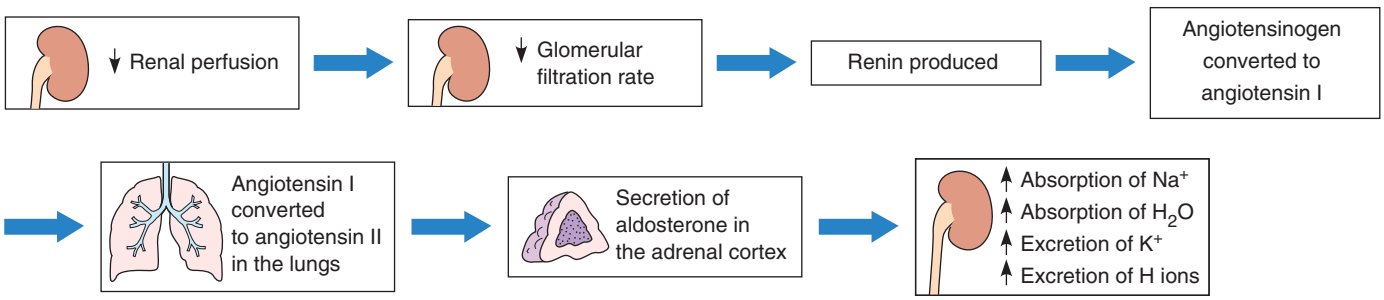

FIGURE 9.9 ■ The renin–angiotensin–aldosterone system. Decreased blood volume and renal perfusion set off a chain of reactions, leading to release of aldosterone from the adrenal cortex. Increased levels of aldosterone regulate serum K^+ and Na^+, blood pressure and water balance through effects on the kidney tubules

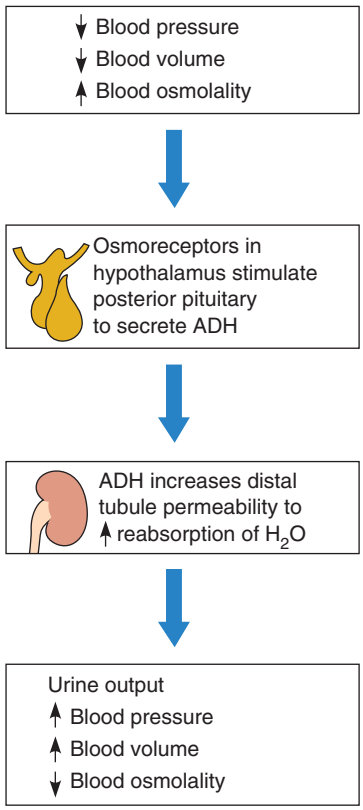

FIGURE 9.10 ■ Antidiuretic hormone (ADH) release and effect. Increased serum osmolality or a fall in blood volume stimulates the release of ADH from the posterior pituitary. ADH increases the permeability of distal tubules, promoting water reabsorption

release is inhibited by ethanol, medications such as phenytoin, as well as increased circulating blood volume and decreased serum osmolality.

Two disorders of ADH production illustrate the effect of ADH on water balance and urine output. First, diabetes insipidus is a condition characterised by deficient ADH production. The lack of ADH causes the distal tubules and collecting ducts of the kidney to be impermeable to water, so little water is reabsorbed into the bloodstream. As a result, copious, very dilute urine is excreted. Water loss leads to increased concentration of the plasma or increased serum osmolality. ADH is not released in response to the serum hyperosmolality, but the thirst mechanism is stimulated and the person drinks additional fluids, maintaining high urine output. In the other condition, the syndrome of inappropriate ADH secretion (SIADH), excess ADH is released. Increased water reabsorption causes increased fluid volume and scant, concentrated urine output. These diseases of the pituitary gland are discussed in Chapter 18.

Atrial natriuretic peptide

Atrial natriuretic peptide (ANP) is a hormone released by atrial muscle cells in response to distension from fluid overload. ANP affects several body systems, including the cardiovascular, renal, neural, gastrointestinal and endocrine systems, but it primarily affects the renin–angiotensin–aldosterone system. ANP opposes this system by inhibiting renin secretion and blocking the secretion and sodium-retaining effects of aldosterone. As a result, ANP promotes sodium wasting and diuresis (increased urine output) and causes vasodilation.

FLUID AND ELECTROLYTE IMBALANCES

THE PERSON WITH FLUID VOLUME DEFICIT

Fluid volume deficit (FVD) is a decrease in intravascular, interstitial and/or intracellular fluid in the body. Fluid volume deficits may be due to excessive fluid losses, insufficient fluid intake, or failure of regulatory mechanisms and fluid shifts within the body. FVD is a relatively common problem that may exist alone or in combination with other electrolyte or acid–base imbalances. The term **dehydration** refers to loss of water alone, even though it often is used interchangeably with fluid volume deficit.

Pathophysiology

The most common cause of fluid volume deficit is excessive loss of gastrointestinal fluids from vomiting, diarrhoea, gastrointestinal suctioning, intestinal fistulas and intestinal drainage. Other causes of fluid losses include excessive renal losses of water and sodium from diuretic therapy, renal disorders or endocrine disorders, inability to swallow fluids, oral trauma, water and sodium losses during sweating from excessive exercise or increased environmental temperature, haemorrhage and chronic abuse of laxatives and/or enemas. Older adults in particular are at risk of fluid volume deficit (see the 'Nursing care of the older adult' box below).

Fluid volume deficit can develop slowly or rapidly, depending on the type of fluid loss. Loss of extracellular fluid volume can lead to *hypovolaemia*, decreased circulating blood volume. Electrolytes often are lost along with fluid, resulting in an *isotonic fluid volume deficit*. When both water and electrolytes are lost, the serum sodium level remains normal, although levels of other electrolytes such as potassium may fall. Fluid is drawn into the vascular compartment from the interstitial spaces as the body attempts to maintain tissue perfusion. This eventually depletes fluid in the intracellular compartment as well.

Hypovolaemia stimulates regulatory mechanisms to maintain circulation. The sympathetic nervous system is stimulated, as is the thirst mechanism. ADH and aldosterone are released, prompting sodium and water retention by the kidneys. Severe fluid loss can lead to cardiovascular collapse.

NURSING CARE OF THE OLDER ADULT Fluid volume deficit

Changes in the normal ageing process affect homeostasis in several ways. In older adults, the percentage of total body water is about 10% lower than in younger or middle-aged adults, and thus they have less body reserve. Lean muscle mass is lower in older adults, and the percentage of body fat is higher; as a result, water accounts for about 50% of the total body weight (TBW) of an older man and about 45% of the TBW of an older woman. Sodium and water regulation become less efficient with ageing. Renal blood flow and glomerular filtration decline with ageing; the kidneys are less able to effectively concentrate the urine and conserve sodium and water. The perception of thirst decreases, interfering with the thirst mechanism. Consequently, the older adult may become dehydrated without being aware of the need to increase fluid intake.

Undetected fever in older adults can increase the total body need for water with every degree of temperature. Dehydration can cause a fever and further compound dehydration in the older adult. Older adults who have self-care deficits, or who are confused, depressed, tube fed, on bed rest or taking medications (such as sedatives, tranquillisers, diuretics and laxatives) are at greatest risk for fluid volume imbalance. Older adults without air-conditioning are at risk during extremely hot weather. In addition, functional changes and illnesses can affect fluid balance. For example, fear of incontinence can lead to self-limiting of fluid intake; physical disabilities associated with age-related illnesses, such as arthritis or stroke, may limit access to fluids; and cognitive impairments can interfere with recognition of thirst and the ability to respond to it.

Manifestations of fluid volume deficit may be more difficult to recognise in the older adult. A change in mental status, memory or attention may be an early manifestation. Skin turgor is less reliable as an indicator of dehydration, although assessing turgor over the sternum or on the inner aspect of the thigh may be more effective. Dry oral mucous membranes, increased tongue furrows, subnormal temperature, tachycardia and a pinched facial expression are also indicative of dehydration. Orthostatic vital signs may not demonstrate typical changes in the dehydrated older adult.

Two other types of fluid volume deficit—hypovolaemic fluid volume deficit and hypertonic fluid volume deficit—are discussed as effects of sodium imbalance in that section of this chapter.

Third spacing

Third spacing is a shift of fluid from the vascular space into an area where it is not available to support normal physiological processes. Fluid may be sequestered in the abdomen or bowel, or in such other actual or potential body spaces as the pleural or peritoneal spaces. Fluid may also become trapped within soft tissues following trauma or burns. The trapped fluid is unavailable to support cardiovascular or renal function; therefore, it represents a volume loss.

Increased vascular permeability or decreased protein levels can trigger third spacing (Longo et al., 2012). Stress hormones released in response to tissue trauma or sepsis (catecholamines in particular) promote redistribution of blood to vital organs (heart and brain). Renal blood flow falls, stimulating the renin–angiotensin–aldosterone system. This promotes sodium and water retention to maintain intravascular volume. The blood vessel and tissue damage caused by surgery stimulates the release of inflammatory mediators such as histamine and prostaglandins. These substances lead to local vasodilation and increased capillary permeability, allowing fluid to accumulate in interstitial tissues.

Assessing the extent of FVD resulting from third spacing is difficult. It may not be reflected by changes in weight or intake-and-output records and it may not become apparent until after organ malfunction occurs (Metheny, 2012). Delays in recognition and treatment can lead to irreversible shock and multiorgan system failure (Perrin, 2012).

Manifestations

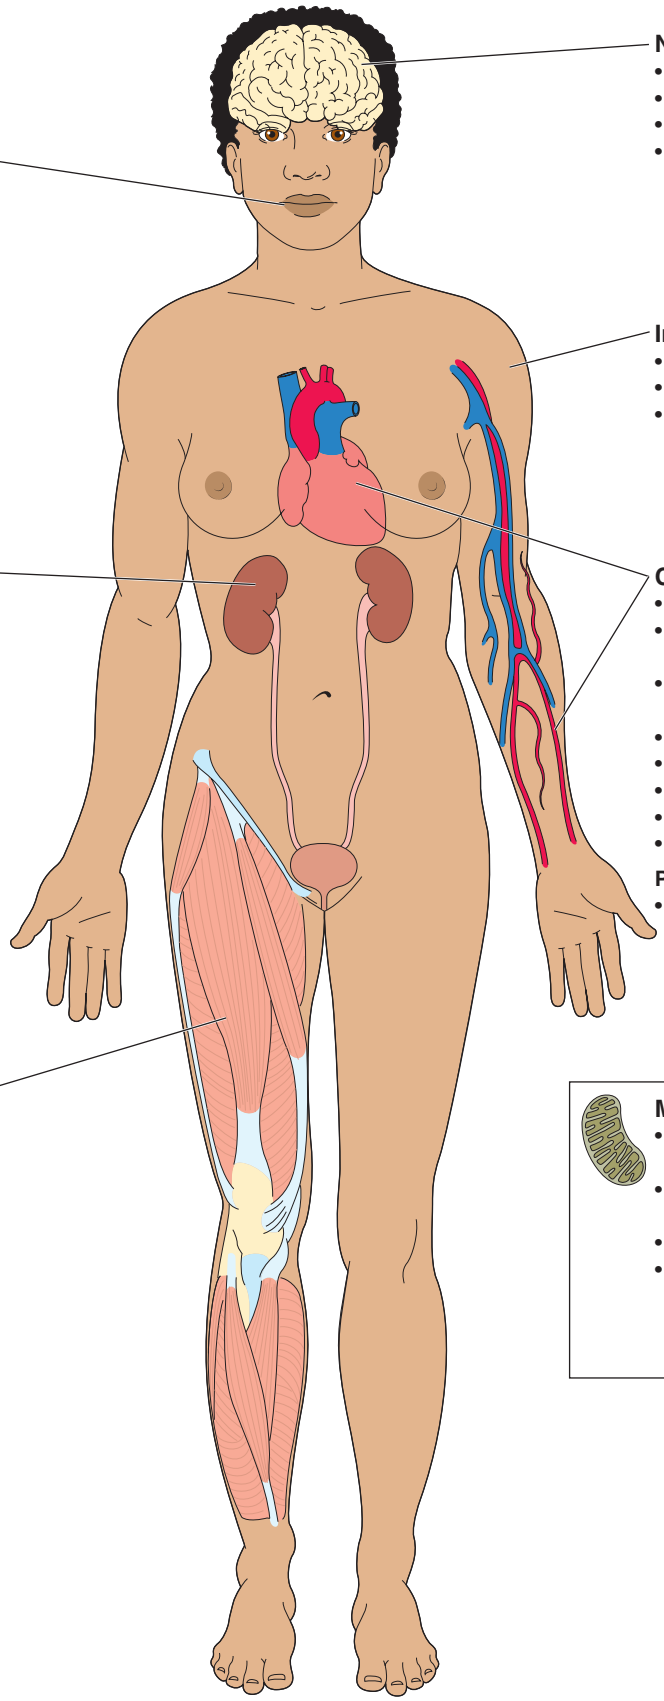
With a rapid fluid loss (such as with haemorrhage or uncontrolled vomiting), manifestations of hypovolaemia develop rapidly. When the loss of fluid occurs more gradually, the person's fluid volume may be very low before symptoms develop. The *multisystem effects of fluid volume deficit* are illustrated on the following page.

Rapid weight loss is a good indicator of fluid volume deficit. Each litre of body fluid weighs about 1 kg. The severity of the fluid volume deficit can be estimated by the percentage of rapid weight loss: a loss of 2% to 5% of total body weight represents a mild FVD; 6% to 9%, moderate FVD; and 10% or greater, severe FVD (Metheny, 2012).

Loss of interstitial fluid causes skin turgor to diminish. When pinched, the skin of a person with FVD remains elevated. Loss of skin elasticity with ageing makes this assessment finding less accurate in older adults. Tongue turgor is not generally affected by age; therefore, assessing the size, dryness and longitudinal furrows of the tongue may be a more accurate indicator of FVD.

Postural or orthostatic hypotension is a sign of hypovolaemia. A drop of more than 15 mmHg in systolic blood pressure when changing from a lying to a standing position often indicates loss of intravascular volume. Venous pressure falls as well, causing flat neck veins, even when the person is recumbent. Loss of intravascular fluid causes the haematocrit to increase. Compensatory mechanisms to conserve water and sodium and maintain circulation account for many of the manifestations of fluid volume deficit, such as tachycardia; pale, cool skin (vasoconstriction); and decreased urine output. The specific gravity of urine increases as water is reabsorbed in the tubules. Table 9.3 compares assessment findings for fluid deficit and fluid excess.

MULTISYSTEM EFFECTS OF FLUID VOLUME DEFICIT (FVD)



Neurological
- Altered mental status
- Anxiety, restlessness
- Diminished alertness/cognition
- Possible coma (severe FVD)

Mucous membranes
- Dry; may be sticky
- ↓ tongue size, longitudinal furrows ↑

Integumentary
- Diminished skin turgor
- Dry skin
- Pale, cool extremities

Urinary
- ↓ urine output
- Oliguria (severe FVD)
- ↑ urine-specific gravity

Cardiovascular
- Tachycardia
- Orthostatic hypotension (moderate FVD)
- Falling systolic/diastolic pressure (severe FVD)
- Flat neck veins
- ↓ venous filling
- ↓ pulse volume
- ↓ capillary refill
- ↑ haematocrit

Potential complication
- Hypovolaemic shock

Musculoskeletal
- Fatigue

Metabolic processes
- ↓ body temperature (isotonic FVD)
- ↑ body temperature (dehydration)
- Thirst
- Weight loss
  - 2–5% mild FVD
  - 6–9% moderate FVD
  - >10% severe FVD

TABLE 9.3 Comparison of assessment findings in a person with fluid imbalance

ASSESSMENT	FLUID DEFICIT	FLUID EXCESS
Blood pressure	Decreased systolic Postural hypotension	Increased
Heart rate	Increased	Increased
Pulse amplitude	Decreased	Increased
Respirations	Normal	Moist crackles Wheezes
Jugular vein	Flat	Distended
Oedema	Rare	Dependent
Skin turgor	Loose, poor turgor	Taut
Output	Low, concentrated	May be low or normal
Urine-specific gravity	High	Low
Weight	Loss	Gain

INTERPROFESSIONAL CARE

The primary goals of care related to fluid volume deficit are to prevent deficits in people at risk and to correct deficits and their underlying causes. Depending on the acuity of the imbalance, treatment may include replacement of fluids and electrolytes by the intravenous, oral or enteral routes. When possible, the oral or enteral route is preferred for administering fluids. In acute situations, however, intravenous fluid administration is necessary.

Diagnosis

Laboratory and diagnostic tests may be ordered when fluid volume deficit is suspected. Such tests measure:

- *Serum electrolytes*. In an isotonic fluid deficit, sodium levels are within normal limits; when the loss is water only, sodium levels are high. Decreases in potassium are common.
- *Serum osmolality*. Measurement of serum osmolality helps to differentiate isotonic fluid loss from water loss. With water loss, osmolality is high; it may be within normal limits with an isotonic fluid loss.
- *Haemoglobin and haematocrit*. The haematocrit often is elevated due to loss of intravascular volume and haemoconcentration.
- *Urine-specific gravity and osmolality*. As the kidneys conserve water, both the specific gravity and osmolality of urine increase.
- *Haemodynamic pressures*. The mean arterial pressure (MAP), *central venous pressure* (CVP), right atrial pressure (RAP) and pulmonary artery wedge pressure (PAWP) are decreased in severe FVD (Perrin, 2012). The technique for measuring CVP is outlined in Box 9.1.

Fluid management

Oral rehydration is the safest and most effective treatment for fluid volume deficit in alert people who are able to take oral fluids. Adults require a minimum of 1500 mL of fluid per day or approximately 30 mL per kg of body weight (ideal body weight is used to calculate fluid requirements for the person who is obese) for maintenance. Fluids are replaced gradually, particularly in older adults, to prevent rapid rehydration of the cells. In general, fluid deficits are replaced at a rate of approximately 30% to 50% of the deficit per 24 hours.

For mild fluid deficits in which the loss of electrolytes has been minimal (e.g. moderate exercise in warm weather), water alone may be used for fluid replacement. When the fluid deficit is more severe and when electrolytes have also been lost (e.g. FVD due to vomiting and/or diarrhoea, strenuous exercise for longer than an hour or two), a carbohydrate/electrolyte solution such as a sports drink, ginger ale or a rehydrating solution is more appropriate. These solutions provide sodium, potassium, chloride and kilojoules to help meet metabolic needs.

INTRAVENOUS THERAPY When the fluid deficit is severe or the person is unable to ingest fluids, the intravenous route is used to administer replacement fluids. Table 9.4 describes the types, tonicity and uses of commonly administered intravenous fluids. Isotonic electrolyte solutions (0.9% NaCl or Ringer's solution) are used to expand plasma volume in a hypotensive person or to replace abnormal losses, which are usually isotonic in nature. Normal saline (0.9% NaCl) tends to remain in the vascular compartment, increasing blood volume. When administered rapidly, however, this solution can precipitate acid–base imbalances, so balanced electrolyte solutions such as lactated Ringer's solution are preferred to expand plasma volume.

Five per cent dextrose in water (D_5W) or 0.45% NaCl (one-half normal saline or 1/2 NS) is given to provide water to treat total body water deficits. D_5W is isotonic (similar in tonicity to the plasma) when administered and thus does not provoke haemolysis of red blood cells. The dextrose is metabolised to carbon dioxide and water, leaving free water available for tissue needs. Hypotonic saline solution (0.45% NaCl with or without added electrolytes) or 5% dextrose in 0.45% sodium chloride (D_5 1/2 NS) are used as maintenance solutions (Metheny, 2012). These solutions provide additional electrolytes such as potassium, a buffer (lactate or acetate) as needed and water. When dextrose is added, they also provide a minimal number of kilojoules.

FLUID CHALLENGE A fluid challenge, the rapid administration of a designated amount of intravenous fluid, may be performed to evaluate fluid volume when urine output is low and cardiac or renal function is questionable. A fluid challenge

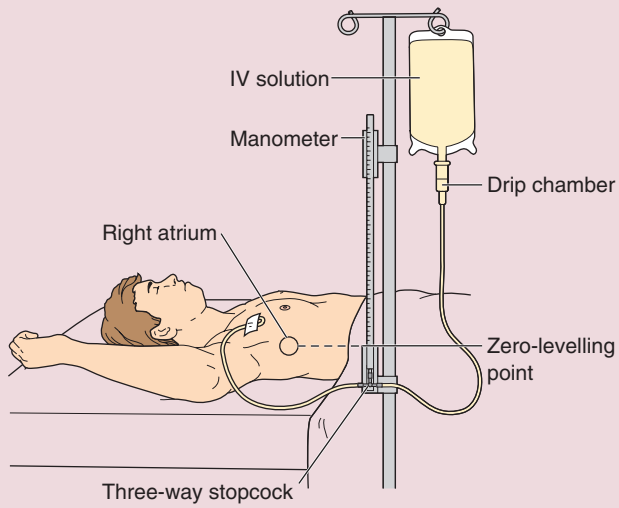
BOX 9.1 Measuring central venous pressure with a manometer

CVP is a haemodynamic monitoring method for evaluating fluid volume status. It measures mean right atrial pressure by means of a catheter. The CVP catheter is inserted by a doctor, most often at the person's bedside, into the antecubital, internal jugular or subclavian vein. Either a haemodynamic monitoring system (see Chapter 29) or a manual system may be used to measure the CVP. Nursing responsibilities in measuring CVP are as follows:

1. Explain to the person and their family what is being done.
2. Prior to the first measurement, take baseline vital signs and measure the level of the right atrium on the person's thorax. This is usually at the fourth intercostal space on the lateral chest wall, midway between the anterior and posterior chest. This site, called the *phlebostatic axis*, is marked and used as the reference point for all measurements.
3. If possible, place the bed in the same position for each reading, usually with the person supine and the head of the bed flat. Elevating the head of the bed to as much as 60 degrees usually does not affect the accuracy of the CVP reading in a person who is haemodynamically stable (Urden, Stacy & Lough, 2009).
4. Use a carpenter's level to check the level of the measuring device to make sure the transducer or the 0 on the manometer is level with the phlebostatic axis (see figure).
5. Remove any air bubbles in the line.
6. If using a manometer, turn the stopcock so that fluid flows into the manometer, filling it a few centimetres above the expected reading. Then turn the stopcock to open the line between the manometer and the person. The fluid level will fall and then reach a point at which it fluctuates with the person's respirations. This point is recorded as the CVP.
7. After the measurement is taken, turn the stopcock so that the fluid can again flow from the fluid source to the person.

Normal values

When CVP is measured using a manometer, normal values range from 2 to 8 cm water. With a haemodynamic monitoring system, the normal CVP range is 2 to 5 mmHg. A low CVP indicates inadequate venous return from fluid deficit and hypovolaemia or due to peripheral vasodilation. A high CVP indicates fluid overload, cardiac problems that decrease cardiac contractility or pulmonary disorders that increase pulmonary vascular resistance.



helps prevent fluid volume overload resulting from intravenous fluid therapy when cardiac or renal function is compromised. Nursing responsibilities for a fluid challenge are as follows:

- Obtain and document baseline vital signs, breath sounds, urine output and mental status.
- Administer (by IV infusion) an initial fluid volume of 200 to 300 mL over 5 to 10 minutes.
- Re-evaluate baseline data at the end of the 5- or 10-minute infusion period.
- Administer additional fluid until a specified volume is infused or the desired haemodynamic parameters are achieved.

Nursing care

Nurses are responsible for identifying if a person is at risk of fluid volume deficit, initiating and carrying out measures to prevent and treat fluid volume deficit, and monitoring the effects of therapy.

Health promotion

Health promotion activities focus on teaching people to prevent fluid volume deficit. Discuss the importance of maintaining adequate fluid intake, particularly when exercising and during hot weather. Advise people to use commercial sports drinks to replace both water and electrolytes when exercising during warm weather. Instruct people to maintain fluid intake when ill, particularly during periods of fever or when diarrhoea is a problem.

Discuss the increased risk of fluid volume deficit with older adults and provide information about prevention. Teach older adults (and their caregivers) that thirst decreases with ageing and urge them to maintain a regular fluid intake of about 1500 mL per day, regardless of perception of thirst.

Carefully monitor a person at risk of abnormal fluid losses through routes such as vomiting, diarrhoea, nasogastric suction, increased urine output, fever or wounds. Monitor fluid intake in a person with a decreased level of consciousness, disorientation, nausea and anorexia, and physical limitations.

Assessment

Collect assessment data through the health history interview and physical examination.

TABLE 9.4 Commonly administered intravenous fluids

	FLUID AND TONICITY	USES
Dextrose in water solutions	5% dextrose in water (D_5W)	Replaces water losses
	Isotonic	Provides free water necessary for cellular rehydration
		Lowers serum sodium in hypernatraemia
	10% dextrose in water ($D_{10}W$)	Provides free water
	Hypertonic	Provides nutrition (supplies 340 kcal/L)
	20% dextrose in water ($D_{20}W$)	Supplies 680 kcal/L
	Hypertonic	May cause diuresis
	50% dextrose in water ($D_{50}W$)	Supplies 1700 kcal/L
	Hypertonic	Used to correct hypoglycaemia
Saline solutions	0.45% sodium chloride	Provides free water to replace hypotonic fluid losses
	Hypotonic	Maintains levels of plasma sodium and chloride
	0.9% sodium chloride	Expands intravascular volume
	Isotonic	Replaces water lost from extracellular fluid
		Used with blood transfusions
		Replaces large sodium losses (as from burns)
	3% sodium chloride	Corrects serious sodium depletion
	Hypertonic	
Combined dextrose and saline solution	5% dextrose and 0.45% sodium chloride	Provides free water
	Isotonic	Provides sodium chloride
		Maintenance fluid of choice if there are no electrolyte imbalances
Multiple electrolyte solutions	Hartmann's solution	Expands the intracellular fluid
	Isotonic (electrolyte concentrations of sodium, potassium, chloride and calcium are similar to plasma levels)	Replaces extracellular fluid losses
	Lactated Ringer's solution Isotonic (similar in composition of electrolytes to plasma but does not contain magnesium)	Replaces fluid losses from burns and the lower gastrointestinal tract Fluid of choice for acute blood loss

- *Health history*: risk factors such as medications, acute or chronic renal or endocrine disease; precipitating factors such as hot weather, extensive exercise, lack of access to fluids, recent illness (especially if accompanied by fever, vomiting and/or diarrhoea); onset and duration of symptoms.
- *Physical assessment*: weight; vital signs including orthostatic blood pressure and pulse; peripheral pulses and capillary refill; jugular neck vein distension; skin colour, temperature, turgor; level of consciousness and mentation; urine output. See Box 9.2 for physical assessment changes in the older adult.
- *Diagnostic tests*: serum osmolality and electrolytes, haemoglobin and haematocrit (expect values to fall with rehydration), urine-specific gravity and osmolality, central venous pressure readings.

BOX 9.2 Assessing older adults: fluid volume deficit

With ageing, the elasticity of skin decreases. As a result, turgor diminishes, even in the well-hydrated older adult. This makes skin turgor less reliable when assessing for fluid volume deficit. In addition, some older adults experience postural hypotension, even when well hydrated. Allow the older adult to stand quietly for a full minute before rechecking blood pressure and pulse when measuring orthostatic vital signs.

Nursing diagnoses and interventions

The focus for nursing diagnoses and interventions for the person with *Fluid volume deficit* is on managing the effects of the deficit and preventing complications.

Deficient fluid volume

A person with a fluid volume deficit due to abnormal losses, inadequate intake or impaired fluid regulation requires close monitoring as well as immediate and ongoing fluid replacement.

- Assess intake and output accurately, monitoring fluid balance. In acute situations, hourly intake and output may be indicated. *Urine output should be 30 to 60 mL per hour (unless renal failure is present). Urine output of less than 30 mL per hour indicates inadequate renal perfusion and an increased risk of acute renal failure and inadequate tissue perfusion* (Perrin, 2012).

CONSIDERATION FOR PRACTICE

Report a urine output of less than 30 mL per hour to the attending doctor.

- Assess vital signs, CVP and peripheral pulse volume at least every 4 hours. *Hypotension, tachycardia, low CVP and weak, easily obliterated peripheral pulses indicate hypovolaemia.*
- Weigh daily under standard conditions (time of day, clothing and scale). *In most instances (except third spacing), changes in weight accurately reflect fluid balance.* (See the 'Translation to practice' box below.)
- Administer and monitor the intake of oral fluids as prescribed. Identify beverage preferences and provide these on a schedule. *Oral fluid replacement is preferred when the person is able to drink and retain fluids.*
- Administer IV as prescribed using an electronic infusion pump. Monitor for indicators of fluid overload if rapid fluid replacement is ordered: dyspnoea, tachypnoea, tachycardia, increased CVP, jugular vein distension and oedema. *Rapid fluid replacement may lead to hypervolaemia, resulting in pulmonary oedema and cardiac failure, particularly in the person with compromised cardiac and renal function.*
- Monitor laboratory values: electrolytes, serum osmolality and haematocrit. *Rehydration may lead to changes in serum electrolytes, osmolality and haematocrit. In some cases, electrolyte replacement may be necessary during rehydration.*

Ineffective tissue perfusion

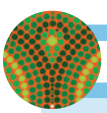
A fluid volume deficit can lead to decreased perfusion of renal, cerebral and peripheral tissues. Inadequate renal perfusion can lead to acute renal failure. Decreased cerebral perfusion leads to changes in mental status and cognitive function, causing restlessness, anxiety, agitation, excitability, confusion, vertigo, fainting and weakness.

- Monitor for changes in level of consciousness and mental status. *Restlessness, anxiety, confusion and agitation may indicate inadequate cerebral blood flow and circulatory collapse.*
- Monitor serum urea and creatinine and cardiac enzymes, reporting elevated levels to the physician. *Elevated levels may indicate impaired renal function or cardiac perfusion related to circulatory failure.*
- Turn at least every 2 hours. Provide good skin care and monitor for evidence of skin or tissue breakdown. *Impaired circulation to peripheral tissues increases the risk of skin breakdown. Turn frequently to relieve pressure over bony prominences. Keep skin clean, dry and moisturised to help maintain integrity.*

Risk of injury

The person with fluid volume deficit is at risk of injury because of dizziness and loss of balance resulting from decreased cerebral perfusion secondary to hypovolaemia.

- Institute safety precautions, including keeping the bed in a low position, using side rails as needed, and slowly raising



TRANSLATION TO PRACTICE Evidence-based practice for determining fluid needs for the person in long-term care

Residents of long-term care facilities are at significant risk of developing fluid volume deficit. Most are elderly, many have some degree of dementia, and a significant number are dependent on caregivers to provide fluids. Dehydration, when it occurs, can be a sentinel health event leading to serious and potentially life-threatening secondary problems (Gaspar, 2011).

Various standards for determining the amount of fluid a resident requires have been developed. These standards vary in complexity from a simple 30 mL fluid per kilogram of body weight to a formula that uses body surface area to determine fluid needs. A retrospective study by Gaspar (2011) compared four different formulas, ultimately recommending a formula based on the height and weight of the resident to determine fluid intake.

IMPLICATIONS FOR NURSING

As noted at the beginning of this chapter, the percentage of total body water varies with age and the amount of lean body tissue to adipose tissue. Likewise, fluid requirements of residents in long-term care facilities vary, necessitating attention to the needs of the individual. Furthermore, caregivers are more likely to attend to an individualised plan for a resident's fluid intake than to a generalised recommendation to 'push fluids'. This plan should include not only the target amount of daily fluid intake but also residents' preferences for the type, temperature and timing of fluid intake.

CRITICAL THINKING IN PERSON-CENTRED CARE

1. Why are older adults more vulnerable to dehydration and fluid volume deficit than younger adults?
2. Identify factors in long-term care settings that increase the risk for fluid volume deficit. Consider the setting, residents and caregivers.
3. Develop a teaching plan about resident fluid intake for caregivers in a long-term care facility.

the person from supine to sitting or sitting to standing position. Using safety precautions and allowing time for the blood pressure to adjust to position changes will reduce the risk of injury.

- Teach the person and their family members how to reduce orthostatic hypotension:
  a. Move from one position to another in stages; for example, raise the head of the bed before sitting up, and sit for a few minutes before standing.
  b. Avoid prolonged standing.
  c. Rest in a recliner rather than in bed during the day.
  d. Use assistive devices to pick up objects from the floor, rather than stooping.

Teaching measures to reduce orthostatic hypotension reduces the person's risk of injury. Prolonged bed rest increases skeletal muscle weakness and decreases venous tone, contributing to postural hypotension. Prolonged standing allows blood to pool in the legs, reducing venous return and cardiac output.

Community-based care

Depending on the severity of the fluid volume deficit, the person may be managed in the home or residential facility or may be admitted to an acute care facility. Assess the person's understanding of the cause of the deficit and the fluids necessary for providing replacement. Address the following topics when preparing the person and their family for home care:

- The importance of maintaining adequate fluid intake (at least 1500 mL per day; more if extra fluid is being lost through perspiration, fever or diarrhoea).
- Manifestations of fluid imbalance and how to monitor fluid balance.
- How to prevent fluid deficit:
  - Avoid exercising during extreme heat.
  - Increase fluid intake during hot weather.
  - If vomiting, take small frequent amounts of ice chips or clear liquids, such as weak tea, flat cola or ginger ale.
  - Reduce intake of coffee, tea and alcohol, which increase urine output and can cause fluid loss.
- Replacement of fluids lost through diarrhoea with fruit juices or bouillon, rather than large amounts of tap water.
- Alternative sources of fluid (such as gelatin, frozen juices or ice-cream) for effective replacement of lost fluids.

FLUID VOLUME EXCESS

Fluid volume excess (FVE) results when both water and sodium are retained in the body. Fluid volume excess may be caused by fluid overload (excess water and sodium intake) or by impairment of the mechanisms that maintain homeostasis. The excess fluid can lead to excess intravascular fluid (hypervolaemia) and excess interstitial fluid (**oedema**).

Pathophysiology

Fluid volume excess usually results from conditions that cause retention of both sodium and water. These conditions include heart failure, cirrhosis of the liver, renal failure, adrenal gland disorders, corticosteroid administration and stress conditions causing the release of ADH and aldosterone. Other causes include an excessive intake of sodium-containing foods, drugs that cause sodium retention and the administration of excess amounts of sodium-containing intravenous fluids (such as 0.9% NaCl or Ringer's solution). This *iatrogenic* (induced by the effects of treatment) cause of fluid volume excess primarily affects a person with impaired regulatory mechanisms.

In fluid volume excess, both water and sodium are gained in about the same proportions as normally exists in extracellular fluid. The total body sodium content is increased, which in turn causes an increase in total body water. Because the increase in sodium and water is isotonic, the serum sodium and osmolality remain normal and the excess fluid remains in the extracellular space.

Stress responses activated before, during and immediately after surgery commonly lead to increased ADH and aldosterone levels, leading to sodium and water retention. In the immediate postoperative period, however, this additional fluid tends to be sequestered in interstitial tissues and is unavailable to support cardiovascular and renal function (see the 'Third spacing' section earlier in this chapter.) This sequestered fluid is reabsorbed into the circulation within about 48 to 72 hours after surgery. Although it is then normally eliminated through a process of diuresis, a person with heart or kidney failure is at risk of developing fluid overload.

Manifestations and complications

Excess extracellular fluid leads to hypervolaemia and circulatory overload. Excess fluid in the interstitial space causes peripheral or generalised oedema. Manifestations of fluid volume excess with related pathophysiology are described in Table 9.5.

Heart failure is not only a potential cause of fluid volume excess, but also a potential complication of the condition if the heart is unable to increase its workload to handle the excess blood volume. Severe fluid overload and heart failure can lead to pulmonary oedema, a medical emergency. See Chapter 30 for more information about heart failure and pulmonary oedema.

INTERPROFESSIONAL CARE

Managing fluid volume excess focuses on prevention in a person at risk, treating its manifestations and correcting the underlying cause. Management includes limiting sodium and water intake and administering diuretics.

Diagnosis

The following laboratory tests may be ordered.

- *Serum electrolytes* and *serum osmolality* are measured. Serum sodium and osmolality usually remain within normal limits.
- *Serum haematocrit* and *haemoglobin* often are decreased due to plasma dilution from excess extracellular fluid.

TABLE 9.5 Manifestations of fluid volume excess

MANIFESTATIONS	RELATED PATHOPHYSIOLOGY
Peripheral oedema, or if severe, **anasarca** (severe, generalised oedema)	Excess fluid in the interstitial spaces, usually resulting from conditions that cause retention of both sodium and water (e.g. heart failure, renal failure and stress responses causing the release of ADH and aldosterone, such as surgery)
Full bounding pulse, distended neck and peripheral veins, increased central venous and right atrial pressures, cough, **dyspnoea** (laboured or difficult breathing), **orthopnoea** (difficult breathing when supine)	Circulatory overload from increased water and sodium retention
Dyspnoea at rest	Mobilisation (reabsorption) of fluid from peripheral tissues increases circulatory fluid volume
Tachycardia and hypertension	Increased circulatory fluid volume
Reduced oxygen saturation	As fluid increases in the interstitial spaces and alveoli, gas exchange is impaired, leading to hypoxia and hypercapnia
Moist crackles on auscultation of the lungs, pulmonary oedema	Excess fluid in pulmonary interstitial spaces and alveoli
Increased urine output (**polyuria**)	Increased circulatory volume and increased perfusion of the renal arteries increases amount of filtrate produced in glomerulus
Ascites (excess fluid in the peritoneal cavity)	Increased filtration pressure due to hypervolaemia
Decreased haematocrit and BUN	Dilutional effect of increased circulatory volume
Altered mental status and anxiety	Pressure on the cerebral cortex from cerebral hypertension and oedema causes decreased oxygenation (hypoxia) of neurons
Pulmonary oedema	Elevation of left-sided filling pressures from increased circulatory volume and heart failure increase pressures in pulmonary vascular system

- Additional tests of *renal* and *liver function* (such as serum urea and creatinine and liver enzymes) may be ordered to help determine the cause of fluid volume excess if it is unclear.

Medications

Diuretics are commonly used to treat fluid volume excess. They inhibit sodium and water reabsorption, increasing urine output. The three major classes of diuretics, each of which acts on a different part of the kidney tubule, are as follows:

1. Loop diuretics act in the ascending loop of Henle.
2. Thiazide-type diuretics act on the distal convoluted tubule.
3. Potassium-sparing diuretics affect the distal nephron.

The nursing implications for diuretics are outlined in the 'Medication administration' box below.

Treatments

FLUID MANAGEMENT Fluid intake may be restricted in a person who has fluid volume excess. The amount of fluid allowed per day is prescribed by the primary attending doctor. All fluid intake must be calculated, including meals and that used to administer medications orally or intravenously. Box 9.3 provides guidelines for a person with a fluid restriction.

DIETARY MANAGEMENT Because sodium retention is a primary cause of fluid volume excess, a sodium-restricted diet is often prescribed. This is particularly important for people with a history of heart or renal failure (Baraz et al., 2010; Son et al., 2011). Australian adults typically consume 2.5 to 3 g of sodium every day; recommended sodium intake is 500 to 2300 mg per day (Food Standards Australia New Zealand, 2015). The primary dietary sources of sodium are the salt shaker, processed foods and foods themselves (see Box 9.4).

A mild sodium restriction can be achieved by instructing the person and primary food preparer in the household to reduce the amount of salt in recipes by half, avoid using the salt shaker during meals and avoid foods that contain high levels of sodium (either naturally or because of processing).

BOX 9.3 Fluid restriction guidelines

- Subtract requisite fluids (e.g. ordered IV fluids, fluid used to dilute IV medications) from total daily allowance.
- Divide remaining fluid allowance:
  - day shift: 50% of total
  - evening shift: 25% to 33% of total
  - night shift: remainder.
- Explain the fluid restriction to the person and family members.
- Identify preferred fluids and intake pattern.
- Place allowed amounts of fluid in small glasses (gives perception of a full glass).
- Offer ice chips (when melted, ice chips are approximately half the frozen volume).
- Provide frequent mouth care.
- Provide sugarless chewing gum (if allowed) to reduce thirst sensation.

MEDICATION ADMINISTRATION Diuretics for fluid volume excess

Diuretics increase urinary excretion of water and sodium. They are categorised into three major groups: loop diuretics, thiazide and thiazide-like diuretics, and potassium-sparing diuretics. Diuretics are used to enhance renal function and to treat vascular fluid overload and oedema. Common side effects include orthostatic hypotension, dehydration, electrolyte imbalance and possible hyperglycaemia. Diuretics should be used with caution in the older adult. Examples of each major type follow.

LOOP DIURETICS

Frusemide (Lasix)
Ethacrynic acid
Bumetanide

Loop diuretics inhibit sodium and chloride reabsorption in the ascending loop of Henle. (See Chapter 27 for the anatomy of the kidneys.) As a result, loop diuretics promote the excretion of sodium, chloride, potassium and water.

THIAZIDE AND THIAZIDE-LIKE DIURETICS

Bendroflumethiazide
Chlorothiazide
Hydrochlorothiazide
Chlorthalidone
Indapamide

Thiazide and thiazide-like diuretics promote the excretion of sodium, chloride, potassium and water by decreasing absorption in the distal tubule.

POTASSIUM-SPARING DIURETICS

Spironolactone (Aldactone)
Amiloride HCl (Midamor)

Potassium-sparing diuretics promote excretion of sodium and water by inhibiting sodium–potassium exchange in the distal tubule.

HEALTH EDUCATION FOR THE PERSON AND THEIR FAMILY

- The drugs will increase the amount and frequency of urination.
- The drugs must be taken even when you feel well.
- Take the drugs in the morning and afternoon to avoid having to get up at night to urinate.
- Change position slowly to avoid dizziness.
- Report the following to your attending doctor: dizziness; trouble breathing; or swelling of face, hands or feet.
- Weigh yourself every day and report sudden gains or losses.
- Avoid using the salt shaker when eating.
- If the drug increases potassium loss, eat foods high in potassium, such as orange juice and bananas.
- Do not use salt substitutes if you are taking a potassium-sparing diuretic.

BOX 9.4 Foods high in sodium

Processed meat and fish
- Bacon
- Sausage
- Luncheon meat and other cold cuts
- Smoked fish

Selected dairy products
- Buttermilk
- Cottage cheese
- Cheeses
- Ice-cream

Processed grains
- Cracker biscuits
- Most dry cereals

Most canned goods
- Meats
- Vegetables
- Soups

Snack foods
- Salted popcorn
- Nuts
- Potato chips/pretzels
- Gelatin desserts

Condiments and food additives
- Barbecue sauce
- Saccharin
- Pickles
- Chilli sauce
- Soy sauce
- Meat tenderisers
- Salted margarine
- Worcestershire sauce
- Salad dressings

Naturally high in sodium
- Brains
- Oysters
- Kidneys
- Prawns
- Dried fruit
- Crab
- Spinach
- Lobster
- Carrots

In moderate and severely sodium-restricted diets, salt is avoided altogether, as are all foods containing significant amounts of sodium.

Nursing care

Nursing care focuses on preventing fluid volume excess in a person at risk and on managing problems resulting from its effects. See 'Nursing care plan: A person with fluid volume excess' below.

Health promotion

Health promotion related to fluid volume excess focuses on teaching preventive measures to a person who are at risk (e.g. people who have heart or kidney failure). Discuss the relationship between sodium intake and water retention. Provide guidelines for a low-sodium diet and teach the person to carefully read food labels to identify 'hidden' sodium, particularly in processed foods. Instruct the person at risk to weigh themselves on a regular basis, using the same scales, and to notify their primary attending doctor if they gain more than 2 kg in a week or less. Carefully monitor the person receiving intravenous fluids for signs of hypervolaemia. Reduce the flow rate and promptly report manifestations of fluid overload to the physician.

NURSING CARE PLAN A person with fluid volume excess

Dorothy Smith is a 45-year-old Aboriginal woman hospitalised with acute renal failure that developed as a result of acute glomerulonephritis. She is expected to recover, but she has very little urine output. Ms Smith is a single mother of two teenage sons. Until her illness, she was active in caring for her family, her career as a primary school teacher's aide and community activities.

ASSESSMENT

Mike Penning, Ms Smith's nurse, notes that she is in the oliguric phase of acute renal failure and that her urine output for the previous 24 hours is 250 mL; this low output has been constant for the past 8 days. She gained 0.45 kg in the past 24 hours. Laboratory test results from that morning are sodium, 155 mEq/L (normal 135 to 145 mEq/L); potassium, 5.3 mEq/L (normal 3.5 to 5.0 mEq/L); calcium, 7.6 mg/dL (normal 8.0 to 10.5 mg/dL) and urine-specific gravity 1.008 (normal 1.010 to 1.030). Ms Smith's serum creatinine and urea are high; however, her ABGs are within normal limits.

In his assessment of Ms Smith, Mike notes the following:

- BP 160/92; P 102, with obvious neck vein distension; R 28, with crackles and wheezes; head of bed elevated 30 degrees; T 37.0°C.
- Periorbital and sacral oedema present; 3+ pitting bilateral pedal oedema; skin cool, pale and shiny.
- Alert, oriented; responds appropriately to questions.
- States she is thirsty, slightly nauseated and extremely tired.

Ms Smith is receiving intravenous frusemide and is on a 24-hour fluid restriction of 500 mL plus the previous day's urine output to manage her fluid volume excess.

DIAGNOSES

- *Excess fluid volume* related to acute renal failure
- *Risk of impaired skin integrity* related to fluid retention and oedema
- *Risk of impaired gas exchange* related to pulmonary congestion
- *Activity intolerance* related to fluid volume excess, fatigue and weakness

PLANNING

- Advise the person that they need to be weighed twice daily, at 0600 and 1800 hours to monitor fluid balance daily.
- Explain to the person that the nurses will be monitoring vital signs and SaO_2 every 4 hours and the reasons for monitoring vital signs.
- Explain the purpose for the person being placed on restricted fluids and suggested ways to maintain the fluid restriction.
- Explain to the person that all fluids consumed and all urine output will need to be measured and documented on a fluid balance chart.
- Instruct and educate the person on the importance of oral hygiene and the effectiveness of moistened oral applicators to prevent mouth dryness.
- Advise the person of the importance to sit out of bed on a chair three times a day and of the necessity to call for assistance when ambulating or if dyspnoea is increasing.
- Explain the importance of keeping the head of the bed elevated 30 to 40 degrees and the importance of not staying in one position for a prolonged period of time.
- Attend to pressure area care as required to maintain skin integrity.

Expected outcomes

- Regain fluid balance, as evidenced by weight loss, decreasing oedema and normal vital signs.
- Experience decreased dyspnoea.
- Maintain intact skin and mucous membranes.
- Increase activity levels as prescribed.

IMPLEMENTATION

- Weigh the person at 0600 and 1800 daily and record the findings.
- Document and review the vital signs, fluid balance chart 4 hourly.
- Obtain, measure and document urine-specific gravity every 8 hours.
- Discuss and consult with the person about her compliance with the prescribed fluid restriction.
- Consult with the person about her ability to move and inspect her skin for any signs of pressure areas.
- Consult with the person and identify her ability to maintain oral hygiene. Provide extra assistance if required to maintain oral care every 2 to 4 hours.
- Consult with the person and identify if the elevation of the head of bed is reducing the dyspnoea.
- Observe and monitor the person's ability to sit out of bed and ambulate safely without increasing shortness of breath and fatigue.

EVALUATION

At the end of the shift, Mike evaluates the effectiveness of the plan of care and continues all diagnoses and interventions. Ms Smith has gained no weight and her urinary output during this shift is 170 mL. Her urine-specific gravity remains at 1.008. Her vital signs are unchanged, but her crackles and wheezes have decreased slightly. Her skin and mucous membranes are intact. Ms Smith tolerated the bedside chair without dyspnoea or fatigue.

CRITICAL THINKING IN THE NURSING PROCESS

1. What is the pathophysiological basis for Ms Smith's increased respiratory rate, blood pressure and pulse?
2. Explain how elevating the head of the bed 30 to 40 degrees facilitates respirations.
3. Suppose Ms Smith says, 'I would really like to have all my fluids at once instead of spreading them out.' How would you reply and why?
4. Outline a plan for teaching Ms Smith about diuretics.

REFLECTION ON THE NURSING PROCESS

1. As the Registered Nurse, how do you know if the education pertaining to fluid restriction has been effective?
2. Outline what you have learned from this case study that you will apply to your future practice.

Assessment

Collect assessment data through the health history interview and physical examination.

- *Health history*: risk factors such as medications, heart failure, acute or chronic renal or endocrine disease; precipitating factors such as a recent illness, change in diet or change in medications; recent weight gain; complaints of persistent cough, shortness of breath, swelling of feet and ankles, or difficulty sleeping when lying down.
- *Physical assessment*: weight; vital signs; peripheral pulses and capillary refill; jugular neck vein distension; oedema; lung sounds (crackles or wheezes), dyspnoea, cough and sputum; urine output; mental status.
- *Diagnostic tests*: monitor serum electrolytes and osmolality, haemoglobin and haematocrit, urine-specific gravity.

Nursing diagnoses and interventions

Nursing diagnoses and interventions for the person with fluid volume excess focus on the multisystem effects of the fluid overload.

Excess fluid volume

Nursing care for the person with excess fluid volume includes collaborative interventions such as administering diuretics and maintaining a fluid restriction, as well as monitoring the status and effects of the excess fluid volume. This is particularly critical in older adults because of the age-related decline in cardiac and renal compensatory responses.

- Assess vital signs, heart sounds, CVP and volume of peripheral arteries. *Hypervolaemia can cause hypertension, bounding peripheral pulses, a third heart sound (S_3) due to the volume of blood flow through the heart and high CVP readings.*
- Assess for the presence and extent of oedema, particularly in the lower extremities, the back, and sacral and periorbital areas. *Initially, oedema affects the dependent portions of the body—the lower extremities of the ambulatory person and the sacrum of the bedridden person. Periorbital oedema indicates more generalised oedema.*

CONSIDERATION FOR PRACTICE

Assess urine output hourly. Maintain accurate intake and output records. Note urine output of less than 30 mL per hour or a positive fluid balance on 24-hour total intake and output calculations. Heart failure and inadequate renal perfusion may result in decreased urine output and fluid retention.

- Obtain daily weights at the same time of day, using approximately the same clothing and balanced scales. *Daily weights are one of the most important gauges of fluid balance. Acute weight gain or loss represents fluid gain or loss. Weight gain of 2 kg is equivalent to 2 L of fluid gain.*
- Administer oral fluids cautiously, adhering to any prescribed fluid restriction. Discuss the restriction with the person and significant others, including the total volume allowed, the rationale, and the importance of reporting all fluid taken. *All sources of fluid intake, including ice chips, are recorded to avoid excess fluid intake.*
- Provide oral hygiene at least every 2 hours. *Oral hygiene contributes to the comfort of the person and keeps mucous membranes intact; it also helps to relieve thirst if fluids are restricted.*
- Teach the person and significant others about the sodium-restricted diet and emphasise the importance of checking before bringing foods to the person on this diet. *Excess sodium promotes water retention; a sodium-restricted diet is ordered to reduce water gain.*
- Administer prescribed diuretics as ordered, monitoring the person's response to therapy. *Loop or high-ceiling diuretics such as frusemide can lead to rapid fluid loss and signs of hypovolaemia and electrolyte imbalance.*
- Promptly report significant changes in serum electrolytes or osmolality or abnormal results of tests done to determine contributing factors to the fluid volume excess. *Gradual correction of serum electrolytes and osmolality is expected; however, aggressive diuretic therapy can lead to over-correction.*

Risk of impaired skin integrity

Tissue oedema decreases oxygen and nutrient delivery to the skin and subcutaneous tissues, increasing the risk of injury.

- Frequently assess skin, particularly in pressure areas and over bony prominences. *Skin breakdown can progress rapidly when circulation is impaired.*
- Reposition the person at least every 2 hours. Provide skin care with each position change. *Frequent position changes minimise tissue pressure and promote blood flow to tissues.*
- Provide an egg-crate mattress or alternating pressure mattress, foot cradle, heel protectors and other devices to reduce pressure on tissues. *These devices, which distribute pressure away from bony prominences, reduce the risk of skin breakdown.*

Risk of impaired gas exchange

With fluid volume excess, gas exchange may be impaired by oedema of pulmonary interstitial tissues. Acute pulmonary oedema is a serious and potentially life-threatening complication of pulmonary congestion.

- Auscultate lungs for presence or worsening of crackles and wheezes; auscultate heart for extra heart sounds. *Crackles and wheezes indicate pulmonary congestion and oedema. A gallop rhythm (S_3) may indicate diastolic overloading of the ventricles secondary to fluid volume excess.*
- Place in Fowler's position if dyspnoea or orthopnoea is present. *Fowler's position improves lung expansion by decreasing the pressure of abdominal contents on the diaphragm.*
- Monitor oxygen saturation levels and **arterial blood gases (ABGs)** for evidence of impaired gas exchange ($SaO_2 < 92\%$ to 95%; $PaO_2 < 80$ mmHg). Administer oxygen as indicated. *Oedema of interstitial lung tissues can interfere with gas exchange and delivery to body tissues. Supplemental oxygen promotes gas exchange across the alveolar–capillary membrane, improving tissue oxygenation.*

Community-based care

Teaching for home care focuses on managing the underlying cause of fluid volume excess and preventing future episodes of excess fluid volume. Address the following topics when preparing the person and the family for home care:

- Signs and symptoms of excess fluid and when to contact the attending doctor.
- Prescribed medications: when and how to take, intended and adverse effects, what to report to attending doctor.
- Recommended or prescribed diet; ways to reduce sodium intake; how to read food labels for salt and sodium content; use of salt substitutes, if allowed.
- If restricted, the amount and type of fluids to take each day; how to balance intake over 24 hours.
- Monitoring weight; changes reported to attending doctor.
- Ways to decrease dependent oedema:
  a. Change position frequently.
  b. Avoid restrictive clothing.
  c. Avoid crossing the legs when sitting.
  d. Wear support stockings or hose.
  e. Elevate feet and legs when sitting.
- How to protect oedematous skin from injury:
  a. Do not walk barefoot.
  b. Buy good-fitting shoes; shop in the afternoon when feet are more likely to be swollen.
- Using additional pillows or a recliner to sleep, to relieve orthopnoea.

BOX 9.5 Teaching people to reduce sodium intake

- Reducing sodium intake will help the body excrete excess sodium and water.
- The body needs less than one-tenth of a teaspoon of salt per day.
- Approximately one-third of sodium intake comes from salt added to foods during cooking and at the table; one-quarter to one-third comes from processed foods; and the rest comes from food and water naturally high in sodium.
- Sodium compounds are used in foods as preservatives, leavening agents and flavour enhancers.
- Many non-prescription drugs (such as analgesics, cough medicine, laxatives and antacids), as well as toothpastes and mouthwashes, contain high amounts of sodium.
- Low-sodium salt substitutes are not really sodium-free and may contain half as much sodium as regular salt.
- Use salt substitutes sparingly; larger amounts often taste bitter instead of salty.
- The preference for salt will eventually diminish.
- Salt, monosodium glutamate, baking soda and baking powder contain substantial amounts of sodium.
- Read labels.
- In place of salt or salt substitutes, use herbs, spices, lemon juice, vinegar and wine as flavouring when cooking.

SODIUM IMBALANCE

Sodium is the most plentiful electrolyte in ECF, with normal serum sodium levels ranging from 135 to 145 mEq/L. Sodium is the primary regulator of the volume, osmolality and distribution of ECF. It is also important for maintaining neuromuscular activity. Because of the close interrelationship between sodium and water balance, disorders of fluid volume and sodium balance often occur together. Sodium imbalances affect the osmolality of ECF and water distribution between the fluid compartments. When sodium levels are low (hyponatraemia), water is drawn into the cells of the body, causing them to swell. In contrast, high levels of sodium in ECF (hypernatraemia) draw water out of body cells, causing them to shrink. See Box 9.5 for information on teaching the person to help reduce sodium intake.

Overview of normal sodium balance

Most of the body's sodium comes from dietary intake. Other sources of sodium include prescription drugs and certain self-prescribed remedies. Sodium is primarily excreted by the kidneys. A small amount is excreted through the skin and the gastrointestinal (GI) tract.

The kidney is the primary regulator of sodium balance in the body. The kidney excretes or conserves sodium in response to changes in vascular volume. A fall in blood volume prompts several mechanisms that lead to sodium and water retention:

- The renin–angiotensin–aldosterone system (see Figure 9.9) is stimulated. Angiotensin II prompts the renal tubules to reabsorb sodium. It also causes vasoconstriction, slowing blood flow through the kidney and reducing glomerular filtration. This further reduces the amount of sodium excreted. Angiotensin II promotes the release of aldosterone from the adrenal cortex. In the presence of aldosterone, more sodium is reabsorbed in the cortical collecting tubules of the kidney and more potassium is eliminated in the urine.
- ADH is released from the posterior pituitary (see Figure 9.10). ADH promotes sodium and water reabsorption in the distal tubules of the kidney, reducing urine output and expanding blood volume.

By contrast, when blood volume expands, sodium and water elimination by the kidneys increases.

- The **glomerular filtration rate** (the rate at which plasma is filtered through the glomeruli of the kidney) increases, allowing more water and sodium to be filtered and excreted.
- ANP is released by cells in the atria of the heart. ANP increases sodium excretion by the kidneys.
- ADH release from the pituitary gland is inhibited. In the absence of ADH, the distal tubule is relatively impermeable to water and sodium, allowing more to be excreted in the urine. Table 9.6 summarises the causes and effects of sodium imbalances.

TABLE 9.6 Causes and manifestations of sodium imbalances

IMBALANCE	POSSIBLE CAUSES	MANIFESTATIONS
Hyponatraemia Serum sodium < 135 mEq/L Critical value < 120 mEq/L *Other lab values* Serum osmolality < 280 mOsm/kg Critical value < 250 mOsm/kg	• Excess sodium loss through kidneys, GI tract or skin • Water gains related to renal disease, heart failure or cirrhosis of the liver • SIADH • Excessive hypotonic IV fluids	• Anorexia, nausea, vomiting, abdominal cramping and diarrhoea • Headache • Altered mental status • Muscle cramps, weakness and tremors • Seizures and coma
Hypernatraemia Serum sodium > 145 mEq/L Critical value > 160 mEq/L *Other lab values* Serum osmolality > 295 mOsm/kg Critical value > 325 mOsm/kg	• Altered thirst • Inability to respond to thirst sensation or obtain water • Profuse sweating • Diarrhoea • Diabetes insipidus • Oral electrolyte solutions or hyperosmolar tube-feeding formulas • Excess IV fluids such as normal saline, 3% or 5% sodium chloride or sodium bicarbonate	• Thirst • Increased temperature • Dry, sticky mucous membranes • Restlessness • Weakness • Altered mental status • Decreasing level of consciousness • Muscle twitching • Seizures

The person with hyponatraemia

Hyponatraemia is a serum sodium level of less than 135 mEq/L. Hyponatraemia usually results from a loss of sodium from the body, but it may also be caused by water gains that dilute ECF.

Pathophysiology

Excess sodium loss can occur through the kidneys, GI tract or skin. Diuretic medications, kidney diseases or adrenal insufficiency with impaired aldosterone and cortisol production can lead to excessive sodium excretion in urine. Vomiting, diarrhoea and gastrointestinal suction are common causes of excess sodium loss through the GI tract. Neurological conditions such as stroke, cerebral haemorrhage, trauma or surgery can cause cerebral salt wasting (Tocco, 2010). Sodium may also be lost when gastrointestinal tubes are irrigated with water instead of saline or when repeated tap-water enemas are administered (Porth & Matfin, 2009). Excessive sweating or loss of skin surface (as with an extensive burn) can also cause excessive sodium loss.

Water gains that can lead to hyponatraemia may occur with:

- systemic diseases such as heart failure, renal failure or cirrhosis of the liver
- syndrome of inappropriate secretion of antidiuretic hormone (SIADH), in which water excretion is impaired
- excessive administration of hypotonic intravenous fluids.

Hyponatraemia causes a drop in serum osmolality. Water shifts from ECF into the intracellular space, causing cells to swell and reducing the osmolality of intracellular fluid. Many of the manifestations of hyponatraemia can be attributed to cellular oedema and hypo-osmolality.

Manifestations

The manifestations of hyponatraemia depend on the rapidity of onset, the severity and the cause of the imbalance. If the condition develops slowly, manifestations are usually not experienced until the serum sodium levels reach 125 mEq/L. In addition, the manifestations of hyponatraemia vary depending on extracellular fluid volume. Early manifestations of hyponatraemia include muscle cramps, weakness and fatigue from its effects on muscle cells. Gastrointestinal function is affected, causing anorexia, nausea and vomiting, abdominal cramping and diarrhoea.

As sodium levels continue to decrease, the brain and nervous system are affected by cellular oedema. Neurological manifestations progress rapidly when the serum sodium level falls below 120 mEq/L and include headache, depression, dulled sensorium, personality changes, irritability, lethargy, hyperreflexia, muscle twitching and tremors. If serum sodium falls to very low levels, convulsions and coma are likely to occur. When hyponatraemia is associated with decreased ECF volume, the manifestations are those of hypovolaemia (*hypotonic dehydration*). In hyponatraemia associated with fluid volume excess, manifestations include those of hypervolaemia.

INTERPROFESSIONAL CARE

Interprofessional management of hyponatraemia focuses on restoring normal blood volume and serum sodium levels.

Diagnosis

The following laboratory tests may be ordered:

- *Serum sodium* and *osmolality* are decreased in hyponatraemia (serum sodium < 135 mEq/L; serum osmolality < 275 mOsm/kg).
- A *24-hour urine specimen* is obtained to evaluate sodium excretion. In conditions associated with normal or increased extracellular volume (such as SIADH), urinary sodium is increased; in conditions resulting from losses of isotonic fluids (e.g. sweating, diarrhoea, vomiting and third-space fluid accumulation), by contrast, urinary sodium is decreased.

Medications

When both sodium and water have been lost (hyponatraemia with hypovolaemia), sodium-containing fluids are given to replace both water and sodium. These fluids may be given by mouth, nasogastric tube or intravenously. Isotonic Ringer's solution or isotonic saline (0.9% NaCl) solution may be administered. Cautious administration of intravenous 3% or 5% NaCl

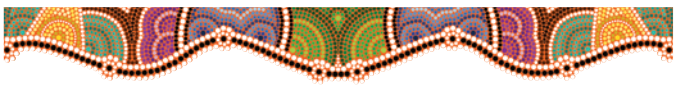
solution may be necessary in a person who has very low plasma sodium levels (110 to 115 mEq/L).

Loop diuretics are administered to a person who has hyponatraemia with normal or excess ECF volume. Loop diuretics promote an isotonic diuresis and fluid volume loss without hyponatraemia. Thiazide diuretics are avoided because they cause a relatively greater sodium loss in relation to water loss.

In addition, drugs to treat the underlying cause of hyponatraemia may be administered.

Fluid and dietary management

If hyponatraemia is mild, increasing the intake of foods high in sodium may restore normal sodium balance. Fluids often are restricted to help reduce ECF volume and correct hyponatraemia.



Nursing care

Nursing care of the person with hyponatraemia focuses on identifying the person at risk and managing problems resulting from the systemic effects of the disorder.

Health promotion

People at risk of mild hyponatraemia include those who participate in activities that increase fluid loss through excessive perspiration (diaphoresis) and then replace those losses by drinking large amounts of water. This includes athletes, people who do heavy labour in high environmental temperatures and older adults living in non-air-conditioned settings during hot weather. Teach the following to people who are at risk:

- manifestations of mild hyponatraemia, including nausea, abdominal cramps and muscle weakness
- the importance of drinking liquids containing sodium and other electrolytes at frequent intervals when perspiring heavily, when environmental temperatures are high and/or if watery diarrhoea persists for several days.

Assessment

Assessment data related to hyponatraemia include the following:

- *Health history*: current manifestations, including nausea and vomiting, abdominal discomfort, muscle weakness, headache and other symptoms; duration of symptoms and any precipitating factors such as heavy perspiration, vomiting or diarrhoea; chronic diseases such as heart or renal failure, cirrhosis of the liver or endocrine disorders; current medications.
- *Physical assessment*: mental status and level of consciousness; vital signs, including orthostatic vitals and peripheral pulses; presence of oedema or weight gain.
- *Diagnostic tests*: serum sodium and osmolality; serum potassium.

Nursing diagnoses and interventions

Risk of imbalanced fluid volume

Because of its role in maintaining fluid balance, sodium imbalances often are accompanied by water imbalances. In addition, treatment of hyponatraemia can affect the person's fluid balance.

- Monitor intake and output, weigh daily and calculate 24-hour fluid balance. *Fluid excess or deficit may occur with hyponatraemia.*

CONSIDERATION FOR PRACTICE

Carefully monitor the person receiving sodium-containing intravenous solutions for signs of hypervolaemia (increased blood pressure and CVP, tachypnoea, tachycardia, gallop rhythm S3 and/or S4 heart sounds, shortness of breath, crackles). Hypertonic saline solutions can lead to hypervolaemia, particularly in the person with cardiovascular or renal disease.

- Use an intravenous flow control device to administer hypertonic saline (3% and 5% NaCl) solutions; carefully monitor flow rate and response. *Hypertonic solutions can increase the risk of pulmonary and cerebral oedema due to water retention. Careful monitoring is vital to prevent these complications and possible permanent damage.*
- If fluids are restricted, explain the reason for the restriction, the amount of fluid allowed and how to calculate fluid intake. *Teaching increases the person's sense of control and compliance.*

For additional nursing interventions that may apply to the person with hyponatraemia, review the discussions of fluid volume deficit and fluid volume excess.

Risk of ineffective cerebral tissue perfusion

The person with severe hyponatraemia experiences fluid shifts that cause an increase in intracellular fluid volume. This can cause brain cells to swell, increasing pressure within the cranial vault.

- Monitor serum electrolytes and serum osmolality and report abnormal results. *As serum sodium levels fall, the manifestations and neurological effects of hyponatraemia become increasingly severe.*
- Assess for neurological changes, such as lethargy, altered level of consciousness, confusion and convulsions. Monitor mental status and orientation. Compare baseline data with continuing assessments. *Serum sodium levels of 115 to 120 mEq/L can cause headache, lethargy and decreased responsiveness; sodium levels less than 110 to 115 mEq/L may cause seizures and coma.*
- Assess muscle strength and tone and deep tendon reflexes. *Increasing muscle weakness and decreased deep tendon reflexes are manifestations of increasing hyponatraemia.*

CONSIDERATION FOR PRACTICE

Maintain a quiet environment and institute seizure precautions in the person with severe hyponatraemia. Severe hyponatraemia can lead to seizures and it is evidenced that a quiet environment reduces neurological stimulation. It is pertinent to maintain the person's safety and reduce the risk of injury from seizures by using precautions, such as ensuring that side rails are up, lowering the height of the bed and having airway equipment readily available.

Community-based care

Teaching for home care focuses on the underlying cause of the sodium deficit and often on prevention. Teach the person who

has experienced hyponatraemia and those who are at risk of developing hyponatraemia about the following:

- manifestations of mild and more severe hyponatraemia to report to the primary attending doctor
- the importance of regular serum electrolyte monitoring if taking a potent diuretic or on a low-sodium diet
- types of foods and fluids to replace sodium orally if dietary sodium is not restricted
- older adults' increased risk for hyponatraemia from the effects of medications and potential fluid imbalances.

The person with hypernatraemia

Hypernatraemia is a serum sodium level greater than 145 mEq/L. It may develop when sodium is gained in excess of water or when water is lost in excess of sodium. Either fluid volume deficit or fluid volume excess often accompanies hypernatraemia. Older adults with diminished thirst or who have limited access to water are at particular risk for hypernatraemia (Mount, 2012).

Pathophysiology

Two regulatory mechanisms protect the body from hypernatraemia: (1) excess sodium in ECF stimulates the release of ADH so more water is retained by the kidneys, and (2) the thirst mechanism is stimulated to increase the intake of water (Metheny, 2012). These two factors increase extracellular water, diluting the excess sodium and restoring normal levels. Because of the effectiveness of these mechanisms, hypernatraemia almost never occurs in the person who has an intact thirst mechanism and access to water.

Water deprivation is a cause of hypernatraemia in the person who is unable to respond to thirst due to altered mental status or physical disability. Excess water loss may occur with watery diarrhoea or increased insensible losses (due to fever, hyperventilation, excessive perspiration or massive burns). Unless water is adequately replaced, the person with diabetes insipidus (see Chapter 18) also may develop hypernatraemia. Excess sodium intake can result from ingestion of excess salt or hypertonic intravenous solutions. People who experience near-drowning in seawater are at risk of hypernatraemia, as are people with heat stroke.

Manifestations

Hypernatraemia (also known as *hypertonic dehydration*) causes hyperosmolality of ECF. As a result, water is drawn out of cells, leading to cellular dehydration. The most serious effects of cellular dehydration are seen in the brain. As brain cells contract, neurological manifestations develop. The brain itself shrinks, causing mechanical traction on cerebral vessels. These vessels may tear and bleed. Although the brain rapidly adapts to hyperosmolality to minimise the water loss, acute hypernatraemia can cause widespread cerebral vascular bleeding (Grossman & Porth, 2014; Metheny, 2010).

Thirst is the first manifestation of hypernatraemia. If thirst is not relieved, the primary manifestations relate to altered neurological function (see Table 9.6). Initial lethargy, weakness and irritability can progress to seizures, coma and death in severe hypernatraemia. Both the severity of the sodium excess and the rapidity of its onset affect the manifestations of hypernatraemia.

INTERPROFESSIONAL CARE

Treatment of hypernatraemia depends on its cause. Hypernatraemia is corrected slowly (over a 48-hour period) to avoid development of cerebral oedema secondary to a shift of water into the brain cells.

Diagnosis

The following laboratory and diagnostic tests may be ordered:

- *Serum sodium levels* are greater than 145 mEq/L in hypernatraemia.
- *Serum osmolality* is greater than 295 mOsm/kg in hypernatraemia.
- The *water deprivation test* may be conducted to identify diabetes insipidus. Water and all other fluids are withheld for a specified period of time. During this time, urine specimens are obtained for osmolality and specific gravity. No change in these values supports the diagnosis of diabetes insipidus.

Medications

The principal treatment for hypernatraemia is oral or intravenous water replacement. Hypotonic intravenous fluids such as 0.45% NaCl solution or 5% dextrose in water (which is isotonic when administered, but provides pure water when the glucose is metabolised) may be administered to correct the water deficit. Diuretics may also be given to increase sodium excretion (Lukitsch, 2012).

Nursing care

The primary focus of nursing care related to hypernatraemia is prevention. Measures to prevent hypernatraemia include identifying risk factors, teaching the person and caregivers, monitoring laboratory test results and working with the interprofessional team to reduce the potential for hypernatraemia.

Health promotion

Education pertaining to hypernatremia is required for the person at risk of hypernatraemia, as well as their attending doctors, and is essential to prevent this electrolyte disorder. Instruct caregivers of debilitated people who are unable to perceive or respond to thirst to offer fluids at regular intervals. If the person is unable to maintain adequate fluid intake, contact the medical staff about an alternative route for fluid intake (e.g. a feeding tube). Teach attending doctors the importance of providing adequate water for the person receiving tube feedings (many of which are hypertonic).

Assessment

Assessment data related to hypernatraemia include the following:

- *Health history*: duration of symptoms and any precipitating factors such as water deprivation, increased water loss due

to heavy perspiration, temperature or rapid breathing, diarrhoea, excess salt intake or diabetes insipidus; current medications; perception of thirst.
- *Physical assessment*: vital signs including temperature; mucous membranes; altered mental status or level of consciousness; manifestations of fluid volume excess or fluid volume deficit.
- *Diagnostic tests*: monitor serum sodium and osmolality, serum potassium.

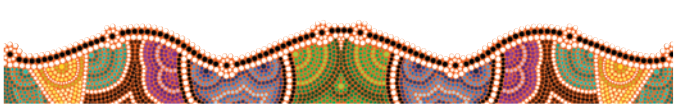
Nursing diagnoses and interventions

Risk of injury

Mental status and brain function may be affected by hypernatraemia itself or by rapid correction of the condition that leads to cerebral oedema. In either case, closely monitor the person and take precautions to reduce risk of injury.
- Monitor and maintain fluid replacement to within the prescribed limits. Monitor serum sodium levels and osmolality; report rapid changes to the attending doctor. *Rapid water replacement or rapid changes in serum sodium or osmolality can cause fluid shifts within the brain, increasing the risk of bleeding or cerebral oedema.*
- Monitor neurological function, including mental status, level of consciousness and other manifestations such as headache, nausea, vomiting, elevated blood pressure and decreased pulse rate. *Both hypernatraemia and rapid correction of hypernatraemia affect the brain and brain function. Careful monitoring is vital to detect changes in mental status that may indicate cerebral bleeding or oedema.*
- Institute safety precautions as necessary: keep the bed in its lowest position, side rails up and padded, and an airway at the bedside. *The person with a sodium disorder is at risk of injury due to seizure activity and changes in mental status.*
- Keep clocks, calendars and familiar objects at the bedside. Orient to time, place and circumstances as needed. Allow significant others to remain with the person as much as possible. *An unfamiliar environment and altered thought processes can further increase the person's risk of injury. Significant others provide a sense of security and reduce the person's anxiety.*

Community-based care

When preparing the person who has experienced hypernatraemia for home care, discuss the following topics:
- the importance of responding to thirst and consuming adequate fluids (if the person is dependent on a caregiver, stress to the caregiver the importance of regularly offering fluids)
- if prescribed, guidelines for following a low-sodium diet (see Box 9.5)
- use and effects (intended and unintended) of any prescribed diuretic or other medication
- the importance of following a schedule for regular monitoring of serum electrolyte levels and reporting manifestations of imbalance to the attending doctor.



POTASSIUM IMBALANCE

Potassium, the primary intracellular cation, plays a vital role in cell metabolism and cardiac and neuromuscular function. The normal serum (ECF) potassium level is 3.5 to 5.0 mEq/L.

Overview of normal potassium balance

Most potassium in the body is found within the cells (ICF), which have a concentration of 140 to 150 mEq/L. This significant difference in the potassium concentrations of ICF and ECF helps maintain the resting membrane potential of nerve and muscle cells; either a deficit or an excess of potassium can adversely affect neuromuscular and cardiac function. The higher intracellular potassium concentration is maintained by the sodium–potassium pump.

To maintain its balance, potassium must be replaced daily. Normally, potassium is supplied in food. Virtually all foods contain potassium, although some foods and fluids are richer sources of this element than others (see Box 9.6).

The kidneys eliminate potassium very efficiently; even when potassium intake is stopped, the kidneys continue to excrete it. Because the kidneys do not conserve potassium well, significant amounts may be lost through this route. However, because the kidneys are the principal organs involved in the elimination of potassium, renal failure can lead to potentially serious elevations of serum potassium.

Aldosterone helps regulate potassium elimination by the kidneys. An increased potassium concentration in ECF stimulates aldosterone production by the adrenal gland. The kidneys respond to aldosterone by increasing potassium excretion. Changes in aldosterone secretion can profoundly affect the serum potassium level.

Normally only small amounts of potassium are lost in the faeces, but substantial amounts may be lost from the gastrointestinal tract with diarrhoea or through drainage from an ileostomy (a permanent opening into the small bowel).

Potassium constantly shifts into and out of the cells. This movement between ICF and ECF can significantly affect the

BOX 9.6 Foods high in potassium

Fruits
- Apricots
- Avocados
- Bananas
- Dates
- Oranges
- Raisins

Vegetables and vegetable juices
- Carrots
- Cauliflower
- Mushrooms
- Peas

TABLE 9.7 Causes and manifestations of potassium imbalances

IMBALANCE	CAUSES	MANIFESTATIONS
Hypokalaemia Serum potassium < 3.5 mEq/L Critical value < 2.5 mEq/L	• Excess GI losses: vomiting, diarrhoea, ileostomy drainage • Renal losses: diuretics, hyperaldosteronism • Inadequate intake • Shift into cells: alkalosis, rapid tissue repair	Cardiovascular • Arrhythmias • ECG changes Gastrointestinal • Nausea and vomiting • Anorexia • Decreased bowel sounds • Ileus Musculoskeletal • Muscle weakness • Leg cramps
Hyperkalaemia Serum potassium > 5.0 mEq/L Critical value > 6.5 mEq/L	• Renal failure • Potassium-sparing diuretics • Adrenal insufficiency • Excess potassium intake (e.g. excess potassium replacement) • Aged blood • Shift out of cells: cell and tissue damage, acidosis	Cardiovascular • Tall, peaked T waves, widened QRS • Arrhythmias • Cardiac arrest Gastrointestinal • Nausea and vomiting • Abdominal cramping • Diarrhoea Neuromuscular • Muscle weakness • Paraesthesias • Flaccid paralysis

serum potassium level. For example, potassium shifts into or out of the cells in response to changes in hydrogen ion concentration (pH, discussed later in this chapter) as the body strives to maintain a stable acid–base balance.

The significant difference between intracellular and extracellular potassium concentrations is vital to the resting membrane potential of cells. Resting membrane potential, in turn, is necessary for transmitting nerve impulses. Potassium imbalances affect transmission and conduction of nerve impulses, maintenance of normal cardiac rhythms and contraction of skeletal and smooth muscle (McCance & Huether, 2014).

As the primary intracellular cation, potassium plays a major role in regulating the osmolality of ICF and is involved in metabolic processes. Potassium is necessary for the storage of glycogen in skeletal muscle cells. Table 9.7 summarises the causes and manifestations of potassium imbalances.

The person with hypokalaemia

Hypokalaemia is an abnormally low serum potassium (less than 3.5 mEq/L). It usually results from excess potassium loss, although the hospitalised person may be at risk of hypokalaemia because of inadequate potassium intake.

Pathophysiology

Excess potassium may be lost through the kidneys or the GI tract. These losses deplete total potassium stores in the body.

- Excess potassium loss through the kidneys often is secondary to drugs such as potassium-wasting diuretics, corticosteroids, amphotericin B and large doses of some antibiotics. Hyperaldosteronism, a condition in which the adrenal glands secrete excess aldosterone, also causes excess elimination of potassium through the kidneys. Glucosuria and osmotic diuresis (e.g. associated with diabetes mellitus) also cause potassium wasting through the kidneys (Metheny, 2012).
- Gastrointestinal losses of potassium result from severe vomiting, gastric suction, or loss of intestinal fluids through diarrhoea or ileostomy drainage.

Potassium intake may be inadequate in the person who is unable or unwilling to eat for prolonged periods. The person who is hospitalised is at risk, especially when on extended parenteral fluid therapy with solutions that do not contain potassium. The person with anorexia nervosa or alcoholism may develop hypokalaemia due to both inadequate intake and loss of potassium through vomiting, diarrhoea, or laxative or diuretic use.

A *relative* loss of potassium occurs when potassium shifts from ECF into the cells. This usually is due to loss of hydrogen ions and alkalosis, although it also may occur during periods of rapid tissue repair (e.g. following a burn or trauma), in the presence of excess insulin (insulin promotes potassium entry into skeletal muscle and liver cells), during acute stress or because of hypothermia. In these instances, the total body stores of potassium remain adequate.

Manifestations

Hypokalaemia affects the transmission of nerve impulses, interfering with the contractility of smooth, skeletal and cardiac muscle, as well as the regulation and transmission of cardiac impulses.

- Characteristic electrocardiogram (ECG) changes of hypokalaemia include flattened or inverted T waves, the development of U waves and a depressed ST segment (see Figure 9.11). The most serious cardiac effect is an increased risk of atrial and ventricular arrhythmias (abnormal rhythms). Hypokalaemia increases the risk of digitalis toxicity in the person receiving this drug used to treat heart failure (see Chapter 30).

- Hypokalaemia affects both the resting membrane potential and intracellular enzymes in skeletal and smooth muscle cells. This causes skeletal muscle weakness and slowed peristalsis of the GI tract. Muscles of the lower extremities are affected first, then the trunk and upper extremities. This effect of hypokalaemia is magnified when serum calcium levels are above normal.
- Carbohydrate metabolism is affected by hypokalaemia. Insulin secretion is suppressed, as is the synthesis of glycogen in skeletal muscle and the liver.

Hypokalaemia also can affect kidney function, particularly the ability to concentrate urine. Severe hypokalaemia can lead to rhabdomyolysis, a condition in which muscle fibres disintegrate, releasing myoglobin to be excreted in the urine.

Manifestations of hypokalaemia are more pronounced when potassium losses occur acutely. When hypokalaemia develops gradually, potassium shifts out of the cells, helping maintain the ratio of intracellular to extracellular potassium. As a result, the neuromuscular manifestations of hypokalaemia are less severe. The *multisystem effects of hypokalaemia* are summarised on the following page.

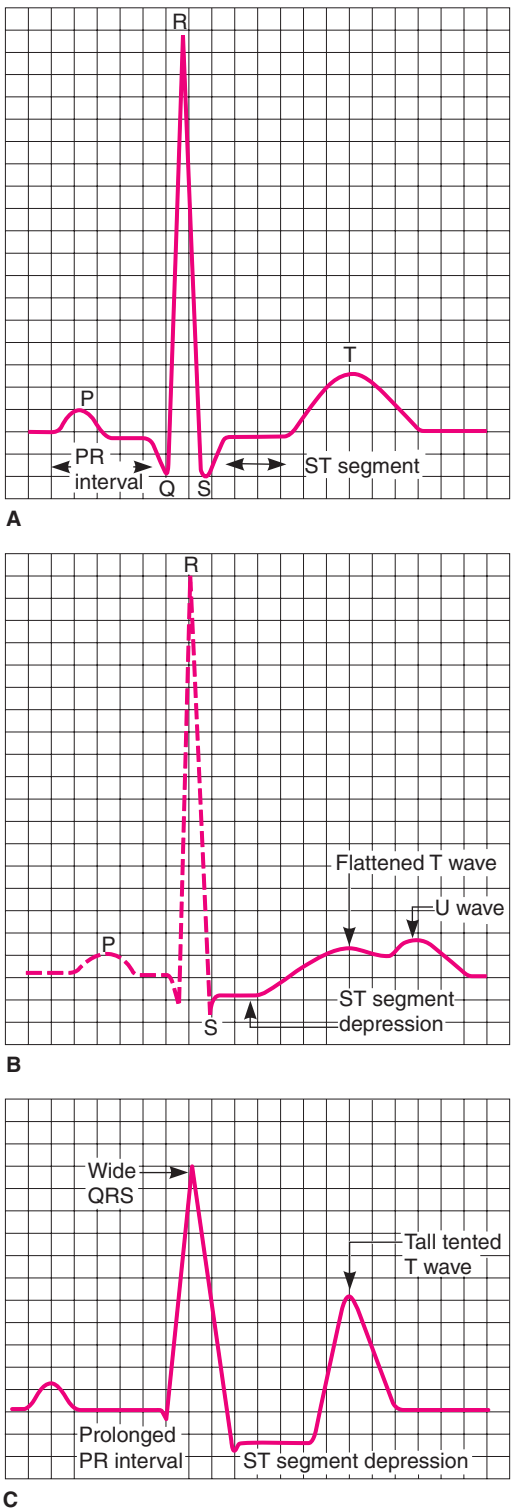

FIGURE 9.11 ■ The effects of changes in potassium levels on the electrocardiogram (ECG). *A*, Normal ECG; *B*, ECG in hypokalaemia; *C*, ECG in hyperkalaemia

INTERPROFESSIONAL CARE

The management of hypokalaemia focuses on prevention and treatment of a deficiency.

Diagnosis

The following laboratory and diagnostic tests may be ordered:

- *Serum potassium* (K^+) is used to monitor potassium levels in the person who is at risk of, or who is being treated for, hypokalaemia. A serum K^+ of 3.0 to 3.5 mEq/L is considered mild hypokalaemia. Moderate hypokalaemia is defined as a serum K^+ of 2.5 to 3.0 mEq/L and severe hypokalaemia as a serum K^+ of less than 2.5 mEq/L (Metheny, 2012).
- *Arterial blood gases (ABGs)* are measured to determine acid–base status. An increased pH (alkalosis) often is associated with hypokalaemia. (See Table 9.11 later in this chapter for normal ABG values.)
- *Renal function studies*, such as *serum urea and creatinine,* may be ordered to evaluate for potential causes or effects of hypokalaemia.
- *ECG recordings* are obtained to evaluate the effects of hypokalaemia on the cardiac conduction system.

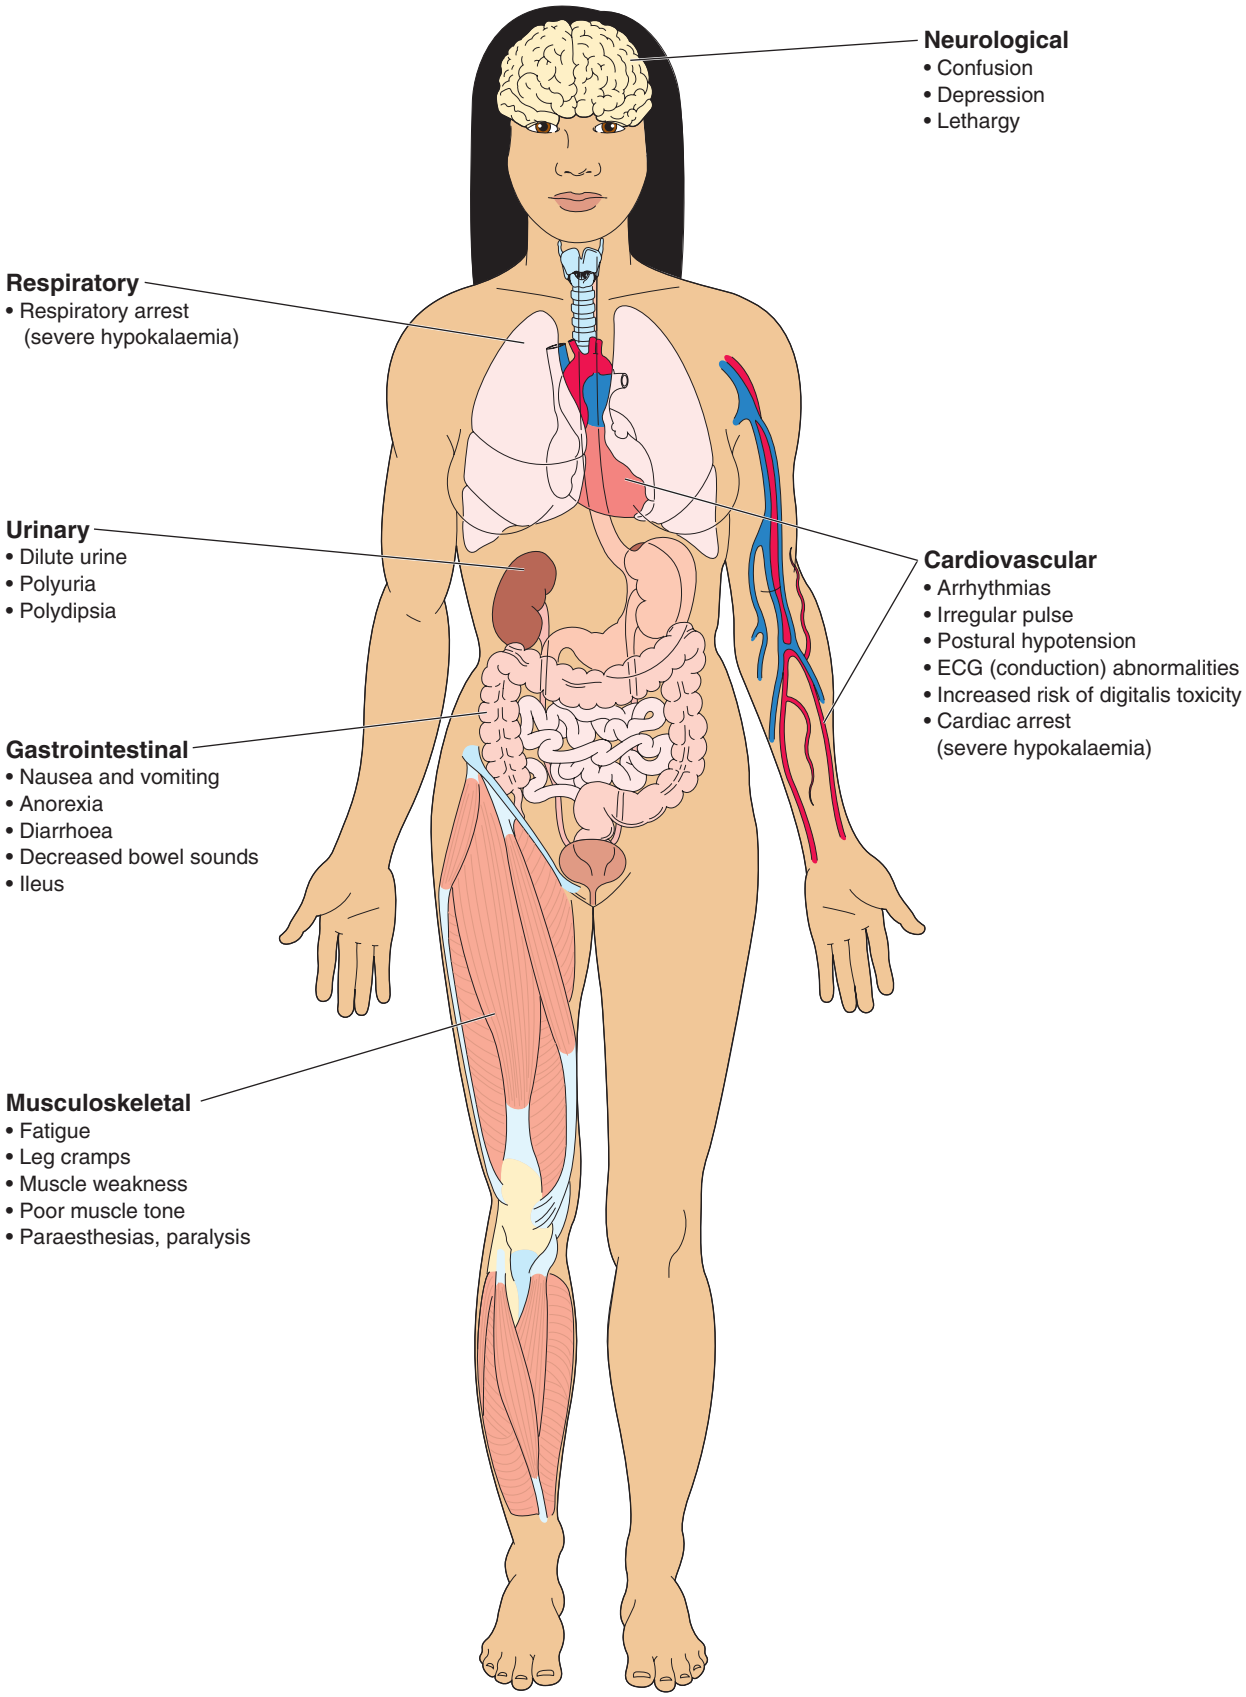
Medications

Oral and/or parenteral potassium supplements are given to prevent and, as needed, treat hypokalaemia. To prevent hypokalaemia in the person taking nothing by mouth, potassium chloride is added to IV fluids. The dose used to treat hypokalaemia includes the daily maintenance requirement, replacement of ongoing losses (e.g. gastric suction) and additional potassium to correct the existing deficit. Several days of therapy may be required. Commonly prescribed potassium supplements, their actions and nursing implications are described in the 'Medication administration' box below.

Nutrition

A diet high in potassium-rich foods is recommended for the person at risk of developing hypokalaemia or to supplement drug therapy (see Box 9.6).

MULTISYSTEM EFFECTS OF HYPOKALAEMIA



MEDICATION ADMINISTRATION Hypokalaemia

POTASSIUM SOURCES

Potassium acetate
Potassium bicarbonate
Potassium citrate
Potassium chloride
Potassium gluconate

Potassium is rapidly absorbed from the gastrointestinal tract; potassium chloride is the agent of choice, because low chloride often accompanies low potassium. Potassium is used to prevent and/or treat hypokalaemia (e.g. with parenteral nutrition and potassium-wasting diuretics and prophylactically after major surgery).

Nursing responsibilities

- When giving oral forms of potassium:
  a. Dilute or dissolve effervescent, soluble or liquid potassium in fruit or vegetable juice or cold water.
  b. Chill to increase palatability.
  c. Give with food to minimise GI effects.
- When giving parenteral forms of potassium:
  a. Check correct infusion rate and administer slowly.
  b. Check appropriate administration mode and use as an additive (usually NOT administered IV push and NOT added to fluids already hanging).
  c. Do *not* administer undiluted.
  d. Assess injection site frequently for signs of pain and inflammation.
  e. Use an infusion control device.
- Assess for abdominal pain, distension, gastrointestinal bleeding; if present, do not administer medication. Notify the attending doctor.
- Monitor fluid intake and output.
- Assess for manifestations of hyperkalaemia: weakness, feeling of heaviness in legs, mental confusion, hypotension, cardiac arrhythmias, changes in ECG, increased serum potassium levels.

Health education for the person and their family

- Do not take potassium supplements if you are also taking a potassium-sparing diuretic.
- When parenteral potassium is discontinued, eat potassium-rich foods.
- Do not chew enteric-coated tablets or allow them to dissolve in the mouth, as this may affect the potency and action of the medications.
- Take potassium supplements with meals.
- Do not use salt substitutes when taking potassium (most salt substitutes are potassium-based).

Nursing care

See below for 'Nursing care plan: A person with hypokalaemia'.

Health promotion

When providing general health education, discuss the use of balanced electrolyte solutions (e.g. sports drinks) to replace abnormal fluid losses (excess perspiration, vomiting or severe diarrhoea). Discuss the necessity of preventing hypokalaemia with the at-risk person. Provide diet teaching and refer the person with anorexia nervosa for counselling. Stress the potassium-losing effects of taking diuretics and using laxatives to enhance weight loss. Discuss the potassium-wasting effects of most diuretics with the person taking these drugs and encourage a diet rich in high-potassium foods, as well as regular monitoring of serum potassium levels.

Assessment

Assessment data related to hypokalaemia include the following:

- *Health history*: current manifestations, including anorexia, nausea and vomiting, abdominal discomfort, muscle weakness or cramping, and other symptoms; duration of symptoms and any precipitating factors such as diuretic use, prolonged vomiting or diarrhoea; chronic diseases such as diabetes, hyperaldosteronism or Cushing's syndrome; current medications.
- *Physical assessment*: mental status; vital signs, including orthostatic vitals, apical and peripheral pulses; bowel sounds, abdominal distension; muscle strength and tone.
- *Diagnostic tests*: serum electrolytes, K^+, Na^+ and Ca^{2+} in particular, arterial pH and other ABG results, renal function tests (urea and creatinine), ECG changes.

Nursing diagnoses and interventions

The effects of hypokalaemia on cardiac impulse transmission and cardiac and skeletal muscle function are the highest priority nursing care focus.

Decreased cardiac output

Hypokalaemia affects the strength of cardiac contractions and can lead to arrhythmias that further impair cardiac output. Hypokalaemia also alters the response to cardiac drugs, such as digitalis and the anti-arrhythmics.

- Monitor serum potassium levels, particularly in the person at risk of hypokalaemia (those with excess losses due to drug therapy, gastrointestinal losses or who are unable to consume a normal diet). Report abnormal levels to the attending doctor. *Potassium must be replaced daily, because the body is unable to conserve it. Either lack of intake or abnormal losses of potassium in the urine or gastric fluids can lead to hypokalaemia.*
- Monitor vital signs, including orthostatic vitals and peripheral pulses. *As cardiac output falls, the pulse becomes weak and thready. Orthostatic hypotension may be noted with decreased cardiac output.*
- Monitor the person taking digitalis for toxicity. Monitor response to antiarrhythmic drugs. *Hypokalaemia potentiates digitalis effects and increases resistance to certain anti-arrhythmics.*

NURSING CARE PLAN A person with hypokalaemia

Rose Ortiz is a 72-year-old widow who lives alone, although close to her daughter's home. Ms Ortiz has mild heart failure and is being treated with digoxin (Lanoxin) 0.125 mg, frusemide (Lasix) 40 mg PO daily and a mildly restricted sodium diet (2 g daily). For the last several weeks, Ms Ortiz has complained that she feels weak and sometimes faint, lightheaded and dizzy. Serum electrolyte tests ordered by her physician reveal a potassium level of 2.4 mEq/L. Potassium chloride solution (K Ciel 20 mEq/15 mL) PO twice daily is prescribed and Ms Ortiz is referred to Nancy Walters, RN, for follow-up care.

ASSESSMENT

Ms Ortiz's health history reveals that she has rigidly adhered to her sodium-restricted diet and has been compliant in taking her prescribed medications, with the exception of occasionally taking an additional 'water pill' when her ankles swell. She takes a laxative every evening to ensure a daily bowel movement. Ms Ortiz states that she is reluctant to take the potassium chloride the doctor has ordered because her neighbour complains that his potassium supplement upsets his stomach. Physical assessment findings include T 36.8°C, P 70, R 20 and BP 138/84. Muscle strength in her upper extremities is normal and equal; lower extremity strength is weak but equal. No sensory deficits are apparent.

DIAGNOSES

- *Risk of injury* related to muscle weakness.
- *Risk of ineffective health maintenance* related to lack of knowledge about how diuretic therapy and laxative use affect potassium levels.

