Accidental CO poisoning is most often a result of exposure to fumes of heaters or smoke from structural fires, although poorly ventilated recreational vehicles with improperly operated or maintained gas lamps or stoves and cooking in under-ventilated areas with charcoal grills are also frequent causes. CO is produced by incomplete combustion of carbon or carbonaceous material, such as wood or charcoal. Purposeful CO poisoning can also occur in an attempted suicide with a vehicle parked in a closed garage for a long period.

The signs and symptoms of CO poisoning are secondary to tissue hypoxia and vary with the level of COHb. Mild manifestations include headache, visual disturbances, irritability, and nausea; more severe intoxication causes confusion, hallucinations, ataxia, and coma. The bright, cherry red lips and skin often described are less common than pallor and cyanosis.

Therapeutic Management

Treatment of children with smoke inhalation injury is largely symptomatic. The most widely accepted treatment is placing the child on humidified 100% oxygen as quickly as possible (assuming no previous medical conditions exist contraindicating this) to rapidly reverse tissue hypoxia and to displace CO and cyanide from protein-binding sites. The child is monitored for signs of respiratory distress and impending failure and intubation may be required. A laryngoscopy or bronchoscopy evaluation may be done to assess for airway damage. Baseline ABGs and COHb levels are obtained. PaO₂ may be within normal limits unless there is marked respiratory depression. If CO poisoning is confirmed, 100% oxygen is continued until COHb levels fall to the nontoxic range of about 10%. If CO poisoning is severe, the patient may benefit from hyperbaric oxygen therapy. Hyperbaric oxygen therapy may be useful in the treatment of neurologic complications related to CO poisoning. In a hyperbaric oxygen therapy chamber, the air pressure is increased to three times higher than normal air pressure and so lungs can gather more oxygen than would be possible breathing pure oxygen at normal air pressure. Pulmonary care may be facilitated by bronchodilators, humidification, chest percussion, and postural drainage to enhance the removal of necrotic material, minimize bronchoconstriction, and avoid atelectasis. Bronchoscopy may be needed to clear heavy secretions.

Respiratory distress may occur early in the course of smoke inhalation as a result of hypoxia, or patients who are breathing well on admission may suddenly develop respiratory distress. Therefore, endotracheal intubation equipment should be readily available. Transient edema of the airways can occur at any level in the tracheobronchial tree. Assessment and localization of the obstruction should be accomplished before severe swelling of the head, neck, or oropharynx occurs. Intubation is often necessary when (1) severe burns in the area of the nose, mouth, and face increase the likelihood of developing oropharyngeal edema and obstruction; (2) vocal cord edema causes obstruction; (3) the patient has difficulty handling secretions; and (4) progressive respiratory distress requires artificial ventilation. Controversy surrounds tracheostomy, but many prefer this procedure when the obstruction is proximal to the larynx and reserve nasotracheal intubation for lower tract involvement.

Nursing Care Management

Nursing care of the child with inhalation injury is the same as that for any child with respiratory distress. The initial goal is to maintain a patent airway and effective ventilation status. Vital signs and other respiratory assessments (oxygenation, work of breathing, acid-base status) are performed frequently, and the pulmonary status is carefully observed and maintained. The administration of nebulized bronchodilators, humidified oxygen, and inhaled corticosteroids is often part of the nursing care. Chest percussion and postural drainage may be part of the therapy, as well as mechanical ventilation if needed. Fluid requirements for children experiencing inhalation injury are greater than for those with surface burns alone; however, one concern is the development of PE. Therefore, accurate monitoring of fluid intake and output is essential.

In addition to observation and management of the physical aspects of inhalation injury, the nurse

also deals with the psychological needs of a frightened child and distraught parents. The parents may feel overwhelming guilt even when the injury occurred through no fault of their own. Parents need support, reassurance, and information regarding the child's condition, treatment, and progress. The nurse can provide anticipatory guidance and education families on prevention of inhalation injuries and the importance of CO detectors in the home.