PLANNING

- Advise the person about the potential hazards of negotiating stairs.
- Highlight awareness of potential medication side effects and adverse effects and explain how taking additional tablets may have contributed to hypokalaemia.
- Consider alternative measures to prevent constipation without using laxatives on a regular basis (e.g. high-fibre diet, adequate fluid intake).
- Explain purpose of the prescribed potassium and its role in reversing muscle weakness.
- Instruct and educate the person of the importance of taking the medication (potassium supplement) after breakfast and supper. Advise to call if gastric irritation occurs.
- Discuss dietary sources of potassium and provide a list of potassium-rich foods.

Expected outcomes

- Maintain potassium level within normal limits (3.5 to 5.0 mEq/L).
- Regain normal muscle strength.
- Remain free of injury.
- Verbalise understanding of the effects of diuretic therapy and laxatives on potassium levels.
- Identify measures to avoid gastrointestinal irritation when taking oral potassium.
- Identify potassium-rich foods.

IMPLEMENTATION

- To observe and monitor Ms Ortiz's ability to safely ambulate up and down stairs.
- Discuss and consult with Ms Ortiz if there have been any heart palpations, dizziness which could be a result of side effects of frusemide.
- Discuss and consult with Mrs Ortiz about her dietary intake with a focus on high fibre and fluids.
- Discuss with Mrs Ortiz her compliance with medication administration after food, advising report of any gastric irritation.
- Review Ms Ortiz's dietary intake, identifying that she is eating potassium-rich food sources.

EVALUATION

On a follow-up visit 1 week later, Ms Ortiz states that her muscle weakness, dizziness and other symptoms have resolved. She is taking the prescribed drugs as directed and is using laxatives only 2 or 3 times a week. Ms Ortiz reports that she has increased her intake of both potassium-rich foods and fluids and high-fibre foods. Her potassium level is within normal limits.

CRITICAL THINKING IN THE NURSING PROCESS

1. What is the pathophysiological basis for Ms Ortiz's muscle weakness and dizziness?
2. How might the chronic overuse of laxatives contribute to hypokalaemia?
3. Describe the interaction of digitalis, diuretics and potassium.
4. Develop a plan of care for Ms Ortiz for the nursing diagnosis of *Perceived constipation*.

REFLECTION ON THE NURSING PROCESS

1. As the Registered Nurse, how do you know that education pertaining to medication compliance has been effective?
2. What communication and education strategies could you use when providing care for a person with hypokalaemia?

CONSIDERATION FOR PRACTICE

Place the person with severe hypokalaemia on a cardiac monitor. Closely monitor cardiac rhythm and observe for characteristic ECG changes of hypokalaemia (ST segment depression, flattened T waves and U waves). Report rhythm changes immediately and treat as indicated. Severe hypokalaemia can cause life-threatening arrhythmias.

- Dilute intravenous potassium and administer using an electronic infusion device. In general, potassium is given no faster than 10 to 20 mEq/hour. Closely monitor intravenous flow rate and response to potassium replacement. *Rapid potassium administration is dangerous and can lead to hyperkalaemia and cardiac arrest.*

CONSIDERATION FOR PRACTICE

Never administer undiluted potassium directly into the vein.

Activity intolerance

Muscle cramping and weakness are common early manifestations of hypokalaemia. The lower extremities are usually affected initially. This muscle weakness can cause the person to fatigue easily, particularly with activity.

- Monitor skeletal muscle strength and tone, which are affected by moderate hypokalaemia. *Increasing weakness, paraesthesias or paralysis of muscles or progression of affected muscles to include the upper extremities or trunk can indicate a further drop in serum potassium levels.*
- Monitor respiratory rate, depth and effort; heart rate and rhythm; and blood pressure at rest and following activity. *Tachypnoea, dyspnoea, tachycardia and/or a change in blood pressure may indicate decreasing ability to tolerate activities. Report changes to the attending doctor.*
- Assist with self-care activities as needed. *Increasing muscle weakness can lead to fatigue and affect the ability to meet self-care needs.*

Risk of imbalanced fluid volume

- Maintain accurate intake and output records. *Gastrointestinal fluid losses can lead to significant potassium losses.*
- Monitor bowel sounds and abdominal distension. *Hypokalaemia affects smooth muscle function and can lead to slowed peristalsis and paralytic ileus.*

Acute pain

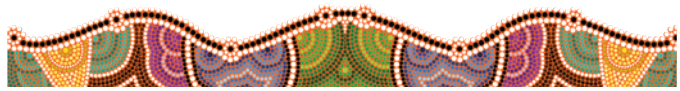
Discomfort is common when intravenous potassium chloride at a concentration of more than 40 mEq/L is given into a peripheral vein.

- When possible, administer intravenous KCl through a central line. *The rapid blood flow through central veins dilutes the KCl solution, decreasing discomfort.*
- Spread the total daily dose of KCl over 24 hours to minimise the concentration of intravenous solutions. *High concentrations of KCl are irritating to vein walls, particularly if inflammation is present.*
- Discuss with the physician the use of a small amount of lidocaine prior to or with the infusion. *Both a lidocaine bolus given at the infusion site and a small amount of lidocaine in the intravenous infusion have been shown to at least partially relieve discomfort associated with concentrated potassium solutions* (Metheny, 2012).

Community-based care

The focus in preparing the person with or at risk of hypokalaemia is prevention. Discharge planning focuses on teaching self-care practices. Include the following topics when preparing the person and family for home care:

- recommended diet, including a list of potassium-rich foods
- prescribed medications and potassium supplements, their use, and desired and unintended effects
- using salt substitutes (if recommended) to increase potassium intake; avoiding substitutes if taking a potassium supplement or potassium-sparing diuretic
- manifestations of potassium imbalance (hypokalaemia or hyperkalaemia) to report to the attending doctor
- recommendations for monitoring serum potassium levels
- if taking digitalis, manifestations of digitalis toxicity to report to the attending doctor
- managing gastrointestinal disorders that cause potassium loss (vomiting, diarrhoea, ileostomy drainage) to prevent hypokalaemia.



The person with hyperkalaemia

Hyperkalaemia is an abnormally high serum potassium level (greater than 5 mEq/L). Hyperkalaemia can result from inadequate excretion of potassium, excessively high intake of potassium, or a shift of potassium from the intracellular to the extracellular space. *Pseudohyperkalaemia* (an erroneously high serum potassium reading) can occur if the blood sample haemolyses, releasing potassium from blood cells, before it is analysed. Hyperkalaemia affects neuromuscular and cardiac function.

Pathophysiology

Impaired renal excretion of potassium is a primary cause of hyperkalaemia. Untreated renal failure, adrenal insufficiency (e.g. Addison's disease or inadequate aldosterone production) and medications (such as potassium-sparing diuretics, the antimicrobial drug trimethoprim and some NSAIDs) impair potassium excretion by the kidneys.

In the person with a normal renal excretion of potassium, excess oral potassium (e.g. by supplement or use of salt substitutes) rarely leads to hyperkalaemia. Rapid intravenous administration of potassium or transfusion of aged blood can lead to hyperkalaemia. A shift of potassium ions from the intracellular space can occur in acidosis, with severe tissue trauma, during chemotherapy and due to starvation. In acidosis, excess hydrogen ions enter the cells, displacing potassium and causing it to shift into the extracellular space. The extent of this shift is greater with metabolic acidosis than with respiratory acidosis (see 'Acid–base disorders' later in this chapter).

Hyperkalaemia alters the cell membrane potential, affecting the heart, skeletal muscle function and the GI tract. The most harmful consequence of hyperkalaemia is its effect on cardiac function. The cardiac conduction system is affected first, with slowing of the heart rate, possible heart blocks and prolonged depolarisation. ECG changes include peaked T waves, a prolonged PR interval and widening of the QRS complex (see Figure 9.11). Ventricular arrhythmias develop and cardiac arrest may occur. Severe hyperkalaemia decreases the strength of myocardial contractions.

Skeletal muscles become weak and paralysis may occur with very high serum potassium levels. Hyperkalaemia causes smooth muscle hyperactivity, leading to gastrointestinal disturbances.

The seriousness of hyperkalaemia is based on the serum potassium (K^+) level and ECG changes.

- *Mild hyperkalaemia:* serum K^+ between 5 and 6.5 mEq/L; ECG changes limited to peaked T wave.
- *Moderate hyperkalaemia:* serum K^+ between 6.5 and 8 mEq/L; ECG changes limited to peaked T wave.
- *Severe hyperkalaemia:* serum K^+ greater than 8 mEq/L; ECG shows absent P waves and widened QRS pattern.

Manifestations

The manifestations of hyperkalaemia result from its effects on the heart, skeletal and smooth muscles. Early manifestations include diarrhoea, colic (abdominal cramping), anxiety, paraesthesias, irritability, and muscle tremors and twitching. As serum potassium levels increase, muscle weakness develops, progressing to flaccid paralysis. The lower extremities are affected first, progressing to the trunk and upper extremities. The heart rate may be slow (bradycardia) and irregular. The ECG shows T-wave changes and, at high serum potassium levels, widening of the QRS complex and absence of P waves.

INTERPROFESSIONAL CARE

The management of hyperkalaemia focuses on returning the serum potassium level to normal by treating the underlying cause and avoiding additional potassium intake. The choice of therapy for existing hyperkalaemia is based on the severity of the hyperkalaemia.

Diagnosis

The following laboratory and diagnostic tests may be ordered:

- *Serum electrolytes* show a serum potassium level greater than 5.0 mEq/L. Low calcium and sodium levels may increase the effects of hyperkalaemia; therefore, these electrolytes are usually measured as well.
- *ABG*s are measured to determine if acidosis is present.
- An *ECG* is obtained and *continuous ECG monitoring* is instituted to evaluate the effects of hyperkalaemia on cardiac conduction and rhythm.

Medications

Medications are administered to lower the serum potassium and to stabilise the conduction system of the heart. For moderate to severe hyperkalaemia, calcium gluconate is given intravenously to counter the effects of hyperkalaemia on the cardiac conduction system. While the effect of calcium gluconate lasts only for 1 hour, it allows time to initiate measures to lower serum potassium levels. To rapidly lower these levels, regular insulin and 50 g of glucose are administered. Insulin and glucose promote potassium uptake by the cells, shifting potassium out of ECF. In some cases, a $ß_2$-agonist such as salbutamol may be given by nebuliser to temporarily push potassium into the cells. Sodium bicarbonate may be given to treat acidosis. As the pH returns towards normal, hydrogen ions are released from the cells and potassium returns into the cells.

To remove potassium from the body, sodium polystyrene sulfonate, a resin that binds potassium in the GI tract, may be administered orally or rectally. If renal function is normal, diuretics such as frusemide are given to promote potassium excretion. Commonly prescribed drugs, their actions and nursing implications are listed in the 'Medication administration' box below.

Dialysis

When renal function is severely limited, either peritoneal dialysis or haemodialysis may be implemented to remove excess potassium. These measures are invasive and are typically used only when other measures are ineffective. See Chapter 27 for more information about dialysis.

Nursing care

Nursing care focuses related to hyperkalaemia include identifying the at-risk person, preventing hyperkalaemia and addressing problems resulting from the systemic effects of hyperkalaemia. A 'Nursing care plan: A person with hyperkalaemia' is found below.

Health promotion

Those at the greatest risk of developing hyperkalaemia include people taking potassium supplements (prescribed or over-the-counter), using potassium-sparing diuretics or salt substitutes, and experiencing renal failure. Athletes participating in competition sports such as body building and using anabolic steroids, muscle-building compounds or 'energy drinks' also may be at risk of hyperkalaemia.

Teach all people to read food and dietary supplement labels carefully. Discuss the importance of taking prescribed potassium supplements as ordered and not increasing the dose unless prescribed by the attending doctor. Advise the person taking a potassium supplement or potassium-sparing diuretic to avoid salt substitutes, which usually contain potassium. Discuss the importance of maintaining an adequate fluid intake (unless a fluid restriction has been prescribed) to maintain renal function and eliminate potassium from the body.

Assessment

Assessment data related to hyperkalaemia include the following:

- *Health history*: current manifestations, including numbness and tingling, nausea and vomiting, abdominal cramping, muscle weakness, palpitations; duration of symptoms and any precipitating factors such as use of salt substitutes, potassium supplements or reduced urine output; chronic diseases such as renal failure or endocrine disorders; current medications.
- *Physical assessment*: apical and peripheral pulses; bowel sounds; muscle strength in upper and lower extremities; ECG pattern.
- *Diagnostic tests*: serum electrolytes, potassium, sodium and calcium in particular; ABGs; digitalis levels; ECG.

MEDICATION ADMINISTRATION Hyperkalaemia

DIURETICS

Potassium-wasting diuretics, such as frusemide (Lasix), may be used to enhance renal excretion of potassium.

Nursing responsibilities

- Monitor serum electrolytes.
- Monitor and record weight at regular intervals under standard conditions (same time of day, balanced scale, same clothing).
- Monitor intake and output.

INSULIN, HYPERTONIC DEXTROSE AND SODIUM BICARBONATE

Insulin, hypertonic dextrose (10% to 50%) and sodium bicarbonate are used in the emergency treatment of moderate to severe hyperkalaemia. Insulin promotes the movement of potassium into the cell and glucose prevents hypoglycaemia. The onset of action of insulin and hypertonic dextrose occurs within 30 minutes and is effective for approximately 4 to 6 hours.

Sodium bicarbonate elevates the serum pH; potassium is moved into the cell in exchange for hydrogen ion. Sodium bicarbonate is particularly useful in the person with metabolic acidosis. Onset of effects occurs within 15 to 30 minutes and is effective for approximately 2 hours.

Nursing responsibilities

- Administer intravenous insulin and dextrose over prescribed interval of time using an infusion pump.
- Administer sodium bicarbonate as prescribed. It may be administered as an intravenous bolus or added to a dextrosein-water solution and given by infusion.
- In the person receiving sodium bicarbonate, monitor for sodium overload, particularly in the person with hypernatraemia, heart failure and renal failure.
- Monitor the ECG pattern closely.
- Monitor serum electrolytes (K^+, Na^+, Ca^{2+}, Mg^{2+}) frequently during treatment.

CALCIUM GLUCONATE AND CALCIUM CHLORIDE

Intravenous calcium gluconate or calcium chloride is used as a temporary emergency measure to counteract the toxic effects of potassium on myocardial conduction and function.

Nursing responsibilities

- Closely monitor the ECG of the person receiving intravenous calcium, particularly for bradycardia.
- Calcium should be used cautiously in the person receiving digitalis, because calcium increases the cardiotonic effects of digitalis and may precipitate digitalis toxicity, leading to arrhythmias.

SODIUM POLYSTYRENE SULFONATE AND SORBITOL

Sodium polystyrene sulfonate is used to treat moderate or severe hyperkalaemia. Categorised as a cation exchange resin, sodium polystyrene sulfonate exchanges sodium or calcium for potassium in the large intestine. Sorbitol is given with sodium polystyrene sulfonate to promote bowel elimination. Sodium polystyrene sulfonate and sorbitol may be administered orally, through a nasogastric tube or rectally as a retention enema. The usual dosage is 20 g three or four times a day with 20 mL of 70% sorbitol solution.

Nursing responsibilities

- Because sodium polystyrene sulfonate contains sodium, monitor the person with heart failure and oedema closely for water retention.
- Monitor serum electrolytes (K^+, Na^+, Ca^{2+}, Mg^{2+}) frequently during therapy.
- Restrict sodium intake in the person who is unable to tolerate increased sodium load (e.g. those with CHF or hypertension).
- Sodium polystyrene sulfonate should not be given to people at risk of intestinal necrosis, including postoperative patient, those who have a history of bowel obstruction, ischaemic bowel disease or those who have had a renal transplant.

Nursing diagnoses and interventions

The effects of excess potassium on the electrical conduction and contractility of the heart are the highest priority for nursing care, particularly when the serum potassium level is 6.5 mEq/L or higher.

Risk of decreased cardiac output

Hyperkalaemia affects depolarisation of the atria and ventricles of the heart. Severe hyperkalaemia can cause arrhythmias with ventricular fibrillation and cardiac arrest. The cardiac effects of hyperkalaemia are more pronounced when the serum potassium level rises rapidly. Low serum sodium and calcium levels, high serum magnesium levels and acidosis contribute to the adverse effects of hyperkalaemia on the heart muscle.

- Closely monitor the response to intravenous calcium gluconate, particularly in people taking digitalis. *Calcium increases the risk of digitalis toxicity.*

CONSIDERATION FOR PRACTICE

Monitor the ECG pattern for development of peaked, narrow T waves, prolongation of the PR interval, depression of the ST segment, widened QRS interval and loss of the P wave. Notify the physician of changes. Progressive ECG changes from a peaked T wave to loss of the P wave and widening of the QRS complex indicate an increasing risk of arrhythmias and cardiac arrest.

Risk of activity intolerance

Both hypokalaemia (low serum potassium levels) and hyperkalaemia (high serum potassium levels) affect neuromuscular activity and the function of cardiac, smooth and skeletal muscles. Hyperkalaemia can cause muscle weakness and even paralysis.

- Monitor skeletal muscle strength and tone. *Increasing weakness, muscle paralysis or progression of affected muscles to affect the upper extremities or trunk can indicate increasing serum potassium levels.*

NURSING CARE PLAN A person with hyperkalaemia

Monty Longacre, a 51-year-old male, has end-stage renal failure. He arrives at the emergency clinic complaining of shortness of breath on exertion and extreme weakness.

ASSESSMENT

Mr Longacre tells the nurse, Janet Allen, RN, that he normally receives dialysis 3 times a week. He missed his last treatment, however, to attend his father's funeral. During the past several days, he has eaten a number of fresh oranges he received as a gift. Physical assessment findings include T 37.3°C, P 100, R 28, BP 168/96, 2^+ pretibial oedema and a 3.6-kg weight gain since his last haemodialysis treatment 4 days ago. Laboratory and diagnostic tests show the following abnormal results:

- K^+ 6.5 mEq/L (normal 3.5 to 5 mEq/L)
- urea 118 mg/dL (normal 7 to 18 mg/dL)
- creatinine 14 mg/dL (normal 0.7 to 1.3 mg/dL)
- HCO_3^- 17 mEq/L (normal 22 to 26 mEq/L)
- peaked T wave noted on ECG.

Mr Longacre is placed on continuous ECG monitoring and the physician prescribes haemodialysis. As an interim measure to lower the serum potassium, the medical officer prescribes $D_{50}W$ (25 g of dextrose), one ampule, to be administered intravenously with 10 units of regular insulin over 30 minutes.

DIAGNOSES

- *Activity intolerance* related to skeletal muscle weakness.
- *Risk of decreased cardiac output* related to hyperkalaemia.
- *Risk of ineffective health maintenance* related to inadequate knowledge of recommended diet.
- *Excess fluid volume* related to renal failure.

PLANNING

- Advise the person that the nurses will be monitoring and documenting in the case notes all fluid intake and urine output.
- Explain the purpose of follow up treatments of venepuncture and electrocardiographs (ECGs).
- Educate the person about the causes of hyperkalaemia.
- Explain the importance of the medically prescribed requirement of haemodialysis.
- Discuss dietary sources and provide a list of foods to prevent hyperkalaemia.

Expected outcomes

- Gradually resume usual physical activities.
- Maintain serum potassium level within normal range.
- Verbalise causes of hyperkalaemia, the importance of haemodialysis treatments as scheduled and the role of diet in preventing hyperkalaemia.

IMPLEMENTATION

- To observe, monitor and document fluid intake and fluid output.
- To follow up on the collection of serum potassium and review serum potassium results and report abnormalities to the medical officer. Attend to ECGs as ordered by the medical officer or as required and report findings to the medical officer.
- Review Mr Longacre's knowledge pertaining to causes of hyperkalaemia and the relationship between haemodialysis and hyperkalaemia.
- Discuss and consult with Mr Longacre about the importance of avoiding foods high in potassium to prevent or control hyperkalaemia.

EVALUATION

Following emergency treatment and haemodialysis, Mr Longacre's ECG and serum potassium level have returned to normal. His muscle strength has returned to near normal and he verbalises an understanding of his prescribed haemodialysis regimen. Janet Allen provides verbal and written information about hyperkalaemia, and the importance of complying with the haemodialysis regimen and of limiting intake of dietary sources of potassium in renal failure. She also furnishes a list of foods high in potassium and cautions against using potassium-containing salt substitutes and non-prescription drugs.

CRITICAL THINKING IN THE NURSING PROCESS

1. What information given by Mr Longacre indicated that he might be experiencing hyperkalaemia?
2. Why was continuous ECG monitoring instituted as an emergency measure?
3. What additional emergency measures might have been instituted if Mr Longacre's serum potassium level had been 8.5 mEq/L and his ECG had shown changes in impulse conduction?
4. Develop a care plan for Mr Longacre for the nursing diagnosis of *Anxiety*.

REFLECTION ON THE NURSING PROCESS

1. Identify and outline what you have learned from this case study and how will you apply it to your future nursing practice.
2. What communication and education strategies could you use when caring for a person with a nursing diagnosis of *Anxiety*?

- Monitor respiratory rate and depth. Regularly assess lung sounds. *Muscle weakness due to hyperkalaemia can impair ventilation. In addition, medications such as sodium bicarbonate or sodium polystyrene sulfonate can cause fluid retention and pulmonary oedema in the person with pre-existing cardiovascular disease.*
- Assist with self-care activities as needed. *Increasing muscle weakness can lead to fatigue and affect the ability to meet self-care needs.*

Risk of imbalanced fluid volume

Renal failure is a major cause of hyperkalaemia. The person with renal failure also is at risk of fluid retention and other electrolyte imbalances.

- Closely monitor serum potassium, serum urea and creatinine. Notify the physician if serum potassium level is greater than 5 mEq/L or if serum urea and creatinine levels are increasing. *Serum urea and creatinine are the primary indicators of renal function. Levels of these substances rise*

rapidly in acute renal failure, more slowly in chronic renal failure (see Chapter 27).

- Maintain accurate intake and output records. Report an imbalance of 24-hour totals and/or urine output less than 30 mL/hour. *Oliguria (scant urine) or anuria (no urine output) may indicate renal failure and an increased risk of hyperkalaemia and fluid volume excess.*
- Monitor the person receiving sodium bicarbonate for fluid volume excess. *Increased sodium from injection of a hypertonic sodium bicarbonate solution can cause a shift of water into the extracellular space.*
- Monitor the person receiving cation exchange resins and sorbitol for fluid volume excess. *The resin exchanges potassium for sodium or calcium in the bowel. Excessive sodium and water retention may occur.*

Community-based care

Preventing future episodes of hyperkalaemia is the focus when preparing the person for home care. Include the family, a significant other or a caregiver when teaching the following topics:

- recommended diet and any restrictions, including salt substitutes and foods high in potassium
- medications to be avoided, including over-the-counter and fitness supplements
- follow-up appointments for lab work and evaluation.

CALCIUM IMBALANCE

Calcium is one of the most abundant ions in the body. The normal adult total serum calcium concentration is 8.5 to 10.0 mg/dL.

Overview of normal calcium balance

Calcium is obtained from dietary sources, although only about 20% of the calcium ingested is absorbed into the blood. The remainder is excreted in faeces. Extracellular calcium is excreted by the kidneys. Approximately 99% of the total calcium in the body is bound to phosphorus to form the minerals in bones and teeth. The remaining 1% is in extracellular fluid. About half of this extracellular calcium is ionised (free); it is this ionised calcium that is physiologically active. The remaining extracellular calcium is bound to protein or other ions. Ionised calcium is essential to a number of processes: stabilising cell membranes; regulating muscle contraction and relaxation; and maintaining cardiac function and blood clotting.

Serum calcium levels are regulated by the interaction of three hormones: parathyroid hormone (PTH), calcitonin and calcitriol (a metabolite of vitamin D). When serum calcium levels fall, the parathyroid glands secrete PTH, which mobilises skeletal calcium stores, increases calcium absorption in the intestines and promotes calcium reabsorption by the kidneys (see Figure 9.12).

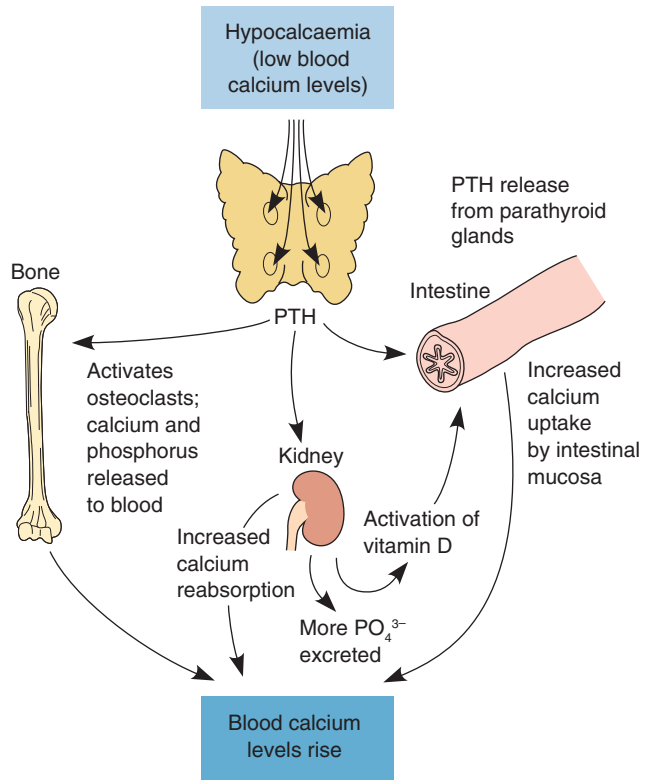


FIGURE 9.12 ■ Low calcium levels (hypocalcaemia) trigger the release of parathyroid hormone (PTH), increasing calcium ion levels through stimulation of bones, kidneys and intestines

Calcitriol facilitates this process by stimulating calcium release from the bones, absorption in the intestines and reabsorption by the kidneys. Calcitonin is secreted by the thyroid gland in response to high serum calcium levels. Its effect on serum calcium levels is the opposite of PTH: it inhibits the movement of calcium out of bone, reduces intestinal absorption of calcium, and promotes calcium excretion by the kidneys.

Serum calcium levels are also affected by acid–base balance. When hydrogen ion concentration falls and the pH rises (alkalosis), more calcium is bound to protein. While the total serum calcium remains unchanged, less calcium is available in the ionised, active form. Conversely, when hydrogen ion concentration increases and the pH falls (acidosis), calcium is released from protein, making more ionised calcium available.

Finally, the total amount of calcium in blood plasma fluctuates with plasma protein levels, particularly the albumin level. As the albumin level falls, the total amount of plasma calcium declines. Table 9.8 summarises the causes and manifestations of calcium imbalances.

The person with hypocalcaemia

Hypocalcaemia is a total serum calcium level of less than 8.5 mg/dL. Hypocalcaemia can result from decreased total body calcium stores or low levels of extracellular calcium with normal amounts of calcium stored in bone. The systemic effects of hypocalcaemia are caused by decreased levels of ionised calcium in extracellular fluid.

TABLE 9.8 Causes and manifestations of calcium imbalances

IMBALANCE	CAUSES	MANIFESTATIONS
Hypocalcaemia Serum calcium < 8.5 mg/dL or 4.3 mEq/L Critical value < 6.0 mg/dL	• Parathyroidectomy or neck surgery • Acute pancreatitis • Inadequate dietary intake • Lack of sun exposure • Lack of weight-bearing exercise • Drugs: loop diuretics, calcitonin • Hypomagnesaemia, alcohol abuse • Acute renal failure with hyperphosphataemia	Neuromuscular • Tetany • Paraesthesias • Muscle spasms • Positive Chvostek's sign • Positive Trousseau's sign • Laryngospasm • Seizures • Anxiety, confusion, psychoses Cardiovascular • Decreased cardiac output • Hypotension • Arrhythmias Gastrointestinal • Abdominal cramping • Diarrhoea
Hypercalcaemia Serum calcium >10 mg/dL or 5.3 mEq/L Critical value >13.0 mg/dL	• Hyperparathyroidism • Some cancers • Prolonged immobilisation • Paget's disease • Excess milk or antacid intake • Chronic renal failure with associated hyperparathyroidism	Neuromuscular • Muscle weakness, fatigue • Decreased deep tendon reflexes Behavioural • Personality changes • Altered mental status • Decreasing level of consciousness Gastrointestinal • Abdominal pain • Constipation • Anorexia, nausea, vomiting Cardiovascular • Arrhythmias • Hypertension Renal • Polyuria, thirst

Risk factors

Certain populations of people are at greater risk of hypocalcaemia: people who have had a parathyroidectomy (removal of the parathyroid glands), older adults (especially women), people with lactose intolerance and those with alcoholism. People who have undergone bariatric surgery for weight loss are at risk due to decreased food intake and malabsorption (Dewey & Heuberger, 2011). Older adults often consume less milk and milk products (good sources of calcium) and may have less exposure to the sun (a source of vitamin D). Older adults also may be less active, promoting calcium loss from bones. They are more likely to be taking drugs that interfere with calcium absorption or promote calcium excretion (e.g. frusemide). Older women are at particular risk after menopause because of reduced oestrogen levels. Intolerance to lactose (found in milk and milk products) causes diarrhoea and often limits the intake of milk and milk products, leading to possible calcium deficiency. Ethanol, or drinking alcohol, has a direct effect on calcium balance, reduces its intestinal absorption and interferes with other processes involved in regulating serum calcium levels.

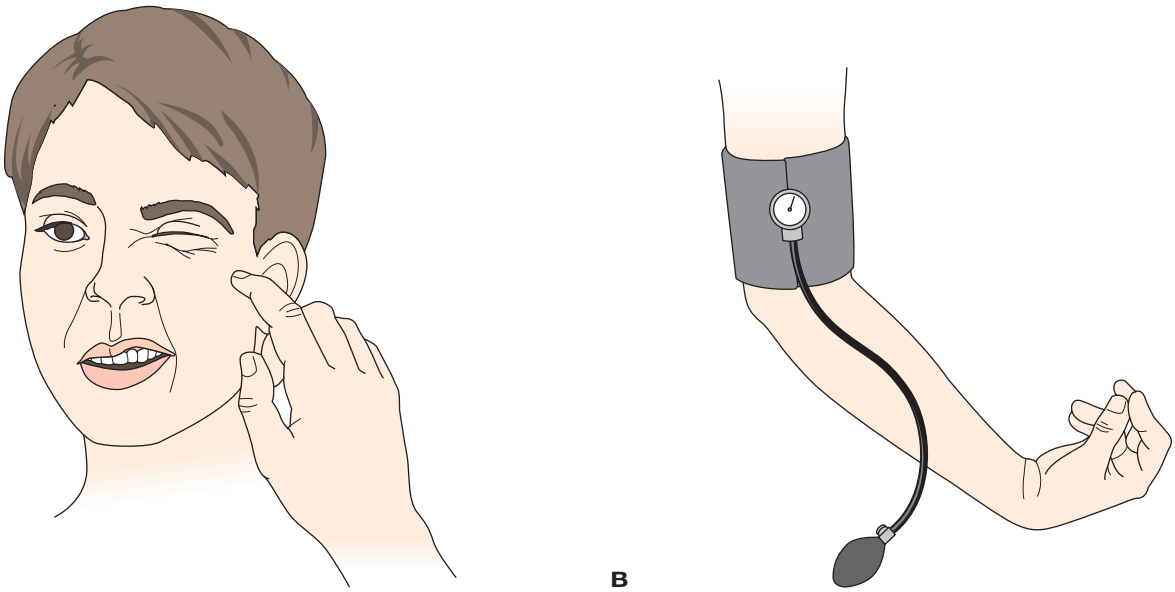
Pathophysiology

Common causes of hypocalcaemia are hypoparathyroidism (see Chapter 18) resulting from surgery (parathyroidectomy, thyroidectomy, radical neck dissection) and acute pancreatitis. In the person who has undergone surgery, symptoms of hypocalcaemia usually occur within the first 24 to 48 hours, but may be delayed.

CONSIDERATION FOR PRACTICE

Carefully monitor the person who has undergone neck surgery for manifestations of hypocalcaemia. Check serum calcium levels and report changes.

Additional causes of hypocalcaemia include other electrolyte imbalances (such as hypomagnesaemia or hyperphosphataemia), alkalosis, malabsorption disorders that interfere with calcium absorption in the bowel, and inadequate vitamin D (due to lack of sun exposure or malabsorption). Hyperphosphataemia often occurs in acute renal failure, with reciprocal hypocalcaemia. Massive transfusion of banked blood also can lead to hypocalcaemia. Citrate is added to blood to prevent clotting and as a preservative. When blood is administered faster than the liver can metabolise the citrate, it can bind with calcium, temporarily removing ionised calcium from circulation. Many drugs increase the risk of hypocalcaemia, including



A B

FIGURE 9.13 ■ *A*, Positive Chvostek's sign. *B*, Positive Trousseau's sign

loop diuretics (such as frusemide), anticonvulsants (such as phenytoin and phenobarbital), phosphates (including phosphate enemas) and drugs that lower serum magnesium levels (such as cisplatin and gentamicin) (Metheny, 2012).

Extracellular calcium acts to stabilise neuromuscular cell membranes. This effect is reduced in hypocalcaemia, increasing neuromuscular irritability. The threshold of excitation of sensory nerve fibres is lowered as well, leading to paraesthesias (altered sensation). The nervous system becomes more excitable and muscle spasms develop. In the heart, this change in cell membranes can lead to arrhythmias such as ventricular tachycardia and cardiac arrest. Hypocalcaemia decreases the contractility of cardiac muscle fibres, leading to decreased cardiac output.

Manifestations and complications

The most serious manifestations of hypocalcaemia are **tetany** (tonic muscular spasms) and convulsions. Numbness and tingling around the mouth (circumoral) and in the hands and feet develop. Muscle spasms of the face and extremities occur and deep tendon reflexes become hyperactive. Chvostek's sign, contraction of the facial muscles produced by tapping the facial nerve in front of the ear (see Figure 9.13A), and Trousseau's sign, carpal spasm induced by inflating a blood pressure cuff on the upper arm to above systolic blood pressure for 2 to 5 minutes (see Figure 9.13B), indicate increased neuromuscular excitability in the person without obvious symptoms.

Tetany can cause bronchial muscle spasms, simulating an asthma attack and visceral muscle spasms, producing acute abdominal pain. Cardiovascular manifestations include hypotension, possible bradycardia (slow heart rate) and ventricular arrhythmias.

Serious complications of hypocalcaemia include airway obstruction and possible respiratory arrest from laryngospasm, ventricular arrhythmias and cardiac arrest, heart failure and convulsions.

INTERPROFESSIONAL CARE

Management of hypocalcaemia is directed towards restoring normal calcium balance and correcting the underlying cause.

Diagnosis

The following laboratory and diagnostic tests may be ordered when hypocalcaemia is known or suspected.

- *Total serum calcium*, the amount of ionised (active) calcium available, is usually estimated. In the person who is critically ill, however, *ionised calcium* may be directly measured using ion selective electrodes. Direct measurement of ionised calcium requires special handling of the blood specimen, including placing the specimen on ice and analysing it immediately.
- *Serum albumin*, because the albumin level affects serum calcium results. When the albumin level is low (hypoalbuminaemia), the amount of ionised calcium may remain normal even though the total calcium level is low.
- *Serum magnesium*, because hypocalcaemia is often associated with hypomagnesaemia (serum magnesium < 1.6 mg/dL). In this case, normal magnesium levels must be restored to correct the hypocalcaemia.
- *Serum phosphate*; hyperphosphataemia (serum phosphate > 4.5 mg/dL) can lead to hypocalcaemia because of the inverse relationship between phosphorus and calcium. (As phosphate levels rise, calcium levels fall.)
- *Parathyroid hormone (PTH)*, to identify the possible diagnoses of hyperparathyroidism.
- An *ECG*, to evaluate the effects of hypocalcaemia on the heart, such as a prolonged ST segment.

Medications

Hypocalcaemia is treated with oral or intravenous calcium. The person with severe hypocalcaemia is treated with intravenous

BOX 9.7 Foods high in calcium

- Cottage cheese
- Canned sardines and salmon
- Cheese
- Rhubarb
- Milk
- Broccoli
- Cream
- Yoghurt
- Ice-cream
- Spinach
- Tofu

calcium to prevent life-threatening problems such as airway obstruction. The most common intravenous calcium preparations include calcium chloride and calcium gluconate. Although calcium chloride contains more elemental calcium than calcium gluconate, it also is more irritating to the veins and may cause venous sclerosis (hardening of the vein walls) if given into a peripheral vein. Intravenous calcium preparations can cause necrosis and sloughing of tissue if they extravasate into subcutaneous tissue. Rapid drug administration can lead to bradycardia and possible cardiac arrest due to overcorrection of hypocalcaemia with resulting hypercalcaemia. See the 'Medication administration' box below for further information on calcium administration.

Oral calcium preparations (calcium carbonate, calcium gluconate or calcium lactate) are used to treat chronic, asymptomatic hypocalcaemia. Calcium supplements may be combined with vitamin D, or vitamin D may be given alone to increase gastrointestinal absorption of calcium.

Nutrition

A diet high in calcium-rich foods may be recommended for the person with chronic hypocalcaemia or with low total body stores of calcium. Box 9.7 lists foods that are high in calcium.

Nursing care

Health promotion

Because of the large stores of calcium in bones, most healthy adults have a very low risk of developing hypocalcaemia. However, a deficit of total body calcium is often associated with ageing, increasing the risk of osteoporosis, fractures and disability. Women have a higher risk of developing osteoporosis than men, due to lower bone density and hormonal influences. Educate women of all ages about the importance of maintaining adequate calcium intake through diet and, as needed, calcium supplements. Stress the relationship between weight-bearing exercise and bone density, and encourage women to engage in a regular aerobic and weight-training exercise regimen. Discuss hormone replacement therapy and its potential benefits during and after menopause. See Chapter 39 for more information about osteoporosis.

Assessment

Assessment data related to hypocalcaemia include the following:

- *Health history*: current manifestations, including numbness and tingling around mouth and of hands and feet, abdominal pain, shortness of breath; acute or chronic

MEDICATION ADMINISTRATION Calcium salts

CALCIUM SALTS

Calcium carbonate
Calcium chloride
Calcium citrate
Calcium gluconate
Calcium lactate

Calcium salts are given to increase calcium levels when there is a deficit (a total body deficit or inadequate levels of extracellular calcium). Calcium is necessary to maintain bone structure and for multiple physiological processes, including neuromuscular and cardiac function as well as blood coagulation. In the presence of vitamin D, calcium is well absorbed from the gastrointestinal tract. Severe hypocalcaemia is treated with intravenous calcium preparations.

Nursing responsibilities

Oral calcium salts:

- Administer 1 to 1.5 hours after meals and at bedtime.
- Give calcium tablets with a full glass of water.

Intravenous calcium salts:

- Assess IV site for patency. Do not administer calcium if there is a risk of leakage into the tissues.
- May be given by slow IV push (dilute with sterile normal saline for injection prior to administering) or added to compatible parenteral fluids such as NS, lactated Ringer's solution or D_5W.
- Administer into the largest available vein; use a central line if available.
- Do not administer with bicarbonate or phosphate because a precipitate (insoluble salt) will form (Metheny, 2012).
- Continuously monitor ECG when administering IV calcium to the person taking digitalis, due to increased risk of digitalis toxicity.
- Frequently monitor serum calcium levels and response to therapy.

Health education for the person and their family

- Take calcium tablets with a full glass of water 1 to 2 hours after meals. Do not take with food or milk. If possible, do not take within 1 to 2 hours of other medications.
- Maintain adequate vitamin D intake through diet or exposure to the sun to promote calcium absorption.
- Calcium carbonate can cause constipation. Eat a high-fibre diet and maintain a generous fluid intake to prevent constipation.

diseases such as pancreatitis, liver or kidney disease; current medications.
- *Physical assessment*: muscle spasms; deep tendon reflexes; Chvostek's sign and Trousseau's sign; respiratory rate and depth; vital signs and apical pulse; heart rate and rhythm; presence of convulsions.
- *Diagnostic tests*: serum electrolytes (calcium, magnesium, phosphate and potassium, in particular), serum albumin, thyroid and parathyroid hormone levels; ECG.

Nursing diagnoses and interventions

The effect of hypocalcaemia on neuromuscular irritability, with the risk of muscle spasm and convulsions, is the highest priority for nursing care of the person.

Risk of injury

The person with hypocalcaemia is at risk of injury from possible laryngospasm, cardiac arrhythmias or convulsions. In addition, too rapid administration of intravenous calcium or extravasation of the medication into subcutaneous tissues can lead to injury.

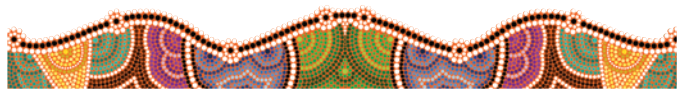
- Frequently monitor airway and respiratory status. Report changes such as respiratory **stridor** (a high-pitched, harsh inspiratory sound indicative of upper airway obstruction), or increased respiratory rate or effort, to the physician. *These changes may indicate laryngeal spasm due to tetany.*

CONSIDERATION FOR PRACTICE
Laryngeal spasm is a respiratory emergency, requiring immediate intervention to maintain ventilation and gas exchange.

- Monitor cardiovascular status, including heart rate and rhythm, blood pressure and peripheral pulses. *Hypocalcaemia decreases myocardial contractility, causing reduced cardiac output and hypotension. It also can cause bradycardia or ventricular arrhythmias. Cardiac arrest may occur in severe hypocalcaemia.*
- Continuously monitor ECG in the person receiving intravenous calcium preparations, especially if the person also is taking digitalis. *Rapid administration of calcium salts can lead to hypercalcaemia and cardiac arrhythmias. Calcium administration increases the risk of digitalis toxicity and resultant arrhythmias.*
- Provide a quiet environment. Institute seizure precautions such as raising the side rails and keeping an airway at the bedside. *A quiet environment reduces central nervous system stimuli and the risk of convulsions in the person with tetany.*

Community-based care

In preparing the person with hypocalcaemia for discharge and home care, consider the circumstances leading to low serum calcium levels. Discuss risk factors for hypocalcaemia specific to the person and provide information about managing these risk factors to avoid future episodes of hypocalcaemia. Educate about prescribed medications, including calcium supplements. Provide a list of foods high in calcium, as well as sources of vitamin D if recommended. Discuss symptoms to report to the attending doctor and stress the importance of follow-up care as scheduled.



The person with hypercalcaemia

Hypercalcaemia is a serum calcium value greater than 10.0 mg/dL. Excess ionised calcium in ECF can have serious widespread effects.

Pathophysiology

Hypercalcaemia usually results from increased resorption of calcium from the bones. The two most common causes of bone resorption are hyperparathyroidism and malignancies. In hyperparathyroidism, excess PTH is produced. This causes calcium to be released from bones, as well as increased calcium absorption in the intestines and retention of calcium by the kidneys. Hypercalcaemia is a common complication of malignancies. It may develop as a result of bone destruction by the tumour or due to hormone-like substances produced by the tumour itself. Prolonged immobility and lack of weight-bearing activity also causes increased resorption of bone with calcium release into extracellular fluids. Self-limiting hypercalcaemia also may follow successful kidney transplant. Levels of parathyroid hormone may be altered in chronic renal failure, leading to increased serum calcium levels.

Increased intestinal absorption of calcium also can lead to hypercalcaemia. This may result from excess vitamin D, overuse of calcium-containing antacids or excessive milk ingestion. Renal failure and some drugs such as thiazide diuretics and lithium can interfere with elimination of calcium by the kidneys, causing high serum calcium levels.

The effects of hypercalcaemia largely depend on the degree of serum calcium elevation and the length of time over which it develops. In general, higher serum calcium levels are associated with more serious effects. Calcium has a stabilising effect on the neuromuscular junction; hypercalcaemia decreases neuromuscular excitability, leading to muscle weakness and depressed deep tendon reflexes. Gastrointestinal motility is reduced as well. In the heart, calcium exerts an effect similar to digitalis (see Chapter 30), strengthening contractions and reducing the heart rate. Hypercalcaemia affects the conduction system of the heart, leading to bradycardia and heart blocks. The ability of the kidneys to concentrate urine is impaired by hypercalcaemia, causing excess sodium and water loss and increased thirst.

Extremely high serum calcium levels affect mental status. This is thought to be due to increased calcium in cerebrospinal fluid. Behavioural effects range from personality changes to confusion, impaired memory and acute psychoses.

Manifestations and complications

Manifestations of hypercalcaemia relate to its effects on neuromuscular activity, the central nervous system (CNS), the cardiovascular system and the kidneys. Decreased neuromuscular

excitability causes muscle weakness and fatigue, as well as gastrointestinal manifestations such as anorexia, nausea, vomiting and constipation. CNS effects may include confusion, lethargy, behaviour or personality changes, and coma. Cardiovascular effects include arrhythmias, ECG changes and possible hypertension. Hypercalcaemia causes polyuria and, as a result, increased thirst.

Complications of hypercalcaemia can affect several different organ systems. Peptic ulcer disease may develop due to increased gastric acid secretion. Pancreatitis can occur as a result of calcium deposits in pancreatic ducts. Excess calcium can precipitate out of urine to form kidney stones. Hypercalcaemic crisis, an acute increase in the serum calcium level, can lead to cardiac arrest.

INTERPROFESSIONAL CARE

The management of hypercalcaemia focuses on correcting the underlying cause and reducing the serum calcium level. Treatment is particularly important in the person who has one or more of the following: serum calcium levels greater than 12 mg/dL, overt symptoms of hypercalcaemia, compromised renal function and inability to maintain an adequate fluid intake.

Diagnosis

The laboratory and diagnostic tests that may be ordered and the resultant findings are as follows:

- *Serum electrolytes* show a total serum calcium greater than 10.0 mg/dL.
- *Serum PTH* levels are measured to identify or rule out hyperparathyroidism as the cause of hypercalcaemia.
- *ECG* changes in hypercalcaemia include a shortened QT interval, shortened and depressed ST segment and widened T wave. Bradycardia or heart block may be identified on the ECG.
- *Bone density* scans may be done to monitor bone resorption and the effects of treatment measures on mineralisation of bone.

Medications

Measures to promote calcium elimination by the kidneys and reduce calcium resorption from bone are used to treat hypercalcaemia. In acute hypercalcaemia, intravenous fluids are given (see the 'Fluid management' section that follows) with a loop diuretic such as frusemide to promote elimination of excess calcium. Calcitonin, which promotes the uptake of calcium into bones, also may be used to rapidly lower serum calcium levels.

A number of drugs that inhibit bone resorption are available. The bisphosphonates (pamidronate and etidronate) are commonly used to treat hypercalcaemia associated with malignancies. These drugs also are used to prevent and treat osteoporosis. Nursing implications for calcitonin and bisphosphonate drugs are presented in the 'Medication administration' boxes in Chapter 39. When a bisphosphonate drug is ineffective in correcting hypercalcaemia, mithramycin (a chemotherapeutic agent) may be used.

Rapid reversal of hypercalcaemia in emergency situations may be accomplished by intravenous administration of sodium phosphate or potassium phosphate. Calcium binds to phosphate, thus decreasing serum calcium levels. Paradoxically, complications of this therapy can include fatal hypocalcaemia resulting from binding of the ionised calcium and soft tissue calcifications.

Other drug therapies include the use of intravenous plicamycin to inhibit bone resorption. Glucocorticoids (cortisone), which compete with vitamin D, and a low-calcium diet may be prescribed to decrease gastrointestinal absorption of calcium, inhibit bone resorption and increase urinary calcium excretion. Also, calcitonin may be prescribed to decrease skeletal mobilisation of calcium and phosphorus, and to increase renal output of calcium and phosphorus. See Chapter 18 for more information about and nursing implications of glucocorticoid therapy.

Fluid management

Intravenous fluids, usually isotonic saline, are administered to the person with severe hypercalcaemia to restore vascular volume and promote renal excretion of calcium. Isotonic saline is used because sodium excretion is accompanied by calcium excretion. Careful assessment of cardiovascular and renal function is done prior to fluid therapy; the person is carefully monitored for evidence of fluid overload during treatment.

Nursing care

Health promotion

Identify and monitor the person at risk of hypercalcaemia. Promote mobility in the person when possible. Assist the hospitalised person to ambulate as soon as possible. In the home setting, discuss the benefits of regular weight-bearing activity with the person, families and caregivers. Encourage a generous fluid intake of up to 3 to 4 L per day. Encourage the person at risk to limit their intake of milk and milk products, as well as calcium-containing antacids and supplements. In addition, the person with prolonged immobility or hypercalcaemia is encouraged to consume fluids that increase the acidity of urine (which inhibits calcium stone formation), such as cranberry or prune juice.

Assessment

Assessment data related to hypercalcaemia include the following:

- *Health history*: current manifestations, including weakness or fatigue, abdominal discomfort, nausea or vomiting, increased urination and thirst; changes in memory or thinking; duration of symptoms and any risk factors such as excess intake of milk or calcium products, prolonged immobility, malignancy, renal failure or endocrine disorders; current medications.
- *Physical assessment*: mental status and level of consciousness; vital signs, including apical pulse; bowel sounds; muscle strength of upper and lower extremities; deep tendon reflexes.
- *Diagnostic tests*: serum electrolytes, urinary calcium, ECG and cardiac rhythm monitoring.

CONSIDERATION FOR PRACTICE

Remember, calcium has a stabilising or sedative effect on neuromuscular transmission. Therefore:

- Hypocalcaemia → increased neuromuscular excitability, muscle twitching, spasms and possible tetany
- Hypercalcaemia → decreased neuromuscular excitability, muscle weakness and fatigue.

Nursing diagnoses and interventions

Risk of injury

The person with hypercalcaemia is at risk of injury due to changes in mental status, the effects of hypercalcaemia on muscle strength and loss of calcium from bones.

- Institute safety precautions if confusion or other changes in mental status are noted. *Changes in mental status may impair judgment and the person's ability to maintain own safety.*

CONSIDERATION FOR PRACTICE

Monitor cardiac rate and rhythm, treating and/or reporting arrhythmias as indicated. Prepare for possible cardiac arrest; keep emergency resuscitation equipment readily available. Hypercalcaemia can cause bradycardia, various heart blocks and cardiac arrest. Immediate treatment may be necessary to preserve life.

- Observe for manifestations of digitalis toxicity, including vision changes, anorexia, and changes in heart rate and rhythm. Monitor serum digitalis levels. *Hypercalcaemia increases the risk of digitalis toxicity.*
- Promote fluid intake (oral and/or intravenous) to keep the person well hydrated and maintain dilute urine. Encourage fluids such as prune or cranberry juice to help maintain acidic urine. *Acidic, dilute urine reduces the risk of calcium salts precipitating out to form kidney stones.*
- If excess bone resorption has occurred, use caution when turning, positioning, transferring or ambulating. *Bones that have lost excess calcium may fracture with minimal stress or trauma (pathological fractures).*

Risk of excess fluid volume

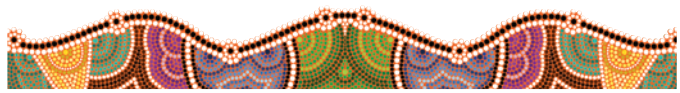
Large amounts of isotonic intravenous fluid often are administered to help correct acute hypercalcaemia, leading to a risk of hypervolaemia. The person with pre-existing cardiac or renal disease is at particular risk.

- Closely monitor intake and output. *A loop diuretic such as frusemide may be necessary if urinary output does not keep up with fluid administration.*
- Frequently assess vital signs, respiratory status and heart sounds. *Increasing pulse rate, dyspnoea, adventitious lung sounds and an S_3 on auscultation of the heart may indicate excess fluid volume and potential heart failure.*
- Place in semi-Fowler's to Fowler's position. *Elevating the head of the bed improves lung expansion and reduces the work of breathing.*
- Administer diuretics as ordered, monitoring response. *Loop diuretics may be ordered to help eliminate excess fluid and calcium.*

Community-based care

Discuss the following topics when preparing the person for discharge:

- Avoid excess intake of calcium-rich foods and antacids.
- Use prescribed drugs to prevent excess calcium resorption. Discuss their dose, use, and desired and possible adverse effects.
- Increase fluid intake to 3 to 4 L per day; increase the intake of acid ash foods (meats, fish, poultry, eggs, cranberries, plums, prunes); increase dietary fibre and fluid intake to prevent constipation.
- Maintain weight-bearing physical activity to prevent hypercalcaemia.
- Report early manifestations of hypercalcaemia.
- Follow recommended schedule for monitoring serum electrolyte levels.



MAGNESIUM IMBALANCE

Only about 1% of the magnesium in the body is in extracellular fluid; the rest is found within the cells and in bone. The normal serum concentration of magnesium ranges from 1.8 to 2.6 mg/dL (1.5 to 2.5 mEq/L).

Overview of normal magnesium balance

Magnesium is obtained through the diet (it is plentiful in green vegetables, grains, nuts, meats and seafood) and is excreted by the kidneys. Magnesium is vital to many intracellular processes, including enzyme reactions and synthesis of proteins and nucleic acids. Magnesium exerts a sedative effect on the neuromuscular junction, decreasing acetylcholine release. It is an essential ion for neuromuscular transmission and cardiovascular function. The physiological effects of magnesium are affected by both potassium and calcium levels. Approximately 65% of extracellular magnesium is ionised; the remainder is bound to protein. Table 9.9 summarises common causes and manifestations of magnesium imbalances.

The person with hypomagnesaemia

Hypomagnesaemia is a magnesium level of less than 1.6 mg/dL. It is a common problem, particularly in the critically ill person. Hypomagnesaemia may be caused by deficient magnesium intake, excessive losses, or a shift between the intracellular and extracellular compartments.

Risk factors

Loss of gastrointestinal fluids, particularly from diarrhoea, an ileostomy or intestinal fistula, is a major risk factor for hypomagnesaemia. Disruption of nutrient absorption in the small intestine also increases the risk. Chronic alcoholism is a common cause of deficient magnesium levels. Multiple factors associated with alcoholism contribute to hypomagnesaemia: deficient nutrient intake, increased gastrointestinal losses, impaired absorption and increased renal excretion. Other risk factors for hypomagnesaemia include:

- protein–kilojoule malnutrition or starvation
- endocrine disorders, including diabetic ketoacidosis

TABLE 9.9 Causes and manifestations of magnesium imbalances

IMBALANCE	CAUSES	MANIFESTATIONS
Hypomagnesaemia Serum magnesium < 1.6 mg/dL Critical value < 1 mg/dL	• Chronic alcoholism • GI losses: intestinal suction, diarrhoea, ileostomy • Impaired absorption • Inadequate replacement • Increased excretion: drugs, renal disease, osmotic diuresis	Neuromuscular • Muscle weakness, tremors • Tetany, seizures Gastrointestinal • Dysphagia • Anorexia, nausea, vomiting, diarrhoea Cardiovascular • Tachycardia • Arrhythmias • Hypertension CNS • Mood and personality changes • Paraesthesias
Hypermagnesaemia Serum magnesium > 2.6 mg/dL or 2.1 mEq/L Critical value > 4.7 mg/dL	• Renal insufficiency or failure • Excess intake of antacids, laxatives • Excess magnesium administration	Neuromuscular • Muscle weakness • Depressed deep tendon reflexes Gastrointestinal • Nausea and vomiting Cardiovascular • Hypotension • Bradycardia • Cardiac arrest CNS • Respiratory depression • Coma

- drugs such as loop or thiazide diuretics, aminoglycoside antibiotics, amphotericin B and cyclosporin
- rapid administration of citrated blood (banked blood)
- kidney disease.

Pathophysiology

Magnesium deficiency usually occurs along with low serum potassium and calcium levels. The effects of hypomagnesaemia relate not only to the magnesium deficiency but also to hypokalaemia and hypocalcaemia.

Hypomagnesaemia causes increased neuromuscular excitability, with muscle weakness and tremors. The accompanying hypocalcaemia contributes to this effect. In the CNS, this increased neural excitability can lead to seizures and changes in mental status. Deficient intracellular magnesium in the myocardium increases the risk of cardiac arrhythmias and sudden death. Hypokalaemia increases this risk. Hypomagnesaemia also increases the risk of digitalis toxicity. Chronic hypomagnesaemia may contribute to hypertension, probably due to increased vasoconstriction.

Manifestations and complications

Neuromuscular manifestations of hypomagnesaemia include tremors, hyper-reactive reflexes, positive Chvostek's and Trousseau's signs (see Figure 9.13), tetany, paraesthesias and seizures. CNS effects include confusion, mood changes (apathy, depression, agitation), hallucinations and possible psychoses. An increased heart rate and ventricular arrhythmias are common, especially when hypokalaemia is present or the person is taking digitalis. Cardiac arrest and sudden death may occur. Gastrointestinal manifestations include nausea, vomiting, anorexia, diarrhoea and abdominal distension.

INTERPROFESSIONAL CARE

Hypomagnesaemia is diagnosed by measuring serum electrolyte levels. The ECG shows a prolonged PR interval, widened QRS complex and depression of the ST segment with T-wave inversion. Treatment is directed towards prevention and identification of an existing deficiency. Magnesium is added to intravenous total parenteral nutrition solutions to prevent hypomagnesaemia.

In the person able to eat, a mild deficiency may be corrected by increasing the intake of foods rich in magnesium (see Box 9.8) or with oral magnesium supplements. Oral magnesium supplements may cause diarrhoea, however, limiting their use.

BOX 9.8 Foods high in magnesium

- Green, leafy vegetables
- Oranges
- Seafood
- Grapefruit
- Meat
- Chocolate
- Wheat bran
- Milk
- Coconut
- Legumes
- Refined sugar
- Bananas

The person with manifestations of hypomagnesaemia is treated with parenteral magnesium sulfate. Treatment is continued for several days to restore intracellular magnesium levels. Magnesium may be given intravenously or by deep intramuscular injection. Renal function is evaluated prior to administration, and serum magnesium levels are monitored during treatment. The intravenous route is used for severe magnesium deficiency or if neurological changes or cardiac arrhythmias are present. See the 'Medication administration' box below for the nursing implications of parenteral magnesium sulfate.

Nursing care

Health promotion

Discuss the importance of maintaining adequate magnesium intake through a well-balanced diet, particularly with those at risk (people with alcoholism, malabsorption or bowel surgery). Many hospitalised people are at risk of hypomagnesaemia due to protein–kilojoule malnutrition and other disorders. Monitor serum magnesium levels, reporting changes to the healthcare provider.

Assessment

In addition to asking questions related to risk factors for hypomagnesaemia, use the guidelines for assessing the person with hypokalaemia and hypocalcaemia for subjective and objective assessment data. Monitor diagnostic studies such as serum electrolytes, serum albumin levels and the ECG. Monitor GI function, including bowel sounds and abdominal distension.

Nursing diagnoses and interventions

Nursing care for the person with hypomagnesaemia focuses on careful monitoring of manifestations and responses to treatment, promoting safety, the person and family education, and administering prescribed medications.

Risk of injury

- Monitor serum electrolytes, including magnesium, potassium and calcium. *Magnesium deficiency often is accompanied by deficiencies of potassium and calcium.*
- Monitor gastrointestinal function, including bowel sounds and abdominal distension. *Hypomagnesaemia reduces gastrointestinal motility.*
- Initiate cardiac monitoring, reporting and treating (as indicated) ECG changes and arrhythmias. In the person receiving digitalis, monitor for digitalis toxicity. *Low magnesium levels can precipitate ventricular arrhythmias, including lethal arrhythmias such as ventricular fibrillation.*
- Assess deep tendon reflexes frequently during intravenous magnesium infusions and prior to each intramuscular dose. *Depressed tendon reflexes indicate a high serum magnesium level.*
- Maintain a quiet, darkened environment. Institute seizure precautions. *Increased neuromuscular and CNS irritability can lead to seizures. A quiet, dark environment reduces stimuli.*

Community-based care

Prior to discharge, instruct the person to increase dietary intake of foods high in magnesium and provide information about magnesium supplements. In addition, if alcohol abuse has precipitated a magnesium deficit, discuss alcohol treatment options, including inpatient treatment and support groups such as Alcoholics Anonymous, Al-Anon and/or Al Teen.

The person with hypermagnesaemia

Hypermagnesaemia is a serum magnesium level greater than 2.6 mg/dL. It is much less common than hypomagnesaemia. Hypermagnesaemia can develop in renal failure, particularly if magnesium is administered parenterally or orally (e.g. magnesium-containing antacids or laxatives). Older adults are at risk of hypermagnesaemia, as renal function declines with

MEDICATION ADMINISTRATION Magnesium sulfate

Magnesium sulfate is used to prevent or treat hypomagnesaemia. It is also used as an anticonvulsant in severe eclampsia or pre-eclampsia. It may be given intravenously or by intramuscular injection.

NURSING RESPONSIBILITIES

- Assess serum magnesium levels and renal function tests (serum urea and creatinine) prior to administering. Notify the attending doctor if magnesium levels are above normal limits or renal function is impaired.
- Frequently monitor neurological status and deep tendon reflexes during therapy. Withhold magnesium and notify the attending doctor if deep tendon reflexes are hypoactive or absent.
- Monitor intake and output.
- Administer IM doses deep into the ventral or dorsal gluteal sites.
- Intravenous magnesium sulfate may be given slowly by IV or by continuous infusion.

HEALTH EDUCATION FORTHE PERSON AND FAMILY

Explain purpose and duration of treatment. Discuss reason for frequent neurological and reflex assessments.

ageing and they are more likely to use over-the-counter laxatives and other preparations that contain magnesium.

Pathophysiology and manifestations

Elevated serum magnesium levels interfere with neuromuscular transmission and depress the central nervous system. Hypermagnesaemia also affects the cardiovascular system, potentially causing hypotension, flushing, sweating and brady-arrhythmias.

Predictable manifestations occur with increasing serum magnesium levels. With lower levels, nausea and vomiting, hypotension, facial flushing, sweating and a feeling of warmth occur. As levels increase, signs of CNS depression appear (weakness, lethargy, drowsiness, weak or absent deep tendon reflexes). Marked elevations cause respiratory depression, coma and compromised cardiac function (ECG changes, bradycardia, heart block and cardiac arrest).

INTERPROFESSIONAL CARE

The management of hypermagnesaemia focuses on identifying and treating the underlying cause. All medications or compounds containing magnesium (such as antacids, intravenous solutions or enemas) are withheld. In the person with renal failure, haemodialysis or peritoneal dialysis is instituted to remove the excess magnesium.

Calcium gluconate is administered intravenously to reverse the neuromuscular and cardiac effects of hypermagnesaemia. The person may require mechanical ventilation to support respiratory function and a pacemaker to maintain adequate cardiac output.

Nursing care

Nursing care includes instituting measures to prevent and identify hypermagnesaemia in the person at risk, monitoring for critical effects of hypermagnesaemia and providing measures to ensure the person's safety. Consider the following nursing diagnoses for the person with hypermagnesaemia:

- *Decreased cardiac output* related to altered myocardial conduction.
- *Risk of ineffective breathing pattern* related to respiratory depression.
- *Risk of injury* related to muscle weakness and altered level of consciousness.
- *Risk of ineffective health maintenance* related to lack of knowledge about use of magnesium-containing supplements, antacids, laxatives and enemas.

Community-based care

Discharge teaching and planning focus on instructions to avoid magnesium-containing medications, including antacids, mineral supplements, cathartics and enemas (see Box 9.9).

BOX 9.9 Medications containing magnesium

Antacids
- Gelusil
- Milk of magnesia
- Mylanta
- Gaviscon

Laxatives
- Milk of magnesia
- Magnesium oxide
- Magnesium citrate
- Epsom salts

PHOSPHATE IMBALANCE

Although most phosphate (85%) is found in bones, it is the primary intracellular anion. About 14% is in intracellular fluid and the remainder (1%) is in extracellular fluid. The normal serum phosphate (or phosphorus) level in adults is 2.5 to 4.5 mg/dL. Phosphorus levels vary with age, gender and diet.

Overview of normal phosphate balance

Phosphate is essential to intracellular processes such as the production of ATP, the fuel that supports muscle contraction, nerve cell transmission and electrolyte transport. Phosphate is vital for red blood cell function and oxygen delivery to tissues; nervous system and muscle function; and the metabolism of fats, carbohydrates and protein. It also assists in maintaining acid–base balance.

Phosphorus is ingested in the diet, absorbed in the jejunum and primarily excreted by the kidneys. When phosphate intake is low, the kidneys conserve phosphorus, excreting less. An inverse relationship exists between phosphate and calcium levels: when one increases, the other decreases. Regulatory mechanisms for calcium levels (parathyroid hormone, calcitonin and vitamin D) also influence phosphate levels. The causes and manifestations of phosphate imbalances are summarised in Table 9.10.

The person with hypophosphataemia

Hypophosphataemia is a serum phosphorus of less than 2.5 mg/dL. Low serum phosphate levels may indicate a total body deficit of phosphate or a shift of phosphate into the intracellular space, the most common cause of hypophosphataemia. Decreased gastrointestinal absorption of phosphate or increased renal excretion of phosphate also can cause low phosphate levels. Hypophosphataemia often is *iatrogenic*—that is, related to treatment. Selected causes of hypophosphataemia include the following:

- *Refeeding syndrome* can develop when the malnourished person is started on enteral or total parenteral nutrition. Glucose in the formula or solution stimulates insulin release, which promotes the entry of glucose and phosphate into the cells, depleting extracellular phosphate levels.
- Medications frequently contribute to hypophosphataemia, including intravenous glucose solutions, antacids (aluminium- or magnesium-based antacids bind with phosphate), anabolic steroids and diuretics.
- Alcoholism affects both the intake and absorption of phosphate.

TABLE 9.10 Causes and manifestations of phosphate imbalances

IMBALANCE	CAUSES	MANIFESTATIONS
Hypophosphataemia Serum phosphorus < 2.5 mg/dL Critical value < 1 mg/dL	• Shift of phosphorus into cells • IV glucose administration • Total parenteral nutrition without phosphorus • Aluminium- or magnesium-based antacids • Diuretic therapy • Alcoholism	• Paraesthesias • Muscle weakness • Muscle pain and tenderness • Confusion, decreasing level of consciousness • Seizures • Bone pain, osteomalacia • Anorexia, dysphagia • Decreased bowel sounds • Possible acute respiratory failure
Hyperphosphataemia Serum phosphate > 4.5 mg/dL Critical value > 90 mg/dL	• Renal failure • Chemotherapy • Muscle tissue trauma • Sepsis • Severe hypothermia • Heat stroke	• Circumoral and peripheral paraesthesias • Muscle spasms • Tetany • Soft tissue calcification

- Hyperventilation and respiratory alkalosis cause phosphate to shift out of extracellular fluids into the intracellular space.
- Other causes include diabetic ketoacidosis with excess phosphate loss in the urine, stress responses and extensive burns.

Pathophysiology and manifestations

Most effects of hypophosphataemia result from depletion of ATP and impaired oxygen delivery to the cells due to a deficiency of the red blood cell enzyme 2,3-DPG. Severe hypophosphataemia affects virtually every major organ system:

- *Central nervous system*: reduced oxygen and ATP synthesis in the brain causes neurological manifestations such as irritability, apprehension, weakness, paraesthesias, lack of coordination, confusion, seizures and coma.
- *Haematological*: oxygen delivery to the cells is reduced. Haemolytic anaemia (excessive red blood cell destruction) may develop due to lack of ATP in red blood cells.
- *Musculoskeletal*: decreased ATP causes muscle weakness and release of creatinine phosphokinase (CPK, a muscle enzyme); acute rhabdomyolysis (muscle cell breakdown) can develop. Muscle cell destruction, in turn, can lead to acute renal failure as myoglobin, a muscle cell protein, exerts a toxic effect on the kidney tubule.
- *Respiratory*: chest muscle weakness can interfere with effective ventilation, leading to respiratory failure.
- *Cardiovascular*: hypophosphataemia decreases myocardial contractility; decreased oxygenation of the heart muscle can cause chest pain and arrhythmias.
- *Gastrointestinal*: anorexia can occur, as well as dysphagia (difficulty swallowing), nausea and vomiting, decreased bowel sounds and possible ileus due to reduced gastrointestinal motility.

INTERPROFESSIONAL CARE

Treatment for hypophosphataemia is directed at prevention, treating the underlying cause of the disorder and replacing phosphate. An improved diet and oral phosphate supplement may restore normal phosphate levels in the person with a mild to moderate deficiency. Intravenous phosphate (sodium phosphate or potassium phosphate) is given when serum phosphate levels are less than 1 mg/dL. Oral phosphate supplements are then continued for up to 1 week to restore intracellular phosphate levels (Metheny, 2012).

Nursing care

Nurses can be instrumental in identifying the person at risk of phosphate deficiency and preventing it from developing. Nurses should closely monitor serum electrolyte values in the person at risk, including those who are malnourished, receiving intravenous glucose solutions or total parenteral nutrition, or being treated with diuretic therapy or antacids that bind with phosphate. Nursing diagnoses that may be appropriate for the person with hypophosphataemia include:

- *impaired physical mobility* related to muscle weakness and poor coordination
- *ineffective breathing pattern* related to weakened muscles of respiration
- *decreased cardiac output* related to reduced myocardial contractility
- *risk of injury* related to muscle weakness and altered mental status.

Community-based care

In preparing for discharge, educate the person and family about the causes and manifestations of hypophosphataemia. Discuss the importance of avoiding phosphorus-binding antacids, unless prescribed. Stress the need for a well-balanced diet to maintain an adequate intake of phosphate.

The person with hyperphosphataemia

Hyperphosphataemia is a serum phosphate level greater than 4.5 mg/dL. As with other electrolyte imbalances, it may be the result of impaired phosphate excretion, excess intake or a shift of phosphate from the intracellular space into extracellular fluids.

- Acute or chronic renal failure is the primary cause of impaired phosphate excretion.
- Rapid administration of phosphate-containing solutions can increase serum phosphate levels. This can include phosphate enemas. In addition, excess vitamin D increases phosphate absorption and can lead to hyperphosphataemia in the person with impaired renal function.
- A shift of phosphate from the intracellular to the extracellular space can occur during chemotherapy, due to sepsis or hypothermia, or because of extensive trauma or heat stroke.
- Because phosphate levels are affected by serum calcium concentrations, disruption of the mechanisms that regulate calcium levels (e.g. hypoparathyroidism, hyperthyroidism or vitamin D intoxication) can lead to hyperphosphataemia.

Pathophysiology and manifestations

Excessive serum phosphate levels cause few specific symptoms. The effects of high serum phosphate levels on nerves and muscles (muscle cramps and pain, paraesthesias, tingling around the mouth, muscle spasms, tetany) are more the result of hypocalcaemia that develops secondary to an elevated serum phosphorus level. The phosphate in the serum combines with ionised calcium and the ionised serum calcium level falls.

Calcification of soft tissues can occur with high phosphate levels. Phosphates bind with calcium to precipitate in soft tissues such as the kidneys and other organs. Soft tissue calcification can impair the function of affected organs.

INTERPROFESSIONAL CARE

Treatment of the underlying disorder often corrects hyperphosphataemia. When this is not feasible, phosphate-containing drugs are eliminated and intake of phosphate-rich foods such as organ meats and milk and milk products is restricted. Agents that bind with phosphate in the GI tract (such as calcium-containing antacids) may be prescribed. If renal function is adequate, intravenous normal saline may be given to promote renal excretion of phosphate. Dialysis may be necessary to reduce phosphate levels in the person with renal failure.

Nursing care

When providing nursing care for the person with hyperphosphataemia, monitor the person for laboratory data revealing an excess of phosphorus and a deficit of calcium, as well as the signs of hypocalcaemia.

Community-based care

Discuss the risk of hyperphosphataemia related to using phosphate preparations as laxatives or enemas, particularly with the person who has other risk factors for the disorder. When preparing the person for discharge, teach about the use of phosphate-binding preparations as ordered and dietary phosphate restrictions.

ACID–BASE DISORDERS

Homeostasis and optimal cellular function require maintenance of the hydrogen ion (H^+) concentration of body fluids within a relatively narrow range. Hydrogen ions determine the relative acidity of body fluids. **Acids** release hydrogen ions in solution; **bases** (or **alkalis**) accept hydrogen ions in solution. The hydrogen ion concentration of a solution is measured as its pH. The relationship between hydrogen ion concentration and pH is inverse; that is, as hydrogen ion concentration increases, the pH falls and the solution becomes more acidic. As hydrogen ion concentration falls, the pH rises and the solution becomes more alkaline or basic. The pH of body fluids is slightly basic, with the normal pH ranging from 7.35 to 7.45. (A pH of 7 is neutral.)

REGULATION OF ACID–BASE BALANCE

A number of mechanisms work together to maintain the pH of the body within this normal range. Metabolic processes in the body continuously produce acids, which fall into two categories: volatile acids and non-volatile acids. **Volatile acids** can be eliminated from the body as a gas. Carbonic acid (H_2CO_3) is the only volatile acid produced in the body. It dissociates (separates) into carbon dioxide (CO_2) and water (H_2O); the carbon dioxide is then eliminated from the body through the lungs. All other acids produced in the body are *non-volatile acids* that must be metabolised or excreted from the body in fluid. Lactic acid, hydrochloric acid, phosphoric acid and sulfuric acid are examples of non-volatile acids. Most acids and bases in the body are weak; that is, they neither release nor accept a significant amount of hydrogen ions.

Three systems work together in the body to maintain the pH despite continuous acid production: buffers, the respiratory system and the renal system.

Buffer systems

Buffers are substances that prevent major changes in pH by removing or releasing hydrogen ions. When excess acid is present in body fluid, buffers bind with hydrogen ions to minimise

the change in pH. If body fluids become too basic or alkaline, buffers release hydrogen ions, restoring the pH. Although buffers act within a fraction of a second, their capacity to maintain pH is limited. The major buffer systems of the body are the bicarbonate–carbonic acid buffer system, the phosphate buffer system and protein buffers.

The bicarbonate–carbonic acid buffer system can be illustrated by the following equation:

$$CO_2 + H_2O \leftrightarrow H_2CO_3 \leftrightarrow H^+ + HCO_3^-$$

Bicarbonate (HCO_3^-) is a weak base; when an acid is added to the system, the hydrogen ion in the acid combines with bicarbonate and the pH changes only slightly. Carbonic acid (H_2CO_3) is a weak acid produced when carbon dioxide dissolves in water. If a base is added to the system, it combines with carbonic acid and the pH remains within the normal range. Although the amounts of bicarbonate and carbonic acid in the body vary to a certain extent, as long as a ratio of 20 parts bicarbonate (HCO_3^-) to 1 part carbonic acid (H_2CO_3) is maintained, the pH remains within the 7.35 to 7.45 range (see Figure 9.14).

The normal serum bicarbonate level is 24 mEq/L and that of carbonic acid is 1.2 mEq/L. Thus, the ratio of bicarbonate to carbonic acid is 20:1. It is this ratio that maintains the pH within the normal range. Adding a strong acid to extracellular fluid depletes bicarbonate, changing the 20:1 ratio and causing the pH to drop below 7.35. This is known as **acidosis**. Addition of a strong base depletes carbonic acid as it combines with the base. The 20:1 ratio again is disrupted and the pH rises above 7.45, a condition known as **alkalosis**.

Intracellular and plasma proteins also serve as buffers. Plasma proteins contribute to buffering of extracellular fluids. Proteins in intracellular fluid provide extensive buffering for organic acids produced by cellular metabolism. In red blood cells, haemoglobin acts as a buffer for hydrogen ions when carbonic acid dissociates. Inorganic phosphates also serve as extracellular buffers, although their roles are not as important as the bicarbonate–carbonic acid buffer system. Phosphates are, however, important intracellular buffers, helping to maintain a stable pH within cells.

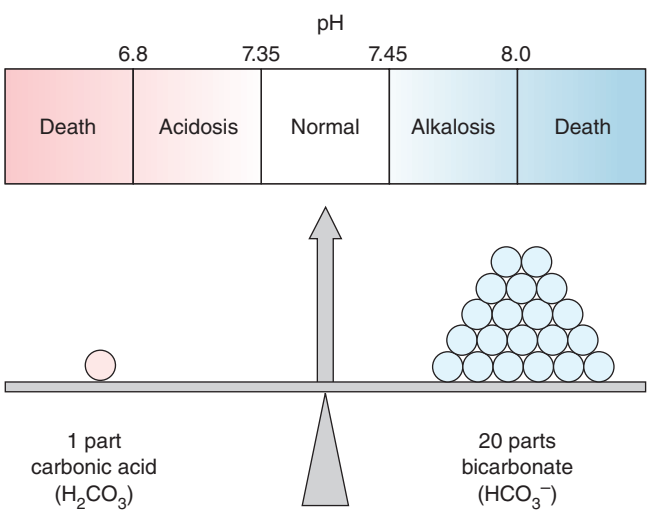


FIGURE 9.14 ■ The normal ratio of bicarbonate to carbonic acid is 20:1. As long as this ratio is maintained, the pH remains within the normal range of 7.35 to 7.45

Respiratory system

The respiratory system (and the respiratory centre of the brain) regulates carbonic acid in the body by eliminating or retaining carbon dioxide. Carbon dioxide is a potential acid; when combined with water, it forms carbonic acid (see previous equation), a volatile acid. Acute increases in either carbon dioxide or hydrogen ions in the blood stimulate the respiratory centre in the brain. As a result, both the rate and depth of respiration increase. The increased rate and depth of lung ventilation eliminate carbon dioxide from the body and carbonic acid levels fall, bringing the pH to a more normal range. Although this compensation for increased hydrogen ion concentration occurs within minutes, it becomes less effective over time. The person with chronic lung disease may have consistently high carbon dioxide levels in their blood.

Alkalosis, by contrast, depresses the respiratory centre. Both the rate and depth of respiration decrease and carbon dioxide is retained. The retained carbon dioxide then combines with water to restore carbonic acid levels and bring the pH back within the normal range.

Renal system

The renal system is responsible for the long-term regulation of acid–base balance in the body. Excess non-volatile acids produced during metabolism normally are eliminated by the kidneys. The kidneys also regulate bicarbonate levels in extracellular fluid by regenerating bicarbonate ions as well as reabsorbing them in the renal tubules. Although the kidneys respond more slowly to changes in pH (over hours to days), they can generate bicarbonate and selectively excrete or retain hydrogen ions as needed. In acidosis, when excess hydrogen ion is present and the pH falls, the kidneys excrete hydrogen ions and retain bicarbonate. In alkalosis, the kidneys retain hydrogen ions and excrete bicarbonate to restore acid–base balance.

Assessment of acid–base balance

Acid–base balance is evaluated primarily by measuring arterial blood gases (ABGs).

CONSIDERATION FOR PRACTICE

Arteries are high-pressure vessels, in contrast to veins. Obtaining an arterial blood sample requires specialised training. It may be done by a doctor, a Registered Nurse, a respiratory therapist or a laboratory technician who has been trained in drawing ABGs. Apply firm pressure to the puncture site for 2 to 5 minutes after the needle is withdrawn to prevent bleeding into the surrounding tissues.

Arterial blood is used because it reflects acid–base balance throughout the entire body better than venous blood. Arterial blood also provides information about the effectiveness of the lungs in oxygenating blood. The elements measured are pH, $PaCO_2$, PaO_2 and bicarbonate level.

The **$PaCO_2$** measures the pressure exerted by dissolved carbon dioxide in the blood, and reflects the respiratory component of acid–base regulation and balance. The $PaCO_2$ is regulated by the lungs. The normal value is 35 to 45 mmHg. A $PaCO_2$ of less than 35 mmHg is known as *hypocapnia*; a $PaCO_2$ greater than 45 mmHg is *hypercapnia*.

The **PaO_2** is a measure of the pressure exerted by oxygen that is dissolved in the plasma. Only about 3% of oxygen in the blood is transported in solution; most is combined with haemoglobin. However, it is the dissolved oxygen that is available to the cells for metabolism. As dissolved oxygen diffuses out of plasma into the tissues, more is released from haemoglobin. The normal value for PaO_2 is 80 to 100 mmHg. A PaO_2 of less than 80 mmHg is indicative of *hypoxaemia*. The PaO_2 is valuable for evaluating respiratory function, but is not used as a primary measurement in determining acid–base status.

CONSIDERATION FOR PRACTICE

You will see the abbreviations $PaCO_2$ and PaO_2 used interchangeably with PCO_2 and PO_2. The 'P' stands for partial pressure: the pressure exerted by the gas dissolved in the blood. The 'a' indicates that the sample is arterial blood. Because these measurements rarely are done on venous blood, the 'a' is often omitted from the abbreviation.

The **serum bicarbonate** (HCO_3^-) reflects the renal regulation of acid–base balance. It is often called the metabolic component of arterial blood gases. The normal HCO_3^- value is 22 to 26 mEq/L.

The **base excess (BE)** is a calculated value also known as *buffer base capacity*. The base excess measures substances that can accept or combine with hydrogen ions. It reflects the degree of acid–base imbalance by indicating the status of the body's total buffering capacity. It represents the amount of acid or base that must be added to a blood sample to achieve a pH of 7.4. This is essentially a measure of increased or decreased bicarbonate. The normal value for base excess for arterial blood is –3.0 to +3.0. Normal ABG values are summarised in Table 9.11.

TABLE 9.11 Normal arterial blood gas values

VALUE	NORMAL RANGE	SIGNIFICANCE
pH	7.35 to 7.45	Reflects hydrogen ion (H^+) concentration • < 7.35 = acidosis • > 7.45 = alkalosis
$PaCO_2$	35 to 45 mmHg	Partial pressure of carbon dioxide (CO_2) in arterial blood • < 35 mmHg = hypocapnia • > 45 mmHg = hypercapnia
PaO_2	80 to 100 mmHg	Partial pressure of oxygen (O_2) in arterial blood • < 80 mmHg = hypoxaemia
HCO_3^-	22 to 26 mEq/L	Bicarbonate concentration in plasma
BE	–3 to +3	Base excess; a measure of buffering capacity

ABGs are analysed to identify acid–base disorders and their probable cause, to determine the extent of the imbalance and to monitor treatment. When analysing ABG results, it is important to use a systematic approach. First evaluate each individual measurement, then look at the interrelationships to determine the person's acid–base status (see Box 9.10).

BOX 9.10 Interpreting arterial blood gases

1. Look at the pH.
   - pH < 7.35 = acidosis
   - pH > 7.45 = alkalosis
2. Look at the $PaCO_2$.
   - $PaCO_2$ < 35 mmHg = hypocapnia; more carbon dioxide is being exhaled than normal
   - $PaCO_2$ > 45 mmHg = hypercapnia; carbon dioxide is being retained
3. Evaluate the pH–$PaCO_2$ relationship for a possible respiratory problem.
   - If the pH is < 7.35 (acidosis) and the $PaCO_2$ is > 45 mmHg (hypercapnia), retained carbon dioxide is causing increased H^+ concentration and respiratory acidosis.
   - If the pH is > 7.45 (alkalosis) and the $PaCO_2$ is < 35 mmHg (hypocapnia), low carbon dioxide levels and decreased H^+ concentration are causing respiratory alkalosis.
4. Look at the bicarbonate.
   - If the HCO_3^- is < 22 mEq/L, bicarbonate levels are lower than normal.
   - If the HCO_3^- is > 26 mEq/L, bicarbonate levels are higher than normal.
5. Evaluate the pH, HCO_3^- and BE for a possible metabolic problem.
   - If the pH is < 7.35 (acidosis), the HCO_3^- is < 22 mEq/L and the BE is < –3 mEq/L, then low bicarbonate levels and high H^+ concentrations are causing metabolic acidosis.
   - If the pH is > 7.45 (alkalosis), the HCO_3^- is > 26 mEq/L and the BE is > +3 mEq/L, then high bicarbonate levels are causing metabolic alkalosis.
6. Look for compensation.
   Renal compensation:
   - In respiratory acidosis (pH < 7.35, $PaCO_2$ > 45 mmHg), the kidneys retain HCO_3^- to buffer the excess acid, so the HCO_3^- is > 26 mEq/L.
   - In respiratory alkalosis (pH > 7.45, $PaCO_2$ < 35 mmHg), the kidneys excrete HO_3^- to minimise the alkalosis, so the HCO_3^- is < 22 mEq/L.

   Respiratory compensation:
   - In metabolic acidosis (pH < 7.35, HCO_3^- < 22 mEq/L), the rate and depth of respirations increase, increasing carbon dioxide elimination, so the $PaCO_2$ is < 35 mmHg.
   - In metabolic alkalosis (pH > 7.45, HCO_3^- > 26 mEq/L), respirations slow, carbon dioxide is retained, so the $PaCO_2$ is > 45 mmHg.
7. Evaluate oxygenation.
   - PaO_2 < 80 mmHg = hypoxaemia; possible hypoventilation
   - PaO_2 > 100 mmHg = hyperventilation

ACID–BASE IMBALANCE

Acid–base imbalances fall into two major categories: acidosis and alkalosis. Acidosis occurs when the hydrogen ion concentration increases above normal (pH below 7.35). Alkalosis occurs when the hydrogen ion concentration falls below normal (pH above 7.45).

Acid–base imbalances are further classified as *metabolic* or *respiratory* disorders. In metabolic disorders, the primary change is in the concentration of bicarbonate. In metabolic acidosis, the amount of bicarbonate is decreased in relation to the amount of acid in the body (see Figure 9.15A). It can develop as a result of abnormal bicarbonate losses or because of excess non-volatile acids in the body. The pH falls below 7.35 and the bicarbonate concentration is less than 22 mEq/L. Metabolic alkalosis, by contrast, occurs when there is an excess of bicarbonate in relation to the amount of hydrogen ion (see Figure 9.15B). The pH is above 7.45 and the bicarbonate concentration is greater than 26 mEq/L.

In respiratory disorders, the primary change is in the concentration of carbonic acid. Respiratory acidosis occurs when carbon dioxide is retained, increasing the amount of carbonic acid in the body (see Figure 9.16A). As a result, the pH falls to less than 7.35 and the $PaCO_2$ is greater than 45 mmHg. When too much carbon dioxide is 'blown off', carbonic acid levels fall and respiratory alkalosis develops (see Figure 9.16B). The pH rises to above 7.45 and the $PaCO_2$ is less than 35 mmHg.

Acid–base disorders are further defined as primary (simple) and mixed. Primary disorders usually are due to one cause. For example, respiratory failure often causes respiratory acidosis due

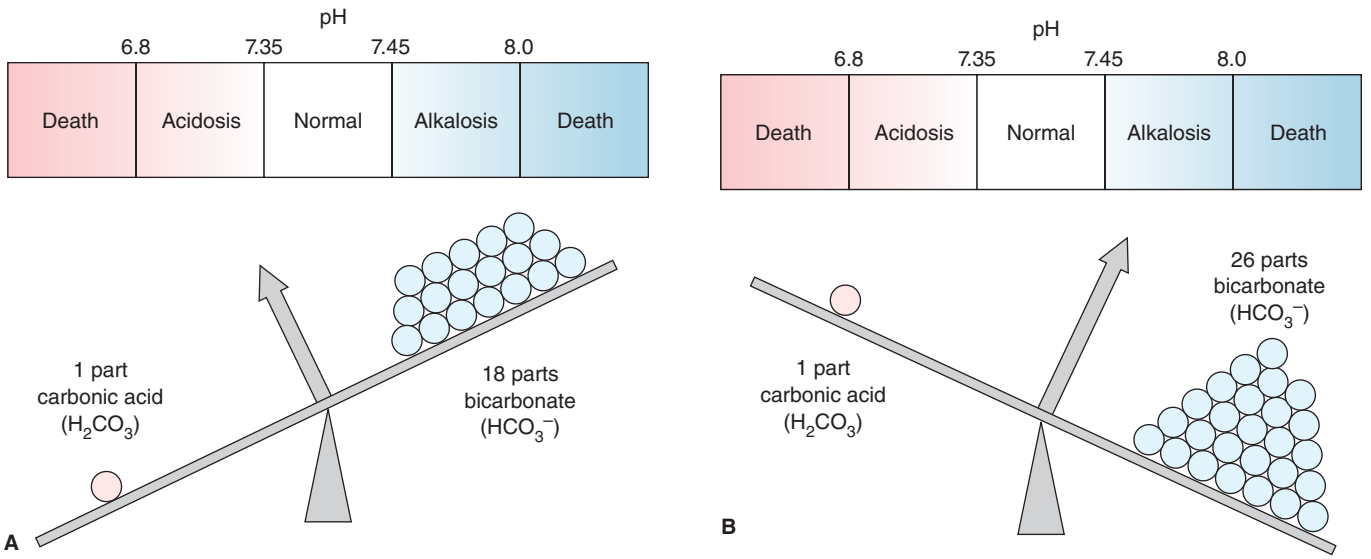

FIGURE 9.15 ■ Metabolic acid–base imbalances. *A*, Metabolic acidosis. *B*, Metabolic alkalosis

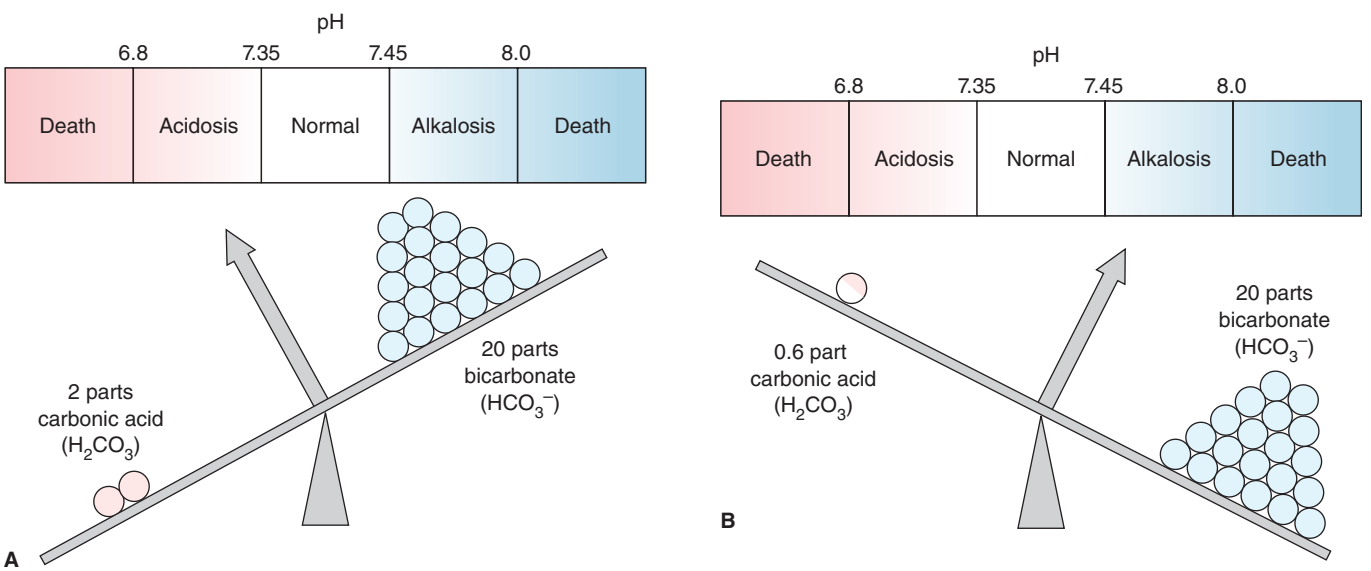

FIGURE 9.16 ■ Respiratory acid–base imbalances. *A*, Respiratory acidosis. *B*, Respiratory alkalosis

to retained carbon dioxide; renal failure usually causes metabolic acidosis due to retained hydrogen ion and impaired bicarbonate production. Table 9.12 summarises primary acid–base imbalances with common causes of each. Mixed disorders occur from combinations of respiratory and metabolic disturbances. For example, a person in cardiac arrest develops a mixed respiratory and metabolic acidosis due to lack of ventilation (and retained CO_2) and hypoxia of body tissues that leads to anaerobic metabolism and acid by-products (excess non-volatile acids).

FAST FACTS

- Simple acid–base imbalances are more commonly seen than mixed imbalances. Common causes of simple acid–base imbalances include:
  - diabetic ketoacidosis (metabolic acidosis)
  - chronic obstructive lung disease (respiratory acidosis)
  - anxiety-related (psychogenic) hyperventilation (respiratory alkalosis).
- The critically ill person is at higher risk of mixed acid–base imbalances.

Compensation

With primary acid–base disorders, compensatory changes in the other part of the regulatory system occur to restore a normal pH and homeostasis. In metabolic acid–base disorders, the change in pH affects the rate and depth of respirations. Therefore, this affects carbon dioxide elimination and the $PaCO_2$, helping restore the carbonic acid to bicarbonate ratio. The kidneys compensate for simple respiratory imbalances. The change in pH affects both bicarbonate conservation and hydrogen ion elimination (see Table 9.12).

Compensatory changes in respirations occur within minutes of a change in pH. These changes, however, become less effective over time. The renal response takes longer to restore the pH, but is a more effective long-term mechanism. If the pH is restored to within normal limits, the disorder is said to be *fully compensated*. When these changes are reflected in ABG values but the pH remains outside normal limits, the disorder is said to be *partially compensated*.

The person with metabolic acidosis

Metabolic acidosis (bicarbonate deficit) is characterised by a low pH (< 7.35) and a low bicarbonate (< 22 mEq/L). It may be

TABLE 9.12 Common causes of primary acid–base imbalances

IMBALANCE	COMMON CAUSES
Metabolic acidosis pH < 7.35 HCO_3^- < 22 mEq/L *Critical values* pH < 7.20 HCO_3^- < 10 mEq/L	↑ Acid production • Lactic acidosis • Ketoacidosis related to diabetes, starvation or alcoholism • Salicylate toxicity ↓ Acid excretion • Renal failure ↑ Bicarbonate loss • Diarrhoea, ileostomy drainage, intestinal fistula • Biliary or pancreatic fistulas ↑ Chloride • Sodium chloride IV solutions • Renal tubular acidosis • Carbonic anhydrase inhibitors
Metabolic alkalosis pH > 7.45 HCO_3^- > 26 mEq/L *Critical values* pH > 7.60 HCO_3^- > 40 mEq/L	↑ Acid loss or excretion • Vomiting, gastric suction • Hypokalaemia ↑ Bicarbonate • Alkali ingestion (bicarbonate of soda) • Excess bicarbonate administration
Respiratory acidosis pH < 7.35 $PaCO_2$ > 45 mmHg *Critical values* pH < 7.2 $PaCO_2$ > 77 mmHg	Acute respiratory acidosis • Acute respiratory conditions (pulmonary oedema, pneumonia, acute asthma) • Opiate overdose • Foreign body aspiration • Chest trauma Chronic respiratory acidosis • Chronic respiratory conditions (COPD, cystic fibrosis) • Multiple sclerosis, other neuromuscular diseases • Stroke
Respiratory alkalosis pH > 7.45 $PaCO_2$ > 35 mmHg *Critical values* pH > 7.60 $PaCO_2$ < 20 mmHg	• Anxiety-induced hyperventilation (e.g. anxiety) • Fever • Early salicylate intoxication • Hyperventilation with mechanical ventilator

caused by excess acid in the body or loss of bicarbonate from the body. When metabolic acidosis develops, the respiratory system attempts to return the pH to normal by increasing the rate and depth of respirations. Carbon dioxide elimination increases and the $PaCO_2$ falls (< 35 mmHg).

Risk factors

Metabolic acidosis rarely is a primary disorder; it usually develops during the course of another disease:

- *Acute lactic acidosis* usually results from tissue hypoxia due to shock or cardiac arrest.
- A person with type 1 diabetes mellitus is at risk of developing *diabetic ketoacidosis*. (See Chapter 19 for more information about diabetes and its complications.)
- *Acute* or *chronic renal failure* impairs the excretion of metabolic acids.
- Diarrhoea, intestinal suction or abdominal fistulas increase the *risk of excess bicarbonate loss*.

Other common causes of metabolic acidosis are listed in Table 9.12.

Pathophysiology

Three basic mechanisms that can cause metabolic acidosis are:

- accumulation of metabolic acids
- excess loss of bicarbonate
- an increase in chloride levels.

An accumulation of metabolic acids can result from excess acid production or impaired elimination of metabolic acids by the kidney. Lactic acidosis develops due to tissue hypoxia and a shift to anaerobic metabolism by the cells. Lactate and hydrogen ions are produced, forming lactic acid. Both oxygen and glucose are necessary for normal cell metabolism. When intracellular glucose is inadequate due to starvation or a lack of insulin to move it into cells, the body breaks down fatty tissue to meet its metabolic needs. In this process, fatty acids are released, which are converted to ketones; ketoacidosis develops. Aspirin (acetylsalicylic acid) breaks down into salicylic acid in the body. Substances such as aspirin, methanol (wood alcohol) and ethylene (contained in antifreeze and solvents) cause a toxic increase in body acids by either breaking down into acid products (salicylic acid) or stimulating metabolic acid production (Grossman & Porth, 2014). Renal failure impairs the body's ability to excrete excess hydrogen ions and form bicarbonate.

Excess metabolic acids increase the hydrogen ion concentration of body fluids. The excess acid is buffered by bicarbonate, leading to what is known as a high **anion gap** acidosis (see Box 9.11).

The pancreas secretes bicarbonate-rich fluid into the small intestine. Intestinal suction, severe diarrhoea, ileostomy drainage or fistulas can lead to excess loss of bicarbonate. Hyperchloraemic acidosis can develop when excess chloride solutions (such as NaCl or ammonium chloride) are infused, causing a rise in chloride concentrations. It may be related to renal disease or administration of carbonic anhydrate inhibitor diuretics. The anion gap remains normal in metabolic acidosis due to bicarbonate loss or excess chloride.

Acidosis depresses cell membrane excitability, affecting neuromuscular function. It also increases the amount of free calcium in ECF by interfering with protein binding. Severe acidosis (pH of 7.0 or less) depresses myocardial contractility, leading to a fall in cardiac output. If kidney function is normal, acid excretion and ammonia production increase to eliminate excess hydrogen ions.

Acid–base imbalances also affect electrolyte balance (see Table 9.13). In acidosis, potassium is retained as the kidney excretes excess hydrogen ions. Excess hydrogen ions also enter the cells, displacing potassium from the intracellular space to maintain the balance of cations and anions within the cells. The effect of both processes is to increase serum potassium levels. Also in acidosis, calcium is released from its bonds with plasma proteins, increasing the amount of ionised (free) calcium in the blood. Magnesium levels may fall in acidosis. See Box 9.11 for information on anion gap acidosis.

Manifestations

Metabolic acidosis affects the function of many body systems. Its general manifestations include weakness and fatigue, headache and general malaise. Gastrointestinal function is affected, causing anorexia, nausea, vomiting and abdominal pain. The level of consciousness declines, leading to stupor and coma. Cardiac arrhythmias develop and cardiac arrest may occur. The skin is often warm and flushed. Skeletal problems may develop in chronic acidosis, as calcium and phosphate are released

TABLE 9.13 Compensation for simple acid–base imbalances

PRIMARY DISORDER	CAUSE	COMPENSATION	EFFECT ON ABGs
Metabolic acidosis	Excess non-volatile acids; bicarbonate deficiency	Rate and depth of respirations increase, eliminating additional CO_2	↓ pH ↓ HCO_3^- ↓ $PaCO_2$
Metabolic alkalosis	Bicarbonate excess	Rate and depth of respirations decrease, retaining CO_2	↑ pH ↑ HCO_3^- ↑ $PaCO_2$
Respiratory acidosis	Retained CO_2 and excess carbonic acid	Kidneys conserve bicarbonate to restore carbonic acid : bicarbonate ratio of 1:20	↓ pH ↑ $PaCO_2$ ↑ HCO_3^-
Respiratory alkalosis	Loss of CO_2 and deficient carbonic acid	Kidneys excrete bicarbonate and conserve H^+ to restore carbonic acid : bicarbonate ratio	↑ pH ↓ $PaCO_2$ ↓ HCO_3^-

BOX 9.11 Unravelling the anion gap

Calculation of the anion gap can help identify the underlying mechanism in metabolic acidosis if it is unclear.

The number of cations (positively charged ions) and anions (negatively charged ions) in ECF normally is equal (see Figure 9.2). Not all of these ions, however, are measured in laboratory testing (e.g. organic acids and proteins). The anion gap is calculated by subtracting the sum of two measured anions, chloride and bicarbonate, from the concentration of the major cation, sodium (see figure). The normal anion gap is 8 to 12 mEq/L.

Excess acids in ECF are buffered by bicarbonate, reducing serum bicarbonate levels and the total measured concentration of anions. This increases the anion gap (B in figure). When bicarbonate is lost from the body or chloride levels increase, however, the anion gap remains within normal limits (C in figure). This occurs because an increase or decrease in one of these negatively charged ions causes a corresponding change in the other to maintain balance (e.g. $\downarrow HCO_3^- \leftrightarrow \uparrow Cl^-$) and there is no change in the amount of unmeasured anions.

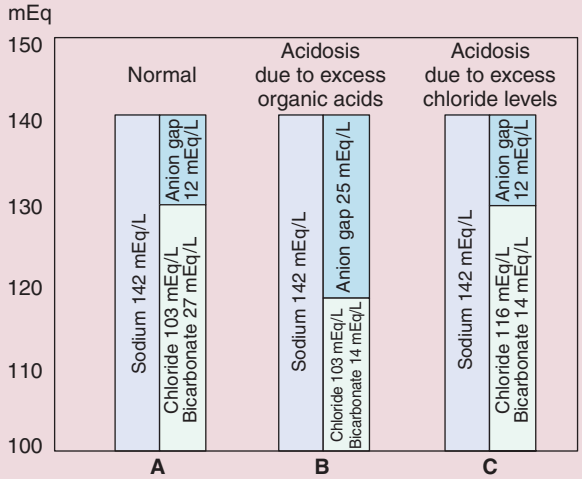

Illustration of the anion gap in metabolic acidosis. *A*, Normal anion gap. *B*, High anion gap caused by excess acids. *C*, Normal anion gap with hyperchloremia

from the bones. Manifestations of compensatory mechanisms are seen. The respirations are deep and rapid, known as Kussmaul's respirations. The person may complain of shortness of breath or dyspnoea. (See 'Manifestations' box below.)

MANIFESTATIONS Metabolic acidosis

- Anorexia
- Nausea and vomiting
- Abdominal pain
- Weakness
- Fatigue
- General malaise
- Decreasing levels of consciousness
- Arrhythmias
- Bradycardia
- Warm, flushed skin
- Hyperventilation (Kussmaul's respirations)

INTERPROFESSIONAL CARE

Management of metabolic acidosis focuses on treating the underlying cause of the disorder and correcting the acid–base imbalance.

Diagnosis

The following laboratory and diagnostic tests may be ordered:

- *ABGs* generally show a pH of less than 7.35 and a bicarbonate level of less than 22 mEq/L. A compensatory decrease in $PaCO_2$ to less than 35 mmHg is usually present.
- *Serum electrolytes* demonstrate elevated serum potassium levels and possible low magnesium levels. The total calcium may remain unchanged, although more physiologically active ionised calcium is available. Sodium, chloride and bicarbonate levels are used to calculate the anion gap.
- The *ECG* may show changes that reflect both the acidosis (particularly when severe) and the accompanying hyperkalaemia.
- Other diagnostic studies such as the blood glucose and renal function studies may be ordered to identify the underlying cause of metabolic acidosis.

Medications

An alkalinising solution such as bicarbonate may be given if the pH is less than 7.1 to reduce the effects of the acidosis on cardiac function. Sodium bicarbonate is the most commonly used alkalinising solution; others include lactate, citrate and acetate solutions (which are metabolised to bicarbonate). Alkalinising solutions are given intravenously for severe acute metabolic acidosis. In chronic metabolic acidosis, the oral route is used.

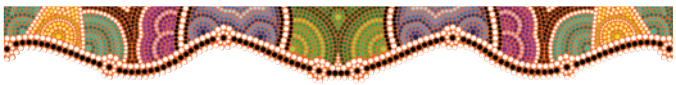
The person treated with bicarbonate must be carefully monitored. Rapid correction of the acidosis may lead to metabolic alkalosis and hypokalaemia. Hypernatraemia and hyperosmolality may develop as well, leading to water retention and fluid overload.

CONSIDERATION FOR PRACTICE

As metabolic acidosis is corrected, potassium shifts back into the intracellular space. This can lead to hypokalaemia and cardiac arrhythmias. Carefully monitor serum potassium levels during treatment.

Treatment for diabetic ketoacidosis includes intravenous insulin and fluid replacement. (See Chapter 19 for the treatment of diabetic ketoacidosis.) Alcoholic ketoacidosis is treated with saline solutions and glucose. Treatment for lactic acidosis

from decreased tissue perfusion (e.g. shock or cardiac arrest) focuses on correcting the underlying problem and improving tissue perfusion. The person with chronic renal failure and mild or moderate metabolic acidosis may or may not require treatment, depending on the pH and bicarbonate levels. When metabolic acidosis is due to diarrhoea, treatment includes correcting the underlying cause and providing fluid and electrolyte replacement.



Nursing care

Nurses frequently provide care for people diagnosed with metabolic acidosis, although the focus of care often is the disorder underlying the acidosis (e.g. diabetes mellitus, renal failure) rather than the acidosis itself. For this reason, it is vital for the nurse to be aware of the effects of the acidosis and its implications for nursing care.

Health promotion

To promote health in the person at risk of metabolic acidosis, it is important for the nurse to discuss the management of the underlying disease process (e.g. type 1 diabetes or renal failure) preventing complications such as diabetic ketoacidosis and metabolic acidosis. Because early manifestations of metabolic acidosis (e.g. fatigue, general malaise, anorexia, nausea, abdominal pain) resemble those of common viral disorders such as 'the flu', stress the importance of promptly seeking treatment if these symptoms develop.

Assessment

Assessment data related to metabolic acidosis include the following:

- *Health history*: current manifestations, including anorexia, nausea, vomiting, abdominal discomfort, fatigue, lethargy, other symptoms; duration of symptoms and any precipitating factors such as diarrhoea, ingestion of a toxin such as aspirin, methanol or ethylene; chronic diseases such as diabetes or renal failure, cirrhosis of the liver or endocrine disorders; current medications.
- *Physical assessment*: mental status and level of consciousness; vital signs including respiratory rate and depth; apical and peripheral pulses; skin colour and temperature; abdominal contour and distension; bowel sounds; urine output.
- *Diagnostic tests*: ABGs, serum electrolytes, tests for underlying disorders.

Nursing diagnoses and interventions

Nursing management of a person with metabolic acidosis often focuses on the primary disorder (e.g. diabetic ketoacidosis or renal failure); however, the acidosis itself has effects that must be attended to when providing care.

Decreased cardiac output

Metabolic acidosis affects cardiac output by decreasing myocardial contractility, slowing the heart rate and increasing the risk of arrhythmias. The accompanying hyperkalaemia increases the risk of decreased cardiac output as well (see earlier discussion about hyperkalaemia).

- Monitor vital signs, including peripheral pulses and capillary refill. *Hypotension, diminished pulse strength and slowed capillary refill may indicate decreased cardiac output and impaired tissue perfusion. Poor tissue perfusion can increase the risk of lactic acidosis.*
- Monitor the ECG pattern for arrhythmias and changes characteristic of hyperkalaemia. Notify the physician of changes. *Progressive ECG changes such as widening of the QRS complex indicate an increasing risk of arrhythmias and cardiac arrest. Arrhythmias further decrease cardiac output, possibly intensifying the degree of acidosis.*
- Monitor laboratory values, including ABGs, serum electrolytes and renal function studies (serum urea and creatinine). *Frequent monitoring of laboratory values allows evaluation of the effectiveness of treatment as well as early identification of potential problems.*

Risk of excess fluid volume

Administering bicarbonate to correct acidosis increases the risk of hypernatraemia, hyperosmolality and fluid volume excess.

- Monitor and maintain fluid replacement as ordered. Monitor serum sodium levels and osmolality. *Bicarbonate administration can cause hypernatraemia and hyperosmolality, leading to water retention.*
- Monitor heart and lung sounds, CVP and respiratory status. *Increasing dyspnoea, adventitious lung sounds, a third heart sound (S3) due to the volume of blood flow through the heart, and high CVP readings are indicative of hypervolaemia and should be reported to the attending doctor.*
- Assess for oedema, particularly in the back, sacral and periorbital areas. *Initially, oedema affects dependent tissues—the back and sacrum in the person who is bedridden. Periorbital oedema indicates more generalised oedema.*
- Assess urine output hourly. Maintain accurate intake and output records. Note urine output less than 30 mL/hour or a positive fluid balance on 24-hour total intake and output calculations. *Heart failure and inadequate renal perfusion may lead to decreased urine output.*
- Obtain daily weights using consistent conditions. *Daily weights are an accurate indicator of fluid balance.*
- Administer prescribed diuretics as ordered, monitoring the person's response to therapy. *Loop or high-ceiling diuretics such as frusemide can lead to further electrolyte imbalances, especially hypokalaemia. This is a significant risk like that seen during correction of metabolic acidosis.*

Risk of injury

Mental status and brain function are affected by acidosis, increasing the risk of injury.

- Monitor neurological function, including mental status, level of consciousness and muscle strength. *As the pH falls, mental functioning declines, leading to confusion, stupor and a decreasing level of consciousness.*

- Institute safety precautions as necessary: keep the bed in its lowest position, side rails raised. *These measures help protect the person from injury resulting from confusion or disorientation.*
- Keep clocks, calendars and familiar objects at the bedside. Orient to time, place and circumstances as needed. Allow significant others to remain with the person as much as possible. *An unfamiliar environment and altered thought processes can further increase the risk of injury. Significant others provide a sense of security and reduce anxiety.*

Nursing care also includes measures to treat the underlying disorder, such as diabetic ketoacidosis. Refer to the chapters on diabetes (Chapter 19) and renal failure (Chapter 27) for specific interventions.

Community-based care

Discharge planning and teaching focus on the underlying cause of the imbalance. The person who has developed ketoacidosis as a result of diabetes mellitus, starvation or alcoholism needs interventions and teaching to prevent future episodes of acidosis. Diet, medication management and alcohol dependency treatment are vital teaching areas. When metabolic acidosis is related to renal failure, the person should be referred for management of the renal failure itself. The person who has experienced diarrhoea or excess ileostomy drainage leading to bicarbonate loss requires information about appropriate diarrhoea treatment strategies and when to call their healthcare provider.

The person with metabolic alkalosis

Metabolic alkalosis (bicarbonate excess) is characterised by a high pH (> 7.45) and high bicarbonate (> 26 mEq/L). It may be caused by loss of acid or excess bicarbonate in the body. When metabolic alkalosis develops, the respiratory system attempts to return the pH to normal by slowing the respiratory rate. Carbon dioxide is retained and the $PaCO_2$ increases (> 45 mmHg).

Risk factors

As is the case with other acid–base imbalances, metabolic alkalosis rarely occurs as a primary disorder. Risk factors include hospitalisation, hypokalaemia and treatment with alkalinising solutions (e.g. bicarbonate).

Pathophysiology

Hydrogen ions may be lost via gastric secretions, through the kidneys or because of a shift of H^+ into the cells. Metabolic alkalosis due to loss of hydrogen ions usually occurs because of vomiting or gastric suction. Gastric secretions are highly acidic (pH 1 to 3). When these are lost through vomiting or gastric suction, the alkalinity of body fluids increases. This increased alkalinity results from both the loss of acid and selective retention of bicarbonate by the kidneys as chloride is depleted. (Chloride is the major anion in ECF; when it is lost, bicarbonate is retained as a replacement anion.)

Increased renal excretion of hydrogen ions can be prompted by hypokalaemia as the kidneys try to conserve potassium, excreting hydrogen ions instead. Hypokalaemia contributes to metabolic alkalosis in another way as well. When potassium shifts out of cells to maintain extracellular potassium levels, hydrogen ions shift into the cells to maintain the balance between cations and anions within the cell.

Excess bicarbonate usually occurs as a result of ingesting antacids that contain bicarbonate or overzealous administration of bicarbonate to treat metabolic acidosis. Common causes of metabolic alkalosis are summarised in Table 9.12.

In alkalosis, more calcium combines with serum proteins, reducing the amount of ionised (physiologically active) calcium in the blood. This accounts for many of the common manifestations of metabolic alkalosis. Alkalosis also affects potassium balance: hypokalaemia not only can cause metabolic alkalosis (see above), but it also can result from metabolic alkalosis. Hydrogen ions shift out of the intracellular space to help restore the pH, prompting more potassium to enter the cells and depleting ECF potassium. The high pH depresses the respiratory system as the body retains carbon dioxide to restore the carbonic acid to bicarbonate ratio.

Manifestations and complications

Manifestations of metabolic alkalosis (see the box below) occur as a result of decreased calcium ionisation and are similar to those of hypocalcaemia, including numbness and tingling around the mouth, fingers and toes; dizziness; Trousseau's sign; and muscle spasm. As the respiratory system compensates for metabolic alkalosis, respirations are depressed, and respiratory failure with hypoxaemia and respiratory acidosis may develop.

MANIFESTATIONS Metabolic alkalosis

- Confusion
- Decreasing level of consciousness
- Hyperreflexia
- Tetany
- Arrhythmias
- Hypotension
- Seizures
- Respiratory failure

INTERPROFESSIONAL CARE

Interprofessional management of metabolic alkalosis focuses on diagnosing and correcting the underlying cause.

Diagnosis

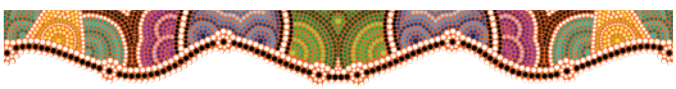
The following laboratory and diagnostic tests may be ordered:

- *ABGs* show a pH greater than 7.45 and bicarbonate level greater than 26 mEq/L. With compensatory hypoventilation, carbon dioxide is retained and the $PaCO_2$ is greater than 45 mmHg.
- *Serum electrolytes* often demonstrate decreased serum potassium (< 3.5 mEq/L) and decreased chloride (< 95 mEq/L)

levels. The serum bicarbonate level is high. Although the total serum calcium may be normal, the ionised fraction of calcium is low.
- *Urine pH* may be low (pH 1 to 3) if metabolic acidosis is caused by hypokalaemia. The kidneys selectively retain potassium and excrete hydrogen ions to restore ECF potassium levels. Urinary chloride levels may be normal or greater than 250 mEq/24 hours.
- The *ECG pattern* shows changes similar to those seen with hypokalaemia. These changes may be due to hypokalaemia or to the alkalosis.

Medications

Treatment of metabolic alkalosis includes restoring normal fluid volume and administering potassium chloride and sodium chloride solution. The potassium restores serum and intracellular potassium levels, allowing the kidneys to more effectively conserve hydrogen ions. Chloride promotes renal excretion of bicarbonate. Sodium chloride solutions restore fluid volume deficits that can contribute to metabolic alkalosis. In severe alkalosis, an acidifying solution such as dilute hydrochloric acid or ammonium chloride may be administered. In addition, drugs may be used to treat the underlying cause of the alkalosis.



Nursing care

Health promotion

Health promotion activities focus on teaching a person the risks of using sodium bicarbonate as an antacid to relieve heartburn or gastric distress. Stress the availability of other effective antacid preparations and the need to seek medical evaluation for persistent gastric symptoms. In the hospital setting, carefully monitor laboratory values for the person at risk of developing metabolic alkalosis, particularly people undergoing continuous gastric suction.

Assessment

Focused assessment data related to metabolic alkalosis include the following:
- *Health history*: current manifestations, such as numbness and tingling, muscle spasms, dizziness, other symptoms; duration of symptoms and any precipitating factors such as bicarbonate ingestion, vomiting, diuretic therapy or endocrine disorders; current medications.
- *Physical assessment*: vital signs, including apical pulse and rate and depth of respirations; muscle strength; deep tendon reflexes.
- *Diagnostic tests*: ABGs, serum electrolytes.

Nursing diagnoses and interventions

As with metabolic acidosis, nursing care of the person with metabolic alkalosis often focuses on intervening for responses to the primary problem, rather than the alkalosis itself. However, the risk of impaired gas exchange is a priority problem, especially with severe metabolic alkalosis.

Risk of impaired gas exchange

Respiratory compensation for metabolic alkalosis depresses the respiratory rate and reduces the depth of breathing to promote carbon dioxide retention. As a result, the person is at risk of impaired gas exchange, especially in the presence of underlying lung disease.
- Monitor respiratory rate, depth and effort. Monitor oxygen saturation continuously, reporting an oxygen saturation level of less than 95% (or as ordered). *The depressed respiratory drive associated with metabolic alkalosis can lead to hypoxaemia and impaired oxygenation of tissues. Oxygen saturation levels of less than 90% indicate significant oxygenation problems.*
- Assess skin colour; note and report cyanosis around the mouth. *Central cyanosis, seen around the mouth and oral mucous membranes, indicates significant hypoxia.*
- Monitor mental status and level of consciousness (LOC). Report decreasing LOC or behaviour changes such as restlessness, agitation or confusion. *Changes in mental status or behaviour may be early signs of hypoxia.*
- Place in semi-Fowler's or Fowler's position as tolerated. *Elevating the head of the bed facilitates alveolar ventilation and gas exchange.*
- Schedule nursing care activities to allow rest periods. *The person who is hypoxaemic has limited energy reserves, necessitating frequent rest and limited activities.*
- Administer oxygen as ordered or necessary to maintain oxygen saturation levels. *Supplemental oxygen can help maintain blood and tissue oxygenation despite depressed respirations.*

Deficient fluid volume

A person with metabolic alkalosis often has an accompanying fluid volume deficit.

CONSIDERATION FOR PRACTICE

Assess intake and output accurately, monitoring fluid balance. In acute situations, hourly intake and output may be indicated. Urine output of less than 30 mL/hour indicates inadequate tissue perfusion, inadequate renal perfusion and an increased risk of acute renal failure.

- Assess vital signs, CVP and peripheral pulse volume at least every 4 hours. *Hypotension, tachycardia, low CVP and weak, easily obliterated peripheral pulses indicate hypovolaemia.*
- Weigh daily under standard conditions (time of day, clothing and scale). *Rapid weight changes accurately reflect fluid balance.*
- Administer intravenous fluids as prescribed using an electronic infusion pump. Monitor for indicators of fluid overload if rapid fluid replacement is ordered: dyspnoea, tachypnoea, tachycardia, increased CVP, jugular vein distension and oedema. *Rapid fluid replacement may lead*

to hypervolaemia, resulting in pulmonary oedema and cardiac failure, particularly in a person with compromised cardiac and renal function.

- Monitor serum electrolytes, osmolality and ABG values. *Rehydration and administration of potassium chloride will affect both acid–base and fluid and electrolyte balance. Careful monitoring is important to identify changes.*

Community-based care

When preparing the person with metabolic alkalosis for discharge, consider the cause of the alkalosis and any underlying factors. For example, provide teaching about the following:

- using appropriate antacids for heartburn and gastric distress
- using potassium supplements as ordered or eating high-potassium foods to avoid hypokalaemia if taking a potassium-wasting diuretic or if aldosterone production is impaired
- contact the primary attending doctor if uncontrolled or extended vomiting develops.

The person with respiratory acidosis

Respiratory acidosis is caused by an excess of dissolved carbon dioxide or carbonic acid. It is characterised by a pH less than 7.35 and a $PaCO_2$ greater than 45 mmHg. Respiratory acidosis may be either acute or chronic. In chronic respiratory acidosis, the bicarbonate is higher than 26 mEq/L as the kidneys compensate by retaining bicarbonate.

Risk factors

Acute or chronic lung disease (e.g. pneumonia or chronic obstructive pulmonary disease (COPD)) is the primary risk factor for respiratory acidosis. Other conditions that depress or interfere with ventilation, such as excess narcotic analgesics, airway obstruction or neuromuscular disease, also are risk factors for respiratory acidosis. Selected causes of respiratory acidosis are listed in Table 9.12.

Pathophysiology

Both acute and chronic respiratory acidosis results from carbon dioxide retention caused by alveolar hypoventilation. Hypoxaemia (low oxygen in the arterial blood) frequently accompanies respiratory acidosis.

ACUTE RESPIRATORY ACIDOSIS Acute respiratory acidosis occurs due to a sudden failure of ventilation. Chest trauma, aspiration of a foreign body, acute pneumonia and overdoses of narcotic or sedative medications can lead to this condition. Because acute respiratory acidosis occurs with the sudden onset of hypoventilation—for example, with cardiac arrest—the $PaCO_2$ rises rapidly and the pH falls markedly. A pH of 7 or lower can occur within minutes (Metheny, 2012). The serum bicarbonate level initially is unchanged because the compensatory response of the kidneys occurs over hours to days.

Hypercapnia (increased carbon dioxide levels) affects neurological function and the cardiovascular system. Carbon dioxide rapidly crosses the blood–brain barrier. Cerebral blood vessels dilate and, if the condition continues, intracranial pressure increases and *papilloedema* (swelling and inflammation of the optic nerve where it enters the retina) develops. Peripheral vasodilation also occurs and the pulse rate increases to maintain cardiac output.

CHRONIC RESPIRATORY ACIDOSIS Chronic respiratory acidosis is associated with chronic respiratory or neuromuscular conditions such as COPD, asthma, cystic fibrosis or multiple sclerosis. These conditions affect alveolar ventilation because of airway obstruction, structural changes in the lung or limited chest wall expansion. Most people with chronic respiratory acidosis have COPD with chronic bronchitis and emphysema. (See Chapter 36 for more information about COPD.)

In chronic respiratory acidosis, the $PaCO_2$ increases over time and remains elevated. The kidneys retain bicarbonate, increasing bicarbonate levels, and the pH often remains close to the normal range.

The acute effects of hypercapnia may not develop because carbon dioxide levels rise gradually, allowing compensatory changes to occur. When carbon dioxide levels are chronically elevated, the respiratory centre becomes less sensitive to the gas as a stimulant of the respiratory drive. The PaO_2 provides the primary stimulus for respirations. A person with chronic respiratory acidosis is at risk of developing *carbon dioxide narcosis*, with manifestations of acute respiratory acidosis, if the respiratory centre is suppressed by administering excess supplemental oxygen.

CONSIDERATION FOR PRACTICE

Carefully monitor neurological and respiratory status in the person with chronic respiratory acidosis who is receiving oxygen therapy. Immediately report a decreasing LOC or depressed respirations.

Manifestations

The manifestations of acute and chronic respiratory acidosis differ. In acute respiratory acidosis, the rapid rise in $PaCO_2$ levels causes manifestations of hypercapnia. Cerebral vasodilation causes manifestations such as headache, blurred vision, irritability and mental cloudiness. If the condition continues, the level of consciousness progressively decreases. Rapid and dramatic changes in ABGs can lead to unconsciousness and ventricular fibrillation, a potentially lethal cardiac arrhythmia. The skin of the person with acute respiratory acidosis may be warm and flushed and the pulse rate is elevated.

The manifestations of chronic respiratory acidosis include weakness and a dull headache. Sleep disturbances, daytime sleepiness, impaired memory and personality changes also may be manifestations of chronic respiratory acidosis (see 'Manifestations' box).

MANIFESTATIONS Respiratory acidosis

ACUTE RESPIRATORY ACIDOSIS
- Headache
- Warm, flushed skin
- Blurred vision
- Irritability, altered mental status
- Decreasing level of consciousness
- Cardiac arrest

CHRONIC RESPIRATORY ACIDOSIS
- Weakness
- Dull headache
- Sleep disturbances with daytime sleepiness
- Impaired memory
- Personality changes

INTERPROFESSIONAL CARE

A person with acute respiratory failure usually requires treatment in the emergency department or intensive care unit. The focus is on restoring adequate ventilation and gas exchange. Hypoxaemia often accompanies acute respiratory acidosis, so oxygen is administered as well. Supplemental oxygen is administered with caution to the person with chronic respiratory acidosis.

Diagnosis

The following laboratory and diagnostic tests may be ordered:
- *ABGs* show a pH of less than 7.35 and a $PaCO_2$ of more than 45 mmHg. In acute respiratory acidosis, the bicarbonate level is initially within normal range but increases to greater than 26 mEq/L if the condition persists. In chronic respiratory acidosis, both the $PaCO_2$ and the HCO_3^- may be significantly elevated.
- *Serum electrolytes* may show hypochloraemia (chloride level < 98 mEq/L) in chronic respiratory acidosis.
- *Pulmonary function tests* may be done to determine if chronic lung disease is the cause of the respiratory acidosis. However, these studies would not be done during the acute period.

Additional diagnostic tests may be done to identify the underlying cause of the respiratory acidosis. *Chest x-ray* and *sputum studies* (cytology and culture) may be ordered to identify an acute or chronic lung disorder. If drug overdose is suspected, *serum levels* of the drug may be obtained.

Medications

Bronchodilator drugs may be administered to open the airways and antibiotics prescribed to treat respiratory infections. If excess narcotics or anaesthetic has caused acute respiratory acidosis, drugs to reverse their effects (such as naloxone) may be given.

Respiratory support

Treatment of respiratory acidosis, either acute or chronic, focuses on improving alveolar ventilation and gas exchange. The person with severe respiratory acidosis and hypoxaemia may require intubation and mechanical ventilation. (See Chapter 36 for more information about these procedures.) The $PaCO_2$ level is lowered slowly to avoid complications such as cardiac arrhythmias and decreased cerebral perfusion. In a person with chronic respiratory acidosis, oxygen is administered cautiously to avoid carbon dioxide narcosis.

Pulmonary hygiene measures, such as breathing treatments or percussion and drainage, may be instituted. Adequate hydration is important to promote removal of respiratory secretions.

Nursing care

See 'Nursing care plan: A person with acute respiratory acidosis' below.

Health promotion

Health promotion activities related to respiratory acidosis focus on identifying, monitoring and teaching the person at risk. Carefully monitor the person receiving anaesthesia, narcotic analgesics or sedatives for signs of respiratory depression. Monitor the response of a person with a history of chronic lung disease to oxygen therapy. Educate the person who has an identified risk of respiratory acidosis (such as people using narcotic analgesia for cancer pain and those with chronic lung disease) and their families about early manifestations of respiratory depression and acidosis, and instruct them to contact their attending doctor immediately if manifestations develop.

Assessment

Assessment data related to respiratory acidosis include the following:
- *Health history*: current manifestations, including headache, irritability or lethargy, difficulty thinking, blurred vision and other symptoms; duration of symptoms and any precipitating factors such as drug use or respiratory infection; chronic diseases such as cystic fibrosis or COPD; current medications.
- *Physical assessment*: mental status and level of consciousness; vital signs; skin colour and temperature; rate and depth of respirations, pulmonary excursion, lung sounds; examination of optic fundus for possible papilloedema.
- *Diagnostic tests*: ABGs, serum electrolytes; white blood cell count (indicator of infection), sputum culture results, serum drug and toxicology results.

Nursing diagnoses and interventions

Restoring effective alveolar ventilation and gas exchange is the priority of interprofessional and nursing care for the person with respiratory acidosis.

Impaired gas exchange

- Frequently assess respiratory status, including rate, depth, effort and oxygen saturation levels. *Decreasing respiratory rate and effort along with decreasing oxygen saturation levels may signal worsening respiratory failure and respiratory acidosis.*

NURSING CARE PLAN A person with acute respiratory acidosis

Marlene Hurd, age 76, is eating lunch with her friends when she suddenly begins to choke and is unable to breathe. After several minutes of trying, an attendant at the senior centre successfully dislodges some meat caught in Ms Hurd's throat using the Heimlich manoeuvre. Ms Hurd is taken by ambulance to the emergency department for follow-up because she was apnoeic for 3 to 4 minutes, her respirations are shallow and she is disoriented.

ASSESSMENT

Ms Hurd is placed in an observation room. Oxygen is started at 4 L/min per nasal cannula. David Love, the nurse admitting Ms Hurd, makes the following assessments: T 37.6°C, P 102, R 36 and shallow, BP 146/92. Skin is warm and dry. Alert but restless and not oriented to time or place; she responds slowly to questions. Stat ABGs are drawn, a chest x-ray is done and D_5 1/2 NS is started intravenously at 50 mL/h.

The chest x-ray shows no abnormality. ABG results are pH 7.38 (normal: 7.35 to 7.45), $PaCO_2$ 48 mmHg (normal: 35 to 45 mmHg), PaO_2 92 mmHg (normal: 80 to 100 mmHg) and HCO_3^- 24 mEq/L (normal: 22 to 26 mEq/L).

DIAGNOSES

- *Impaired gas exchange* related to temporary airway obstruction.
- *Anxiety* related to emergency hospital admission.
- *Risk of injury* related to confusion.

PLANNING

- Explain the need to monitor vital and the need for oxygen therapy to the person and significant others.
- Explain the purpose for follow-up treatments of ABGs and continuous monitoring.
- Maintain a calm, quiet environment.
- Provide reorientation and explain all activities.
- Explain the importance of keeping the side rails in place and call bell within reach.

Expected outcomes

- Regain normal gas exchange and ABG values.
- Be oriented to time, place and person.
- Regain baseline mental status.
- Remain free of injury.

IMPLEMENTATION

- Monitor ABGs as per medical officer orders and collect ABG every 2 hours and report findings to the medical officer.
- Review ABG collection site pre and post collection of bloods.
- Monitor vital signs and respiratory status (including oxygen saturation) every 15 minutes for the first hour then every hour.
- Assess colour of skin, nail beds and oral mucous membranes every hour.
- Provide mouth hygiene hourly while O_2 being administered.
- Assess mental status and orientation every hour.
- Monitor anxiety level as evidenced by restlessness and agitation.

EVALUATION

Ms Hurd remains in the emergency department for 6 hours. Her ABGs are still abnormal and David Love now notes the presence of respiratory crackles and wheezes. She is less anxious and responds appropriately when asked about her name, time and place. Because she has not regained normal gas exchange, Ms Hurd is admitted to the hospital for continued observation and treatment.

CRITICAL THINKING IN THE NURSING PROCESS

1. Describe the pathophysiological process that leads to acute respiratory acidosis in Ms Hurd.
2. Describe the effect of acidosis on mental function.
3. What teaching would you provide to Ms Hurd to prevent future episodes of choking?

REFLECTION ON THE NURSING PROCESS

1. Identify and outline what you have learned from this case study and how you will apply it to your future nursing practice.
2. As the Registered Nurse, what communication and education strategies can you use to ensure Ms Hurd is able to prevent further episodes of choking?

CONSIDERATION FOR PRACTICE

Frequently assess level of consciousness. A decline in LOC may indicate increasing hypercapnia and the need for increasing ventilatory support (such as intubation and mechanical ventilation).

- Promptly evaluate and report ABG results to the physician and respiratory therapist. *Rapid changes in carbon dioxide or oxygen levels may necessitate modification of the treatment plan to prevent complications of overcorrection of respiratory acidosis.*
- Place in semi-Fowler's to Fowler's position as tolerated. *Elevating the head of the bed promotes lung expansion and gas exchange.*
- Administer oxygen as ordered. Carefully monitor response. Reduce the oxygen flow rate or percentage and immediately report increasing somnolence. *Supplemental oxygen can suppress the respiratory drive in the person with chronic respiratory acidosis.*

Ineffective airway clearance

- Frequently auscultate breath sounds (whether on or off a mechanical ventilator). *Increasing adventitious sounds or decreasing breath sounds (faint or absent) may indicate worsening airway clearance due to obstruction or fatigue.*
- Encourage the person with chronic respiratory acidosis to use pursed-lip breathing. *Pursed-lip breathing helps maintain open airways throughout exhalation, promoting carbon dioxide elimination.*

- Frequently reposition and encourage ambulation as tolerated. *Repositioning, sitting at the bedside and ambulation promote airway clearance and lung expansion.*
- Encourage fluid intake of up to 3000 mL per day as tolerated or allowed. *Fluids help liquefy secretions and hydrate respiratory mucous membranes, promoting airway clearance.*
- Administer medications such as inhaled bronchodilators as ordered. *Inhaled bronchodilators help to relieve bronchial spasm, dilating airways.*
- Provide percussion, vibration and postural drainage as ordered. *Pulmonary hygiene measures such as these help to loosen respiratory secretions so they can be coughed out of airways.*

Community-based care

Planning and educating for home care focuses on the problem that caused the person to develop respiratory acidosis. The person who developed acute respiratory acidosis as a result of acute pneumonia or chest trauma may only require education to prevent future problems. If acute respiratory acidosis occurred secondary to a narcotic overdose, determine if the drug was prescribed for pain or if it was an illicit street drug. Provide education to the person who requires narcotic medication on a continuing basis. Refer the person using illicit drugs to a substance abuse counsellor or treatment centre as appropriate.

For a person with chronic lung disease, discuss ways to avoid future episodes of acute respiratory failure. Encourage the person to be immunised against pneumococcal pneumonia and influenza. Discuss ways to avoid acute respiratory infections and measures to take when respiratory status is further compromised.

The person with respiratory alkalosis

Respiratory alkalosis is characterised by a pH greater than 7.45 and a $PaCO_2$ of less than 35 mmHg. It is always caused by hyperventilation leading to a carbon dioxide deficit.

Risk factors

Anxiety with hyperventilation is the most common cause of respiratory alkalosis; therefore, anxiety disorders increase the risk of this acid–base imbalance. In the person who is critically ill, mechanical ventilation is a risk factor for respiratory alkalosis.

Pathophysiology

In acute respiratory alkalosis, the pH rises rapidly as the $PaCO_2$ falls. Because the kidneys are unable to rapidly adapt to the change in pH, the bicarbonate level remains within normal limits. Anxiety-based hyperventilation is the most common cause of acute respiratory alkalosis. Other physiological causes of hyperventilation include high fever, hypoxia, gram-negative bacteraemia and thyrotoxicosis. Early salicylate intoxication (aspirin overdose), encephalitis and high progesterone levels in pregnancy directly stimulate the respiratory centre, potentially leading to hyperventilation and respiratory alkalosis. Hyperventilation also can occur during anaesthesia or mechanical ventilation if the rate and tidal volume (depth) of ventilations are excessive.

If hyperventilation continues, the kidneys compensate by eliminating bicarbonate to restore the bicarbonate to carbonic acid ratio. The bicarbonate level is lower than normal in chronic respiratory alkalosis and the pH may be close to the normal range.

Alkalosis increases binding of extracellular calcium to albumin, reducing ionised calcium levels. As a result, neuromuscular excitability increases and manifestations similar to hypocalcaemia develop. Low carbon dioxide levels in the blood cause vasoconstriction of cerebral vessels, increasing the neurological manifestations of the disorder.

Manifestations

The manifestations of respiratory alkalosis include lightheadedness, a feeling of panic and difficulty concentrating, circumoral and distal extremity paraesthesias, tremors and positive Chvostek's and Trousseau's signs. The person also may experience tinnitus, a sensation of chest tightness and palpitations (cardiac arrhythmias). Seizures and loss of consciousness may occur. (See 'Manifestations' box below.)

MANIFESTATIONS Respiratory alkalosis

- Dizziness
- Numbness and tingling around mouth, hands and feet
- Palpitations
- Dyspnoea
- Chest tightness
- Anxiety/panic
- Tremors
- Tetany
- Seizures, loss of consciousness

INTERPROFESSIONAL CARE

Management of respiratory alkalosis focuses on correcting the imbalance and treating the underlying cause.

Diagnosis

ABGs generally show a pH greater than 7.45 and a $PaCO_2$ of less than 35 mmHg. In chronic hyperventilation, there is a compensatory decrease in serum bicarbonate to less than 22 mEq/L and the pH may be near normal.

Medications

A sedative or anti-anxiety agent may be necessary to relieve anxiety and restore a normal breathing pattern. Additional drugs to correct underlying problems other than anxiety-induced hyperventilation may be ordered.

Respiratory therapy

The usual treatment for anxiety-related respiratory alkalosis involves instructing the person to breathe more slowly and having the person breathe into a paper bag or rebreather mask. This allows rebreathing of exhaled carbon dioxide, increasing $PaCO_2$ levels and reducing the pH. If excessive ventilation by a mechanical ventilator is the cause of respiratory alkalosis,

ventilator settings are adjusted to reduce the respiratory rate and tidal volume as indicated. When hypoxia is the underlying cause of hyperventilation, oxygen is administered.

Nursing care

Health promotion

Identify the person at risk in the hospital (e.g. a person on mechanical ventilation or who has a fever or infection) and monitor assessment data and ABGs to identify early manifestations of hyperventilation and respiratory alkalosis.

Assessment, diagnoses and interventions

Ineffective breathing pattern

The usual cause of hyperventilation and respiratory alkalosis is psychological, although physiological disorders also can lead to hyperventilation. It is important not only to address the hyperventilation but also to identify the underlying cause.

- Assess respiratory rate, depth and ease. Monitor vital signs (including temperature) and skin colour. *Assessment data can help identify the underlying cause, such as a fever or hypoxia.*
- Obtain subjective assessment data such as the circumstances leading up to the current situation, current health and recent illnesses, or medication use and current manifestations. *Subjective data provide cues to the cause and circumstances of the hyperventilation response.*
- Reassure the person that they are not experiencing a heart attack and that symptoms will resolve when breathing returns to normal. *Manifestations of hyperventilation and respiratory alkalosis such as dyspnoea, chest tightness, or pain and palpitations can mimic those of a heart attack.*
- Instruct the person to maintain eye contact and breathe with you to slow the respiratory rate. *These measures help to make the person aware of respirations and provide a sense of support and control* (Ackley & Ladwig, 2011).
- Have the person breathe into a paper bag. *This allows the person to rebreathe exhaled carbon dioxide, increasing the $PaCO_2$ and decreasing the pH.*
- Protect the person from injury. *If hyperventilation continues to the point at which the person loses consciousness, respirations will return to normal, as will acid–base balance.*
- If the person has experienced repeated episodes of hyperventilation or has a chronic anxiety disorder, refer for counselling. *Counselling can help the person develop alternative strategies for dealing with anxiety.*

Community-based care

Planning and teaching for home care are directed towards the underlying cause of hyperventilation. If anxiety precipitated the episode, discuss anxiety management strategies with the person. Refer the person and family to a counsellor if appropriate. Teach the person to identify a hyperventilation reaction and how to breathe into a paper bag to manage it at home.

CHAPTER HIGHLIGHTS

- The volume and composition of body fluid are normally maintained by a balance of fluid and electrolyte intake; elimination of water, electrolytes and acids by the kidneys; and hormonal influences. Change in any of these factors can lead to a fluid, electrolyte or acid–base imbalance that adversely impacts on health.
- Fluid, electrolyte and acid–base imbalances can affect all body systems, especially the cardiovascular system, the central nervous system and the transmission of nerve impulses. Conversely, primary disorders of the respiratory, renal, cardiovascular, endocrine or other body systems can lead to an imbalance of fluids, electrolytes or acid–base status.
- Fluid and sodium imbalances commonly are related; both affect serum osmolality.
- Potassium imbalances are commonly seen in the person with acute or chronic illnesses. Both hypokalaemia and hyperkalaemia affect cardiac conduction and function. Carefully monitor cardiac rhythm and status in the person with very low or very high potassium levels.
- Calcium imbalances primarily affect neuromuscular transmission: hypocalcaemia increases neuromuscular irritability; hypercalcaemia depresses neuromuscular transmission. Magnesium imbalances have a similar effect.
- Acid–base imbalances may be caused by either metabolic or respiratory problems. Simple acid–base imbalances (respiratory or metabolic acidosis or alkalosis) are more commonly seen than mixed imbalances.
- Buffers, lungs and kidneys work together to maintain acid–base balance in the body. Buffers respond to changes almost immediately; the lungs respond within minutes; the kidneys, however, require hours to days to restore normal acid–base balance.
- The lungs compensate for metabolic acid–base imbalances by excreting or retaining carbon dioxide. This is accomplished by increasing or decreasing the rate and depth of respirations.
- The kidneys compensate for respiratory acid–base imbalances by producing and retaining or excreting bicarbonate and by retaining or excreting hydrogen ions.
- Careful monitoring of respiratory and cardiovascular status, mental status, neuromuscular function and laboratory values is an important nursing responsibility for the person with fluid, electrolyte or acid–base imbalances.

CONCEPT CHECK

1 A person is admitted to the emergency department with hypovolaemia. Which intravenous solution would the nurse anticipate administering?
1 Ringer's solution
2 10% dextrose in water
3 3% sodium chloride
4 0.45% sodium chloride

2 When assessing a person with fluid volume deficit, the nurse would expect to find:
1 increased pulse rate and blood pressure
2 dyspnoea and respiratory crackles
3 headache and muscle cramps
4 orthostatic hypotension and flat neck veins

3 The nurse caring for a person with acute hypernatraemia includes which of the following in the plan of care? (Select all that apply.)
1 Conduct frequent neurological checks.
2 Restrict fluids to 1500 mL per day.
3 Orient to time, place and person frequently.
4 Maintain intravenous access.
5 Limit length of visits.

4 Laboratory results for a person show a serum potassium level of 2.2 mEq/L. Which of the following nursing actions is of highest priority for this person?
1 Keep the person on bed rest.
2 Initiate cardiac monitoring.
3 Start oxygen at 2 L/min.
4 Initiate seizure precautions.

5 The nurse evaluates teaching about calcium supplement therapy as effective when the person states that she will take her calcium tablets:
1 all at one time in the morning
2 with meals
3 as needed for tremulousness
4 with a full glass of water

6 A person who is known to be an alcoholic presents with confusion, hallucinations and a positive Chvostek's sign. Which medication(s) should the nurse anticipate administering?
1 magnesium sulfate
2 calcium chloride
3 insulin and glucose
4 sodium bicarbonate

7 Arterial blood gas results for a person show pH 7.21, PaO_2 98 mmHg, $PaCO_2$ 32 mmHg and HCO_3^- 17 mEq/L. The nurse correctly interprets these values as indicative of which of the following acid–base imbalances?
1 metabolic acidosis
2 metabolic alkalosis
3 respiratory acidosis
4 respiratory alkalosis

8 A person is admitted with a suspected heroin overdose and a respiratory rate of 5 to 6 breaths per minute. Which of the following assessment data would the nurse anticipate? (Select all that apply.)
1 pH 7.29
2 alert and oriented
3 $PaCO_2$ 54 mmHg
4 HCO_3^- 32 mEq/L
5 skin warm and flushed

9 The nurse caring for a person undergoing several days of gastric decompression recognises that the person is at risk of which of the following acid–base imbalances?
1 metabolic acidosis
2 metabolic alkalosis
3 respiratory acidosis
4 respiratory alkalosis

10 A person undergoing mechanical ventilation following a severe chest wall injury and flail chest complains of chest tightness, anxiety and feeling as though she cannot get enough air. She is afraid she is having a heart attack. The nurse should first:
1 administer prescribed analgesic
2 contact respiratory therapy to evaluate ventilator settings
3 obtain arterial blood gases
4 notify the physician

CHAPTER 10

NURSING CARE OF PEOPLE EXPERIENCING TRAUMA AND SHOCK

LISA GATZONIS

KEY TERMS

LEARNING OUTCOMES

- Describe the components and types of trauma including causes, effects to diagnose and management of life-threatening injuries.
- Discuss diagnostic tests, medications, blood transfusion and intravenous fluids used in assessing people experiencing trauma and shock.
- Explain organ donation and forensic implications of traumatic injury or death.
- Discuss the risk factors, aetiologies and pathophysiologies of hypovolaemic shock, cardiogenic shock, obstructive shock and distributive shock.
- Describe the role of the nurse in trauma prevention education and evaluate a plan of care to restore the functional health status of people experiencing trauma.

CLINICAL COMPETENCIES

- Obtain initial data about the person experiencing trauma to include history taking, assessment, review of medical history and communication with pre-hospital and other healthcare providers and family members.
- Communicate and document significant data and changes in the condition of a person who has sustained trauma.
- Evaluate responses to medical and surgical interventions for people sustaining multiple trauma and shock.
- Formulate nursing diagnoses based on manifestations recognised during the nursing assessment.
- Develop a plan of care for the person experiencing trauma based on scientific knowledge and individual diversity.
- Describe the role of the nurse in trauma prevention education and evaluate a plan of care to restore the functional health status of people experiencing trauma.
- Advocate for people's rights as indicated by documents that address end-of-life issues.

THE PERSON EXPERIENCING TRAUMA

Trauma is defined as injury to human tissues and organs resulting from the transfer of energy from the environment. In the past the term 'trauma' has been associated with the word 'accident'. *Accident* means that the injury occurred without intent, a result of random chance. We now know that a considerable number of injuries are preventable and not of random chance. Intentional and non-intentional trauma encompass a variety of injuries resulting from motor vehicle crashes, pedestrian injuries, gunshot wounds, falls, violence towards others or self-inflicted violence. The injuries, disabilities and deaths resulting from these acts constitute a major healthcare challenge.

- Traumatic injury is the leading cause of death in people under 45 years of age, a leading cause of morbidity, mortality and permanent disability, and a major source of health costs in Australia.
- Approximately 27 people die as a result of injury every day—almost 10 000 lives are lost each year (Australian Institute of Health and Welfare (AIHW), 2010).

Trauma usually occurs suddenly, leaving the person and family with little time to prepare for its consequences. Nurses provide a vital link in both the physical and psychosocial care for the injured person and family. In caring for the person who has experienced trauma, nurses must consider not only the initial physical injury but also its long-term consequences, including rehabilitation. Trauma may alter the person's previous way of life, potentially affecting independence, mobility, cognitive thinking and appearance.

Components of trauma

Trauma results from an abnormal exchange of energy between a host and a mechanism in a predisposing environment. The *host* is the person or group at risk of injury. Multiple factors influence the host's potential for injury: age, sex, race, economic status, pre-existing illnesses and use of substances such as street drugs and alcohol.

The *mechanism* is the source of the energy transmitted to the host. The energy exchanged can be mechanical, gravitational, thermal, electrical, physical or chemical. Table 10.1 lists the most common mechanisms for each type of energy. Mechanical energy is the most common type of energy transferred to a host in trauma. The most common mechanical source of injury in all adult age groups is the motor vehicle.

When describing a traumatic injury, *intention* is included as a component. Most gunshot and stab wounds are examples of intentional injuries. It is important to remember, however, that some gunshot wounds are unintentional, such as those that occur when children play with guns. Other common unintentional injuries result from motor vehicle crashes, falls, drowning and fires.

The final component of trauma is the *environment*. For example, a road that has become slippery after a storm is a physical environment that may contribute to an injury. Occupation is an important environmental factor to consider. Those in certain occupations face a high risk of trauma; examples include police officers, firefighters, professional athletes, race car drivers and taxi cab drivers. One's social environment also influences risk of injury; see the 'Meeting individualised needs' box on the next page for one example—domestic violence.

Types of trauma

Minor trauma causes injury to a single part or system of the body and is usually treated in a general practitioner's clinic or in the hospital emergency department. A fracture of the clavicle, a small second-degree burn and a laceration requiring sutures are examples of minor trauma. **Major** or **multiple trauma** involves

TABLE 10.1 Common mechanisms of injury by energy source

ENERGY SOURCE	COMMON MECHANISMS OF INJURY
Mechanical	Motor vehicles Firearms Machines
Gravitational	Falls
Thermal	Heating appliances Fire Freezing temperatures
Electrical	Wires, sockets and other electrical objects Lightning
Physical	Fists, feet and other body parts (as in physical assault) Sharp objects, such as knives Ultraviolet radiation Ionising radiation Water (drowning) Other submersion agents (e.g. grain) Explosions
Chemical	Drugs Poisons Industrial chemicals

serious single-system injury (such as the traumatic amputation of a leg) or multiple-system injuries. Multiple trauma is most often the result of a motor vehicle crash.

Trauma is further classified as either blunt or penetrating. **Blunt trauma** occurs when there is no communication between the damaged tissues and the outside environment. It is caused by various forces including *deceleration* (a decrease in the speed of a moving object), *acceleration* (an increase in the speed of a moving object), *shearing* (forces occurring across a plane, with structures slipping across each other), *compression* and *crushing*. Blunt forces often cause multiple injuries that can affect the head, spinal cord, bones, thorax and abdomen. Blunt trauma is frequently caused by motor vehicle crashes, falls, assaults and sports activities.

Penetrating trauma occurs when a foreign object enters the body causing damage to body structures. Structures commonly affected include the brain, lungs, heart, liver, spleen, the intestines and the vascular system. Examples of penetrating trauma are gunshot or stab wounds and impalement.

Other types of trauma include inhalation injuries from gases, smoke or steam; burn or freezing injuries; and blast injuries from explosions. Blast injuries result from the temperature and velocity of air movement and the force of projectiles from the explosion. Blast injuries are more severe in water than in air because blast waves travel further and faster in water. Trauma from blast injuries includes pulmonary oedema and haemorrhage, damage to abdominal organs, burns, penetrating injuries and ruptured tympanic membranes.

Outcome studies show a correlation between survival rates of multiple trauma victims and rapid response times by pre-hospital providers, coupled with appropriate decision making with regard to transporting the victim to a facility capable of treating their injuries (American College of Emergency Physicians, 2013). As a result, a system was devised to assist pre-hospital providers to make the appropriate decisions. People experiencing trauma are classified as class 1, 2 or 3 based on factors including mechanism of injury, vehicle speed, height of falls and location of penetrating injuries. Class 3 trauma is the least severe. An example would be a same-level fall without loss of consciousness or significant injury. Class 1 trauma involves life-threatening injuries likely to require medical specialists or immediate surgical intervention. While any hospital emergency department should be capable of caring for class 3 trauma people, people meeting class 1 or 2 criteria should be transported to a designated trauma centre when possible. Facilities designated as trauma centres have medical specialists and surgical coverage available or on call 24 hours a day.

Effects of traumatic injury

Death is a common result of serious traumatic injury, and falls into one of three categories related to the time span between injury and death: immediate, early or late. Immediate death happens within minutes at the scene from such injuries as a torn thoracic aorta or decapitation. Early death occurs within several hours of the injury from shock or delay in recognising injuries—causes may be major abdominal or thoracic injuries, or progression of intracranial haemorrhage. Late death generally occurs one or more days after the injury and results from multiple organ failure, sepsis and coagulopathies.

Because of the serious consequences of trauma, it is important to rapidly identify the person's injuries and institute appropriate interventions quickly. Following are common results of trauma and interventions necessary for good outcomes.

MEETING INDIVIDUALISED NEEDS **Assessing older adult abuse and domestic violence**

Intimate partner violence (IPV)

Most incidents of domestic violence are not reported; thus it is believed that the available data greatly underestimate the true magnitude of the problem. From the findings of the Personal Safety Survey conducted in 2012, it is estimated that 49% of men and 41% of women have experienced some form of violence since the age of 15, and that 62% of women compared to 8% of men have experienced their most recent incident of physical assault by a male in their home (Phillips & Vandenbroek, 2014). Domestic violence is one of the most common causes of injury to women in Australia.

Domestic violence is a widespread problem that occurs regardless of age, sex, race, socioeconomic status or education.

Violence and the older adult

Older adult abuse is defined as anything that endangers the life of an older adult. This can range from physical or emotional assault to intimidation, neglect or financial exploitation. Wilful deprivation of food or medical care is also included.

Data indicate that between 2% and 5% of Australians over the age of 65 years have experienced abuse, up to 80% of perpetrators are family members of the victims (the large majority being their children), financial and psychological abuse are the most common forms of abuse, and women are twice as likely to be victims of abuse (Lacey, 2012).

Diagnosis of abuse

The general approach to diagnosis in abuse situations is challenging as the abuse is often hidden. With spousal, older adult or child abuse, the task of identification is complex. The following are clues to identify violence-related injuries:

- injuries that do not correlate with the history
- injuries that suggest a defensive posture
- injuries during pregnancy
- pattern injuries
- pattern burns
- sexual abuse/rape
- unusual or unexplained fractures
- signs of confinement
- unusual interaction between the person and the caregiver
- lack of medical attention; immunisations not up to date; poor dental health
- unexplained dehydration or malnutrition.

Airway obstruction

Maintenance of the airway and cervical spine are the highest priority in the trauma patient. Other distracting injuries may take the inexperienced practitioner away from the airway, but if the airway is not patent (open) and the person is unable to deliver oxygen to vital organs all other interventions are futile.

Assessment includes determining airway patency. If the person is unresponsive, manual opening of the airway using a jaw-thrust or chin-lift manoeuvre is necessary. The jaw thrust is the recommended manoeuvre for people having suspected cervical spine injury. Once the airway is opened, the practitioner must identify any potential obstruction from the tongue, loose teeth, foreign bodies, bleeding, secretions, vomitus or oedema. If the person is responsive and can vocalise, that is a good indication that the airway is clear.

Any time the nurse performs an intervention it is important to reassess the effectiveness of the intervention. For example, if the nurse suctions the airway to remove vomitus, they would reassess the airway after suctioning to determine if that intervention was successful or if the airway needs to be suctioned a second time.

All trauma victims should receive high-flow oxygen until stabilised. Assessment of breathing effectiveness is paramount. Assessment should include whether the person has spontaneous breathing, good rise and fall of the chest, determination of skin colour, general rate and depth of respirations, use of abdominal or accessory muscles, position of the trachea, observation of chest wall integrity and presence of jugular vein distension, bilateral breath sounds and any surface trauma. Consider pulse oximetry and cardiac monitoring as well.

In addition to suctioning, other available airway adjuncts include oral or nasal pharyngeal airways, oxygen delivery devices, laryngeal mask airways, Combitubes and endotracheal intubation (see Figure 10.1). Intubation is the preferred method of airway management if the person is unable to maintain oxygenation or an open airway.

People experiencing trauma may exhibit several aspects of airway management that are unique and require special preparation and precautions, as discussed next.

CLOSED HEAD INJURY Changes in haemodynamics, oxygenation and ventilation should be minimised in order to maintain adequate cerebral perfusion pressure. Laryngoscopy causes a marked increase in intracranial pressure (ICP).

The goal is to maintain a $PaCO_2$ of 30 to 35 mmHg. Lignocaine administered 3 to 5 minutes prior to intubation can blunt an increase in ICP that is secondary to laryngeal stimulation. In a normotensive person, beta-blockers are given 2 to 3 minutes prior to intubation to attenuate the sympathetic response. Effective induction agents such as etomidate or thiopental have not been shown to increase ICP (Turner, Wakim & Secrest, 2005).

MAXILLOFACIAL TRAUMA Significant distortion of normal anatomy occurs in facial trauma and respiratory compromise is not uncommon. Even in victims who present with mild respiratory compromise, rapid deterioration from oedema or haemorrhage can occur. A surgical airway may be the only alternative.

DIRECT AIRWAY TRAUMA Penetrating trauma to the neck is associated with a high degree of morbidity and mortality.

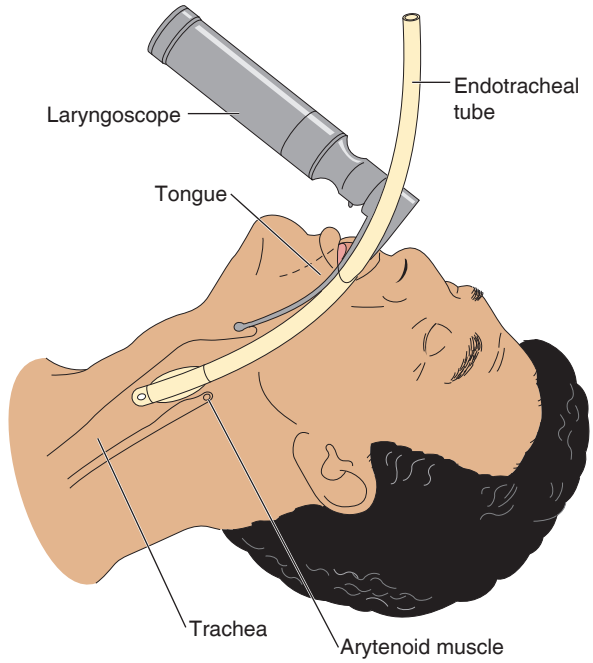

FIGURE 10.1 ■ Placement of an oral endotracheal tube (ETT) for intubation. When the ETT is in place, air or oxygen can be blown into the external opening of the tube and enter the trachea

Airway involvement includes dyspnoea, cyanosis, subcutaneous emphysema, hoarseness or air bubbling from the wound. Orotracheal intubation with rapid-sequence intubation is the technique of choice. The key is early identification of the need for intubation before the person has no airway at all. Tracheobronchial injury occurs in approximately 10% to 20% of people with penetrating neck injuries.

CERVICAL SPINE INJURY In the presence of a presumed cervical spine injury, precautions for securing an airway are consistently applied. Approximately 1.5% to 3% of major trauma victims have clinically significant cervical spine injuries (Desjardins, 2013). Oral intubation with manual in-line axial head and neck stabilisation is a safe method. The probability of cervical spine injury is decreased if the following criteria are met:

- absence of midline cervical spine tenderness
- normal alertness
- absence of intoxication
- absence of a painful distracting injury
- no focal neurological defects.

BURNS Burn victims with airway compromise require aggressive management. Upper airway oedema associated with inhalation or enclosed-space fires can progress during the post-burn phase. Securing an airway sooner rather than later is the goal. See Chapter 16 for nursing care of the person with burns.

Thoracic effects

TENSION PNEUMOTHORAX A **pneumothorax** results when air enters the potential space between the parietal and visceral pleura. The thorax is completely filled by the lungs, and

surface tension between the pleural surfaces holds the lungs to the chest wall. Air present in the pleural space will eventually collapse the lungs. A **tension pneumothorax** is a life-threatening condition and requires immediate intervention. On inspiration, air enters the pleural space which cannot escape on expiration; this then increases intrapleural pressure. This pressure collapses the lung and causes a shift in the mediastinal contents, resulting in compression of the heart, great vessels, trachea and, eventually, the unaffected lung. In turn, this causes the following signs and symptoms:

- severe respiratory distress
- hypotension
- jugular vein distension
- tracheal deviation towards the uninjured side
- cyanosis.

The immediate short-term lifesaving intervention is a needle thoracotomy, in which a large-bore needle is inserted into the second intercostal space at the midclavicular line (see Figure 10.2).

FLAIL CHEST Flail chest is the fracture of two or more ribs in two or more separate locations, leading to an unstable thoracic wall segment. Paradoxical movement of the chest wall is seen, with the area sinking into the chest cavity with inspiration and protruding with expiration. The area must be supported quickly to re-establish effective respiration and subsequent ventilation.

THORACIC CONTUSION AND RUPTURE Bruising of thoracic tissue is referred to as contusion. Pulmonary contusion is the most common traumatic chest injury, mostly from motor vehicle accidents. As a shock wave force travels through the parenchyma, diffuse haemorrhage and alveolar oedema develop, impairing gas exchange. Diaphragmatic rupture is a rare traumatic injury but can result in herniation of abdominal contents into the thoracic cavity, causing respiratory compromise.

Myocardial contusion results in extravasation of red blood cells into the myocardial fibres. As myocardial cells are injured, it is believed that cardiac output diminishes due to reduction in contractile strength. Myocardial rupture is an acute traumatic tear of any structures of the heart, and although rare it is fatal.

Cardiac tamponade occurs when blood or fluid collects in the pericardial sac. Resulting in myocardial compression, this condition is potentially life threatening and should be addressed immediately with pericardiocentesis (see Chapter 30).

Aortic rupture (transection) can result from acceleration–deceleration injury or blunt chest trauma. This injury is commonly fatal due to profuse bleeding.

Haemorrhage

When the person has suffered an injury that causes external haemorrhage, such as severing of an artery, the bleeding must be controlled immediately. This may be done by applying direct pressure over the wound and applying pressure over arterial pressure points (see Figure 10.3).

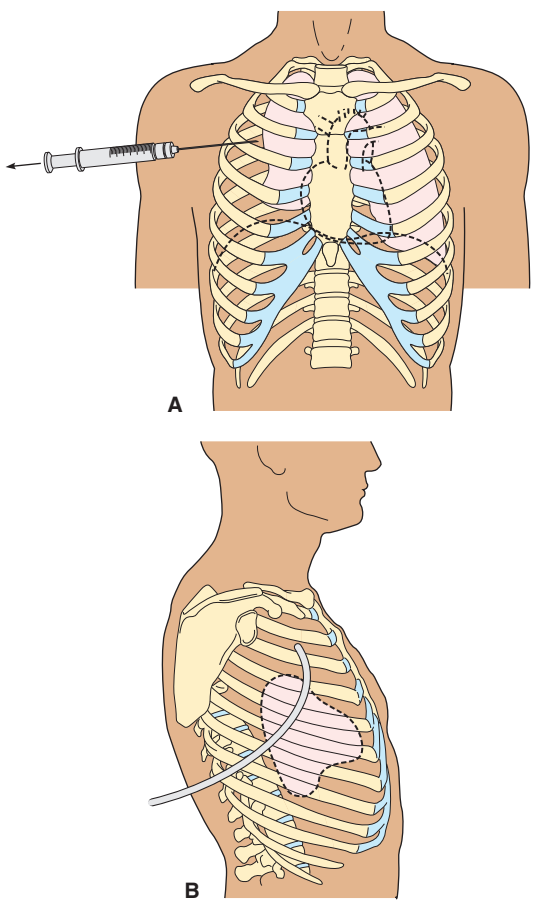

FIGURE 10.2 ■ A needle thoracostomy may be used in the emergency treatment of a tension pneumothorax. *A*, A large-gauge needle is introduced and air and fluid are aspirated. *B*, Alternatively, a chest tube may be inserted and connected to a chest drainage system

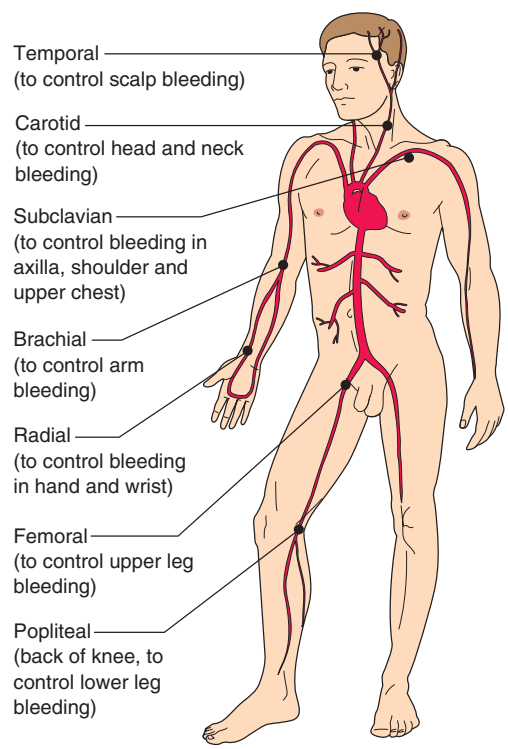

FIGURE 10.3 ■ The major pressure points used for the control of bleeding

Internal haemorrhage may result from either blunt or penetrating traumatic injury. Discovering the cause and location of the injury, as well as the extent of related blood loss, are the most important concerns. Several potential spaces in the body can accommodate large amounts of blood that may accumulate (called third spacing) following injury. For example, bleeding into the pleural space may occur with chest trauma (haemothorax) and bleeding into the abdominal cavity may occur with abdominal trauma. A pelvic fracture may cause massive haemorrhage into the retroperitoneal region. Once the source of internal haemorrhage has been recognised, interventions are initiated, including operative control of bleeding and continual assessment. Haemorrhage may result in hypovolaemic shock (discussed later in the chapter).

Integumentary effects

Injuries to the integument generally are not as serious as other injuries, with the exception of burns (see Chapter 16). The primary organ involved in integumentary trauma is the skin; however, underlying structures may also be injured. Injuries may result from either blunt or penetrating sources. It is important to evaluate all injuries to the integument because they may indicate a more serious injury such as an open fracture. Additionally, large wounds may contribute to significant blood loss.

Five specific injuries to the integument are contusions, abrasions, puncture wounds, lacerations and full-thickness avulsion injuries (see Figure 10.4). **Contusions**, or superficial tissue injuries, result from blunt trauma that causes the breakage of small blood vessels and bleeding into the surrounding tissue. **Abrasions** or partial-thickness denudations of an area of integument generally result from falls or scrapes. **Puncture wounds** occur when a sharp or blunt object penetrates the integument. **Lacerations** are open wounds that result from sharp cutting or tearing. Injuries to the integument are at risk of contamination from dirt, debris or foreign objects. Infection may cause further physical stress to the person with multiple injuries. **Full-thickness avulsion injuries** are injuries that result in loss of all of the layers of the skin, causing fat and muscle to be exposed. The size of the wound impacts on both the length of time necessary for healing to take place and the risk of infection. These types of injuries are treated by allowing new skin to grow from the edges, suturing the wound together, reattaching avulsed skin or by skin grafting.

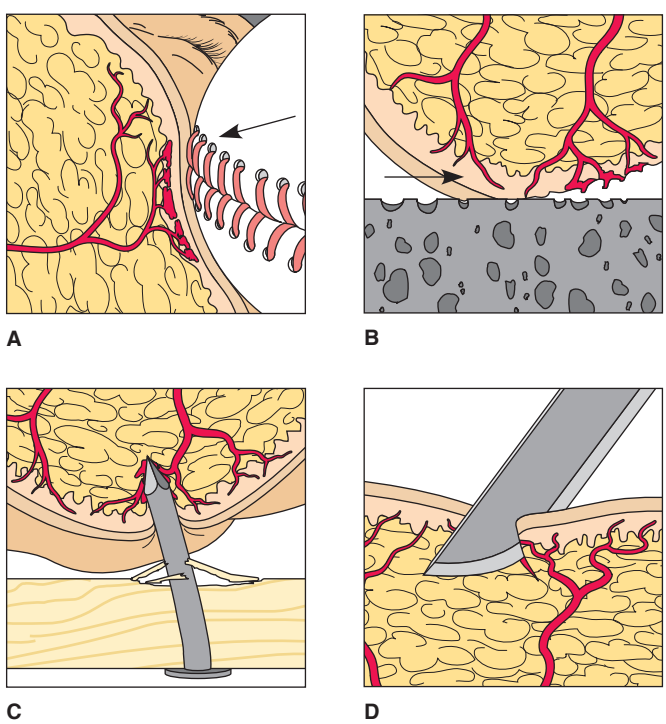

FIGURE 10.4 ■ Traumatic injuries to the skin include *A*, contusion; *B*, abrasion; *C*, puncture wound; *D*, laceration

Abdominal effects

The abdomen contains both solid organs (liver, spleen and pancreas) and hollow organs (stomach and intestines). Direct trauma to the abdomen can lacerate and compress the solid organs and cause burst injuries to the hollow organs. Blood vessels may be torn and organs may be displaced from their blood supply, producing life-threatening haemorrhage. Damage to the mesenteric vessels supplying the bowel can result in bowel ischaemia and infarction. Injury to the stomach, pancreas and small bowel may allow digestive enzymes to leak into the abdominal cavity. Rupture of the large bowel results in escape of faeces which causes peritonitis. Blunt or penetrating trauma to the abdomen may also cause rupture of the diaphragm with herniation of the abdominal organs into the thoracic cavity. The immediate threat following abdominal trauma is haemorrhage and the later threat is peritonitis.

Musculoskeletal effects

Musculoskeletal injuries may occur alone or with multiple injuries as the result of blunt or penetrating trauma. Musculoskeletal injuries usually are not considered a high priority in the care of the person with multiple injuries. Exceptions are the life- or limb-threatening musculoskeletal injury, such as a dislocated hip, pulseless extremity or significant blood loss such as from a femur or pelvic fracture. Musculoskeletal injuries may provide clues to the presence of other serious injuries; for example, a fractured clavicle may indicate an associated thoracic injury. Care of the person who has suffered a musculoskeletal injury is discussed in Chapter 39.

Neurological effects

Head injuries are a common type of injury sustained as the result of trauma. Injuries to the spinal cord resulting in loss of neurological function are devastating outcomes of trauma, but they are much less common than head injuries. Most head and spinal cord injuries result from blunt trauma and are sustained in motor vehicle crashes. Falls, sports injuries and assault are other sources of neurological injury. Care of the person with a neurological injury is discussed in Chapters 41 and 43.

Multiple organ dysfunction syndrome

Multiple organ dysfunction syndrome (MODS) is a common complication of severe injury and a frequent cause of death in intensive care units. MODS is a progressive impairment of two or more organ systems. This is the result of an uncontrolled inflammatory response to severe injury or illness.

People at risk of MODS are those with a disturbance in homeostasis resulting from one or a combination of the following conditions:

- infection
- injury
- inflammation
- ischaemia
- immune response
- intoxication of substances
- iatrogenic factors.

The primary organ systems involved in MODS are the respiratory, renal, hepatic, haematological, cardiovascular, gastrointestinal and neurological systems. Supportive therapy depends on the identification of correctable causes and this may be one or a combination of several therapies. Surgical intervention, antibiotic administration, corticosteroid administration and correction coagulopathies are some of the therapies used for this condition. The occurrence of MODS following traumatic injuries causes more than half of the late mortality following trauma.

Effects on the family

Trauma usually occurs suddenly and with little warning. It may result in death or cause injury serious enough to alter both the person's and the family's lives. The suddenness and seriousness of the event are precipitating factors in the development of a psychological crisis. During the past decade, some emergency departments have instituted care plans that allow families to be present during resuscitation. This policy is not without controversy, but it should be considered when appropriate in conjunction with institution work practices.

INTERPROFESSIONAL CARE

Interprofessional care of the trauma victim depends on a team approach. Providing trauma care with a team focus helps each team member know their role. Prompt delegation of tasks and responsibilities improves the person's chances of survival and decreases the morbidity that may result from traumatic injuries.

Pre-hospital care

The major functions of pre-hospital care include injury identification, critical interventions and rapid transport.

INJURY IDENTIFICATION Emergency care of the person experiencing trauma is based on rapid assessment to identify injuries and begin appropriate interventions. Injuries that indicate the need for trauma centre care include:

- penetrating injuries to the abdomen, pelvis, chest, neck or head
- spinal cord injuries with deficit
- crushing injuries to the abdomen, chest or head
- major burns
- injuries leading to airway compromise or obstruction.

Many methods help healthcare providers determine the seriousness of the person's injuries and the potential for survival. Scoring systems such as the Champion Revised Trauma Scoring System can be helpful (see Table 10.2). A primary trauma assessment must be rapid and comprehensive. As a prompt, using an alphabetical mnemonic can be helpful:

- **A** is airway assessment (with cervical spine immobilisation) to determine if the airway is patent, maintainable or non-maintainable.
- **B** is breathing evaluation for spontaneous respirations or ventilator impedance—such as by rib fractures or a collapsed lung.
- **C** is circulatory assessment by palpating peripheral and central pulses; assessing capillary refill, skin colour and temperature; and identifying any external sources of bleeding.
- **D** is disability and refers to neurological status. Assessment includes level of consciousness and pupillary function assessment, response to verbal or painful stimuli, and assessment of blood glucose level.
- **E** is exposure/environment where a whole-body assessment for any obvious injuries is completed while ensuring that hypothermia does not occur (i.e. use of heated blankets, warmed intravenous fluids).

Secondary assessment usually begins while the primary assessment is underway. This assessment extends the alphabetical mnemonic.

LINKS TO NATIONAL PATIENT SAFETY STANDARDS

NSQHS Standard 9:
Recognising and Responding to Clinical Deterioration in Acute Health Care

'The intention of this standard is to ensure a patient's deterioration is recognised promptly and appropriate action is taken.' (ACSQHC, 2012, p. 61)

Implementing this standard is achieved by the establishment and maintenance of systems for recognising and responding to clinical deterioration.

These systems include processes that recognise clinical deterioration and escalating care to ensure appropriate action is taken in patients whose condition is deteriorating.

Effective communication should exist across all individuals involved in a person's care (including the person themselves and their significant others).

Caring for individuals experiencing trauma and shock requires the need to observe, recognise and monitor physiological changes that could signal a patient's deterioration.

Efficient and appropriate systems are imperative to ensure the safety of not only the person receiving appropriate care, but also any other individual involved in their care.

TABLE 10.2 Champion Revised Trauma Scoring System

TEST	SCORE	CODED VALUE
Glasgow Coma Scale*	13 to 15	4
	9 to 12	3
	6 to 8	2
	4 to 5	1
	3	0
Systolic blood pressure (mmHg)	> 89	4
	76 to 89	3
	50 to 75	2
	1 to 49	1
	0	0
Respiratory rate (breaths/min)	10 to 29	4
	> 29	3
	6 to 9	2
	1 to 5	1
	0	0
	Total score:	_____

The highest possible total score is 12. The lowest possible score is 0. The higher the total score, the greater the chance of survival.

*See Chapter 40 for instructions for using the Glasgow Coma Scale.

Source: Based on Centers for Disease Control and Prevention (2009). Guidelines for field triage of injured patients. *Morbidity and Mortality Weekly Report,* 58(RR-1), 15. Retrieved from www.cdc.gov/mmwe/pdf/rr/rr5801.pdf.

- **F** is a full set of vital signs. It may also stand for having family members present during treatment.
- **G** is giving comfort measures, both physical and emotional, to the person and family.
- **H** is head-to-toe assessment and medical history that includes visual and manual assessment as well as auscultation.
- **I** is inspection of posterior surfaces for any injuries.

The Glasgow Coma Scale is another scoring system that is used to quantify the level of consciousness following traumatic brain injury (see Chapter 40).

CRITICAL INTERVENTIONS As life-threatening problems are identified during the primary assessment, appropriate on-the-scene interventions must be performed immediately. These include providing life support, immobilising the cervical spine, managing the airway and treating haemorrhage and shock.

Immobilisation of the person's cervical spine is a primary intervention. The person is placed on a spine board and a cervical collar and head immobiliser are applied (see Figure 10.5). The cervical spine may also be immobilised by log rolling the person onto a board, placing towel rolls or a head immobiliser along the sides of their head, and securing them to the board. If the person was wearing a helmet at the time of injury, the helmet should remain on until they arrive at the hospital, unless their airway is at risk. If necessary, healthcare personnel at the scene will remove the helmet by manipulating it over the person's nose and ears while holding their head and neck immobile; safe removal requires at least two people. Improper removal risks injury or additional injury to the spinal cord.

FIGURE 10.5 ■ Immobilisation of the cervical spine at the scene of the accident is essential to prevent further injury to the spinal cord. The combined use of a hard cervical collar, head blocks and tape best restricts flexion, extension, rotation and lateral bending of the neck

Source: © Michael Donne/SPL/Getty Images.

If the person's airway is patent, oxygen is administered. Ventilations may be assisted with a bag-valve-mask resuscitator until airway management is achieved. Active external bleeding is controlled by direct pressure. Measures to reverse shock (discussed later in the chapter) are initiated.

RAPID TRANSPORT People who have multiple injuries must be transported as soon as possible to a regional trauma centre. The most common modes of rapid transport are ground ambulance and air ambulance, which includes helicopters specially staffed and equipped to care for trauma victims. Figure 10.6 shows a flight nurse assessing a person. Stable people within access of a ground ambulance are best transported by ground. Unstable people and those injured in the wilderness or other areas in which ground access is difficult may best be transported by air. When these transport systems are unavailable, the person is transported by any possible means.

Emergency department care

ON ARRIVAL Multidisciplinary care and teamwork are required to ensure assessment and resuscitation strategies are implemented in a timely manner. Initial assessment and evaluation follows the process of primary survey, resuscitation, secondary survey, diagnosis, then definitive treatment or transfer to an appropriate healthcare facility that can provide this treatment.

DIAGNOSIS The diagnostic tests ordered once the person reaches the hospital depend on the type of injury they have sustained. Tests that may be ordered for victims of trauma include the following:

- *Blood type and crossmatch* involves typing the person's blood for ABO antigens and Rhesus (Rh) factor, screening the blood for antibodies and crossmatching the person's serum and donor red blood cells.

FIGURE 10.6 ■ Flight nurses provide initial assessment, stabilisation and support for people with trauma

Source: © Robert Garvey/Corbis.

- *Arterial blood gases* evaluates oxygenation, acid–base balance and the presence of metabolic or respiratory compensatory mechanisms.
- *Full blood examination, electrolytes and coagulation* may be ordered after stabilisation and resuscitation.
- *Blood glucose level* to identify correctable cause of decreased level of consciousness; also early hypoglycaemia has been linked to increase risk of infection and mortality post trauma.
- *Blood alcohol level* measures the amount of alcohol in a person's blood. Studies have found that between 20% and 50% of people who are injured may be intoxicated. Alcohol alters the person's level of consciousness and response to pain.
- *Urinalysis*—perform dipstick to exclude occult haematuria. *Urine drug screen* may also be ordered. Like alcohol, drugs such as cocaine alter the person's level of consciousness and overall response to the primary survey.
- *Radiography*—anterior posterior chest x-ray to aid in diagnosis and confirmation of endotracheal or invasive central line placement; pelvic film for identification of pelvic fractures.
- *Focused abdominal sonography in trauma (FAST)* exam is a portable ultrasound examination used to identify the presence of free fluid in body cavities where it is not supposed to be. Primary focus is on the peritoneum but can also look at the pleura and pericardium.
- *Diagnostic peritoneal lavage* determines the presence of blood in the peritoneal cavity, which may indicate abdominal injury. This test is generally done in the emergency department. A local anaesthetic (such as lignocaine) is injected subcutaneously and a small incision is made in the lower abdomen. A catheter is placed into the peritoneal cavity and any free blood is aspirated. If free blood is found, the person is taken to the operating room for exploratory surgery. If no free blood is aspirated, 1 L of a warm isotonic crystalloid solution (such as normal saline) is rapidly infused into the peritoneal cavity and then allowed to drain by gravity. If the solution returns pink and is found to have the presence of red blood cells, white blood cells, bile, food or faeces, the test is considered positive and the person is taken to the operating room for exploratory surgery. This procedure has been used less since the inception of the FAST exam.
- *Pregnancy test* for any woman of childbearing age rules out the potential for pregnancy and foetal injury.
- *Computed tomography (CT) scans* can discover injuries to the brain, skull, spine, spinal cord, chest and abdomen.
- *Magnetic resonance imaging (MRI) scans* can discover injuries to the brain and spinal cord.

MEDICATIONS

Medications used to treat the person who has experienced trauma depend on the type and severity of the injuries, as well as the degree of traumatic shock that is present. The following general categories of medications may be used. (Fluid administration and the drugs listed are covered later in the chapter in discussion of the collaborative care of the person in shock.)

- Blood components and crystalloids are administered intravenously in the initial treatment of traumatic shock to replace intravascular volume.
- Inotropic drugs (drugs that increase myocardial contractility) are given to increase cardiac output and improve tissue perfusion. These drugs, administered only after fluid volume restoration, include dopamine hydrochloride, dobutamine hydrochloride and isoprenaline hydrochloride (Isuprel).
- Vasopressors may be administered in conjunction with fluid replacement to treat neurogenic, septic or anaphylactic shock. Examples of vasopressors include dopamine, adrenaline and noradrenaline.
- Opioids administered by bolus or continuous infusion are used to treat pain as soon as possible. However, the effects of the pain medications may alter the person's responses and mask potential injuries. If pain medications are administered they must be carefully regulated and the person must be closely monitored.
- Immunisation: if the person has penetrating and open wounds, tetanus immunisation status must be determined. If they are unable to remember when the last tetanus immunisation was given or are unable to answer, tetanus prophylaxis is given.

BLOOD TRANSFUSIONS

Blood and blood components are initially produced in the body and then donated for use by another person through a **transfusion** (an infusion of blood or blood components). A person may be given whole blood, packed red blood cells (RBCs), platelets, plasma, albumin, clotting factors, prothrombin or cryoprecipitate (see Table 10.3). Blood and blood components increase the amount of haemoglobin available to carry oxygen to the cells, improve haemoglobin and haematocrit levels during active bleeding, increase intravascular volume and replace deficient substances such as platelets and clotting factors.

Each person has one of four blood types: A, B, AB or O. The blood group antigens A and B, present on RBC membranes, form the basis for the ABO blood categorisation. The presence or absence of these inherited antigens determines one's blood type. People with blood type A have A antigens, those with type B have B antigens, those with type AB have both antigens and those with neither antigen have blood type O (called a universal donor).

FAST FACTS

- Type AB blood is the 'universal recipient'.
- Type O blood is the 'universal donor'.

ABO antibodies develop in the serum of people whose RBCs lack the corresponding antigen; these antibodies are called anti-A and anti-B. The person with blood type B has A antibodies, the person with type A has B antibodies, the person with type O has both types of antibodies and the person with blood type AB has no antibodies (called a universal recipient).

A third antigen on the RBC membrane is D. People who are Rh positive (RH^+) have the D antigen, whereas people who are Rh negative (RH^-) do not. These antigens and antibodies may cause ABO and Rh incompatibilities.

TABLE 10.3 Volume resuscitation therapies

COMPONENT	INDICATIONS	ADVANTAGES	DISADVANTAGES
Compound sodium lactate (or Hartmann's solution)	Restoration of circulating volume Replacement of electrolyte deficits	Good availability Safe to use Low cost Aids in buffering acidosis	Rapid movement from the intravascular to the extravascular space, leading to three or more times requirement for replacement
Normal saline	Restoration of circulating volume Vehicle compatible with administration of blood	Good availability Low cost Safe to use	Hyperchloraemic acidosis associated with prolonged use of sodium solutions
Whole blood	Replaces blood volume and oxygen-carrying capacity in haemorrhage and shock	Contains RBCs, plasma proteins, clotting factors and plasma	Contains few platelets or granulocytes; deficient in clotting factors V and VII Greatest risks are for incompatibility or circulatory overload Risk of transmitting blood-borne pathogens
Packed RBCs	Restoration of intravascular volume Replacement of oxygen-carrying capacity	One unit of RBCs should increase the haemoglobin of a 70 kg adult by approximately 1 g/L in the absence of volume overload or continuing blood loss	Red cells require compatibility testing Risk of transmitting blood-borne pathogens Should be warmed to prevent hypothermia Contains little or no clotting factors
Platelets	Significant thrombocytopenia (platelet count less than 50×10^9/L) Continued haemorrhage	Compatibility testing is not required Typical platelet transfusion should raise the platelets of a 70 kg adult approximately $20–40 \times 10^9$/L	Post-exposure prophylaxis with anti-Rh immune globulin should be considered following Rh^+ platelet transfusion to an Rh^- woman Risk of transmitting blood-borne pathogens
Albumin	Expends blood volume in shock and trauma	Good availability	Is not a substitute for whole blood Hypersensitivity reactions can occur Risk of transmitting blood-borne pathogens
Fresh frozen plasma (FFP)	Documented coagulopathy Restoration of clotting factors Supplies plasma proteins	Crossmatching and Rh compatibility not required	Thawed by transfusion service provider—takes approx. 30 mins Should be ABO compatible Risk of transmitting blood-borne pathogens
Cryoprecipitate	Coagulopathy with low fibrinogen Restoration of fibrinogen	Rh type not important	Risk of transmitting blood-borne pathogens Contains haemagglutinins Should be ABO compatible, as intravascular haemolysis can occur if a large volume of ABO-incompatible cryoprecipitate is administered

TABLE 10.4 Blood group types and compatibilities

BLOOD GROUP	RBC AGGLUTINOGENS	SERUM AGGLUTINOGENS	COMPATIBLE DONOR BLOOD GROUPS	INCOMPATIBLE DONOR BLOOD GROUPS
A	A	Anti-B	A, O	B, AB
B	B	Anti-A	B, O	A, AB
AB	A, B	None	A, B, AB, O	None
O	None	Anti-A, anti-B	O	A, B, AB

Note: Group O is often called the universal donor, and group AB is called the universal recipient.

A transfusion of incompatible blood causes haemolysis (breakdown) of the RBCs and agglutination of erythrocytes. (*Agglutination* is the clumping of cells which results from their interaction with specific antibodies.) The ABO blood group names and compatibilities are listed in Table 10.4.

Before RBCs or whole blood can be administered, a series of procedures determine donor and recipient ABO types and Rh groups. These procedures—called a *type and crossmatch*—are performed by mixing the donor cells with the recipient's serum and watching for agglutination. If none occurs, the blood is considered compatible.

Despite meticulous procedures for matching blood types and antigens, blood transfusion reactions may still occur. The most common is a *febrile reaction*. Antibodies within the person receiving the blood are directed against the donor's white blood cells, causing fever and chills. Febrile reactions typically begin during the first 15 minutes of the transfusion. Using leucocyte-reduced blood avoids future febrile reactions.

Hypersensitivity reactions result when antibodies in the person's blood react against proteins, such as immunoglobulin A, in the donor blood. Hypersensitivity reactions may appear during or after the transfusion. The manifestations of hypersensitivity reaction include *urticaria* (the appearance of reddened wheals of various sizes on the skin) and itching.

Haemolytic reactions, the most dangerous transfusion reactions, usually result from an ABO incompatibility. Clumping RBCs block capillaries, decreasing blood flow to vital organs. In addition, macrophages engulf the clumped RBCs, releasing free haemoglobin into the circulating blood; the haemoglobin is then filtered by the kidneys and may block the renal tubules causing renal failure. Haemolytic reactions usually begin after infusion of 100 to 200 mL of the incompatible blood. Manifestations of a haemolytic reaction include flushing of the face, a burning sensation along the vein, headache, urticaria, chills, fever, lumbar pain, abdominal pain, chest pain, nausea and vomiting, tachycardia, hypotension and dyspnoea. If any of these manifestations appear, the blood transfusion must be immediately discontinued.

Other risks to people receiving blood include circulatory overload, electrolyte imbalances and infectious diseases such as hepatitis or cytomegalovirus.

People who have experienced trauma of any severity have had substantial blood loss and are usually in hypovolaemic shock. Blood replacement is the treatment of choice to restore oxygen-carrying capacity. People in severe shock with active bleeding are given universal type O red blood cells immediately. Those with less severe injuries or bleeding may be stabilised with other types of fluids until type-specific or crossmatched blood is available.

LINKS TO NATIONAL PATIENT SAFETY STANDARDS

NSQHS Standard 7:
Blood and Blood Products

'The intention of this standard is to ensure that the patients who receive blood and blood products do so appropriately and safely.' (ACSQHC, 2012, p. 48)

Implementing this standard is achieved by the establishment of systems that ensure safe and appropriate prescription and administration of blood and blood products. These systems include processes facilitating accurate documentation, storage, transport, use and disposal. Effective communication regarding risks, benefits and use should exist across all individuals involved in a person's care (including the person themselves and their significant others).

Caring for individuals experiencing haematological conditions will often result in the need to administer blood or blood products in order to manage the person's condition. As with any biological material, various risks are involved in all facets of this treatment. Efficient and appropriate systems are imperative to ensure the safety of not only the person receiving the product, but also any other individual involved in their care.

Source: © Australian Commission on Safety and Quality in Health Care.

Some emergency departments and trauma centres use autotransfusion to provide blood for transfusions for the person with multiple injuries and/or severe shock. Autotransfusion is a method of blood administration in which special equipment collects and returns the person's own blood. The chest cavity is the typical source of blood to be autotransfused.

Nursing considerations for blood transfusion therapy are described in the following 'Medication administration' box.

MEDICATION ADMINISTRATION Blood transfusion

The risk of and seriousness of blood transfusion reactions require that extreme caution be taken when blood is administered. Most fatal transfusion reactions are the result of human error. Although general guidelines are provided here, each institution has specific policies and procedures that must be followed. Prior to beginning the transfusion, the nurse must determine that typed and crossmatched blood is available and collect the needed equipment: a blood administration set, a large-bore intravenous catheter (usually 18- or 19-gauge) and normal saline solution. Only normal saline is used with a blood transfusion as dextrose causes clumping of RBC and distilled water causes haemolysis.

NURSING RESPONSIBILITIES

- Obtain the person's consent.
- Assess for any previous reactions to blood.
- Explain the procedure to the person and answer any questions.
- Using aseptic non-touch technique, prepare the intravenous equipment. Prime the administration set with the saline.
- If venous access is not already in place, organise insertion of the intravenous needle (following body substance precautions) and begin administering the saline.
- Using institutional procedure, obtain the blood from the blood bank or laboratory. Administer the blood immediately; if this is not possible, return it to the blood bank or laboratory.
- Check and document that the donor and recipient blood have been tested and are compatible. This usually involves two nurses, each verifying that:
  a. An order for blood has been written.
  b. Type and crossmatch have been done.
  c. The name of the person and the name on the blood bag are identical.
  d. The number assigned to the unit of blood is identical to the one on the requisition for the blood.
  e. Blood type and Rh factor are compatible.
  f. The blood has not exceeded its expiration date.
  g. The unit of blood is intact and has no bubbles or discolouration.
- Identify the person by reading the armband identification and, if conscious, asking the person to tell you their name. Check the armband identification against the unit of blood labelling.
- Gently invert the blood bag several times to mix the plasma and RBCs.
- Take and record vital signs as a baseline.
- Attach the unit of blood to the administration set and begin the transfusion at a slow rate of about 2 mL per minute. (Some trauma victims may have blood infused at a rapid rate. If blood is infused rapidly, it may need to be warmed through an appropriate warming device during administration to prevent hypothermia.) Stay with the person for at least the first 15 minutes of the transfusion, monitoring for manifestations of a reaction and taking their vital signs.
- Continue to monitor the person during the transfusion, assessing for manifestations of hypersensitivity or haemolytic reactions, and taking and recording vital signs as directed by institutional policy.
- After the first 15 minutes the rate of infusion is increased. If there is no danger of fluid volume overload, most people can tolerate an infusion of a unit of blood (ranging from 250 to 500 mL depending on the blood component administered) in 2 hours. The unit of blood must be administered within 3 to 4 hours; after this time it has warmed and begins to deteriorate.
- Take the following actions if manifestations of a reaction occur:
  a. Stop the infusion of blood immediately and notify the physician. Continue to infuse the saline.
  b. Take vital signs and assess manifestations.
  c. Compare the blood slip with the unit of blood to ensure that an identification error was not made.
  d. Save the blood bag and any remaining blood for return to the laboratory for further tests to determine the cause of the reaction.
  e. Follow institutional policy for collecting urine and venous blood samples.
  f. Continue to monitor the person and provide prescribed interventions to treat hypersensitivity or haemolytic manifestations.

HEALTH EDUCATION FOR THE PERSON AND FAMILY

- In terms of viral safety, Australia has one of the safest blood supplies in the world. The possible risks of blood transfusions include transmission of infectious diseases and acquired immune deficiency syndrome (AIDS). However, with careful handling and storage of blood, bacterial contamination is rare. Although hepatitis may be transmitted by contaminated blood, new tests for hepatitis antibodies in donor blood are reducing this risk. Many people are afraid of contracting AIDS from blood even though donor screening and HIV-antibody testing of donor blood have virtually eliminated the transmission of HIV by blood transfusion.
- During the transfusion, immediately report any warm feelings, chills, itching, feelings of weakness or fainting, or difficulty breathing.
- Report any signs of a delayed transfusion reaction: chills, fever, cough, difficulty breathing, hives, itching or changes in circulation, and seek medical care immediately.
- Discuss any religious or cultural considerations related to blood transfusion.

Emergency surgery

Immediate surgical intervention is indicated when the person remains in shock despite resuscitation and there is no obvious external sign of blood loss. Abdominal and chest x-ray, ultrasound studies, diagnostic peritoneal lavage or CT scan may be performed to help identify the potential source of the blood loss. It is important for the emergency or trauma nurse to speak with the family as soon as possible and keep them informed about what is happening to their family member. Unfortunately, the need for emergency surgery may not allow time for family members or significant others to see their loved one before transfer to the operating room.

Organ donation

The *Australian Organ and Tissue Donation and Transplantation Authority Act 2008* was passed by the federal parliament in November 2008 and saw the establishment of the Australian Transplant Authority in January 2009. The focus of the Act was to implement the national reform package on organ and tissue donation by working with states and territories, clinicians, consumers and the community sector to build a world-leading organ and tissue donation and transplantation system for Australia. Under this Act, the Australian Organ Donor Registry (AODR) is the register of legal consent and is the only official national register for organ and tissue donation in Australia. The AODR ensures that consent (or objection) to donating organs and tissue for transplantation can be verified 24 hours a day, 7 days a week by authorised medical personnel, anywhere in Australia.

Consent for organ donation may be given not only by the donor but also by a spouse, adult children, parents, adult siblings, guardian or any adult authorised to do so. The Act also encourages people to carry donor cards. It is rare for a donation to proceed without the agreement of family or next-of-kin with their loved one's decision.

The increased success of organ transplant has made it a more common and valuable method of prolonging and improving life; however, many people are still waiting for organs and many people who may be suitable organ donors die each year from trauma. Organs and tissues that may be transplanted include bones, eyes, liver, lungs, skin, muscles and tendons, pancreas, intestines, kidneys, heart and heart valves.

The organ donation process begins with identification of the potential organ donor, which includes most people.

Certain factors are considered when determining if a person is an appropriate organ donor. They include:

- the circumstances of how, where and when a person dies
- any medical history
- age is considered, but it is more important to assess how the organs are working/functioning.

The family needs to be made aware of the person's prognosis and presented with the option of donating their organs. Both the family's and the person's feelings about organ donation must be explored. Even if the person carries an organ donation card, many institutions will not remove any organs without a signature from a family member or other authorised person. The nurse must always respect the family's concerns and feelings during this process. Some members of certain cultural groups may have religious constraints or issues of mistrust that may interfere with the donation process. Donation coordinators facilitate the process and are responsible for contacting family and discussing options.

Box 10.1 lists **brain death criteria**. Irreversible loss of all brain function is to be clinically confirmed. Along with the person being examined by two experienced medical practitioners, in some cases ancillary testing such as angiography or radionucleotide imaging will be used to provide additional evidence. Once brain death has been confirmed, the family must also understand the diagnosis and be allowed time to accept the person's death.

BOX 10.1 Brain death criteria

Clinical signs

- Irreversible condition
- Apnoea with a $PaCO_2$ greater than 60 mmHg
- No response to deep stimuli
- No spontaneous movement (some spinal cord reflexes may be present)
- No gag or corneal reflex
- No oculocephalic or oculovestibular reflex
- Absence of toxic or metabolic disorders

Confirmatory tests

- Cerebral blood flow study
- Electroencephalogram

LINKS TO NATIONAL PATIENT SAFETY STANDARDS

NSQHS Standard 5:
Patient Identification and Procedure Matching

'The intention of this standard is to correctly identify all patients whenever care is provided and correctly match patients to their intended treatment.' (ACSQHC, 2012, p. 40)

Implementing this standard is achieved by the establishment and maintenance of systems that use at least three approved patient identifiers to ensure that patients are correctly identified and crossmatched when providing care, therapy and/or services. Effective communication should exist across all individuals involved in a person's care (including the person themselves and their significant others). Clinicians and other members of the workforce use the patient identification and procedure matching systems.

The development of safety routines in patient identification and treatment matching ensures patient safety against any mistakes that may progress and cause harm, whether those components are diagnostic, therapeutic or supportive.

Source: © Australian Commission on Safety and Quality in Health Care.

When caring for an adult person who is an organ donor, the nurse ensures the following are maintained:

- systolic blood pressure of 90 mmHg to keep the person's organs perfused until removal
- urine output at >0.5 mL/kg/hr. This is usually accomplished by administering fluids and/or inotropic agents such as dopamine
- oxygen saturation at 90% or greater.

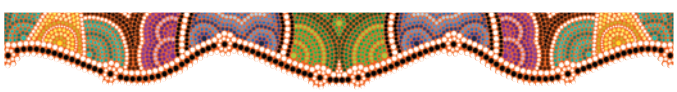
Forensic considerations

Injuries often happen under circumstances that require legal investigation. Many injuries, particularly penetrating trauma, may involve criminal activity. Therefore, the nurse must recognise the need to identify, store and properly transfer potential evidence for medico-legal investigations.

Each item of clothing removed from the person must be placed in a breathable container, such as a paper bag, and documented appropriately. Bullets or knives should be labelled, with their source specified and given to the proper authorities. Holes found in clothing should not be disturbed. When it is necessary to cut off clothing, these areas should be avoided and never cut through if at all possible.

The person's hands may yield important evidence, such as powder burns or residue on the skin, or tissue or hair samples beneath the fingernails. In the case of death, it is recommended that paper bags be placed over the person's hands if the presence of evidence is suspected; otherwise the evidence should be collected from nail clippings.

Identify all wounds and document these findings with pictures, diagrams or written descriptions. Once the evidence has been collected, identified and properly stored, ensure that it is given to the appropriate authorities. A chain of custody needs to be maintained throughout the entire process. All evidence must be identified and labelled, and documentation procedures must chronicle where and in whose possession the evidence has been. For the chain of custody to remain intact, the evidence must remain in the continuous possession of identified people and be marked and sealed in tamper-proof containers.



Nursing care

Nursing care of the person who has been injured begins with a primary assessment and the initiation of collaborative interventions for any life-threatening injuries. Nursing care is directed towards the person's specific responses to trauma.

Health promotion

Prevention efforts can reduce the incidence and severity of trauma. Areas of health promotion and trauma prevention interventions for individuals and communities include the following:

- *Motor vehicle safety*: seat belts, air bags, helmets, driving under the influence of alcohol or drugs, reckless driving, visual or cognitive deficits in the older adult, mobile phone use, driver fatigue.
- *Home safety*: electrical wiring, falls, burns, drowning, snow and ice removal.
- *Farm safety*: operating heavy equipment, safe storage of chemicals such as fertilisers.
- *Work safety*: operating work equipment, wearing safety equipment, removal of jewellery.
- *Relationships*: domestic violence, child abuse, older adult abuse or neglect.
- *Communities*: condition of streets, neighbourhood safety, gun control, gangs.

In providing information about trauma prevention to members of the community, the nurse serves as a healthcare educator, political activist and safety advocate.

Assessment

See 'Interprofessional care', above, for assessment of the person experiencing trauma.

Nursing diagnoses and interventions

The person experiencing trauma has many complex and interrelated actual or potential alterations in health. The nursing care in this section focuses on person and family problems with respirations, infection, immobility, spirituality and stress. Nursing interventions for decreased cardiac output and altered perfusion are discussed in the section of the chapter on nursing care of the person in shock.

Ineffective maintenance of airway

The person with multiple injuries is at great risk of developing airway obstruction and apnoea. Facial injuries, loose teeth, blood and vomitus increase the risk of aspiration and obstruction. Neurological injuries and cerebral oedema alter the person's respiratory drive and ability to keep the airway clear.

- Assess if airway is patent, maintainable or non-maintainable. Assess for manifestations of airway obstruction: stridor, tachypnoea, bradypnoea, cough, cyanosis, dyspnoea, decreased or absent breath sounds, changes in oxygen levels and changes in level of consciousness. *Assessing the airway and initiating interventions are the first steps in managing the person with multiple injuries.*
- Monitor oxygen saturation by applying a pulse oximeter. Adjust oxygen flow to maintain oxygen saturation above 95%. *Changes in oxygen saturation as measured by the pulse oximeter reflect the effectiveness of the person's ventilation. Pulse oximetry in people who have been exposed to carbon monoxide (i.e. house fires) is unreliable since it cannot differentiate carboxyhaemoglobin from oxyhaemoglobin.*
- Monitor level of consciousness. *An early sign of an ineffective airway is change in the person's behaviour. If the person becomes restless, anxious, combative or unresponsive, airway patency and ventilation effectiveness need to be immediately evaluated and appropriate interventions initiated.*

NURSING CARE PLAN A person with multiple injuries

Jane Souza is a 25-year-old married woman with two children who provides daycare for preschool children in her home. As she is driving on the highway at 100 km per hour, a car crosses the median strip and strikes her vehicle head on. Jane, who is not wearing a seat belt, is thrown forward against the steering wheel. The front of her car is pushed up against her by the car that struck her, entrapping her lower extremities.

After extensive efforts to extricate her from the car, Jane is transported to the local trauma centre. She is still conscious, is receiving high-flow oxygen by mask and has one intravenous line in place. Her vital signs are a palpable systolic blood pressure of 80, a pulse rate of 120 and a respiratory rate of 36. On arrival, she states that she is having difficulty breathing.

ASSESSMENT

- *Airway*: Maintainable with high-flow oxygen in place.
- *Breathing*: Respiratory rate of 36, decreased breath sounds on the right side, equal chest wall movement.
- *Circulation*: No palpable radial pulses; palpable brachial pulses. Cardiac monitor shows sinus tachycardia. No active external bleeding noted. Skin colour pale, cool to the touch and diaphoretic. One intravenous access in place and crystalloid fluids running.
- *Disability*: Moved her fingers when asked; complains of difficulty breathing; denies that she is hurt. Pupils 4 mm, equal and reacting to light. Extremity movement is limited due to broken limbs.
- *Exposure*: Has a broken right arm and an open fracture of the left ankle. Multiple bruising and abrasions on right side of chest.

Because of Jane's respiratory distress, she is intubated and ventilated with 100% oxygen. Another intravenous line is inserted and O-negative blood administered. It is determined that she has sustained a pneumothorax in the right side and an intercostal catheter is inserted.

DIAGNOSES

- *Ineffective breathing pattern* related to multiple bruises and abrasions on the right side of the chest and respiratory difficulty.
- *Deficient fluid volume* related to acute internal blood loss (presumed because no active bleeding can be found).
- *Risk of injury* related to trauma resuscitation.

PLANNING

- Continuously monitor airway and oxygenation.
- Continuously monitor circulatory status.
- Prepare for ongoing care.

Expected outcomes

- Maintain adequate oxygenation.
- Maintain adequate circulating blood volume.

IMPLEMENTATION

- Ensure patency of airway maintained—secure and monitor endotracheal tube.
- Assess and maintain ventilation—monitor ventilatory support, visualise chest expansion, assess air entry through lung auscultation, monitor oxygen saturations.
- Monitor the effects of fluid and blood administration, including any changes in blood pressure, heart rate and rhythm, skin colour and turgor.
- Insert urinary catheter and monitor urine output.
- Prepare for transfer to the operating room for emergency surgery.
- Explain all procedures.
- Keep family informed about her condition.

EVALUATION

- Jane is transferred to the operating room, where it is determined that she has a ruptured spleen and a serious pelvic fracture. Jane's treatment continues in the operating room.

CRITICAL THINKING IN THE NURSING PROCESS

1. Is the nursing diagnosis *Deficient fluid volume* appropriate for Jane Souza? Why or why not?
2. The assessment of a person who has experienced trauma is, in order: A = airway, B = breathing and C = circulation. What is the rationale for this sequence?
3. Following surgery, Jane is moved to the surgical intensive care unit. She is very anxious and restless. What assessments would you perform to identify the cause of her restlessness?
4. Infection is a common complication for a person experiencing trauma. Describe five risks for infection that are present from the time of injury to the time of hospital discharge.

REFLECTION ON THE NURSING PROCESS

1. What communication and education strategies would you use with Jane following surgery?

Risk of infection

Traumatic injuries are considered dirty wounds. Projectiles enter the body through dirty surfaces and clothing, carrying dirt and debris into the wound. Open fractures provide a portal for the entry of bacteria and dirt. Even with surgical intervention, the wounds often remain contaminated.

- Practise effective hand hygiene. *Handwashing remains the single most important factor in preventing the spread of infection.*
- Use standard precautions and aseptic technique when caring for wounds. *Standard precautions are essential to protect the person and the nurse from infection.*

In addition:

- Monitor wounds for odour, redness, heat, swelling and copious or purulent drainage.
- Monitor hidden wounds, such as those under casts, by asking the person whether pain has increased and by observing for increased drainage and heat over the area of the wound.
- Ensure that cross-contamination between wounds does not occur. Collect drainage in ostomy bags if it is copious. The skin is the first line of defence against infection; wounds provide a portal of entry for organisms. Risk factors for wound infection include contamination, inadequate wound care and the condition

of the wound at the time of closure. *Aseptic techniques used in applying and changing dressings reduce the entry of organisms.*

- Measure and record vital signs, including temperature every 2 to 4 hours. *Vital signs, particularly an elevated body temperature, may indicate the presence of an infection.*
- Provide adequate fluids and nutrition. *Adequate fluids, kilojoules and protein are essential to wound healing.*
- Assess for manifestations of gas gangrene: fever, pain and swelling in traumatised tissues; drainage with a foul odour. *Gas gangrene is usually caused by the organism* Clostridium perfringens. *This bacterium is found in the soil and can be introduced into the body during a traumatic injury. The organism grows in the tissues, causing necrosis; hydrogen and carbon dioxide are released with resultant swelling of tissues. If the infection continues, tissues are progressively destroyed and sepsis and death may result.*
- Assess status of tetanus immunisation and administer tetanus toxoid or human toxin–antitoxin as prescribed. *Tetanus is caused by an exotoxin produced by* Clostridium tetani*, usually introduced through an open wound. The organism is commonly found in the soil.*
- Use strict aseptic technique when inserting catheters, suctioning, administering parenteral medications or performing any other invasive procedure. *Using aseptic technique during invasive procedures reduces the risk of entry of organisms.*

Impaired physical mobility

The person with trauma injuries is often unable to change position independently and is at risk of complications of the integumentary, cardiovascular, gastrointestinal, respiratory, musculoskeletal and renal systems. At greatest risk are those who have had multiple injuries, spinal cord injuries, peripheral nerve injuries and traumatic amputations. Collaborate with the physiotherapist and occupational therapist (if available) to determine the most effective types and schedule of exercises and assistive devices.

The aim of therapy is to ensure the person will maintain joint range of motion and avoid development of contractures and pulmonary complications such as atelectasis.

- If active bleeding or oedema is not present, provide active or passive exercises to affected and unaffected extremities at least once every 8 hours. *Exercise improves muscle tone, maintains joint mobility, improves circulation and prevents contractures.*
- Assist the person to turn, cough and deep breathe, and use an incentive spirometer at least every 2 hours. *Changing positions, coughing, deep breathing and incentive spirometry reduce the risk of integumentary and respiratory complications.*
- If the person is unable to be moved and positioned, consider a specialty bed such as the kinetic continuous rotation bed (see Figure 10.7). *The kinetic continuous rotation bed allows continuous turning of the person; the motion decreases pulmonary complications, venous stasis, postural hypotension, urinary stasis, muscle wasting and bone demineralisation.*
- Monitor the lower extremities each day for manifestations of deep venous thrombosis: heat, swelling and pain. If anti-embolic stockings or intermittent compression stockings are used, remove them for 1 hour during each shift and assess the skin. *Venous stasis results when surrounding muscles are unable to contract and help move the blood through the veins. Thrombus (clot) formation in deep veins is a major risk of pulmonary embolism.*

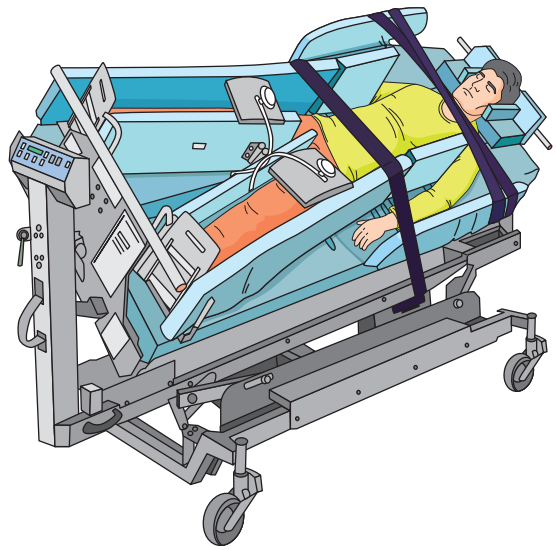


FIGURE 10.7 ■ A kinetic continuous rotation bed provides a means of turning the person with multiple injuries to decrease the hazards of immobility

Spiritual distress

Trauma generally strikes without warning and carries potentially devastating consequences, including severe alterations in the lives of the victim and family, and death. The traumatic death of a loved one may be the most difficult event a family ever experiences. The decision to cease life support systems or to donate organs challenges the family's belief systems and psychological stability. Nursing care of the family (or person) experiencing spiritual distress includes the following:

- Give the family information about the option to donate the person's organs. The decision to donate organs needs to be based on information about the person's condition, prognosis and the criteria by which brain death is determined. *It is important to convey to family members that organ donation is only an option and that they should not feel they are obligated to consent or are doing something wrong if they do not consent.*
- Encourage the family to ask questions and express their feelings about the traumatic event and/or organ donation. *Allowing families to express their feelings may help prevent long-term consequences such as guilt.*

- Refer the family for follow-up care. Long-term follow-up is important for the family facing the sudden death of a loved one. *Grieving is not an overnight process and providing the family with resources that may be used in the future may help prevent future crises and dysfunction.* (For more information see Chapter 4.)

Post-traumatic stress disorder

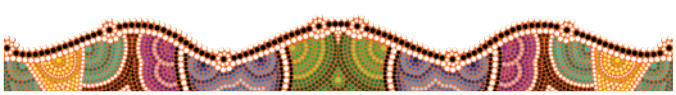
Post-traumatic stress disorder is an intense, sustained emotional response to a disastrous event. It is characterised by emotions that range from anger to fear and by flashbacks or psychic numbing. In the initial stage, the person may be calm or may express feelings of anger, disbelief, terror and shock. In the long-term phase, which begins anywhere from a few days to several months after the event, the person often experiences flashbacks and nightmares of the traumatic event. The person may call on ineffective coping mechanisms, such as alcohol or drugs, and withdraw from relationships.

- Assess emotional responses while providing physical care. Observe for excessive crying, sleep problems, suspiciousness and fear during the initial phase of treatment. If the person is unconscious, encourage family members and friends to express their feelings. *These assessments provide valuable information about the person's ability to cope with the trauma.*
- Be available if the person wishes to talk about the trauma and encourage expression of feelings. *The person may initially deny negative feelings; this denial is a coping mechanism in the initial phase of recovery.*
- Teach relaxation techniques such as deep breathing, progressive muscle relaxation or imagery (see Chapter 8). *These techniques are often useful in coping when thoughts of the trauma recur.*
- Refer the person and family members for counselling, psychotherapy or support groups as appropriate. *Continued therapy may be necessary in assisting the person and family to resolve the acute and long-term effects of trauma.*

Community-based care

Address the following topics to prepare the person and family for home care:

- the type of home environment to which the person will be returning, including any changes that will be required to let them function in that environment
- medications, dressings, wound care, equipment and supplies
- special diet, if needed
- rehabilitation plan and its effect on the person's family
- follow-up appointments with the general practitioner or at the trauma clinic
- emotional changes that the person may undergo as a result of the trauma
- helpful resources
  - home healthcare
  - community support groups
  - National Stroke Foundation.



THE PERSON EXPERIENCING SHOCK

Shock is a clinical syndrome characterised by a systemic imbalance between oxygen supply and demand. This imbalance results in a state of inadequate blood flow to body organs and tissues, causing life-threatening cellular dysfunction.

Overview of cellular homeostasis and haemodynamics

To maintain cellular metabolism, cells of all body organs and tissues require a regular and consistent supply of oxygen and the removal of metabolic wastes. This homeostatic regulation is maintained primarily by the cardiovascular system and depends on four physiological components:

1. A cardiac output sufficient to meet bodily requirements.
2. An uncompromised vascular system in which the vessels have a diameter sufficient to allow unimpeded blood flow and have good tone (the ability to constrict or dilate to maintain normal pressure).
3. A volume of blood sufficient to fill the circulatory system and a blood pressure adequate to maintain blood flow.
4. Tissues that are able to extract and use the oxygen delivered through the capillaries.

In a healthy person, these components function as a system to maintain tissue perfusion. During shock, however, one or more of these components are disrupted. An understanding of basic haemodynamics is necessary to understand the pathophysiology of shock:

- **Stroke volume (SV)** is the amount of blood pumped into the aorta with each contraction of the left ventricle.
- **Cardiac output (CO)** is the amount of blood pumped per minute into the aorta by the left ventricle. CO is determined by multiplying the stroke volume (SV) by the heart rate (HR): CO = SV × HR.

CONSIDERATION FOR PRACTICE

Cardiac output (CO) = stroke volume (SV) × heart rate (HR).

- **Mean arterial pressure (MAP)** is the product of cardiac output and systemic vascular resistance (SVR): MAP = CO × SVR. When CO, SVR or total blood volume rises, MAP and tissue perfusion increase. Conversely, when CO, SVR or total blood volume falls, MAP and tissue perfusion decrease. A MAP of 70 to 110 is normal. A MAP of 60 mmHg is required to maintain adequate perfusion to the brain, heart and kidneys.
- The sympathetic nervous system maintains the smooth muscle surrounding the arteries and arterioles in a state of partial contraction called *sympathetic tone*. Increased sympathetic stimulation increases vasoconstriction and SVR; decreased sympathetic stimulation allows vasodilation which decreases SVR.

Pathophysiology

When one or more cardiovascular components do not function properly, the body's haemodynamic properties are altered. Consequently, tissue perfusion may be inadequate to sustain normal

cellular metabolism. The result is the clinical syndrome known as shock. The manifestations of shock result from the body's attempts to maintain vital organs (heart and brain) and to preserve life following a drop in cellular perfusion. However, if the injury or condition triggering shock is severe enough or of long enough duration, cellular hypoxia and cellular death will occur.

Shock is triggered by a sustained drop in mean arterial pressure. This drop can occur after a decrease in cardiac output, a decrease in the circulating blood volume or an increase in the size of the vascular bed due to peripheral vasodilation. If intervention is timely and effective, the physiological events that characterise shock may be stopped; if not, shock may lead to death. See Table 10.5 for classification of haemorrhagic shock.

Stage I: Early, reversible and compensatory shock

The initial stage of shock begins when baroreceptors in the aortic arch and the carotid sinus detect a sustained drop in MAP of less than 10 mmHg from normal levels. The circulating blood volume may decrease (usually to less than 500 mL) but not enough to cause serious effects.

The body reacts to the decrease in arterial pressure. The cerebral integration centre initiates the body's response systems causing the sympathetic nervous system to increase the heart rate and the force of cardiac contraction, thus increasing cardiac output. Sympathetic stimulation also causes peripheral vasoconstriction, resulting in increased systemic vascular resistance and a rise in arterial pressure. The net result is that the perfusion of cells, tissues and organs is maintained.

Symptoms are almost imperceptible during the early stage of shock. The pulse rate may be slightly elevated. If the injury is minor or of short duration, arterial pressure is usually maintained and no further symptoms occur.

Compensatory shock begins after the MAP falls 10 to 15 mmHg below normal levels. The circulating blood volume is reduced by 25% to 35% (1000 mL or more), but compensatory mechanisms are able to maintain blood pressure and tissue perfusion to vital organs thereby preventing cell damage.

- Stimulation of the sympathetic nervous system results in the release of adrenaline from the adrenal medulla and the release of noradrenaline from the adrenal medulla and the sympathetic fibres. Both hormones rapidly stimulate the alpha- and beta-adrenergic fibres. Stimulated alpha-adrenergic fibres cause vasoconstriction in the blood vessels supplying the skin and most of the abdominal viscera. Perfusion of these areas decreases. Stimulated beta-adrenergic fibres cause vasodilation in vessels supplying the heart and skeletal muscles (beta-1 response) and increase the heart rate and force of cardiac contraction ($beta_2$ response). Further, blood vessels in the respiratory system dilate and the respiratory rate increases ($beta_2$ response). Thus, stimulation of the sympathetic nervous system results in increased cardiac output and oxygenation of these tissues.
- The renin–angiotensin response occurs as the blood flow to the kidneys decreases. Renin released from the kidneys converts a plasma protein to angiotensin II, which causes vasoconstriction and stimulates the adrenal cortex to release aldosterone. Aldosterone causes the kidneys to reabsorb water and sodium and to lose potassium. The absorption of water maintains circulating blood volume, while increased vasoconstriction increases SVR, maintaining central vascular volume and raising blood pressure.
- The hypothalamus releases adrenocorticotropic hormone causing the adrenal glands to secrete aldosterone. Aldosterone promotes the reabsorption of water and sodium by the kidneys, preserving blood volume and pressure.
- The posterior pituitary gland releases antidiuretic hormone, which increases renal reabsorption of water to increase intravascular volume. The combined effects of hormones released by the hypothalamus and posterior pituitary glands work to conserve central vascular volume.
- As MAP falls in the compensatory stage of shock, decreased capillary hydrostatic pressure causes a fluid shift from the interstitial space into the capillaries. The net gain of fluid raises the blood volume.

Working together, these compensatory mechanisms can maintain MAP for only a short period of time. During this period, the perfusion and oxygenation of the heart and brain are adequate. If effective treatment is provided, the process is arrested and no permanent damage occurs. However, unless the underlying cause of shock is reversed, these compensatory mechanisms soon become harmful and shock perpetuates shock.

TABLE 10.5 Classification of haemorrhagic shock and presentation of the person

	COMPENSATED/ CLASS I	MILD/CLASS II	MODERATE/ CLASS III	SEVERE/CLASS IV
Blood loss	Up to 750 mL	750–1500 mL	1500–2000 mL	>2000 mL
Percentage of blood volume loss	Up to 15%	15–30%	30–40%	>40%
Heart rate (bpm)	<100	>100	>120	>140
Blood pressure	Normal or increased	Normal	Decreased	Markedly decreased
Pulse pressure	Normal or increased	Decreased	Decreased	Decreased
Capillary refill	Normal	Mild increase	Usually delayed	Delayed
Respiratory rate	Normal	Mild increase	Moderate tachypnoea	Marked tachypnoea
Urine output	>0.5 mL/kg/hr	>0.3 mL/kg/hr	<0.3 mL/kg/hr	Anuria
Mental status	Normal–slightly anxious	Mildly anxious–agitated	Anxious–confused	Lethargic–obtunded

Stage II: Intermediate or progressive shock

The progressive stage of shock occurs after a sustained decrease in MAP of 20 mmHg or more below normal levels and a fluid loss of 35% to 50% (1800 to 2500 mL of fluid). Although the compensatory mechanisms in the previous state remain activated, they are no longer able to maintain MAP at a level sufficient to ensure perfusion of vital organs.

The vasoconstriction response that first helped sustain MAP eventually limits blood flow to the point that cells become oxygen deficient. To remain alive, the affected cells switch from aerobic to anaerobic metabolism. The lactic acid formed as a by-product of anaerobic metabolism contributes to an acidotic state at the cellular level. As a result, adenosine triphosphate, the source of cellular energy, is produced inefficiently. Lacking energy, the sodium–potassium pump fails. Potassium moves out of the cell while sodium and water move inward. As this process continues the cell swells, cell membrane integrity is lost and cell organelles are damaged. Lysosomes within the cell spill out their digestive enzymes which disintegrate any remaining organelles. Some enzymes spread to adjacent cells where they erode and rupture cell membranes.

The acid by-products of anaerobic metabolism dilate the precapillary arterioles and constrict the postcapillary venules. This causes increased hydrostatic pressure within the capillary and fluid shifts back into the interstitial space. The capillaries also become increasingly permeable, allowing serum proteins to shift from the vascular space into the interstitium. The build-up of plasma proteins increases the osmotic pressure in the interstitium, further accelerating the fluid shift out of the capillaries.

Throughout this period, the heart rate and vasoconstriction increase; however, perfusion of the skin, skeletal muscles, kidneys and gastrointestinal organs is greatly diminished. Cells in the heart and brain become hypoxic, while other body cells and tissues become ischaemic and anoxic. A generalised state of acidosis and hyperkalaemia ensues (see Chapter 9). Unless this stage of shock is treated rapidly, the person's chances of survival are poor.

Stage III: Refractory or irreversible shock

If shock progresses to the irreversible stage, tissue anoxia becomes so generalised and cellular death so widespread that no treatment can reverse the damage. Even if MAP is temporarily restored, too much cellular damage has occurred to maintain life. Death of cells is followed by death of tissues, which results in death of organs. Death of vital organs contributes to subsequent death of the body.

Effects of shock on body systems

Whatever its causes, shock produces predictable effects on the body's organ systems. (See 'Multisystem effects of shock' on the following page.)

CARDIOVASCULAR SYSTEM The perfusion and oxygenation of the heart are adequate in the early stages of shock. As shock progresses, myocardial cells become hypoxic and myocardial muscle function diminishes. Initially, the blood pressure may be normal or even slightly elevated (as a result of compensatory mechanisms) and the heart rate only slightly increased. Sympathetic stimulation increases the heart rate (a sinus tachycardia of 120 beats per minute is common) in an effort to increase cardiac output. As a result of vasoconstriction and decreased blood volume, the palpated pulse is rapid, weak and thready; as shock progresses, peripheral pulses are usually non-palpable.

Tachycardia reduces the time available for left ventricular filling and coronary artery perfusion, further reducing cardiac output. With progressive shock, altered acid–base balance, hypoxia and hyperkalaemia damage the heart's electrical systems and contractility. Consequently, cardiac arrhythmias may develop. Decreased blood volume with decreased venous return also decreases cardiac output, and blood pressure falls.

The blood pressure changes produced by shock are characterised by a progressive decrease in both systolic and diastolic pressures and a narrowing pulse pressure. Auscultation of blood pressure is often difficult or impossible and is an inaccurate reflection of blood pressure status. For this reason, haemodynamic monitoring is usually instituted to follow the person's cardiovascular status accurately.

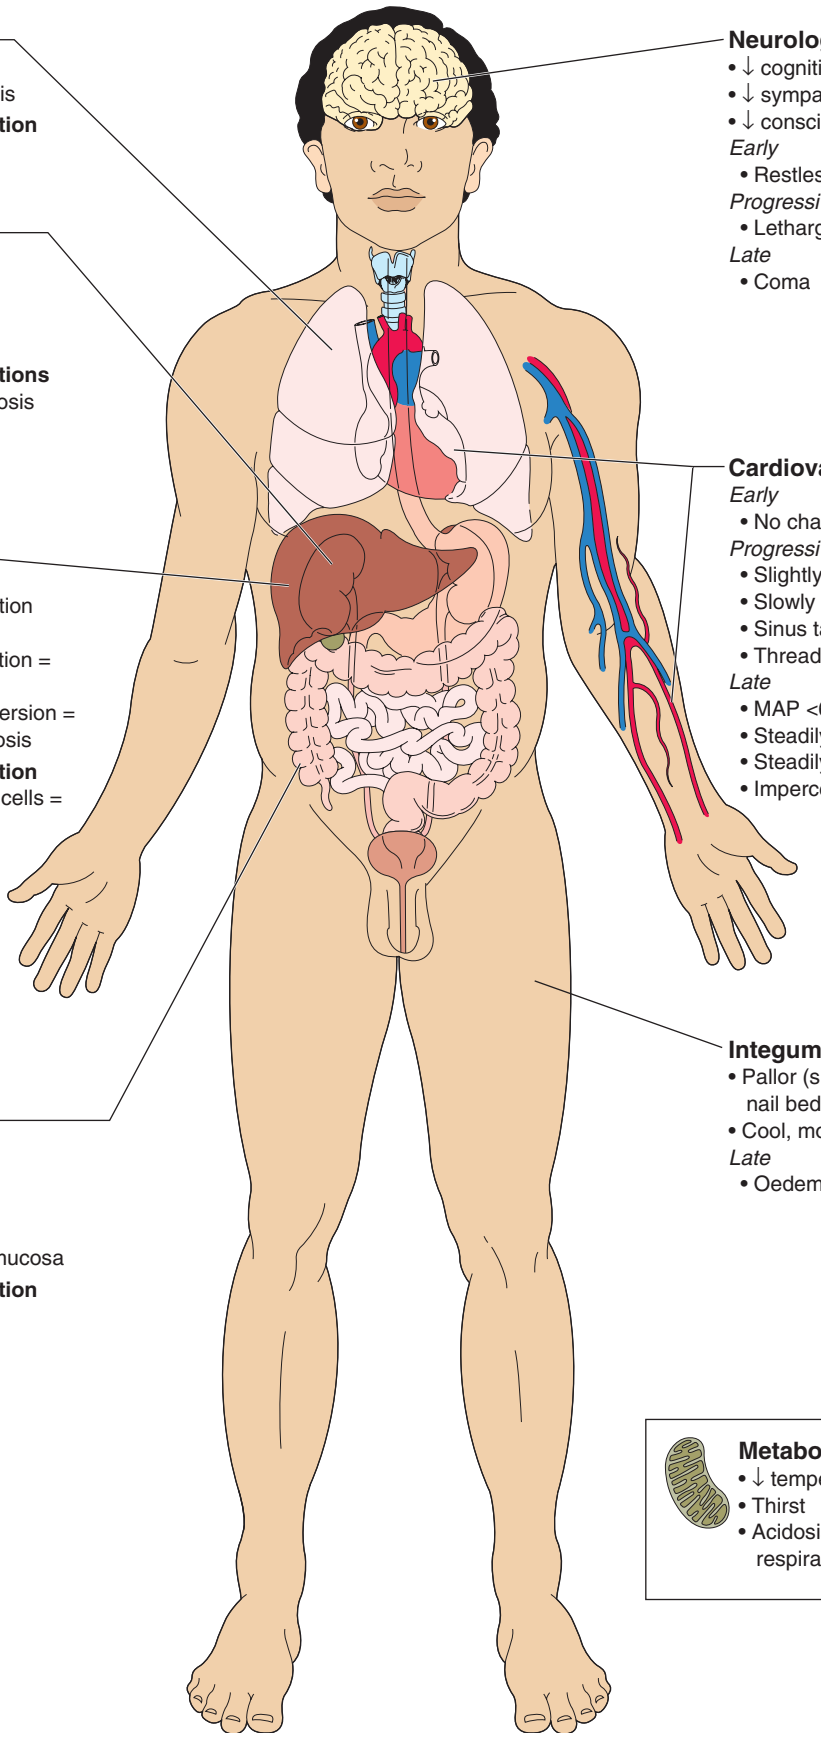
RESPIRATORY SYSTEM During shock, oxygen delivery to cells may be impaired by a drop in circulating blood volume or, in the case of blood loss, by an insufficient number of red blood cells that carry oxygen. Although the respiratory rate increases because of compensatory mechanisms that promote oxygenation, the number of alveoli that are perfused decreases and gas exchange is impaired. As a result, oxygen levels in the blood decrease and carbon dioxide levels increase. As perfusion of the lungs diminishes, carbon dioxide is retained and respiratory acidosis occurs.

A complication of decreased perfusion of the lungs is acute respiratory distress syndrome (ARDS), or 'shock lung'. The exact mechanism that produces ARDS is unknown, but some contributing factors have been identified. The pulmonary capillaries become increasingly permeable to proteins and water, resulting in non-cardiogenic pulmonary oedema. Production of surfactant (which controls surface tension within alveoli) is impaired and the alveoli collapse or fill with fluid. This potentially lethal form of respiratory failure may result from any condition that causes hypoperfusion of the lungs, but is more common in shock caused by haemorrhage, severe allergic responses, trauma and infection. (ARDS is discussed further in Chapter 36.)

GASTROINTESTINAL AND HEPATIC SYSTEMS The gastrointestinal organs normally receive 25% of the cardiac output through the splenic circulation. Shock constricts the splenic arterioles and redirects arterial blood flow to the heart and brain. Consequently, gastrointestinal organs become ischaemic and may be irreversibly damaged.

Gastric mucosa tends to ulcerate when it becomes ischaemic. Lesions of the gastric and duodenal mucosa (called *stress ulcers*) can develop within hours of severe trauma, sepsis or burns (Porth & Matfin, 2009). Gastrointestinal ulcers may haemorrhage within 2 to 10 days following the original cause of shock. In addition, the permeability of damaged mucosa increases, allowing enteric bacteria or their toxins to enter the abdominal cavity and then progress to the circulation, resulting in sepsis.

MULTISYSTEM EFFECTS OF SHOCK



Respiratory
- ↑ respiratory rate
- Respiratory acidosis

Potential complication
- ARDS

Urinary
- ↓ renal perfusion
- ↓ GFR

Late
- Oliguria

Potential complications
- Acute tubular necrosis
- Kidney failure

Hepatic

Early
- ↑ glucose production

Progressive
- ↓ glucose production = hypoglycaemia
- ↓ lactic acid conversion = metabolic acidosis

Potential complication
- Destroyed Kupffer cells = systemic bacterial infections

Gastrointestinal

Early
- ↓ GI motility

Late
- Paralytic ileus
- Ulceration of GI mucosa

Potential complication
- Bowel necrosis

Neurological
- ↓ cognition
- ↓ sympathetic activity
- ↓ consciousness

Early
- Restlessness, apathy

Progressive
- Lethargy

Late
- Coma

Cardiovascular

Early
- No change

Progressive
- Slightly ↑ BP
- Slowly ↑ HR
- Sinus tachycardia
- Thready pulse

Late
- MAP <60 mmHg
- Steadily ↓ BP
- Steadily ↓ CO
- Imperceptible pulses

Integumentary
- Pallor (skin, lips, oral mucosa, nail beds, conjunctiva)
- Cool, moist skin

Late
- Oedema

Metabolic processes
- ↓ temperature
- Thirst
- Acidosis (metabolic and respiratory)

Gastric and intestinal motility is impaired during shock and paralytic ileus may result. If the episode of shock is prolonged, necrosis of the bowel may occur. In many cases, alterations in the structure and function of the gastrointestinal tract impair absorption of nutrients such as protein and glucose.

Shock also alters the metabolic functions of the liver. Initially, *gluconeogenesis* (the process of forming glucose from non-carbohydrate sources) and *glycogenolysis* (the breakdown of glycogen into glucose) increase. This process allows blood glucose levels to increase as the body attempts to respond to the stressor; however, as shock progresses, liver functions are impaired and hypoglycaemia develops. Metabolism of fats and protein is impaired and the liver can no longer effectively remove lactic acid, contributing to the development of metabolic acidosis.

The destruction of the liver's reticuloendothelial Kupffer cells (phagocytes that destroy bacteria) causes a further problem. Bacteria may proliferate within the circulatory system, causing overwhelming bacterial infection and toxicity.

NEUROLOGICAL SYSTEM The primary effects of shock on the neurological system involve changes in mental status and orientation. Cerebral hypoxia produces altered levels of consciousness beginning with apathy and lethargy and progressing to coma. A common early symptom of cerebral hypoxia is restlessness. Continued ischaemia of brain cells eventually causes swelling, resulting in cerebral oedema, neurotransmitter failure and irreversible brain cell damage.

As cerebral ischaemia worsens, the sympathetic activity and vasomotor centres are depressed. This leads to a loss of sympathetic tone, causing systemic vasodilation and pooling of blood in the periphery. As a result, venous return and cardiac output further decrease.

CONSIDERATION FOR PRACTICE

An early sign of shock is a change in the level of consciousness. Late signs of shock include mental status changes, hypotension and marked tachycardia.

RENAL SYSTEM Blood that normally perfuses the kidneys is shunted to the heart and brain during the progressive stage of shock, resulting in renal hypoperfusion. The drop in renal perfusion is reflected in a corresponding decrease in the glomerular filtration rate. Urine output is reduced and the urine that is produced is highly concentrated. Oliguria of <0.5 mL/kg/hr indicates progressive shock.

Healthy kidneys can tolerate a drop in perfusion for only about 20 minutes; thereafter, acute tubular necrosis develops (Porth & Matfin, 2009). As tubular necrosis occurs, epithelial cells slough off and block the tubules, disrupting nephron function. The accumulating loss of functional nephrons eventually causes renal failure. Without normal renal function, metabolic waste products are retained in the plasma.

If treatment restores renal perfusion, the kidneys can regenerate the lost epithelial cells in the tubules and renal function usually returns to normal. However, in a person who is older or chronically ill or in sustained shock, loss of renal function may become permanent.

EFFECTS ON SKIN, TEMPERATURE AND THIRST In most types of shock, blood vessels supplying the skin are vasoconstricted and the sweat glands are activated. As a result, changes in skin colour occur. The skin of Caucasian people becomes pale. In people with darker skin (such as those of Indigenous Australian, African or Mediterranean descent), shock-related skin colour changes may be assessed as paleness of the lips, oral mucous membranes, nail beds and conjunctiva. The skin is usually cool and moist and, in the later stages of shock, often oedematous.

The body temperature decreases as shock progresses, the result of a decrease in overall body metabolism. Some people in shock become thirsty, probably a response to decreased blood volume and increased serum osmolality (Huether & McCance, 2013).

Types of shock

Shock is identified according to its underlying cause. All types of shock progress through the same stages and exert similar effects on body systems. Any differences are noted in the following discussion.

Hypovolaemic shock

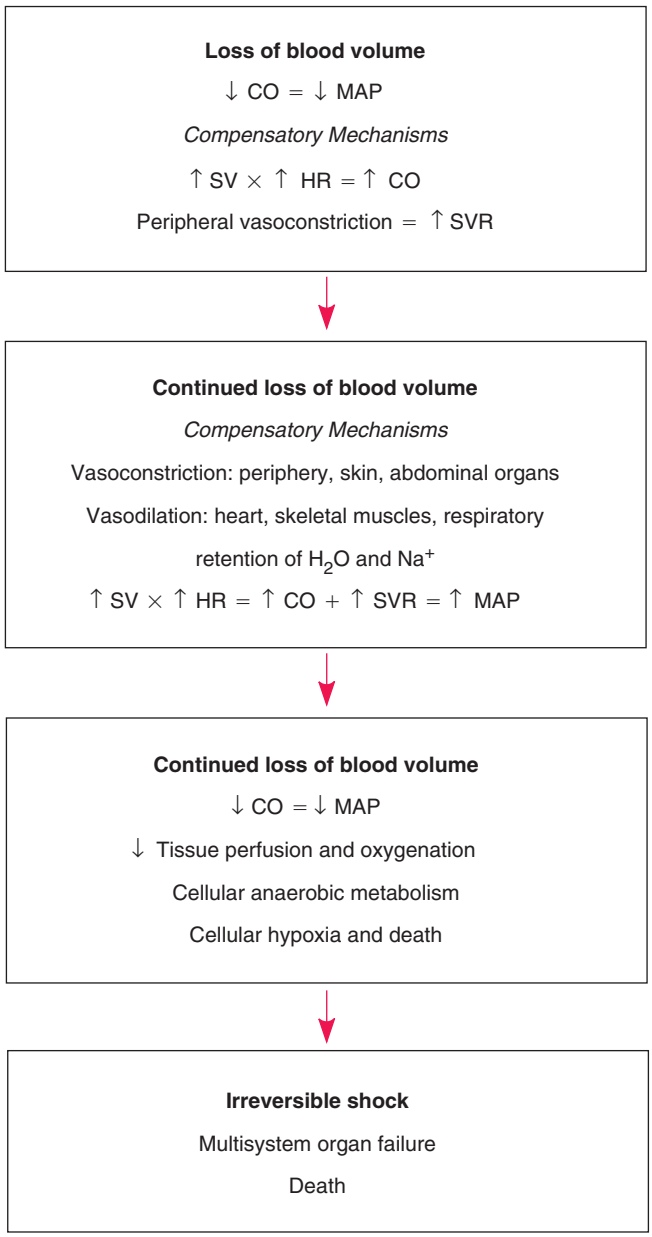
Hypovolaemic shock is caused by a decrease in intravascular volume of 15% or more (Huether & McCance, 2013). In hypovolaemic shock, the venous blood returning to the heart decreases and ventricular filling drops. As a result, stroke volume, cardiac output and blood pressure decrease. Hypovolaemic shock is the most common type of shock and often occurs simultaneously with other types.

The decrease in circulating blood volume that triggers hypovolaemic shock may result from:

- loss of blood volume from haemorrhage (from surgery, trauma, gastrointestinal bleeding, blood coagulation disorders, ruptured oesophageal varices)
- loss of intravascular fluid from the skin due to injuries such as burns (see Chapter 16)
- loss of intravascular volume from severe dehydration
- loss of body fluid from the gastrointestinal system due to persistent and severe vomiting or diarrhoea, or continuous nasogastric suctioning
- renal losses of fluid due to the use of diuretics or to endocrine disorders such as diabetes insipidus
- conditions causing fluid shifts from the intravascular compartment to the interstitial space
- third spacing due to such disorders as liver diseases with ascites, pleural effusion or intestinal obstruction.

Hypovolaemic shock affects all body systems. Its effects vary depending on the person's age, general state of health, extent of injury or severity of illness, length of time before treatment is provided and the rate of volume loss.

The manifestations of hypovolaemic shock result directly from the decrease in circulating blood volume and the initiation of compensatory mechanisms (see Figure 10.8). The loss of circulating blood volume reduces cardiac output by decreasing



Key CO: Cardiac output
HR: Heart rate
MAP: Mean arterial pressure
SV: Stroke volume
SVR: Systemic vascular resistance

FIGURE 10.8 ■ The stages of hypovolaemic shock

venous return to the heart. As a result, blood pressure drops. The carotid and cardiac baroreceptors sense the decrease in blood pressure and communicate it to the vasomotor centres in the brainstem. The vasomotor centres then induce the sympathetic compensatory responses. If the fluid loss is less than 500 mL, activation of the sympathetic response is generally adequate to restore cardiac output and blood pressure to near normal, although the heart rate may remain elevated.

With a sustained loss of blood volume (1000 mL or more), the shock stage progresses. Heart rate and vasoconstriction increase and blood flow to the skin, skeletal muscles, kidneys and abdominal organs decreases. Several renal mechanisms and a decline in capillary pressure help conserve blood volume. Eventually, the amount of blood flowing to cells is too low to oxygenate them and sustain production of cellular energy. Anaerobic metabolism begins, producing an acidotic environment for cells. As a result, cells lose their physical integrity. If untreated, shock causes multiple organ failure and death results. Manifestations of various stages of hypovolaemic shock are listed in the box below.

MANIFESTATIONS Hypovolaemic shock

INITIAL STAGE
- *Blood pressure*: normal to slightly decreased
- *Pulse*: slightly increased from baseline
- *Respirations*: normal (baseline)
- *Skin*: cool, pale (in periphery), moist
- *Mental status*: alert and oriented
- *Urine output*: slight decrease
- *Other*: thirst, decreased capillary refill time

COMPENSATORY AND PROGRESSIVE STAGES
- *Blood pressure*: hypotension
- *Pulse*: rapid, thready
- *Respirations*: increased
- *Skin*: cool, pale (includes trunk); poor turgor with fluid loss, oedematous with fluid shift
- *Mental status*: restless, anxious, confused or agitated
- *Urine output*: oliguria (less than 0.5 mL/kg/hr)
- *Other*: marked thirst, acidosis, hyperkalaemia, decreased capillary refill time, decreased or absent peripheral pulses

IRREVERSIBLE STAGE
- *Blood pressure*: severe hypotension (often systolic pressure is below 80 mmHg)
- *Pulse*: very rapid, weak
- *Respirations*: rapid, shallow; crackles and wheezes
- *Skin*: cool, pale, mottled with cyanosis
- *Mental status*: disoriented, lethargic, comatose
- *Urine output*: anuria
- *Other*: loss of reflexes, decreased or absent peripheral pulses

Cardiogenic shock

Cardiogenic shock occurs when the heart's pumping ability is compromised to the point that it cannot maintain cardiac output and adequate tissue perfusion. Cardiac disorders are discussed in Chapters 29 and 30; this section focuses only on the effects of shock caused by these disorders.

The loss of the pumping action of the heart may be caused by the following conditions:
- myocardial infarction
- cardiac tamponade
- restrictive pericarditis
- cardiac arrest
- arrhythmias, such as fibrillation or ventricular tachycardia
- pathological changes in the valves

- cardiomyopathies from hypertension, alcohol, bacterial or viral infections, or ischaemia
- complications of cardiac surgery
- electrolyte imbalances (especially changes in normal potassium and calcium levels)
- drugs affecting cardiac muscle contractility
- head injuries causing damage to the cardioregulatory centre.

Myocardial infarction is the most common cause of cardiogenic shock. People admitted to the hospital for treatment of myocardial infarction or cardiac surgery are at risk of cardiogenic shock. The severity and progression of shock are related to the amount of myocardial damage.

Whatever the cardiogenic cause, the decrease in cardiac output causes a decrease in MAP. Heart rate may increase in response to compensatory mechanisms. However, tachycardia increases myocardial oxygen consumption and decreases coronary perfusion. The myocardium becomes progressively depleted of oxygen, causing further myocardial ischaemia and necrosis. The typical sequence of shock is essentially unchanged in cardiogenic shock.

Cyanosis, however, is more common in cardiogenic shock because stagnating blood increases extraction of oxygen from the haemoglobin at the capillary beds. As a result, the skin, lips and nail beds may appear cyanotic. As cardiac failure and cardiogenic shock progress, left ventricular end-diastolic pressure increases. The increase is transmitted to the pulmonary capillary bed and pulmonary oedema may occur. Retention of blood in the right side of the heart increases right atrial pressure which leads to jugular venous distension as a result of backflow through the vena cava. Manifestations of cardiogenic shock are listed in the following box.

MANIFESTATIONS Cardiogenic shock

- *Blood pressure*: hypotension
- *Pulse*: rapid, thready; distension of veins of hands and neck
- *Respirations*: increased, laboured; crackles and wheezes; pulmonary oedema
- *Skin*: pale, cyanotic, cold, moist
- *Mental status*: restless, anxious, lethargic progressing to comatose
- *Urine output*: oliguria to anuria
- *Other*: dependent oedema; elevated central venous pressure (CVP); elevated pulmonary capillary wedge pressure; arrhythmias

Obstructive shock

Obstructive shock is caused by an obstruction in the heart or great vessels that either impedes venous return or prevents effective cardiac pumping action. The causes of obstructive shock are impaired diastolic filling (e.g. pericardial tamponade or pneumothorax), increased right ventricular afterload (e.g. pulmonary emboli) and increased left ventricular afterload (e.g. aortic stenosis, abdominal distension). The manifestations are the result of decreased cardiac output and blood pressure, with reduced tissue perfusion and cellular metabolism.

NURSING CARE OF THE OLDER ADULT

Experiencing hypovolaemia

With ageing comes a relative decrease in sympathetic activity in relation to the cardiovascular system. Cardiac compliance also decreases with age. Atherosclerosis affects many vital organs' sensitivity to even the slightest reduction in blood flow. Many older adults experience secondary volume depletion due to chronic diuretic use or malnutrition. Also, people prescribed beta-blockers may not present with tachycardia as an early indicator of shock. This important sign can be masked due to beta-adrenergic blockade. This group of people will require early invasive monitoring in order to avoid excessive or inadequate volume restoration. This should be considered early in the treatment phase.

Distributive shock

Distributive shock (also called **vasogenic shock**) includes several types of shock that result from widespread vasodilation and decreased peripheral resistance. Because the blood volume does not change, relative hypovolaemia results. Examples of distributive shock include septic, neurogenic and anaphylactic shock. Treatment is based on the underlying pathogenesis.

Septic shock

Septic shock, the leading cause of death for people in critical care units, is one part of a progressive syndrome called *systemic inflammatory response syndrome* (SIRS). This condition is most often the result of gram-negative bacterial infections (i.e. *Pseudomonas*, *E. coli*, *Klebsiella*) but may also follow gram-positive infections from *Staphylococcus* and *Streptococcus* bacteria. Gram-negative sepsis has greatly increased in the past 10 years with a 60% mortality rate despite treatment. The pathophysiology of septic shock is complex and not completely understood.

People at risk of developing infections leading to septic shock include those who are hospitalised, have debilitating chronic illnesses or have poor nutritional status. The risk is heightened after invasive procedures or surgery. Others at risk of septic shock include older adults and those who are immunocompromised. Portals of entry for infection that may lead to septic shock are as follows:

- *Urinary system*: catheterisations, suprapubic tubes, cystoscopy.
- *Respiratory system*: suctioning, aspiration, tracheostomy, endotracheal tubes, respiratory therapy, mechanical ventilators.
- *Gastrointestinal system*: peptic ulcers, ruptured appendix, peritonitis.
- *Integumentary system*: surgical wounds, intravenous catheters, intra-arterial catheters, invasive monitoring, decubitus ulcers, burns, trauma.
- *Female reproductive system*: elective surgical abortion, ascending infections from transmission of bacteria during the intrapartal and postpartal periods, tampon use, sexually transmitted infections.

Septic shock begins with *septicaemia* (the presence of pathogens and their toxins in the blood). As pathogens are destroyed, their ruptured cell membranes allow endotoxins to leak into the plasma. The endotoxins disrupt the vascular system, coagulation mechanism and immune system, and trigger an immune and inflammatory response. (See Chapter 11 for more information.) For this reason, the initial effects of septic shock differ from those of hypovolaemic and cardiogenic shock: cardiac output is high and systemic vascular resistance is low.

Endotoxins directly damage the endothelial lining of small blood vessels first; the small blood vessels of the kidneys and lungs are most susceptible. Cellular damage stimulates the release of vasoactive proteins and activates coagulation factor XII. The vasoactive proteins stimulate peripheral vasodilation and increase capillary permeability; the activation of coagulation factors results in the production of multiple intravascular blood clots.

As a result of the increased capillary permeability and vasodilation, fluid shifts from the intravascular space to the interstitial space. Hypovolaemia results as fluid volume is lost from the circulating blood. Hypovolaemia and intravascular coagulation alter oxygenation and cellular metabolism, leading to anaerobic metabolism, lactic acidosis and cellular death.

Septic shock has an early phase and a late phase. In early septic shock (sometimes called the *warm phase*), vasodilation results in weakness and warm, flushed skin, and the septicaemia often causes high fever and chills. In late septic shock (sometimes called the *cold phase*), hypovolaemia and activity of the compensatory mechanisms result in typical shock manifestations including cold, moist skin, oliguria and changes in mental status. Death may result from respiratory failure, cardiac failure or renal failure.

Toxic shock syndrome is an especially virulent form of septic shock occurring most frequently in menstruating women who use tampons. It is thought that bacterial toxins diffuse from the site of infection in the vagina into the circulation. The toxins then trigger a widespread inflammatory response and septic shock. The manifestations of toxic shock syndrome include extreme hypotension, hyperpyrexia, headache, myalgia, confusion, skin rash, vomiting and diarrhoea (Huether & McCance, 2013).

Disseminated intravascular coagulation (DIC), a generalised response to injury, is a potential risk in septic shock. This condition is characterised by simultaneous bleeding and clotting throughout the vasculature. Sepsis injures blood cells, causing platelet aggregation and decreased blood flow. As a result, blood clots form throughout the microcirculation. The clotting slows circulation further while stimulating excess fibrinolysis. As the body's stores of clotting factors are depleted, generalised bleeding begins. DIC is further discussed in Chapter 32.

MANIFESTATIONS Septic shock

EARLY (WARM) SEPTIC SHOCK
- *Blood pressure*: normal to hypotension
- *Pulse*: increased, thready
- *Respirations*: rapid and deep
- *Skin*: warm, flushed
- *Mental status*: alert, oriented, anxious
- *Urine output*: normal
- *Other*: increased body temperature; chills; weakness; nausea, vomiting, diarrhoea; decreased CVP

LATE (COLD) SEPTIC SHOCK
- *Blood pressure*: hypotension
- *Pulse*: tachycardia, arrhythmias
- *Respirations*: rapid, shallow, dyspnoeic
- *Skin*: cool, pale, oedematous
- *Mental status*: lethargic to comatose
- *Urine output*: oliguria to anuria
- *Other*: normal to decreased body temperature; decreased CVP

Neurogenic shock

Neurogenic shock is the result of an imbalance between parasympathetic and sympathetic stimulation of vascular smooth muscle. If parasympathetic overstimulation or sympathetic understimulation persists, sustained vasodilation occurs and blood pools in the venous and capillary beds.

Neurogenic shock causes dramatic reduction in systemic vascular resistance as the size of the vascular compartment increases. As SVR decreases, pressure in the blood vessels becomes too low to drive nutrients across capillary membranes and cellular metabolism is impaired.

The following conditions can cause neurogenic shock by increasing parasympathetic stimulation or inhibiting sympathetic stimulation of the smooth muscle of blood vessels:
- head injury
- trauma to the spinal cord (spinal shock, a form of neurogenic shock, is described in Chapter 42)
- insulin reactions (which cause hypoglycaemia, decreasing glucose to the medulla)
- central nervous system depressant drugs (such as sedatives, barbiturates or narcotics)
- anaesthesia (spinal and general)
- severe pain
- prolonged exposure to heat.

Bradycardia occurs early, but tachycardia begins as compensatory mechanisms are initiated. Central venous pressure drops as veins dilate, venous return to the heart decreases, stroke volume decreases and MAP falls. In early stages, the extremities are warm and pink (from the pooling of blood), but as shock progresses the skin becomes pale and cool. Manifestations of neurogenic shock are listed in the box on the next page.

Anaphylactic shock

Anaphylactic shock is the result of a widespread hypersensitivity reaction (called *anaphylaxis*). The pathophysiology in this type of shock includes vasodilation, pooling of blood in the periphery and hypovolaemia with altered cellular metabolism. These physiological alterations occur when a sensitised person has contact with an *allergen* (a foreign substance to which an individual is hypersensitive). Many different allergens can cause anaphylactic shock, including medications, blood administration, latex, foods, snake venom and insect stings.

Anaphylactic shock does not occur with the first exposure to an allergen. With the first exposure to a foreign substance

MANIFESTATIONS Neurogenic shock

- *Blood pressure*: hypotension
- *Pulse*: slow and bounding
- *Respirations*: vary
- *Skin*: warm, dry
- *Mental status*: anxious, restless, lethargic progressing to comatose
- *Urine output*: oliguria to anuria
- *Other*: lowered body temperature

(the *antigen*), the body produces specific immunoglobulin E (IgE) antibodies against this antigen. The person is thus sensitised to that specific antigen. With subsequent exposure, the antigen reacts with the already formed IgE antibodies, disrupting cellular integrity. In addition, large amounts of histamine and other vasoactive amines are released and distributed through the circulatory system. These substances cause increased capillary permeability and massive vasodilation resulting in profound hypotension and eventual vascular collapse.

Histamine also causes constriction of smooth muscles in the bladder, uterus, intestines and bronchioles. Respiratory distress, bronchospasm, laryngospasm and severe abdominal cramping result. Serotonin (a neurotransmitter with vasoconstrictive properties) is released, further affecting respiratory status by increasing capillary permeability in the lungs. As a result, plasma leaks into the alveoli, gas exchange is impaired and pulmonary oedema may occur.

Anaphylactic shock begins and progresses rapidly. Manifestations may begin within 20 minutes of contact with an antigen. Unless appropriate intervention is provided, death can occur within a matter of minutes. Because anaphylaxis is rapid and potentially lethal, people with known allergies should carry some form of warning (such as a MedicAlert® bracelet) informing others of their susceptibility. Some patients carry an Epipen (adrenaline) to use if required. Healthcare providers should be extremely careful to assess and document allergies or previous drug reactions. Manifestations of anaphylactic shock are listed in the box below.

Similar, but not related, are anaphylactoid reactions that are not humorally mediated and do not require prior exposure to a trigger. These can have similar symptoms and are treated in a similar manner.

MANIFESTATIONS Anaphylactic shock

- *Blood pressure*: hypotension
- *Pulse*: increased, arrhythmias
- *Respirations*: dyspnoea, stridor, wheezes, laryngospasm, bronchospasm, pulmonary oedema
- *Skin*: warm, oedematous (lips, eyelids, tongue, hands, feet, genitals)
- *Mental status*: restless, anxious, lethargic to comatose
- *Urine output*: oliguria to anuria
- *Other*: paraesthesias; pruritus; abdominal cramps, vomiting, diarrhoea

INTERPROFESSIONAL CARE

Medical care for the person in shock focuses on treating the underlying cause, increasing arterial oxygenation and improving tissue perfusion. Depending on the cause and type of shock, interventions include emergency care measures, oxygen therapy, fluid replacement and medications. Emergency care is often the first course of collaborative action taken to arrest shock, as discussed earlier in this chapter.

Diagnosis

The following diagnostic tests can help identify the type of shock and assess the person's physical status. Measurements include:

- *Blood haemoglobin* and *haematocrit* to detect the cell concentration that usually occurs in hypovolaemic shock which reflects the underlying aetiology. In hypovolaemic shock resulting from haemorrhage, the haemoglobin and haematocrit concentrations are lower than normal. In hypovolaemic shock resulting from intravascular fluid loss, by contrast, the haemoglobin and haematocrit concentrations are higher than normal.
- *Arterial blood gases (ABGs)* to determine oxygen and carbon dioxide levels and pH. The effects of shock and of the body's compensatory mechanisms cause a decrease in pH (indicating acidosis), a decrease in the partial pressure of oxygen (PaO_2) and in total oxygen saturation, and an increase in the partial pressure of carbon dioxide ($PaCO_2$).
- *Serum electrolytes* to monitor the severity and progression of shock. As shock progresses, glucose and sodium levels decrease, and potassium levels increase.
- *Blood urea nitrogen (BUN)*, *serum creatinine levels*, *urine specific gravity* and *osmolality* to check renal function. As perfusion of the kidneys is decreased and renal function is reduced, the BUN and creatinine levels increase as does urine specific gravity and osmolality.
- *Blood cultures* to identify the causative organism in septic shock.
- *White blood cell (WBC) count* and *differential* in the person with septic or anaphylactic shock. The total WBC count is increased in septic shock. Elevated neutrophils indicate acute infection, increased monocytes indicate a bacterial infection and increased eosinophils indicate an allergic response.
- *Serum cardiac enzymes*, which are elevated in cardiogenic shock: lactate dehydrogenase (LDH), creatine kinase (CK), creatinine kinase MB (CKMB) and troponin levels.

Other diagnostic tests may be ordered to determine the extent of injury or damage, or to locate the site of internal haemorrhage. These tests might include x-ray studies, computed tomography (CT) scans, magnetic resonance imaging (MRI), endoscopic examinations and echocardiograms. Newer diagnostic methods for hypoperfusion include gastric tonometry and sublingual $PaCO_2$. Gastric tonometry measures the partial pressure of carbon dioxide in the gastric lumen. The measurement of sublingual carbon dioxide correlates well with decreased MAP.

Medications

When fluid replacement alone is not sufficient to reverse shock, vasoactive drugs (drugs causing vasoconstriction or vasodilation) and inotropic drugs (drugs improving cardiac contractility) may be administered. When used to treat shock, these drugs increase venous return through vasoconstriction of peripheral vessels; they also improve the pumping ability of the heart by facilitating myocardial contractility and by dilating coronary arteries to increase perfusion of the myocardium.

Drugs used to treat shock are discussed in the following 'Medication administration' box. Other drugs that may be administered to the person in shock include:

- diuretics to increase urine output after fluid replacement has been initiated
- sodium bicarbonate to treat acidosis

MEDICATION ADMINISTRATION The person in shock

ADRENERGICS (SYMPATHOMIMETICS)

Vasoconstrictors
- **Adrenaline**
- **Noradrenaline**
- **Metaraminol (Aramine)**

Inotropes
- **Dopamine**
- **Dobutamine**
- **Isoprenaline**

Adrenergic drugs (also called sympathomimetics) mimic the fight-or-flight response of the sympathetic nervous system, selectively stimulating alpha-adrenergic and beta-adrenergic receptors. Many of these drugs have both vasopressor (vasoconstricting) effects and positive inotropic effects. Stimulation of alpha-adrenergic receptors results in vasoconstriction and increased systemic blood pressure. Stimulation of beta-adrenergic receptors increases the force and rate of myocardial contraction.

The physiological effect of these drugs includes improved perfusion and oxygenation of the heart, with increased stroke volume and heart rate and increased cardiac output. Increased cardiac output in turn increases tissue perfusion and oxygenation. The main disadvantage is that increases in stroke volume and heart rate also increase the oxygen requirements of the myocardium. These drugs may be used in the early stages of shock, especially in types of shock characterised by vasodilation.

Nursing responsibilities

- Carefully monitor responses in the older adult, who may be especially sensitive to sympathomimetics and require lower doses.
- Document lung sounds, vital signs and haemodynamic parameters before starting the medication and then according to institutional policy (usually every 5 to 15 minutes).
- When administering these drugs by the subcutaneous route, carefully aspirate the injection site to avoid injecting the drug directly into a blood vessel.
- Use the intravenous route only with continuous infusion pumps. Carefully adjust the dose to accommodate the person's cardiovascular status (as ordered by the physician or by written protocol).
- Record and monitor urine output. Report output of less than 0.5 mL/kg/hr.
- Be aware that the sympathomimetics are incompatible with sodium bicarbonate or alkaline solutions.
- When administering drugs that cause vasoconstriction, such as noradrenaline and metaraminol, monitor the intravenous insertion site for infiltration. If infiltration does occur, stop the infusion and notify the physician immediately as infiltration may cause ischaemia and necrosis of tissue.

Health education for the person and family

- Because these drugs mimic a physiological reaction to stress, they may cause feelings of anxiety.
- Close monitoring to adjust the dose will be carried out by qualified nurses using written protocols.
- Report heart palpitations or chest pain immediately.

VASODILATORS

Nitroglycerin (Glycerol trinitrate)
Nitroprusside (Nipride)

Drugs that cause vasodilation act directly on smooth muscle affecting both arterioles and veins. Peripheral resistance, cardiac output and pulmonary wedge pressure are all reduced as a result of the vasodilation. These effects decrease the oxygen need of the heart and decrease pulmonary congestion. Vasodilators are used primarily in the treatment of cardiogenic shock and may be combined with a sympathomimetic (e.g. dopamine).

Nursing responsibilities

- Protect these drugs from light by wrapping the intravenous bag in the package that is provided.
- Mix with 5% dextrose only.
- Infuse via an infusion pump and use within 4 hours of reconstitution.
- Do not add other medications to the solution.
- Assess mental status, blood pressure and pulse prior to initiating medication. Thereafter, assess blood pressure and pulse according to institutional policy (usually every 5 minutes initially, then every 15 minutes until stable and then hourly).
- Monitor for confusion, dizziness, tachycardia, arrhythmias, hypotension and adventitious breath sounds. Report these immediately if they occur and slow infusion to a keep-open rate.
- With nitroprusside infusions, monitor for signs of thiocyanate poisoning (nausea, disorientation, muscle spasms, decreased or absent reflexes) if infusion lasts longer than 72 hours.
- Keep the person in bed with side rails up.

Health education for the person and family

- It is important for the person to stay in bed and change positions slowly to avoid dizziness.
- The blood pressure and pulse are taken frequently to adjust the dose of medication.
- Headache is a common side effect.

- calcium to replace calcium lost as a result of blood transfusions
- antiarrhythmic agents to stabilise heart rhythm
- broad-spectrum antibiotics to suppress organisms responsible for septic shock
- adrenaline, antihistamines, corticosteroids and inhaled beta$_2$ agonists to treat anaphylactic shock
- morphine to dilate veins and decrease anxiety.

Oxygen therapy

Establishing and maintaining a patent airway and ensuring adequate oxygenation are critical interventions in reversing shock. All people in shock (even those with adequate respirations) should receive oxygen therapy (usually by mask or nasal cannula) to maintain the PaO_2 at greater than 80 mmHg during the first 4 to 6 hours of care. If the person's unassisted respiration cannot maintain PaO_2 at this level, ventilatory assistance may be necessary. Care of the person requiring ventilatory assistance is discussed in Chapter 36.

Fluid resuscitation

The most effective treatment for the person in hypovolaemic shock is the administration of intravenous fluids or blood. Fluids are also appropriate in the management of septic and neurogenic shock. However, depending on pulmonary artery pressure, the person with cardiogenic shock may require either fluid replacement or restriction.

Various fluids may be administered alone or in combination as part of fluid replacement therapy in treating shock. Fluid replacements are administered through two large-bore cannulae via peripheral intravenous access or through a central line. Current fluid resuscitation guidelines include rapid crystalloid infusion followed by blood transfusion. Whole blood or blood products increase the oxygen-carrying capacity of the blood and thus increase oxygenation of cells. Fluid replacements, such as crystalloid and colloid solutions, increase circulating blood volume and tissue perfusion.

CRYSTALLOID SOLUTIONS Crystalloid solutions contain dextrose or electrolytes dissolved in water; those used for management of shock are either isotonic or hypotonic. Isotonic solutions include normal saline (0.9%) and compound sodium lactate (Hartmann's solution). Hypotonic solutions include one-half normal saline (0.45%) and 5% dextrose in water (D_5W).

All crystalloid solutions increase fluid volume in both the intravascular and the interstitial space. Of the total amount infused, only about 25% remains in the intravascular system; the remaining 75% moves into the interstitial space. Consequently, fluid volume is only minimally expanded and the potential for peripheral oedema is increased when crystalloid solutions are used. However, compound sodium lactate (an electrolyte solution) and 0.9% saline are the fluids of choice in treating hypovolaemic shock, especially in the emergency phase of care while blood is being typed and crossmatched. Large amounts of these solutions may be infused rapidly, increasing blood volume and tissue perfusion.

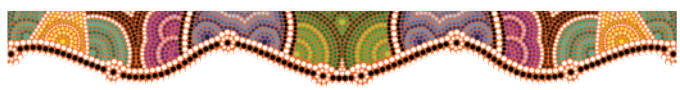
COLLOID SOLUTIONS Colloid solutions contain substances (colloids) that do not diffuse through capillary walls. Hence, colloids tend to remain in the vascular system and increase the osmotic pressure of the serum. This causes fluid to move into the vascular compartment from the interstitial space, resulting in the plasma volume expanding. Colloid solutions used to treat shock include 5% albumin, 25% albumin, Gelofusine, Haemaccel, plasma protein fraction and Dextran.

Colloid products reduce platelet adhesiveness and have been associated with reductions in blood coagulation. Consequently, the person's prothrombin time (PT), International Normalised Ratio (INR), platelet count and activated partial thromboplastin time (APTT) should be monitored when these solutions are administered. Normal values are as follows:

PT	10–15 seconds
INR	1–1.2 seconds
Platelets	150–400 × 10^9/L
APTT	<35 seconds

See the 'Medication administration' box on the next page for further information about colloid solutions and associated nursing responsibilities and teaching.

BLOOD AND BLOOD PRODUCTS If hypovolaemic shock is due to haemorrhage, the infusion of blood and blood products may be indicated. Available blood and blood products include fresh whole blood, stored whole blood, packed RBCs, platelet concentrate, fresh-frozen plasma and cryoprecipitate. Often, packed RBCs are given to provide haemoglobin concentration and are supplemented with crystalloids to maintain an adequate circulatory volume. (See discussion of blood administration earlier in the chapter.)



Nursing care

Nursing assessments and interventions to prevent shock are an essential part of the nursing care of every person. The primary nursing interventions to prevent shock are assessment and monitoring.

Health promotion and assessment

Nursing assessments are critical in preventing shock. Identifying people at risk and making focused assessments are essential. Although shock may occur at any age, physiological changes with ageing make the older adult a high-risk population. (See the 'Nursing care of the older adult' box on the next page).

- *Hypovolaemic shock*: people who have undergone surgery, have sustained multiple traumatic injuries or have been seriously burned are most likely to develop hypovolaemic shock. Monitoring fluid status is essential in preventing shock and includes daily assessments of weight, fluid intake by all routes, measurable fluid loss (e.g. urine, vomitus, wound drainage, gastric drainage and chest tube drainage) and fluid loss that must be estimated, such as fluid lost via

MEDICATION ADMINISTRATION Colloid solutions

COLLOID SOLUTIONS (PLASMA EXPANDERS)

Albumin 4% (Albumex 4)
Albumin 20% (Albumex 20)
Gelofusine (GelofuG)
Haemaccel
Stable plasma protein solution (SPPS)

These solutions are blood volume expanders and are used to treat hypovolaemic shock due to surgery, haemorrhage, burns or other trauma. Albumin and plasma protein solutions are prepared from healthy blood donors. Gelofusine and Haemaccel are synthetically prepared large molecules. The solutions promote circulatory volume and tissue perfusion by rapidly expanding plasma volume.

Nursing responsibilities

- Before infusion begins, establish baseline of vital signs, lung sounds, heart sounds and (if possible) CVP and pulmonary artery wedge pressure.
- Start administration of ordered intravenous fluids, using a large-gauge (18- or 19-gauge) infusion needle.
- Take and record vital signs as required by institutional policy (usually every 15 to 60 minutes) and assess status.
- Take and record intake and output every 1 to 2 hours.
- Monitor for manifestations of congestive heart failure or pulmonary oedema (dyspnoea, cyanosis, cough, crackles, wheezes). If these manifestations appear, stop the fluids and notify the physician immediately.
- Monitor for bleeding from new sites; an increase in blood pressure may cause bleeding in severed vessels that did not bleed with decreased blood pressure.
- Monitor for manifestations of dehydration (dry lips; scant, dark-coloured urine; loss of skin turgor). Increased intravenous fluids are usually ordered if the person becomes dehydrated.
- Monitor for manifestations of circulatory overload (jugular vein distension, increase in CVP, increase in pulmonary artery wedge pressure). If these manifestations occur, slow rate of infusion and notify physician.
- Monitor prothrombin time, partial thromboplastin time and platelet counts.
- If administering albumin or plasma protein solution, have adrenaline and antihistamines readily available for any manifestations of a hypersensitivity reaction (fever, chills, rash, headache, wheezing, flushing).
- Maintain the person on bed rest with side rails elevated.

Health education for the person and family

- The solutions are given to replace lost serum protein, which helps maintain the volume of blood.
- The vital signs are taken frequently to ensure the safety of the person.

profuse perspiration and wound drainage. Assessments for the critically ill person are ongoing and include fluid balance, haemodynamic values and vital signs.

- *Cardiogenic shock*: people with left anterior wall myocardial infarctions are at risk of developing cardiogenic shock. Nursing care to prevent the development of cardiogenic shock focuses on maintaining or improving myocardial oxygen supply by providing immediate pain relief, maintaining rest and administering supplemental oxygen.
- *Neurogenic shock*: the risk of neurogenic shock is increased in people who have spinal cord injuries and those who have received spinal anaesthesia. Preventive nursing care includes maintaining immobility of people with spinal cord trauma and elevating the head of the bed 15 to 20 degrees following spinal anaesthesia. Elevations of more than 20 degrees, however, can potentiate headaches following spinal anaesthesia and should be avoided.
- *Anaphylactic shock*: prevent anaphylactic shock by collecting information about allergies and drug reactions during the health history. Note these allergies clearly on all documents and place a special armband on the person. Careful and frequent assessments during blood administration may prevent serious reactions to blood or blood products.
- *Septic shock*: people who are hospitalised, are debilitated, are chronically ill or have undergone invasive procedures or tube insertions are at high risk of septic shock. Nursing care to prevent septic shock includes careful and consistent handwashing, the use of aseptic techniques for procedures (e.g. catheterisations, suctioning, changing dressings, starting and maintaining intravenous fluids or medications) and monitoring for local and systemic manifestations (e.g. WBC and differential counts) of infection.

NURSING CARE OF THE OLDER ADULT Variations in assessment findings—shock

- Cardiac changes may include a thickened left ventricular wall, decreased elasticity of the myocardium and more rigid valves. These changes result in a decreased stroke volume and cardiac output, thus decreasing responses to shock in general and increasing the risk of cardiogenic shock.
- Decreased arterial wall elasticity and vasomotor tone reduce the older adult's ability to respond to a decrease in oxygenation.
- Decreased elasticity and turgor of the skin make assessments of skin turgor more difficult.
- Previous medication and blood administration increase the risk of anaphylactic shock.
- Decreased immune system response increases the risk of septic shock.

Nursing diagnoses and interventions

Nursing care for the person in shock focuses on assessing and monitoring overall tissue perfusion and on meeting psychosocial needs of the person and the family. This section discusses nursing diagnoses that are appropriate for the person with hypovolaemic shock. See the accompanying 'Nursing care of the older adult'.

Decreased cardiac output

Decreased cardiac output is the primary problem for the person in shock. Although much of the care related to this diagnosis is collaborative, many independent nursing interventions are critical to the care of the person in shock.

- Assess and monitor cardiovascular function via the following:
  - blood pressure
  - heart rate and rhythm
  - pulse oximetry
  - peripheral pulses
  - haemodynamic monitoring of arterial pressures, pulmonary artery pressures and central venous pressures (CVPs). *A baseline assessment is necessary to establish the stage of shock. If palpable peripheral pulses and audible (to auscultation) blood pressure are lost, inserting central arterial, venous and pulmonary artery catheters is essential to establish progression of shock accurately and to evaluate the person's response to therapy.*
- Measure and record intake and output (total output and urinary output) hourly. *A decrease in circulating blood volume with hypotension and the effect of the compensatory mechanisms associated with shock can cause renal failure. Urinary output of <0.5 mL/kg/hr in an acutely ill adult indicates reduced renal blood flow.*
- Monitor bowel sounds, abdominal distension and abdominal pain. *Decreased splenic blood flow reduces bowel motility and peristalsis; paralytic ileus may result.*
- Monitor for sudden sharp chest pain, dyspnoea, cyanosis, anxiety and restlessness. *Haemoconcentration and increased platelet aggregation may result in pulmonary emboli.*
- Maintain bed rest and provide (to the extent possible) a calm, quiet environment. Place in a supine position with the legs elevated to about 20 degrees, trunk flat, and head and shoulders elevated higher than the chest (see Figure 10.9). *Limiting activity and ensuring rest decreases the workload of the heart. The supine position with legs elevated increases venous return; however, this position should not be used for people in cardiogenic shock. The Trendelenburg position is no longer recommended because it causes the abdominal organs to press against the diaphragm (limiting respirations), decreases filling of the coronary arteries and initiates aortic and carotid sinus reflexes.*

Ineffective tissue perfusion

As shock progresses, diminished tissue perfusion causes ischaemia and hypoxia of major organ systems. As shock worsens, blood flow and oxygenation of the lungs, heart and brain

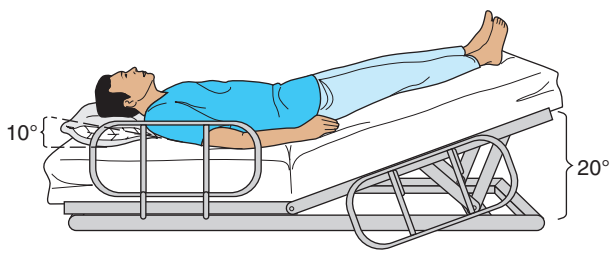


FIGURE 10.9 ■ The person in shock should be positioned with the lower extremities elevated approximately 20 degrees (knees straight), trunk horizontal and the head elevated about 10 degrees

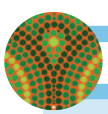


TRANSLATION TO PRACTICE Evidence-based practice for care of ICU people sustaining multiple trauma

Ventilator-associated pneumonia (VAP) is an important person safety issue in critically injured people. The Association for Professionals in Infection Control and Epidemiology (APIC) published an evidence-based clinical guideline for the prevention and elimination of VAP in 2009 (APIC, 2009). The Association recommends the use of a facility-wide VAP infection prevention and control program and overall infection prevention and antimicrobial stewardship. The guideline describes the critical topics of problem identification, surveillance and how it is defined, risk assessment, and the development and use of a surveillance plan and prevention strategies. The guideline also provides examples of documents and reminders that can be used to provide systematic surveillance and management strategies.

IMPLICATIONS FOR NURSING

The APIC evidence-based guidelines recommend elements related to VAP prevention:

- prevention of complications in ventilated patients focusing on positioning specific to reduce VAP
- educational programs for healthcare personnel focusing on VAP prevention
- use of quality improvement projects with VAP prevention focus
- organisational issues related to leadership, staffing and informatics which can impact on patient outcomes
- setting a target of zero VAP cases
- key prevention strategies related to unit and institutional processes, supportive early innovators, consistent communication, connecting actions to outcomes and review of deviation from practice standards.

CRITICAL THINKING IN PERSON-CENTRED CARE

1. Considering the information from this guideline, how would you communicate the recommendations to the medical staff for the person with mechanical ventilation?
2. What is the rationale behind the preceding recommendations?

NURSING CARE PLAN A person with septic shock

Huang Mei Lan is a 43-year-old unmarried female who lives alone in a major city. Ms Huang came to Australia 15 years ago from China and now speaks English well. Her family still lives in China. She worked in a neighbourhood sewing shop until 3 years ago when she was diagnosed with breast cancer. Her treatment included mastectomy of the affected breast and follow-up chemotherapy.

Last month, Ms Huang experienced a recurrence of cancer in the lymph glands of the affected side. Surgery to remove the glands was performed and chemotherapy started. Ms Huang has a central line, a urinary catheter and a surgical incision. She is underweight, weak and depressed. Although she has multiple physical problems, she never complains or asks for any kind of medication.

ASSESSMENT

Ms Huang's nurse, Robert O'Brien, enters her room early in the morning to make an initial assessment. He finds Ms Huang huddled in the middle of the bed, shivering violently. Her vital signs are T 40°C, P 110, R 30 and BP 106/66. Her skin is hot, dry and flushed, with poor turgor. She is alert and oriented but is restless and appears anxious. Ms Huang states she is nauseated and suddenly begins vomiting and is incontinent of liquid stool. Laboratory data indicate leucocytosis, respiratory alkalosis and reduced platelet count. Blood cultures, as well as cultures of Ms Huang's sputum, urine and wound drainage, are conducted. She is diagnosed as having septic shock.

Gelofusine is ordered per intravenous line and intravenous broad-spectrum antibiotics are begun until the organism and its portal of entry can be determined. Despite treatment Ms Huang's condition worsens. Her blood pressure continues to drop, her skin becomes cool and cyanotic, and she begins to have periods of disorientation. She is transferred to the critical care unit. As she is being prepared for the transfer, she begins to cry and asks, 'Am I going to die?'.

DIAGNOSES

- *Ineffective breathing pattern* related to rapid respirations and progression of septic shock.
- *Ineffective tissue perfusion* related to progression of septic shock with decreased cardiac output, hypotension and massive vasodilation.
- *Deficient fluid volume* related to vomiting, diarrhoea, high fever and shift of intravascular volume to interstitial spaces.
- *Anxiety* related to feelings that illness is worsening and is potentially life threatening, and to the transfer to the critical care unit.

PLANNING

- Monitor respiratory status, including respiratory rate, rhythm and breath sounds.
- Monitor neurological status, including mental status and level of consciousness.
- Monitor cardiovascular status, including arterial blood pressure; rate, rhythm and quality of pulses; central venous pressure; pulmonary artery pressure and cardiac output.
- Monitor colour and character of skin.
- Monitor body temperature every 2 hours.
- Monitor results of ABGs, blood counts, clotting times and platelet counts.
- Monitor urinary output hourly, reporting any output of <0.5 mL/kg/hr.

Expected outcomes

- Maintain adequate circulating blood volume.
- Regain and maintain blood gas parameters within normal limits.
- Regain and maintain stable haemodynamic levels.
- Verbalise increased ability to cope with stressors.

IMPLEMENTATION

- Perform hourly neurological assessment, including mental status and level of consciousness.
- Implement continuous cardiac monitoring, including arterial blood pressure; rate, rhythm and quality of pulses; central venous pressure; pulmonary artery pressure and cardiac output.
- Regularly assess colour and character of skin.
- Take samples of blood for ABGs, blood counts, clotting times and platelet counts and report results.
- Assess respiratory status, including respiratory rate, rhythm and breath sounds.
- Assess body temperature every 2 hours.
- Measure urinary output hourly and report output of <0.5 mL/kg/hr.
- Explain procedures and provide comfort measures (oral care, skin care, turning, positioning).
- Report abnormal findings to medical team.

EVALUATION

Despite intensive nursing and medical care, Ms Huang's condition remains critical. The interventions are continued.

CRITICAL THINKING IN THE NURSING PROCESS

1. Vasoconstrictors may be used in the treatment of septic shock. Explain the rationale for their use.
2. While monitoring Ms Huang's ABGs, the nurse notes that her PaO_2 is < 60 mmHg and her $PaCO_2$ is > 50 mmHg. What do these findings indicate and why have they occurred?
3. Ms Huang has been given large amounts of colloids intravenously. Haemodynamic monitoring indicates a higher than normal CVP and pulmonary artery pressure. What do these findings indicate? What physical assessments would you make to confirm the changes?

REFLECTION ON THE NURSING PROCESS

1. Outline the component of Ms Huang's condition and physical status that posed potential risks for her developing septic shock.
2. What education strategies could have been used to assist Ms Huang to identify and communicate issues prior to her deterioration?

are also impaired. Hypoxia and ischaemia result from decreased tissue perfusion in the kidneys, brain, heart, lungs, gastrointestinal tract and the periphery.

- Monitor skin colour, temperature, turgor and moisture. *Decreased tissue perfusion is evidenced by the skin becoming pale, cool and moist; as haemoglobin concentrations decrease, cyanosis occurs.*
- Monitor cardiopulmonary function by assessing/monitoring the following:
  - blood pressure (by auscultation or by haemodynamic monitoring)
  - rate and depth of respirations
  - lung sounds
  - pulse oximetry
  - peripheral pulses (brachial, radial, dorsalis pedis and posterior tibial); include presence, equality, rate, rhythm and quality. (If unable to palpate pulses, use a device such as a Doppler ultrasound to assess peripheral arterial blood flow.)
  - jugular vein distension
  - central venous pressure measurements.
    Baseline vital signs are necessary to determine trends in subsequent findings. As shock progresses, the blood pressure decreases and the pulse becomes rapid, weak and thready. As perfusion of the lungs decreases, crackles, wheezes and dyspnoea are commonly assessed. Capillary refill is prolonged and peripheral pulses are weak or non-palpable. Neck veins that cannot be seen when the person is in the supine position indicate decreased intravascular volume. CVP is an accurate means of determining fluid status in the person in shock; the findings will be low (5 to 15 cm of water is normal) in hypovolaemic shock because of the decreased blood volume. (See Chapter 9 for a discussion of CVP.)
- Monitor body temperature. *An elevated body temperature increases metabolic demands, depleting reserves of bodily energy. It also increases myocardial oxygen demand and may place the person with previous cardiac problems at even greater risk of hypoperfusion.*
- Monitor urinary output per indwelling catheter hourly, using a urine drainage measure bag. *Urine output is a reliable indicator of renal perfusion.*
- Assess mental status and level of consciousness. *The appropriateness of the person's behaviour and responses reflects the adequacy of cerebral circulation. Restlessness and anxiety are common early in shock; in later stages, the person may become lethargic and progress to a comatose state. Altered levels of consciousness are the result of both cerebral hypoxia and the effects of acidosis on brain cells.*

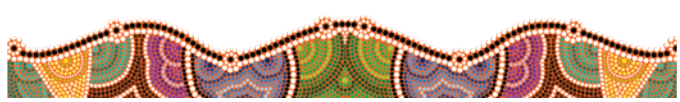
Anxiety

Many people in hypovolaemic shock have experienced some form of major trauma and may have life-threatening, multiple injuries. Following on-the-scene treatment, the person is usually admitted to the healthcare setting through the emergency department. Surgery may be required to treat injuries, followed by care in a critical care unit. Throughout this sequence of crisis events, treatment is invasive and contact with family is minimal. In situations of uncertainty, instability and change people and their families may respond with anxiety, fear and powerlessness. These responses are affected by age, developmental level, cultural and ethnic group, experience with illness and the healthcare system, and support systems.

- Assess the cause(s) of the anxiety and manipulate the environment to provide periods of rest. *Reducing stimuli that cause anxiety is calming and facilitates rest, which is necessary in the person at risk of bleeding.*
- Administer prescribed pain medications on a regular basis. *Pain precipitates and/or aggravates anxiety.*
- Provide interventions to increase comfort and reduce restlessness:
  - Maintain a clean environment.
  - Provide skin and oral care.
  - Monitor the effectiveness of ventilation or oxygen therapy.
  - Eliminate all non-essential activities.
  - Remain with the person during procedures.
  - Speak slowly and calmly, using short sentences.
  - Use touch to provide support.
    Unfamiliar sounds, sights and odours can increase anxiety. Damp skin or a dry mouth increases discomfort. Inadequate gas exchange with a decrease in oxygen or an increase in carbon dioxide in the blood may cause the person to experience a 'feeling of doom'. Activity increases the body's need for oxygen. Listening and touch provide support in an environment in which the person often feels alone and abandoned. Severe anxiety interferes with the ability to understand others and to respond appropriately.
- Provide support for the person and family:
  - Provide time, space and privacy for family members.
  - Allow family members access to the person when feasible.
  - Encourage the expression of feelings and concerns. Provide anticipatory guidance to prepare for recovery or death and to support realistic hope.
  - Acknowledge the beliefs, values and expectations of the person and family.
    Allowing the family access to the person reduces anxiety and gives both the person and the family some feeling of control. If the prognosis is poor, access and involvement allow the family to begin the grieving process. If recovery is expected, contact provides the person and family with a feeling of hope. Supporting the person and family facilitates concrete problem solving, promotes acceptance of the illness and its implications, and helps them begin to establish ways of managing the illness experience.
- Provide information about the current setting to both the person and family; give the family information about available resources (such as pastoral care, social services, temporary housing, meals). *Knowing what to expect and how to control the environment to meet basic needs reduces anxiety.*

Community-based care

Home care for the person who has experienced shock is highly individualised, depending on the cause and the illness or injury that caused shock. Therefore, topics for consideration are not included in this section.



CHAPTER HIGHLIGHTS

- Traumatic injuries affect human tissues and organs resulting from a transfer of energy from the environment. Energy sources can be mechanical, gravitational, thermal, electrical, physical or chemical.
- Trauma types include minor trauma, which causes minimal damage to underlying tissues, or major trauma, which can involve a serious single-system injury or multiple trauma. Trauma is further categorised into blunt and penetrating trauma. Blunt trauma is caused by various forces such as deceleration, acceleration, shearing, compression or crushing. Penetrating trauma occurs when a foreign object enters the body.
- Maintenance of the airway and cervical spine are the highest priority in the trauma victim, with airway assessment superseding all other interventions.
- The primary assessment conducted by the nurse identifies all life-threatening injuries and performance of appropriate interventions. The secondary assessment is when the nurse identifies all injuries in order to prioritise care.
- Shock is a clinical syndrome characterised by a systemic imbalance between oxygen supply and demand. This imbalance results in a state of inadequate blood flow to body organs and tissues, causing life-threatening cellular dysfunction.
- The symptoms of shock arise from the body's attempts to maintain vital organs (heart and brain) and to preserve life in response to a decrease in oxygen delivery to the cells.
- An important early sign of shock is a change in the level of consciousness, with restlessness being a common symptom of cerebral hypoxia.
- Shock is defined in three stages: compensatory (stage 1), an early and reversible stage; progressive (stage 2), occurring after a fluid loss of 35–50% (1800 to 2500 mL), where the affected cells switch from aerobic to anaerobic metabolism in order to remain alive; and the final stage is irreversible (stage 3), where tissue anoxia and cellular death become widespread.
- Hypovolaemic shock is the most common type of shock and is caused by a decrease in the circulating blood volume by 15% or greater.
- Cardiogenic shock is caused when the pumping ability of the heart is compromised to the point where adequate cardiac output cannot be maintained.
- Obstructive shock is caused by an obstruction in the heart or great vessels that either impedes venous return or prevents effective cardiac pumping action. Causes can include cardiac tamponade, pneumothorax, pulmonary embolism and aortic stenosis.
- Septic shock is a part of a progressive syndrome called systemic inflammatory response syndrome (SIRS), a condition most often caused by gram-negative infections.
- Anaphylactic shock is caused by a fulminating hypersensitivity reaction to a foreign substance.

CONCEPT CHECK

1 What is the most common mechanical source of injury in adults of all ages?
1. gunshot wounds
2. fire
3. drowning
4. motor vehicles

2 Severe facial injuries, such as those resulting from going through a windshield, increase the risk of all of the following. Which would you assess first?
1. airway obstruction
2. haemorrhage
3. contusions
4. fractures

3 Which on-the-scene intervention would be a priority?
1. Determine cause of injury.
2. Assess airway patency.
3. Assess peripheral capillary refill.
4. Palpate for internal haemorrhage.

4 You are monitoring blood administration to a trauma victim in shock. Which of the following assessments indicate a dangerous transfusion reaction?
1. red raised areas (wheals) on the skin that itch
2. an increase in body temperature by 3°C
3. decreasing blood pressure and dyspnoea
4. increasing blood pressure and pulse

5 What type of shock causes widespread vasodilation and decreased peripheral resistance?
1. cardiogenic shock
2. septic shock
3. hypovolaemic shock
4. obstructive shock

6 What is the best method to manage uncontrolled bleeding?
1. apply direct pressure
2. clamp a visible vessel
3. apply a tourniquet
4. elevate the injured part

7 Trauma is defined as:
1. injury to human tissues from the transfer of energy
2. result of random chance
3. accidental injury
4. an intentional injury

8 Shock is defined as:
1. a systemic imbalance between oxygen supply and demand
2. sufficient cardiac output
3. haemorrhage
4. abnormal blood pressure

9 Distributive shock is caused by:
1. blood loss
2. widespread vasodilation
3. ineffective cardiac pumping action
4. hypersensitivity reaction

10 What actions should you perform when receiving handover of care immediately postoperative in order to prevent the onset of hypovolaemic shock?
1. Elevate the head of the bed.
2. Provide immediate pain relief.
3. Monitor strict intake and output.
4. Practise careful and consistent hand hygiene.

CHAPTER 11

NURSING CARE OF PEOPLE WITH INFECTIONS

LISA GATZONIS

LEARNING OUTCOMES

- Discuss the components and functions of the immune system and the immune response.
- Compare antibody-mediated and cell-mediated immune responses.
- Describe the pathophysiology of wound healing, inflammation and infection.
- Identify factors responsible for and the implications of healthcare-associated infections.
- Discuss the nursing implications and health education in the prevention and treatments of inflammation and infection.

CLINICAL COMPETENCIES

- Apply standard precautions and evidence-based practices to prevent the spread of infection within the person, to other people in the facility, to members of the interprofessional team and to visitors.
- Provide safe, effective and respectful patient-centred care for patients with inflammation and infection.
- Collaborate with the interprofessional care team to integrate care of people with infection.
- Promote therapeutic levels and completed dosage of anti-inflammatory and anti-infective medication through prompt administration and person and family teaching.
- Assess for hypersensitivities to anti-inflammatories and anti-infectives prior to and during administration.
- Participate in quality improvement processes to reduce the rates and risk of infection.

KEY TERMS

OVERVIEW OF THE IMMUNE SYSTEM

The human body is continually threatened by foreign substances, infectious agents and abnormal cells. The immune system is the body's major defence mechanism against these threats. Recent years have seen the emergence of resistant microorganisms such as methicillin-resistant *Staphylococcus aureus* (MRSA) and altered strains of familiar diseases, such as multiple-drug-resistant tuberculosis. Other diseases have also emerged, including severe acute respiratory syndrome (SARS), *Clostridium difficile* and human immunodeficiency virus (HIV). The critical need to prevent healthcare-associated infections and their resulting impact on the patient and healthcare costs is an emerging theme.

A thorough knowledge of the immune system increases understanding of inflammatory responses, resistance to infectious disease and the importance of immunisation. This foundation can help the nurse to promote health by preventing and identifying infections and teaching people and families about recommended treatment regimens.

The immune system is a complex and intricate network of specialised cells, tissues and organs. Cells of the immune system seek out and destroy damaged cells and foreign tissue, yet recognise and preserve host cells. The immune system defends and protects the body from invading pathogens, removes and destroys damaged or dead cells, and identifies and destroys malignant cells, thereby preventing their further development into tumours.

The immune system is activated by minor injuries, such as small lacerations or bruises, or by major injuries, such as burns, surgeries and systemic diseases (e.g. pneumonia). The immune response may be innate or adaptive. **Innate immunity** provides non-specific, generic responses to harmful events. These responses prevent or limit the entry of invaders into the body, thereby limiting the extent of tissue damage and reducing the workload of the adaptive immune system. Inflammation is a non-specific response activated by both minor and major injuries. When the inflammatory process is unable to destroy invading organisms or toxins, a more specific response called the **adaptive immune response** is activated. Adaptive immunity provides a response that is specific to unique organisms. It includes memory that hastens future responses to the organism.

Immune system components

The immune system consists of molecules, cells and organs that produce the immune response (see Table 11.1). These components may be involved in the non-specific inflammatory response, the specific immunological response, or both.

Leucocytes

Leucocytes, or white blood cells (WBCs), are the primary cells involved in both innate and adaptive immune system responses. Like all blood cells, leucocytes derive from stem cells, the haemocytoblasts, in the bone marrow (see Figure 11.1). Leucocytes are not confined to the circulation; they use it to transport themselves to the site of an inflammatory or immune response. As the mobile units of the immune system, leucocytes detect, attack and destroy anything that is recognised as 'foreign'. They are able to move through tissue spaces, locating damaged

TABLE 11.1 Cells and tissues of the immune system

COMPONENT	LOCATION	FUNCTION
Leucocytes		
Granulocytes		
Neutrophils	Circulation	Phagocytosis and chemotaxis
Eosinophils	Circulation, respiratory tract and gastrointestinal tract	Phagocytosis Protection against parasites Involved in allergic response
Basophils	Circulation	Release of chemotactic substances
Monocytes and macrophages	Circulation (monocytes) and body tissue, such as skin (histocytes), liver (Kupffer cells), alveoli, spleen, tonsils, lymph nodes, bone marrow, brain	Trapping and phagocytising of foreign substances and cellular debris Secretion of interleukin-1 to stimulate lymphocyte growth
Lymphocytes		
T cells (mature in thymus gland)	Circulation, lymph system, tissues	Activation of T and B cells Control of viral infections and destruction of cancer cells Involved in hypersensitivity reactions and graft tissue rejection
B cells (mature in bone marrow)	Circulation, spleen	Production of antibodies (immunoglobulins) to specific antigens
NK (natural killer) cells	Circulation	Cytotoxic; killing of tumour cells, fungi, viral-infected cells and foreign tissue
Lymphoid tissues		
Primary or central lymphoid structures	Bone marrow and thymus gland	Production of immune cells; sites for cell maturation
Secondary or peripheral lymphoid structures	Lymph nodes, spleen, tonsils, intestinal lymphoid tissue, lymphoid tissue in other organs	Sites for activation of immune cells by antigens

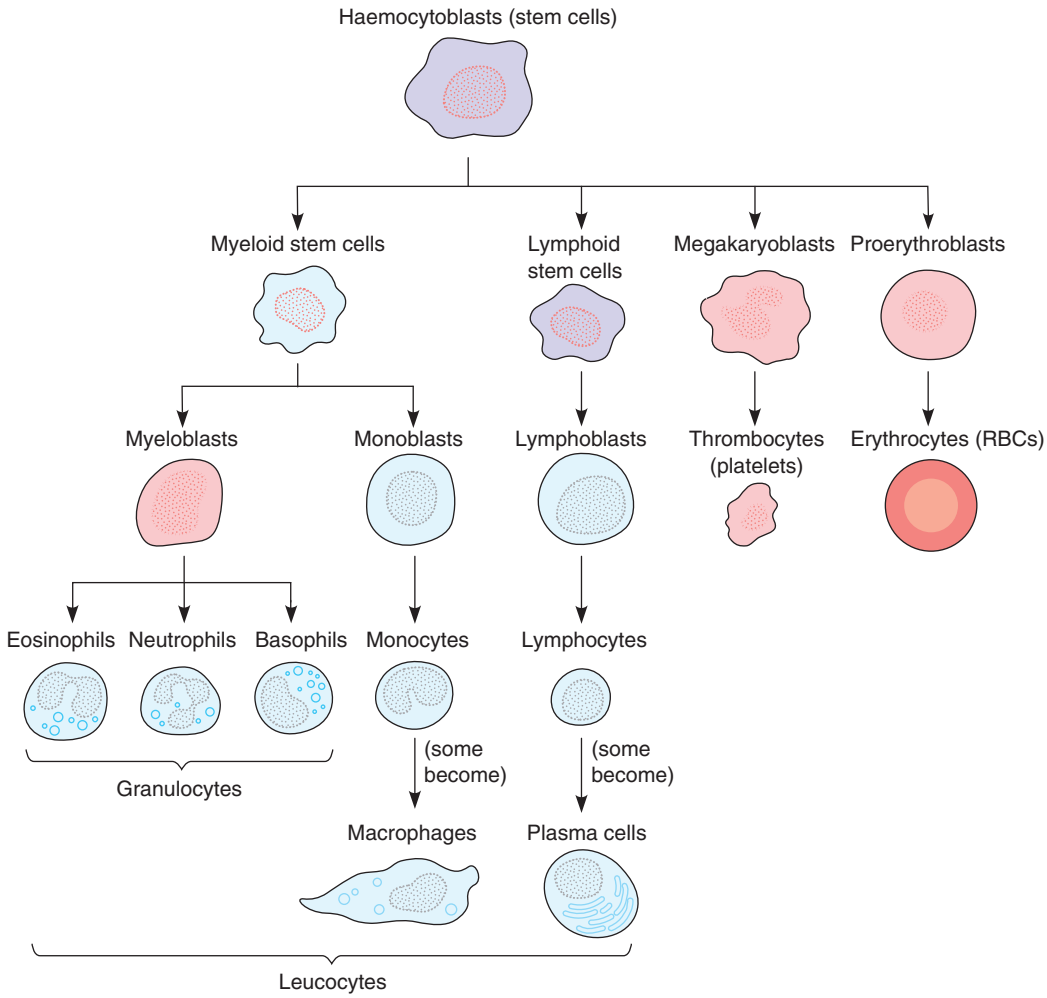

FIGURE 11.1 ■ The development and differentiation of leucocytes from haemocytoblasts

tissue and infection by responding to chemicals released by other leucocytes and damaged tissue.

The normal number of circulating leucocytes is 4500 to 10 000 cells per cubic millimetre (mm^3) of blood. Many more leucocytes are marginated. Margination refers to adhesion of leucocytes to vascular epithelial cells along the vessel walls, in other tissue spaces or in the lymph system. Marginated leucocytes migrate into injured areas or areas where pathogens infiltrate as part of the innate immune response. In the presence of an attack such as an infection, additional WBCs are released from the bone marrow, leading to **leucocytosis**, a WBC count of greater than 10 000/mm^3. As WBCs move out of the bone marrow into the blood, the bone marrow increases its production of additional leucocytes. A decrease in the number of circulating leucocytes, known as **leucopenia**, occurs when bone marrow activity is suppressed or leucocyte destruction increases.

Leucocytes are divided into three major groups: granulocytes, monocytes and lymphocytes. The granulocytes and monocytes derive from the myeloid stem cells of the bone marrow and are instrumental in the inflammatory response. Lymphocytes derive from the lymphoid stem cells of the bone marrow and are the primary cells involved in the specific immune response. In laboratory tests, the WBC count indicates the total number of circulating leucocytes. The White Cell Count (WCC) differential identifies the portion of the total represented by each type of leucocyte.

GRANULOCYTES Granulocytes constitute 60% to 80% of the total number of normal blood leucocytes. Their cytoplasm has a granular appearance and their nuclei are distinctively multilobular (see Figure 11.1). Granulocytes have a short life span, measured in hours to days, compared to the lifespan of monocytes, which is measured in months to years. Granulocytes play a key role in protecting the body from harmful microorganisms during acute inflammation and infection. There are three types of granulocytes: neutrophils, eosinophils and basophils.

Neutrophils, also called polymorphonuclear leucocytes (PMNs or polys), are the most plentiful of the granulocytes, constituting 55% to 70% of the total number of circulating leucocytes. Neutrophils are phagocytic cells, responsible for engulfing and destroying foreign agents, particularly bacteria and small particles. Neutrophils are the first phagocytic cells to arrive at the site of invasion, drawn by chemicals released by damaged tissue and invading organisms.

Neutrophils are produced in the bone marrow and released into the circulation when they mature. Segmented neutrophils (or segs) are mature forms and usually account for about 55% of total leucocytes. *Bands* are immature neutrophils and usually comprise 5% of leucocytes. As neutrophils mature, their nucleus changes from round to kidney-bean-shaped (banded) and then the nucleus separates into small, attached segments; thus the designations 'banded' versus 'segmented' neutrophils. It takes about 10 days for a neutrophil to mature and be released into the circulation. Once released, neutrophils have a circulating half-life of 6 to 10 hours. They cannot replicate and must be replaced constantly to maintain adequate numbers in the circulation. They do not return to the bone marrow.

Eosinophils account for 1% to 4% of the total number of circulating leucocytes. They mature in the bone marrow in 3 to 6 days before being released into the circulation. Eosinophils have a circulating half-life of 30 minutes and a tissue half-life of 12 days. They are phagocytic cells but are less efficient at this process than neutrophils. Eosinophils are found in large numbers in the respiratory and gastrointestinal tracts, where they are thought to be responsible for protecting the body from parasitic worms, including tapeworms, flukes, pinworms and hookworms. Eosinophils surround the parasite and release toxic enzymes from their cytoplasmic granules. The parasite, although too large to be phagocytised, is destroyed. Eosinophils are also involved in a hypersensitivity response, inactivating some of the inflammatory chemicals released during the inflammatory response.

Basophils constitute about 0.5% to 1% of the circulating leucocytes. These cells are not phagocytic. Granules within basophils contain proteins and chemicals such as heparin, histamine, bradykinin, serotonin and slow-reacting substances of anaphylaxis (leukotrienes). These substances are released into the bloodstream during an acute hypersensitivity reaction or stress response.

MONOCYTES, MACROPHAGES AND DENDRITIC CELLS Monocytes, macrophages and dendritic cells are the mediators of immunity. They recognise foreign matter (from molecules to cells) and initiate immune responses. *Monocytes* are the largest of the leucocytes and constitute 2% to 3% of circulating leucocytes. After their release from the bone marrow, monocytes circulate in the serum for 1 to 2 days. They then migrate throughout the body, attaching themselves to the tissues, where they remain for months or even years until they are activated. Monocytes mature into **macrophages** after settling into the tissues. Once they have migrated and matured, macrophages are differentiated by the tissues in which they reside. *Histiocytes* are tissue macrophages in loose connective tissue, *Kupffer cells* are found in the liver, *alveolar macrophage*s in the lungs and *microglia* in the brain. Tissue macrophages are also found in the spleen, tonsils, lymph nodes and bone marrow. Dendritic cells are star-shaped cells that serve as intermediaries between the innate and adaptive immune systems. Dendritic cells capture antigens, transporting them to lymphoid organs such as regional lymph nodes (Grossman & Porth, 2014). Monocytes, macrophages and dendritic cells are antigen-presenting cells (APCs) which activate immune responses in both B and T lymphocytes.

Monocytes, macrophages and dendritic cells are actively phagocytic with the capacity to phagocytise large foreign particles and cell debris. Like neutrophils, macrophages are drawn to an inflamed area by chemicals released from damaged tissue in a process known as chemotaxis. Once they are in the tissue, macrophages can multiply to encapsulate and trap foreign matter that cannot be phagocytised. Monocytes and macrophages activate the immune response against chronic infections such as tuberculosis, viral infections and certain intracellular parasitic infections. Dendritic cells have long processes that can capture antigens and migrate to lymphoid tissue. They serve as sentinels for antigens in most organs including the heart, lungs, liver, kidneys and gastrointestinal tract. Like neutrophils, macrophages are drawn to an inflamed area by chemicals released from damaged tissue, a process known as chemotaxis. Dendritic cells activate T cells against cancer, assist B lymphocytes to produce antibodies and down regulate the immune system.

LYMPHOCYTES **Lymphocytes** account for 20% to 40% of circulating leucocytes. Lymphocytes are the principal effector and regulator cells of specific immune responses that protect the body from microorganisms, foreign tissue, and cell mutations or alterations. Through a process known as immune surveillance, lymphocytes monitor the body for cancerous cells and eliminate or destroy them.

Like other leucocytes, lymphocytes derive from the stem cells in the bone marrow (see Figure 11.2). Lymphocytes have 'homing' patterns: they constantly circulate then return to concentrate in lymphoid tissues (the lymph nodes, spleen, thymus, tonsils, Peyer's patches in the submucosa of the distal ileum and the appendix).

The three types of lymphocytes are **T lymphocytes (T cells)**, **B lymphocytes (B cells)** and **natural killer cells (NK cells)**. None of these cells acts independently. Their functions are closely interrelated. T cells mature in the thymus gland, whereas B cells complete their maturation in the bone marrow. T cells and B cells are integral to the adaptive immune response. On contact with an antigen, B lymphocytes are activated and mature into either plasma cells, which secrete antibodies, or memory cells. On contact with APCs, T lymphocytes mature into active helper T cells, cytotoxic T cells or memory T cells. Memory cells stay inactive, sometimes for years, but activate immediately with subsequent exposure to the same antigen. They then proliferate rapidly, producing an intense immune response. Memory cells are responsible for providing acquired immunity.

NK cells are large, granular cells found in the spleen, lymph nodes, bone marrow and blood. They constitute 15% of circulating lymphocytes. NK cells provide immune surveillance and resistance to infection, and they play an important role in the destruction of early malignant cells. Like B cells and T cells, NK cells are cytotoxic; however, unlike T cells, they do not require a specific antigen to become activated and kill cancer cells, virus-infected cells and cells infected with microbes (Grossman & Porth, 2014). Fortunately, NK cells are inhibited when contact is made with normal host cells.

ANTIGENS Substances the immune system recognises as foreign or 'non-self' are called **antigens**. Antigens provoke a specific immune response when introduced into the body.

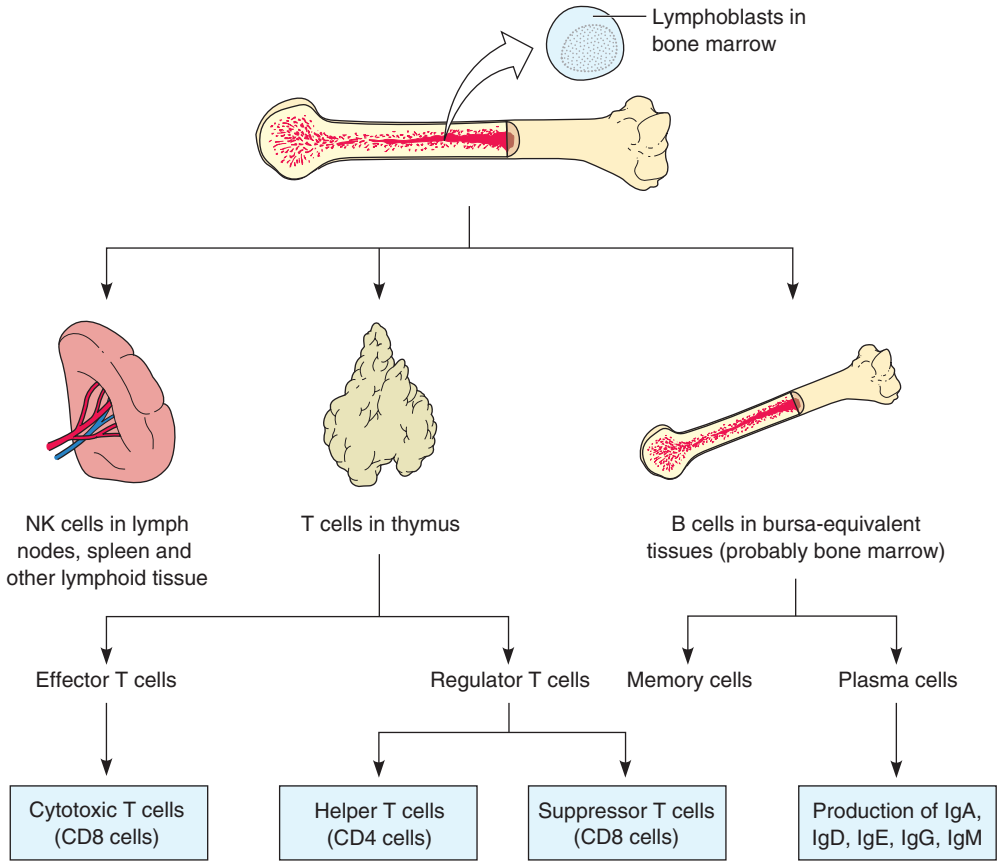

FIGURE 11.2 ■ The development and differentiation of lymphocytes from the lymphoid stem cell (lymphoblasts)

Typically, antigens are large protein molecules found on the cell membrane or cell wall of microorganisms or tissues such as transplanted tissue or organs. Other potentially antigenic substances include pollens, insect venom and the resin of poison ivy (Grossman & Porth, 2014).

Complete antigens, known as immunogens, have two characteristics: (1) *immunogenicity,* the ability to stimulate a specific immune response, and (2) *specific reactivity,* the stimulation of specific immune system components. In contrast, haptens are small molecules (e.g. chemical toxins or dust) that must link with proteins to evoke an antigenic response. When an antigen is encountered in the body, generation of an effective immune response involves two major groups of cells: lymphocytes and antigen-presenting cells (APCs). Macrophages and dendritic cells function as APCs as they capture, process and present antigens to the lymphocytes. Lymphocyte receptors recognise and respond to specific antigens, generating the immune response. Two separate but overlapping immune responses may occur, depending on the antigen itself and the type of immune cell activated by contact with the antigen. The B cell or humoral branch of the immune system mainly targets extracellular antigens such as bacteria, bacterial toxins and free viruses through the production of **antibodies**, molecules that bind with the antigen and inactivate it. The five classes of antibodies are IgG, IgA, IgM, IgD and IgE. These proteins make up the **antibody-mediated (humoral) immune response**. Intracellular pathogens, such as viral-infected cells, cancer cells and foreign tissue, activate T lymphocytes which are the primary agents of the **cell-mediated (cellular) immune response**. In this immune response, the lymphocytes themselves in the form of helper T cells, cytotoxic T cells and NK cells inactivate the antigen either directly or indirectly.

Lymphoid system

The *lymphoid system* consists of the lymph nodes, spleen, thymus, tonsils, lymphoid tissue scattered in connective tissues and mucosa, and the bone marrow. The thymus and bone marrow, in which T cells and B cells mature, are considered central lymphoid organs. The spleen, lymph nodes, tonsils and other peripheral lymphoid tissue are peripheral lymphoid organs (see Figure 11.3). The lymphoid system recovers proteins such as albumin for the vascular system and protects the bloodstream from invading organisms. Immune cells continuously circulate through lymphoid tissues and organs, identifying and destroying foreign antigens. Lymph nodes, the most numerous elements of the lymphoid system, are small, round or bean-shaped encapsulated bodies that vary in size from 1 mm to 2 cm. Lymph nodes generally occur in groups at the junction of the lymphatic vessels. They can be found in the neck, axillae, abdomen and groin.

Lymph nodes filter foreign products or antigens from the lymph and house and support proliferation of lymphocytes and macrophages. Lymph, a clear, protein-containing fluid transported within lymph vessels, enters the node through afferent lymphatic vessels. Inside the node, the lymph flows through sinuses in the

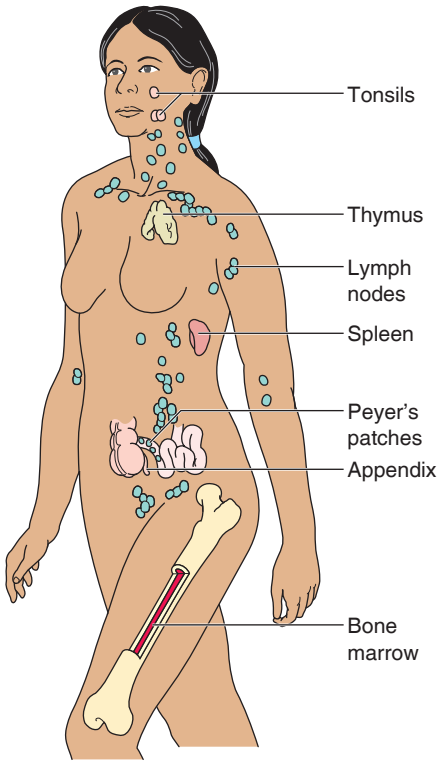

FIGURE 11.3 ■ The lymphoid system: the central organs of the thymus and bone marrow, and the peripheral organs, including the spleen, tonsils, lymph nodes and Peyer's patches

cortex of the lymph node where T and B lymphocytes and macrophages are abundant, then through sinuses of the medulla of the lymph node which contains macrophages and plasma cells. The presence of a foreign antigen stimulates lymphocytes and macrophages to proliferate in the lymph nodes. Macrophages destroy the antigen by phagocytosis. Immune cells and lymph then leave the lymph node through efferent vessels. An abundant blood supply to the node also facilitates lymphocyte movement.

The spleen is the largest lymphoid organ in the body and the only lymphoid organ that can filter blood. The spleen is located in the upper left quadrant of the abdomen. The spleen has two kinds of tissue: white pulp and red pulp. White pulp is lymphoid tissue that serves as a site for lymphocyte proliferation and immune surveillance. B cells predominate in the white pulp. Blood filtration occurs in the red pulp. In blood-filled venous sinuses, phagocytic cells dispose of damaged or aged RBCs and platelets. Other debris and foreign matter, such as bacteria, viruses and toxins, are also removed from the blood. The spleen also stores blood and the breakdown products of RBCs for future use. The spleen is not essential for life. If it is removed because of disease or trauma, the liver and the bone marrow assume its functions.

The *thymus gland* is located in the superior anterior mediastinal cavity beneath the sternum. It reaches its maximum size at puberty, then begins to atrophy slowly. By adulthood, it is difficult to differentiate from surrounding adipose tissue even though it remains active. In the older adult, the vast majority of thymus tissue has been replaced by adipose and fibrous connective tissue. During foetal life and childhood, the thymus serves as a site for the maturation and differentiation of thymic lymphoid cells, the T cells. Thymosin, an immunoregulatory hormone of the thymus, stimulates lymphopoiesis, the formation of lymphocytes or lymphoid tissue.

Bone marrow is soft organic tissue found in the hollow cavity of the long bones, particularly the femur and humerus, as well as the flat bones of the pelvis, ribs and sternum. Bone marrow produces and stores haematopoietic stem cells from which all cellular components of the blood are derived (see Figure 11.1).

Lymphoid tissues are also located at key sites of potential invasion by microorganisms: the submucosa of the genitourinary, respiratory and gastrointestinal tracts and the skin. Plasma cells in these lymphoid tissues defend the body against bacterial invasion at areas exposed to the external environment. In general, these tissues are known as *mucosa-associated lymphoid tissue* (MALT). Diffuse collections of lymphocytes, plasma cells and phagocytes are scattered throughout the respiratory tract, concentrating at bifurcations of the bronchi and bronchioles. Peyer's patches, or gut-associated lymphoid tissue (GALT), comprise the largest collection of immune cells in the body. Ingestion and absorption of solid foodstuffs and liquids continually expose the lining of the gut to resident microflora and infectious pathogens. Unlike peripheral lymph nodes, which respond to pathogens with acute inflammatory responses, GALT processes common intestinal antigens without producing acute inflammation. Collections of immune cells make up the GALT. Intraepithelial lymphocytes fill the spaces between mucosal epithelial cells. Beneath the basement membrane of gut epithelium lie abundant T cells and mature plasma cells, which are sources of IgA. Peyer's patches hold dense collections of lymphocytes in lymphoid nodules. As naive B and T cells migrate through Peyer's patches, they are sensitised to specific antigens. In mesenteric lymph nodes, these sensitised cells proliferate and circulate throughout the vascular tree where they produce secretory IgA. Secretory IgA coats mucosal cells and prevents attachment of intraluminal bacteria in the intestine, upper respiratory tract, bronchi, mammary ducts and salivary glands. Thus the GALT collection of immune cells effectively protects mucosa throughout the body that is exposed to resident and foreign pathogens.

Tonsils and adenoids protect the body from inhaled or ingested foreign agents. Skin-associated lymphoid tissue contains lymphocytes and dendritic cells such as Langerhans cells in the epidermis, which transport antigens to regional lymph nodes for destruction and development of specific immunity to the antigen.

Innate immune response

Innate or natural immunity is the first line of defence against infection. It is non-specific and includes skin and mucosal barriers, vascular and cellular responses and phagocytosis. Cells involved in innate immunity include phagocytic neutrophils and macrophages, and NK cells which target intracellular pathogens. Soluble molecules such as opsonins, cytokines, acute-phase proteins (such as C-reactive protein) and the complement system also are involved in innate immunity.

Barrier protection is the body's first line of defence against infection. Intact skin prevents invasion by external organisms. When the skin is damaged or lost (e.g. as a result of injury, surgery

or burns), infection is much more likely. A barrier of mucus, which traps microorganisms and other foreign substances, protects the membranes lining inner surfaces of the body. These can then be removed by other protective mechanisms, such as ciliary movement or the washing action of tears or urine. In addition, many body fluids contain bactericidal substances that provide barrier protection. These include acid in gastric fluid, zinc in prostatic fluid and lysosyme in tears, nasal secretions, saliva and sweat.

When these defences are breached, the resulting tissue damage or foreign material entering the body induces inflammation, another innate defence mechanism. **Inflammation** is a response to injury that brings fluid, dissolved substances and blood cells into the interstitial tissues where the invasion or damage has occurred. The response is *non-specific* as the same events occur regardless of the cause of the inflammatory process. Through the inflammatory reaction, the invader is neutralised and eliminated, destroyed tissue is removed and the process of healing and repair is initiated.

The inflammatory response has two stages: (1) a vascular response characterised by vasodilation and increased permeability of blood vessels, and (2) a cellular response. Phagocytosis sets the stage for healing (tissue repair).

Vascular response

After tissue cells are damaged, local blood vessels briefly constrict. Vasodilation of the capillary arterioles and venules follows almost immediately as inflammatory mediators such as histamine and kinins are released from damaged tissue (see Box 11.1). Increased blood flow causes vasocongestion at the injury site with resultant redness and heat. The congestion also increases local hydrostatic pressure. This, along with increased vessel permeability that results from chemical mediators, moves fluid out of the capillaries and into the interstitial spaces of the tissue. The escaping fluid, called fluid exudate, contains large amounts of protein. This protein increases osmotic pressure in the interstitial spaces, which draws fluid and causes local oedema. Fluid exudate provides protection to the injured tissue by transporting to the tissue certain nutrients needed for tissue healing, diluting bacterial toxins and transporting cells needed for phagocytosis. Exudate may range from *serous,* primarily plasma with some proteins, to *sanguineous* containing large amounts of blood cells. *Fibrinous* exudate forms a thick, sticky meshwork of fibrinogen, in effect 'walling off' inflamed tissues and preventing the spread of infection. In more severe or acute inflammation, the fluid contains fibrin, RBCs and dead and live bacteria. This type of exudate, called *purulent* exudate, has an odour and colour characteristic of the bacteria present.

The vascular response localises invading bacteria and keeps them from spreading. Increased capillary permeability enhances the release of clotting factors such as fibrinogen which converts to fibrin threads, entrapping the bacteria and walling them off from contact with the rest of the body.

Cellular response

The cellular stage of the inflammatory process begins within less than an hour after the injury. This stage is marked by changes in the lining of blood vessels and movement of phagocytic blood cells into the damaged tissue.

As serous fluid escapes the capillaries, the viscosity of blood in the area increases and its flow becomes more sluggish. Leucocytes move to the edges of the blood vessels where they accumulate, their movement slows and they begin to adhere to

BOX 11.1 Inflammatory mediators

Many of the manifestations of inflammation are produced by chemicals released as a result of immunological processes or tissue injury or damage. These inflammatory mediators are broadly classified as follows:

- Vasoactive substance (e.g. histamine, prostaglandins, leukotrienes and platelet-activating factor) produce smooth muscle constriction, vasodilation and increased capillary permeability.
- Chemotactic factors (e.g. complement fragments and chemokines) attract leucocytes to the damaged tissue.
- Plasma enzymes (proteases) activate the complement system, the clotting cascade and the vasoactive kinins system, contributing to the vascular phase of the inflammatory response.
- Miscellaneous cell products (e.g. oxygen metabolites and lysosomal enzymes) damage surrounding tissue.

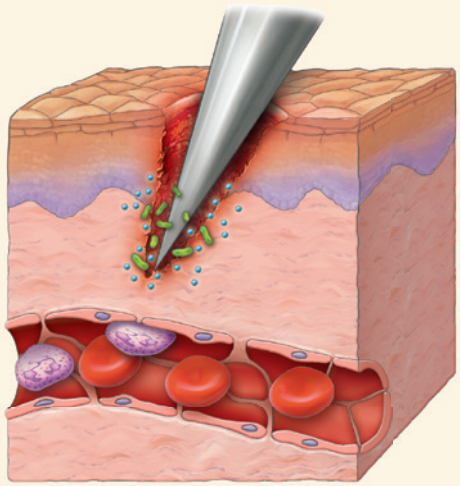
Many of the outward manifestations of inflammation result from vasoactive substances such as histamine, prostoglandins and leukotrienes. Stored in mast cells, basophils and platelets, *histamine* is released when an injury occurs or with stimulation by the immune system. An important component of the early inflammatory response, histamine causes vasodilation and vascular permeability in the affected area. Histamine is also a key factor in many hypersensitivity reactions. The *leukotrienes*, collectively known as slow-reacting substances of anaphylaxis (SRS-A), play a significant vasoactive role in the later stages of the inflammatory response.

Prostaglandins are chemotactic substances that draw leucocytes to the inflamed tissue. In addition, they play a vasoactive role and are pain and fever inducers. Aspirin and other non-steroidal anti-inflammatory drugs (NSAIDs), as well as the glucocorticoids, inhibit prostaglandin synthesis, thereby reducing fever, pain and inflammation.

Plasma proteases activate the clotting cascade, kinin system and complement system. With activation of the clotting cascade, bacteria and other foreign substances are trapped in the area of tissue damage. Fibrin, which has vasoactive by-products, is also released. Activation of the complement system causes vasodilation, increases vessel permeability and facilitates the phagocytic process. Through the release of bradykinin, the kinin system has similar effects. Bradykinin also stimulates pain receptors.

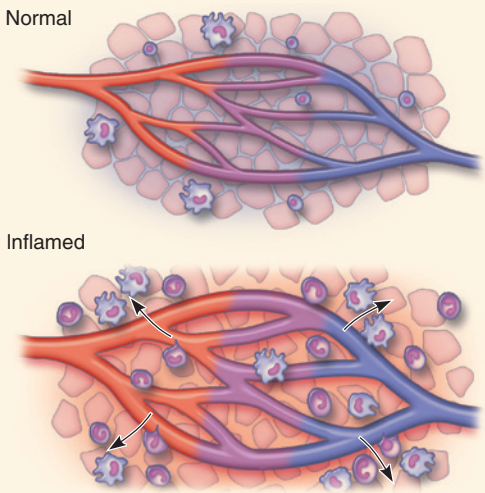
Major chemical mediators of inflammation are summarised in Table 11.2.

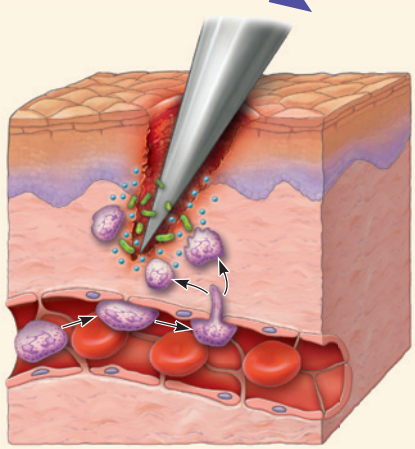
Acute inflammation



1. Inflammation is a key component of innate immunity, the body's immediate response to tissue damage or invasion of the body by foreign material. The inflammatory response serves to contain, control and eliminate damaged cells and tissue, microorganisms and antigens.

2. Vascular response. Tissue damage causes brief, initial vasoconstriction which is rapidly followed by vasodilation, with resulting redness and warmth. Inflammatory mediators (e.g. histamine, prostaglandins, bradykinins) released in the innate immune response and by damaged tissue dilate local blood vessels and increase the permeability of capillaries in the area. Protein-rich fluid (exudate) accumulates in interstitial spaces, causing swelling and pain. Resulting oedema slows blood flow and, together with activation of clotting in the area, helps localise and prevent microorganisms from spreading.





3. Cellular response. Within less than an hour after the injury, the cellular stage of the inflammatory process brings phagocytic blood cells into the damaged tissue. Loss of serous fluid from capillaries increases blood viscosity in the area and slows its flow. Leucocytes marginate, moving to the vessel periphery and adhering to the capillary endothelium. As a result, endothelial cells separate, allowing leucocytes to transmigrate through vessel walls into the tissue spaces. Chemotactic signals draw the leucocytes to the site of the injury or infection.

4. Phagocytosis. Once attracted to the inflammatory site, phagocytes engulf the foreign agent or target cell by projecting pseudopodia ('false feet') in all directions around it. This produces a phagosome containing the antigen, which is ingested into the cytoplasm. Once engulfed, lysosomes fuse with the phagosome, killing any live organism and releasing digestive enzymes, which destroy the antigen.

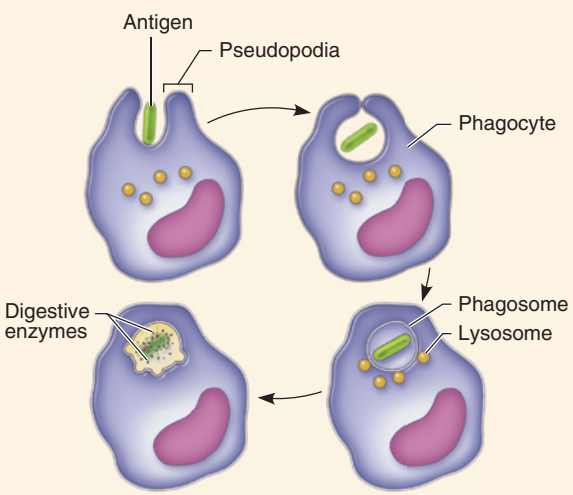


TABLE 11.2 Major chemical mediators of inflammation

FACTOR	SOURCE	EFFECT
Histamine	Mast cells, basophils and platelets	Vasodilation and increased capillary permeability producing tissue redness, warmth and oedema
Kinins (bradykinin and others)	Plasma proteins	Histamine-like effects; chemotaxis and pain inducers
Prostaglandins	Formed from arachidonic acid found in cell membranes	Histamine-like effects; chemotaxis, pain, and fever inducers
Leukotrienes	Formed from arachidonic acid	Smooth muscle constriction (especially bronchoconstriction), increased vascular permeability, chemotaxis

the capillary endothelium. This process is known as *margination*. Leucocyte adhesion causes separation of endothelial cells, allowing leucocytes to transmigrate through the blood vessel wall into the tissue spaces. Within hours, millions of leucocytes emigrate into the area of inflammation.

Once leucocytes have emigrated, they are drawn to the damaged or inflamed tissues by chemotactic signals. Infectious agents, damaged tissues and activated plasma substances such as complement fractions provide chemotaxic signals that attract an army of neutrophils, monocytes and macrophages to the injury site.

The number of neutrophils around the site increases to about 15 000 to 25 000/mm^3 and they begin their role in phagocytosis within a few hours. Monocytes become transient macrophages to augment the activity of the fixed macrophages and dendritic cells; together they engulf dead cells, damaged tissue, non-functioning neutrophils and invading bacteria.

Phagocytosis

Phagocytosis is a process by which a foreign agent or target cell is recognised, engulfed and destroyed. Neutrophils, monocytes and macrophages, known as *phagocytes*, are the primary cells involved in phagocytosis. Once attracted to the inflammatory site, phagocytes select and engulf foreign material.

The following factors or processes help phagocytes differentiate foreign tissue from normal cells:

- *Smooth surface*. Normal tissue has a smooth surface that is resistant to phagocytosis, whereas the rough surface of a foreign agent or target cell promotes phagocytosis.
- *Surface charge*. Healthy body cells present an electronegative surface charge that repels phagocytes. Cellular debris and foreign agents, by contrast, have an electropositive charge that attracts them.
- *Opsonisation*. This immune system process coats the surface of bacteria or target cells with soluble molecules (opsonins) such as complement, lectins and other proteins (see Box 11.2). Opsonisation enables the phagocyte to bind tightly with the foreign tissue, facilitating phagocytosis.

Phagocytes engulf the foreign agent or target cell by projecting pseudopodia in all directions around it. This produces a chamber called a *phagosome* containing the antigen, which is ingested into the cytoplasm. Once the phagosome has been engulfed, lysosomes fuse with the phagosome, releasing antimicrobial molecules and digestive enzymes which destroy the antigen. Phagocytes produce bactericidal agents that kill most pathogens. These agents include toxic oxygen and nitrogen radicals, such as nitric oxide, hydrogen peroxide and hydroxyl ions, as well as

BOX 11.2 The complement system

The *complement system* consists of approximately 20 complex plasma proteins that are activated by a tissue injury or antigen–antibody reaction. The complement system is involved in both innate and adaptive immune responses. Its activation results in the production of effector molecules that are involved in the processes of inflammation, phagocytosis, and cell lysis or destruction (Grossman & Porth, 2014). Specifically, complement activation leads to the following:

- *Mediation of the inflammatory response*. When the complement system is activated, chemical mediators such as histamine are released from mast cells and basophils, leading to smooth muscle contraction, increased vascular permeability and oedema, and the attraction of leucocytes.
- *Opsonisation* (or coating) of microbes and antigen–antibody complexes. Opsonisation facilitates recognition of and binding to the antigen by phagocytes, and activation of phagocytosis.
- *Alteration of the cell membrane or viral capsule*. Complement can alter cell membranes, forming pores that cause cell lysis and death. Bacteria and viruses are destroyed; certain normal cells such as RBCs that are damaged or old may also be destroyed through this process.

The complement system has three 'arms', or pathways, of protein and enzyme reactions. The *classic pathway* is activated by antibody-containing immunoglobulins and other substances such as DNA and C-reactive protein. The *alternative* and *lectin pathways* function in innate immunity; they do not require antibodies but are activated by tissue injury, properties of the microbial antigen and proteins produced in response to injury (e.g. C-reactive protein) (Grossman & Porth, 2014). Complement activation results in mediation of the inflammatory process, attraction of phagocytes, facilitation of phagocytosis and lysis of microbes.

digestive enzymes (e.g. lysozyme) that break down bacterial cell walls (Mayer, 2011). They also can produce antimicrobial molecules known as *defensins* (Grossman & Porth, 2014).

Some antigens, such as the tubercle bacillus, have coats or secrete substances that are resistant to lysosomal and bactericidal agents. To destroy such antigens, lysosomes release digestive enzymes into the phagosome. The lysosomes of neutrophils and macrophages contain an abundance of proteolytic (protein-destroying) enzymes that digest bacteria and other foreign protein components. The macrophage's lysosomes also contain lipases (fat-splitting enzymes) capable of digesting the thick lipid membranes of such bacteria as *Mycobacterium tuberculosis* and *Mycobacterium leprae*.

Once neutrophils have ingested toxic substances to their capacity, they in turn are destroyed. Neutrophils have the capacity to phagocytise 5 to 20 bacteria before they become inactive. Macrophages then digest the dead neutrophils. Monocytes or macrophages are capable of phagocytising up to 100 bacteria. Because of their size, they can ingest larger particles than neutrophils can ingest, such as whole RBCs, necrotic tissue, cell fragments, malarial parasites and dead neutrophils. Dendritic cells are also phagocytic and secrete IL-12, which is an important cytokine in the maturation of helper T cells. Macrophages have the ability to extrude (release) the toxic substances and lysosomal enzymes within their phagosomes. As a result, they can continue to function for months and even years.

Healing

During the inflammatory process, particulate matter, bacteria, damaged cells and inflammatory exudate are removed by phagocytosis. This process, called *debridement*, prepares the wound for healing. Adequate nutrition is essential for inflammation and healing to proceed. Protein, glucose and oxygen are needed by leucocytes for chemotaxis, phagocytosis and intercellular killings.

The second phase of the healing process, known as *reconstruction*, may overlap the inflammatory phase. The ideal result of the healing process is *resolution*, the restoration of the original structure and function of the damaged tissue. Simple resolution occurs when there is no destruction of the normal tissue and the body is able to neutralise and remove the offending agent through the inflammatory process.

Resolution may also occur when the damaged tissue is capable of regeneration. The ability to regenerate or replace lost *parenchyma* (functional tissue) with new functional cells varies by tissue and cell type.

- *Labile cells* continue to regenerate throughout life. These cells are found in tissues where there is a daily turnover of cells—namely, bone marrow and the epithelial cells of the skin, mucous membranes, cervix, gastrointestinal tract and genitourinary tract.
- *Stable cells* normally stop replicating when growth ceases but are capable of regeneration when stimulated by an injury. Osteocytes (which are found in bone) and parenchymal cells of the kidneys, liver and pancreas are stable cells.
- *Permanent* or *fixed cells* are unable to regenerate. When these cells are destroyed they are replaced by fibrous scar tissue. Nerve cells, skeletal muscle cells and cardiac muscle cells are fixed cells.

When regeneration and complete resolution are not possible, healing occurs by replacement of the destroyed tissue with collagen scar tissue. This process is known as *repair*. Although tissue that has undergone repair lacks the physiological function of the destroyed tissue, the scar fills the lesion and provides tensile tissue strength.

Adaptive immune response

The adaptive immune response is a more specific reaction than innate immunity. On the first exposure to an antigen, a change occurs in the host, resulting in a specific and rapid response following subsequent exposures.

The adaptive immune response has the following distinctive properties:

- The immune response typically is directed against materials recognised as foreign (i.e. from outside the body) and is not usually directed against the self (i.e. cells or structures produced by the body). This property is known as *self-recognition*.
- The immune response is *specific*. It is initiated by and directed against particular antigens (such as a specific virus, bacterium or transplanted tissue).
- Unlike a localised inflammatory response, the immune response is systemic. Immunity is not restricted to the initial site of infection or entry of foreign tissue.
- The immune response has memory. Repeated exposures to an antigen produce a more rapid response.

A person whose immune system is able to identify antigens and effectively destroy or remove them is said to be **immunocompetent**.

There are two types of adaptive immune responses: humoral or antibody-mediated immunity, and cellular or cell-mediated immunity.

Antibody-mediated immune response

The antibody-mediated (humoral) immune response is produced by B lymphocytes (B cells). B cells are constantly replaced through cell division and proliferation in the bone marrow. It is believed that B cells mature in the bone marrow and then migrate to the spleen to await activation. They normally constitute 10% to 15% of circulating lymphocytes.

B cells are activated by contact with an antigen and by T cells (discussed in the next section). Each B cell has receptor sites for a specific antigen or antigens. When the antigen is encountered, the activated B cell proliferates and differentiates into antibody-producing plasma cells and memory cells (see Figure 11.4). Plasma cells are short-lived, lasting only about 1 day. While alive, however, they can produce thousands of antibody molecules per second. Memory cells retain antibody-producing information, allowing a rapid response if the antigen is again encountered.

An antibody is an **immunoglobulin (Ig)** molecule with the ability to bind to and inactivate a specific antigen. Immunoglobulins fall into five classes: IgG, IgA, IgM, IgD and IgE. Each has a slightly different structure and function. Their roles are summarised in Table 11.3.

Antibodies are Y-shaped molecules with two light and two heavy polypeptide chains (see Figure 11.5). The top portion of the Y, called the *Fab* or *antigen-binding fragment*, is chemically variable and specific to the antigen. The lower portion, the

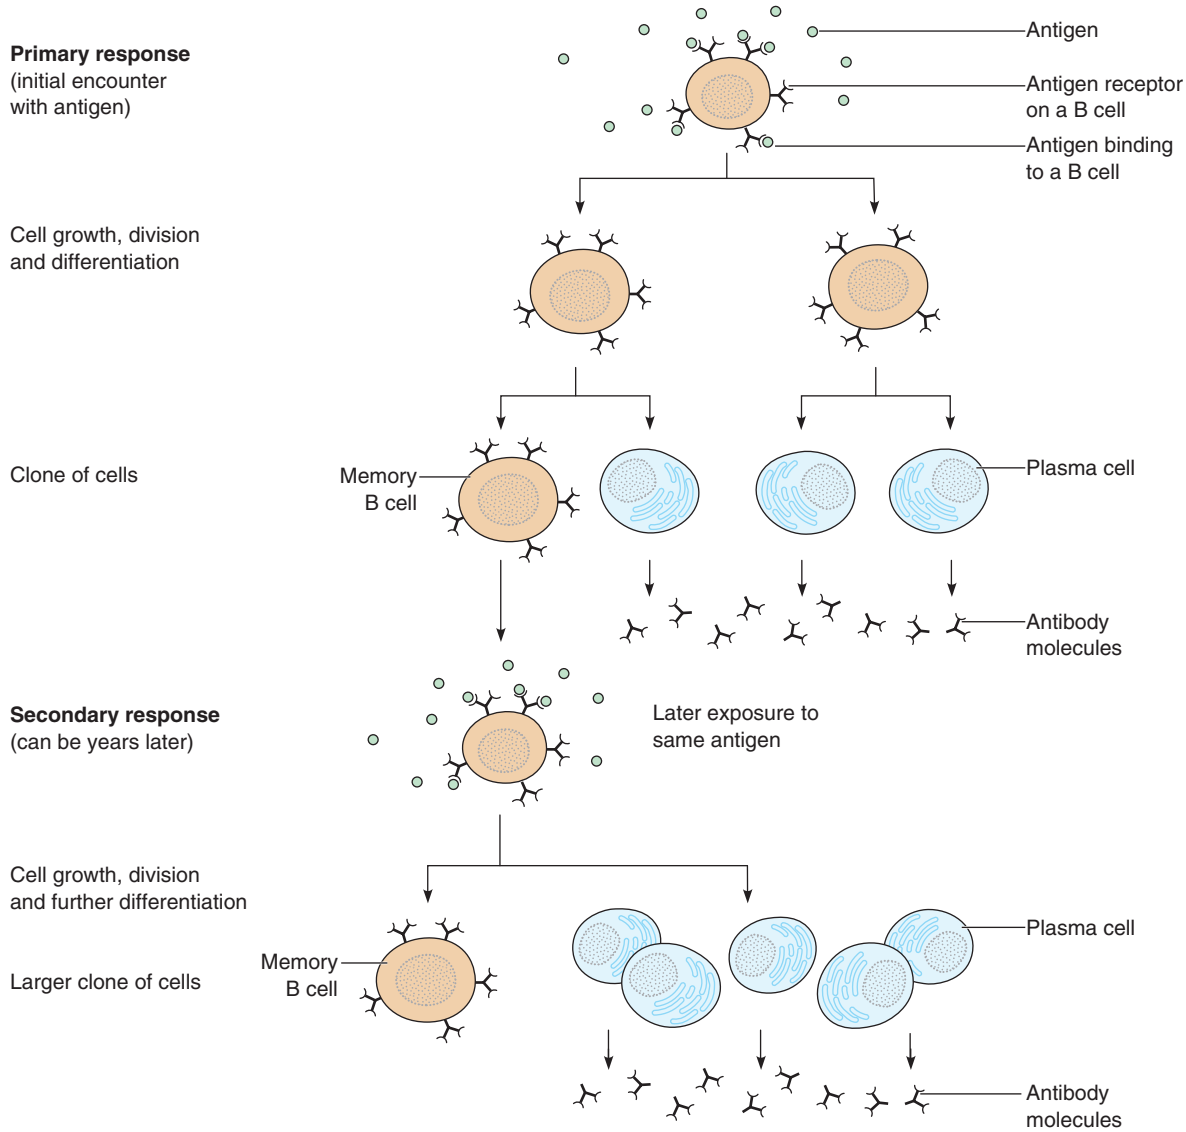

FIGURE 11.4 ■ Antibody-mediated (humoral) immunity. On initial exposure to the antigen, B cells with appropriate receptor sites are activated to become plasma cells and produce antibodies or memory cells. This is known as the primary response. With subsequent exposures, memory cells respond rapidly with antibody production. This is known as the secondary response.

Fc or *crystallised fragment*, is constant for its class of immunoglobulin and directs the biological activity of the immunoglobulin (the manner in which it functions). For example, the lower portion of immunoglobulin molecules produced against hepatitis A and hepatitis B are the same (IgG), but the upper portion is different and specific to the virus.

The antibodies produced by B cells (see Figure 11.5) link with the antigen (see Figure 11.6) and inactivate it through one or more of the following processes:

- covering the antigen with antibodies to attract phagocytes, including neutrophils, macrophages and eosinophils
- precipitation—combining with soluble antigens to form an insoluble complex or precipitate that can be captured and destroyed by phagocytes
- neutralisation—combining with a virus or toxin to neutralise its effects by preventing it from attaching to cells and tissues; the antigen–antibody complex is then destroyed by the process of phagocytosis
- complement activation and fixation to the antigenic cell surface, leading to cell lysis
- agglutination (clumping) of insoluble antigens (e.g. a cell or virus) to form a large complex
- opsonisation—coating of the antigen with antibodies and complement, making them more susceptible to phagocytosis.

The complete antibody-mediated response occurs in two phases. With initial exposure to an antigen, the primary response develops. B cells are activated to proliferate and begin producing antibodies. There is a latency period of 3 to 6 days before antibodies become detectable in the blood. Levels then continue to rise, peaking at 10 to 14 days after the initial exposure. With many illnesses (e.g. chickenpox), this peak correlates with recovery.

TABLE 11.3 Immunoglobulin characteristics and functions

CLASS	PERCENTAGE OF TOTAL	CHARACTERISTICS AND FUNCTION
IgG	75%	Most abundant Ig; also known as gamma globulin; found in blood, lymph and intestines Active against bacteria, bacterial toxins and viruses Activates complement and binds to macrophages The only Ig to cross the placenta, providing immune protection to neonates
IgA	10–15%	Found in saliva, tears and bronchial, gastrointestinal, prostatic and vaginal secretions, as well as blood and lymph Provides local protection on exposed mucous membrane surfaces and potent antiviral activity by preventing binding of the virus to epithelial cells Levels decrease during stress
IgM	5–10%	Found in blood and lymph First antibody produced with primary immune response High concentration early in infection decreases within about a week Mediates cytotoxic response and activates complement
IgD	< 1%	Found in blood, lymph and surfaces of B cells Exact function unknown; may be receptor-binding antigens to B-cell surface
IgE	< 0.1%	Found on mast cells and basophils Involved in release of chemical mediators responsible for immediate hypersensitivity (allergic and anaphylactic) response and parasitic infections

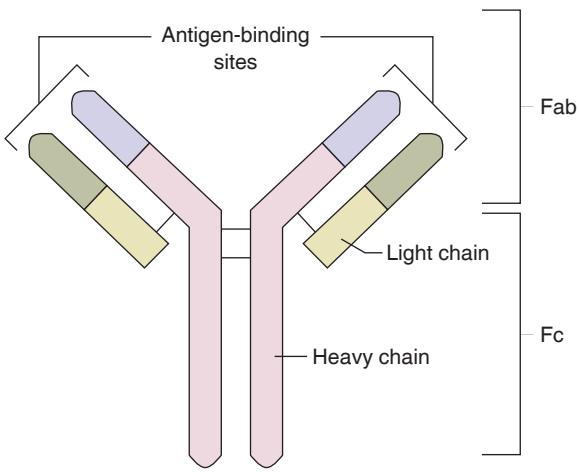

FIGURE 11.5 ■ An antibody molecule. The Fab section is unique, providing an antigen-specific binding site. The Fc section is common to each class of immunoglobulin (IgG, IgA, IgM, IgD, IgE)

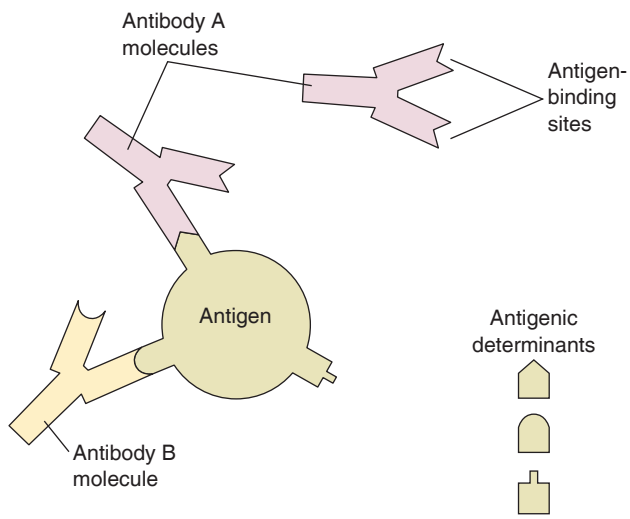

FIGURE 11.6 ■ Antigen–antibody binding. The unique Fab site on the antibody binds with specific receptor sites on the antigen. As shown, more than one kind of antibody may be produced for an antigen

Subsequent exposure to the same antigen elicits a secondary response. Memory cells (see Figure 11.4) formed during the primary response stimulate the production of plasma cells and an almost immediate rise in antibody levels occurs (see Figure 11.7). This rapid secondary response is the basis of acquired immunity and is instrumental in preventing disease. It is also the mechanism through which vaccines provide protection from disease.

Cell-mediated immune response

Many antigens cannot stimulate the antibody-mediated response or are hidden from it because they live inside the body's cells (e.g. viruses and mycobacteria). The cell-mediated immune response, also known as *cellular immunity,* provides protection against these antigens. T lymphocytes (T cells) initiate this type of immune response.

Approximately 70% to 80% of circulating lymphocytes are T cells. T cells migrate to the thymus during foetal and early life, establishing the lifetime pool of cells. T cells have a lifespan measured in years, maintaining their numbers through proliferation, primarily in the lymph nodes.

T cells are much more complex than B cells. There are two major classes of T cells: CD4 cells and CD8 cells, *differentiated by their cell surface proteins (or markers).*

T cells are antigen-specific; that is, each subset is activated by a particular antigen. The antigens that activate T cells must

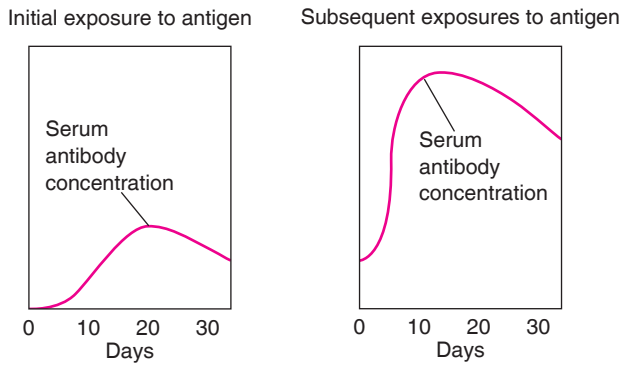

FIGURE 11.7 ■ Antibody production in the primary and secondary responses of the antibody-mediated immune response. Note the more rapid and effective production following subsequent exposure

be presented on another cell surface, such as pieces of virus presented on the surface of an infected cell or the histocompatibility locus antigen on a cell of transplanted tissue. When activated, T cells divide and proliferate, forming antigen-specific *clones* (see Figure 11.8). Activated T cells further differentiate to become *cytotoxic cells*, *helper cells* or *suppressor cells.* *Memory cells* are also formed; these remain in reserve for future encounters with the antigen.

The *cytotoxic T cell* (T_C cell), an effector cell with the CD8 markers, seeks out and destroys abnormal cells and cells harbouring anything foreign (e.g. viruses). Cytotoxic T cells bind with cell surface antigens on virus-infected or foreign cells. T_C cells destroy the identified cell by combining with it and then either destroying its cell membrane or releasing cytotoxic substances into the cell. They are vital in the control of viral and bacterial infections.

Helper T cells (T_H cells) develop from T cell populations with the CD4 marker. T_H cells coordinate immune responses to an antigen. They stimulate the proliferation of other T cells, amplify the cytotoxic activity of T_C cells and amplify the innate immune response. T_H cells interact directly with B cells to promote their multiplication and conversion into plasma cells capable of producing antibodies.

Suppressor T cells (T_S cells), a much smaller subgroup of T cells, are important regulators of immune responses. Suppressor T cells release inhibitory cytokines, which inhibit the activity of other T cells and B cells and limit the extent of the immune response to an antigenic stimulus.

On activation, both effector and regulator T cells synthesise and release soluble proteins known as **cytokines** (see Box 11.3).

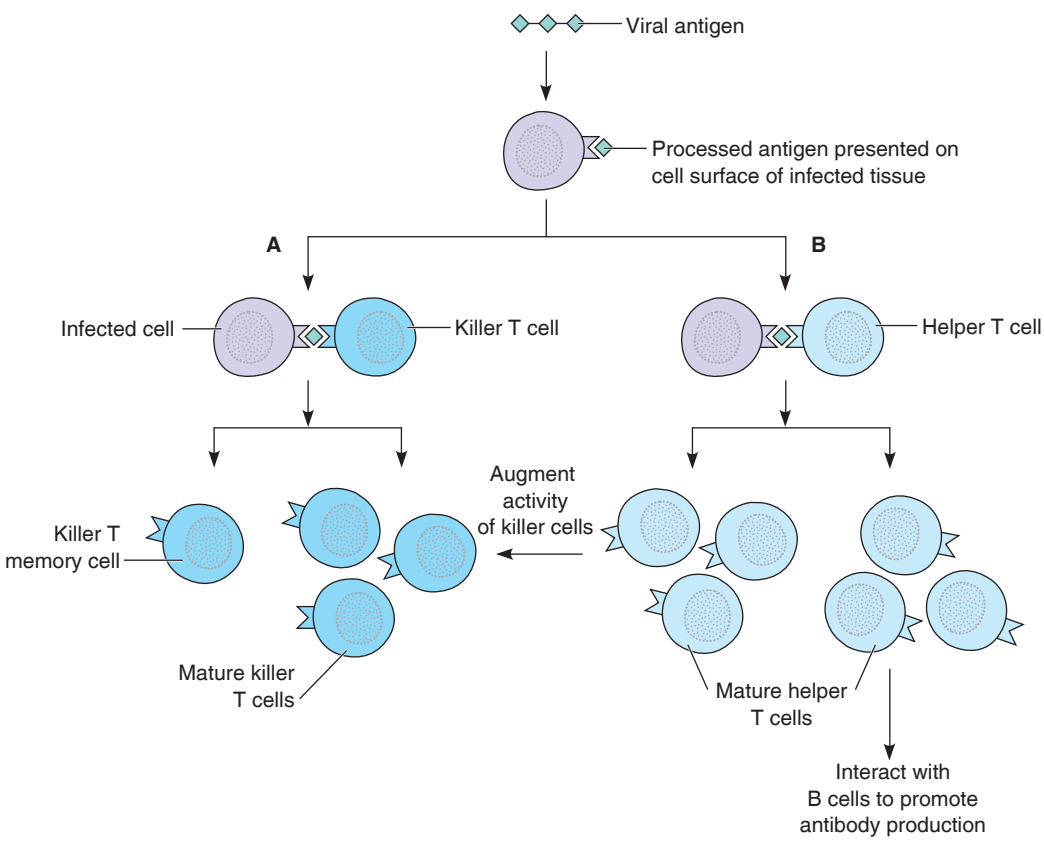

FIGURE 11.8 ■ Cellular immune response. *A*, An infected cell, abnormal cell or phagocyte presents antigen on its surface that binds with a receptor site on a killer T cell or a helper T cell. The killer T cell is activated to proliferate into memory cells or mature cytotoxic cells. *B*, The helper T cell is activated to augment the cytotoxic response and stimulate the antibody-mediated immune response

BOX 11.3 Cytokines

Cytokines, essential components of an adequate immune response, are hormone-like polypeptides produced primarily by cells of the immune system. Cytokines are produced in small quantities in many different tissues throughout the body. Cytokines act as messengers of the immune system, facilitating communication between the cells to adjust or vary the inflammatory reaction or to initiate immune cell proliferation and differentiation. The major cytokines and their functions are summarised in Table 11.4.

The inflammatory cytokines contribute to illness behaviours. People respond to increases in these chemicals with increased sleep, a need to seek warmth and reduced energy output. These are considered adaptive responses to illness. Interventions to reduce or eliminate the production of certain cytokines are common. Aspirin and NSAIDs to reduce pain and fever are commonly used. Because some cytokines cross the blood–brain barrier, their increase may explain depression and anxiety experienced during illness.

Interferons are a class of cytokine with broad antiviral and anticancer effects. A number of different forms of interferon exist, broadly grouped as alpha, beta and gamma interferons. Interferon is synthesised by cells infected with a virus and secreted into extracellular fluid. It then binds to specific receptors on uninfected neighbouring cells, protecting them from infection. The spread of the virus is thus inhibited and recovery from infection enhanced. It appears that interferons also moderate the activity of NK cells and may be involved in preventing the spread of abnormal malignant cells.

TABLE 11.4 Major cytokines and their functions

CYTOKINE	WHERE PRODUCED	PRIMARY FUNCTIONS
Interleukin-1 (IL-1)	Monocytes, macrophages and dendritic cells	Activates T and B cells Induces fever and tissue catabolism Enhances NK activity Attracts neutrophils, macrophages and lymphocytes Stimulates bone marrow and endothelial cell growth, collagen and collagenases
Interleukin-2 (IL-2)	Helper T cells	Stimulates T and B cell proliferation, aids in discriminating between self and non-self Activates killer T and NK cells
Interleukin-3 (IL-3) Interleukin-4 (IL-4)	T cells	Stimulates growth and differentiation of bone marrow stem cells Stimulates proliferation of T cells Increases IgE secretion by B cells
Interleukin-5 (IL-5)	T cells and activated mast cells	Promotes differentiation of B cells and eosinophils Stimulates production of IgA
Interleukin-6	T cells and macrophages	Is a pro-inflammatory and anti-inflammatory cytokine Induces fever
Interleukin-8	Macrophages	Mediates the innate immune response Induces fever Is angiogenic (stimulates vessel formation)
Gamma interferon	T and NK cells	Stimulates phagocytosis by neutrophils and macrocytes Activates NK cells Augments B cell proliferation, enhancing both cellular and humoral immune responses
Alpha and beta interferons	Virus-infected cells; macrophages	Activate macrophages and endothelial cells; beta interferon induces fever Augment NK cell activity Act at gene level to protect neighbouring cells from invasion by intracellular parasites, such as viruses, rickettsia, malaria
Macrophage inflammatory proteins (MP-1-4CC)	Macrophages, dendritic cells and lymphocytes	Are chemokines (CC), which are small cytokines Promote inflammatory response, chemotaxis and homeostasis (control migration of cells in maintenance and development)
Tumour necrosis factor (TNF)	Activated macrophages, T cells and NK cells	Major chemical mediator of inflammatory response Stimulates T-cell activation, antibody production and accumulation of leucocytes at inflammatory site Directly cytotoxic to some tumour cells Induces fever

Cytokines are important in amplifying innate immunity and the specific immune response. They stimulate:

- B cells to become plasma cells and produce antibodies
- attraction and activation of macrophages to become aggressive phagocytes
- proliferation of cytotoxic T cells and memory helper T cells
- cytotoxic T cells to destroy abnormal cells and pathogens.

Although T cells are activated by specific antigens, much of the resulting effect is non-specific—in other words, an enhanced inflammatory response. Like the antibody-mediated response, the cell-mediated response has memory. Subsequent exposures to an antigen result in a more rapid and effective inflammatory response and more effective phagocytosis by macrophages. This memory provides the basis for skin testing. For example. a person previously exposed to tuberculosis develops a more pronounced inflammatory response when minute amounts are injected under the skin.

The person with natural or acquired immunity

Immunity refers to the protection of the body against disease. Immunity to disease may be either natural or acquired, active or passive.

Immunity develops from the activation of the body's immune response. Depending on the antigen, antibody-mediated or cell-mediated responses are activated. The immune response typically involves components of both. In the immunocompetent (having an immune system capable of responding to pathogens and tissue damage) person, these responses inactivate and remove the antigen, allowing recovery to occur or preventing the development of disease. People with suppressed or impaired immune function are more susceptible to disease and require protection from exposure to environmental elements. Isolation techniques are employed to prevent the spread of disease and protect immunosuppressed people.

Pathophysiology

The processes of antibody-mediated and cell-mediated immunity result in the development of **active immunity**. Active immunity occurs when the body produces antibodies or develops immune lymphocytes against specific antigens. Memory cells, which can produce an immediate immune response on re-exposure to the antigen, provide long-term immunity. Active immunity can develop naturally, resulting from contact with the disease-producing antigen and subsequent development of the disease.

For many diseases, however, the potential consequences of a single disease episode for the individual and society make prevention desirable, especially for highly contagious diseases capable of causing epidemics. In these instances, immunisation, or vaccination, is used to provide artificially acquired immunity. The purpose of vaccination is to establish adequate levels of antibody and/or memory cells to provide effective immunity. Vaccination introduces the disease-producing antigen into the body in a manner that will stimulate the immune system to form antibodies and memory cells but will not produce disease. Vaccines may be made of killed organisms or of live organisms that have been attenuated or modified to reduce their disease-producing capability. Typhoid is an example of a killed organism vaccine; measles-mumps-rubella (MMR) vaccine, by contrast, is made from attenuated organisms. Many newer vaccines use subunits of the antigen; these are portions of the organism that have antigenic properties but are unable to produce disease.

Passive immunity provides temporary protection against disease-producing antigens. Antibodies produced by other people or animals are the source of passive immunity. These acquired antibodies are used up; they either combine with the antigen or they are naturally degraded by the body and their protection is gradually lost. The transfer of maternal antibodies via the placenta and breast milk to the infant provides naturally acquired passive immunity. Rabies human immune globulin and hepatitis B immune globulin (HBIG) are examples of immunisations used to provide artificially acquired passive immunity. The types of active and passive immunity are summarised in Table 11.5.

INTERPROFESSIONAL CARE

Interprofessional care is preventive, focusing primarily on assessing the person's immune status and ensuring acquired immunity to prevent disease.

Diagnosis

A number of diagnostic tests can be performed to assess the person's immune status.

- *Serum protein* measures the total protein in the blood, including albumin and globulins. Normal levels for the adult are 62 to 80 g/L; albumin is approximately 60% (32 to 45 g/L) of the total serum protein; and globulins are normally 23 to 34 g/dL. Total protein levels, albumin and globulin are decreased in malnutrition and liver disease. Decreased globulin levels are noted with immunological deficiencies.

TABLE 11.5 Types of acquired immunity

TYPE OF IMMUNITY		HOW DEVELOPED	EXAMPLES
Active immunity	Natural	Acquired by infection with an antigen, resulting in the production of antibodies	Chickenpox
	Artificial	Acquired by immunisation with an antigen, such as attenuated live virus vaccine	MMR, polio, DTP, hepatitis B vaccine
Passive immunity	Natural	Acquired by transfer of maternal antibodies to the foetus or neonate via the placenta or breast milk	Neonate initially protected against MMR if mother immune
	Artificial	Acquired by administration of antibodies or antitoxins in immune globulin	Gamma globulin injection following hepatitis A exposure

- *Protein electrophoresis* analyses protein content, especially for albumin and gamma globulin, and is used to assess immune function. Gamma globulins subjected to further electrophoresis separate into immunoglobulins: IgA, IgD, IgE, IgG and IgM (see Table 11.3). Analysis of specific levels of each provides clues about the immune status of the person. IgG levels are increased during acute infection. Decreased levels of IgG, IgA and IgM are found in malignancies.
- *Antibody testing* is ordered to determine if a person has developed antibodies in response to an infection or immunisation. Antibodies for hepatitis, HIV, rubella, varicella (chickenpox) and certain other diseases can be identified. An elevated titre level for varicella and rubella indicates immunity. Antibody testing may also be used to determine if the person has the disease.
- *Skin testing* can assess cell-mediated immunity. A known antigen such as streptokinase, tuberculin-purified protein derivative or *Candida* protein is injected intradermally. The site is then observed for induration and erythema, which typically peak at 24 to 48 hours. An induration of at least 10 mm in diameter is a positive reaction, indicating previous exposure and sensitisation to the antigen. No reaction to common antigens, or **anergy**, indicates depressed cell-mediated immunity.

Immunisations

Vaccines are suspensions of whole or fractionated bacteria or viruses that have been treated to make them non-pathogenic. Vaccines are given to induce an immune response and subsequent immunity. Although vaccine development has been a major factor in improving public health, no vaccine is completely effective or entirely safe. Table 11.6 outlines the vaccines recommended for the adult person to maintain optimal health and immune status (Centers for Disease Control and Prevention (CDC), 2014).

Adults born before 1966 are generally considered to be immune to measles, mumps and rubella by prior infection. Individuals born after 1966 should have documentation of one or more doses of MMR vaccine unless they have a medical contraindication to the vaccine or laboratory evidence of immunity to the three diseases (CDC, 2014).

Vaccination against diphtheria, tetanus and pertussis (DTP) is part of the National Immunisation Program (NIP) schedule. A combined vaccine is administered in a series of injections. The paediatric form of the vaccine is known as DTPa, while the adult

TABLE 11.6 Recommended immunisations for adults

VACCINE	TYPE	DOSE	INDICATIONS	PRECAUTIONS AND NURSING IMPLICATIONS
Measles-mumps-rubella (MMR)	Live virus	0.5 mL SC	All adults born after 1966, particularly those who are at risk of infection, such as healthcare workers, those working with children, and overseas travellers. MMR vaccination is particularly recommended for males without history of previous infection; rubella vaccination recommended for all seronegative females.	As a live virus vaccine, should not be administered to pregnant women or immunocompromised people. Do not administer to people with a history of anaphylactic reaction to egg protein or neomycin.
Diphtheria, tetanus and pertussis toxoids (dTpa)	Inactivated toxins	0.5 mL IM	Initial series of 3 injections (minimum intervals of 4 weeks) if never immunised then booster at 10 and 20 years; adults who reach 50 and have not had booster in previous 10 years; following a major or contaminated wound if more than 5 years since last booster.	Do not give in first trimester of pregnancy or to people with a history of anaphylactic reaction to previous dose or any vaccine component; administer deep IM in deltoid of dominant arm.
Hepatitis B (HB)	Inactive viral antigen	1.0 mL IM	Series of 3 doses: initial then at 1 to 2 months, then 2 to 5 months after second dose. Recommended for anyone at risk of exposure and for postexposure prophylaxis.	Use with caution in pregnant or lactating females, older people and people with active infection.
Influenza	Inactivated virus or viral components	0.5 mL IM	Yearly for all people > 6 months of age; strongly recommended for over age 65, all Aboriginal and Torres Strait Islander people > 15 years of age and those with predisposing conditions to severe influenza, including debilitated people and people with chronic disease.	Do not administer to people who are acutely ill or people with history of anaphylactic reaction to egg protein.
Pneumococcal	Bacterial polysaccharides	0.5 mL IM or SC	One dose for people over age 65, and Aboriginal and Torres Strait Islander people > 50 years of age; and those aged > 10 who are at risk of pneumococcal pneumonia, including people with chronic lung disease or other chronic diseases.	Do not administer to pregnant women.

form is dTpa. The vaccine stimulates active immunity by inducing the production of antibodies and antitoxins. After an initial series of a three-dose primary schedule as an infant, a booster dose is given around 4 years of age. A recent update of the *Immunisation Handbook* (Department of Health and Ageing and National Health and Medical Research Council (NHMRC), 2013) in March 2015 recommends a further booster at 18 months of age in addition to 4 years of age. A further booster dose is recommended for adolescents around 11 to 13 years. It is also recommended that pregnant women in the third trimester of each pregnancy receive a dose of dTpa. Adults who reach 50 years of age without having a booster dose in the prior 10 years should receive a booster dose.

Hepatitis B (HB) vaccine is given as a series of three immunisations to promote active immunity to hepatitis B. This vaccine is recommended for everyone at high risk of exposure through blood or other body fluids, including healthcare workers, and emergency and essential service workers. Other high-risk populations include intravenous drug users, sexual partners of infected individuals, people on haemodialysis, prison guards, tattooists, body piercers and embalmers. A universal hepatitis B vaccination program was recommended for infants and adolescents in 1996. The adolescent program commenced in 1997 and the universal infant program, with the first dose given at birth, began nationally in 2000.

Influenza vaccine is recommended annually for all adults. The antigenic strains included in the influenza vaccine vary each year according to the predicted predominant strains affecting the population; therefore, yearly re-immunisation is required.

Pneumococcal vaccine is recommended for all children and is included in the infant immunisation program.

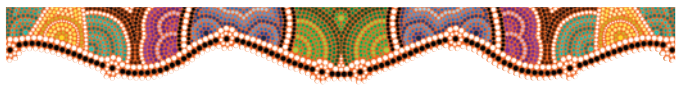
Indigenous Australians historically have had a very high rate of infectious diseases. In the early period of European colonisation, this was mainly due to a lack of previous exposure, followed by high-density living in newly established settlements. In recent decades, for some diseases such as diphtheria, polio, tetanus, hepatitis B, measles, mumps and rubella, vaccination has been very successful in eliminating or substantially reducing disease in all Australians, significantly contributing to reducing child mortality in Indigenous Australian populations. However, other diseases such as pneumococcal disease and influenza have a higher rate of illness in Indigenous compared to non-Indigenous people and therefore are specifically recommended for administration of vaccine to a broader age group.

In addition to routine immunisations, people travelling outside Australia should receive vaccines against diseases that are endemic in the regions of the world that they intend to visit.

Other immunological substances may be administered as indicated. Immunoglobulins provide passive immunity as protection against a known or potential exposure to an antigen. Normal human immunoglobulin is given to household contacts of people with hepatitis A and people travelling to areas in which it is endemic. HB immunoglobulin contains higher titres of antibody to hepatitis B virus and is used for people exposed by blood or sexual contact. Following confirmed or suspected contact with a pathogen, selected vaccines may be administered to stimulate an immediate immune response.

For most vaccines, a sensitivity test should be performed prior to administration to detect sensitivity to substances such as horse serum or eggs. The substance is injected intradermally; if after 20 minutes there is no evidence of a reaction, the selected vaccine can be administered.

Moderate to severe local reactions may occur following administration of an immunisation. Common reactions include redness, swelling, tenderness and muscle ache. Administering the vaccine in the dominant arm of the person helps minimise local reactions because use and movement of the arm facilitates absorption of the solution. Applying heat to the site is also beneficial. Occasionally local ulcerations occur; when they do, warm wet packs or sterile wet-to-dry dressings may be prescribed.



Nursing care

Maintaining a population that is fully immunised against common, potentially epidemic and devastating diseases is a major public health task for nursing. Nurses not only recommend and administer vaccines to individual people and their families, but also plan and implement preventive care for whole communities.

Although this process may appear to be straightforward, multiple issues affect society's ability to immunise the entire population. For some people, for example, religious beliefs may preclude the use of immunisations to prevent disease. Also, people who are not citizens and the medically indigent population have difficulty accessing immunisation services. Lack of immunisation not only puts the individual at increased risk of infectious disease, but also increases the cost of medical services and the possibility of exposing immunocompromised people to disease.

Health promotion

In the public health setting, the nurse looks at the immunisation needs and illness risk of an entire community. Communities include not only cities and localities, but also groups of people, such as university populations and employees in a workplace. Public education needs may be met through presentations to groups of people, feature articles in newspapers and other local publications, advertising, radio presentations, public service announcements, one-to-one discussion and teaching.

Assessment

Collect the following data through the health history and physical examination. Further focused assessments are described with nursing interventions in the next section.

- *Health history*: age, medication use (corticosteroids and antibiotics) and blood transfusion, nutrition, known allergies, pregnancy status, infection, immunisations, autoimmune disorders, chronic diseases such as asthma, diabetes mellitus, cancer.
- *Physical assessment*: skin lesions or rashes, breath sounds, respiratory rate.

Nursing diagnoses and interventions

Nursing care focuses on preventing injury from the immunisation and educating the person. See the accompanying 'Nursing care plan' box.

CONSIDERATION FOR PRACTICE

Observe the person for 20 to 30 minutes following vaccine administration to monitor for possible adverse reactions.

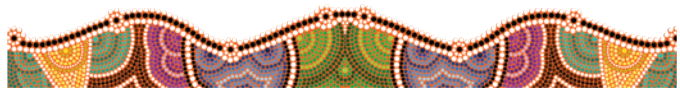
Readiness for enhanced immunisation status

For individual people and their families, nurses promote immunocompetence by assessing immune status, recommending appropriate immunisations and administering vaccines as ordered or indicated. Once a person reaches adulthood, routine immunisations often become a neglected part of healthcare.

- Determine knowledge level, understanding, attitudes and religious beliefs about immunisation. *This provides a basis for further education and determines if religious beliefs may contraindicate immunisation.*
- Discuss the value and reasons for recommended immunisations. *Understanding promotes adherence.*
- Reinforce positive health-seeking behaviours. *This will help promote future health maintenance activities.*
- Using recommended immunisation schedules, develop a plan to attain optimal immunisation status. *Adherence with recommended schedules for immunisation is important in preventing disease and disability.*
- Do not administer MMR or influenza vaccine if allergic to eggs, or tetanus antitoxin if sensitive to horse serum. *Vaccines prepared from chicken or duck embryos are contraindicated in people who are allergic to eggs. Tetanus antitoxin is prepared from horse serum. Both will cause a severe allergic reaction.*
- Withhold administration of active immunological products in the presence of an upper respiratory infection or other infection. *Active immunisations can cause a greater inflammatory reaction in the presence of infections.*
- Do not administer oral polio vaccine, MMR or any live virus vaccine to immunosuppressed people or to those who are in close household contact with an immunosuppressed person. *Live virus vaccines can cause disease in the immunosuppressed person. The virus may be transmitted from close household contacts during the initial post-vaccination period.*
- Do not administer vaccines such as MMR, pneumococcal or varicella to women who are pregnant. *Although the risk to the developing foetus is greatest during the first trimester, these vaccines are avoided throughout pregnancy.*
- Do not administer live attenuated virus vaccines and passive immunisations such as gamma globulin simultaneously. *Passive antibodies interfere with the response of the live attenuated virus.*
- Prior to administering the prescribed vaccine, check the expiration date and manufacturer's instructions. *Outdated vaccines cannot provide adequate immunisation protection. Certain injection sites have better absorption than others.*
- Keep adrenaline 1:1000 readily available for subcutaneous injection when administering immunisations. *Adrenaline causes vasoconstriction and reduces laryngospasm; in acute anaphylaxis, it can be lifesaving.*

Community-based care

Clinically significant medical events including high fever, injection-site hypersensitivity, unspecified rash and injection-site oedema that occur after vaccination should be reported as an adverse event following immunisation (AEFI). Reporting an AEFI is important as it provides a better understanding of the safety issues around vaccines. The ongoing reporting of adverse events following immunisation allows the Therapeutic Goods Administration (TGA) to monitor rates and trends across Australia and assist in identifying issues such as incorrect vaccine administration, manufacture, storage and delivery.



NORMAL IMMUNE RESPONSES

The person with tissue inflammation

Inflammation is a non-specific response to injury that serves to destroy, dilute or contain the injurious agent or damaged tissue. Acute inflammation is a short-term reaction of the body to all types of tissue damage. It is immediate and aimed at protecting the body and preventing further invasion or injury. Acute inflammation usually lasts less than 1 to 2 weeks. Once the injurious agent is removed, the inflammation subsides. Healing with tissue repair or scar formation occurs and the body functions in normal or near-normal capacity.

Chronic inflammation is slower in onset and may not have an acute phase. Its clinical manifestations occur over months or years. While the effects of some chronic inflammatory processes may be evident (such as the joint damage and destruction associated with rheumatoid arthritis), the role chronic inflammation plays in diseases such as asthma, obesity and heart disease has only recently been recognised.

Pathophysiology and manifestations

The tissue damage that evokes an inflammatory response may be caused by specific or non-specific agents. These agents may be *exogenous*, from outside the body, or *endogenous*, from within the body. Causes of inflammation include the following:

- mechanical injuries such as cuts or surgical incisions
- physical damage such as burns
- chemical injury from toxins or poisons
- microorganisms such as bacteria, viruses or fungi
- extremes of heat or cold
- immunological responses, such as hypersensitivity reactions
- ischaemic damage or trauma, such as a stroke or myocardial infarction.

Acute inflammation

Regardless of the cause, location or extent of the injury, the acute inflammatory response follows the previously outlined sequence of vascular response, cellular and phagocytic response, and healing.

Many of the manifestations of inflammation are produced by inflammatory mediators, such as histamine and prostaglandins, released when tissue is damaged (see Box 11.1).

The primary manifestations of inflammation include the following:

- erythema (redness)
- local heat caused by the increased blood flow to the injured area (hyperaemia)

NURSING CARE PLAN A person with acquired immunity

Terry Adams is a 48-year-old executive who is planning a trip to central Africa. In preparation, he contacts his local healthcare provider to obtain the necessary immunisations. Jane Wong, the Registered Nurse in the clinic, obtains a nursing history of Mr Adams.

ASSESSMENT

Mr Adams' history reveals that he has always been very healthy and active, apart from a mild case of asthma. As an adult he has had little problem with his asthma, 'except for those rare occasions when I am dumb enough to smoke more than one cigarette!'. He is divorced and is not currently in a continuing relationship. He has two grown daughters with whom he has a good relationship. Since contracting hepatitis A several years ago, he drinks alcohol only rarely and never more than one or two drinks at any one time. He confesses to doing little organised exercise, but plays golf two or three times a week. He says he is such a hyperactive workaholic that he rarely sits for any length of time. Mr Adams has not seen a physician since recovering from the hepatitis and is unsure when he last received any immunisations. He does not know if he had all the recommended childhood immunisations, but recalls getting both Salk and Sabin polio vaccines when they became available. His physical examination reveals an alert and healthy individual with no abnormalities noted. His vital signs are as follows: T 37.1°C, P 64, R 14 and BP 142/82.

The physician orders the following immunisations for Mr Adams:

- measles-mumps-rubella (MMR)
- combined tetanus, diphtheria and pertussis toxoids (dTpa)
- yellow fever vaccine
- typhoid vaccine
- meningococcal meningitis vaccine.

DIAGNOSES

- *Health-seeking behaviours: immunisation* related to impending international travel.
- *Ineffective health maintenance* related to apparent lapse in immunisation status.
- *Risk of injury* related to adverse response to immunisation.

PLANNING

- Obtain MMR, dTpa and meningococcal meningitis vaccines for administration.
- Schedule return visit in 1 week for typhoid vaccine.
- Refer Mr Adams to a registered vaccination centre for yellow fever vaccine.
- Ensure instructions are provided for comfort measures to relieve local and systemic adverse effects of vaccines and manifestations that should be reported to the physician.
- Complete documentation of immunisations on a permanent record at the clinic and for Mr Adams.
- Provide information for ongoing requirements to maintain immunisation status.

Expected outcomes

- Complete necessary immunisations.
- Verbalise a schedule for maintaining up-to-date immunisation status.
- Experience no significant adverse effects from immunisation.

IMPLEMENTATION

- Administer MMR, dTpa and meningococcal meningitis vaccines prior to discharge from clinic.
- Observe closely for 30 minutes following immunisation for potential adverse responses.
- Schedule return visit in 1 week for typhoid vaccine.
- Provide referral to a registered vaccination centre for yellow fever vaccine and documentation of vaccination.
- Provide instructions for comfort measures to relieve local and systemic adverse effects of vaccines.
- Provide written instructions on signs and symptoms that should be reported to the physician.
- Document immunisations on a permanent record at the clinic and for Mr Adams.
- Discuss ongoing requirements to maintain immunisation status.

EVALUATION

Terry Adams completes his prescribed immunisations without major adverse effects, although he does complain of fever, malaise and general achiness for several days following the typhoid vaccination. His trip to Africa is successful and he returns to Australia without contracting any infectious diseases.

CRITICAL THINKING IN THE NURSING PROCESS

1. Explain why it is important for adults to continue receiving immunisations throughout their lifespan.
2. If a person says to you, 'I don't believe in immunisations. I hear they are dangerous', how would you respond?
3. When should a person contact the primary caregiver after receiving an immunisation?

REFLECTION ON THE NURSING PROCESS

1. What sources of knowledge or evidence influenced the decision making in this case study?
2. Outline what you have learned from this case study that you could apply in your future practices.

- swelling due to accumulated fluid at the site
- pain from tissue swelling and chemical irritation of nerve endings
- loss of function caused by the swelling and pain.

The degree of functional loss depends on the location and extent of the injury. With increased tissue damage, more fluid exudate is formed, resulting in more swelling, pain and functional impairment. Pain may be immediate or delayed. Prostaglandins intensify and prolong the pain. Kinins cause irritation to the nerve endings and contribute to the pain sensation.

Dead neutrophils, necrotic tissue and, if the tissue is infected, digested bacteria accumulate as a result of inflammation and phagocytosis, forming *pus*. Pus usually forms and remains until after the infection subsides. Pus may push itself to the surface of the body or become internalised. In the latter case, pus is gradually autolysed (self-digested) by enzymes

over a period of days. The end product is then absorbed by the body. On occasion, pus may remain after the infection is resolved. An abscess, or localised collection of pus, may form, necessitating drainage by a surgical procedure.

Systemic responses to inflammation include lymph node swelling (*lymphadenopathy*) due to the proliferation of macrophages within the nodes in response to microorganisms in the lymph. Enlarged lymph nodes are usually noted in the groin, axillae and neck, Fever, often precipitated by inflammatory mediators or bacterial toxins, inhibits the growth of many microorganisms and increases tissue repair functions. Loss of appetite and fatigue may occur in the effort to conserve energy during the inflammatory process. Leucocytosis occurs with increased WBC production to support inflammation and phagocytosis.

Chronic inflammation

Whereas acute inflammation is a self-limiting process lasting less than 2 weeks, chronic inflammation tends to be self-perpetuating, lasting weeks to months or years. Chronic inflammation may develop when the acute inflammatory process has been ineffective in removing the offending agent. Persistent low-grade fever or irritation by chemicals, particulate matter or physical irritants such as talc, asbestos or silica may also result in chronic inflammation.

GRANULOMATOUS INFLAMMATION *Granulomatous inflammation* is characterised by dense infiltration of the site by lymphocytes and macrophages. The macrophages mass to surround the site; they in turn are surrounded by lymphocytes and other immune cells, forming a lesion called a *granuloma*. The granuloma isolates the offending agent from the rest of the body; however, the infectious agent or irritant may not be destroyed and can survive within the granuloma for a long period of time. Chronic inflammation and granuloma formation are common with *Mycobacterium tuberculosis*. The granuloma formed in tuberculosis is called a tubercle. *M. tuberculosis* can survive for many years within the tubercle, emerging when the person's immune system is no longer able to contain it.

NON-SPECIFIC CHRONIC INFLAMMATION *Non-specific chronic inflammation* is implicated in such disorders as pulmonary airway disease (asthma and chronic obstructive lung disease), cardiovascular disease and autoimmune disorders such as inflammatory bowel disease (Reilkoff et al., 2011). This type of chronic inflammation is characterised by diffuse accumulation of macrophages and proliferation of fibroblasts in response to ongoing chemotaxis. The fibroblasts and fibrocytes, unique cells formed from monocytes, lead to formation of excessive fibrous connective tissue, disrupting normal tissue functions (Reilkoff et al., 2011). Inflammatory markers such as C-reactive protein, complement fractions and inflammatory cytokines are present in non-specific chronic inflammation and associated disorders (Bartunek & Vanderheyden, 2012: Engström, 2011; Pellizzaro & Heuertz, 2010; Strowig et al., 2012).

Complications

Inflammation and wound healing are highly metabolic processes that may be affected by a number of factors. Without adequate nutrition, blood supply and oxygenation, tissues cannot effectively complete the process. Impaired inflammatory and immune processes can interfere with phagocytosis and preparation of the wound for healing. Infection prolongs the inflammatory process and delays healing.

Chronic diseases may also impair healing. High blood glucose levels and small-blood-vessel disease associated with diabetes mellitus impair chemotactic and phagocytic function. Collagen formation and tensile strength of the wound are also impaired. Arterial and venous disorders impair the delivery of oxygen and nutrients to healing tissues, as well as the removal of toxins, bacteria and other waste products from the area. Drug therapy, particularly corticosteroid medications, may suppress the immune and inflammatory responses, delaying healing (Porth & Matfin, 2009). Other external factors, such as exposure to ionising radiation and wound cleansing agents, can also affect healing. Table 11.7 summarises major factors that affect the inflammatory process and wound healing.

TABLE 11.7 Factors that may impair healing

FACTOR	EFFECT
Malnutrition	
Protein deficit	Prolongs inflammation and impairs healing process
Carbohydrate and kilocalorie deficit	Impairs metabolic processes and promotes catabolism; proteins are used for energy rather than for healing
Fat deficit	Impairs cell membrane synthesis in tissue repair
Vitamin deficiencies	
Vitamin A	Limits epithelialisation and capillary formation
B-complex	Inhibits enzymatic reactions that contribute to wound healing
Vitamin C	Impairs collagen synthesis
Tissue hypoxia	Associated with an increased risk of infection and impaired healing because oxygen is required to support cell function and collagen synthesis
Impaired blood supply	Results in inadequate delivery of oxygen and nutrients to healing tissues and removal of waste products
Impaired inflammatory and immune processes	Results in decreased phagocytosis and wound debridement; increased risk of infection; delayed healing

INTERPROFESSIONAL CARE

Management of the person with inflamed tissue focuses on promoting healing. Care is generally supportive, allowing the person's own physiological processes to remove foreign matter and damaged cells. Wound care may be minimal, involving only simple cleaning, or may require irrigations and debridement. The person is encouraged to rest, to increase fluid intake and to eat a well-balanced, nutritious diet. Antibiotics may be prescribed to help eliminate infectious causes of inflammation.

Diagnosis

The following diagnostic tests may be ordered to identify the source and extent of inflammation.

- *WCC with differential* provides information about the type and extent of inflammatory response. The differential count (the percentage of the total WBC made up by each type of leucocyte) provides further clues about inflammatory processes (see Table 11.8).
- *Erythrocyte sedimentation rate (ESR)* is a non-specific test to detect inflammation. The rate at which RBCs fall to the bottom of a vertical tube is an indicator of inflammation. An increased ESR may indicate acute or chronic inflammation.
- *C-reactive protein (CRP) test* is used to detect CRP. This abnormal glycoprotein is produced by the liver and is excreted into the bloodstream during the acute phase of an inflammatory process. The expected result of this test is negative for CRP. A positive result indicates an acute or chronic inflammatory process.

In addition to the above diagnostic tests, cultures of the blood and other body fluids may be ordered to determine if infection is the cause of inflammation.

Medications

Although inflammation is a beneficial process to prepare acutely injured tissue for healing, its manifestations can be distressing. Chronic inflammation can lead to tissue damage and scarring with resulting loss of function. Anti-inflammatory medications may be prescribed to manage these effects. Anti-inflammatory medications fall into three broad groups: salicylates such as aspirin, other NSAIDs and corticosteroids.

Aspirin (acetylsalicylic acid or ASA) is a NSAID with antipyretic, analgesic and antiplatelet effects. Its beneficial effects are largely dose related. Low doses (as little as 75 mg/day) inhibit platelet aggregation and normal blood clotting. A 600 mg dose of aspirin is an effective analgesic and antipyretic dosage. Higher doses (600 to 900 mg, 4 to 5 times per day) are required to produce its anti-inflammatory effects. To relieve pain, aspirin acts primarily on peripheral sensory nerves by inhibiting the synthesis of prostaglandins and kinins, which are chemical stimuli of sensory nerves. As an antipyretic, aspirin acts both centrally and peripherally. It inhibits the formation of pyrogenic substances that raise the hypothalamic thermostat. It also dilates peripheral blood vessels and promotes diaphoresis, increasing the dissipation of heat (Adams, Holland & Urban, 2014).

In therapeutic doses, aspirin mediates the inflammatory process by inhibiting the enzyme cyclooxygenase (COX) and preventing synthesis of prostaglandins. Inflammation is reduced, along with the swelling, redness and impaired function that accompanies it.

The other NSAIDs have activity similar to that of aspirin. They inhibit COX and prostaglandin synthesis, reducing the inflammatory and pain responses. Each NSAID has a slightly different mode of action; sometimes several different agents must be tried before the most effective is identified. Side effects also differ to a certain extent; however, all have a potential

TABLE 11.8 The white blood cell count and differential

CELL TYPE AND NORMAL VALUE	INCREASED	DECREASED
Total WBCs: 4.5–13.5 × 10^9/L	*Leucocytosis:* infection or inflammation, leukaemia, trauma or stress, tissue necrosis	*Leucopenia:* bone marrow depression, overwhelming infection, viral infections, immunosuppression, autoimmune disease, dietary deficiency
Neutrophils (segs, PMNs or polys): 2.0–7.5 × 10^9/L	*Neutrophilia:* acute infection or stress response, myelocytic leukaemia, inflammatory or metabolic disorders	*Neutropenia:* bone marrow depression, overwhelming bacterial infection, viral infection, Addison's disease
Eosinophils (eos): 0.04–0.4 × 10^9/L	*Eosinophilia:* parasitic infections, hypersensitivity reactions, autoimmune disorders	*Eosinopenia:* Cushing's syndrome, autoimmune disorders, stress, certain drugs
Basophils (basos): < 0.1 × 10^9/L	*Basophilia:* hypersensitivity responses, chronic myelogenous leukaemia, chickenpox or smallpox, splenectomy, hypothyroidism	*Basopenia:* acute stress or hypersensitivity reactions, hyperthyroidism
Monocytes (monos): 0.2–0.8 × 10^9/L	*Monocytosis:* chronic inflammatory disorders, tuberculosis, viral infections, leukaemia, Hodgkin's disease, multiple myeloma	*Monocytopenia:* bone marrow depression, corticosteroid therapy
Lymphocytes (lymphs): 1.5–4.0 × 10^9/L	*Lymphocytosis:* chronic bacterial infection, viral infections, lymphocytic leukaemia	*Lymphocytopenia:* bone marrow depression, immunodeficiency, leukaemia, Cushing's syndrome, Hodgkin's disease, renal failure

cross-sensitivity with aspirin, all irritate the gastrointestinal tract and all are associated with an increased risk of cardiovascular events. NSAIDs are more costly than aspirin, but they have a longer duration of action; therefore, fewer daily doses are required to achieve the desired effect.

For acute hypersensitivity reactions, or for inflammation that cannot be managed using NSAIDs, corticosteroid therapy may be prescribed. The glucocorticoids are hormones produced by the adrenal cortex that have widespread effects on body metabolism and the immune response. Glucocorticoids inhibit inflammation and may be lifesaving in acute fulminating or chronic progressive inflammation. When glucocorticoids are prescribed to manage inflammation, the smallest possible effective dose is used. Wherever possible, a local-acting preparation such as a topical agent, metered-dose inhaler or intra-articular injection is prescribed to minimise systemic effects of the drug.

The incidence of potentially harmful side effects increases with higher doses and prolonged therapy. Wound healing is impaired and the metabolism of fats, proteins and carbohydrates is altered. Blood glucose control is impaired. Fat distribution changes, producing a cushingoid appearance with a moon face and increased truncal fat. Fluid retention and hypertension are potential problems, as are osteoporosis, gastrointestinal bleeding and emotional disturbances.

Paracetamol may be administered to reduce the fever and pain associated with inflammation. Paracetamol has no anti-inflammatory effect, and will not reduce the inflammatory process, but can relieve associated symptoms such as fever and pain.

Antibiotics may be used either prophylactically to prevent infection from interfering with the healing process of damaged tissue, or therapeutically to treat the infection. If infection is present, the organism and its response or sensitivity to various antibiotics is used to guide therapy. Antibiotic therapy is presented in greater depth in the section of this chapter on infectious diseases.

Nutrition

Healing depends on cell replication, protein synthesis and the function of specific organs—the liver, heart and lungs, in particular. Malnutrition and protein depletion are risk factors for poor healing and wound complications. Even a few days of severely impaired nutritional intake can noticeably affect healing (Tucker & Dauffenbach, 2011).

The person with an inflammatory process or healing wound requires a well-balanced diet of sufficient kilojoules to meet the metabolic needs of the body (see Table 11.7). Inflammation often produces *catabolism*, a state in which body tissues are broken down. By contrast, healing is a process of *anabolism*, or building up. Without sufficient kilojoules and nutrients, catabolism may predominate, impairing healing.

Adequate protein is necessary for tissue healing and the production of antibodies and WBCs. Lack of adequate protein increases the risk of infection. Complete protein sources, those that provide the essential amino acids, are preferred. Carbohydrates are important to meet energy demands, as well as to support leucocyte function. Care is taken to avoid hyperglycaemia in persons with diabetes, as hyperglycaemia interferes with oxygen delivery to the tissues as well as with the chemotactic and phagocytic function of neutrophils, impairing healing. Dietary fats are used in the synthesis of cell membranes.

Vitamins A, B-complex, C and K are also important to the healing process. Vitamin A is necessary for capillary formation and epithelialisation. B-complex vitamins promote wound healing, and vitamin C is necessary for collagen synthesis. Vitamin K provides a vital component for the synthesis of clotting factors in the liver.

Although it has been established that minerals contribute to the inflammatory and healing processes, less is known about required amounts. Minerals serve important roles in maintaining normal cell function and as cofactors in enzyme reactions necessary for cell proliferations. Zinc, a micronutrient, is involved in cell growth and in T-cell development (Tucker & Dauffenbach, 2011).

Oxygen is another important element in healing. It is necessary for collagen synthesis. Phagocytes such as neutrophils and macrophages require oxygen to digest bacteria engulfed in the phagocytic process. Impaired oxygen delivery to the tissues slows healing and increases the risk of infections. Supplemental oxygen administered via nasal cannula or mask improves the oxygen saturation of haemoglobin and its availability to tissues. Hyperbaric oxygen delivery improves leucocyte and fibroblast function as well as the development of new blood vessels, and may be beneficial to promote healing of inflamed ischaemic tissue (Bennett & Mitchell, 2012).

Nursing care

Acute inflammation may be self-limiting, or extensive and require hospitalisation. Nursing care includes teaching people with acute and chronic inflammatory conditions self-management at home.

Health promotion

Health promotion activities to prevent inflammation focus on reducing the risk of accidents and exposure to harmful agents that can result in subsequent injury. It is important to educate the public about potential hazards in both the work and home environments. In addition, safety education guidelines, such as not drinking and driving, wearing a protective helmet when riding a bicycle and using a seat belt in the car, are important areas for discussion. Because most injuries occur at home, it is also important to discuss ways to make the home safer.

Assessment

The following data are collected through the health history and physical examination. Further focused assessments are described with nursing interventions in the next section.

- *Health history*: risk factors, nutrition, medication use (anti-inflammatory and corticosteroids), location, duration and type (redness, heat, pain, swelling and impaired function) of symptoms.
- *Physical assessment*: movement of injured area, circulation, wounds, lymph nodes.

Nursing diagnoses and interventions

The nursing care needs of the person with an inflammatory process are related to the manifestations of inflammation and resulting altered tissue integrity. Nursing care priorities focus on relieving pain, supporting tissue healing and preventing infection.

Acute pain

Along with redness, warmth, swelling and impaired function, pain is one of the primary manifestations of inflammation. Depending on the cause, affected area and degree of inflammation, pain may be acute and immobilising or chronic and demoralising. It is important to remember that pain is a subjective experience and that people's responses to pain vary.

- Assess pain using a scale of 0 to 10, with 0 being no pain and 10 being the worst pain; note the character and location of the pain. *Because pain is subjective, the person provides the most accurate information regarding their pain experience.*
- Use physical and non-verbal cues to further assess the level of pain. *This intervention is especially important if the person is non-verbal or tends to under-report pain.*
- Administer anti-inflammatory medications as prescribed. *These medications help reduce the pain resulting from acute inflammation. Most NSAIDs also have analgesic and antipyretic effects, further promoting comfort* (Adams et al., 2014).
- Administer analgesic medications as prescribed. *Moderate to severe pain may require treatment with an analgesic (e.g. opioid). Paracetamol and opioid analgesics act within the CNS to reduce pain. Opioids provide the most effective pain relief overall, activating pain inhibitory neurons and inhibiting pain transmission neurons* (Rathmell & Fields, 2012).

CONSIDERATION FOR PRACTICE

Because opioids can depress respirations, it is important to monitor oxygen saturation and encourage the person to take deep breaths to maintain adequate oxygen saturation.

- Provide comfort measures, such as back rubs, position changes or relaxation techniques. *These measures reduce muscle tension, relieve areas of pressure and provide distraction.*
- Encourage activities such as reading, watching television and taking part in social interactions. *Such activities provide distraction from the pain experience.*
- Encourage rest. *Strenuous activity or exercising an inflamed body part may increase discomfort and tissue damage.*
- Provide cold or heat as pain relief measures as ordered. *For an acute injury, cold reduces swelling and relieves pain; after the initial stage, heat increases blood flow to the affected tissue and relieves pain and swelling by promoting absorption of oedema. Do not apply either heat or cold for more than 20 minutes at a time and ensure there is a covering between the skin and the application.*
- Elevate the inflamed area if possible. *Elevation promotes venous return and reduces swelling.*
- Teach about the appropriate use and expected effects of anti-inflammatory medications. *If the person's pain continues after the initial doses of anti-inflammatory medication, they may become discouraged and stop taking the medication before it becomes fully effective.*

CONSIDERATION FOR PRACTICE

Use heat or cold application cautiously in older people who have fragile skin and are at risk of tissue injury.

Impaired tissue integrity

The inflammatory response can either precipitate or result from an impairment in the integrity of skin, support or other tissues.

- Assess general health and nutritional status. *Poor general health or chronic diseases such as diabetes mellitus or renal failure interfere with the healing processes and increase the risk of infection.*
- Assess circulation to the affected area. *Adequate tissue perfusion and oxygenation are necessary for healing* (Grossman & Porth, 2014).
- Monitor the skin and surrounding tissue for increased signs of inflammation. *Inflammation can spread to adjacent tissues, leading to conditions such as cellulitis.*
- Provide protection and support for inflamed tissue. *This reduces discomfort and decreases the risk of further tissue damage.*
- Clean inflamed tissue gently; if possible, use water, normal saline or non-toxic wound cleansers only. *Soap and harsh cleansers such as povidone-iodine (Betadine) and hydrogen peroxide can cause further drying and tissue damage. Granulation tissue in a healing wound is fragile and easily damaged.*
- Keep the inflamed area dry and expose it to air as much as possible. *This promotes healing and helps prevent infection.*
- Balance rest with activity. *Rest decreases metabolic demands and allows for cell regeneration, while mobility helps to promote oxygenation and perfusion of the tissues.*
- Provide supplemental oxygen as ordered. *Supplemental oxygen improves tissue oxygenation and reduces hypoxia.*
- Provide a well-balanced diet with adequate kilojoules to meet the body's metabolic and healing needs. If the person is allowed nothing by mouth (NBM), suggest parenteral or enteral nutrition. For the person who is unable to consume an adequate diet, consult with a dietitian for between-meal supplements and/or multivitamin supplements. *Careful attention to diet and nutrient intake is important to provide the nutrients necessary for immune function and healing and to prevent catabolism* (Tucker & Dauffenbach, 2011).

Risk of infection

The inflammatory response often indicates that body defence mechanisms have been set in motion to protect against invading microorganisms. The person with a healing wound is at particular risk of infection.

- Assess the wound for specific signs of infection, including purulent drainage, odour and delayed healing. *The normal inflammatory response can indicate infection and, on occasion, mask its presence.*
- Evaluate complete blood counts for adequate WBC response. *Leucocytosis may indicate infection or healthy*

response to injury and protection from infection. Immune-impaired people may not respond with increased WBCs, and manifestations of inflammation may be diminished in those individuals.

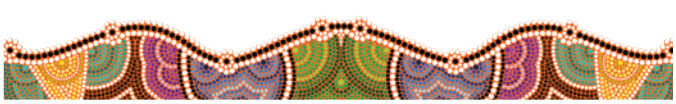
- Monitor vital signs at least every 4 hours. *In response to the inflammatory process the temperature rises, usually in the range 37.4ºC–38.2ºC. A temperature of 38.3ºC or above usually indicates infection. Fever is usually accompanied by increased heart and respiratory rates.*
- Culture purulent or odorous wound drainage. *Wound culture is used to determine the infectious organism and to direct antibiotic therapy.*
- Apply dry or moist heat to the affected area for no longer than 20 minutes several times a day. Monitor the temperature closely to prevent burns and further damage to the affected area. *Heat increases the circulation of blood to and from the inflamed tissue. Time is limited to prevent burns.*
- Provide and encourage fluid intake of 2500 mL/day as allowed. *Adequate hydration promotes blood flow and nutrient supply to the tissues and also dilutes and removes waste products from the body.*
- Ensure adequate nutrition. *Adequate nutrition enhances the function and production of T cells and B cells, which are important in the immune response.*
- Use good hand hygiene techniques consistently. *Hand hygiene removes transient microorganisms and is the best mechanism to prevent the spread of infection to a susceptible person.*
- Use aseptic technique when providing wound care. *Using sterile gloves and aseptic technique helps prevent further contamination of the wound and the spread of infection to other people.*

Community-based care

Education for the person and their family enhances understanding of the inflammatory process, its cause and its management. Teaching is also important to prevent further compromise that could result in infection.

Instructions, verbal and written, should include the following:

- Increase fluid intake to 2500 mL per day.
- Eat a well-balanced diet high in vitamins and minerals and with adequate protein and kilojoules for healing.
- Use good hand hygiene, particularly when caring for wounds or inflamed tissue and after using the bathroom.
- Elevate the inflamed area to reduce swelling and pain.
- Apply heat or cold for no longer than 20 minutes at a time to reduce the risk of tissue damage from burns or frostbite.
- Take all medications as prescribed, notifying the physician if adverse effects or hypersensitivity responses are noted.
- Rest acutely inflamed tissue; do not engage in strenuous activity until the inflammation has subsided.



The person with an infection

Microorganisms—including bacteria, viruses, fungi and parasites—often invade the human body and proliferate if undetected and not controlled or eliminated by inflammatory and immune responses. In most cases, contact between humans and microorganisms is incidental and may even be beneficial to both organisms. Resident bacteria of the skin, mucous membranes and gastrointestinal tract are an important part of the body's defence system. However, many microorganisms are virulent; that is, they have the ability to cause disease.

Pathogens are virulent organisms rarely found in the absence of disease. Some microorganisms, known as opportunistic pathogens, rarely cause harm to people with intact immune systems but are capable of producing infectious disease in the immunocompromised host (Porth & Matfin, 2009).

To a certain extent, modern medicine has contributed to the development of infectious diseases caused by antibiotic-resistant strains of microorganisms. Tuberculosis is on the rise in many countries, partially because organisms have become resistant to standard therapies. People receive immunosuppressive therapy following organ or tissue transplant, or in the treatment of neoplasms, making them more susceptible to infection. Metal and plastic prosthetic devices are implanted, providing potential sites for colonisation by disease-producing organisms. It has also become apparent that many diseases long considered unrelated to microorganisms may actually be infectious; for example, colonisation of the gastric mucosa with *Helicobacter pylori* is the predominant cause of peptic ulcer disease, and oncogenic viruses have the ability to transform normal cells into malignant cells.

Pathophysiology

Infection occurs when an organism is able to colonise and multiply within a host. The host can be any organism capable of supporting the nutritional and physical growth requirements of the microorganism—for example, humans. When the host experiences injury, pathological changes, inflammation or organ dysfunction in response to an infection or from intoxication by cellular poisons produced by a pathogen, the host is said to have an infectious disease.

For a microorganism to cause infection, it must have disease-causing potential (virulence), be transmitted from its reservoir and gain entry into a susceptible host. This is known as the chain of infection (see Figure 11.9).

PATHOGENS Pathogens capable of infecting and causing disease in a susceptible host include bacteria, viruses, *Mycoplasma*, *Rickettsia*, *Chlamydia*, fungi and parasites such as protozoa, helminths (worms) and arthropods (see Box 11.4). Each organism causes a different specific reaction in the host.

A number of different mechanisms have evolved in pathogens to facilitate their transmission and increase their ability to invade the host and cause disease. Factors influencing the transmission of an organism include its resistance to drying and to variations in environmental temperature. For example, spore-forming organisms are extremely resistant to drying.

Adhesion factors produced by or incorporated into the cell wall or membrane of the pathogen improve its ability to attach

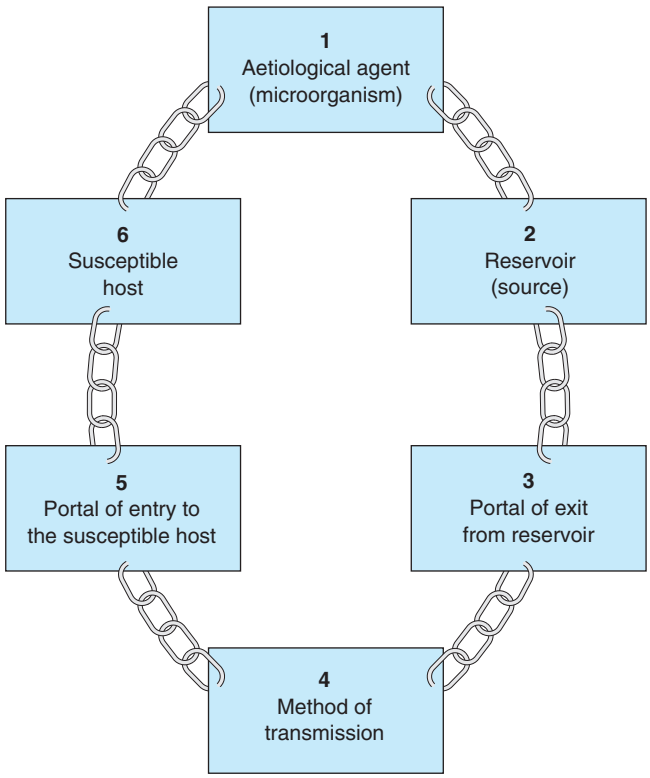


FIGURE 11.9 ■ The chain of infection

and colonise the host. Pathogens may also produce enzymes to enhance their spread to local tissues, chemicals to block specific immune processes or deplete neutrophils and macrophages, or extracellular capsules to discourage phagocytosis.

Pathogens are often capable of producing toxins that alter or destroy the normal function of host cells and promote colonisation, proliferation and invasion by the pathogen. Toxins often increase the disease-producing capability of the pathogen and, in some cases, are totally responsible for it; for example, cholera, tetanus and botulism result from bacterial toxins, not from the direct effects of the infection. **Exotoxins** are soluble proteins secreted into surrounding tissue by the microorganism. Exotoxins are highly poisonous, causing cell death or dysfunction. **Endotoxins** are found in the cell wall of Gram-negative bacteria and are released only when the cell is disrupted. Endotoxins have less-specific effects than exotoxins but they act as activators of many human regulatory systems, producing fever, inflammation and, potentially, clotting, bleeding or hypotension when released in large quantities.

RESERVOIR AND TRANSMISSION The reservoir or source, where the pathogen lives and multiplies, may be either endogenous or exogenous. Organisms that reside on skin or mucosal surfaces of the host are endogenous. Exogenous sources can include other humans, animals, soil, water, intravenous fluid or equipment. Infectious diseases are usually transmitted from human sources—that is, people who have clinical

BOX 11.4 Pathogenic organisms

Bacteria

Bacteria are single-celled organisms capable of autonomous reproduction. Relatively small and simple organisms, they contain a single chromosome. A flexible cell membrane and rigid cell wall surrounds their cytoplasm, giving them a distinctive shape; some also have an extracellular capsule for additional protection. Bacteria have different characteristics and growth requirements: the colonies formed by replicating bacteria differ from one another. *Aerobes* require oxygen for survival, whereas *anaerobes* cannot survive in the presence of oxygen; *Gram-positive* bacteria stain purple when subjected to crystal violet stain, whereas *Gram-negative* bacteria do not stain with crystal violet but turn red when subjected to safranin stain.

Prions

Prions are not independent organisms but small molecules that can modify host proteins. They primarily affect the neurological system, causing neurological degeneration in diseases such as mad cow disease (bovine spongiform encephalopathy) in animals and Creutzfeldt-Jakob disease in humans. These are slowly progressive, non-inflammatory conditions leading to dementia, lack of coordination and death. Prions' entry into the neurological cells makes them resistant to the host immune system and antibacterial and antiviral medications. They enter the host by injections, transplantation of contaminated tissue or medical devices, and possibly food. They are very resistant to disinfection, requiring special procedures for sterilising instruments, especially those used in CNS surgeries (Prusiner & Miller, 2012; Rothrock, 2011).

Viruses

Viruses are obligate intracellular parasites that are incapable of reproducing outside of a living cell. Viruses consist of a protein coat around a core of either DNA or RNA. Some viruses are shed continuously from infected cell surfaces; others, after inserting their genetic material into that of the infected cell, remain latent until they are stimulated to replicate. Viruses may or may not cause lysis and death of the host cell during replication. Oncogenic viruses are able to transform normal cells into malignant cells.

Mycoplasma

Although similar to bacteria, *mycoplasma* are smaller and have no cell wall, making them resistant to antibiotics that inhibit cell wall synthesis (e.g. penicillins).

Rickettsia and *Chlamydia*

As obligate intracellular parasites with a rigid cell wall, *Rickettsia* and *Chlamydia* have some features of both bacteria and

(continued)

BOX 11.4 Pathogenic organisms (continued)

viruses. Rather than depending on the host cell for reproduction, they use vitamins, nutrients or products of metabolism (e.g. ATP) from the host. *Chlamydia* are transmitted by direct contact, whereas many *Rickettsiae* infect the cells of arthropods (e.g. fleas, ticks and lice) and are transmitted from these vectors to humans.

Fungi

Fungi are prevalent throughout the world but few are capable of causing disease in humans. Most fungal infections are self-limited, affecting the skin and subcutaneous tissue. Some fungi, such as *Pneumocystis carinii*, can cause life-threatening opportunistic infections in the immunocompromised host.

Parasites

The term *parasite* is typically applied to members of the animal kingdom that infect and cause disease in other animals. Protozoa, helminths and arthropods are considered parasites. Protozoa are single-celled organisms (e.g. *Giardia lamblia* and *Trichomonas vaginalis*) transmitted via direct or indirect contact or an arthropod vector. Helminths are worm-like parasites: roundworms, tapeworms and flukes are examples. They gain entry into humans primarily through ingestion of fertilised eggs or penetration of larvae through the skin or mucous membranes. Arthropod parasites, such as scabies (mites), lice and fleas, typically infest external body surfaces, causing localised tissue damage and inflammation. Transmission is by direct contact with the arthropod or its eggs.

disease or are carriers with subclinical infection. Carriers harbour the pathogen without showing evidence of clinical disease. Pathogens exit human hosts via respiratory secretions, body fluids from the gastrointestinal and genitourinary tracts, skin or mucous membrane lesions, the placenta and blood.

Organisms may be transmitted from the source to the susceptible host by direct or indirect contact, droplet or airborne transmission, or a vector. Direct contact includes person-to-person spread or contact with infected body fluids, as well as transmission from contaminated food or water. Indirect contact occurs when the infectious agent is contracted by use of inanimate objects such as dirty eating utensils. Sneezing, talking and coughing allow transmission by droplet contact when the host is within 1 metre of the source. Smaller respiratory particles that stay suspended in air and are carried via air currents allow airborne transmission. Vectors are insects and animals such as flies, mosquitoes or rodents that act as intermediate hosts between the source and host. Microorganisms usually first colonise the portal of entry: non-intact skin, wounds, mucous membranes and the respiratory, gastrointestinal or genitourinary tracts.

HOST FACTORS The susceptible host is the final link in the chain of infection. Exposure to pathogens does not automatically cause infection or infectious disease. The outcome of contact with a pathogenic microorganism is determined by the balance of microbial virulence and host resistance. Factors that can enable the host to resist infection include the following:

- physical barriers such as the skin and mucous membranes
- the hostile environment created by acid stomach secretions, urine and vaginal secretions
- antimicrobial factors in saliva, tears and prostatic fluid
- respiratory defences, including humidification, filtration, the mucociliary escalator, cough reflex and alveolar macrophages
- innate and adaptive immune responses to pathogenic invasion.

Stages of the infectious process

When infectious disease develops in the host, it typically follows a predictable course with stages based on the progression and intensity of manifestations.

The initial stage is the *incubation period*, during which the pathogen begins active replication but does not yet cause manifestations. Depending on the organism and host factors, the incubation period may last from hours, as with *Salmonella* infection, to years, as with HIV infection.

The *prodromal stage* follows, during which symptoms first begin to appear. At this stage, manifestations are often nonspecific and include general malaise, fever, myalgias, headache and fatigue.

Maximal impact of the infectious process is felt during the *acute phase* as the pathogen proliferates and disseminates rapidly. Toxic by-products of microorganism metabolism and cell lysis, along with the immune response, produce tissue damage and inflammation during this stage (Grossman & Porth, 2014). Manifestations are more pronounced and specific to the infecting organism and site during the acute stage. Fever and chills may be significant during this phase. However, people with alcoholism and the very old may respond to severe infection by becoming hypothermic. The person is often tachycardic and tachypnoeic because of increased metabolic demands. Localised manifestations include redness, heat, swelling, pain and impaired function. When the infectious disease affects an internal organ, manifestations are related to inflammatory changes in that organ and surrounding tissue. The person may experience tenderness to palpation over the site or show signs of impaired function, such as the haematuria and proteinuria characteristic of renal infections.

If the infectious process is prolonged, manifestations of the continuing immune response may become apparent. Catabolic and anorexic effects of the infection can lead to loss of body fat and muscle wasting. Immune complexes may be deposited at sites other than the primary infection, resulting in an inflammatory process. Glomerulonephritis (e.g. following strep throat) and vasculitis are possible results. Another possible consequence of prolonged infection and immune response is the triggering of an autoimmune disease process such as rheumatic cardiomyopathy or coeliac disease.

As the infection is contained and the pathogen eliminated, the *convalescent stage* of the disease occurs. During this stage, affected tissues are repaired and manifestations resolve.

Resolution of the infection is total elimination of the pathogen from the body without residual manifestations. If a balance between organism and host factors occurs, with neither predominating, chronic disease may develop or the organism may be driven into a protected site such as an abscess. A carrier state develops when host defences eliminate the infectious disease but the organism continues to multiply on mucosal sites.

Complications

Multiple and varied complications are associated with infectious diseases. They are typically specific to the infecting organism and the body system affected.

Acute invasion of the blood by certain microorganisms or their toxins can result in septicaemia and septic shock. Whereas *bacteraemia*, the presence of bacteria in the blood, may not have serious effects, **septicaemia** refers to systemic disease associated with their presence or toxins. Septic shock indicates a state of hypotension and impaired organ perfusion resulting from sepsis. Unless treated aggressively, septic shock leads to diffuse cell and tissue injury and potentially to organ failure.

FAST FACTS

- Urinary tract infection is the most common type of **healthcare-associated infection** (HAI), usually associated with indwelling urinary catheters or urological procedures.
- Other common HAIs are bloodstream infections, pneumonia, surgical wound infections and *Clostridium difficile* colitis (CDC, 2011; Chin-Hong & Guglielmo, 2012).
- Pathogens associated with HAI are often different from those causing community-acquired infections and frequently are multidrug resistant, necessitating treatment with multiple, broad-spectrum and potentially toxic antibiotics (Chin-Hong & Guglielmo, 2012).

Healthcare-associated infections

Healthcare-associated infections (HAIs) are acquired in any healthcare setting, such as a hospital or nursing home. Also called *nosocomial* infections, HAIs account for an estimated 200 000 infections, 2 million bed days lost and, for the surgical post-discharge infection subgroup, $21 million in excess healthcare costs annually in Australia (ACSQHC, 2008). HAIs add hospital days, reduce admissions by occupying available beds and add to the cost of healthcare (CDC, 2010; Mirza, 2012).

Many HAIs result from the use of invasive devices such as intravascular catheters, urinary catheters and endotracheal tubes for ventilator support. People developing HAIs often are critically ill and among those least able to mount an effective immune defence against infection. HAIs also occur when antibiotic therapy has altered natural defences and impaired resistance to harmful microorganisms. Endogenous organisms outside their normal habitats (such as in *Escherichia coli* in the urinary tract) become a threat to the person. Other pharmacological and therapeutic procedures such as chemotherapy, the use of corticosteroids or radiation therapy also contribute to HAIs. Surgical site infections rank second in frequency of HAIs and add up to 7 to 10 extra days to postoperative hospitalisation (CDC, 2010; Weinstein, 2012).

BOX 11.5 Interventions to reduce healthcare-associated infections

- Central venous catheter infections have decreased by using chlorhexidine antiseptic for disinfection and maximal barrier precautions during insertion.
- Ventilator-associated pneumonia is decreased by weaning patients off ventilators as soon as possible, limiting sedation of the patient, positioning patients with the head of the bed elevated to prevent gastric reflux and for maximal ventilation, and using proper hand hygiene and sterile technique for all ventilator-associated care.
- Surgical site infections are reduced by administering a prophylactic antibiotic 1 hour before the incision and discontinuing it within 24 hours after surgery, limiting hair removal (no shaving), controlling perioperative glucose levels (especially in cardiac surgeries) and ensuring normothermia for the patient during the perioperative period (especially in colorectal surgeries).
- Insert urinary catheters only when clearly indicated, using aseptic technique during insertion; minimise manipulation or opening of drainage systems (Weinstein, 2012).

Superficial or deep wounds may be contaminated by endogenous or exogenous sources. Infections in body cavities or those associated with prosthetics are difficult to diagnose and may necessitate removal of the prosthetic device. Box 11.5 lists interventions that should be used to prevent HAIs.

Hospital-acquired pneumonia accounts for 15% of HAIs. It is usually associated with ICU stays and mechanical ventilation. Organisms causing the infection are often resistant to many drugs, not responding to antibiotics usually effective in treating infections acquired outside the hospital. More deaths are associated with hospital-acquired pneumonia than any other site of infections (Weinstein, 2012).

CONSIDERATION FOR PRACTICE

Existing guidelines and literature reviews agree that hand hygiene using alcohol-based hand rubs is more effective against the majority of common infectious agents on hands than hand hygiene with plain or antiseptic soap and water (NHMRC, 2010).

A soap-and-water wash is recommended for visibly soiled hands. Wearing gloves does not eliminate the need to perform hand hygiene.

Prevention is the most important control measure for HAIs. Cross-infection—the spread of pathogens from one person to another on the inadequately cleaned hands of healthcare workers—is one of the primary sources of HAIs (Weinstein, 2012). *Effective hand hygiene is the single most important measure in infection control* (WHO, 2009) (see Figure 11.10). Although infections may also be transmitted by the airborne

FIGURE 11.10 ■ 5 Moments for Hand Hygiene

route, from contaminated equipment or from the environment, these are less significant causes. Invasive procedures and equipment should be used only when absolutely necessary; for example, it is not appropriate to insert an indwelling catheter when the only indication is incontinence. Peripheral intravenous equipment and sites must be kept clean and changed regularly: intravenous bags and bottles every 24 hours, tubing every 24 to 72 hours and sites every 2 to 3 days according to agency policy.

Antibiotic-resistant microorganisms

Antibiotic-resistant microorganisms are increasing at an alarming rate, primarily due to prolonged or inappropriate use of antibiotic therapy. Although antibiotic therapy is expected to eradicate all targeted microorganisms, sometimes a few bacteria survive, leading to bacteria that reproduce with antibiotic resistance already encoded into their genetic make-up (ACSQHC, 2010; Lehne, 2012). Other bacteria produce enzymes that inactivate drugs, change drug-binding sites or alter their cell membrane to prevent drug absorption.

Standard precautions, most importantly hand hygiene and the use of carefully selected antibiotics, are critical actions for stopping the spread of these diseases. Equipment such as stethoscopes, blood pressure cuffs and thermometers should be restricted to use by each person identified with one of these diseases. Personal protective equipment, used and disposed of appropriately, is an important safeguard.

NURSING CARE OF THE OLDER ADULT Infections

Because immune function declines with ageing, older adults are more susceptible to infections. Infections are among the top five causes for hospitalisation and among the leading causes of death among people over 65 years of age (Weir et al., 2011). Physiological changes that often occur with ageing place the older adult at greater risk than younger people of acquiring an infection.

- *Cardiovascular changes:* decreased tissue perfusion delays the inflammatory response and healing.
- *Respiratory system changes:* decreased mucociliary clearance, decreased elastic recoil and diminished cough and laryngeal reflexes decrease the clearance of respiratory secretions and increase the risk of pneumonia. The older adult with pneumonia may not present with cough or sputum production due to decreased immune function. The leading causes of pneumonia in older adults include *Streptococcus pneumoniae*, *Haemophilus influenzae* and *Staphylococcus aureus*. Influenza A, a viral infection, is a significant risk factor for secondary bacterial pneumonia in older adults (Tabloski, 2014). Both pneumonia and influenza cause high mortality rates in the older person.
- *Genitourinary changes:* loss of muscle tone, reduced bladder contractility, altered bladder reflexes and prostatic hypertrophy in men increase the risk for incomplete bladder emptying, urinary incontinence and urinary tract infection (UTI). UTI is the most common infection and the leading cause of bacteraemia and sepsis in older adults, particularly those aged 85 and older.
- *Gastrointestinal system changes:* impaired swallow reflex, decreased gastric acidity and delayed gastric emptying increase the risk of aspiration with subsequent pneumonia.
- *Skin and subcutaneous tissue changes:* thinning of skin, decreased cushioning, decreased sensation and decreased vasculature increase the risk of injury, ulceration and infection.
- *Immune changes:* decreased phagocytosis, reduced inflammatory response, diminished antibody-mediated and cellular immune responses, and slowed or impaired healing processes increase the risk for infection. Immunoglobulin levels remain relatively stable, but primary and secondary antibody responses decline with ageing. The thymus gland atrophies and some T-cell populations decrease or decline in function. T-cell activation and the ability to proliferate following activation also decline with advancing age (Grossman & Porth, 2014). Resistance to antigens such as *Mycobacterium tuberculosis*, influenza and varicella-zoster viruses, malignant cells and tissue grafts is reduced.

Other factors, such as a lower activity level, poor nutrition and an increased risk for dehydration, a higher prevalence of chronic diseases such as diabetes, use of multiple medications and altered mentation contribute to the older adult's risk for infection.

HAIs are more common in older adults. The nurse must steadfastly adhere to principles of infection control. Nursing interventions to reduce the risk of HAIs include: (1) avoiding prolonged bed rest, (2) encouraging patients to take deep breaths, (3) providing adequate fluids, (4) providing regular toileting schedules with good hygiene, and (5) avoiding use of invasive devices such as indwelling catheters unless medically necessary.

The older adult may not exhibit the classic manifestations of inflammation and infection. The manifestations of inflammation—redness, heat and swelling—tend to be diminished or absent in older adults. The classic manifestations of infection—fever and chills—may be absent altogether because of age-related changes in the immune system, loss of central temperature control mechanisms, decreased muscle mass and loss of shivering ability. The older adult may have only subtle manifestations of infection or sepsis, including changes in mental status, disorientation, restlessness and tachypnoea.

Prompt identification and treatment of infection improves outcomes in the older adult. In addition to monitoring for changes in the patient's mental status or behaviour, the nurse should assess fluid intake and urinary output, activity levels, complaints of fatigue and respiratory status. Older adults are at increased risk for dehydration due to diminished thirst sensation and impaired water conservation by the kidneys. Carefully evaluate intake and output to determine if input is adequate.

INTERPROFESSIONAL CARE

The goals of care for the person with an infection are to identify the organ system affected by the infection and the causative agent, and to achieve a cure by the least toxic, least expensive and most effective means. Fortunately, most infectious diseases are self-limiting and will resolve with little or no medical care. However, medical treatment can be lifesaving in an overwhelming infection or immunocompromised host.

The site of the infection is often obvious from the person's history and presenting manifestations. Identifying the affected organ system allows the range of possible infecting organisms to be narrowed to those known to affect that system.

Once the infecting agent has been identified, either positively or by probability, therapy can be specifically tailored to the person's needs. Viral infections often resolve without treatment other than supportive care, such as providing rest and fluids. Skin infections may respond to a topical agent, avoiding the potential adverse effects of one administered systemically.

Diagnosis

To assess the person's response to infection, identify the infecting organism and monitor the progress of therapy, the following diagnostic tests may be ordered:

- *WBC count* provides clues about the infecting organism and the body's immune response to it.
- *WCC differential* is also ordered (see Table 11.8). Neutrophilia, increased numbers of circulating neutrophils (or PMNs),

LINKS TO NATIONAL PATIENT SAFETY STANDARDS

NSQHS Standard 3:
Preventing and Controlling Healthcare Associated Infections

'The intention of this standard is to prevent patients from acquiring preventable healthcare associated infections and effectively manage infections when they occur.' (ACSQHC, 2012, p. 26)

Implementing this standard is achieved by implementing systems to prevent and manage healthcare-associated infections and communicate these to the workforce to achieve appropriate outcomes. This includes governance and systems for infection prevention, control and surveillance; infection prevention and control strategies; infections or colonisations; antimicrobial stewardship (the safe and appropriate antimicrobial prescribing); and cleaning, disinfection and sterilisation.

Infection prevention and control is necessary to reduce the development of resistant pathogens and to minimise the risk of transmission by isolating the infectious organism or the patient, and by using standard and transmission-based precautions.

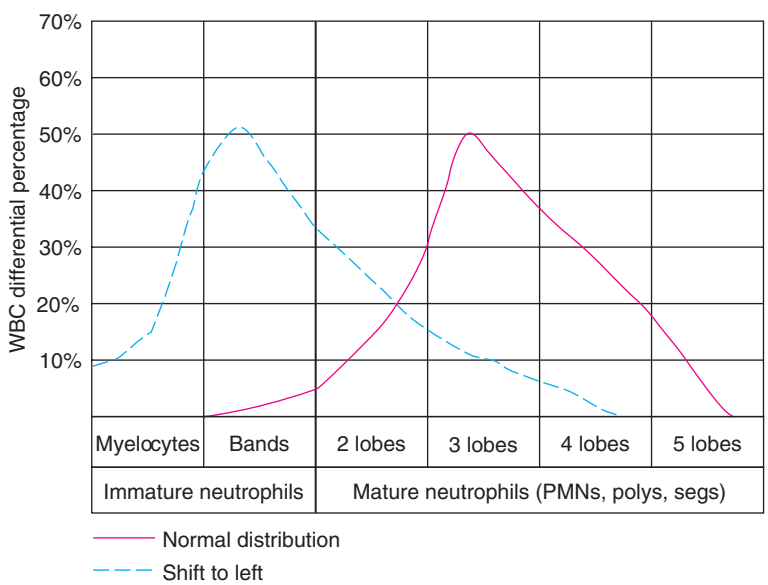
Efficient and appropriate systems are imperative to ensure the safety of not only the person receiving appropriate care, but also any other individual involved in their care.

Effective communication should exist across all individuals involved in a person's care (including the person themselves and their significant others).

Source: © Australian Commission on Safety and Quality in Health Care.

is a common response with infection as the bone marrow responds to an increased need for phagocytes. Along with neutrophilia, a shift to the left is common in acute infection. This means that there are more immature neutrophils in circulation than normal, indicating an appropriate bone marrow response (see Figure 11.11).

- *Procalcitonin (CTpr) and C-reactive protein (CRP)* are diagnostic markers of infection that can be measured in the blood. Blood levels of CTpr and CRP increase dramatically with serious bacterial infection and sepsis, making these markers useful early indicators of systemic infections.
- *Cultures of the wound, blood or other infected body fluids* are used to identify probable microorganisms by their characteristics, such as shape, growth patterns and Gram-staining qualities. After the organism is cultured, it is subjected to various antibiotics known to be effective against its particular strain to determine which antibiotic is likely to be most effective. Generally, 24 to 48 hours are required to grow the organism, potentially delaying the institution of therapy. Because antibiotics can alter the ability to culture an organism, specimens should be obtained before instituting therapy.
- *Serological testing* provides an indirect means of identifying infecting agents by detecting antibodies to the suspected organism. When the antibody titre against a specific organism rises during the acute phase of an infectious disease and



Type of WBC	Normal differential	Shift to left
Myelocytes	0%	Present
Band neutrophils (bands)	3–5%	Increased
Segmented neutrophils (segs, polys, PMNs)	50–65%	May be stable, increased, or decreased

FIGURE 11.11 ■ Neutrophils by stage of maturity and normal distribution in the blood

begins to fall during convalescence, the diagnosis is supported. Although it is not as accurate as culture, serology is particularly useful for organisms that cannot easily be cultured, such as hepatitis B or HIV.

- *Direct antigen detection methods* use monoclonal antibodies (purified antibody forms) to detect antigens in specimens from the diseased host. The tests offer rapid and accurate identification of the offending microorganism.
- *Antibiotic peak and trough levels* monitor therapeutic blood levels of the prescribed medication(s). The therapeutic range—that is, the minimum and maximum blood levels at which the drug is effective—is known for a given drug. By measuring blood levels at the predicted peak (1 to 2 hours after oral administration, 1 hour after intramuscular administration and 30 minutes after intravenous administration) and trough (lowest level, usually a few minutes before the next scheduled dose), healthcare personnel can determine that the person is maintaining a level within the therapeutic range at all times, ensuring maximal effect from the drug. It is also possible to determine whether the drug is reaching a toxic or harmful level during therapy, increasing the likelihood of adverse effects.
- *Radiological examination of the chest, abdomen or urinary system* may be ordered to detect organ abnormalities indicating an inflammatory response or tissue damage.
- *Lumbar puncture* is performed to obtain cerebrospinal fluid (CSF) for examination and culture if a central nervous system (CNS) infection, such as meningitis or encephalitis, is suspected.
- *Ultrasonic examination* is a non-invasive diagnostic test such as an echocardiogram or renal ultrasonography to identify an infectious site or evaluate the effects of an infection on organ function.

Medications

After the infecting organism and affected body system have been identified, specific therapy to cure the infectious disease can be instituted.

Antimicrobial preparations are broadly classified as bacteriostatic or bactericidal. **Bacteriostatic agents** inhibit the growth of the microorganism, leaving its destruction to the host's immune system. These agents are generally not indicated for the immunocompromised host. Tetracyclines, erythromycin and chloramphenicol are bacteriostatic preparations. **Bactericidal agents**, including pencillins, cephalosporins and aminoglycoside antibiotics, are capable of killing the organism without immune system intervention.

The activity of antimicrobial agents on bacteria, fungi and viruses falls under five basic mechanisms:

1. impairing cell wall synthesis, leading to lysis and cell destruction
2. inhibiting protein synthesis, causing impaired microbial function
3. altering cell membrane permeability, causing intracellular contents to leak
4. inhibiting the synthesis of nucleic acids
5. inhibiting cell metabolism and growth.

Many microorganisms have the ability to develop resistance to an anti-infective agent; that is, the pathogen continues to live and grow in the presence of the anti-infective. Resistance develops as a result of a chance mutation by the pathogen, allowing a subpopulation of cells to survive. The chance of an organism becoming resistant to an agent is partially related to the dose delivered. Resistance is less likely to occur when a lethal dose is administered; therefore, it is vital that people understand the need to take all doses of the prescribed drug as ordered.

ANTIBIOTICS

Medications used to treat bacterial infections are generally known as antibiotics. Most antibiotics are biological substances; that is, substances produced by other microorganisms. Antibiotics fall into classes of drugs with related chemical structure and activity. Some are effective against only Gram-positive bacteria and others are effective against only Gram-negative organisms. Broad-spectrum antibiotics have activity against a wide variety of bacteria including both Gram-positive and Gram-negative forms.

No antibiotic is totally safe. Hypersensitivity responses occur, so always check for allergies before administering the first dose. Some drugs are toxic to organ systems, exhibiting hepatotoxicity, nephrotoxicity, ototoxicity or bone marrow suppression. The antibiotics presented in the following 'Medication administration' box are organised according to their antibacterial action.

ANTIVIRALS

Most antibiotics have little effect on viruses because the virus has no cell wall and no cytoplasm, produces no enzymes and sequesters itself in a host cell to reproduce. Antiviral agents must be very selective in differentiating normal cellular activity from viral activity. In addition, the immune function of the host is a vital component in fighting viral infections; antiviral therapy may be relatively ineffective in the severely immunocompromised host. Timely diagnosis of viral infections can be an additional problem because viruses are less easily identified using laboratory techniques. Antiviral agents in common use are summarised in the 'Medication administration' box.

ANTIFUNGALS

Antifungal agents are available in both topical and systemic forms. They act by interfering with the cytoplasmic membrane of the fungus. Topical agents include preparations for cutaneous use to treat candidiasis, tineas and ringworm. Vaginal preparations to treat vulvovaginal candidiasis are also available, as are several non-prescription topical and vaginal antifungal agents.

Amphotericin B is a systemic antifungal agent for parenteral administration. It is used to treat severe, life-threatening fungal infections including histoplasmosis, blastomycosis and candidiasis. Another systemic antifungal in current use is flucytosine (Ancobon), which can be administered orally. It is used to treat severe candidiasis infections such as *Candida* septicaemia, endocarditis, pulmonary or urinary tract infections, and *Cryptococcus* meningitis.

Fluconazole (Diflucan) has the broadest use as an antifungal agent. It can be administered either orally or parenterally and is

used to treat candidiasis infections as well as *Cryptococcus* meningitis. It is generally better tolerated than other systemic antifungal medications.

ANTIPARASITICS Drugs used to treat parasitic infections are as varied as the organisms that cause them. Generally, agents classified as antiparasitic are both expensive and likely to be toxic. Quinine was one of the first antiparasitic drugs developed in the treatment of malaria. Quinine is highly toxic, but newer forms such as chloroquine, hydroxychloroquine (Plaquenil) and paludrine (Proguanil hydrochloride) are widely used as antimalarial drugs. Metronidazole (e.g. Flagyl) is used to treat infections of protozoan parasites (see the 'Medication administration' box).

MEDICATION ADMINISTRATION Antibiotic therapy

I. Cell wall synthesis inhibitors

PENICILLINS

Penicillin G
Penicillin V
Amoxicillin (Amoxil)
Amoxicillin and clavulanic acid (Augmentin)
Ampicillin (Austrapen)
Dicloxacillin (Diclocil, Distaph)
Flucloxacillin (Staphylex, Floxapen)
Piperacillin and tazobactam (Tazocin)
Ticarcillin and clavulanic acid (Timentin)

Penicillins are bactericidal and interfere with cell wall synthesis and the enzymes involved in cell division and synthesis. They are more effective on Gram-positive than Gram-negative organisms. Penicillins are considered to be safe, effective and of low toxicity. Resistance is now more common among *Streptococci* and *Staphylococci.* Penicillins and related antibiotics such as cephalosporins contain a molecular structure known as a beta-lactam ring. Some bacteria produce enzymes (beta-lactamases or penicillinases) that cleave this ring, making the antibiotics ineffective. To combat this *resistance, beta-lactamase or penicillinase inhibitors such as sulbactam and clavulanate are combined with some antibiotics to create an antibiotic effective against drug-resistant bacterial strains.*

Nursing responsibilities

- Monitor for hypersensitivity responses such as local erythema and itching at the site of injection, skin rashes, urticaria (hives), itching, fever, chills and anaphylaxis.
- Observe people receiving parenteral penicillin for at least 30 minutes.
- Discontinue the drug immediately if any hypersensitivity response occurs. Be prepared to administer antihistamines or corticosteroids for a mild reaction. Anaphylaxis is treated with adrenaline subcutaneously or intravenously and with airway support.
- Do not administer penicillin to anyone with a history of a severe allergic reaction to any form of the drug; a cross-reactivity may occur in people allergic to cephalosporin or carbapenem antibiotics.
- Assess for superinfection (vaginitis, stomatitis or diarrhoea) due to elimination of resident bacteria.

Health education for the person and family

- Notify the physician if you see white patches on the oral mucosa or if vaginitis develops. An antifungal drug may be prescribed and the antibiotic continued.
- Consuming yoghurt may prevent superinfection. Do not take these products within 1 hour of taking the drug.

CEPHALOSPORINS

1st generation
Cephalexin (Keflex, Ibilex)
Cephazolin (Kefzol)

2nd generation
Cefoxitin (Mefoxin)
Cefaclor (Aclor, Ceclor)

3rd generation
Cefotaxime (Claforan)
Ceftazidime (Fortrum)
Ceftriaxone (Rocephin)

4th generation
Cefepime (Maxipime)

Cephalosporins are structurally similar to the penicillins and also inhibit cell wall synthesis. They are divided into four groups or generations. First-generation cephalosporins act primarily against Gram-positive organisms. Second- and third-generation drugs are more effective against Gram-negative organisms than against Gram-positive ones. Fourth-generation cephalosporins act effectively against both Gram-positive and Gram-negative organisms.

Nursing responsibilities

- Monitor for previous hypersensitivity response to cephalosporins or penicillins.
- Assess intravenous site for phlebitis; intramuscular site may cause local pain.
- Monitor laboratory results for adverse response, such as leucopenia and thrombocytopenia, nephrotoxicity (elevated BUN and serum creatinine) or hepatotoxicity (elevated bilirubin, LDH, ALT, AST and alkaline phosphatase).
- Assess for signs of superinfection.

Health education for the person and family

- Take the medication on an empty stomach, 1 hour before or 2 hours after meals.
- Avoid alcohol as alcohol intolerance can develop with these antibiotics. These same drugs intensify bleeding tendencies.
- Space doses of the medication relatively evenly throughout the day and evening hours.
- Increased consumption of yoghurt may prevent intestinal superinfection.

CARBAPENEMS

This class of antibiotics includes only three drugs and all must be given parenterally. Imipenem has the broadest antimicrobial spectrum of any drug (Lehne, 2012). This makes it especially useful against mixed-organism infections. Imipenem, meropenem and ertapenem cross the meninges and achieve therapeutic doses in CSF; they are

MEDICATION ADMINISTRATION Antibiotic therapy (continued)

effective against methicillin-resistant *Staphylococcus aureus* (MRSA). These antibiotics cause bacterial cell wall lysis and subsequent death of the bacteria. Side effects include nausea and vomiting, diarrhoea, hypersensitivity reactions, occasional superinfections with bacteria or fungi, and, rarely, seizures.

Nursing responsibilities

Ertapenem should not be mixed with dextrose or other drugs containing dextrose. IV infusions should be slow and given over at least 30 minutes.

- Check for history of hypersensitivity to cephalosporins and penicillins and monitor for signs of reactions.
- Assess for signs of superinfection.
- Monitor laboratory indicators of renal function.

Health education for the person and family

- Instruct the person to report any signs or symptoms of allergy such as skin rash, itching or hives.

VANCOMYCIN

This antibiotic inhibits cell wall synthesis and is used for serious infections. It is only effective against Gram-positive bacteria, especially *S. aureus* and *Staphylococcus epidermidis*, including the strains resistant to methicillin. *C. difficile* is also susceptible to this antibiotic, but infection with *C. difficil*e is often treated first with metronidazole to delay emergence of resistance to vancomycin.

Nursing responsibilities

- Infuse slowly over 60 minutes or more to avoid 'red man' syndrome. The syndrome is characterised by erythematous rash, flushing, tachycardia and hypotension. People may become dizzy and agitated. The occurrence is usually associated with a first dose of vancomycin and is seen within 4 to 6 minutes of the start of a dose or after completion.
- Ototoxicity is a more serious adverse effect of vancomycin because hearing loss may be irreversible. Notify the physician immediately if a sensation of fullness in the ears is reported, as this indicates ototoxicity.

II. Bacterial protein synthesis inhibitors

TETRACYCLINES

Tetracycline HCl **Minocycline HCl (Minomycin, Akamin)**
Doxycycline (Vibramycin)

Tetracyclines are active against many Gram-positive and Gram-negative bacteria, such as *Mycoplasma*, *Rickettsia* and *Chlamydia*. They are bacteriostatic, interfering with microbial protein synthesis. Tetracycline binds readily with metal and solid elements in the bowel, limiting its absorption when administered with food; the other preparations are highly soluble in lipids and can be administered with food.

Nursing responsibilities

- Schedule doses 1 hour before or 2 hours after meals. Do not give with milk, milk products or antacids.
- Monitor for signs of superinfection.
- If the person is taking an anticoagulant, monitor prothrombin time and for signs of bleeding.

Health education for the person and family

- Avoid excessive sun exposure to reduce the risk of photosensitivity reactions.
- Tetracyclines can stain the enamel of developing teeth when taken during pregnancy; although deciduous (baby) teeth are affected, permanent teeth are not.

MACROLIDES

Erythromycin (Eryc) **Clarithromycin (Klacid)**
Azithromycin (Zithromax) **Roxithromycin (Rulide)**

Macrolides are bacteriostatic and act effectively against Gram-positive and Gram-negative organisms. Erythromycin is used to treat streptococcal pharyngitis in people who are allergic to penicillin. Azithromycin produces less nausea than erythromycin, increasing patient adherence.

Nursing responsibilities

- Administer erythromycin on an empty stomach or immediately before meals.
- Give the drug with a full glass of water. Do not administer with acidic fruit juice.
- Intravenous doses are very irritating to veins; give slowly (20 to 60 minutes per gram).

Health education for the person and family

- Gastric distress is a common side effect with erythromycin.

AMINOGLYCOSIDES

Amikacin (Amikin) **Gentamicin**
Neomycin (Neosulf) **Tobramycin**

Aminoglycosides are bactericidal, interfering with protein synthesis in the pathogen. They are especially effective against Gram-negative organisms. To provide a broader spectrum of activity, they are often combined with other antibiotics, especially penicillins. Aminoglycosides can be administered in multiple or single daily doses. They are ototoxic and nephrotoxic; the risk is highest for older adults, people with pre-existing renal disease and people receiving other ototoxic or nephrotoxic drugs.

Nursing responsibilities

- Assess renal function before and during aminoglycoside therapy. Monitor intake and output, daily weight, BUN and serum creatinine.
- Assess for adverse effects on hearing such as loss of perception of high tones, tinnitus and vertigo.
- Notify the physician if the person is receiving other nephrotoxic or ototoxic drugs such as frusemide (Lasix) and ethacrynic acid (Edecrin).
- Administer intravenous preparations separately from other drugs; flush tubing before and after administration.

Health education for the person and family

- Monitor for a sudden weight gain, which may indicate adverse effects on the kidney, and report it to the physician.

(continued)

MEDICATION ADMINISTRATION Antibiotic therapy (continued)

OXAZOLIDINONES

Linezolid is the first antibiotic in the class of oxazolidinones. This antibiotic inhibits protein synthesis and is effective against organisms that are resistant to both vancomycin and methicillin. Because of its usefulness against those organisms, it should be reserved for infections caused by vaoncomycin-resistant enterococci (VRE) and MRSA (Lehne, 2012).

Nursing responsibilities

- Monitor for side effects including nausea, diarrhoea, hypertension and headache.
- Monitor platelets if person is at risk for bleeding; this drug may cause thrombocytopaenia.

Health education for the person and family

- It can be taken with or without food.
- Avoid taking adrenaline, pseudoephedrine, methylphenidate or cocaine with this drug as hypertension may develop.

III. Bacterial nucleic acid inhibitors

FLUOROQUINOLONES

Ciprofloxacin (Ciproxin) **Norfloxacin (Noroxin)**
Moxifloxacin (Avelox)

Fluoroquinolones are bactericidal and especially active against Gram-negative and some Gram-positive organisms. They are used to manage infections of the respiratory, gastrointestinal and genitourinary tracts. Rarely, drugs in this class can cause tendon rupture, with the highest risk in people aged 60 and older and in those taking glucocorticoid medications (Adams et al., 2014).

Nursing responsibilities

- Increase fluid intake to 2000 to 3000 mL/day, unless contraindicated, to prevent crystalluria.
- Monitor laboratory results for hepatotoxicity (elevated ALT, AST).

Health education for the person and family

- If tendon inflammation or pain develops, stop taking the drug and immediately report to your healthcare provider.
- Drink 6 to 8 glasses of water per day.
- Avoid exposure to sunlight while taking these drugs.

SULFONAMIDES AND TRIMETHOPRIM

Sulfadiazine
Trimethoprim (Alprim)
Timethoprim and Sulfamethoxazole (Bactrim, Septrin)

Sulfonamides are bacteriostatic. Trimethoprim is an antibiotic effective against most Gram-positive and many Gram-negative organisms. It is often combined with sulfamethoxazole to manage urinary tract infections, *P. carinii* pneumonia and otitis media. Skin rashes and pruritus are the most common hypersensitivity reactions. Severe reactions include exfoliative dermatitis and Stevens–Johnson syndrome.

Nursing responsibilities

- Assess for history of hypersensitivity to sulfonamides and related medications, such as thiazide diuretics and hypoglycaemic preparations.
- Monitor intake and output. Unless contraindicated, maintain a fluid intake of at least 1500 mL/day.
- Assess for evidence of bleeding, easy bruising or systemic infection, and monitor blood count for possible bone marrow depression.

Health education for the person and family

- Take medication on an empty stomach with a full glass of water. Maintain a fluid intake of at least 2 L per day.
- Protect the skin from excessive sun exposure with clothing and sunscreens to reduce the risk of photosensitivity.

NITROIMIDAZOLES

Metronidazole (Flagyl)
Tinidazole (Fasigyn)

Nitroimidazoles are metabolised to active metabolites that are thought to interfere with DNA synthesis. Metronidazole is effective against anaerobic Gram-negative and Gram-positive bacteria and protozoan infections caused by amoebiasis, giardiasis and trichomoniasis. It is commonly used to prevent and treat infections following intestinal surgery and is the drug of first choice with *C. difficile*.

Nursing responsibilities

- Monitor for CNS effects of dizziness, headache, ataxia, confusion, depression and peripheral neuropathy.
- Administer with food to minimise gastric distress and metallic taste. Infuse intravenous metronidazole over 60 minutes.
- Discontinue the medication and notify the physician if neurological reactions occur.
- Increase fluid intake to 2500 mL/day to minimise the risk of nephrotoxicity.

Health education for the person and family

- This medication may turn urine reddish brown; caution the person that this is expected and not harmful.
- Stop taking the drug and notify the physician if hypersensitivity reaction or adverse effects occur, such as changes in mentation or coordination, painful or frequent urination, painful or difficult intercourse, impotence.
- Do not drink alcohol while taking this medication; an Antabuse-type reaction (flushing, sweating, headache, vomiting and abdominal cramps) may occur.
- Maintain a fluid intake of 2.5 to 3 L per day.
- When the drug is prescribed for *Trichomonas* infections, treatment of both partners is necessary. Use condoms to prevent cross-contamination during intercourse.

MEDICATION ADMINISTRATION Antiviral agents

NEURAMINIDASE INHIBITORS

Oseltamivir (Tamiflu) and zanamivir (Relenza) are used to prevent and treat influenza. They are both active against both influenza A and B. They are generally well tolerated.

ADAMANTANES

Amantadine is used to treat influenza A. When administered within 48 hours of symptom onset, common manifestations are reduced. Generally well tolerated, CNS side effects such as dizziness, anxiety, insomnia and difficulty concentrating may occur.

ACICLOVIR (ZOVIRAX) GANCICLOVIR (CYMEVENE)

Guanine analogues are used primarily in the treatment of herpes viruses. Aciclovir is prescribed mainly in the treatment of genital herpes simplex and varicella. Although it does not kill the virus, it is effective in reducing the severity, duration and frequency of recurrence of symptoms. Ganciclovir is indicated primarily in the treatment of cytomegalovirus infection. Although aciclovir is generally well tolerated with little toxicity, ganciclovir may profoundly suppress bone marrow function.

PROTEASE INHIBITORS

Protease inhibitors prevent viral maturation and replication of HIV. These drugs are used alone or in combination with some taken orally or administered parenterally. Many people are unable to tolerate recommended doses due to adverse effects, including nausea, anorexia, malaise, severe anaemia and granulocytopenia.

INTERFERONS

Interferons (IFNs) are naturally produced cytokines that have antiviral activity. Pegylated interferon is used to treat chronic hepatitis B and hepatitis C, often in combination therapy. Common adverse effects include fatigue, flu-like symptoms, muscle and joint pain, and possible depression and insomnia (Adams et al., 2014; Wells et al., 2012).

Isolation precautions

Controlling the spread of infectious diseases in the hospital or long-term care setting is particularly important to preventing healthcare-associated infections. Hand hygiene remains the single most important factor in preventing the transmission of infections. Most infectious diseases are transmitted by either direct or indirect contact and their spread is prevented through the use of standard precautions. However, diseases such as chickenpox (caricella) are highly contagious and are spread by the airborne route, requiring special precautions to protect other hospitalised patients.

In determining the need for transmission-based precautions, healthcare personnel consider the usual reservoir or source of the microorganism, the mode of transmission and the susceptibility of hospital staff and other persons.

Standard precautions

The *Australian guidelines for the prevention and control of infection in healthcare* (NHMRC, 2010) describe *standard precautions* as work practices that are applied to everyone, regardless of their perceived or confirmed infectious status. The aim of standard precautions is to prevent or reduce the likelihood of transmission of infectious agents from one person or place to another and to maintain objects and areas as free as possible from infectious agents.

Standard precautions include the following work practices:

- Personal hygiene practices, particularly hand hygiene.
- Use of personal protective equipment (PPE) including gloves, plastic aprons and gowns, masks, face shields and eye protection.
- Appropriate handling and disposal of sharps.
- Environmental controls including cleaning and spills management.
- Appropriate processing of reusable equipment and instruments.
- Practising respiratory hygiene and cough etiquette.
- Aseptic non-touch technique.
- Appropriate handling of waste and linen.

Barrier protection (i.e. use of PPE) is used to prevent exposing skin and mucous membrane surfaces to blood and body fluids. Barrier protection involves using gloves for touching and handling body fluids, and adding other protection such as gowns, masks and goggles if splashing or spraying is likely. Use of aseptic technique, sterile single-use disposable needles and syringes, single-use vials for preparing and administering parenteral medication is emphasised. Needles and other sharp objects are not recapped or bent, but disposed of in puncture-proof containers to prevent inadvertent percutaneous (needle-stick) exposure.

Transmission-based precautions

In addition to the use of hand hygiene and standard precautions, additional work practices are recommended in situations where standard precautions are not sufficient to prevent transmission. Not all infectious diseases spread readily; however, diseases such as chickenpox (varicella) and pulmonary tuberculosis are highly contagious and are spread by the airborne route, requiring special precautions to protect other hospitalised people.

The NHMRC (2010) identifies three types of transmission-based precautions: contact, droplet and airborne precautions. Transmission-based precautions may be combined for diseases that have multiple routes of transmission. Indications for the use of transmission-based isolation precautions and the specific work practices to be taken are outlined in Table 11.9.

TABLE 11.9 Transmission-based precautions

CATEGORY	INFECTIOUS DISEASES	PURPOSE	PRECAUTIONS
Contact precautions	Acute diarrhoea, multidrug-resistant organisms (MROs), intestinal tract pathogens, *C. difficile*, highly contagious skin infections	Reduce risk of transmission by direct or indirect contact. Direct contact transmission involves physical transfer of organisms from skin and blood. Indirect contact involves contact with a contaminated object.	Hand hygiene. Private room with handwashing and toilet facilities. Gown and glove on entry to care areas and remove before leaving to provide barrier protection. Single-use or dedicated devices (or decontamination prior to use on another person).
Droplet precautions	Influenza, pertussis respiratory syncytial virus (RSV), norovirus, meningococcus	Reduce risk of droplet transmission of infectious agents. Droplet transmission involves contact of mucosal surfaces with respiratory droplets generated during coughing, sneezing, talking or procedures such as suctioning.	Hand hygiene. Private room with handwashing and toilet facilities. Surgical mask, goggles or face shields to be worn by everyone entering room.
Airborne precautions	Pulmonary tuberculosis, chickenpox (with contact precautions), measles, SARS	Reduce risk of airborne transmission of infectious agents. Airborne transmission occurs by dissemination of either airborne droplet nuclei or particles containing the infectious agent.	Hand hygiene. Private room with negative pressure or special ventilation not allowing air to circulate to general facility ventilation, with handwashing and toilet facilities. P2 respirators for everyone entering room.

Nursing care

Nursing management related to infectious disease focuses on health promotion, prevention and prompt identification and treatment.

Health promotion

Preventing infection requires education of healthcare personnel and the general public. Education includes understanding the importance of immunisations, guidelines for using antibiotics to prevent the development of drug-resistant microorganisms and how to prevent the spread of infection.

Check immunisation records for all family members and encourage them to keep immunisations up to date. Increase public awareness regarding appropriate antibiotic use. Guidelines for preventing the spread of infection to others include the following:

- Avoid crowds and contact with susceptible people, especially those who are immunosuppressed (e.g. people who have HIV infection, who are undergoing therapy for cancer or who have had an organ transplant).
- Use disposable tissues to contain respiratory secretions when coughing or sneezing.
- Use appropriate food-handling precautions for diseases spread via the faecal–oral route, such as hepatitis A.
- Avoid contact with or sharing of body fluids. For example, do not share needles or razors; use a condom during sexual activity or abstain; have each person clean their own blood spills or wounds, if possible.

Assessment

The following data are collected through the health history and physical examination. Further focused assessments are described with nursing interventions in the next section.

- *Health history*: age, medication use (antipyretics and anti-infectives), nutrition, exposure to infectious people, immunisations, invasive procedures and therapies, chronic diseases such as diabetes mellitus, cancer.
- *Physical assessment*: vital signs, body system(s) where infection is suspected, lymph node enlargement and tenderness.

Nursing diagnoses interventions

People with an infection may be managed in the hospital or at home. During the acute phase, nursing care includes administering prescribed antibiotics, implementing and maintaining aseptic technique and infection control measures, and encouraging a balance of rest and activity, good nutritional intake, and other general health measures to support immunological function and healing.

Risk of infection

The spread of infection is a risk in any facility that houses many people. It is a particular risk in hospitals, where many people have at least some degree of immunosuppression and

many drug-resistant strains of pathogens are prevalent. It is vital that nurses use good hand hygiene techniques at all times, employ standard precautions in all situations and use transmission-based precautions as indicated to prevent infectious spread to other people, themselves and their families.

- Admit people with known or suspected infections to a private room. *This is important to minimise the risk of infection transmission to others.*
- Practise effective hand hygiene techniques following the '5 moments' (Hand Hygiene Australia, 2009). Utilise alcohol-based hand rubs or, when hands are visibly soiled, wash hands with soap or antibacterial scrub solution and water using a minimum 15-second hand rub. *The appropriate technique for cleansing of hands is as equally important as the selection of correct product.*
- Use standard precautions and personal protective equipment to reduce the risk of transmission. *Gloves, gowns and masks are to be worn whenever there is a risk of skin or mucous membrane contamination by direct contact with infectious material, airborne spread of organisms or droplet nuclei.*
- Explain the reasons for and importance of transmission-based precautions during hospitalisation. *Application of transmission-based precautions may make the person feel neglected, dirty or shunned. Explanation of reasons and procedures can enhance the person's and family's understanding and acceptance.*
- Place a mask on the person and/or cover all infectious lesions or wounds completely when transporting the person to other parts of the facility for diagnostic or treatment procedures. *These measures help minimise air contamination and the risk to visitors and personnel.*
- Collect a culture and sensitivity (C&S) specimen as ordered or indicated by purulent drainage, pyuria or other manifestations of infection. *C&S is performed to determine the presence and type of infectious organisms, as well as the antibiotics most likely to be effective in eradicating them.*
- Administer prescribed anti-infective agents. *Anti-infectives are used to destroy the invading microorganism.*
- Inform all healthcare workers and visitors in contact with the person requiring transmission-based precautions. *Utilise appropriate signage at the entrance to the person's room with appropriate personal protective equipment at hand so that appropriate precautions can be taken.*
- Use appropriate measures for disposing of contaminated tissues, dressings or other material, and for removing soiled linen and equipment from the person's room. *Check hospital policy or published guidelines for appropriate disposal and cleaning procedures.*

CONSIDERATION FOR PRACTICE

Collect the specimen for culture and sensitivity (C&S) before the first dose of antibiotics is administered to ensure adequate organisms for culture.

- Teach the importance of complying with prescribed treatment for the entire course of the regimen. *Because anti-infective agents kill only a portion of the pathogen population with each dose, completion of the entire course of therapy is necessary to reduce the risk of relapse and of creating drug-resistant organisms.*

Anxiety

The person with an infectious disease may experience anxiety related to their manifestations, treatment measures, the prognosis and expected outcome of the disease. The diagnosis of an infection can be traumatic, causing feelings of uneasiness, isolation, guilt (e.g. in regard to sexually transmitted infections), apprehension or depression.

- Assess level of anxiety. *The level of anxiety influences the person's response to and interpretation of the situation and the degree of threat it poses.*
- Discuss the infection, treatments, prognosis and outcomes. *Discussions help to allay fears and misconceptions.*
- Support and enhance the person's coping strategies. *A person uses intrapersonal and interpersonal mechanisms to reduce or relieve anxiety.*
- Include significant others in the plan of care. *Inclusion of family members or significant others promotes understanding and compliance supporting reassurance and confidence.*
- Explain transmission-based precautions and answer any concerns. *Separation may be necessary to prevent the spread of infection and could cause great anxiety for the person and family members.*
- Provide referrals as needed for continuing care—for example, to home health agencies or for dressing changes or periodic assessment. *Referrals are often necessary to provide ongoing interventions and to maintain continuity of care.*

Hyperthermia

Hyperthermia is an expected consequence of the infectious disease process. Fever may produce mild, short-term effects or, when prolonged, may cause serious life-threatening effects.

- Monitor temperature, especially during episodes of chills; note heart rate and rhythm. *Chills indicate a rising temperature. Hyperthermia can cause arrhythmias.*
- Administer prescribed antipyretic as indicated for elevated temperature. Although antipyretics lower the temperature and enhance comfort for the person, this benefit must be weighed against the possible beneficial effect of an elevated temperature in the immune response. *Fever increases the motility and activity of WBCs, stimulates the production of interferon and activates T cells. In addition, temperatures above the normal range inhibit the growth of many microorganisms* (Grossman & Porth, 2014).
- Promote body cooling through lowering the room temperature. *Rapid cooling stimulates the hypothalamus to increase the body's temperature; this increases both shivering and metabolic rate.*
- Monitor fluid loss; encourage increased fluid and electrolyte intake either orally or intravenously. *Hyperthermia causes fluid loss from evaporation and may result in dehydration and electrolyte imbalance.*

- If diaphoretic, bathe and provide dry clothing and bedding. *These measures increase comfort and decrease further water evaporation.*
- Promote rest periods. *Rest increases energy reserve that is depleted by an increased metabolic, heart and respiratory rate.*

CONSIDERATION FOR PRACTICE

Use ice packs, cool/tepid baths or fans with caution to prevent unnecessary shivering.

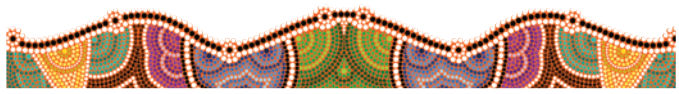
Acute pain

Pain often accompanies infections as part of the inflammatory process or secondary to delayed healing. Increasing pain in a wound may signal infection, especially if accompanied by erythema or purulence. *Keep the wound clean and dry and administer prescribed antibiotics to promote healing and decrease pain.*

Community-based care

Health education for the person and family is directed towards helping the person recover from the infection or disease, preventing its spread to others and preventing life-threatening complications. Instructions should include the following points:

- Promote the use of effective hand hygiene techniques, particularly after touching infected wounds or lesions, coughing, sneezing, blowing the nose or using the bathroom. Wash hands thoroughly before performing any procedures such as dressing changes. Wash hands with soap and water before and after preparing food or eating, using the toilet or handling nappies. Do not share eating utensils.
- Take all prescribed antibiotics as ordered, even after symptoms have subsided. Take the prescription at intervals around the clock as directed.
- Never allow anyone else to use your medications and never use anyone else's prescription even if they appear to be the same.
- Notify your healthcare provider in the following cases:
  - Symptoms do not improve within 24 to 48 hours after antibiotic therapy is instituted, or they worsen.
  - Signs of antibiotic allergy (itching, rash, difficulty breathing or swallowing, swelling of the face or tongue) occur. Discontinue medication and contact prescriber.
  - Adverse responses, such as gastrointestinal distress, that interfere with completion of the prescription.
  - Manifestations of infection that recur after completing prescribed antibiotic.
- Report redness, swelling or drainage around wounds, or persistent high fever.
- Increase fluid intake to at least 2500 mL per day.
- Report any signs of opportunistic infections: loose, watery and foul-smelling diarrhoea; vaginal discharge or itching; fuzzy growth or white plaques in mouth or on tongue; blood in urine; chills, fever or unusual cough.
- In addition, suggest the following resources:
  - state public health department
  - Australian Government Department of Health.



CHAPTER HIGHLIGHTS

- Innate immunity, a non-specific response to tissue injury, and the adaptive immune response, which directly targets invading microorganisms and invading cells, are critical components of the body's defences. Supporting these defences is a key nursing responsibility in promoting patient health.
- Both natural barriers and the immune system prevent the invasion and replication of pathogens.
- The adaptability and specificity of immune responses is possible because immune cells are genetically encoded to capture pathogens, move them to lymph nodes and develop specific immune reactions to destroy them.
- The inflammatory response serves to isolate invading antigens. When it occurs in response to acute injury, inflammation produces discomfort but serves a protective role. In contrast, chronic inflammation can damage affected tissue and may serve no protective function.
- Inflammation is a protective mechanism designed to prevent pathogens from entering the bloodstream and populating functional tissues such as heart, liver and kidney. Pain acts as a signal that tissue has been damaged and stimulates protective responses, such as cleansing wounds and limiting function, while healing progresses. Healing occurs as the inflammatory process isolates the injury and repairs damaged tissue.
- A fully immunised population is an important infection control strategy and a major factor in maintaining the health of individuals and the population as a whole.
- Nurses are instrumental in protecting vulnerable patients from infection, identifying early manifestations of infection, participating with the interprofessional team in treating infection and educating patients and their families about effective treatment of infection.
- Localised infections may damage tissue and create pain, but systemic infections are life threatening. Unfortunately, hospitals are hazardous environments populated with collections of pathogens. Healthcare-associated infections are often introduced into the body by medical procedures.
- Hygiene, protection from harm and nutrition support the immune defences. Antimicrobial medications limit the spread of pathogens but can lose their effectiveness when microbes mutate and develop resistance.

CONCEPT CHECK

1 When a person receives gamma globulin following exposure to hepatitis A, the nurse expects the person to develop:

1 natural active immunity
2 natural passive immunity
3 acquired active immunity
4 acquired passive immunity

2 The nurse is caring for the person with an infection. Which nursing action is a priority when providing the prescribed treatment?
1 Administer prescribed anti-infective.
2 Obtain specimen for culture and sensitivity.
3 Assess for history of hypersensitivities and allergies.
4 Monitor for reaction to prescribed anti-infective.

3 The nurse is providing medications to a patient with an inflammation. Which medication provided by the nurse will inhibit prostaglandin synthesis?
1 aspirin
2 penicillin
3 morphine sulfate
4 warfarin

4 While reviewing a patient's recent complete blood count, the nurse notes a large percentage of banded neutrophils. What does this finding indicate to the nurse?
1 renal failure
2 acute infection
3 hyperthyroidism
4 autoimmune disorder

5 A person is admitted with methicillin-resistant *Staphylococcus aureus* in a draining sacral wound. Which type of precaution should the nurse implement for this person?
1 droplet precautions
2 contact precautions
3 airborne precautions
4 protective precautions

6 A patient with a systemic inflammation is resting in bed, periodically sleeping, and wants additional blankets. Which part of the immune system is responsible for this patient's illness behaviour?
1 interferons
2 phagocytes
3 complement system
4 inflammatory cytokines

7 A patient is diagnosed with neutrophilia. What does this finding indicate to the nurse?
1 a decrease in total white blood cells
2 a decrease in circulating neutrophils
3 an increase in circulating neutrophils
4 an expected average number of white blood cells

8 The nurse is preparing discharge instructions for a person with an inflammation who is at risk for infection. What should the nurse include in the teaching?
1 Limit daily intake of calories.
2 Apply heat for 20 minutes at a time.
3 Resume normal activities of daily living.
4 Take prescribed antibiotics until fever drops.

9 The nurse is caring for an older patient recovering from an acute illness. Which intervention should the nurse implement to reduce the person's risk of developing a healthcare-associated infection?
1 Teach the patient to restrict fluids throughout the day.
2 Coach the patient to breathe deeply and cough frequently.
3 Recommend placement of an indwelling urinary catheter.
4 Wash hands with soap and water before entering the person's room.

10 The nurse is instructing unregistered health workers to use standard precautions when providing morning care to assigned patients. What should the nurse teach them specifically to do?
1 Perform hand hygiene, wear masks and recap needles.
2 Apply a mask and gown, and spray working surfaces with disinfectant.
3 Apply gloves, gowns and goggles if coming in contact with body fluids.
4 Wash hands with alcohol-based hand rub for visibly dirty or blood-contaminated hands.

CHAPTER 12

NURSING CARE OF PEOPLE WITH ALTERED IMMUNITY

CATHERINE BETHELL

LEARNING OUTCOMES

- Review the normal anatomy and physiology of the immune system.
- Describe the four types of hypersensitivity reactions.
- Discuss the pathophysiology of autoimmune disorders and tissue transplant rejection.
- Discuss the characteristics of immunodeficiencies.
- Identify laboratory and diagnostic tests used to diagnose and monitor immune response.
- Describe pharmacological and other collaborative therapies used in treating people with altered immunity.
- Correlate the pathophysiological alterations with the manifestations of HIV/AIDS infection.

CLINICAL COMPETENCIES

- Assess functional health status of people with altered immunity and monitor, document and report abnormal manifestations.
- Use evidence-based practice to plan and implement nursing care for people with AIDS.
- Assess for hypersensitivities and anticipate treatment if signs and symptoms develop.
- Provide education about hypersensitivities, avoidance of sensitising agents and prophylactic treatment.
- Determine priority nursing diagnoses, based on assessment data, to select and implement individualised nursing interventions and education for people with altered immunity.
- Protect people who are immunosuppressed.
- Recognise manifestations of developing anaphylaxis.
- Recognise manifestations of infection and minimise healthcare-associated exposure.
- Utilise standard precautions to protect self and other people from HIV exposure.
- Recognise the burden and benefit of highly active antiretroviral therapy (HAART) for the person with HIV infection.
- Integrate interprofessional care into care of the person with altered immunity.
- Revise plan of care as needed to provide effective interventions to promote, maintain or restore functional health status to people with altered immunity.

KEY TERMS

OVERVIEW OF THE IMMUNE SYSTEM

Recent years have seen the emergence of new diseases affecting the immune system. These diseases include human immunodeficiency virus (HIV) infection and altered strains of familiar diseases such as multidrug-resistant tuberculosis. At the same time, our understanding of the components of the immune system and specific immune responses is increasing. Therefore, it is vital that today's nurses understand the foundations of the immune system and the immune response.

The immune system functions to protect the body from invasion by foreign antigens, to identify and destroy potentially harmful cells and to remove cellular debris. These functions are accomplished by the lymphoid organs and specifically designed lymphocytes through the processes of antibody-mediated immune response and cell-mediated immune response.

The effectiveness of the immune system depends on its ability to differentiate normal host tissue from abnormal or foreign tissue. Body cells, tissues and fluids have unique antigenic properties recognised by the immune system as 'self'. External agents, such as microorganisms, cells and tissues from other humans or animals and some inorganic substances, have antigenic properties recognised by the immune system as 'non-self'.

Each body cell displays specific cell surface characteristics, or markers, that are unique to each person. These are known as human leucocyte antigens (HLAs). A person's HLA characteristics are coded within a large cluster of genes known as the major histocompatibility complex (MHC), located on chromosome 6. Recall that chromosomes are paired; each person inherits one member of the pair from each parent. A chromosome pair contains multiple genes, each carrying instructions for production of one polypeptide chain. The number of genes in the MHC results in a multitude of HLA combinations. As a result, the possibility of two people having the same HLA type is extremely remote. Identical twins may be the exception and some siblings have very similar HLA patterns. In tissue grafting and organ transplants, matching the HLA type as closely as possible tends to decrease rejection.

Immunocompetent people have an immune system that identifies antigens and effectively destroys or removes them. When the immune system functions improperly, the result may be an overreaction or deficiency, resulting in health problems. Overreaction of the immune system leads to hypersensitivity disorders, such as allergies. When the immune system loses the ability to recognise self, autoimmune disorders may ensue (see Table 12.1). Immunodeficiency diseases or malignancies can develop when the immune system is incompetent or unable to respond effectively, as is the case with acquired immunodeficiency disorder. These alterations in immunity are discussed later in this chapter.

As discussed previously in Chapter 11, the antibody-mediated immune response is accomplished by B lymphocytes (B cells) that are further divided into memory cells and plasma cells. They are activated by contact with an antigen and by T cells. B cells produce antibodies, also known as immunoglobulins (see Table 11.3), and serve to inactivate an invading antigen. One immunoglobulin in particular, IgM, forms natural antibodies, such as those for ABO blood group antigens, and is an important component of the immune system complexes seen in autoimmune disorders. Memory cells 'remember' an antigen and, when exposed to it a second time, immediately initiate the immune response. This action provides the foundation of acquired immunity.

In contrast, cell-mediated immunity acts at the cellular level by attacking antigens directly and by activating B cells. T lymphocytes comprise the cell-mediated immune response and are subdivided into effector cells and regulator cells. The cytotoxic cell or killer T cell is the primary effector cell. Regulator T cells are divided into two subsets known as helper T cells and suppressor T cells.

Proteins on the surface of the T cell help define its function and also provide a marker that can be used to identify the cell class. These proteins are known as the cluster of differentiation antigen or CD antigen. The two primary CD proteins are CD4 and CD8. Both cytotoxic and suppressor T cells carry the CD8 antigen. Helper T cells have the CD4 antigen and are often called CD4 cells. CD4 cells are the most numerous of the T lymphocytes, making up 70% of the circulating population.

Helper T cells initiate the immune response, whereas suppressor T cells limit it. Helper T cells accomplish their role by promoting growth of additional T cells, by stimulating proliferation of B cells and by activating killer T cells. It is believed that suppressor T cells are important in preventing autoimmune disorders. Proper immune system function depends on the correct balance between helper and suppressor T cells.

In addition to destroying viruses and bacteria, cytotoxic T lymphocytes also attack malignant cells. They also are responsible for the rejection of transplanted organs and grafted tissues.

CHANGES IN IMMUNE FUNCTION IN THE OLDER ADULT

Immune function declines with ageing, although many of the mechanisms leading to this decline are not clear. External factors, such as nutritional status and the effects of chemical exposure, ultraviolet radiation and environmental pollution, affect the older adult's immune status. Internal factors affect it as well, including genetics, the function of the neurological and endocrine systems, chronic and prior illnesses, and individual anatomical and physiological variations. These influences make it difficult to determine the effect of ageing on the immune system. In some older individuals, the immune system is as effective as that of a younger person.

Whereas the antibody response to foreign antigens is diminished, autoantibodies (antibodies that react to the person's own tissues) are more common in older people. The presence of autoantibodies suggests impaired regulation of the immune system, but it is not associated with an increased incidence of autoimmune disorders (Murasko & Gardner, 2003). The hypersensitivity response is also reduced or delayed.

TABLE 12.1 Selected autoimmune disorders

More organ specific	Hashimoto's thyroiditis	A chronic progressive inflammatory disease of the thyroid with lymphocyte infiltration and gradual destruction of the gland. See Chapter 18.
	Primary myxoedema	Thyroid deficiency resulting from destruction of the thyroid gland due to an autoimmune process, often Hashimoto's thyroiditis. See Chapter 18.
	Thyrotoxicosis	Hyperthyroidism resulting from thyroid-stimulating immunoglobulins that stimulate activity of the gland. See Chapter 18.
	Pernicious anaemia	Anaemia resulting from absence of intrinsic factor associated with loss of parietal cells; most people have antibodies to parietal cells. See Chapter 32.
	Addison's disease	Atrophy and hypofunction of the adrenal cortex, probably autoimmune in origin. See Chapter 18.
	Myasthenia gravis	A disease characterised by episodic muscle weakness caused by antibodies to the acetylcholine receptor of the neuromuscular junction. See Chapter 43.
	Insulin-dependent diabetes mellitus	Impaired insulin secretion, often the result of islet cell destruction by antibodies directed at the cell surface or cytoplasm. See Chapter 19.
	Goodpasture's syndrome	A type II hypersensitivity disorder with pulmonary haemorrhage and progressive glomerulonephritis characterised by circulating antiglomerular basement membrane antibodies. See Chapter 27.
	Multiple sclerosis	A probable autoimmune process resulting in disseminated patches of demyelination in the brain and spinal cord and varied neurological manifestations. See Chapter 43.
	Idiopathic thrombocytopenic purpura	A chronic disorder characterised by petechiae, purpura, mucosal bleeding and antibodies against platelets. See Chapter 32.
	Primary biliary cirrhosis	Inflammation and fibrosis of the bile ducts, probably of autoimmune origin. See Chapter 24.
	Active chronic hepatitis	A serious liver disease often resulting in hepatic failure and/or cirrhosis; may be autoimmune with infiltration by T cells and plasma cells. See Chapter 24.
Less organ specific	Ulcerative colitis	A chronic inflammatory disease of colon mucosa, possibly of autoimmune origin. See Chapter 23.
	Sjögren's syndrome	A systemic inflammatory disorder characterised by dryness of the mouth, eye and other mucous membranes with lymphocyte infiltration of affected tissues. See Chapter 39.
	Rheumatoid arthritis	A chronic syndrome with inflammation of peripheral joints and generalised manifestations, characterised by infiltration of synovium by lymphocytes and plasma cells. See Chapter 39.
	Scleroderma	Diffuse fibrosis, degenerative changes and vascular abnormalities of skin, joint structures and internal organs; probably of autoimmune origin. See Chapter 39.
Non-organ specific	Systemic lupus erythematosus	An inflammatory connective tissue disorder characterised by the presence of antinuclear antibodies. See Chapter 39.

ASSESSMENT OF ALTERED IMMUNE SYSTEM FUNCTION

Unlike body systems that are composed of a few closely related organs, the immune system is diverse and scattered. Optimal immune function depends on intact skin and mucous membrane barriers, adequate blood cell production and differentiation, a functional system of lymphatics and the spleen, and the ability to differentiate foreign tissue and pathogens from normal body tissue and flora. Because of this diversity of organs and function, assessment of the immune system is often integrated throughout the history and physical examination.

Health history

Prior to interviewing the person, review the biographical data, including age, sex, race and ethnic background. This information can provide valuable clues about possible immunological disorders. For example, many autoimmune disorders are more prevalent in women than in men. Family history is also important because there is a genetic component in the aetiology of many disorders affecting the immune system.

Many interview questions related to the immune system and disorders that affect it are of a sensitive nature. Be sure to provide for privacy prior to the interview. If family members are present, request that they leave as well. Establish a trusting relationship with the person prior to asking the most sensitive questions (e.g. those related to the use of illicit drugs or sexual activity). Epidemiological data show that social and racial groups have peculiar risks for HIV infection; cultural sensitivity is necessary for effective communication.

Physical assessment

The techniques of inspection and palpation are especially important in assessing a person's immune system.

- Assess the general appearance. Note whether the person's stated and apparent age coincide. Evident fatigue or weakness may indicate acute or chronic illness or immunodeficiency. Assess height, weight and body type for apparent weight loss or wasting. Observe ease of movement and note any evident stiffness or difficulty moving. Check vital signs. An elevated temperature may indicate an infection or inflammatory response.
- Inspect the mucous membranes of the nose and mouth for colour and condition. Pale, boggy (oedematous) nasal mucosa is often associated with chronic allergies. Note petechiae, white patches or lacy white plaques, in the oral mucosa; they may indicate haemolysis or immunodeficiency.
- Assess skin colour, temperature and moisture. Pale or jaundiced skin may indicate a haemolytic reaction. Pallor may also indicate bone marrow suppression with accompanying immunodeficiency. Inspect the skin for evidence of rashes or lesions, such as petechiae, numerous bruises, purple or blue patches, or lesions indicative of Kaposi's sarcoma, and wounds that are infected, inflamed or unhealed. Note the location and distribution of any rashes or lesions.
- Inspect and palpate the cervical lymph nodes for evidence of lymphadenopathy (swelling) or tenderness. Palpate the nodes of the axillae and groin as well.
- Assess the musculoskeletal system by inspecting and palpating the joints for redness, swelling, tenderness or deformity. Such changes may indicate an autoimmune disorder such as rheumatoid arthritis or systemic lupus erythematosus. Check joint range of motion as well, including that of the spine.

ALTERED IMMUNE RESPONSES

Considering the complexity of the immune system, it is not surprising that abnormal or harmful responses occur. Altered immune system responses include those characterised by hyperresponsiveness of the immune system and those characterised by an impaired immune response. Allergies, autoimmune disorders, and reactions to organ or tissue transplants are all examples of hyperresponsive immune function. AIDS and other immunodeficiency disorders result from impairment of the immune system.

THE PERSON WITH A HYPERSENSITIVITY REACTION

Hypersensitivity is an altered immune response to an antigen that results in harm to the person. When the antigen is environmental or exogenous, it is called an **allergy** and the antigen is referred to as an *allergen*. The tissue response to a hypersensitivity reaction may be simply irritating or bothersome, causing a runny nose or itchy eyes, or it may be life threatening, leading to blood cell haemolysis or laryngospasm.

Hypersensitivity reactions are primarily classified by the type of immune response that occurs on contact with the allergen. They may also be classified as immediate or delayed hypersensitivity responses. Anaphylaxis and transfusion reactions are examples of immediate hypersensitivity reactions; contact dermatitis is a typical delayed response. Allergies are sometimes referred to by the affected organ system (e.g. allergic rhinitis) or the allergen involved, as in hay fever. Classification by immunological response is the preferred means of studying allergies. Although more than one type of reaction may occur simultaneously, it is practical and insightful to study and treat allergy by classified types (King et al., 2005). The prevalence of allergy in Australia is one of the highest in the developed world, with 19.6% of the population having at least one allergy (Australasian Society of Clinical Immunology and Allergy (ASCIA), 2007).

Pathophysiology

In a hypersensitivity reaction, an antigen–antibody or antigen–lymphocyte interaction causes a response that is damaging to body tissues. Antigen–antibody responses characterise types I, II and III, also known as immediate hypersensitivity responses. Type IV hypersensitivity is an antigen–lymphocyte reaction, resulting in a delayed hypersensitivity response.

Type I: IgE-mediated hypersensitivity

Common hypersensitivity reactions, such as allergic asthma, allergic rhinitis (hay fever), allergic conjunctivitis, hives and anaphylactic shock, are typical of type I or IgE-mediated hypersensitivity. This type of hypersensitivity response is triggered when an allergen interacts with IgE bound to mast cells and basophils. The antigen–antibody complex prompts release of histamine and other chemical mediators, complement, acetylcholine, kinins and chemotactic factors (see Figure 12.1).

When a potent allergen such as bee or wasp venom or a drug is injected, resulting in widespread antibody–antigen reaction and response to these chemical mediators, a systemic response such as anaphylaxis, urticaria or angio-oedema results.

Anaphylaxis is an acute systemic type I response that occurs in highly sensitive people following injection of a specific antigen. Substances known to trigger anaphylaxis are summarised in Box 12.1. Anaphylaxis rarely follows oral ingestion, although this is possible. The reaction begins within minutes of exposure to the allergen and may be almost instantaneous. The release of histamine and other mediators causes vasodilation and increased capillary permeability, smooth muscle contraction and bronchial constriction. These chemical mediators cause the person to experience the typical manifestations of anaphylaxis. Initially, a sense of foreboding or uneasiness, light-headedness and itching palms and scalp may be noted. Hives may develop, along with angio-oedema (localised tissue swelling) of the eyelids, lips, tongue, hands, feet and

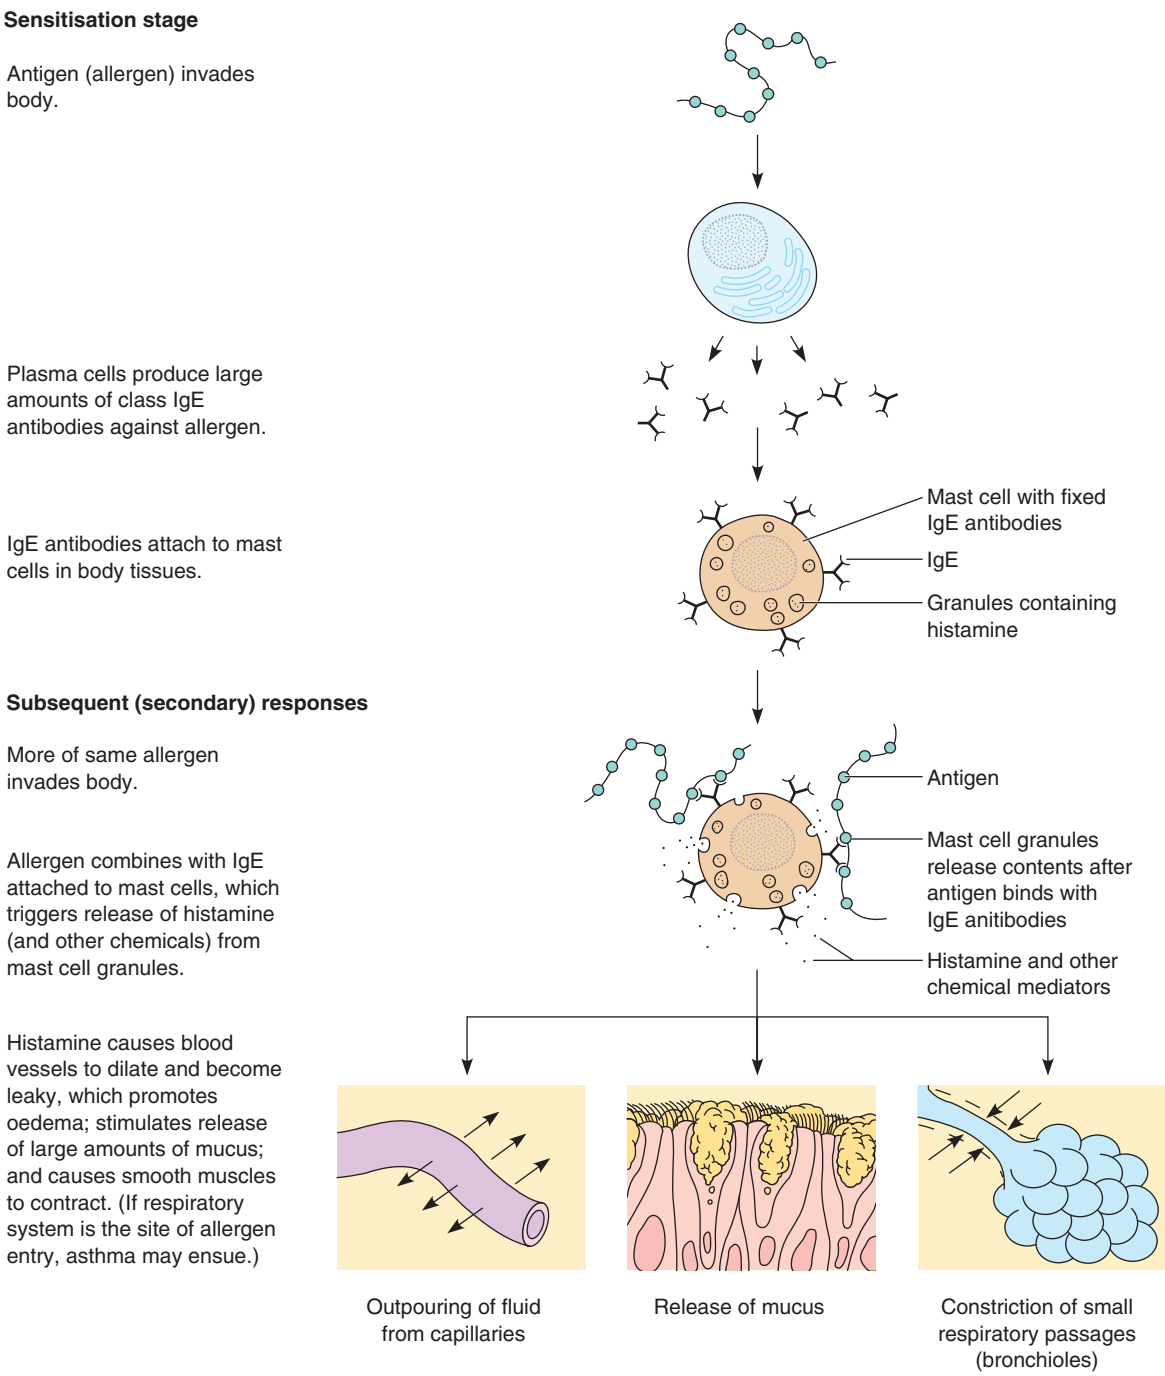

FIGURE 12.1 ■ Type I or IgE-mediated hypersensitivity response

genitals. Swelling can also affect the uvula and larynx, impairing breathing. This is further complicated by bronchial constriction. The person exhibits air hunger, stridor and wheezing, and a barking cough. These respiratory effects can be lethal if the reaction is severe and intervention is not immediately available. Vasodilation and fluid loss from the vascular system can lead to impaired tissue perfusion and hypotension, a condition known as *anaphylactic shock*.

Fortunately, localised responses are more common manifestations of type I hypersensitivity. These are typically atopic responses; that is, they have a strong genetic predisposition. Atopic reactions are the result of localised, rather than systemic, IgE-mediated responses to an allergen. They are prompted by contact of the allergen with cell-bound IgE in the bronchial tree, nasal mucosa and conjunctival tissues. Chemical mediators are released locally, producing symptoms such as asthma, allergic rhinitis (hay fever), conjunctivitis or atopic dermatitis. Allergens commonly associated with atopic reactions of this type include pollens, fungal spores, house dust mites, animal dander and feathers (Porth & Matfin, 2009). Food allergens can also cause localised responses such as diarrhoea or vomiting. If the gastrointestinal mucosa is altered by a

BOX 12.1 Substances known to trigger anaphylaxis in sensitised people

Hormones
- Insulin
- Vasopressin
- Parathormone

Enzymes
- Trypsin
- Chymotrypsin
- Penicillinase

Pollens
- Ragweed
- Grass
- Trees

Foods
- Eggs
- Seafood
- Nuts
- Grains
- Beans
- Chocolate
- Dairy products
- Royal jelly

Vitamins
- Thiamine
- Folic acid

Insect venom
- Australian native ants (Jack Jumper ant)
- Wasps
- Honey bee
- Tick

Occupational agents
- Rubber products
- Industrial chemicals (ethylenes)

Antibiotics
- Penicillins
- Cephalosporins
- Amphotericin B
- Nitrofurantoin

Local anaesthetics
- Procaine
- Lidocaine

Medical diagnostic agents
- Sodium dehydrocholate
- Sulfobromophthalein

Antiserum
- Antilymphocyte gamma globulin

local allergic response, then the allergen may be absorbed, leading to a systemic reaction. Urticaria (hives) is the most common systemic response to food allergies.

Type II: cytotoxic hypersensitivity

Cytotoxic hypersensitivity reactions are characterised by formation of IgG or IgM antibodies against normal or foreign cells or tissues (Grossman & Porth, 2014; Haynes et al., 2012). A haemolytic transfusion reaction to blood of an incompatible type is characteristic of a type II or cytotoxic hypersensitivity reaction. IgG or IgM type antibodies are formed to a cell-bound antigen such as the ABO or Rh antigen. When these antibodies bind with the antigen, the complement cascade is activated, resulting in destruction of the target cell (see Figure 12.2). Haemolytic disease of the newborn is caused by this type of reaction.

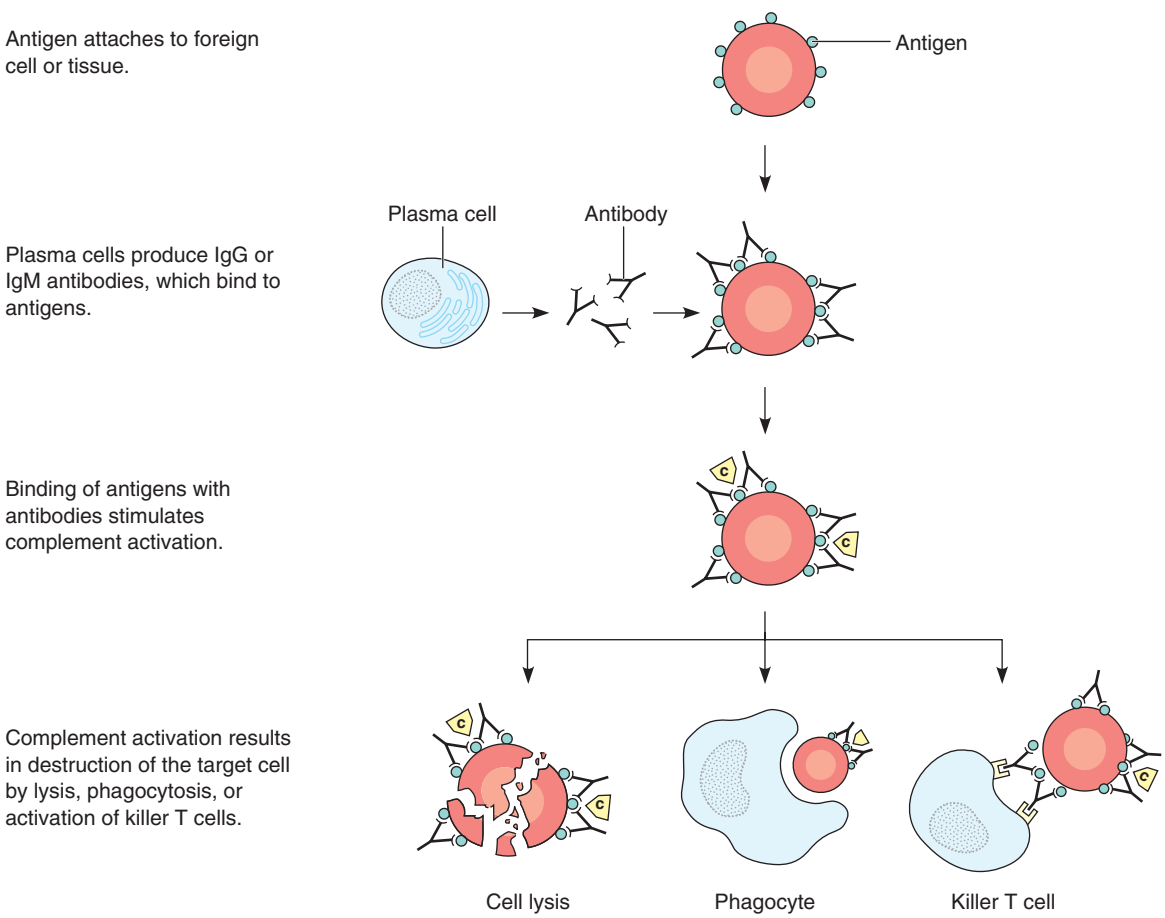

FIGURE 12.2 ■ Type II or cytotoxic hypersensitivity response

Type II reactions may be stimulated by an exogenous antigen, such as foreign tissue or cells, or a drug reaction in which the drug forms an antigenic complex on the surface of a blood cell, stimulating the production of antibodies. The affected cell is then destroyed in the resulting antigen–antibody reaction; for example, haemolytic anaemia is sometimes associated with the administration of drugs such as penicillins, cephalosporins and streptomycin. Withdrawal of the drug stops the reaction and cell destruction (Goldsby et al., 2003).

Endogenous antigens can also stimulate a type II reaction, resulting in an autoimmune disorder such as Goodpasture's syndrome, in which antigens are formed to specific tissues in the lungs and kidneys. Hashimoto's thyroiditis and autoimmune haemolytic anaemia are additional examples of autoimmune type II reactions.

Type III: immune-complex-mediated hypersensitivity

Type III hypersensitivity reactions result from the formation of IgG or IgM antibody–antigen immune complexes in the circulation. When these complexes are deposited in vessel walls and extravascular tissues, complement is activated and chemical mediators of inflammation such as histamine are released. Chemotactic factors attract neutrophils to the site of inflammation. When neutrophils attempt to phagocytise the immune complexes, lysosomal enzymes are released, increasing tissue damage (see Figure 12.3).

Either systemic or local responses may be seen with type III reactions. For example, serum sickness is a systemic response, so named because it was first identified after administration of foreign serum (e.g. horse antitetanus toxin). Although foreign serums are no longer administered, serum

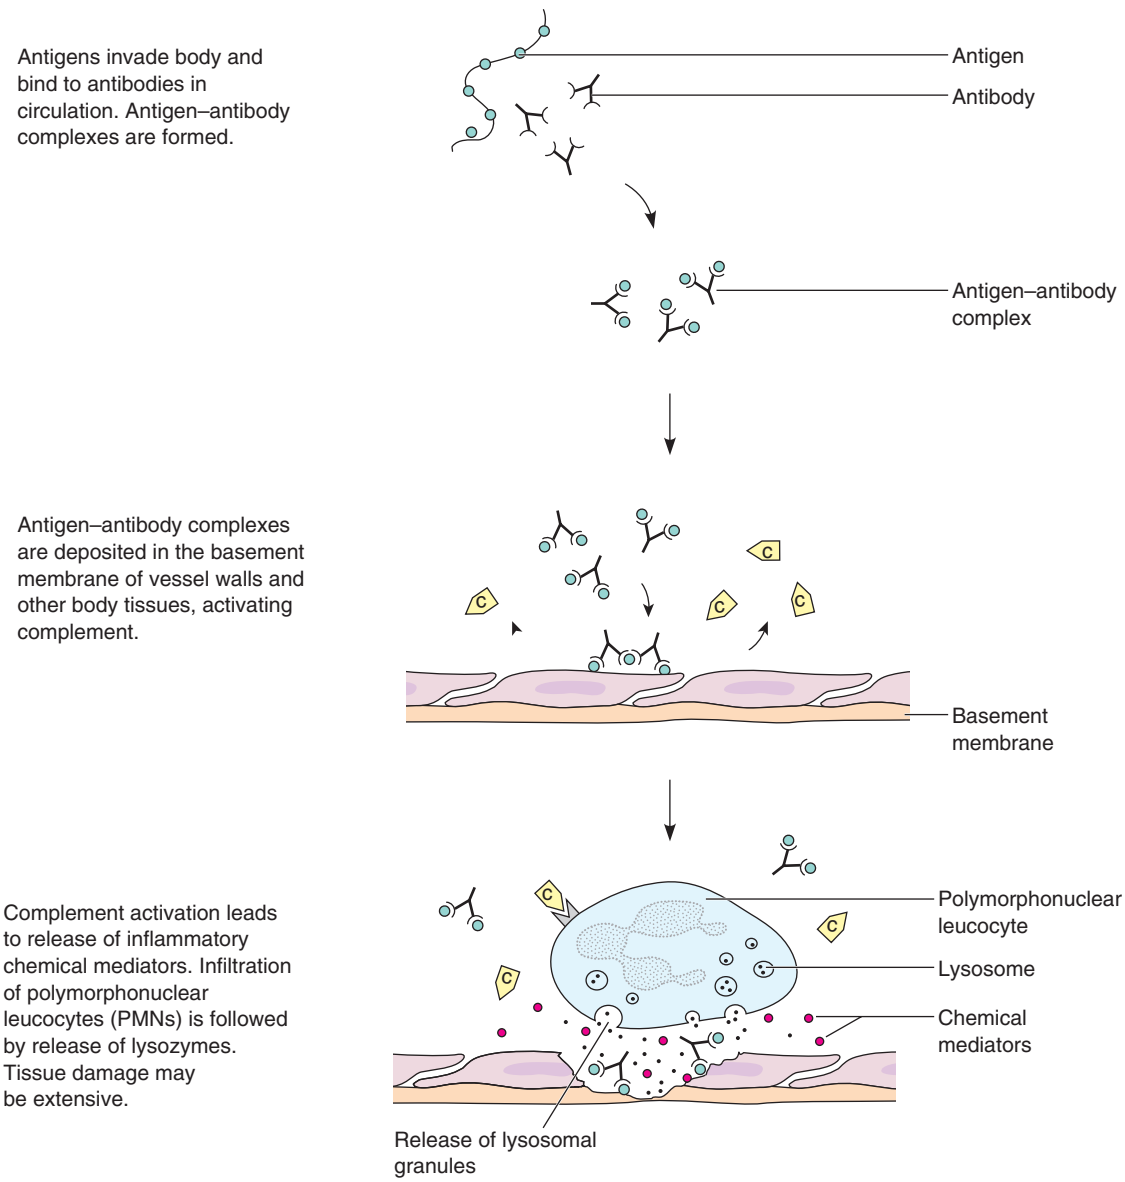

FIGURE 12.3 ■ Type III or immune-complex-mediated hypersensitivity response

sickness still occurs in response to some drugs, such as penicillin and sulfonamides. Immune complexes are deposited in walls of small blood vessels, the kidneys and joints. Manifestations of serum sickness include fever, urticaria or rash, arthralgias, myalgias and lymphadenopathy.

Localised responses may occur at a number of different sites. As immune complexes accumulate in the glomerular basement membrane of the kidneys—for example, following a streptococcal infection or with systemic lupus erythematosus—glomerulonephritis develops. When an antigen such as dust from mouldy hay is inhaled, an acute alveolar inflammatory response can occur. This condition can develop in agricultural workers.

Type IV: delayed hypersensitivity

Type IV reactions differ from other hypersensitivity responses in two ways. First, these reactions are cell mediated rather than antibody mediated, involving T cells of the immune system. Second, type IV reactions are delayed rather than immediate, developing 24 to 48 hours after exposure to the antigen. Type IV hypersensitivity responses result from an exaggerated interaction between an antigen and normal cell-mediated mechanisms. This exaggerated interaction results in the release of soluble inflammatory and immune mediators (from the lysozymes within the macrophages) and recruitment of killer T cells, causing local tissue destruction (see Figure 12.4).

Contact dermatitis is a classic example of a type IV reaction. Intense redness, itching and thickening affect the skin in the area exposed to the antigen. Fragile vesicles are often present as well. Many antigens can provoke this response; poison ivy is a prime perpetrator. In the healthcare setting, an allergic response to latex can also produce contact dermatitis. An estimated 8% to 13% of healthcare workers are allergic to latex (National Institute of Occupational Safety and Health (NIOSH), 2005), and recent Australian studies indicate the likely increase in the risk of latex allergy in Australian healthcare workers due to occupational use of latex gloves (ASCIA, 2010). Other examples of cell-mediated responses include a positive tuberculin test and graft rejection episodes.

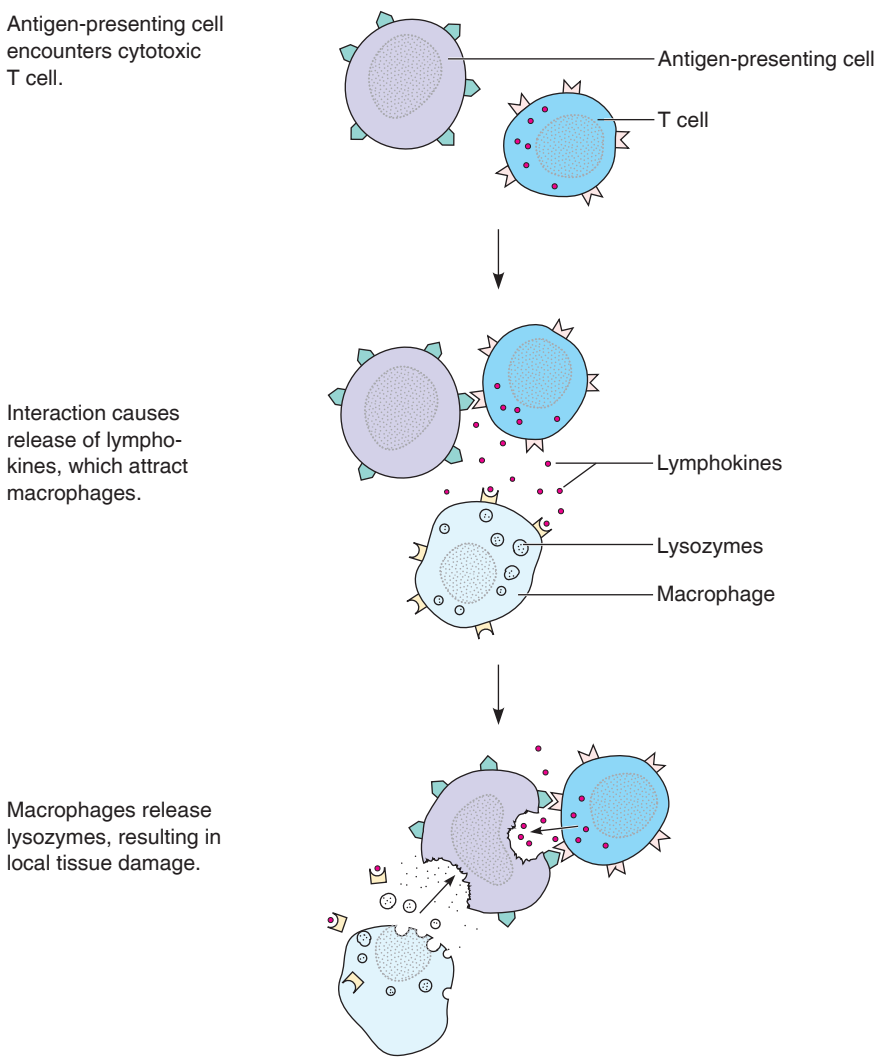

FIGURE 12.4 ■ Type IV or delayed hypersensitivity response

Latex allergy

Although protective against infection, the repetitive use of latex gloves creates a persistent exposure to latex for healthcare workers. Handwashing after using latex products limits exposure. When gloves are powdered with cornstarch to facilitate donning and removal, the cornstarch particles aerosolise when the gloves are removed. The cornstarch includes latex particles. This creates a respiratory exposure as well as dermal exposure to latex. In addition, chemicals used in the manufacture of latex products may be irritating. Products such as balloons, condoms and rubber bands are commonly made of latex.

Sensitivity to latex develops without the user being aware until a rash appears on the hands. Type IV hypersensitivity (contact dermatitis) can progress to type I systemic allergic reactions without previous symptoms signalling an escalation. It is important to protect the person and the healthcare worker who is allergic to latex. Prevention is aided by employers who select products free of latex (vinyl, nitrile, neoprene or polyurethane). Non-latex and synthetic gloves must be used. ASCIA (2010) provides strategies and guidelines for the management of latex-allergy individuals specific to various Australian healthcare settings.

INTERPROFESSIONAL CARE

The focus of care for people with allergic responses is on the following:

- Minimise exposure to the allergen.
- Prevent a hypersensitivity response.
- Provide prompt, effective interventions for allergic responses when they occur.

Identifying allergens for the individual to reduce the likelihood of exposure is a key aspect of management. A complete history of the person's allergies is obtained, including medications, foods, animals, plants and other materials. The type of hypersensitivity response is documented, as is its onset, manifestations and usual treatment.

When a documented or suspected hypersensitivity reaction occurs, the allergen (e.g. intravenous medication or transfusion) is withdrawn immediately. With a type I hypersensitivity response, managing the person's airway takes highest priority, followed by maintenance of cardiac output. Type II hypersensitivity responses may necessitate aggressive management of bleeding or renal failure. A type III (immune complex) reaction is treated by removing the offending antigen and interrupting the inflammatory response.

With a hypersensitivity response, supportive care is important to relieve discomfort. This often involves the administration of selected antihistamine or anti-inflammatory medications. Other therapies, such as plasmapheresis, may be prescribed in selected instances, a procedure that involves the continual withdrawal and reinfusion of blood from the patient, during which time the blood is processed to remove the allergic components of the plasma portion.

Diagnosis

To identify possible allergens or hypersensitivity reactions, the following laboratory tests may be ordered:

- *White blood cell (WBC) count with differential* can detect high levels of circulating eosinophils. Normally, eosinophils constitute a very small percentage (1–4%) of the total WBCs. Eosinophilia, however, is often present in people with type I hypersensitivities.
- *Radioallergosorbent test (RAST)* measures the amount of IgE directed towards specific allergens. Test results are compared with control values and used to identify hypersensitivities. RAST poses no risk of an anaphylactic reaction. It is particularly useful in detecting allergies to some occupational chemicals and toxic allergens (Goldsby et al., 2003).
- *Blood type and crossmatch* are ordered prior to any anticipated transfusions. The person's ABO blood group and Rh status are determined. Two major antigens, designated A and B, may be present on RBCs. People with the A antigen are designated as blood type A; those with blood type B have the B antigen. When neither antigen is found on the RBCs, the person is identified as type O. A third major RBC antigen is the Rh antigen. People with this antigen are called Rh positive; those without are Rh negative. Because a blood transfusion is actually a transplant of living tissue, antigen matching is vital to prevent significant hypersensitivity reactions. Once blood type is determined, a sample of the person's blood is mixed with a sample of matching donor blood and observed for antigen–antibody reactions in the crossmatch portion of this test. Although this procedure greatly reduces the risk of a haemolytic transfusion reaction (type II hypersensitivity), it does not totally eliminate it.
- *Indirect Coombs' test* detects the presence of circulating antibodies (other than ABO antibodies) against RBCs. The person's serum is mixed with the donor's RBCs. If the person's serum contains antibodies to an RBC antigen, agglutination (clumping together) will occur. This is called a positive response. The normal value is negative or no agglutination. This test is also part of the crossmatch of a blood 'type and crossmatch'.
- *Direct Coombs' test* detects antibodies on the person's RBCs that damage and destroy the cells. This is used following a suspected transfusion reaction to detect antibodies coating the transfused RBCs. It can also identify haemolytic anaemia when the cause is unknown. In the direct Coombs' test, the person's RBCs are mixed with Coombs' serum, which contains antibodies to IgG and several complement components. Agglutination will occur if the person's RBCs are coated with antibodies, resulting in a positive test. As with the indirect Coombs' test, the normal test result is negative.
- *Immune complex assays* may be performed to detect the presence of circulating immune complexes in suspected type III hypersensitivity responses. The assays are particularly useful in diagnosing suspected autoimmune disorders. Non-specific assays of IgG-, IgM- and IgA-containing immune complexes, which do not detect specific antibodies, as well as specific antibody assays, may be done. The normal result is a test negative for circulating immune

complexes. A negative test does not, however, rule out an immune complex hypersensitivity response. In some cases, a negative result may indicate that the disease process has reached a later stage, in which complexes are no longer circulating but have initiated extensive tissue damage, such as glomerulonephritis (Fauci et al., 2008).

- *Complement assay* is also useful in detecting immune complex disorders. In these disorders, complement is, in effect, used up by the development of antigen–antibody complexes. Decreased levels are seen on examination. Both total complement level and amounts of individual components of the complement cascade can be determined.

SKIN TEST FOR ALLERGIES Skin tests are also used to determine causes of hypersensitivity reactions. These tests are used to identify specific allergens to which a person may be sensitive. Allergens for testing are selected according to the person's history. Test solutions made from extracts of inhaled, ingested or injected materials, such as pollens, mites, venoms or some drugs, are used for the prick test and intradermal testing. Epicutaneous testing (prick testing) is generally done first to avoid a systemic reaction; it is followed by intradermal testing of allergens with a negative response to prick testing (Papadakis, McPhee & Rabow, 2013).

If the large-dose intradermal tests were done intially, individuals highly allergic to a substance would be at increased risk of an anaphylactic reaction. Substances that cause a reaction to the prick test should not be tested intradermally.

- *Skin prick (epicutaneous or puncture) test:* a drop of diluted allergenic extract is placed on the skin and the skin is then pricked or punctured through the drop. With a positive test, a localised pruritic wheal and erythema occur. The response is maximal at 15 to 20 minutes.
- *Intradermal:* a small amount (just enough to create a wheal) of allergen extract at a 1:500 or 1:1000 dilution is injected on the forearm or intrascapular area. If several allergens are being tested, injections are spaced 0.7 to 1.25 cm apart. As control measures, plain diluent (negative control) and histamine (positive control) are also injected. If there is no response to a particular allergen at 15 to 20 minutes, the test is negative. The appearance of a wheal and erythema, with a wheal diameter at least 5 mm greater than that produced by the control, indicates a positive response (see Figure 12.5). Intradermal is not recommended for routine use for aeroallergens and food allergens, as it carries a greater risk of anaphylaxis (ASCIA, 2010).
- *Patch:* a 2.5 cm patch impregnated with the allergen (e.g. perfume, cosmetics, detergents or clothing fibres) is applied to the skin for 48 hours. Absence of a response indicates a negative test result. Positive responses are graded from mild (erythema in the exposed area) to severe (erythema, papules, vesicles or ulceration).
- *Food allergy testing* is performed when a food allergy is suspected but the source or implicated food item has not been clearly identified. Food allergy symptoms are typically demonstrated within hours of eating. Initially, the person is asked to keep a diary of foods consumed and allergic responses for a week. An elimination diet is then prescribed. The diet excludes most common food allergens and all suspected foods for one week. Any foods that may contain allergens in combination, such as breads, are also eliminated. If symptoms do not improve, a different variation of the elimination diet is prescribed. If symptoms are relieved, foods are reintroduced to the diet one at a time until symptoms recur, indicating allergy to that food.

Medications

When it is impossible to avoid the offending allergen and allergic manifestations are severe or disrupt the person's activities of daily living (ADLs), pharmacological intervention is prescribed. *Immunotherapy*, also called hyposensitisation or desensitisation, consists of injecting an extract of the allergen(s) in gradually increasing doses. Immunotherapy is used primarily for allergic rhinitis or asthma related to inhaled allergens. It has also been shown to be effective in preventing anaphylactic responses to insect venom. With weekly or biweekly subcutaneous injections of the allergen, the person develops IgG antibodies to the allergen that appear to block effectively the allergic IgE-mediated response. Once a therapy plateau is reached, injections are continued indefinitely either monthly or bimonthly.

Antihistamines are the major class of drugs used in treating the symptoms of hypersensitivity responses, type I in particular. They are also useful to some extent in relieving manifestations (such as urticaria) of some type II and type III reactions.

Antihistamines block H1-histamine receptors, acting as a competitive antagonist to histamine, but they do not affect the production or release of histamine. The prototype antihistamine is diphenhydramine (Benadryl). It and other antihistamines alleviate the systemic effects of histamine such as urticaria and angio-oedema. They are also useful in relieving allergic rhinitis, although they are not effective in all people. Antihistamines are available in both prescription and nonprescription preparations. The preferred route of administration is oral, although diphenhydramine and others can be given parenterally, particularly when immediate action is needed, as

in anaphylaxis. They also dry respiratory secretions through an anticholinergic effect. Their use is limited by their side effects, especially drowsiness and dry mouth. Antihistamines are not effective in relieving asthmatic responses to allergens and may actually worsen symptoms by their drying effect on respiratory secretions.

Antihistamines are often combined with a sympathomimetic agent such as pseudoephedrine to improve their decongestant activity and counteract their sedative effect. Antihistamines and decongestants are discussed further in Chapter 34.

The immediate treatment for anaphylaxis is parenteral adrenaline, an adrenergic agonist (sympathomimetic) drug that has both vasoconstricting and bronchodilating effects. These qualities, combined with its rapid action, make adrenaline ideal for treating an anaphylactic reaction. For mild reactions with wheezing, pruritus, urticaria and angio-oedema, preferably an intramuscular injection of 0.3 to 0.5 mg (adults) of 1:1000 adrenaline is generally sufficient and can be repeated every 5 minutes if required as per the organisational protocol. Intravenous adrenaline using a 1:100 000 concentration may be used in the person with a more severe anaphylactic reaction. Refer to the organisational protocols, guidelines and doctor's orders.

People who have experienced an anaphylactic reaction to insect venom or other potentially unavoidable allergens should wear a Medic-Alert® pendant or bracelet identifying allergy triggers. They should also carry an adrenaline autoinjector kit for immediate treatment of future exposures. The adrenaline autoinjector kit contains a prefilled syringe of adrenaline (epinephrine), allowing prompt self-treatment or, in an emergency, administration by a person who has not been medically trained.

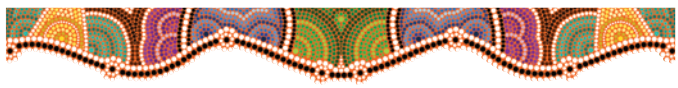
Cromolyn sodium is a drug used to treat allergic rhinitis and asthma. Cromolyn sodium acts by stabilising the mast cell membrane, thus preventing chemical mediator release (Lehne, 2012). It is most effective when applied directly to involved tissue by inhaler or nasal spray. It has few side effects and a wide margin of safety, making it a good choice for people in whom it is effective (Papadakis et al., 2013).

Glucocorticoids (corticosteroids) are used in both systemic and topical forms for many types of hypersensitivity responses. Their anti-inflammatory effects, rather than their immunosuppressive effects, are of most benefit. A short course of corticosteroid therapy is often used for severe asthma, allergic contact dermatitis and some immune-complex disorders: alternate day dosing is preferred in long-term use (Papadakis et al., 2013). Corticosteroids in topical forms or delivered by inhaler may be used for longer periods of time with few side effects; however, systemic absorption can occur.

Other therapies

Other treatments used for hypersensitivity responses are generally dictated by the severity of the response and the organ system affected. Airway management takes highest priority for the person with an acute anaphylactic reaction. Insertion of an endotracheal tube or emergency tracheostomy may be required to maintain airway patency with severe laryngospasm. Because anaphylaxis places the person at risk of vasomotor collapse and significant hypotension, it is necessary to insert an intravenous line and initiate fluid resuscitation with an isotonic solution such as compound sodium lactate (Hartmann's solution).

Plasmapheresis, removal of harmful components in the plasma, may be used to treat immune complex responses such as glomerulonephritis and Goodpasture's syndrome. Plasma and the glomerular-damaging antibody–antigen complexes are removed by passing the person's blood through a blood cell separator. The RBCs are then returned to the person along with an equal amount of albumin or human plasma. This procedure is usually done in a series rather than as a one-time treatment. It is not without risk and informed consent is required. Potential complications of plasmapheresis include those associated with intravenous catheters, shifts in fluid balance and alteration of blood clotting.



Nursing care

Nursing care related to hypersensitivity reactions is primarily directed towards prevention, early identification and providing prompt, effective treatment.

Health promotion

Health promotion activities include helping people to identify possible allergens that prompt a hypersensitivity response and discussing possible strategies to avoid these allergens. Anyone with severe food allergies may need assistance from a dietitian to discuss necessary dietary changes and ways to continue meeting nutrient needs. It is important that people with hypersensitivities inform healthcare personnel of all allergens. People who experience anaphylactic reactions should wear a MedicAlert® bracelet or pendant at all times to identify the substance(s) that provokes this response. Patients who have experienced an anaphylactic reaction to insect venom or other potentially unavoidable allergens may also be required to carry an adrenaline autoinjector (commonly known as an Epipen®) on their person at all times. The need to carry the adrenaline autoinjector is on a prescription basis and is only offered in conjunction with a full anaphylaxis management plan (ASCIA, 2010).

Assessment

Collect the following data through the health history and physical examination. Further focused assessments are described with nursing interventions in the next section.

- *Health history:* risk factors, hypersensitivities (medications, household dust, bee stings, etc.), reaction (rash, hives, difficulty breathing), type of treatment for hypersensitivity reactions; allergy skin testing; asthma, hay fever or dermatitis.
- *Physical assessment:* mucous membranes of nose and mouth, skin for lesions or rashes, eyes (tearing and redness), respiratory rate and adventitious breath sounds.

Nursing diagnoses and interventions

Priority nursing diagnoses will vary according to the type of hypersensitivity reaction experienced by the person. Because nurses are most likely to become involved with a person

experiencing a type I or type II response, this section focuses on diagnoses for these people. Airway, breathing and circulation (the ABCs) are of greatest importance for people with an anaphylactic reaction. When a haemolytic reaction to an incompatible blood transfusion occurs, the person is at risk of injury.

CONSIDERATION FOR PRACTICE

Anaphylaxis is a life-threading emergency. Maintain ABC (airway, breathing, circulation) and, if alone, call for help.

Ineffective airway clearance

In anaphylactic reactions, the airway may be obstructed due to facial angio-oedema, bronchospasm or laryngeal oedema. Establishing and maintaining a patent airway is of highest priority.

- Administer oxygen via nasal prongs at a rate of 2 to 4 L/min or facemask at a rate of > 6 L/min. Apply oxygen and obtain a doctor's order for oxygen administration as per the organisational protocol. *Oxygen administration increases the alveolar oxygen and its availability to cells of the body.*
- Assess respiratory rate and pattern, level of consciousness and anxiety, nasal flaring, use of accessory muscles of respiration, chest wall movement, audible stridor; palpate for respiratory excursion; auscultate lung sounds and any adventitious sounds, such as wheezes. *Extreme anxiety or agitation, nasal flaring, stridor and diminished lung sounds indicate air hunger and possible airway obstruction, necessitating immediate intervention.*
- Position in Fowler's to high Fowler's *to promote optimal lung expansion and ease of breathing*.
- Insert a nasopharyngeal or oropharyngeal airway if required and arrange for immediate intubation as indicated. *Ensuring an adequate airway is vital to preserve life.*
- Administer intramuscular adrenaline 1:1000, 0.3 to 0.5 mL, as prescribed. This may be repeated if necessary as per the prescribed protocol. Administer parenteral antihistamine (deep intramuscular or intravenous) as prescribed. *Adrenaline is a potent vasoconstrictor and bronchodilator, counteracting the effects of histamine. An antihistamine (e.g. promethazine hydrochloride) blocks histamine receptors and their effect. These medications can be effective in rapidly reversing manifestations of anaphylaxis*.
- Provide calm reassurance. Hypoxaemia and air hunger are terrifying for the person. *Anxiety can impair the person's ability to cooperate with treatment and can increase the respiratory rate, making breathing less effective.*

Decreased cardiac output

Peripheral vasodilation and increased capillary permeability from the release of histamine can significantly impair cardiac output. When it falls to the degree that tissue perfusion becomes impaired and hypoxia results, a state of anaphylactic shock exists.

- Monitor vital signs frequently, noting fall in blood pressure, decreasing pulse pressure, tachycardia and tachypnoea. *These vital sign changes may be early indicators of shock.*
- Assess skin colour, temperature, capillary refill, oedema and other indicators of peripheral perfusion. *As cardiac output falls, peripheral vessels constrict and tissue perfusion is impaired.*
- Monitor level of consciousness. *A change in level of consciousness (lethargy, apprehension or agitation) is often the first indicator of decreased cardiac output.*
- Insert one or more large-bore (18-gauge or larger) intravenous catheters. *It is important to insert intravenous catheters as soon as possible to provide sites for rapid fluid replacement.*
- Administer intravenous solutions of normal saline 0.9% or compound sodium lactate, as prescribed. These isotonic solutions help maintain intravascular volume. *Warmed solutions are used to prevent hypothermia from the rapid administration of large amounts of fluid at room temperature (about 21.1°C).*
- Insert an indwelling catheter and monitor urinary output frequently. As the cardiac output drops, the glomerular filtration rate (GFR) falls. *With an output of less than 30 mL/h, the person is at risk of acute renal failure from ischaemia.*

CONSIDERATION FOR PRACTICE

Aggressive fluid therapy may lead to hypervolaemia and acute cardiogenic pulmonary oedema; assess for shortness of breath and crackles in the lungs.

- Once breathing is established safely and maintained, place the person flat with the legs elevated. *This position enhances perfusion of the central organs, such as the brain, heart and kidneys.*

Risk of injury

As noted, the potential for hypersensitivity responses is high in people subjected to medical treatments. Because a blood transfusion is a transplant of living tissue, the risk of adverse immunological response and injury is particularly significant.

- Obtain and record a thorough history of previous blood transfusions and any reactions experienced, *no matter how mild*. Alert the doctor if previous transfusion reactions have occurred. *The person who has received prior blood transfusions is at increased risk of a hypersensitivity reaction, because antibody production may have been stimulated by prior exposure to antigens.*

CONSIDERATION FOR PRACTICE

Begin a blood transfusion within 30 minutes of its delivery from the blood bank to reduce bacterial contamination.

- Check for a signed informed consent as per organisational protocol to administer blood or blood products. *It is important to obtain informed consent for this invasive and risky procedure.*
- Using two registered healthcare professionals, double-check the person's identity, blood type, Rh factor,

crossmatch and expiration date for all blood and blood components received from the blood bank with the person's data. *Check bag for signs of leakage, clots and discolouration. This is an important safety measure to reduce the risk of a haemolytic transfusion reaction due to incompatible blood types.*
- Take and record vital signs within 15 minutes prior to initiating the blood infusion. *This provides a baseline for evaluating any changes related to the blood transfusion.*
- Infuse blood into a site separate from any other intravenous infusion. Use at least a 20-gauge cannula for the infusion to promote flow. This reduces the risk of damage to the blood cells due to incompatibility with other intravenous solutions or physical trauma. *When blood is administered with dextrose solutions (e.g. dextrose 5%, dextrose 5% and normal saline 0.9%), blood cell haemolysis and aggregation occur; administration with Hartmann's can cause agglutination of cells. Administer with normal saline to prime intravenous tubing.*
- Remain with the person for the first 15 minutes of the transfusion (from when the blood enters the vein) and observe for reactions. *Reactions generally occur within the first 15 minutes.*
- During transfusion, monitor observations as per organisational protocol and monitor for complaints of back or chest pain, an increase in the temperature of more than 1˚C, chills, tachycardia, tachypnoea, wheezing, hypotension, hives, rashes or cyanosis. *These signs may indicate an adverse reaction to the blood transfusion.*
- Stop the blood transfusion immediately if a reaction occurs, no matter how mild. Remove the blood bag and the tubing with blood in it. Flush new intravenous tubing with normal saline, keeping the intravenous line open. Notify the doctor and the transfusion service provider.
- If a reaction is suspected, send the blood and administration set to the transfusion service provider with a freshly drawn blood sample and urine specimen from the person. *These will be used to identify the cause of the reaction as well as its effect on the person.*
- If no adverse reaction occurs, administer the transfusion over 2 hours to a maximum of 4 hours as ordered. *This time frame is important to limit the risk of bacterial growth.*

Community-based care

The vast majority of hypersensitivity responses are appropriately treated by the person or family members with little or no medical intervention. Teaching, therefore, is a vital component of care. If the person is at risk of anaphylaxis, involving the family in teaching is essential because the response may occur with such rapidity that the person will be unable to provide self-care.

Include the following points in teaching the person and family about managing hypersensitivities:
- Importance of following the anaphylaxis action plan prepared by a general practitioner.
- When and how to use an anaphylaxis autoinjector pen containing adrenaline and antihistamines in injectable, inhaler and oral forms.
- When to seek medical attention.
- Use of and adverse reactions to prescription and non-prescription antihistamines and decongestants.
- Advantages of autologous blood transfusion if future surgery is scheduled.
- Preventing an immune complex reaction such as glomerulonephritis.
- Skin care to prevent contact dermatitis, including:
  - Expose affected areas to air and sun as much as possible.
  - Avoid direct contact with people who have an infection.
  - Wear cool, light, non-restrictive clothing made of natural fibres, such as cotton, to avoid irritating affected areas.
  - Avoid exposure to extremes of heat or cold.
  - Use bath oils or plain water instead of soaps and detergents.
  - Take baths in cool to lukewarm water rather than showers.
  - To decrease pruritus, maintain a cool environment and avoid exercising.
  - Trim fingernails to reduce the risk of skin damage.

THE PERSON WITH AN AUTOIMMUNE DISORDER

Maintaining optimal health and preventing disease depends not only on the immune system's ability to recognise and destroy foreign tissues and other antigens, but also on the immune system's ability to recognise self. When this self-recognition is impaired and immune defences are directed against normal host tissue, the result is an **autoimmune disorder**.

Autoimmune disorders can affect any tissue in the body. Some are tissue or organ specific, affecting particular tissue or a particular organ. Hashimoto's thyroiditis is an example of an organ-specific autoimmune disorder. Circulating antibodies are formed to certain thyroid components, resulting ultimately in destruction of the gland. In other disorders, autoantibodies are formed that are not tissue specific, but tend to accumulate and cause an inflammatory response in certain tissue—for example, the renal glomerulus or the hepatic small bile ductules.

Additional factors are believed to contribute to the development of autoimmune disorders including age, gender and environmental elements—for example, infectious agents (Diamond & Lipsky, 2012). Autoimmune disorders may also be systemic, with neither antibodies nor the resulting inflammatory lesions confined to any one organ. Rheumatological disorders, such as rheumatoid arthritis and systemic lupus erythematosus (SLE), are characteristic of systemic autoimmune disorders (Goldsby et al., 2003). A list of selected autoimmune disorders is included in Table 12.1.

Pathophysiology

The mechanism that causes the immune system to recognise host tissue as a foreign antigen is not clear. The following factors are under study as possible contributors to the development of autoimmune disorders:

- the release of previously 'hidden' antigens into the circulation, such as DNA or other components of the cell nucleus, which elicit an immune response
- chemical, physical or biological changes in host tissue that cause self-antigens to stimulate the production of autoantibodies
- the introduction of an antigen, such as a bacteria or virus, whose antigenic properties closely resemble those of host tissue, resulting in the production of antibodies that target not only the foreign antigen but also normal tissue. Heart damage in rheumatic fever and encephalitis following rabies vaccination are examples of the development of antibodies against normal tissue (Porth & Matfin, 2009)
- a defect in normal cellular immune function that allows B cells to produce autoantibodies unchecked
- initiation of the autoimmune response by very-slow-growing mycobacteria.

Although the exact mechanism producing autoimmunity is unclear, several characteristics of autoimmune diseases are known. It is apparent that genetics plays a role because a higher incidence is seen in family members of people with autoimmune disorders. Autoimmune disorders are far more prevalent in females than in males. The disorders tend to overlap, so that the person with one autoimmune disorder may develop another or some manifestations of another. The onset of an autoimmune disorder is frequently associated with an abnormal stressor, either physical or psychological. Autoimmune disorders are frequently progressive relapsing–remissing disorders characterised by periods of exacerbation and remission.

Specific autoimmune disorders are discussed in the sections of this textbook related to the affected organ systems or functional disruption.

INTERPROFESSIONAL CARE

For the most part, the diagnosis of an autoimmune disorder is based on the person's clinical manifestations. Serum assays are useful to identify autoantibodies. Other diagnostic tests are generally specific to the suspected disorder and to identifying the degree of tissue damage and destruction. Although the manifestations of these disorders can often be managed, a cure typically is not possible unless the affected target tissue is removed (e.g. colectomy for the person with ulcerative colitis).

Diagnosis

Serological assays are used to identify and measure antibodies directed towards host tissue antigens or normal cellular components. Many detectable autoantibodies are not specific to a single autoimmune disorder and are used to establish the autoimmune process rather than the specific disorder. Although healthy people often have low levels of autoantibodies, levels are much higher in people affected by an autoimmune disorder. The following serological assays may be ordered:

- *Antinuclear antibody (ANA)* detects antibodies produced to DNA and other nuclear material. These antibodies can cause tissue damage characteristic of autoimmune disorders, such as SLE. The person's serum is combined with nuclear material and tagged antihuman antibody to detect ANA–antihuman antibody complexes. Titres are not necessarily comparable between laboratories; refer to the laboratory reference levels. This test is not specific for SLE, because high levels of ANA may be present in rheumatoid arthritis (RA) and cirrhosis of the liver; nevertheless, 95% of people with SLE have a positive ANA titre.
- *Lupus erythematosus (LE) cell test* is also used to detect SLE and monitor its treatment. Neutrophils that contain large masses of phagocytised DNA from the nuclei of PMNs are called LE cells. Like the ANA, the LE cell prep is non-specific for SLE. A positive result may also be seen in RA or with medications such as isoniazid, penicillin, phenytoin, procainamide, streptomycin, tetracycline, oral contraceptives or sulfonamide drugs.
- *Rheumatoid factor (RF)* is an immunoglobulin present in the serum of approximately 80% of people with rheumatoid arthritis. Low titre levels may be present in the elderly. An RF titre 1:80 or higher indicates RA. A titre between 1:20 and 1:80 could indicate SLE, scleroderma or liver cirrhosis (Pagana & Pagana, 2013). Reference factors are variable; refer to the laboratory reference range.
- *Complement assay* may also be useful in identifying autoimmune disorders. In these disorders, complement may be consumed in the development of antigen–antibody complexes. Decreased levels are seen on examination. Both total complement level and amounts of individual components of the complement cascade can be determined.
- *CCP (also known as anti-CCP antibody test)* is a blood test for RA. It measures cyclic citrullinated peptide antibody in the blood. This is a specific test to identify RA from other forms of arthritis.

Medications

Various approaches are used in the treatment of autoimmune disorders. Anti-inflammatory medications such as aspirin, non-steroidal anti-inflammatory drugs (NSAIDs) and corticosteroids may be prescribed to reduce the inflammatory response and minimise tissue damage. (Refer to Chapter 8 for additional detail on these drugs.) When these agents are not effective or well tolerated by the person, slow-acting anti-inflammatory medications may be prescribed. Slow-acting or antirheumatic drugs include such medications as gold salts, hydroxychloroquine and penicillamine. Their use is further detailed in Chapter 39. Cytotoxic drugs may be used in combination with plasmapheresis in treating many autoimmune disorders. Cytotoxic drugs are discussed in further detail in the next

section of this chapter. Disease-modifying antirheumatic drugs (DMARDs) reduce signs and symptoms, reduce or prevent joint damage, and preserve the structure and function of the joints in people with RA. These drugs may reduce health costs for people with RA and allow them to remain active and productive. The most common DMARDs in current use are methotrexate, sulfasalazine, hydroxychloroquine, leflunomide and cyclosporin.

Another class of antirheumatic drugs, referred to as *biologicals* or *biological response modifiers*, consists of laboratory-produced proteins that decrease the inflammatory process. These antibodies bind tumour necrosis factor alpha (TNF-α) and interleukin-1, both inflammatory elements. These medications include infliximab or adalimumab, etanercept and anakinra.

Nursing care

Nursing interventions for the person with an autoimmune disorder are individualised and tailored to needs dictated by manifestations of the disorder. Nurses will often be involved with the person in an outpatient setting such as an office or home, evaluating the person's response to therapy and self-care management.

Consider the following nursing diagnoses in planning care for the person with an autoimmune disorder:

- *Risk of activity intolerance* related to inflammatory effects of autoimmune disorder.
- *Risk of ineffective coping* related to chronic disease process.
- *Risk of interrupted family processes* related to lack of understanding about autoimmune disorder and its effects.
- *Risk of ineffective protection* related to disordered immune function.
- *Risk of ineffective therapeutic regimen management* related to lack of understanding.

Community-based care

Because many autoimmune disorders are chronic, educating the person and family about the disorder and its management is a key nursing care component. The person may be taking drugs with multiple side effects or long-term effects, necessitating effective education. People with autoimmune disorders often do not appear to be ill, making it difficult for friends and families to understand their care needs. The chronicity of these disorders also puts the person at high risk of unproven remedies and quackery. Provide psychological support, listening and teaching. In addition, suggest resources such as local support groups.

THE PERSON WITH A TISSUE TRANSPLANT

Since the first kidney transplant was performed from one identical twin to the other in 1954, organ and tissue transplantation have become increasingly popular and viable treatment options. The transplantation of avascular tissues, such as skin, cornea, bone and heart valves, is considered routine, with little need for tissue matching and **immunosuppression**. Transplants of organs (e.g. the kidney, heart, heart and lung, liver and bone marrow) are increasingly common and are no longer considered experimental or extraordinary procedures. In 2014, 378 organ donors gave 1117 Australians a new chance at life, the highest number since the commencement of Australian record keeping (Australian Government Organ and Tissue Authority, 2015). Common organ transplants are outlined in Table 12.2.

Transplant success is closely tied to obtaining an organ with tissue antigens as close to those of the recipient as possible. As noted earlier in this chapter, every body cell has cell

TABLE 12.2 Organ transplants

ORGAN	GRAFT TYPE	INDICATIONS FOR TRANSPLANT	SUCCESS RATE
Kidney	Allograft; may be isograft	End-stage renal disease	81.1% at 5 years
Heart	Allograft	End-stage cardiac disease refractory to medical management	74.4% at 5 years
Lung	Allograft	Pulmonary hypertension, cystic fibrosis, pulmonary fibrosis, chronic obstructive pulmonary disease	52.6% at 5 years
Liver	Allograft	Severe liver dysfunction due to chronic active hepatitis, primary biliary cirrhosis, sclerosing cholangitis	73.6% 5-year survival
Bone marrow	Autograft or allograft	Leukaemia, aplastic anaemia, congenital immunological defects	30–70% cure
Skin	Autograft, allograft or xenograft	Severe burns, plastic surgery	> 95% at 5 years
Cornea	Allograft	Corneal ulceration and opacification	> 95% at 5 years
Pancreas	Allograft	Pancreatic insufficiency, diabetes	88.1%
Islet cells	Allograft (multiple donor)	Type 1 diabetes mellitus	100% > 2 years

surface antigens known as human leucocyte antigens that are unique to the individual. Although identical twins may have the same HLA type, the chance is reduced to 1 in 4 for siblings and less than 1 in several thousand for unrelated individuals (Papadakis et al., 2013). Matching the HLA type of the donor and recipient as closely as possible decreases the potential for rejection of the transplanted organ or tissue but does not eliminate it.

Pathophysiology

An **autograft**, a transplant of the person's own tissue, is the most successful type of tissue transplant. Skin grafts are the most common example of autografts. Increasingly, autologous bone marrow transplants and blood transfusions are being used to reduce immunological responses. When the donor and recipient are identical twins, the term **isograft** is used. Because of the high likelihood of an HLA match, the success of these grafts is good and rejection episodes are mild.

Few people, however, have an identical twin to provide tissue for donation and when the need is for an organ such as the heart, liver or lungs, a living-donor transplantation is not possible. Most often organ and tissue transplants are **allografts**, which are grafts between members of the same species but who have different genotypes and HLA. Allografts may come from living donors; examples are bone marrow, blood and a kidney. Most often, however, organs for transplantation are obtained from a cadaver. Donors are typically people who meet the criteria for brain death, are less than 65 years old, and are free of systemic disease, malignancy or infection, including HIV, hepatitis B or hepatitis C. The organ is removed immediately before or after cardiac arrest and preserved until it is transplanted into the waiting recipient. Finally, **xenograft** is a transplant from an animal species to a human. These transplants are the least successful but may be used in selected instances, such as the use of pigskin as a temporary covering for a massive burn.

Tissue typing is used to determine **histocompatibility**, the ability of cells and tissues to survive transplantation without immunological interference by the recipient. Tissue typing is performed in an attempt to match the donor and recipient as closely as possible for HLA type and blood type (ABO, Rh) and to identify preformed antibodies to the donor's HLA.

Both antibody-mediated and cell-mediated immune responses are involved in the complex process of transplant rejection. Host macrophages process donor antigen, presenting it to T and B lymphocytes. Activated lymphocytes (B and T cells) produce both antibody- and cell-mediated effects. Killer T cells bind with cells of the transplanted organ, resulting in cell lysis. Helper T cells stimulate the multiplication and differentiation of B cells, and antibodies are produced to graft endothelium. Complement activation or antibody-dependent cell-mediated cytotoxicity leads to transplant cell destruction. Rejection typically begins after the first 24 hours of the transplant, although it may present immediately. Rejection episodes are characterised as hyperacute, acute or chronic, as summarised in Table 12.3.

Hyperacute tissue rejection occurs immediately to 2 to 3 days after the transplant of new tissue. Hyperacute rejection is due to preformed antibodies and sensitised T cells to antigens in the donor organ. Hyperacute rejection is most likely to occur in people who have had a previous organ or tissue transplant, such as a blood transfusion. Hyperacute rejection may be evident even before the transplant procedure is completed. The grafted organ initially appears pink and healthy, but soon becomes soft and cyanotic, as blood flow is impaired. Organ function deteriorates rapidly and symptoms of organ failure develop.

Acute tissue rejection is the most common and treatable type of rejection episode. It occurs between 4 days and 3 months after the transplant. Acute rejection is mediated primarily by the cellular immune response, resulting in transplant cell destruction. The person experiencing acute rejection demonstrates manifestations of the inflammatory process, with fever, redness, swelling and tenderness over the graft site. Signs of impaired function of the transplanted organ may be noted (e.g. elevated blood urea nitrogen (BUN) and creatinine, liver enzyme and bilirubin elevations, or elevated cardiac enzymes and signs of cardiac failure).

TABLE 12.3 Transplant rejection episodes

TYPE	CAUSE	PRESENTATION	TREATMENT
Hyperacute	Pre-existing antibodies to donor ABO or HLA antigens	Occurs within minutes to hours or days of the transplant Rapid deterioration of organ function	The transplant usually cannot be saved; prevent with crossmatch and use antimetabolites or anti-inflammatory drugs before surgery
Acute	Primarily a cell-mediated immune response to HLA antigens; antibody-mediated response may also contribute	Occurs within days to months after the transplant Signs of inflammation and impaired organ function	Increase immunosuppression using steroids, cyclosporin, monoclonal antibodies or antilymphocyte globulins
Chronic	Probably antibody-mediated response; may also involve inflammatory damage to vessel endothelium	Occurs 4 months to years after the transplant Gradual deterioration of organ function	None; loss of graft will occur, requiring retransplant

Chronic tissue rejection occurs from 4 months to years after transplant of new tissue. Chronic rejection is most likely the result of antibody-mediated immune responses. Antibodies and complement are deposited in transplant vessel walls, causing narrowing and decreased function of the organ due to ischaemia. The gradual deterioration of transplanted organ function is seen with chronic tissue rejection.

Graft-versus-host disease (GVHD) is a frequent and potentially fatal complication of bone marrow transplant. When there is no close match between donor and recipient HLA, immunocompetent cells in the grafted tissue recognise host tissue as foreign and mount a cell-mediated immune response. If the host is immunocompromised, as is often the case when a bone marrow transplant is performed, host cells are unable to destroy the graft and instead become the targets of destruction. Of people with very closely matched bone marrow, 30% to 60% nevertheless develop GVHD. Acute GVHD occurs within the first 100 days following a transplant and primarily affects the skin, liver and gastrointestinal tract. The person develops a maculopapular pruritic rash beginning on the palms of the hands and soles of the feet. The rash may spread to involve the entire body and lead to desquamation. Gastrointestinal manifestations include abdominal pain, nausea and bloody diarrhoea. GVHD that lasts longer than 100 days is said to be chronic. If it is limited to the skin and liver, the prognosis is good. If multiple organs are involved, the prognosis is poor (Porth & Matfin, 2009).

INTERPROFESSIONAL CARE

Pre-transplant and post-transplant care are directed towards reducing the risk that transplanted tissue will be rejected or result in GVHD. Diagnostic studies are directed first at identifying a suitable donor, then at monitoring the immune response to the transplant. Immunosuppressive therapy with medications is a vital part of post-transplant care. Indeed, the development of effective immunosuppressive drugs is responsible for the success of organ transplants using allografts.

Diagnosis

The following diagnostic tests may be ordered prior to organ or tissue transplantation:

- *Blood type and Rh factor* of both the donor and recipient are determined. Although there is some question about the benefit of histocompatibility testing prior to transplant of a cadaver organ, there is no question about the need for ABO blood group compatibility.
- *Crossmatching* of the person's serum against the donor's lymphocytes is performed to identify any preformed antibodies against antigens on donor tissues. If present, these antibodies would likely result in an immediate or hyperacute graft rejection with probable loss of the transplant.
- *DNA sequencing* is made on blood cells to determine histocompatibility. Sequencing can be completed quickly. Quick response is important to minimise cold ischaemia in cadaverous organs. Diagnostic testing for recipients can be done less urgently.
- *HLA histocompatibility testing* identifies donors with an HLA type close to that of the recipient. It is used primarily to identify living donors for bone marrow and kidney transplant. Because of GVHD, histocompatibility tests to identify an identical or very close HLA match are particularly important in bone marrow transplant. HLA tests are performed using lymphocytes from a blood sample. The sample should not be obtained within 72 hours of a blood transfusion, because this will interfere with results.
- *Mixed lymphocyte culture (MLC) assay tests* also are used to determine histocompatibility between the donor and the recipient. This test identifies whether mononuclear cells of the recipient will react against the potential donor's leucocyte antigens. The disadvantage of this test is that results cannot be obtained until 7 to 10 days later (Chernecky & Berger, 2004). If the intended recipient is severely immunocompromised, the results may be falsely negative. People treated with chemotherapy within 2 weeks of specimen collection are potentially immunocompromised.
- *Ultrasonography* or magnetic resonance imaging (MRI) of the transplanted organ may be performed to evaluate its size, perfusion and function.
- *Tissue biopsies* of the transplanted organ are performed routinely to assess for evidence of tissue rejection.

Medications

Prior to transplantation, several antibiotic and antiviral drugs may be prescribed, including the following:

- trimethoprim-sulfamethoxazole, which decreases the incidence of gram-negative bacterial infections
- aciclovir, which prevents the development of the herpes simplex virus and pneumonia in bone marrow transplant recipients
- ganciclovir, which prevents the development of cytomegalovirus (CMV) pneumonia in bone marrow transplant recipients.

The mainstays of drug therapy for people following a tissue or organ transplant are immunosuppressive agents. Varying regimens of these drugs are used, depending on the transplanted tissue and the medical centre; however, a combination of corticosteroids and cyclosporin is common for maintenance therapy (see Figure 12.6). Antilymphocyte therapy and the use of monoclonal antibodies are increasingly common in the immediate post-transplant period and for treating steroid-resistant rejection episodes.

Corticosteroids, primarily prednisone and methylprednisolone, were among the first medications used to prevent transplant rejection and they remain important agents today. Although the exact anti-inflammatory and immunosuppressive activity of corticosteroids is unknown, they are known to suppress production of interleukin-1 and -2, decrease monocyte migration and suppress proliferative and cytotoxic T-cell activity. Although they are very effective, large doses of corticosteroids used post-transplant are associated with significant adverse effects. Wound healing is impaired and the metabolism of fats, proteins and carbohydrates is altered. Blood glucose increases with steroid use, impairing glucose control. Fat distribution changes, producing a cushingoid appearance with

moon face, increased truncal fat and 'buffalo hump'. Fluid retention and hypertension are potential problems, as are osteoporosis, gastrointestinal bleeding and emotional disturbances.

Azathioprine has been in use as an immunosuppressant for more than 25 years and continues to be a component of many regimens. Azathioprine inhibits both cell-mediated and antibody-mediated immunity, although its activity is more specific for T cells than B cells. Because it is rapidly metabolised by the liver, azathioprine can be given to people with impaired renal function but may not be effective in people with impaired hepatic function. Bone marrow suppression is the most common adverse effect of this drug, necessitating frequent evaluation of the full blood count (FBC). Hepatotoxicity, pancreatitis and increased risk of neoplasm are also associated with azathioprine administration. Nursing responsibilities related to azathioprine are listed in the following 'Medication administration' box. People who cannot tolerate azathioprine may receive a newer immunosuppressant, mycophenolate mofetil. Primarily, it is prescribed following renal and cardiac transplants.

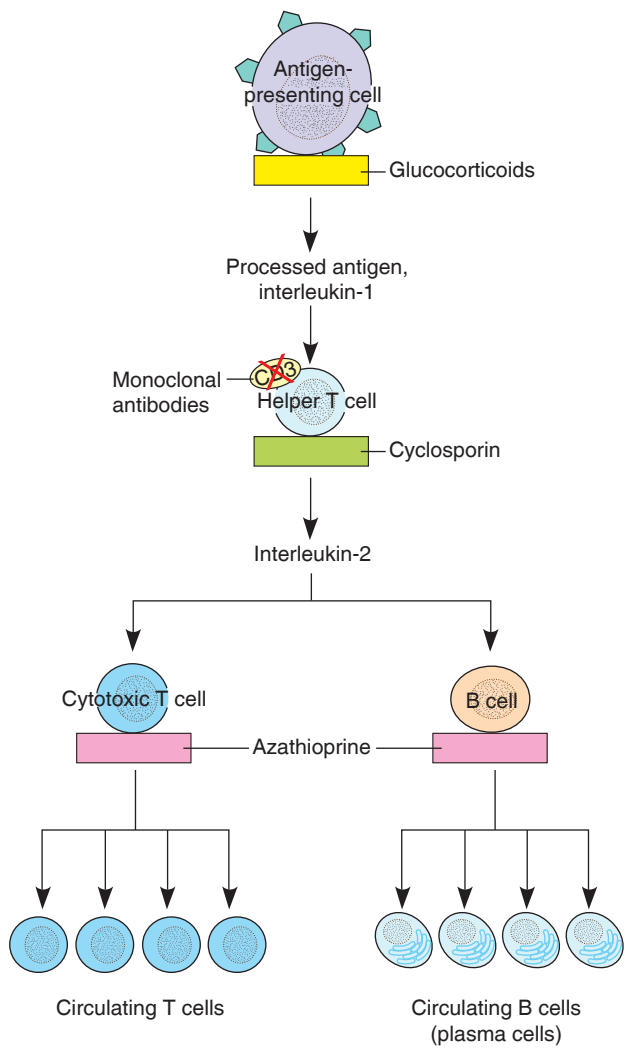

FIGURE 12.6 ■ Sites of action of immunosuppressive agents

Cyclosporin inhibits T-cell function and the normal cell-mediated immune response. The incidence of cyclosporin toxicity and side effects is related to blood levels, so blood levels are monitored closely. Cyclosporin is both nephrotoxic and hepatotoxic, especially at high doses. Observable toxic effects include hypertension and CNS symptoms such as flushing or tingling of the extremities, confusion, visual disturbances and seizures or coma.

Muromonab-CD3, also known as OKT3, is the first monoclonal antibody produced for therapeutic use in humans. As a monoclonal antibody, OKT3 is specific to T cells, blocking their generation and function. It binds with a surface antigen on T cells, inactivating and removing them from circulation. It also blocks killer T cells attached to the graft. Because of significant side effects, the use of OKT3 is limited primarily to treatment of steroid-resistant rejection. Two newer monoclonal antibodies, basiliximab (Simulect) and daclizumab (Zenapax), are a combination of mouse and human antibodies and cause fewer side effects.

Polyclonal antilymphocyte antibodies are also used as adjunctive immunosuppressant therapy. These are administered as antilymphocyte globulin (ALG) or antithymocyte globulin (ATG). These globulins contain antibodies against both T and B cells, as well as other mononuclear leucocytes. When administered, they deplete circulating lymphocytes, platelets and granulocytes.

Nursing care

The person who has an organ or tissue transplant has both immediate and long-term nursing care needs. Both the person and the family must be considered in providing nursing care.

Health promotion

Health promotion activities focus partly on preventing the need for a tissue transplant. It is important to increase public awareness regarding unhealthy lifestyle behaviours, such as excessive alcohol consumption and illegal drug use, and their relationship to organ failure. People with chronic diseases such as diabetes mellitus and hypertension must understand that inadequate management of these disorders could lead to end-stage renal disease. Other risk factors may simply relate to a person's heredity; it is important to understand how heredity could affect future health and might influence the person's lifestyle choices.

Assessment

Assessment data collected following a tissue transplant focus on identifying potential rejection episodes. Further focused assessments are described with nursing interventions in the next section.

Nursing diagnoses and interventions

Because of the continuing risk of transplant rejection and the need for immunosuppression, *Ineffective protection* and *Risk of impaired tissue integrity* are priority nursing care foci. The person's underlying disease process, the transplant and the

continuing need for immunosuppressive drug therapy also have emotional and psychological consequences. Many nursing diagnoses, such as *Powerlessness* or *Ineffective coping*, may be appropriate. The diagnosis *Anxiety* related to potential transplant rejection is considered in this section.

Ineffective protection

Ineffective protection is a problem for the transplant person at all stages. Before the transplant occurs, failure of the affected organ may put the person at risk of infection and other multisystemic problems. Incisions and invasive perioperative procedures impair skin and mucous membrane protection from infectious organisms and other antigens. Immunosuppressive drugs given postoperatively to prevent graft rejection disarm the immune response to a certain extent, increasing the risk of infections and neoplastic growths.

CONSIDERATION FOR PRACTICE

Use strict aseptic technique in changing dressings and caring for invasive catheters such as intravenous lines and indwelling urinary catheters to protect against external and resident host microorganisms.

- Wash hands on entering room and before providing direct care. *Handwashing removes transient organisms from the skin, reducing the risk of transmission to the person.*
- Assess frequently for signs and symptoms of infection. Monitor the temperature and vital signs every 4 hours. Assess for evidence of inflammation, abnormal wound drainage, changes in urine or other body secretions, complaints of pain or behaviour changes that may indicate infection. Culture abnormal wound drainage. The person on immunosuppressive therapy is more susceptible to infection, and the usual signs and symptoms may not be evident. Both the temperature and inflammatory response can be suppressed by therapy. *Prompt identification and intervention for infection is important in the immunosuppressed person.*
- Monitor laboratory values, including FBC and tests of organ function; report changes to the doctor. *An elevation in the WBC count with increased numbers of immature cells (bands) or a decline in function of the transplanted organ (e.g. a rising BUN and creatinine in the renal transplant person) may be early indications of infection or transplant failure.*
- Initiate reverse or protective isolation procedures as indicated by the person's immune status. *These procedures further protect the severely immunocompromised person from infection.*
- Instruct ill family members and visitors to avoid contact with the person. *A 'minor' upper respiratory infection can be a significant illness in the immunocompromised host.*
- Help ensure adequate nutrient intake, offering supplementary feedings as indicated or maintaining parenteral nutrition if necessary. *Adequate nutrition is important for healing and immune system function.*
- Change intravenous bags and tubing as per organisational protocol, generally every 24 hours, and change peripheral intravenous sites every 48 to 72 hours, unless contraindicated. Remove invasive catheters and lines as soon as they are no longer necessary. *Changing lines and sites is important to reduce bacterial contamination. Fewer invasive lines provide fewer sites for bacterial invasion of the body.*
- Emphasise the importance of washing hands thoroughly after using the bathroom and before eating. *This reduces the risk of infection with endogenous organisms.*
- Provide good mouth care. *Good mouth care reduces the population of oral microorganisms and helps maintain an intact mucous membrane lining.*
- Monitor for potential adverse effects of medications:
  - thrombocytopenia and possible bleeding
  - fluid retention with oedema and possible hypertension
  - loss of bone density, osteoporosis and possible pathological fractures
  - renal or hepatic toxicity
  - cardiac effects, particularly in the presence of fluid retention and hypervolaemia.

  Medications used to maintain immunosuppression and preserve the allograft have many potential adverse effects that can alter normal protective and homeostatic mechanisms.

Risk of impaired tissue integrity: allograft

As noted, the risk of transplant rejection is highest in the initial postoperative period, but it is never completely eliminated for the person who has had an allograft. The person who has had a bone marrow transplant has the additional risk of developing GVHD, which can affect the integrity of skin, mucous membranes and other organs.

- Administer immunosuppressive therapy as prescribed. *Suppression of the immune response is necessary to reduce the risk of graft destruction by normal immune responses and to preserve the graft's function.*
- Assess for evidence of graft rejection, including tenderness, erythema and swelling over the site; sudden weight gain, oedema and hypertension; chills and fever; malaise and an increased WBC count and sedimentation rate. Report any changes immediately. *Early identification of rejection allows adjustment of medication regimens and, possibly, preservation of the graft.*
- Monitor results of laboratory studies for function of the transplanted organ. *With a functional graft, results (e.g. renal or liver function studies) will improve; a functional decline may be an early indicator of rejection.*
- Assess for and report signs of GVHD immediately, including maculopapular rash, erythema of the skin and possible desquamation, hair loss, abdominal cramping and diarrhoea, or jaundice with elevated bilirubin and liver enzymes (AST, ALT). *GVHD is a potentially lethal complication in the immunosuppressed person and necessitates immediate intervention.*
- Stress the importance of maintaining immunosuppressive therapy and reporting signs of graft rejection promptly to the doctor. *Continued immunosuppression and prompt treatment of rejection are vital to preserving graft function.*

MEDICATION ADMINISTRATION Immunosuppressive agents

T-CELL SUPPRESSORS

Cyclosporin
Tacrolimus
Sirolimus

These drugs inhibit T-cell development and activation. They are given concurrently with a glucocorticoid and in combination with other immunosuppressants and inhibit immune system activity and organ rejection.

Nursing responsibilities

- Monitor BUN and creatinine for evidence of nephrotoxicity.
- Teach the signs and symptoms of infection unique to immunosuppressed individuals. A temperature of 38.1°C is significant evidence of infection. A sore throat may be a manifestation. Other signs and symptoms of inflammation and infection may be absent.
- Teach people good hygiene to avoid infection, with special emphasis on handwashing and avoiding infected individuals.
- Monitor blood pressure and availability and use of antihypertensive medications.
- Teach to avoid grapefruit juice, which can raise cyclosporin levels by 50% to 200% and increase the risk of toxicity. Sirolimus should not be taken with grapefruit juice. Sirolimus increases cholesterol and triglycerides. Lipid-lowering drugs may be necessary to prevent hyperlipidaemias.

CYTOTOXIC AGENTS

Azathioprine
Cyclophosphamide
Methotrexate
Mycophenolate

Certain drugs that are identified as cytotoxic or antineoplastic agents are effective as immunosuppressive agents. They act by decreasing the proliferation of cells within the immune system and are widely used to prevent rejection following a tissue or organ transplant. They are usually administered concurrently with corticosteroid therapy, allowing lower doses of both preparations and resulting in fewer side effects.

Nursing responsibilities

- Monitor blood count, with particular attention to the WBC and platelet counts. Notify the doctor of decreases in WBCs or platelet counts.
- Monitor renal and liver function studies, including creatinine, BUN, creatinine clearance and liver enzymes. Report abnormal levels to the doctor.
- Administer the drug as ordered. Administer oral preparations with food to minimise gastrointestinal effects. Antacids may be ordered.
- Have the person increase fluids to maintain good hydration and urinary output, void frequently and avoid taking the drug in the evening, which promotes dwelling of the drug in the bladder overnight.
- Monitor intake and output.
- Monitor for signs of abnormal bleeding, bleeding gums, bruising, petechiae, joint pain, haematuria and black or tarry stools.
- Use meticulous handwashing and other appropriate measures to protect the person from infection. Assess for signs of infection.
- Pulmonary fibrosis is a rare (< 1%) potential adverse effect of cyclophosphamides. Therefore, monitor respiratory function using pulmonary function studies, and monitor for clinical signs of dyspnoea or cough.

Health education for the person and family

- Avoid large crowds and situations where exposure to infection is probable.
- Report signs of infection—such as chills, fever, sore throat, fatigue or malaise—to the doctor.
- Use contraceptive measures to prevent pregnancy while on immunosuppressive therapy; these drugs are teratogenic.
- Avoid the use of aspirin or ibuprofen while taking these drugs. Report any signs of bleeding to the doctor. Many over-the-counter products contain aspirin; check labels for aspirin.
- With cyclophosphamide, amenorrhoea may occur. The menses will resume after the drug is discontinued.
- If taking cyclophosphamide, report any difficulty breathing or cough to the doctor.

MONOCLONAL ANTIBODY

Muromonab-CD3 or OKT3

This monoclonal antibody against T cells is formed by immunising a mouse with an antigen to produce a specific antibody. Lymphocytes producing the antibody, OKT3, are cloned and the antibody is harvested. When injected into humans, OKT3 binds with a surface antigen on T cells, removing them from circulation and inactivating those bound to allograft cells. Due to the high incidence of adverse effects, refer to the organisational protocol regarding the administration of initial and subsequent doses of OKT3 and to observation protocols following the administration of OKT3.

Nursing responsibilities

- Be sure a chest x-ray has been performed within 24 hours preceding initiation of OKT3 therapy and that no congestion is present. The risk of anaphylaxis is greater in the person with fluid overload.
- Premedicate as ordered with hydrocortisone, paracetamol and diphenhydramine to reduce potential adverse effects.
- Position the emergency trolley and/or emergency medications in the person's room or in proximity to it. Refer to the organisational protocol.
- Monitor vital signs following administration of OKT3 as per organisational protocols.
- Refer to the organisational protocols for administration of initial and subsequent doses of OKT3 and administer as per guidelines.

MEDICATION ADMINISTRATION Immunosuppressive agents (continued)

- Observe closely for potential adverse effects, including chills and fever; tachycardia; headache and tremor; hypertension or hypotension; nausea, vomiting and diarrhoea; chest pain, dyspnoea and wheezing.
- OKT3 can also cause anaphylaxis; observe for evidence of urticaria, angio-oedema, laryngeal oedema, wheezing or other signs of anaphylactic reaction.
- Monitor FBC for evidence of leucopenia or pancytopenia.
- Assess for infection. Remember that typical signs of infection, including symptoms such as fever and inflammation, may be masked or reduced by immunosuppressive therapy.

Health education for the person and family

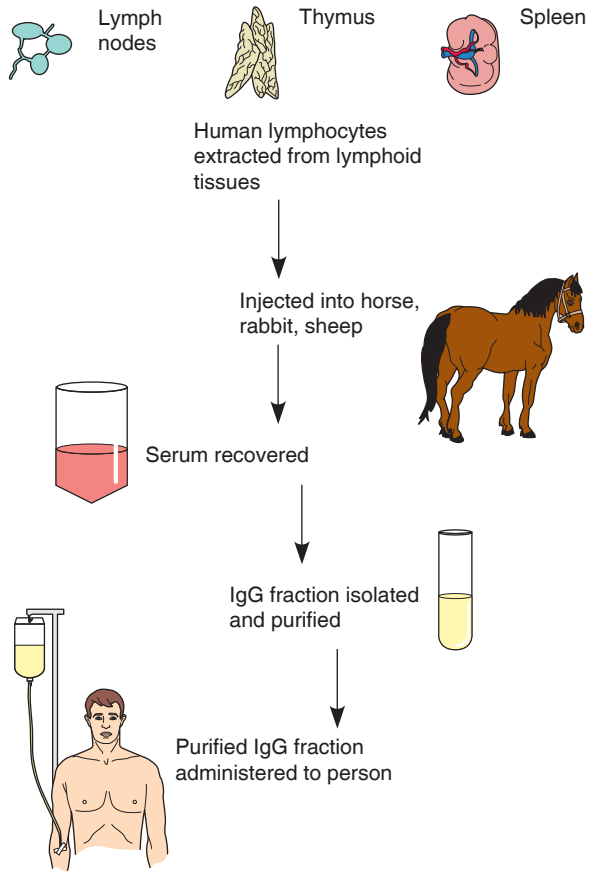
- Teach about the drug and its purpose.
- Discuss potential adverse and side effects and emphasise the need to report symptoms promptly.
- Inform the person that adverse effects are most likely to occur following the first two doses, necessitating close observation at that time. Reassure the person that this is standard protocol for this medication.

ANTILYMPHOCYTE GLOBULINS

Antithymocyte globulin or ATG (ATGAM)
Antilymphocyte globulin or ALG

These globulins containing antilymphocyte antibodies are produced by immunising horses (the main source), rabbits or sheep with human lymphocytes to stimulate production of antibodies (see figure). Serum from the animal is then recovered and the active IgG fraction is isolated, purified and administered parenterally to the person. It binds with peripheral lymphocytes and mononuclear cells, removing them from circulation.

ATG or ALG is used both to induce immunosuppression immediately following a transplant and to treat steroid-resistant rejection episodes. As with monoclonal antibody, multiple side effects are associated with ATG or ALG.



A horse is inoculated with washed human lymphocytes, stimulating the production of immunoglobulin with polyclonal antilymphocyte antibodies. These are then extracted from horse serum, purified, and administered intravenously to the person

Nursing responsibilities

- Ensure a skin test for sensitivity to horse serum has been carried out prior to initial dose. Report any positive reaction to the doctor and hold administration until desensitisation therapy has been completed.
- Premedicate as ordered with paracetamol and diphenhydramine prior to each dose. Steroids may also be administered before the initial dose. Have adrenaline and hydrocortisone injections available at the bedside in case of anaphylactic reaction.
- Administer by intravenous infusion into a central line over 4 to 6 hours as per organisational protocol.
- Monitor vital signs during infusion as per organisational protocol.
- Assess for adverse effects, including chills and fever, erythema and pruritus. Notify the doctor; these may be treated symptomatically.
- Monitor FBC daily; notify the doctor if WBC or platelet count decrease. The medication may be stopped or reduced.
- Assess renal function studies to monitor for serum sickness. Report complaints of joint pain.
- Monitor for signs of infection and report any signs promptly.

Health education for the person and family

- Explain the need for special precautions and close monitoring while this drug is being administered.
- Instruct the person to report any adverse effects, including malaise or joint pain, promptly.
- Ask the person to report any evidence of easy bruising, bleeding gums or black stools.
- Teach family members about the importance of not exposing the person to other people with infectious diseases.

Anxiety

The person who undergoes organ or tissue transplantation often faces the unwelcome choices of death from organ failure or receiving an organ that their body will likely attempt to reject. In most cases, the person understands that to receive this transplant, someone else must die and be willing to give up an organ. When the transplant (bone marrow or kidney) comes from a living donor, the person may not only worry about themselves but also about the condition of the donor. Fear of rejection and guilt may be even greater in this instance.

- Assess level of anxiety by noting such cues as expressions of apprehension, fear or inadequacy; facial expression, tension or shakiness; difficulty focusing; helplessness; poor eye contact and restlessness. *People may have difficulty identifying or verbalising feelings of fear and anxiety. Non-verbal cues are often useful in recognising states of anxiety.*
- Provide opportunities to express feelings. Use opening statements such as, 'Facing an organ transplant must be very stressful.' Listen attentively. *Encouragement and active listening allow the person to express feelings of anxiety or fear.*
- Arrange tasks to allow as much time with the person as possible. When leaving, tell the person when you will return. *Time spent with the person facilitates the development of trust.*
- Provide clear, concise directions. *Highly anxious people have difficulty focusing and retaining information.*
- Encourage involvement in care, but do not request unnecessary decisions. *The person needs to feel a sense of control but may become irritated if asked to make decisions unrelated to the situation.*
- Encourage family members to remain with the person as much as possible. *This can help reduce the person's anxiety.*
- Encourage the use of coping behaviours that have been effective for the person in the past. *Coping mechanisms and behaviours help lower anxiety to a more acceptable level.*
- Reduce or eliminate environmental stressors to the extent possible. *This gives the person a better sense of control.*
- Assist with stress reduction and relaxation techniques, such as guided imagery, meditation and muscle relaxation. *These techniques help the person gain control over physical responses to anxiety.*
- Refer to a counsellor or mental health specialist to work with the person. *Counselling can help the person identify and deal with their feelings.*
- Assess the person's preference and desire for spiritual counselling prior to transplant. *Because there is a risk of death if the transplant fails, the person may want to discuss their concerns with a spiritual counsellor.*

Community-based care

Teaching of the person and family regarding an organ or tissue transplant begins well before the transplant and continues throughout hospitalisation and follow-up treatment.

Initial teaching focuses on the options, risks and potential benefits of the transplant itself. Include the procedure by which the organ is selected and obtained, as well as the procedure by which it is transplanted into the person. If a living related donor is an option, discuss the risks and benefits for both the person and the donor. Outline the post-transplant treatment regimen, including any lifestyle changes that may be necessary.

Following the transplant, provide verbal and written instructions, including the following:

- manifestations of transplant rejection and the importance of notifying the doctor
- immunosuppressive drug regimen and side effects
- wound care
- avoiding exposure to infectious diseases, particularly respiratory infections and wearing a mask when going outside
- meticulous personal hygiene, handwashing technique and frequent mouth care
- wearing a MedicAlert® bracelet or pendant
- follow-up visits to the doctor or clinic
- helpful resources:
  - Transplant Australia
  - local and state support groups and organisations related to the specific organ transplant.

IMPAIRED IMMUNE RESPONSES

Disorders of impaired immune system responses may be either congenital or acquired. Often the function of either T or B cells is impaired, reducing the body's ability to defend against foreign antigens or abnormal host tissue.

No matter what the cause, people with immunodeficiency disorders demonstrate an unusual susceptibility to infection. When the antibody-mediated response is primarily affected, the person is at particular risk of severe and chronic bacterial infections. These people also do not develop long-lasting immunity to such diseases as chickenpox and are prone to recurrent cases. People with a defect of cell-mediated immunity tend to develop disseminated viral infections such as herpes simplex and CMV. Candidiasis and other fungal infections are also common. Because T cells are involved with activating antibody-mediated immune responses as well, overwhelming bacterial infections may occur. Immunodeficiency in its most

severe form occurs when both antibody-mediated and cell-mediated responses are impaired. People with combined immunodeficiency are susceptible to all varieties of infectious organisms, including those not normally considered to be pathogens.

Most immunodeficiency diseases are genetically determined and rare. They affect children more than adults. The noted exception is AIDS, an infectious disease caused by a virus.

THE PERSON WITH HIV INFECTION

In 1981, five cases of *Pneumocystis carinii* pneumonia (PCP) and 26 cases of a rare cancer, Kaposi's sarcoma, were diagnosed in young, previously healthy homosexual males in Los Angeles and New York City. The term **acquired immunodeficiency syndrome (AIDS)** was ascribed to this new phenomenon to describe the immune system deficits associated with these opportunistic disorders. Prior to this time, both PCP and Kaposi's sarcoma had been seen only in the older person, or in debilitated or severely immunodeficient people. Other groups at risk of AIDS were soon identified: injection drug users, people with haemophilia, recipients of blood transfusions and immigrants from Haiti.

Research to identify the cause of this apparently new disease progressed feverishly and, in 1983, a common antibody was identified in people with AIDS. The **human immunodeficiency virus (HIV)** was isolated in 1984. It then became apparent that AIDS was the final, fatal stage of HIV infection.

It began, like so many epidemics, with a few isolated cases and has become a worldwide plague (see the accompanying 'Focus on cultural diversity' box). AIDS invades our lives in ways we never imagined—testing our scientific knowledge, probing our private values and eluding a vaccine or a cure. Progression of HIV-positive disease to AIDS has slowed because of the effectiveness of highly active antiretroviral therapy (HAART) (Centers for Disease Control and Prevention (CDC), 2006). This change in progression to AIDS makes monitoring of AIDS less useful as an indicator of infected cases. For that reason, the CDC developed new surveillance methods based on infection rates in high-risk populations.

Although the incidence of HIV has levelled and mortality due to AIDS has declined, the epidemic is far from over.

Incidence and prevalence

In comparison with other countries, the overall incident rates of HIV/AIDS in Australia are low. In Australia, from the beginning of the HIV/AIDS epidemic to 31 December 2010 there have been 30 486 diagnosed cases of HIV (27 701 males and 2459 females), with an estimated 21 391 people living in Australia with HIV infection in 2010, and with 58% of newly diagnosed cases being Australian born (Kirby Institute, 2011a). A total of 10 446 people have been diagnosed with AIDS (9842 males and 568 females) and there have been a total of 6776 AIDS attributed deaths (6469 male and 307 female) (Kirby Institute, 2010). The relatively stable rates of AIDS diagnosis from 2001 to 2007 and the decrease in deaths from 149 in 2000 to 53 in 2007 are attributed to the use of effective antiviral therapies (Kirby Institute, 2009). Within Australia, funding is provided to professional and community organisations to assist in research and provision of education programs aimed at increasing knowledge and awareness within the community.

FOCUS ON CULTURAL DIVERSITY HIV/AIDS

In Australia, from 2001 to 2010, the rate of HIV among the Indigenous (Aboriginal and Torres Strait Islander) population remained similar to that of the non-Indigenous population. HIV transmission in Australia during 2006–2010 was primarily through male homosexual contact, in 70.8% of the non-Indigenous and 48.5% of the Indigenous cases. Exposure from heterosexual contact is reported as 16% of the non-Indigenous and 18.5% of the Indigenous cases. A higher proportion of incidence attributed to injection drug use was reported in Indigenous cases (19.4%) compared to non-Indigenous cases (2.5%). There was a higher proportion of HIV among Indigenous women (21.4%) compared to non-Indigenous women (8%). In 2010, the rate of HIV diagnosis in both the Indigenous and non-Indigenous Australian population was highest among residents in the major cities of Australia (Kirby Institute, 2011a; 2011b).

HIV/AIDS worldwide

There are an estimated 33 million people infected with AIDS worldwide, with virtually every country in the world reporting cases of AIDS (UNAIDS, 2007). The highest incidence is found in sub-Saharan Africa, South and South-East Asia, the United States, Western Europe, South America and Canada. Approximately 67% of all people infected with HIV or who have AIDS live in sub-Saharan Africa; another 15% live in South and South-East Asia, largely in Thailand and India. The most common mode of transmission is heterosexual intercourse. The cofactors that increase the risk of transmission include the presence of ulcerative or inflammatory sexually transmitted diseases, trauma, menses and lack of male circumcision (Papadakis et al., 2013; UNAIDS, 2007).

Critical thinking in person-centred care

1 Identify specific ways in which an HIV/AIDS prevention program focusing on injection drug use might be tailored to Aboriginal and Torres Strait Islander people.

2 What additional areas for research might further knowledge and guide strategies for HIV prevention in high-risk groups?

A continued decline in deaths is dependent on access to quality care and treatment and continued development of treatments for those already heavily treated (Papadakis et al., 2013).

In Australia, HIV risk criteria and indicators include sharing syringes, STI diagnosis or other clinical indicators of HIV, occupational or non-occupational exposure to HIV, unprotected intercourse with an HIV-positive person, unprotected intercourse between males and being born in or travelling to countries with a high HIV prevalence. Routine HIV testing is provided to antenatal women. Mandatory testing is carried out for specific visas; upon entry to the Australian Armed Forces; for all organ, tissue or blood donations; and in some legal or insurance requirements (National HIV Testing Policy, 2011).

The risk factors for HIV infection are behavioural. In adults in Australia, 79.7% of reported cases from 2006 to September 2008 involved male homosexual/bisexual contact; heterosexual contact was reported in 8.5% of cases. Unprotected anal intercourse is the major route of transmission in this group. Male homosexual/bisexual contact and injection drug use was reported in 5.1% of cases. Haemophiliacs, who require large amounts of intravenous clotting factors, and people infected through blood transfusion or tissue donation account for a small number of cases, approximately 2.8% (Kirby Institute, 2009). From 2004 to 2008, Australian-born people accounted for 58% of new diagnoses of HIV in Australia, and 9% of cases were reported to be in people who spoke English as their second language (Kirby Institute, 2009).

Declining immune system function in older adults significantly increases their risk of contracting HIV/AIDS, along with the belief that they cannot be affected by it. Just as younger people with HIV/AIDS contract the diseases primarily through sexual intercourse, so does the older population. Because older adults are beyond childbearing years, they often fail to use condoms when engaging in sexual activity. Manifestations may be overlooked by healthcare professionals, leading to a delayed diagnosis and increased severity of the disease.

HIV is a retrovirus transmitted by direct contact with infected blood and body fluids. Significant concentrations of the virus are present in blood, semen, vaginal and cervical secretions and cerebrospinal fluid (CSF) of infected individuals. It is also found in breast milk and saliva. Sexual contact is the primary mode of transmission. HIV is also transmitted through contact with infected blood via needle sharing during injection drug use or by transfusion. Approximately 13% to 40% of infants born to HIV-positive mothers are infected perinatally. Breastfeeding is a route of transmission and should be avoided (Papadakis et al., 2013).

Less than 0.04% of people voluntarily donating blood (a process that generally excludes people with high-risk behaviour) are found to be HIV positive. HIV is not transmitted by casual contact, nor is there any evidence of its transmission by vectors such as mosquitoes. Blood donation also poses no risk of contracting HIV to the donor, because only new, sterile equipment is used. A small but real occupational risk exists for healthcare workers. Percutaneous exposure to infected blood or body fluids through a needle-stick injury or non-intact skin is the primary route of transmission. Documented evidence indicates that parenteral exposure poses a 0.3% risk of becoming HIV positive (Carrico, 2001; Papadakis et al., 2013). Mucosal exposures, such as splashing in the eyes or mouth, pose a much smaller risk.

Pathophysiology and manifestations

As mentioned, HIV is a retrovirus, meaning it carries its genetic information in RNA. On entry into the body, the virus infects cells that have the CD4 antigen. Once inside the cell, the virus sheds its protein coat and uses an enzyme called *reverse transcriptase* to convert the RNA to DNA (see Figure 12.7). This viral DNA is then integrated into host cell DNA and duplicated during normal processes of cell division. Within the cell, the virus may remain latent or become activated to produce new RNA and to form *virions*. The virus then buds from the cell surface, disrupting its cell membrane and leading to destruction of the host cell.

Although the virus may remain inactive in infected cells for years, antibodies are produced to its proteins, a process known as **seroconversion**. These antibodies are usually detectable 6 weeks to 6 months after the initial infection. Helper T or CD4 cells are the primary cells infected by HIV. It also infects macrophages and certain cells of the CNS. Helper T cells play a vital role in normal immune system function, recognising foreign antigens and infected cells and activating antibody-producing B cells. They also direct cell-mediated immune activity and influence the phagocytic activity of monocytes and macrophages. The loss of these helper T cells leads to the immunodeficiencies seen with HIV infection (Porth & Matfin, 2009). Figure 12.8 illustrates the typical course of HIV infection.

The clinical manifestations of HIV infection range from no symptoms to severe immunodeficiency with multiple opportunistic infections and cancers (see the 'Manifestations' box below). It appears that the majority of people develop an acute mononucleosis-type illness within days to weeks after contracting the virus. Typical manifestations include fever, sore throat, arthralgias and myalgias, headache, rash and lymphadenopathy. Pathological changes are also noted in the CNS of many infected individuals, although the mechanism of neurological dysfunction is unclear. The person may also experience nausea, vomiting and abdominal cramping. The person often attributes this initial manifestation of HIV infection to a common viral illness such as influenza, upper respiratory infection or stomach virus.

Following this acute illness, people enter a long-lasting asymptomatic period. Although the virus is present and can be transmitted to others, the infected host has few or no symptoms. Clearly, the majority of HIV-infected people are in this stage of the disease. The length of the asymptomatic period varies widely, but its mean length is estimated to be 8 to 10 years.

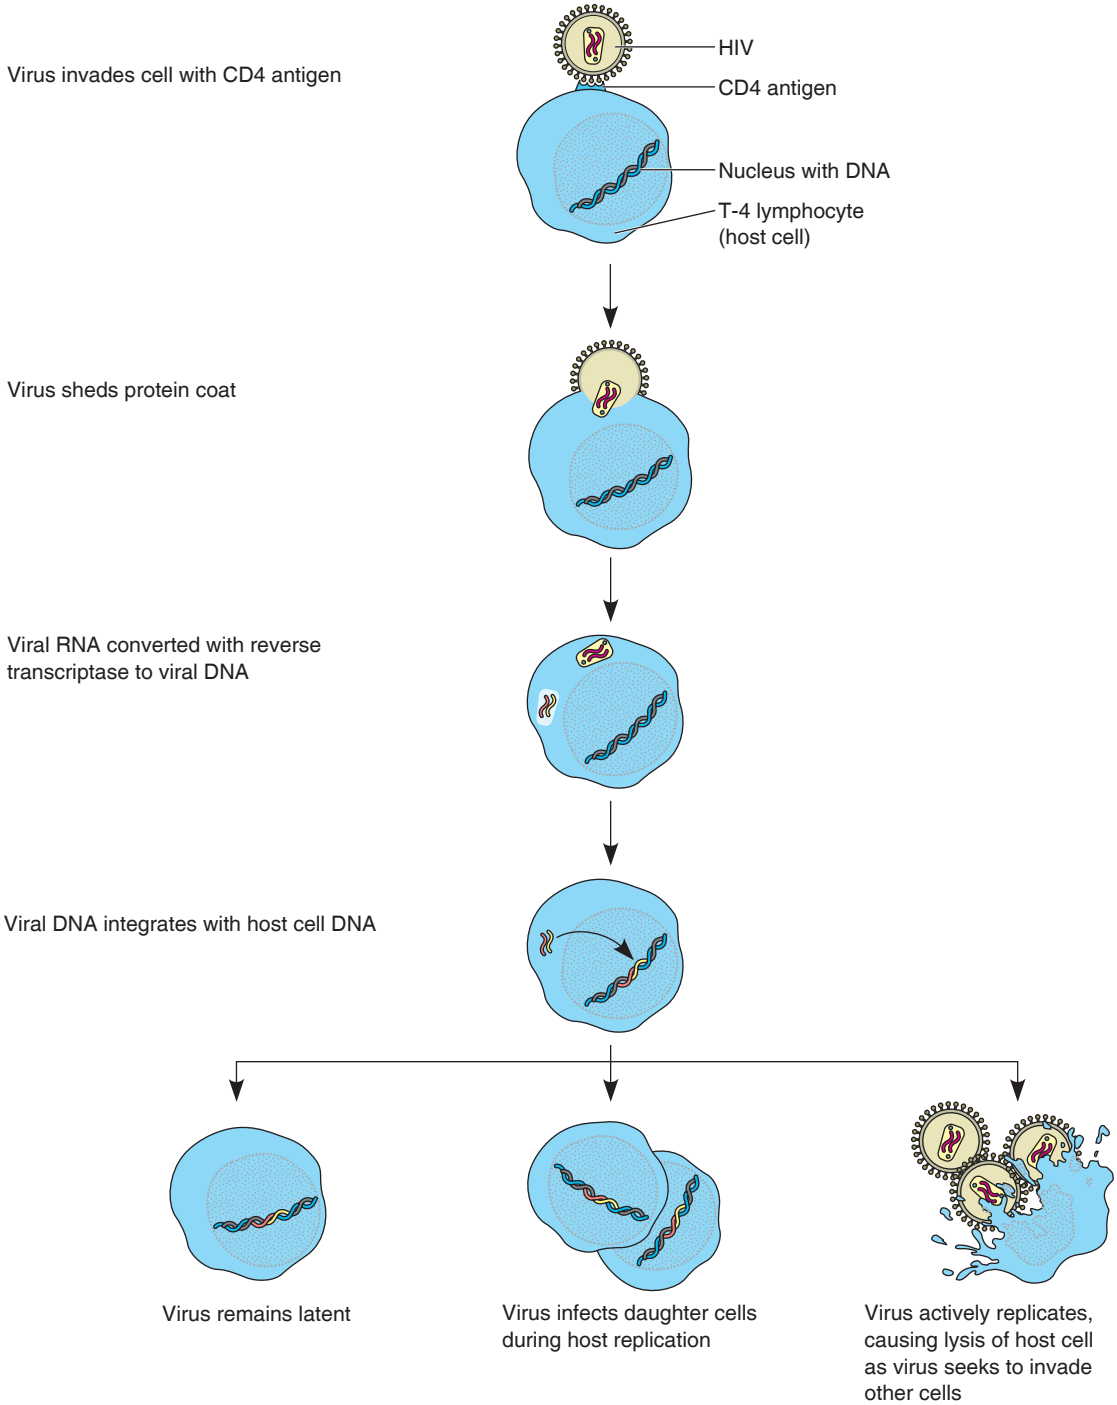


FIGURE 12.7 ■ How HIV infects and destroys CD4 cells

Some people with few other symptoms develop persistent generalised lymphadenopathy. This is defined as enlargement of two or more lymph nodes outside the inguinal chain, with no other illness or condition to account for the lymphadenopathy.

The move from asymptomatic disease or persistent lymphadenopathy to AIDS is often not clearly defined. The person may complain of general malaise, fever, fatigue, night sweats and involuntary weight loss. Persistent skin dryness and rash may be a problem. Diarrhoea is common, as are oral lesions such as hairy leucoplakia, candidiasis, gingival inflammation and ulceration. The development of advanced HIV typically occurs 10 to 11 years after initial infection; this varies according to the viral load, rate of disease progression and the development of resistance to antiretroviral therapy (Kenny, 2004).

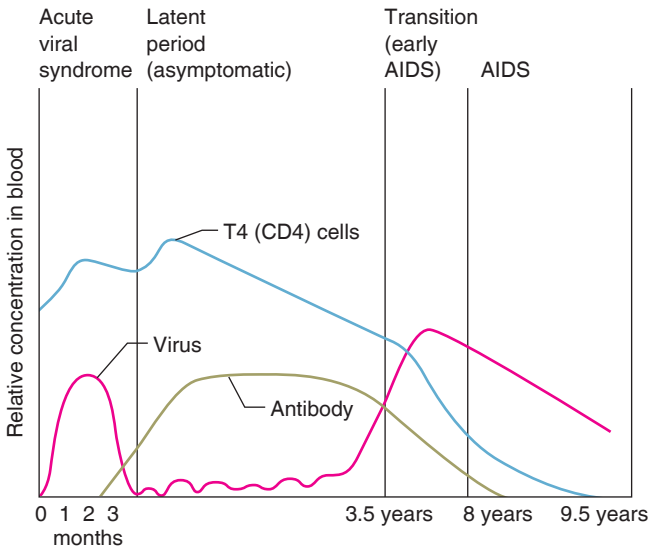

FIGURE 12.8 ■ The progression of HIV infection. Acute illness develops shortly after the virus is contracted, corresponding with a rapid rise in viral levels. Antibodies are formed and remain present throughout the course of infection. Late in the disease, viral activation results in a marked increase in virus while CD4 (T4) cells diminish as they are destroyed with viral replication. Antibody levels gradually decrease as immune function is impaired

With the development of significant constitutional disease, neurological manifestations or opportunistic infections or cancers, the person has manifestations that are characteristic of AIDS and a very poor prognosis. HIV infection and AIDS may be classified by using the CDC's matrix classification system. Under this system, HIV disease is determined by the presence of clinical symptoms (clinical categories A, B and C) and by T4 cell counts (categories 1, 2 and 3) (see Box 12.2). When a person's T4 cell count falls to < 200, they have late-stage AIDS; < 50 is end-stage AIDS (Coyne, Lyne & Watson, 2002).

When clinical manifestations develop, the outcome varies. With antiretroviral therapy (ART), many people are living longer after being diagnosed with AIDS. Today, PCP is most commonly diagnosed in those who are undiagnosed or have a late diagnosis of HIV infection, or who fail to take prophylactic antibiotics when their CD4 count is < 200. ART is credited with decreasing the incidence of opportunistic infections and improving survival (CDC, 2004). The time of survival has increased from about 13 months at the start of the AIDS epidemic; however, survival after diagnosis of HIV-related lymphomas still averages less than 8 months.

AIDS dementia complex and neurological effects

Neurological manifestations of HIV are common, affecting 40% to 60% of people with AIDS. Included among the manifestations are dementia, delirium and seizures. They result from both the direct effects of the virus on the nervous system and opportunistic infections.

AIDS dementia complex is the most common cause of mental status changes for people with HIV infection. This dementia results from a direct effect of the virus on the brain and affects cognitive, motor and behavioural functioning. Fluctuating memory loss, confusion, difficulty concentrating, lethargy and diminished motor speed are typical manifestations of AIDS dementia complex. People become apathetic, losing interest in work and social and recreational activities. As the complex progresses, the person develops severe dementia with motor disturbances such as ataxia, tremor, spasticity, incontinence and paraplegia (Fauci et al., 2008; Porth & Matfin, 2009).

Infections and lesions common with AIDS may also affect the CNS. Toxoplasmosis and non-Hodgkin's lymphoma are space-occupying lesions that may cause headache, altered mental status and neurological deficits. Cryptococcal meningitis and CMV infection also are common in people with AIDS. CNS complications have declined with the use of HAART therapy (Papadakis et al., 2013).

MANIFESTATIONS HIV infection and AIDS

I. Acute retroviral syndrome (ARS) or primary HIV infection
- Fever
- Sore throat
- Arthralgias and myalgias
- Headache
- Rash
- Nausea, vomiting and abdominal cramping

II. Asymptomatic infection
- None; converts to seropositive status

III. Persistent generalised lymphadenopathy
- Enlargement of two or more extrainguinal sites for more than 3 months

IV. Other acute disease symptoms
- General malaise, fatigue
- Low-grade fever
- Night sweats
- Involuntary weight loss
- Skin dryness or rashes

V. Other diseases and AIDS
A. *AIDS dementia complex*
B. *Secondary infectious diseases*
- *Pneumocystis carinii* pneumonia
- *Mycobacterium* tuberculosis
- *Mycobacterium avium* complex
- Candidiasis
- Cryptosporidiosis
- Cryptococcosis
- Toxoplasmosis
- Herpes simplex or herpes zoster
- Cytomegalovirus

C. *Secondary cancers*
- Kaposi's sarcoma
- Non-Hodgkin's lymphoma
- Cervical dysplasia and cervical cancer

D. *Other conditions*
- Pelvic inflammatory disease
- Human papillomavirus

BOX 12.2 Classification system for HIV infection and expanded AIDS surveillance case definition for adolescents and adults

DIAGNOSTIC CATEGORIES	CLINICAL CATEGORIES		
	A	B	C
CD4 + T-CELL CONDITIONS	ASYMPTOMATIC, ACUTE (PRIMARY) HIV OR PERSISTENT GENERALISED LYMPHADENOPATHY (PGL)	SYMPTOMATIC, NOT (A) OR (C) CONDITIONS	AIDS-INDICATOR CATEGORIES
(1) ≥500/mm^3	A1	B1	C1
(2) 200– 499/mm^3	A2	B2	C2
(3) <200/mm^3	A3	B3	C3

As of 1 January 1993, people with AIDS-indicator conditions (clinical category C) and those in categories A3 or B3 were considered to have AIDS.

Clinical category A

One or more of the following conditions in an adolescent or adult with documented HIV infection and without conditions in categories B and C:

- Asymptomatic HIV infection
- Persistent generalised lymphadenopathy
- Acute HIV infection with accompanying illness or history of acute HIV infection

Clinical category B

Examples of conditions, but not limited to:

- Candidiasis oral (thrush) or vulvovaginal (persistent, frequent or poorly responsive to therapy)
- Cervical dysplasia/cervical carcinoma in situ
- Constitutional symptoms, such as fever (38.5°C) or diarrhoea exceeding 1 month duration
- Hairy leucoplakia
- Herpes zoster involving at least two distinct episodes
- Pelvic inflammatory disease
- Peripheral neuropathy

Clinical category C

- Candidiasis of bronchi, trachea or lungs; oesophagus
- Coccidioidomycosis
- Cryptococcosis
- Cryptosporidiosis with persistent diarrhoea
- Cytomegalovirus infection (other than of liver, spleen or lymph nodes)
- CMV retinitis
- HIV encephalopathy
- Herpes simplex: chronic ulcers or bronchitis, pneumonitis or oesophagitis
- *Mycobacterium avium* complex or disseminated
- *Mycobacterium tuberculosis*
- *Pneumocystis carinii* pneumonia
- Progressive multifocal leucoencephalopathy
- *Salmonella* septicaemia
- Toxoplasmosis of the brain
- Kaposi's sarcoma
- Cervical cancer, invasive
- Lymphoma
- HIV wasting syndrome

Source: Adapted from CDC (1993). Revised classification system for HIV infection and expanded case definition for AIDS among adolescents and adults. *MMWR Recommendations and Reports, 41*(RR-17), 1–19.

Peripheral nervous system manifestations are also common in HIV-infected people. Sensory neuropathies with manifestations of numbness, tingling and pain in the lower extremities affect about 30% of people with AIDS. A Guillain-Barré type of inflammatory demyelinating polyneuropathy can also occur, resulting in progressive weakness and paralysis.

Opportunistic infections

Opportunistic infections are the most common manifestations of AIDS, often occurring simultaneously. The risk of opportunistic infections is predictable by the T4 or CD4 cell count. The normal CD4 cell count is 500 to 1350/mm^3. When the CD4 count falls to less than 500/mm^3, manifestations of immunodeficiency are seen. With a count of less than 250/mm^3, opportunistic infections and cancers are likely.

PNEUMOCYSTIS CARINII PNEUMONIA

Pneumocystis carinii pneumonia is the most common opportunistic infection affecting people with AIDS. Approximately 75% to 80% of people develop PCP at some point in their disease (Papadakis et al., 2013). It tends to be recurrent and is the cause of death in about 20% of people with AIDS. PCP is caused by a common environmental fungus that is not pathogenic in people with intact immune systems.

Unlike many pneumonias, the manifestations of PCP are non-specific and may progress insidiously. People often present with fever, cough, dyspnoea, tachypnoea and tacycardia. Complaints of mild chest pain and sputum may also be present. Breath sounds may initially be normal. With severe disease, the person may present with cyanosis and significant respiratory distress.

TUBERCULOSIS In some people, active tuberculosis results from reactivation of a prior infection. In other people, it is a new, primary disease facilitated by impaired immune function. Rapid progression, diffuse pulmonary infiltrates and disseminated disease occur more commonly in people with AIDS. Multidrug-resistant strains of tuberculosis present a significant problem (Papadakis et al., 2013).

People with pulmonary tuberculosis present with a productive cough of purulent sputum, fever, fatigue, weight loss and lymphadenopathy. Disseminated disease affects the bone marrow, bone, joints, liver, spleen, CSF, skin, kidneys, gastrointestinal tract, lymph nodes, brain and other sites.

CANDIDIASIS *Candida albicans* infection is a common opportunistic infection in people with AIDS. It is usually manifested as oral thrush or oesophagitis. In women, vaginal candidiasis is frequent and often recurrent. Oral thrush presents as white, friable plaques on the buccal mucosa or tongue and, in the HIV-infected person, is often the first indication of progression to AIDS. People with oesophagitis have difficulty swallowing and substernal pain or burning that increases with swallowing.

***MYCOBACTERIUM AVIUM* COMPLEX** *Mycobacterium avium* complex (MAC) affects up to 25% of people with AIDS, typically occurring late in the course of the disease when CD4 cell counts are less than 100/mm^3. MAC is more common in women than men. MAC is caused by organisms commonly found in food, water and soil. It is a major cause of 'wasting syndrome' in people with AIDS (see Figure 12.9). Manifestations of MAC include chills and fever, weakness, night sweats, abdominal pain and diarrhoea, and weight loss. Nearly every organ can be infected and most people with MAC develop disseminated disease.

OTHER INFECTIONS Herpesvirus infections are common in people with AIDS and may be severe. CMV can affect the retina, the gastrointestinal tract or lungs. Disseminated herpes simplex or herpes zoster may occur, although severe mucocutaneous manifestations are more common.

Parasitic infections with *Toxoplasma gondii* and *Cryptococcus neoformans* commonly affect the CNS. Toxoplasmosis occurs as encephalitis or an intracerebral mass lesion. Changes in mental status, focal neurological signs and seizures may result. *Cryptococcus* infection may present as either meningitis or disseminated disease primarily affecting the lungs. *Cryptosporidium*, a protozoon affecting the gastrointestinal tract, is an important cause of prolonged diarrhoea in people with AIDS. Bacterial *Salmonella* infections are also a relatively common cause of diarrhoea.

Women with AIDS have a high incidence of pelvic inflammatory disease (PID). Although the pathogens appear to be the same as those in PID affecting non-HIV-infected women, the disease is more severe. Inpatient treatment with intravenous antibiotics is often necessary.

Secondary cancers

As cell-mediated immune function declines, the risk of malignancy increases. The CDC classification of AIDS currently includes four cancers: Kaposi's sarcoma, non-Hodgkin's lymphoma, primary lymphoma of the brain and invasive cervical carcinoma.

KAPOSI'S SARCOMA **Kaposi's sarcoma (KS)** is often the presenting symptom of AIDS. It remains the most common cancer associated with the disease. Kaposi's sarcoma is caused by a virus called the Karposi-sarcoma-associated herpes virus, also known as human herpes virus 8. Men who have sex with men not only have a risk of HIV infection, but are also more likely to be infected with the virus responsible for KS. Women who have sex with these men also have a risk of HIV and KS. The virus associated with KS appears to be mainly transmitted through sexual contact, although cases have also been reported in injection drug users. People whose immune system is suppressed because they have received an organ transplant have a 1 in 200 risk of developing KS (American Cancer Society, 2005).

A tumour of the endothelial cells lining small blood vessels, KS presents as vascular macules, papules or violet lesions affecting the skin and viscera (see Figure 12.10). The face is a common site for skin lesions, especially the tip of the nose and

FIGURE 12.9 ■ Wasting syndrome in a person with AIDS

FIGURE 12.10 ■ Kaposi's sarcoma lesions

Source: © Carolina Biological/Visuals Unlimited/Corbis.

pinnae of the ears. Common sites for visceral disease include the gastrointestinal tract, lungs and lymphatic system.

The lesions of KS are usually painless initially, but may become painful as the disease progresses. Internally, the tumours may obstruct organ function or cause bleeding. When the lungs are involved, gas exchange may be severely impaired, resulting in pulmonary haemorrhage. KS is an indicator of late-stage HIV disease, with an average survival time of 18 months after diagnosis. The disease may progress slowly or rapidly. Rapidly progressing KS is treated with chemotherapy; milder forms may improve with the initiation of HAART therapy (Papadakis et al., 2013).

LYMPHOMAS Lymphomas are malignancies of the lymphoid tissue, including lymphocytes, lymph nodes and the lymphoid organs such as the spleen and bone marrow. In AIDS, two lymphomas are common: non-Hodgkin's lymphoma (including Burkitt's lymphoma) and primary lymphoma of the brain. Hodgkin's disease also occurs five times more frequently in people with HIV infection than in those without. The CNS is the usual site for these lymphomas, although they may be found in the bone marrow, gastrointestinal tract, liver, skin and mucous membranes. They are aggressive tumours, growing and spreading rapidly. Headache and changes in mental status are common early symptoms of lymphomas affecting the CNS.

CERVICAL CANCER Of women with HIV infection, 40% have cervical dysplasia. Cervical cancer develops frequently and tends to be aggressive. Women with concurrent HIV infection and cervical cancer usually die of the cervical cancer, not AIDS. Because of this, it is recommended that women with HIV infection have Papanicolaou (Pap) smears every 6 months and aggressive treatment of cervical dysplasia with colposcopic examination and cone biopsy.

INTERPROFESSIONAL CARE

Although multiple research studies to identify a cure for HIV infection and AIDS are under way, no cure is currently available. This fact, plus the apparent universally fatal nature of the disease, makes prevention a vital strategy in HIV care. New treatments are under investigation (see Box 12.3).

The goals of care for the person with HIV disease are as follows:

- early identification of the infection
- promoting health-maintenance activities to prolong the asymptomatic period as long as possible
- prevention of opportunistic infections
- treatment of disease complications, such as cancers
- providing emotional and psychosocial support.

Diagnosis

Diagnostic testing is used to screen and identify the infection, as well as to monitor the person's disease and immune status. The following diagnostic tests may be ordered. The likelihood that a positive screening test truly indicates the presence of HIV infection decreases as HIV prevalence in the tested population becomes lower. Therefore, false-positive HIV test results are more likely in settings where the tested population prevalence is lower than in settings where the tested population prevalence is higher. When a preliminary, positive rapid test is

BOX 12.3 Investigational immune-based treatment for HIV

HIV infection progressively alters the function of and destroys $CD4^+$ lymphocytes. $CD4^+$ cells are essential to the function of the immune system, including the body's ability to respond to infections. These cells initiate, direct and regulate immune responses and may also directly attack infected cells. They also are a source of cytokines, the chemical messengers of the immune system. Destruction of $CD4^+$ cells by HIV devastates the immune system, facilitating the development of fatal infections and neoplasms in the infected person. Immune-based treatments indirectly affect the HIV by improving the function of the immune system through actions that inhibit cytokines, replenish cytokines or restore immune function. These treatments, used alone or in combination with antiretroviral drugs, are being investigated for use in the treatment of HIV.

Inhibiting cytokines

Tumour necrosis factor alpha (TNF-α) is a cytokine secreted by activated monocytes and macrophages in response to infection, infestation or tumour growth. It causes a proliferation of B cells and T cells. However, high levels of this cytokine may actually facilitate the development of disease by blocking the normal inflammatory response. It is believed that blocking the effect of TNF-α can suppress HIV production, although caution must be used.

Replenishing cytokines

Some cytokines (interleukin-2, interleukin-12 and interferon alpha) may be helpful in treating HIV by stimulating the production of killer cells as well as increasing the function of lymphocytes. The interferons are part of the body's first line of defence against viruses. All of these agents have toxic side effects, requiring careful nursing assessment and care.

Restoring immune system function

HIV infection not only destroys $CD4^+$ cells, but also eventually destroys the lymphoid organs, such as bone marrow and the thymus gland. Lymphocytes, including the $CD4^+$ cells, are derived from stem cells in bone marrow and mature in the thymus. Two investigational treatments to restore the immune system are bone marrow transplant and thymus transplant. Bone marrow transplants have been used to correct other types of immune disorders (such as leukaemia or lymphoma) but have yet to be effective in people with HIV. A few thymus transplants have been done in HIV-infected people, but have provided only temporary benefits.

explained to people, phrases like 'a good chance of being infected' or 'very likely infected' can be used to indicate the likelihood of HIV infection and can be qualified based on the HIV prevalence in the setting and the person's individual risk.

Further testing is always required to confirm a reactive screening test result.

- *HIV rapid antibody tests* are available in many countries but not yet in Australia.
- *Enzyme-linked immunosorbent assay (ELISA)*, also called the HIV antigen/antibody test, is the most widely used screening test for HIV infection. The ELISA test was developed in 1985 to screen blood donors. ELISA tests for HIV antibodies; it does not detect the virus. Therefore, a person may have a negative ELISA test early in the course of infection, before detectable antibodies have developed. The test has a 99.5% or higher sensitivity when performed at least 13 weeks after infection. This means that more than 99.5% of tests performed on blood containing HIV antibodies will show a positive result. False positives can occur; therefore, an initial positive result is always tested repeatedly and confirmed using a different method of antibody detection, usually the Western blot.
- Immediate notification is critical because many people tested for HIV do not return to learn the results; many cannot be located to give the test results and educate about safe behaviours, whether they are positive or negative for HIV. Although confirmation of results is dependent on testing with a second source, ELISA or Western blot test, learning results immediately gives the person more information to make wise choices about their behaviours and self-care.
- *Western blot antibody testing* is more reliable but more time-consuming and more expensive than ELISA. When combined with ELISA, however, a specificity of greater than 99.9% is achieved. Specificity is a measure of the probability that a negative test result indicates that no antibodies are present. In this test, the person's serum is mixed with HIV proteins to detect reaction. If antibodies to HIV are present, a detectable antigen–antibody response will occur.
- *HIV viral load tests* measure the amount of actively replicating HIV. Levels correlate with disease progression and response to antiretroviral medications. Public health guidelines state treatment should be considered for asymptomatic people with HIV with viral loads greater than 5000 to 100 000 copies/mL. HIV viral load testing is used in conjunction with CD4 cell count to inform treatment decisions.
- *FBC* is performed to detect anaemia, leucopenia and thrombocytopenia, which are often present in HIV infection. Lymphopenia (or low levels of lymphocytes) is especially common in this disease.
- *CD4 cell count* is the most widely used test to monitor the progress of the disease and guide therapy. The CD4 cell count correlates very closely with the immunodeficiency disorders seen in AIDS. AIDS is now defined not only by the presence of opportunistic infections and other diseases indicative of immunodeficiency, but also by HIV-seropositive status; the CD4 count goes down as the disease progresses. The standard reference range for CD4 count is dependent on many factors. The doctor monitors the pattern for changes over several months to determine strategies for optimal treatment.

In addition to these widely used tests, several other diagnostic tests may be performed:

- *Blood culture for HIV* provides the most specific diagnosis but is an expensive and cumbersome test that is not widely available.
- *Immune-complex-dissociated p24 assay* is a test for p24 (HIV) antigen in the blood. This antigen indicates active reproduction of HIV and tends to be positive prior to seroconversion and with advanced disease. It is most useful in monitoring disease progression and the antiviral activity of experimental medications (Pagana & Pagana, 2013; Papadakis et al., 2013).

Other diagnostic tests are used primarily to detect secondary cancers and opportunistic infections in the person with HIV. Tests ordered are both general and specific to the person's manifestations and may include the following:

- *tuberculin skin testing* to detect possible tuberculosis infection
- *MRI* of the brain to identify lymphomas
- *specific cultures and serology examinations for opportunistic infections* such as PCP, toxoplasmosis and others
- *Pap smears* every 6 months for early detection of cervical cancer in women with cervical dysplasia (Papadakis et al., 2013).

Medications

Pharmacological management of the person with HIV disease has four primary foci:

1. to suppress the infection itself, decreasing symptoms and prolonging life
2. to provide prophylaxis of opportunistic infections
3. to stimulate haematopoietic response
4. to treat opportunistic infections and malignancies.

Effectiveness of treatment is monitored by viral load and CD4 cell counts; positive results are indicated by a reduction in viral load along with preserving the CD4 count above 350/mm^3. Treatment is recommended when the CD4 count falls below 200/mm^3. People with symptoms of severe disease are treated regardless of their CD4 level or viral load, so monitoring these individuals may reveal higher levels of CD4 or lower viral load. Initiating therapy in asymptomatic individuals with higher CD4 levels has not shown a protective effect and is thought to perhaps increase viral resistance. Today the drugs have been combined and dosing schedules simplified, which helps people adhere to medication administration schedules. Currently, researchers are using clinical trials of asymptomatic people receiving HAART to evaluate alternating drug regimens to prevent drug resistance by the viral organisms (Martinez-Picado et al., 2003).

Four classes of drugs used in antiretroviral treatment include nucleoside reverse transcriptase inhibitors (NRTIs), non-nucleoside reverse transcriptase inhibitors (NNRTIs), protease inhibitors (PIs) and entry inhibitors. HAART combines three or four antiretroviral drugs to reduce the incidence of drug

resistance. Combination therapies increase the likelihood of decreasing viral load and symptoms but also burden people with complicated and expensive medication schedules. People beginning the HAART protocol must understand the benefits, risks, costs and effects on daily life. HAART does not eradicate HIV infection. HAART medications are expensive, particularly the newer triple combinations such as Trizivir. These medications are scheduled for specific times throughout the day; therefore, leading a normal life becomes a challenge. In addition, as with most chronic diseases, all HAART medications cause major adverse reactions leading to less than perfect adherence; however, in this case, the outcome could be fatal.

Each person must be able to adhere to the treatment regimen. It may be preferable to delay initiating therapy until the person is able to agree to adherence so that irregular dosing does not lead to viral resistance. Some providers gauge a person's ability to follow the HAART regimen by their success with prophylaxis for an opportunistic infection.

Several methods to promote and ensure adherence are being used and studied. Wroe and Thomas (2003) found it helpful to distinguish between intentional and unintentional non-adherence and to treat them as separate entities. People's beliefs and internal logic were found to impact on intentional non-adherence; preparing people for the effects of HAART therapy by focusing on lessening people's reasons for not taking medication is believed to reduce intentional non-adherence. Enriquez and McKinsey (2004) emphasise the role of nursing in preventing drug resistance by assessing a person's readiness to adhere to the treatment regimen and intervening to overcome identified barriers to adherence prior to initiating therapy.

Another approach to adherence is the use of electronic monitoring devices EMDs (Bova et al., 2005). By placing a microprocessor in a medication cap, records are created of the time, date and frequency of bottle opening. Although this method does not guarantee that the medication will be taken even if the cap is removed, the record created is a source for follow-up and discussion between the provider and the person. Whether the person is asked to keep a diary of taking the medication, using an EMD to keep a record, or relying on pill count, adherence to medication regimen is critically important.

Ingersoll and Heckman (2005) found the most effective provider–person relationship for fostering adherence is a balance of appropriate challenge and support. Providers who were never confrontational seem to be perceived by people as giving permission to be less adherent. Although depression, substance use and financial considerations undoubtedly influence adherence to HAART therapy and need to be addressed, provider–person relationships seem to have the most influence on adherence behaviour.

NUCLEOSIDE REVERSE TRANSCRIPTASE INHIBITORS

The NRTIs (also called nucleoside analogues) inhibit the action of viral reverse transcriptase, a retroviral enzyme that catalyses the substrates for conversion and copying of viral RNA to DNA sequences. This enzyme is necessary for viral integration into cellular DNA and replication. The nucleoside analogues act as a chemical decoy for building blocks of the formation of the DNA copy, preventing the RNA from being copied into DNA. Each drug substitutes for a particular nucleoside base at different points on the chain. See the 'Medication administration' guidelines below for this group of drugs.

Zidovudine (Retrovir, AZT) was the first antiretroviral agent approved for use with HIV infection. It remains in widespread use and has been shown to decrease symptoms and prolong the lives of people with AIDS. Zidovudine is often given to people with a CD4 cell count of less than 500/mm^3 because of evidence that it slows the progression to severe disease (Papadakis et al., 2013). Zidovudine may also be used prophylactically following a documented parenteral exposure to HIV. It is used in combination with ddI, ddC or 3TC (see below).

- Didanosine (ddI, Videx) also inhibits reverse transcriptase and viral replication. It is used in combination therapy with zidovudine.
- Stavudine (d4T, Zerit) is a retroviral inhibitor that has been shown to increase CD4 cell counts and decrease serum p24 antigen levels. Current use is for people who are intolerant of zidovudine.
- Lamivudine (3-TC, Combivir) is used for low CD4 cell counts or symptomatic disease as a first-line treatment in combination with zidovudine.
- Abacavir (Ziagen) is a potent inhibitor of reverse transcriptase; however, it may cause serious hypersensitivity reactions.
- Zidovudine plus lamivudine (Combivir) is a combination drug in use to decrease HIV zidovudine-resistant strains.

PROTEASE INHIBITORS

Protease is a viral enzyme necessary for the formation of specific viral protein needs for viral assembly and maturation. Protease inhibitors bond chemically with protease to block the function of the enzyme and result in the production of immature, non-infectious viral particles. When combined with other antiviral drugs, these chemicals increase the chance of eliminating the virus by interfering with different stages of its life cycle. However, viral resistance occurs rather quickly. PIs inhibit and induce metabolism of other drugs, so their use with other medications and the dose of those medications must be carefully planned. Some drugs will circulate longer because their metabolism is inhibited; others will be speedily metabolised and eliminated.

Protease inhibitors and nucleoside analogues are associated with serious metabolic derangements. These include elevated cholesterol and triglycerides, insulin resistance and diabetes mellitus, and changes in body fat composition, which are particularly distressing to the person. These body fat changes are primarily abdominal obesity and skeletal wasting. This set of symptoms is referred to as lipodystrophy (Papadakis et al., 2013). Elevated cholesterol should be treated with pravastatin or atorvastatin. Lovastatin and simvastatin react to PIs, so they need to be avoided. Dietary sources of cholesterol should be reduced.

- Saquinavir is used in combination with nucleoside analogues to treat progression of the disease.
- Ritonavir is used in combination with nucleoside analogues to treat progression of the disease.

MEDICATION ADMINISTRATION Antiretroviral nucleoside analogues

ZIDOVUDINE (AZT, AZIDOTHYMIDINE)

Zidovudine is the first antiretroviral agent developed to treat HIV infection. It interferes with reverse transcriptase, thus inhibiting replication of the virus. The usual dose is 250 mg twice daily. It is administered orally. Dose-limiting side effects are anaemia and neutropenia.

Nursing responsibilities

- Assess for possible contraindications to therapy, including allergic response or a CD4 count of greater than 350/mm^3.
- Administer by mouth, instructing the person to swallow capsules whole.
- Assess for adverse effects. Nausea and headache are common. They may be self-limiting, decreasing with time, or significant and continuing, necessitating a change of therapy. Nausea and neutropenia are treated with erythropoietin and G-CSF.
- Assess FBC with differential and creatinine phosphokinase. Notify the doctor of significant changes.

Health education for the person and family

- Antiretroviral medications will not cure HIV infection but slow its progress and reduce significant symptoms.
- Take the drug according to the directions for administration at least 0.5 hour before or 1 hour after meals, if tolerated.
- With this and all antiretroviral drugs, it is important to emphasise that the person is still infective and can pass the infection to others. Use safer sex practices and other measures to prevent transmission to partners. Do not donate blood or breastfeed.
- Notify the doctor if signs of an infection or adverse response to the medication develop: sore throat, swollen lymph glands, fever; unusual fatigue or weakness; easy bruising, bleeding gums or an injury that will not heal; persistent or intractable nausea; muscle pain or wasting.
- Continue all scheduled follow-up visits and laboratory studies to monitor for drug toxicity.
- Check with the doctor before taking any prescription or over-the-counter drug.

DIDANOSINE (DDI, VIDEX)

As with zidovudine, didanosine does not kill HIV but inhibits its replication within the cells. Its activity is similar to that of zidovudine. Didanosine has been shown to increase CD4 cell counts and lower p24 antigen levels (Papadakis et al., 2013). Didanosine is used alone for people who are intolerant or resistant to zidovudine. It is also being used with zidovudine in combination therapy regimens. Didanosine does not cause the anaemia associated with zidovudine, but it may cause neutropenia. Didanosine is also associated with an increased risk of pancreatitis, peripheral neuropathy and dry mouth.

Nursing responsibilities

- Assess for possible contraindications to didanosine therapy, including previous episodes of pancreatitis and impaired renal or liver function.
- Administer as directed and refer to the product information for administration instructions.
- Administer with caution to people taking vincristine, rifampin, pentamidine, ethambutol or metronidazole; the action of both drugs may be affected by concurrent administration. Intravenous pentamidine and trimethoprim-sulfamethoxazole taken concurrently may increase the risk of acute and fatal pancreatitis.
- Didanosine interferes with the absorption of ketoconazole and dapsone. Doses of these drugs should be scheduled at least 2 hours apart from didanosine doses.
- Evaluate for therapeutic response and possible adverse effects. Notify the doctor if manifestations of peripheral neuropathy, diarrhoea, depression or other adverse effects develop.
- Stop the drug and notify the doctor immediately if the person develops manifestations of pancreatitis or hepatic failure, including nausea and vomiting, severe abdominal pain, elevated bilirubin or elevated serum enzymes (e.g. amylase, AST, ALT).

Health education for the person and family

- Take the drug as directed. The prescribed dose must always be taken to get the required amount of antacid to prevent the drug from being destroyed by stomach acid.
- Take on an empty stomach, at least 1 hour before or 2 hours after meals.
- Do not drink alcohol while taking didanosine; alcohol may increase the risk of pancreatitis.
- Stop the drug and call the doctor immediately if nausea, vomiting, abdominal pain or diarrhoea develops. These may indicate pancreatitis.
- Call the doctor if extremity pain, weakness, numbness or tingling occurs. These side effects usually disappear when didanosine is discontinued.
- Other side effects to report to the doctor include unusual bleeding or bruising, fatigue, weakness, fever or persistent sore throat.

ABACAVIR

Abacavir is a nucleoside analogue with activity against some HIV strains resistant to other nucleoside drugs. It is prepared in combination with zidovudine and lamivudine (Trizivir) and one tablet is taken twice daily. This combination drug is composed exclusively of nucleoside analogues, lacking NNRTIs or PIs. As such, it is less effective at decreasing viral load and allowing immune system enhancement, but the ease of administration makes it a useful drug for people who cannot adhere to more complex regimens. The main toxicity is a hypersensitivity response in approximately 5% of people, manifested as flu-like symptoms. Avoid repeated use in those individuals.

Nursing responsibilities

- Assess for possible hypersensitivity reactions, anaemia and neutropenia.
- Evaluate for desired effect of increased CD4 counts and lower blood levels of p24 antigen.
- Notify the doctor if the person develops evidence of pancreatitis, impaired hepatic function or painful peripheral neuropathy.

Health education for the person and family

- Take without regard to food or water.
- Check with the doctor before taking any other prescription or over-the-counter medication.
- Report all signs and symptoms of hypersensitivity to the drug.
- Report to the doctor signs of infection, flu-like symptoms or changes in condition.

- Indinavir is used in combination with nucleoside analogues to treat progression of the disease.
- Nelfinavir is used in cases of failure of or intolerance to other protease inhibitors.
- Amprenavir is the newest protease inhibitor.
- Lopinavir/ritonavir is the first combination of protease inhibitors active against some HIV strains resistant to other protease inhibitors.

NON-NUCLEOSIDE REVERSE TRANSCRIPTASE INHIBITORS Nevirapine, delavirdine and efavirenz are NNRTIs that may be used in combination with nucleoside analogues and protease inhibitors. However, one limitation to NNRTIs is the high incidence of cross-resistance to NRTIs. Some studies have shown that nevirapine and efavirenz may significantly reduce serum levels of the protease inhibitors. Only one NNRTI should be used at the same time. Nevirapine has a reported risk of liver toxicity and Stevens–Johnson syndrome (Bartlett & Weber, 2005).

ENTRY INHIBITORS: ENFUVIRTIDE (FUZEON) This new class of drugs became available in 2003. These entry or fusion inhibitors prevent HIV from entering target cells by binding to the protein envelope that surrounds the virus. When bound to the drug, the virus cannot morph in order to fit and adhere to cell membranes (Covington, 2005). Adding this new class of drug to the regimen of heavily pretreated individuals improves CD4 counts and lowers viral loads (Papadakis et al., 2013).

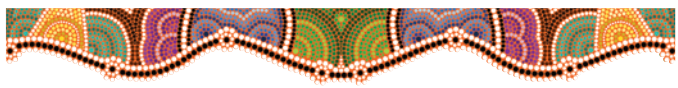
OTHER MEDICATIONS Other agents may also be administered in combination with antiretroviral therapy. Interferons, which are naturally occurring lymphokines, have been used alone and in combination. Interferon alpha may be used to treat KS and in combination with zidovudine to slow disease progression. Interferon gamma is also used. As more drugs become available, the burden to choose the best regimen increases for the healthcare provider. The most important limiting factor when choosing a regimen is a person's adherence. Second to that is selecting an effective combination of drugs without overlapping toxicities or toxicities so debilitating that adherence will be further impaired.

Some people undergoing HAART are developing body composition changes and metabolic abnormalities associated with the therapy, especially the PIs. Increased fat deposition in the midsection, breasts and neck, with atrophy in the face, buttocks and extremities, describes the body composition changes; metabolic abnormalities include increased low-density lipoprotein cholesterol and triglycerides and insulin resistance. The combination of changes is consistent with metabolic syndrome, which increases the risk of cardiovascular disease and diabetes. These conditions are commonly treated with medications. Robinson (2005) has observed these serious changes in HIV-positive people and hopes to prevent and treat the changes with diet and exercise without adding to the polypharmacy already experienced by those undergoing HAART.

A number of pharmacological agents are used to prevent and treat opportunistic infections and malignancies in the person with HIV. These agents are outlined in Table 12.4.

Many people at some point require a central venous access device, such as a Groshong catheter, to facilitate blood sampling, intravenous medication administration, transfusions and parenteral nutrition. See Chapter 13 for nursing care of the person with a central venous catheter.

It is recommended that all HIV-infected people receive pneumococcal, influenza, hepatitis B and *Haemophilus influenzae* b vaccines. People with a positive PPD and negative chest x-ray are given prophylactic isoniazid. When the person's CD4 cell count falls to less than 200/mm^3, prophylactic treatment for PCP is begun, usually with trimethoprim-sulfamethoxazole. People with a CD4 count of less than 100/mm^3 are started on prophylactic treatment for MAC.



Nursing care

The person with HIV and AIDS has many care needs, including both physical and psychosocial support (see the 'Translation to practice' box below). Because there is as yet no cure or effective treatment for HIV disease, many of these needs fall within the realm of nursing to promote knowledge and understanding, self-care, comfort and quality of life. As with many diseases that have an ultimately fatal outcome, the course of HIV infection may well be affected by the person's social support systems, control, perceived self-efficacy in management and coping mechanisms.

As the epidemic continues, nurses are providing care for increasing numbers of people with HIV infection at various stages of disease. These people are not only in special care settings but also in general units, maternal–child units, hospice and home settings. As people with HIV disease live longer, nurses will increasingly encounter people in whom HIV disease is a secondary diagnosis, with another primary diagnosis—for example, seizures, heart disease, diabetes mellitus or an operative procedure.

Prevention

To date, no safe immunisation to protect against HIV infection has been developed. Education, counselling and behaviour modification are the primary tools for AIDS prevention. The benefit of education and behaviour modification is evident in the homosexual male population. The incidence of new HIV infections in this population has declined dramatically in high-prevalence cities. Nurses play a vital role in providing education about this epidemic and infection prevention for individuals and communities.

All sexually active individuals need to know how HIV is spread. Following are the only *totally* safe sex practices:

- no sex
- long-term mutually monogamous sexual relations between two uninfected people
- mutual masturbation without direct contact.

TABLE 12.4 Pharmacological treatment of common opportunistic infections and malignancies in HIV disease

CONDITION	TREATMENT	POTENTIAL ADVERSE EFFECTS
Infections		
Pneumocystis carinii pneumonia	Trimethoprim/sulfamethoxazole Pentamidine	Rash, neutropenia, anaemia, thrombocytopenia, Stevens–Johnson syndrome Hypotension, altered blood glucose levels, hypocalcaemia, anaemia and leucopenia, liver and renal toxicity, pancreatitis
Tuberculosis	Combination drug therapy using isoniazid, rifampicin, ethambutol, pyrazinamide or streptomycin	Multiple; see Chapter 35
Candidiasis	Clotrimazole troches	Few toxic responses noted
Oral thrush	Nystatin suspension	
Oesophagitis or recurrent vaginitis	Ketoconazole Fluconazole Amphotericin B	Hepatitis, adrenal insufficiency Hepatitis Bone marrow toxicity, acute renal or hepatic failure; nausea, vomiting; chills, fever, headache
Mycobacterium avium complex	Combination therapy using • Clarithromycin, plus • Clofazimine • Ethambutol • Rifampin • Ciprofloxacin • Amikacin	 • Hepatitis, nausea, diarrhoea • Diarrhoea, nausea, vomiting; skin discolouration, pruritus, rash • Thrombocytopenia, hepatitis, optic neuritis • Bone marrow depression, renal failure, hepatitis • Nausea, rash • Bone marrow depression, renal failure, ototoxicity, hepatitis
Cytomegalovirus	Ganciclovir	Bone marrow depression, fever
	Foscarnet	Renal failure, electrolyte imbalances, seizures
Herpes simplex or herpes zoster	Aciclovir	Nausea, vomiting, diarrhoea; CNS effects; renal failure
Toxoplasmosis	Pyrimethamine, plus sulfadiazine or clindamycin and folinic acid	Bone marrow depression, rash; respiratory failure; nausea, vomiting, abdominal pain; haematuria
Malignancies		
Kaposi's sarcoma	Intralesional vinblastine	Inflammation and pain at injection site
Lymphoma	Combination chemotherapy	Nausea, vomiting; bone marrow toxicity; alopecia

People who do engage in sexual activity need to know and practise safer sex (see Box 12.4). Reducing the number of sexual partners—for example, by entering into and remaining in a long-term mutually monogamous relationship with an uninfected partner—reduces the risk. People should not engage in unprotected sex, especially if the HIV status of the partner is unknown. Latex condoms have been shown to reduce the risk of transmitting HIV. Their effectiveness is improved when nonoxynol-9, a spermicide, is used for lubrication; however, it may cause genital ulcers, which can facilitate HIV transmission. To be effective, condoms must be used with every sexual encounter involving vaginal, oral or anal intercourse. They also need to be applied and removed properly. A female condom is also available for use.

Healthcare workers exposed to HIV infection or adults who experience a high-risk exposure to HIV may choose postexposure prophylaxis. Risk of exposure for healthcare workers may be through needle sticks or cuts with a sharp object, contact with mucous membranes or non-intact skin, semen, vaginal secretions, fluids contaminated with visible blood and possibly CSF, synovial fluid and pleural, peritoneal, pericardial or amniotic fluids. CDC guidelines recommend treatment with HAART, which includes two NRTIs for lower-risk exposures and the addition of a third drug for higher-risk exposure. A 4-week course of treatment is recommended and should be started within 72 hours, preferably within 2 to 3 hours of exposure (Bartlett & Weber, 2005).

The most difficult group of high-risk people to reach and educate has been injection drug users. People in this group should never share needles, syringes or other drug paraphernalia. Australian cities have established needle-exchange programs, providing a sterile needle and syringe in exchange for a used one. It is important also to teach people in this population about safer sex practices, because most heterosexual HIV transmission occurs between injection drug users and their partners.

Australia's blood screening ensures one of the safest blood supplies in the world. Screening of voluntary blood donors and donated blood supplies commenced in 1985 and has reduced the risk of transmission of HIV/AIDS by transfusion, with no transmission via transfusion since 1985. Because current blood-screening methods use antibody testing, receiving donated blood

BOX 12.4 Guidelines for safer sex

- Practise mutual monogamy; if you are not in a mutually monogamous relationship, limit the number of sexual partners.
- Do not engage in unprotected sex, especially if the HIV status of your partner is unknown. (Remember that a person may be infected and infective for up to 6 months before converting to seropositive status.)
- When entering into a new monogamous relationship, both partners should undergo HIV testing initially. If both are negative, practise abstinence or safer sex for 6 months, followed by re-testing. If results still indicate that both partners are negative, sexual activity can probably be considered safe.
- Use latex condoms for oral, vaginal or anal intercourse; avoid natural or animal-skin condoms, which allow passage of HIV.
- For vaginal or anal sex, lubricate the condom with the spermicidal agent nonoxynol-9 for additional protection.
- Do not use an oil-based lubricant such as petroleum jelly, which can result in condom damage; water-based lubricants are acceptable.
- Women should carry and use a female condom.
- Remember that use of other means of birth control, such as oral contraceptives, provide no protection against HIV; barrier protection with a condom is necessary.
- Engage in safer sexual practices that are less damaging to sensitive tissues (e.g. mutual masturbation, avoiding anal or oral sex).
- Do not use drugs or alcohol.
- Do not share needles, razors, toothbrushes, sexual toys or other items that may be contaminated with blood or body fluids.
- If HIV positive:
  a. Do not engage in unprotected sexual activity.
  b. Inform all current and former sexual partners of HIV status.
  c. Inform all healthcare personnel—primary care providers, doctors and dentists, in particular—of HIV status.
  d. Do not donate blood, plasma, blood products, sperm organs or tissue.
  e. If female, do not become pregnant.

continues to carry a small risk. People in the *window period* between contraction of the virus and the development of detectable antibodies are able to transmit the virus to others, even though they do not yet test positive for HIV. This window period usually lasts from 6 weeks to 6 months; rarely, it lasts up to 1 year. When possible, encourage people to use autologous transfusion, donating their own blood prior to an anticipated surgery. Seeking donations from family members is not encouraged for several reasons. Family members may have engaged in high-risk behaviours but lie about their risk because of embarrassment or fear of discovery. Furthermore, the family member may have a different blood type or have other contraindications to donating.

Encourage HIV-positive people to abstain from donating blood organs or sperm. They should understand tactics to avoid exchange of body fluids by not sharing needles or other drug paraphernalia, not sharing razors and not obtaining a tattoo. Stress the importance of informing all medical personnel providing direct care (especially anyone performing a dental, surgical or obstetric procedure) about the diagnosis.

Healthcare workers can prevent most exposures to HIV by using standard precautions (see Figure 12.11). Testing to determine HIV status remains voluntary and relies on the use of antibody-screening methods. It is therefore impossible to identify every person who is HIV positive. With standard precautions, all people are treated alike, eliminating the need to know the person's HIV status. All high-risk body fluids are treated as if they are infectious and barrier precautions are used to prevent skin, mucous membrane or percutaneous exposure to them. Counselling and testing are provided to healthcare workers with a documented needle-stick exposure. Some clinicians and facilities recommend prophylactic AZT therapy after needle-stick or splash exposure; however, it must be initiated immediately and its effectiveness has yet to be established.

FIGURE 12.11 ■ This nurse is disposing of a needle and syringe in a special container, a necessary practice to avoid the transmission of HIV through needle sticks with contaminated needles

Assessment

Collect the following data through health history and physical examination. Further focused assessments are described with nursing interventions below.

- *Health history:* risk factors (transfusion, unprotected sex, needle exposure), infections (sexually transmitted infections, hepatitis, tuberculosis), medications, recreational drug use, foreign travel, pets.
- *Physical assessment:* height, weight, nutrition, skin and mucous membranes, vision, lymph nodes, breath sounds, abdominal tenderness, motor strength, coordination, cranial nerves, gait, deep tendon reflexes, genitourinary examination, mental status. Remember that symptoms must be interpreted and reported by the person. Like pain, the presence and severity of dyspnoea are determined and reported by the person. We must believe what the person tells us. Assessment is the basis for differential diagnosis; fitting appropriate treatment to the correct aetiology is critical. For example, delirium is an acute confusional state and, unlike dementia, is reversible. There are effective nursing interventions for these conditions (Coyne et al., 2002).

Nursing diagnoses and interventions

Nursing care needs for the person with HIV infection change over the course of the disease. Preventive healthcare measures, health maintenance activities, education and support of coping mechanisms are important in the early stages of the disease. Counselling the person with a new diagnosis of HIV infection is vital. HIV infection and AIDS continue to carry a social stigma that may interfere with the person's usual support systems and coping mechanisms. As the disease progresses and the person experiences more physical symptoms, direct care needs become more important while the need for psychosocial support continues. Acute exacerbation of opportunistic infections may necessitate hospitalisation, but typically the person is managed at home. See the following 'Nursing care plan'.

Ineffective coping

On receiving the test results indicating HIV seropositive status, the person with HIV infection is faced with multiple issues rarely affecting other people. First and foremost, HIV is a disease for which there is no known cure and which is, at this time, thought to be almost universally fatal. Social support systems, family relationships, and the ability to obtain and retain useful work and health insurance may be disrupted by the disease. The person may experience guilt about their lifestyle and how the disease was contracted. As the disease progresses, social isolation, fatigue, body image changes, medication side effects and multiple other issues affect the person's abilities to cope.

- Assess social support network and usual methods of coping. *This will help both the nurse and the person identify people and mechanisms that can help the person cope more effectively with the disease.*
- If possible, assign a primary nurse, whether the setting is community-based, hospice or acute care. *This helps promote the development of a therapeutic and trusting relationship and provides for continuity of care.*
- Plan for consistent, uninterrupted time with the person. *Time and a consistent presence encourage the person to express feelings and work through issues related to HIV infection.*
- Interact at every opportunity outside of providing specific nursing care treatments. *This purposeful interaction communicates caring and acceptance without fear of HIV disease.*
- Support the person's social network. Non-traditional families may offer more support than the traditional family. *This in turn may necessitate a liberal interpretation of the term 'family' if unit policy is 'immediate family' only.*
- Promote interaction between the person, significant others and family. *Hospitalisation and manifestations of HIV disease may bring about isolation from others and decrease the person's ability to cope.*
- Encourage involvement in making care decisions. *This gives the person a greater sense of self-worth and control over the situation, increasing coping abilities.*
- Set and maintain limits on manipulative and other destructive behaviours. *The person who is unable to limit inappropriate behaviours needs the external control established by setting limits.*
- Assist to accept responsibility for actions without blaming others. *Effective coping cannot occur without accepting responsibility for one's actions.*
- Support positive coping behaviours, decisions, actions and achievements. *As self-esteem is enhanced, coping improves* (Côté & Pepler, 2005).

Impaired skin integrity

Dryness, malnutrition, immobility from fatigue and skin lesions on pressure sites contribute to impaired integrity of the skin for the person with HIV disease. Maintaining skin integrity is important because of the progressive and debilitating nature of the disease. It is also a consideration both as the first line of defence against infection in an immunosuppressed person and as a site for secondary manifestations such as KS and herpes.

- Monitor and assess the skin frequently for lesions and areas of breakdown. *Early identification of impaired skin integrity allows prompt intervention.*
- Monitor lesions for signs of infection or impaired healing. *Infection or poor tissue perfusion not only impairs healing but may lead to further skin breakdown.*
- Turn at least every 2 hours, more frequently if necessary. *Turning decreases unrelieved pressure on bony prominences and improves circulation to the tissues.*
- Use pressure-relieving devices, such as alternating air mattresses and overlays, or sheep skin pads for elbows and heels. *These devices provide prophylactic relief of pressure.*
- Keep skin clean and dry using mild, non-drying soaps or oils for cleansing. Night sweats and diarrhoea, if present, can cause breakdown and damage to the skin. *Frequent cleansing with non-drying products discourages bacterial growth, thus reducing the risk of infection.*

TRANSLATION TO PRACTICE Evidence-based practice and nurses' willingness to care for people with AIDS

As reported by the Centers for Disease Control and Prevention in the United States (2006), the number of deaths from AIDS has declined. This is believed to be the result of both the slowing of the epidemic and of improved treatment, which has lengthened the lifespan of people with AIDS. However, as treatment continues to improve survival, a key challenge will be the increasing number of people living with HIV and AIDS and the additional resources needed for services, treatment and care.

Several studies have found that some professional nurses and students are resistant to caring for people with AIDS. One study by Sherman (1996) examined relationships between moral choices and nurses' willingness to care for people with AIDS. The willingness to provide care for people with this illness involves moral choices about one's own mortality (death anxiety), spirituality and social support. In a survey of 220 Registered Nurses employed in eight hospitals in the New York metropolitan area, Sherman found that willingness to care for people with AIDS was positively correlated with spirituality and perceived social support, and negatively correlated with death anxiety. It is suggested that nurses' willingness to care for people with AIDS may be related not only to nurses' personal values and beliefs (expressed in spirituality) but also to their professional identity and role expectations.

Addressing nursing reluctance to treat people with HIV infection, nursing educators Valois et al. (2001) researched the impact of persuasive messages on nursing students' beliefs and attitudes about caring for HIV-positive people. Nursing education certainly increases knowledge and awareness of the science of HIV infection, but it may not modify attitudes or behaviours. According to the underlying theory of the research, individuals who receive evidence-based persuasive messages may develop favourable beliefs that will alter their willingness to perform a given behaviour. Three main types of beliefs were considered in this study: behavioural belief (related to the expected consequences of adopting a behaviour); normative belief (related to perceived social pressures by significant others resulting from adopting a behaviour); and control belief (related to resources or barriers that seem to facilitate or hamper adoption of the behaviour).

In three sessions, the student nurses in the experimental group were given positive persuasive messages about caring for HIV-infected people. The persuasive messages were compelling and specific to caring for people with HIV; case studies provided opportunities for the students to discuss the elements of the case within the framework of the persuasive messages. Students in the control group studied the science of caring for people with HIV but did not receive the persuasive messages. When beliefs and attitudes about caring for HIV-positive people were compared, the researchers found significantly greater willingness to provide care in the experimental group. Nursing students proved to be well prepared and motivated to receive this information.

IMPLICATIONS FOR NURSING

To increase nurses' willingness to care for people with AIDS, students need to be better socialised into their roles and responsibilities. Incorporating education about HIV/AIDS into the undergraduate curriculum; analysing and defining effective nursing care in cases based on evidence-based framework; and utilising the standards of professional nursing all support the development of positive attitudes. Discussions within the classroom and clinical settings provide a safe means of bringing fears into the open and sharing experiences. Student groups can serve as support groups, improving communications, decreasing isolation and anxiety, and improving self-esteem and morale. Within the work setting, perceived support from colleagues and administrators as well as increased contact with people with AIDS are important factors in making caring a rewarding and positive experience.

CRITICAL THINKING IN PERSON-CENTRED CARE

1. These studies were of student nurses and Registered Nurses. What differences do you think might have been found between the two groups today?
2. Carefully consider each of the following people with AIDS and write a brief paragraph about how you would feel if you were assigned to care for them:
   a. a heterosexual female, aged 25
   b. a homosexual male, aged 35
   c. a newborn baby girl
   d. a 40-year-old single mother of three teenagers
   e. a 30-year-old homeless drug user
   f. a 17-year-old male with haemophilia, infected by blood transfusions

- Gently massage around, but not over, affected pressure sites or bony prominence to increase circulation to the surrounding tissue. *Massaging over the affected area or bony prominences can cause skin breakdown.*
- If blisters are noted, leave intact and dress with a hydrocolloid dressing or as per organisational protocol. *Blisters provide natural sterile coverings for damaged tissue, improving healing and preventing bacterial invasion.*

CONSIDERATION FOR PRACTICE

Applying protective creams to reddened areas in the rectal area protects skin from the caustic effects of diarrhoea.

- Caution against scratching. If the person is confused, trim fingernails and use mitts or soft restraints to prevent scratching. Check for circulation of hands and fingers frequently if mitts or restraints are used. *Scratching and skin damage allow bacteria to be introduced into lesions, increasing the risk of infection. Tight or restrictive restraints or mitts may compromise circulation.*
- Avoid the use of heat or occlusive dressings. *Heat can further dry and damage the skin; occlusive dressings may impair circulation and lead to ulceration.*
- Prevent skin shearing by using a slide sheet and adequate personnel when repositioning. *Shearing causes tissue trauma that can lead to decubitus ulcers.*

NURSING CARE PLAN A person with HIV infection

Sara Lu is a 26-year-old primary school teacher who lives with her parents and two younger sisters. Ms Lu is very close to her parents and sisters; they share everything with each other. During a routine medical check-up, Ms Lu tells her doctor that lately she has felt fatigued. She also states that she has had a persistent sore throat, intermittent bouts of diarrhoea and mild shortness of breath for about a month. She takes no routine medications other than a daily multivitamin and an occasional paracetamol tablet for a headache. She is active in a drama club in her community and she jogs 5 km three to four times a week. She is engaged to be married; her wedding date is 6 months away. Her fiancé is the only person with whom she has had sexual relations. Her sexual activity has been unprotected. Ms Lu has a history of open-heart surgery 7 years ago to correct a congenital valve defect. She has been physically healthy since that time, until about a month or two ago. The doctor orders a mononucleosis test, ELISA, Western blot analysis, CD4T-cell count, a p24 antigen test and an erythrocyte sedimentation rate (ESR). Ms Lu has been asked to return in 1 week for follow-up.

ASSESSMENT

On Ms Lu's follow-up visit, Carole Kee, RN, obtains her nursing history. Ms Lu continues to have flu-like symptoms but has improved somewhat. She states that she has not been as active as usual and is worried about her health. Her appetite has decreased because of soreness in her mouth, and she has noted some whitish patches on her tongue and cheeks.

A chest x-ray film reveals no abnormality. The results of her laboratory tests are as follows:

- ELISA: positive for antibodies against HIV
- Western blot analysis: positive for antibodies against HIV
- p24 antigen test: positive for circulating HIV antigens
- ESR: increased to 55 mm/h (normal for women is 15 to 20 mm/h; normal for men is 10 to 15 mm/h)
- CD4T-cell count: 499/mm^3 (normal range is 500–1350/mm^3).

Ms Lu's physical examination reveals that she has enlarged lymph nodes in her neck and white patches on her oral mucosa. Her skin is warm to the touch. Her vital signs are as follows: T 37.7°C, P 84, R 20 and BP 120/78.

Ms Lu is told of the results of her laboratory tests and the medical diagnosis of HIV infection. Ms Lu is obviously distressed and wants to know how this happened, its meaning, whether she has infected her loved ones and whether she will get better.

DIAGNOSES

- *Imbalanced nutrition* related to soreness of mouth and throat as evidenced by nutritional intake being less than body requirements.
- *Risk of deficient fluid volume* related to decreased fluid intake and diarrhoea as evidenced by fluid intake being less than body requirements.
- *Risk of infection* related to altered immune protection as evidenced by elevated ESR.
- *Risk of anxiety* and fear related to diagnosis as evidenced by distress.
- *Knowledge deficit* related to the HIV disease process as evidenced by questions asked.

PLANNING

- Plan time to educate Ms Lu on the importance of nutritionally balanced diet and maintaining adequate fluid intake.
- Identify strategies for coping with anorexia and nausea.
- Referral for dietary consultation.
- Plan time for discussion of concerns and coping strategies.

Expected outcomes

- Maintain adequate nutrition for optimal body and cellular function.
- Consume at least 2500 mL of fluid per day.
- Remain free of infections and their complications.
- Verbalise anxiety and use appropriate coping mechanisms.
- Verbalise and demonstrate knowledge of HIV disease.
- Verbalise measures to prevent HIV transmission to others, including safer sex practices.

IMPLEMENTATION

- Monitor for signs of dehydration, such as poor skin turgor, oliguria and orthostatic hypotension.
- Monitor daily weight and intake and output.
- Monitor dietary habits and serum albumin levels.
- Assess bowel sounds and monitor elimination pattern.
- Administer antiemetic and antimotility medications as ordered.
- Increase fluid to 2500 mL daily.
- Use strict aseptic technique for all invasive procedures.
- Teach Ms Lu to avoid exposure to infection and people with known illnesses.
- Monitor response to prescribed medications.
- Encourage regular physical exercise.
- Provide opportunities for Ms Lu to verbalise her feelings.
- Avoid false reassurances.
- Provide appropriate and adequate information about HIV/AIDS.
- Teach safer sex practices and other measures to prevent HIV transmission.
- Teach anxiety-controlling techniques, such as deep breathing and meditation.

EVALUATION

Ms Lu is eager to learn about her illness and wants her family to come with her for further explanation. She states that she is sure her fiancé will be available as well. Ms Lu is taking home antifungal medication, diet plans and a schedule for increased exercise. She will return in 1 week for counselling and in 1 month for a follow-up medical.

CRITICAL THINKING IN THE NURSING PROCESS

1. How does age affect the body's response to fighting HIV? What other factors affect the risk of HIV infection and its progression?
2. Are the laboratory results for Ms Lu a true indication that she is HIV positive? What additional tests might be ordered?
3. What is the most likely source of Ms Lu's infection? What measures are used to reduce this risk and how did she contract HIV? What is another possible source of Ms Lu's HIV infection?
4. Ms Lu says that her fiancé would like to have a child. How will you counsel her regarding pregnancy and childbearing?

REFLECTION ON THE NURSING PROCESS

1. Outline what you have learned from this case study that you will apply to your future practice.
2. What communication and education strategies could you use when caring for a person newly diagnosed with HIV?

- Encourage ambulation if possible; if the person is confined to bed, encourage active or passive range-of-motion exercises. *Activity increases circulation, decreases pressure and skin breakdown, and helps maintain muscle tone.*
- Monitor nutritional intake and albumin levels. *Maintenance of optimal nutrition decreases the risk of tissue breakdown and improves resistance to infection.*

Imbalanced nutrition: less than body requirements

Many factors associated with HIV disease, including manifestations of the disease itself, put the person at risk of altered nutrition and weight loss. Nausea and anorexia may be manifestations of the disease or the result of antiretroviral therapy. Chronic diarrhoea is a common manifestation of constitutional HIV disease. Wasting syndrome is also common. It is manifested by involuntary weight loss of greater than 10% to 15% of baseline weight, severe diarrhoea, fever, and chronic fatigue and weakness. The exact cause of wasting syndrome is unclear, but the diarrhoea and fatigue contribute, as does the increased metabolic rate associated with fever. Oral and oesophageal candidiasis and KS of the gastrointestinal tract may cause painful swallowing, making eating difficult and thereby contributing to anorexia. Poor nutritional status in the person with HIV can ultimately result in altered comfort, a change in body image, muscle wasting, increased risk of infection, and higher mortality and morbidity.

- Assess nutritional status, including weight; body mass; kilojoule intake, and laboratory studies such as total protein and albumin levels, haemoglobin and haematocrit. *These factors provide a baseline to determine the effectiveness of interventions.*
- Identify possible causes of altered nutrition. *Identification of causes provides direction for planned interventions.*
- Administer prescribed medications for candidiasis and other manifestations as ordered. Eliminating this opportunistic infection improves comfort and facilitates food intake. *Topical viscous anaesthetic can help to reduce pain and improve oral intake.*
- Administer antidiarrhoea medications after stools and antiemetics prior to meals. Provide antipyretics as needed to control fever. Reducing diarrhoea will improve nutrient absorption; preprandial medication with an antiemetic reduces nausea and improves food intake. *Reduction of fever lowers the body's metabolic demands.*
- Provide a diet high in protein and kilojoules. *A high-protein, high-kilojoule diet provides the necessary nutrients to meet metabolic and tissue healing needs.*
- Offer soft foods and serve small portions. *Soft foods are easily digested. Small portions are more appealing to the anorectic or nauseated person.*

CONSIDERATION FOR PRACTICE

High-fibre foods can increase intestinal motility and the incidence of diarrhoea.

- Involve in meal planning and encourage significant others to bring favourite foods from home. *The person is more likely to consume adequate amounts of preferred foods. Allowing food choices enhances the person's sense of control.*
- Assist with eating as needed. *Fatigue and weakness can prevent the person from eating an adequate amount of food.*
- Provide supplementary vitamins and supplements, such as Ensure. *This improves nutritional status and kilojoule intake.*
- Provide or assist with frequent oral hygiene. *Oral hygiene improves comfort and appetite and reduces the risk of mucosal lesions.*
- Administer appetite stimulants, such as megestrol or dexamethasone, as ordered. *Both drugs may increase appetite and promote weight gain.*

Ineffective sexuality patterns

The diagnosis of HIV infection can significantly alter the person's expressions of sexuality. Guilt over the diagnosis may interfere with libido. The person may be angry with a significant other or partner if that person was the probable source of infection. The person may fear spreading the disease to others via sexual relations. As the disease progresses, its manifestations can affect body image and self-esteem, impairing sexuality. Other symptoms, such as nausea, fatigue and weakness, may also interfere with libido and sexual satisfaction.

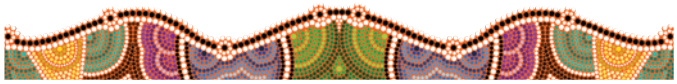
- Examine your feelings about sexuality, your role in dealing with a person's sexuality, the person's lifestyle and sexual preferences. *To deal effectively with the person's concerns, it is vital that the nurse is comfortable with their own feelings of sexuality and is able to accept the person's lifestyle. Referring the person to another nurse or counsellor may be necessary.*
- Establish a trusting, therapeutic relationship through the use of time, active listening, caring and self-disclosure. Maintain a non-threatening, non-judgmental attitude towards the person. *Sexuality is a private issue that will be uncomfortable or impossible for the nurse and person to discuss without a mutually trusting relationship.*
- Provide factual information about HIV infection and its effects. *This helps the person separate fears and myths from reality.*
- Discuss safer sex practices, including hugging, cuddling, non-sexual contact, the use of latex condoms and spermicidal lubricant, and mutual masturbation. *Alternative forms of sexual activity and expressing affection can allow the person and significant other to remain close throughout the course of the disease.*
- Encourage discussion of fears and concerns with significant other. *Open communication helps them to deal with issues related to sexuality.*
- For the person without a significant other, stress the need to continue to meet people and develop social relationships while practising safer sex. *The risk of isolation is high in the person with HIV infection, and relationships with others help the person to cope with the disease.*
- Refer the person and significant other to local support groups for people and partners of people with HIV. *Support groups provide a social and support network of people facing the same issues.*

Community-based care

Teaching needs for both the person and significant others are extensive. The primary need is information about the disease, its spread and its expected course. The person and family need current factual information to plan realistically and to combat myths, misperceptions and prejudices. At the same time, it is important to include information about current research and progress in treating the disease to maintain a sense of hopefulness.

The following topics should be discussed with the person and family to prepare for home care:

- guidelines for safer sex practices
- nutrition, rest and exercise, stress reduction, lifestyle changes and maintaining a positive outlook
- infection prevention and transmission, including handwashing and wearing gloves when handling people's secretions or excretions
- importance of regular medical follow-up and monitoring of immune status
- signs and symptoms of opportunistic infections and malignancies, as well as other symptoms that should be reported
- medications and adverse effects
- use and care of central venous access devices, total parenteral nutrition, intravenous pumps and continuous medication delivery systems, and intravenous or aerosolised medications
- cessation of smoking, alcohol and recreational or illicit drug use
- community health services
- hospice and respite care services
- community resources, such as support groups, social agencies and counsellors
- helpful resources:
  - National Association of People with AIDS
  - ACRON (www.acron.org.au)
  - Australian AIDS Information Services
  - Multicultural HIV/AIDS and Hepatitis C Service (MHAHS).



CHAPTER HIGHLIGHTS

- The immune system is a complex combination of cellular and humoral components that protect against disease. Immunity develops when the body recognises foreign proteins as 'non-self' and develops non-specific inflammatory responses and specific cellular responses to each foreign antigen.
- People suffer when the immune system is excessively or inadequately responsive or when recognition of self fails and reactions escalate against self. The latter occurs in autoimmune diseases.
- With ageing, there is a general decline in the sensitivity and regulation of the immune system, often resulting in autoimmune disease.
- Hypersensitivities are excessive responses to antigens that result in harm to the person. These range from benign to severely life-threatening. Damage to host tissue is caused by chemicals of the immune response, destruction of cells or creation of large antigen–antibody complexes that accumulate in the kidney glomerular capillaries.
- Allergic reactions are treated pharmacologically to prevent or moderate allergic responses. Another method of dampening allergic responses is by desensitisation, a weekly process of introducing increasing amounts of known allergens subdermally.
- People must be taught that the safest practice is to avoid contact with all known allergens.
- Latex allergy is a problem for healthcare professionals. Repeated exposure to latex-containing equipment and gloves results in delayed hypersensitivity.
- Any type of allergic reaction has the potential to escalate to anaphylaxis. Respiratory arrest and cardiac failure are risks with full-blown allergic reactions. Nurses must recognise early signs and symptoms and immediately signal for emergency care.
- Intentional immunosuppression is an essential step in preventing transplant rejection. The person receiving a transplanted organ will be treated with immune-suppressing drugs to prevent initial rejection, to maintain the transplant and to halt any rejection process that may develop. People will take the immune-suppressing, antirejection drugs for their lifetime. The drugs prevent cytokine production that up-regulates an immune reaction and targets the transplanted organ. Most immunosuppressing drugs are nephrotoxic; immunosuppression places people at greater risk of infection and cancers.
- HIV/AIDS continues to spread and many people are unaware they have the virus. AIDs is a profoundly immunosupressed condition that results from viral destruction of cellular components of host immunity.
- A major change in the AIDS epidemic is the disease profile, which has benefited from HAART. HAART is a combination of drugs that limits viral replication and host susceptibility to opportunistic infections and cancer. People are living much longer with the disease without progression to AIDS. 'Pill burden' refers to the number of pills the person must take daily to maintain immune function; side effects of the combination of drugs which make up HAART are appearing as people live longer. In addition to increased susceptibility to infections and cancers, people suffer from a dementia peculiar to AIDS.

CONCEPT CHECK

1 Which one of the following conditions is caused by a type I IgE-mediated hypersensitivity reaction?
   1 autoimmune haemolitic anaemia
   2 systemic lupus erythematosus
   3 graft rejection
   4 anaphylaxis

2 A person received a liver transplant 1 day ago. If the person were to develop an acute transplant rejection episode, when should the nurse expect to see the manifestations?
   1 approximately 4 days to 3 months later
   2 approximately 2 days later
   3 within the first 24 hours
   4 within the first 8 hours

3 The nurse notes a cough, shortness of breath and tachypnoea in a person with AIDS. Which opportunistic infection is probably causing these manifestations?
1 *Toxoplasma gondii*
2 Cytomegalovirus
3 *Pneumocystis carinii*
4 *Cryptococcus neoformans*

4 Which of the following explanations should the nurse give to a person who has tested positive for HIV?
1 'You have been diagnosed with AIDS.'
2 'At this point, AIDS is not active in your blood.'
3 'This means that you will not develop AIDS in the future.'
4 'Antibodies to the AIDS virus are present in the blood.'

5 People taking zidovudine should be monitored for which of the following adverse reactions?
1 cardiotoxicity
2 leucopenia
3 nephrotoxicity
4 polycythaemia

6 The order of administering antigens in allergy testing is based on prevention of anaphylaxis. Which method should be used first?
1 inhalation
2 prick test
3 intradermal injection
4 subcutaneous injection

7 If a hypersensitivity response is suspected when blood products are infusing, the nurse should:
1 discard the product immediately
2 replace all tubing and attach a new line with normal saline
3 backflush the line and run normal saline attached at the Y tubing
4 remove the intravenous catheter and establish access distal to the site

8 Protease inhibitors and nucleoside analogues share correlations to metabolic abnormalities, including:
1 lactose intolerance
2 diabetes mellitus
3 Hashimoto's thyroiditis
4 systemic lupus erythematosus

9 The priority when initiating or changing HIV drug therapy regimens is:
1 cost of therapy
2 access to dental care
3 toxicities associated with each drug
4 the person's willingness to adhere to the drug regimen

10 People receiving kidney transplants will receive immunosuppressant therapy. The agent used to induce immunosuppression immediately following a transplant is often:
1 azathioprine
2 corticosteroids
3 muromonab-CD3
4 antithymocyte globulin

CHAPTER 13

NURSING CARE OF PEOPLE WITH CANCER

CATHERINE BETHELL

LEARNING OUTCOMES

- Define cancer and theories of carcinogenesis, and differentiate benign from malignant neoplasms.
- Explain known carcinogens and identify risk factors for cancer.
- Compare the mechanisms and characteristics of normal cells with those of malignant cells.
- Describe physical and psychological effects of cancer.
- Describe and compare laboratory and diagnostic tests for cancer.
- Discuss and compare the role of surgery, chemotherapy and classification of chemotherapeutic agents, radiation therapy and biotherapy in the treatment of cancer.
- Identify causes and discuss the nursing interventions for common oncological emergencies.
- Develop an appropriate care plan for people with cancer and their families regarding cancer diagnosis, treatment and coping strategies.

CLINICAL COMPETENCIES

- Assess functional health status of people with cancer and monitor, document and report abnormal manifestations.
- Incorporate evidence-based practice and research into the plan of nursing care for people with cancer.
- Prioritise nursing diagnosis based on assessment data and implement appropriate nursing interventions for people with cancer during cancer diagnosis, treatment and rehabilitation.
- Safely administer chemotherapeutic medications and other medications for pain, nausea and vomiting, mucositis or anaemia.
- Use the nursing process as a framework for planning and providing individualised care and integrating interprofessional care for people with cancer to meet their healthcare needs.
- Include cultural variation and diverse values in designing and implementing individualised plans of care for people with cancer.
- Design and provide individualised education to the person and family to restore, promote and maintain the person's functional status.
- Revise the plan of care as needed to provide effective interventions for people with cancer and their families.

KEY TERMS

CANCER AND THEORIES OF CARCINOGENSIS

Cancer is a group of complex diseases with various manifestations, depending on which body system is affected and the type of tumour cells involved. Cancer can affect people of any age, gender, ethnicity or geographical region. Although the incidence and mortality rates of cancer have continued to decline since 1990, it remains one of the most feared diseases. The fear engendered by even the suggestion of a cancer diagnosis often evokes feelings of hopelessness and helplessness (Galway et al., 2012).

This chapter focuses on the general pathogenesis, pathophysiology and aetiology of cancer; identifies current diagnostic and treatment modalities; and discusses nursing care appropriate for people with cancer. Discussions of cancers that affect specific body systems (e.g. leukaemia, lung cancer) can be found in corresponding body system chapters in the text.

Cancer results when normal cells mutate into abnormal, deviant cells that proliferate and spread within the body. Cancer can affect any body tissue. Nursing care of the person with cancer is holistic and comprehensive, focusing on cancer not as one disease but as a constellation of many diseases. The nurse recognises that cancer is a disruptive and life-threatening process that affects the person who has the diagnosis, their family and their significant others. Nursing interventions are based on the understanding that cancer is a chronic disease that has acute episodes, and that the person is usually treated with a combination of therapeutic modalities within the home or community setting. Equally important, the nurse recognises that caring for the person with cancer involves prevention, early detection, treatment, supportive care, education, rehabilitation, long-term follow-up and end-of-life care (Oncology Nursing Society, 2009).

Oncology is the study of cancer. The term is derived from the Greek word *oncoma* ('bulk'). Oncologists specialise in caring for people with cancer. They may be medical doctors, surgeons, radiologists, immunologists or researchers. The oncology nurse is an important and significant member of the multidisciplinary team who has received specialised training in cancer care and treatment. Oncology nurses have specialised skills and knowledge to assist the person and family with the psychosocial issues associated with cancer and terminal illness. Collaboration among healthcare professionals (e.g. surgeons, oncologists, nurses, social workers) ensures a multidisciplinary approach in implementing the most effective care and treatment for the person with cancer.

INCIDENCE AND MORTALITY

In Australia, 114 000 new cases of cancer were diagnosed in 2010 with an estimated 43 000 cancer-related deaths (Australian Institute of Health and Welfare (AIHW) and Australasian Association of Cancer Registries (AACR) 2010a). Cancer is the second leading cause of death in Australia with a mortality rate of 1 in 5 before 85 years of age, with a higher incidence rate in males. Mortality rates for different cancers vary. Lung cancer was the leading cause of all cancer deaths in both men and women in Australia, accounting for 19% of all cancer deaths in 2007, with the second most common cancer-related deaths being prostate cancer in males and breast cancer in females. During 2003 to 2007 it was identified that cancer mortality rates decrease as socioeconomic status increases; and for cervical cancer, lung cancer and cancer with an unknown primary site, the cancer mortality rates increase with the remoteness of the area in which the person resides (AIHW & AACR, 2010a; 2010b).

Due to advances in cancer prevention, early detection and treatment, more than 60% of people with cancer will survive more than 5 years following diagnosis, with increases in survival rates being identified for prostate cancer from 57% to 85%, breast cancer from 72% to 88% and bowel cancer from 49% to 62% (AIHW & AACR, 2010a). Indigenous Australians have a lower 5-year survival rate following a cancer diagnosis and a higher mortality rate (Shahid, Beckmann & Thompson, 2008). During 2003 to 2007 there were 1813 cancer-related deaths and 2291 Indigenous Australians newly diagnosed with cancer (AIHW & AACR, 2010a; 2010b). Cancer has a greater impact on Indigenous Australians, who are more likely to live in a remote area of Australia with limited access to health infrastructures, and are less likely to have an early diagnosis and receive adequate treatment, such as preventive, curative and palliative services. It has been identified that Indigenous Australians have a lower incidence of skin melanoma, lymphoma, bladder and kidney cancer; however, they have a higher incidence of cancers that have poorer prognosis but are largely preventable, such as lung, liver, cervix, lip and oropharynx cancers. The patterns of cancer are related to the higher prevalence of health risk behaviours such as smoking in conjunction with the barriers created by inadequate health systems (Cunningham et al., 2008).

For information about diversity and cancer risk and incidence, see the 'Focus on cultural diversity' box below.

FOCUS ON CULTURAL DIVERSITY Cancer in Indigenous Australians

- The incidence of cancer is lower, but mortality rates are significantly higher, for Indigenous people.
- Indigenous Australians have a higher incidence of cancers of the lung and cervix, and cancer with an unknown primary site.
- Lower incidence rates have been identified for bowel cancer, lymphoid cancer, melanoma of the skin and breast cancer in Indigenous females and prostate cancer in Indigenous males.
- Indigenous Australians have a lower 5-year post-cancer survival rate than non-Indigenous Australians.
- Mortality rate is higher in Indigenous Australians for breast cancer, lung cancer and cancer with an unknown primary site, but lower for melanoma of the skin.

FAST FACTS

Cancer in Australia

- Breast cancer is the most commonly diagnosed cancer in women, with an incidence of 12 670 cases in 2010.
- Prostate cancer is the most commonly occurring cancer in men, with an incidence of 19 403 cases during 2010.
- The second most common cancer in males is bowel cancer (7804 cases) and the third most common cancer is melanoma of the skin (5980 cases); both of these as well as prostate cancer increased in incidence during 2010.
- The second leading cancer for females is bowel cancer (6430 cases) followed by melanoma of the skin (4362 cases); both breast cancer and melanoma of the skin increased in incidence during 2010.
- It is estimated that the number of cancers will continue to increase.
- During 2010 the five most common cancers attributed to 50% of all cancer-related deaths were lung cancer 7626 deaths, bowel cancer 4047 deaths, prostate cancer 2938 deaths, breast cancer 2706 deaths and lymphoid cancers 2552 deaths.

Risk factors

Risk factors make an individual or a population vulnerable to a specific disease or other unhealthy outcome. Risk factors can be divided into those that are controllable and those that are not controllable. Knowledge and assessment of risk factors are especially important in counselling people and families about measures to prevent cancer.

Genetics and heredity

It is estimated that 5% to 10% of cancers may have a hereditary component. Even though the majority of people will not have an inherited form of cancer, it is important to determine which people have a genetic predisposition. The familial pattern of some breast and colon cancers has been well documented. Lung, ovarian and prostate cancers have also shown some familial relationships. Recurring patterns of cancer within a family are a risk factor for a hereditary component, but do not necessarily indicate that a specific gene or mutation is the cause. An increased rate of cancer between relatives can be due to genetics as well as shared environmental exposures, lifestyle and other non-genetic risk factors. The Human Genome Project has identified new cancer-linked genes (Futreal et al., 2001). Familial cancers generally occur during old age, whereas hereditary cancers usually happen at a younger age (Jorde, Carey & Barnshad, 2010). For most cancers, research has yet to distinguish true genetic transfer from environmental causes. Although further research is needed to identify cancers that are due to the inheritance of defective genes, familial predisposition to malignancies should be counted among risk factors so that people at risk can reduce behaviours that promote cancer. For example, a person with a family history of lung cancer should be counselled to avoid smoking, to avoid areas where smoking is allowed and to avoid working in an occupation that may expose them to inhaled carcinogens.

Age

Cancer is a disease associated with ageing; the risk of being diagnosed with cancer before the age of 75 years is 1:3 and before 85 years is 1:2 (AIHW & AACR, 2010a). A number of factors are associated with this increased risk in older adults. One possible factor is that at least five cycles of genetic mutations seem necessary to cause permanent damage to the afflicted cells. In addition, long-term exposure to high doses of promotional agents is usually necessary to allow the cancer to take hold. Also, the immune response alters with ageing, its actions becoming more generalised and less specific (Blaylock, 1998). Another problem is that free radicals (molecules resulting from the body's metabolic and oxidative processes) tend to accumulate in the cells over time, causing damage and mutation.

Hormonal changes that occur with ageing can be associated with cancer. Postmenopausal women receiving exogenous oestrogen have an increased risk of breast and uterine cancers. Older men are at risk of prostate cancer, possibly due to breakdown of testosterone into carcinogenic forms. See the 'Nursing care of the older adult' box for a discussion about older adults and cancer.

Severe and/or cumulative losses also are implicated in promoting cancer (Gregorio et al., 2012; Hasselbalch, 2013). These losses, which are common to older adults, include the death of a spouse or friends, loss of position and status in society and a decline in physical abilities. These repeated stressors are related to changes in the immune system that may lead to the development of cancer.

Gender

Gender is a risk factor for certain types of cancer. Breast cancer is the most frequently diagnosed cancer in women and prostate cancer in men. The incidence of laryngeal cancer is three times higher in men than in women (AIHW & AACR, 2010a; 2010b). Cancer of the peritoneum and the thyroid occurs more commonly among females (AIHW & AACR, 2010a; 2010b). See Chapters 47 and 48 for more information on gender-specific cancers.

Poverty

The poor are at a higher risk of cancer than the population in general. Inadequate access to healthcare, especially preventive screening and counselling, may be a major factor. Other factors that may be involved, such as diet and stress, usually come under the category of controllable risks; however, these risks are frequently uncontrollable in this population.

Stress

Continuous unmanaged stress that keeps hormones such as adrenaline (epinephrine) and cortisol at high levels can result in systematic 'fatigue' and impaired immunological surveillance. When the body attempts to adapt to physiological and psychological stressors, it goes through a series of stages called

NURSING CARE OF THE OLDER ADULT Older adults with cancer

Nurses need to be aware of how cancer and cancer treatments affect older adults. Cancer is the fourth leading cause of death in people over 75. The incidence of cancer increases with advancing age, probably as a result of the accumulated exposure to carcinogens and to age-related declines in the action of the immune system. The most commonly seen cancers in women are breast, colorectal and lung cancers, and melanoma of the skin. In men, prostate, lung and colorectal cancers, and melanoma of the skin, occur most frequently.

The importance of screening and early detection of cancer does not diminish with age. Unfortunately, older adults may be less likely to undergo cancer screening or seek treatment for cancer due to fear, depression, cognitive impairments, poor access to healthcare or financial constraints. Some older adults (and healthcare providers) mistake cancer symptoms for normal age-related changes. Believing that little can be done, they do not seek healthcare for their symptoms. Fear of the cancer diagnosis also keeps older adults from seeking appropriate healthcare. When they do seek treatment, chronic conditions frequently seen in older adults may make the diagnosis of cancer more difficult by masking or confounding the usual symptoms associated with cancer.

Older adults are at greater risk of side effects associated with cancer treatment because of age-related physiological changes and chronic conditions associated with ageing. This is particularly true for the side effects of chemotherapeutic agents. The incidence of toxic effects on the heart and central nervous system is increased. The side effects of chemotherapy can contribute to fatigue and cause problems related to immobility and functional decline. Alterations in the function of the immune system are also more frequent in older adults, which increase their risk of developing infection.

The problems associated with chemotherapy do not rule out its use, but the nurse must be aware of potential problems and monitor the person closely for the development of side effects. The nurse needs to consider the effect of ageing on responses to the disease and its treatment.

HEALTH EDUCATION FOR THE PERSON AND FAMILY

- Discuss signs and symptoms of cancer.
- Stress the importance of seeking healthcare if any of the warning signs develop.
- Stress the importance of having an annual physical examination.
- For women, teach how to perform a monthly breast self-exam (BSE) and emphasise the importance of continuing BSE and regular mammography, available free from age 40 onwards.
- Teach men the early signs of prostate cancer and encourage them to have an annual digital rectal exam.

the general adaptation syndrome (Gregorio et al., 2012; Hasselbalch, 2013). First, the 'alarm reaction' occurs, in which adrenal hormones increase allowing the body to cope with the stressor. Eventually the body reaches the 'stage of resistance', in which the stress hormones are significantly reduced, indicating that adaptation has occurred. If the physiological adaptation is supported by appropriate coping strategies, the stressor is considered managed and the body systems return to pre-alarm functioning. However, if adaptation continues and the stress hormones remain elevated, the 'stage of exhaustion' sets in. This stage will maintain life but at great expense to body systems, resulting in general wear and tear and depression of the immune system (Antoni et al., 2012).

Diet

Some foods are considered genotoxic, such as the nitrosamines and nitrous indoles found in preserved meats and pickled, salted foods. Other foods, such as high-fat, low-fibre foods—the mainstay of many Australian diets—promote colon, breast and sex-hormone-dependent tumours. When fish and meat are excessively fried or grilled, potent carcinogenic compounds can form that may cause tumours in the mammary glands, colon, liver, pancreas and bladder. Also, repeatedly using fat to fry foods at high temperatures produces high levels of polycyclic hydrocarbons, which increase cancer risk considerably. Although many people profess to have changed their dietary habits, one only has to observe the large number of people who still lunch on hamburgers and chips (and teach their children to do the same) to realise that much more educational and motivational work is needed in this area. Other food-related substances believed to increase cancer risk include sodium saccharine, red food dyes and both regular and decaffeinated coffee.

Occupation

Occupational risk might be considered to be either controllable or uncontrollable. For many people, both education and ability limit their choice of occupation, particularly during times of high unemployment. Moreover, changing one's occupation because it poses risk factors may not be a viable option. Federal standards are designed to protect workers from hazardous substances, but many believe that these standards are not strict enough and that inspections are not frequent enough to prevent violations.

Specific risks vary according to the occupation. For example, outdoor workers such as farmers and construction workers are exposed to solar radiation; healthcare workers such as x-ray technicians and biomedical researchers are exposed to ionising radiation and carcinogenic substances; and exposure to asbestos is a problem for people who work in old buildings with asbestos insulation in the walls. Table 13.1 correlates known carcinogens and occupations.

Infection

As a number of viruses have been linked to some cancers, avoiding those specific infections will decrease risk. Although some infections may be unavoidable (e.g. Epstein-Barr) others, such as genital herpes and papillomavirus-induced genital warts, can

TABLE 13.1 Chemical carcinogens and relationship to occupation

CHEMICAL AGENT	ACTION	OCCUPATION AFFECTED
Polycyclic hydrocarbons (smoke, soot, tobacco, smoked foods)	Genotoxic	Miners, coal/gas workers, migrant workers
Benzopyrene		
Arsenic	Genotoxic	Pesticide manufacturers, mining
Vinyl chloride polymers	Promotional	Plastics workers
		Artists
Methylaminobenzine	Genotoxic	Fabric workers
		Rubber and glue workers
Asbestos	Promotional	Construction workers, workers in old, run-down buildings with asbestos insulation, insulation makers
Wood and leather dust	Promotional	Woodworkers, carpenters, leather toolers
Chemotherapy drugs	Genotoxic	Drug manufacturers, pharmacists, nurses

often be avoided by following safer sex practices (e.g. using condoms) or obtaining the human papillomavirus (HPV) vaccine. The HPV vaccine is currently given to 12–13-year-old females and males aged 14–15 years were able to receive it through a catch-up program as part of the Australian National Immunisation program (Department of Health and Ageing, 2012).

Tobacco use

Lung cancer is considered highly preventable because of its relationship to smoking. The genotoxic carcinogenic substances in tobacco are considered weak; therefore, stopping smoking can reverse the damage it causes. However, many other substances in tobacco are highly promotional, so that the larger the dose and longer the use, the higher the risk of developing cancer. Research has shown a significantly lower lung cancer death risk of former smokers compared to current smokers. Smokers who quit before middle age avoid more than 90% of the risk of lung cancer that can be attributed to tobacco.

Tobacco is also related to other forms of cancer. Smokers face an increased risk of oropharyngeal, oesophageal, laryngeal, gastric, pancreatic and bladder cancers. Pipe and cigar smokers are especially susceptible to oropharyngeal and laryngeal cancers. Oral and oesophageal cancers are more common among those who chew tobacco or use snuff. Smokers who have a genetic decrease in $alpha_1$-antitrypsin (an enzyme that protects lung tissue) that results in emphysema face an even higher cancer risk than smokers without this defect.

Additional research has documented the deleterious effects of second-hand tobacco smoke (Dietrich et al., 2002). Tobacco-specific nitrosamines were recovered in the urine of children living with smokers. It is now accepted that non-smokers exposed to tobacco smoke over long periods of time, whether in the workplace or the home, have an increased risk of lung or bladder cancers.

Alcohol use

Alcohol promotes cancer by enhancing the contact between carcinogens, such as those in tobacco, and the stem cells that line the oral cavity, larynx and oesophagus (Porth & Matfin, 2009). People who smoke and drink a considerable amount of alcohol daily have an increased risk of oral, oesophageal and laryngeal cancers.

Recreational drug use

Recreational drug use often promotes an unhealthy lifestyle that increases general cancer risk; for example, drug users often do not maintain adequate nutrition. Furthermore, recreational drugs are implicated as promoters because of their suppressive effect on the immune system. Although it has not been directly implicated in cancer development, marijuana has been demonstrated to cause chromosomal damage that may over time also result in cancer-causing DNA damage and genetic mutations. Marijuana smoke is also much more injurious to lung tissue than tobacco smoke.

Obesity

Excessive body fat has been linked to an increased risk of hormone-dependent cancers. Because sex hormones are synthesised from fat, obese people often have excessive amounts of the hormones that feed hormone-dependent malignancies of the breast, bowel, ovary, endometrium and prostate.

Sun exposure

As the protective ozone layer thins, more of the sun's damaging ultraviolet radiation reaches the earth. As a consequence, the rate of skin cancers has increased. Australia has one of the highest rates of skin cancer in the world, with the majority of skin cancers being caused by exposure to UV radiation in sunlight. Around 95% to 99% of skin cancers in Australia can be attributed to sun exposure (Cancer Council Australia (CCA), 2007). Sun-related skin cancers are considered to be a problem for all people, regardless of skin colour, but people with very fair skin, blue or green eyes, and light-coloured hair are most vulnerable. Older people with decreased pigment are also more at risk, even those with darker skin.

Figure 13.1 summarises the interaction of factors that promote cancer.

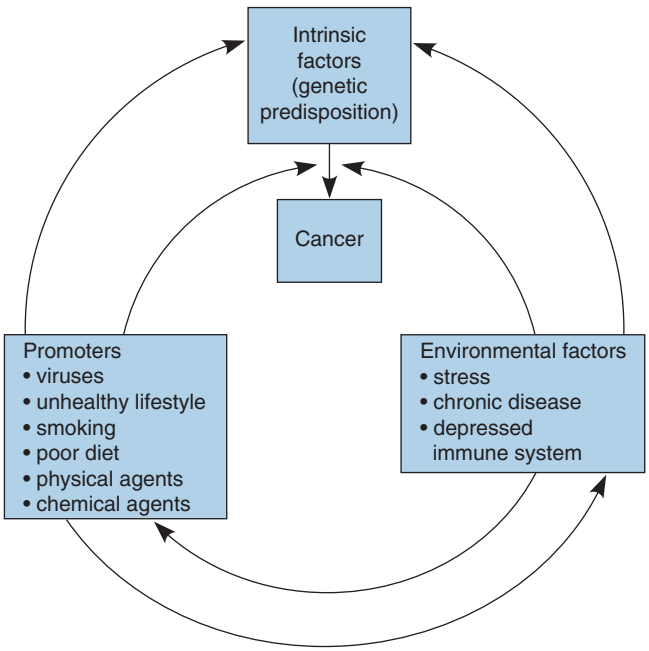

FIGURE 13.1 ■ Interaction of factors that promote cancer. Most people have immune systems that are competent enough to resist the establishment of cancer from an initiated cell. Cancer takes hold when a number of promotional factors occur together and over enough time to weaken immune resistance. Like factors are grouped together for ease of presentation but may occur in any combination

PATHOPHYSIOLOGY

Cancer is a complex disease with hundreds of agents that can contribute to its pathogenesis. Advances in research have greatly increased the understanding of how cancer develops. It is now known that the development of cancer is a process in which normal cells are changed and acquire malignant properties. Before moving on to discuss the various theories of the causes of cancer, it is useful to review how normal cells divide and adapt to changing conditions.

Normal cell growth

Mature normal cells are uniform in size and have nuclei that are characteristic of the tissue to which the cells belong. Within the nucleus of normal cells, chromosomes containing deoxyribonucleic acid (DNA) molecules carry the genetic information that controls the synthesis of polypeptides (proteins). Genes are subunits of chromosomes and consist of portions of DNA that specify the production of particular sets of proteins. Thus, genes control the development of specific traits. The genetic code in the DNA of every gene is translated into protein structures that determine the type, maturity and function of a cell. Any change or disruption in a gene can result in an inaccurate 'blueprint' that can produce an aberrant cell, which may then become cancerous. Box 13.1 lists some of the functions of DNA.

BOX 13.1 Functions of DNA

- Orders production of enzymes
- Instructs cells to produce specific chemicals
- Instructs cells to develop specific structures
- Determines individual traits and characteristics
- Controls other DNA by telling a cell to 'switch on' and use some portion of the genetic information stored in it

The cell cycle

Two coordinated events are responsible for cellular reproduction. Reproduction occurs as the result of replication of cellular DNA and mitosis, when the cell divides into two daughter cells with identical DNA.

The **cell cycle** consists of four phases. In the gap 1 or G_1 phase, the cell enlarges and synthesises proteins to prepare for DNA replication. During this phase the cell prepares to replicate and enter into the synthesis phase. During the synthesis (S) phase, DNA is replicated and the chromosomes in the cell are duplicated. During the next phase, gap 2 (G_2), the cell prepares itself for mitosis. Finally, with all preparation complete, the cell begins mitosis (M). This phase culminates in the division of the parent cell into two exact copies called daughter cells, each having identical genetic material. The cells then immediately enter G_1 where they begin the cell cycle again or divert into a resting phase called G_0. The cell cycle is controlled by cyclins, which combine with and activate enzymes called cyclin-dependent kinases. Some cyclins cause a 'braking' action and prevent the cycle from proceeding (Dunlop & Campbell, 2000). Checkpoints in the cell cycle ensure that it proceeds in the correct order.

A malfunction of any of these regulators of cell growth and division can result in the rapid proliferation of immature cells. In some cases, these cells are considered cancerous (malignant). Knowledge of cell cycle events is used in the development of chemotherapeutic drugs, which are designed to disrupt the cancer cells during different stages of their cell cycle. These drugs and their use are discussed later in the chapter.

Differentiation

Differentiation is a normal process occurring over many cell cycles that allows cells to specialise in certain tasks. For example, some epithelial cells lining the lungs develop into tall columnar cells with cilia. These columnar cells sweep potentially dangerous debris out of the lungs. When adverse conditions occur in body tissues during differentiation, protective adaptations can produce alterations in cells. Some of these alterations are helpful, but in other cases the cells mutate beyond usefulness and become liabilities (Porth & Matfin, 2009). Following are potentially unproductive cellular alterations that occur during cell differentiation:

- **Hyperplasia** is an increase in the number or density of normal cells. Hyperplasia occurs in response to stress, increased metabolic demands or elevated levels of

hormones. Examples include the hyperplasia of myocardial cells in response to a prolonged increase in the body's demand for oxygen and hyperplasia of uterine cells in response to rising levels of oestrogen during pregnancy. Hyperplastic cells are under normal DNA control.

- **Metaplasia** is a change in the normal pattern of differentiation such that dividing cells differentiate into cell types not normally found in that location in the body. The metaplastic cell is normal for its particular type, but it is not in its normal location. Some metaplastic cells are less functional than the cells they replace. Metaplasia is a protective response to adverse conditions. Metaplastic cells are under normal DNA control and are reversible when the stressor or other disruptive condition ceases.
- **Dysplasia** represents a loss of DNA control over differentiation occurring in response to adverse conditions. Dysplastic cells show abnormal variation in size, shape and appearance, as well as a disturbance in their usual arrangement. Examples of dysplasia include changes in the cervix in response to continued irritation, such as from the human papillomavirus or leucoplakia on oral mucous membranes in response to chronic irritation from smoking.
- **Anaplasia** is the regression of a cell to an immature or undifferentiated cell type. Anaplastic cell division is no longer under DNA control. Anaplasia usually occurs when a damaging or transforming event takes place inside the dividing, still undifferentiated cell, leading to loss of useful function. Anaplasia may occur in response to overwhelmingly destructive conditions inside the cell or in surrounding tissue (Porth & Matfin, 2009).

Although hyperplasia, metaplasia and dysplasia often reverse after the irritating factor is eliminated, they can lead to malignancy under certain conditions. This is especially true of dysplasia, which represents a loss of DNA control. Anaplasia is not reversible, but the degree of anaplasia determines the potential risk of cancer.

Theories of carcinogensis

Factors that cause cancer are both external (chemicals, radiation and viruses) and internal (hormones, immune conditions and inherited mutations). Causal factors may act together or in sequence to initiate or promote **carcinogenesis**. Ten or more years often pass between exposures or mutations and detectable cancer.

Central to these theories are two important concepts about the aetiology of cancer. First, damaged DNA, whether inherited or from external sources, sets up the necessary initial step for cancer to occur. Second, impairment of the human immune system, from whatever cause, lessens its ability to destroy abnormal cells.

Cellular mutation

The theory of cellular mutation suggests that carcinogens cause mutations in cellular DNA. It is believed that the carcinogenic process has three stages: initiation, promotion and progression. The initiation stage involves permanent damage in the cellular DNA as a result of exposure to a carcinogen (e.g. radiation, chemicals) that was not repaired or had a defective repair. Promotion may last for years and includes conditions, such as smoking or alcohol use, that act repeatedly on the already affected cells. In the progression stage, further inherited changes acquired during the cell replication develop into a cancer.

Oncogenes

Oncogenes are abnormal genes that promote cell proliferation and are capable of triggering cancerous characteristics. Oncogenes can be classified according to their overall function. Several oncogenes and their relationship to human cancers have been identified. For example, BRCA-1 and BRCA-2 are associated with breast cancer (Riley et al., 2012).

A decrease in the body's immune surveillance may allow the expression of oncogenes; this can occur during times of stress or in response to certain carcinogens. For example, people with AIDS, who have a decreased number of helper T lymphocytes, have a much higher than normal incidence of certain cancers, including non-Hodgkin's lymphoma and Kaposi's sarcoma (Petoumenos et al., 2013).

Tumour suppressor genes

Tumour suppressor genes normally suppress oncogenes. They can become inactive by deletion or mutation. Inherited cancers have been associated with tumour suppressor genes. An example is *p53*, a suppressor gene that has been associated with sarcoma and cancer of the breast and brain.

Known carcinogens

A number of agents are known to cause cancer, or at least are strongly linked to certain kinds of cancers. These known carcinogens include viruses, drugs, hormones and chemical and physical agents.

Carcinogens can be categorised into two groups: genotoxic carcinogens directly alter DNA and cause mutations, and promoter substances cause other adverse biological effects, such as cytotoxicity, hormonal imbalances, altered immunity or chronic tissue damage. Promoter substances do not cause cancer in the absence of previous cell damage (initiation) and often require high-level and long-term contact with the altered cells (see Table 13.1). Although everyone comes into contact with a vast number of substances that are considered carcinogenic, not everyone develops cancer. Other factors, such as genetic predisposition, impairment of the immune response and repeated exposure to the carcinogen, are necessary for a cancer to develop.

Viruses

Several viruses have been associated with the development of cancer. They damage cells and induce hyperplastic cell growth. Viral infection may play a role in cell mutation that can progress to malignant cells. Most people are able to suppress this progression (Spitalnick & diSant'Angnese, 2001). Box 13.2 identifies these viruses and the cancers with which they are associated.

In addition, viruses play a significant role in weakening immunological defences against neoplasms. For example,

BOX 13.2 Cancers associated with different viruses

Herpes simplex virus types I and II (HSV-1 and HSV-2)
- Carcinoma of the lip
- Cervical carcinoma
- Kaposi's sarcoma

Human cytomegalovirus (HCMV)
- Kaposi's sarcoma
- Prostate cancer

Epstein-Barr virus (EBV)
- Burkitt's lymphoma

Human herpesvirus-6 (HHV-6)
- Lymphoma

Hepatitis B virus (HBV)
- Primary hepatocellular cancer

Papillomavirus
- Malignant melanoma
- Cervical, penile and laryngeal cancers

Human T-lymphotropic viruses (HTLV)
- Adult T-cell leukaemia and lymphoma
- T-cell variant of hairy-cell leukaemia
- Kaposi's sarcoma

human immunodeficiency virus (HIV), which infects helper T lymphocytes and monocytes, impairs the person's protection against certain cancers such as lymphoma and Kaposi's sarcoma (Petoumenos et al., 2013).

Other viruses have also been associated with human malignancies. Hepatitis B virus integrates its DNA with liver cell DNA and is believed to cause primary hepatocellular carcinoma. Papillomaviruses cause plantar, common and flat warts, which are benign and usually regress spontaneously; however, they also cause genital warts and laryngeal papillomas, which are associated with malignant melanoma and cervical, penile and laryngeal cancers. Retroviruses have been found to cause cancer in animals. Adult T-cell leukaemia is the only human cancer known to be associated with a retrovirus (Hill, 2001).

Vaccines to prevent virus-induced cancers are being investigated. Preliminary results of the use of vaccines to treat malignancies, such as melanoma, have been encouraging (Berd, 2001).

Drugs and hormones

Certain drugs can be either genotoxic or promotional. For example, chemotherapeutic drugs used to disrupt the cell cycle of malignant cells can be genotoxic for normal cells. They can also be promotional: by drastically reducing the number of leucocytes, they impair immune function. Examples of these chemotherapeutic drugs include busulfan, chlorambucil and cyclophosphamide. Some recreational drugs also are implicated as carcinogens. These include the genotoxic betel nut chewed by many Pacific Islanders and the immunosuppressant promoters heroin and cocaine.

Hormones are also potential genotoxic carcinogens or promoters. Gonadotropic hormones often mediate cancers of the reproductive organs. Oestrogen, both natural and synthetic, and diethylstilbestrol (DES) have been linked to cervical, endometrial and breast cancers. Oestrogen-containing contraceptive pills have been implicated in breast cancer, but have also been shown to decrease the risk of ovarian cancer. Investigators have not reached a final conclusion about the cancer risk posed by contraceptives. Newer research suggests that alterations in the molecular structure of testosterone in older men may promote the development of prostate cancer. Also, glucocorticosteroids (cortisone) and anabolic steroids may act as promoters by altering the immune response or endocrine balance.

Chemical agents

Many chemicals have been demonstrated to be both genotoxic and promotional. As many of these substances are encountered in the workplace, they constitute occupational hazards. Examples of industrial and environmental carcinogens include polycyclic hydrocarbons, found in soot; benzopyrene, found in cigarette smoke; and arsenic, found in pesticides. These chemicals have some genotoxic action, with some altering DNA replication. Other industrial and environmental chemicals are considered promotional agents. These include wood and leather dust, polymer esters (used in plastics and paints), carbon tetrachloride, asbestos and phenol.

Natural substances in the body may also be carcinogenic or promotional. For example, end products of metabolism that are produced in excess amounts or are ineffectively eliminated, such as bile acids from a high-fat diet, may promote cancer.

Some foods contain carcinogens added during preparation or preservation. Examples include the sugar substitute sodium saccharine, and nitrosamines and nitrous indoles, which are found in pickled, salted foods. In some cases, food contaminants produce carcinogenic chemicals. The *Aspergillus* fungi produce aflatoxin, a highly potent carcinogen. These organisms grow on improperly stored vegetable products, such as grains and peanuts.

Polycyclic aromatic hydrocarbons, nitrosamines, phenols and other chemicals in tobacco act as either carcinogens or promoters of cancer (see Table 13.1).

Physical agents

It has been well documented that excessive exposure to radiation causes increased rates of cancer by damaging the DNA in cells, by activating other oncogenetic factors or by suppressing antitumour activity (protein inhibitors). Both solar radiation from ultraviolet rays and ionising radiation from industrial or medical sources are carcinogenic. This fact has implications for workers exposed to these agents and for the population in general. Radon, a naturally formed radioactive gas that can be found in the basements of some buildings, is also a known carcinogen. People who have lived in areas where nuclear weapons have been tested or whose groundwater has been polluted by nuclear wastes are at risk of developing cancers. The effects of high-dose radiation exposure and subsequent cancer

development have been demonstrated in the survivors of the atomic bombs at Nagasaki and Hiroshima and in workers exposed to radiation during the clean up of nuclear disaster sites, such as Chernobyl.

Types of neoplasms

A **neoplasm** is a mass of new tissue (a collection of cells) that grows independently of its surrounding structures and has no physiological purpose. The term *neoplasm* is often used interchangeably with *tumour*, from the Latin word meaning 'swelling'. Neoplasms are said to be autonomous because they grow at a rate uncoordinated with the needs of the body, they share some of the properties of the parent cells but with altered size and shape and they do not benefit the host and in some cases are actively harmful.

Neoplasms are not completely autonomous, as they require a blood supply with nutrients and oxygen to sustain their growth. Neoplasms are typically classified as benign or malignant on the basis of their potential to damage the body and on their growth characteristics.

Benign neoplasms

Benign neoplasms are localised growths. They form a solid mass, have well-defined borders and are frequently encapsulated. Benign neoplasms tend to respond to the body's homeostatic controls. Thus, they often stop growing when they reach the boundaries of another tissue (a process called *contact inhibition*). They grow slowly and often remain stable in size. Since they are usually encapsulated, benign neoplasms are often easily removed and tend not to recur.

Although typically harmless, benign neoplasms nevertheless can be destructive if they crowd surrounding tissue and obstruct the function of organs. For example, a benign meningioma (from the meninges of the brain and spinal cord) can cause severely increased intracranial pressure (ICP), which progressively impairs the person's cerebral function. Unless the meningioma can be successfully removed, the steadily rising ICP will eventually lead to coma and death.

Malignant neoplasms

In contrast to benign neoplasms, malignant neoplasms grow aggressively and do not respond to the body's homeostatic controls. Malignant neoplasms are not cohesive and present with an irregular shape. Instead of slowly crowding other tissues, malignant neoplasms cut through surrounding tissues, causing bleeding, inflammation and necrosis (tissue death) as they grow. This invasive quality of malignant neoplasms is reflected in the word origin of *cancer*, from the Greek *karkinos*, meaning 'crab'. Healthcare professionals are referring to a malignant neoplasm when they use the term *cancer*.

Malignant cells from the primary tumour may travel through the blood or lymph to invade other tissues and organs of the body and form a secondary tumour called a *metastasis*. This term also refers to the process by which such spreading of malignant neoplasms—perhaps their most destructive trait—occurs. Malignant neoplasms can recur after surgical removal of the primary and secondary tumours and after other treatments. Table 13.2 compares benign and malignant neoplasms.

TABLE 13.2 Comparison of benign and malignant neoplasms

BENIGN	MALIGNANT
Local	Invasive
Cohesive	Non-cohesive
Well-defined borders	Does not stop at tissue border
Pushes other tissues out of the way	Invades and destroys surrounding tissues
Slow growth	Rapid growth
Encapsulated	Metastasises to distant sites
Easily removed	Not always easy to remove
Does not recur	Can recur

Malignant neoplasms vary in their degree of differentiation from parent tissue. Highly differentiated cancer cells try to mimic the specialised function of the parent tissue, but undifferentiated cancers, consisting of immature cells, have almost no resemblance to the parent tissue and therefore no useful function. To make matters worse, undifferentiated cancers rob the body of its energy and nutrition as they grow. Undifferentiated anaplastic cells have little structural or functional relationship to the parent cells and are the basis of many malignant neoplasms. The degree of differentiation of anaplastic cells is a consideration in the classification and staging of neoplasms, discussed later in this chapter.

Characteristics of malignant cells

Malignant neoplasms may be identified by the following predictable cellular characteristics:

- *Loss of regulation of the rate of mitosis*. This results in rapid cell division and growth of the neoplasm.
- *Loss of specialisation and differentiation*. Malignant cells do not perform typical cellular functions. Many produce hormones and enzymes similar to those of the parent tissue but usually in excessive amounts, possibly revealing their presence.
- *Loss of contact inhibition*. Malignant cells do not respect other cellular boundaries. They easily invade and destroy other tissues.
- *Progressive acquisition of a cancerous phenotype*. Cellular mutation seems to be a sequential process involving successive generations of cells, with each generation becoming more deviant than the previous one. Additionally, malignant cells seem to be 'immortal' in that they do not stop growing and die, as do normal cells, which have a genetically determined lifespan.
- *Irreversibility*. The transformation into a malignant cell is irreversible. Rarely does a malignant neoplasm revert to a benign state.
- *Altered cell structure*. Cytological examination of malignant cells reveals distinct differences in the cell nucleus and cytoplasm, as well as an overall cell shape that differs from that of normal cells of the particular tissue type.
- *Simplified metabolic activities*. The work of malignant cells is simpler than that of normal cells. They show an increased

synthesis of substances needed for cell division and they have no need to create proteins for the specialised functions of the tissues they invade.

- *Transplantability*. Malignant cells often break away from the primary tissue site and travel to other locations in the body, where they establish new growths.
- *Ability to promote their own survival*. Malignant cells may create ectopic sites to produce the hormones they need for their growth. By their very presence and their ability to initiate vascular permeability, malignant cells promote the development of non-neoplastic stroma, a connective tissue framework consisting of collagen and other components, which then supports the neoplasm. They may also create their own blood supply. Through a process called angiogenesis, tumour cells secrete a polypeptide angiogenic growth factor that stimulates blood vessels from surrounding normal tissue to grow into the tumour. Finally, malignant cells divert nutrition from the host to meet their own needs, by diffusion when the tumour is less than 1 mm and thereafter by means of the newly formed blood vessels. If unchecked, malignant cells eventually destroy their host.

The characteristics of malignant cells are summarised in Box 13.3.

BOX 13.3 Characteristics of malignant cells

- Loss of regulation of mitotic rate
- Loss of cell specialisation
- Loss of contact inhibition
- Progressive acquisition of a cancerous phenotype and immortality
- Irreversibility of cancerous phenotype to greater aggressiveness
- Altered cell structure: differences in cell nucleus and cytoplasm
- Simplified metabolic activity
- Transplantability (metastasis)
- Ability to promote own survival

Tumour invasion and metastasis

The ability of cancer cells to invade adjacent tissues and travel to distant organs is considered their most ominous characteristic. This quality makes treatment a considerable challenge.

Invasion

Aggressive tumours possess several qualities that facilitate invasion (see Figure 13.2):

- *Ability to cause pressure atrophy*. The pressure of a growing tumour can cause atrophy and necrosis of adjacent tissues. The malignancy then moves into the vacated space.
- *Ability to disrupt the basement membrane of normal cells*. Many cancer cells can bind to elements of the basement membrane and secrete enzymes that degrade that physical barrier, thus facilitating their movement into normal tissues, lymph and blood circulation.
- *Motility*. Because malignant cells are less tightly bound to each other than normal cells (reduced adhesiveness), they easily separate from the neoplasm and move into surrounding body fluids and tissues.
- *Response to chemical signals from adjacent tissues*. Chemotaxis (the movement of cells in response to a chemical stimulus) calls the tumour cells into the normal