Environmental Tobacco Smoke Exposure

Numerous investigations indicate that parental or family smoking is an important cause of morbidity in children. Children exposed to (second-hand) passive or environmental tobacco smoke have an increased number of respiratory illnesses, increased respiratory symptoms (i.e., cough, sputum, and wheezing), and reduced performance on pulmonary function tests (PFTs). AOM and OME are also increased in children who have smoking parents. Indoor exposure to tobacco smoke has been linked to asthma in children (Burke, Leonardi-Bee, Hashim, et al, 2012). Among children with asthma, there is an association between parental cigarette smoking and asthma exacerbations, trips to the emergency department (ED), medication use, and impaired recovery after hospitalization for acute asthma. Maternal cigarette smoking is associated with increased respiratory symptoms and illnesses in children; decreased fetal growth; increased deliveries of low birth weight, preterm, and stillborn infants; and a greater incidence of sudden infant death syndrome (SIDS). Antenatal maternal smoking has emerged as a significant risk factor for SIDS (American Academy of Pediatrics Task Force on Sudden Infant Death Syndrome and Moon, 2011; Burke, Leonardi-Bee, Hashim, et al, 2012). The risk for diagnosis of early-onset asthma in the first 6 years of life is associated with in utero exposure to maternal smoking (Neuman, Hohmann, Orsini, et al, 2012). Exposure to tobacco smoke during childhood may also contribute to the development of chronic lung disease in the adult.

The use of electronic cigarettes (e-cigarettes) has become more prevalent with adolescents and adults in recent years. The National Youth Tobacco Survey, 2011–2013 reported a threefold increase in the use of e-cigarettes among adolescents who had never smoked cigarettes (Bunnell, Agaku, Arrazola, et al, 2014). Further studies are needed on the impact of e-cigarette emissions on air quality and on nicotine deposition on surfaces. E-cigarettes may be a source of nicotine exposure to bystanders (Czogala, Goniewicz, Fidelus, et al, 2014), and children may be at risk of poisoning due to ingestion of the nicotine liquid in cartridges.

Nursing Care Management

Nurses must provide information about the hazards of environmental smoke exposure in all of their interactions with children and their family members. This information is especially important for children with respiratory and allergic illnesses. In families in which smokers are unwilling to quit, appropriate guidance is provided for reducing smoke in the child's environment (see [Family-Centered Care](#) box). Nurses should set an example for children and families and become advocates for “no smoking” ordinances in public places, prohibition of advertising tobacco products in the media, and inclusion of health warnings of sidestream smoke on tobacco products.* Nurses have an important role in providing parents with affordable smoking cessation education resources, including the appropriate use of smoking cessation pharmacologic aids. Nurses also have a role in educating adolescents about avoiding using tobacco products or smoking marijuana.

Family-Centered Care

Decreasing Childhood Exposure to Environmental Tobacco Smoke

- Do not smoke around infants and children.
- Maintain a smoke-free home. Do not allow visitors to smoke in the home.
- Restrict smoking to outside the house where the children do not play.
- Encourage exclusive breastfeeding for the first 6 months.

- Change clothing after smoking and before holding an infant in close proximity. Suggest wearing a removable outer garment for smoking that is removed on return to the house or when in contact with the child.
- Do not smoke in motor vehicles with children.

Long-Term Respiratory Dysfunction

Asthma

Asthma is a chronic inflammatory disorder of the airways characterized by recurring symptoms, airway obstruction, bronchial hyperresponsiveness, and an underlying inflammation process (Trent, Zimbro, and Rutledge, 2015). In susceptible children, inflammation causes recurrent episodes of wheezing, breathlessness, chest tightness, and cough, especially at night or in the early morning. The airflow limitation or obstruction is reversible either spontaneously or with treatment. Inflammation causes an increase in bronchial hyperresponsiveness to a variety of stimuli (Liu, Covar, Spahn, et al, 2016). Recognition of the key role of inflammation has made the use of antiinflammatory agents, especially inhaled steroids, a major component in the treatment of asthma.

Asthma is classified into four categories based on the symptom indicators of disease severity. These categories are intermittent, mild, moderate, and severe. Symptoms increase in frequency or intensity until the last category of severe persistent asthma (Box 21-14). These categories provide a stepwise approach to the pharmacologic management, environmental control, and educational interventions needed for each category (Liu, Covar, Spahn, et al, 2016). These categories emphasize the multifaceted aspect of the disease for consideration of effects on present quality of life and functional capacity and the future risk of adverse events.

Box 21-14

Asthma Severity Classification in Children*

Step 5 or 6: Severe Asthma

Continual symptoms throughout the day

Frequent nighttime symptoms (>1 time/week ages 0 to 4 and 7 nights/week, ages 5 and older)

Pulmonary expiratory flow (PEF): <60%

Forced expiratory volume in 1 second (FEV₁): <75% of predicted value

Interference with normal activity: Extremely limited

Use of short-acting β -agonist for symptom control: Several times a day

Step 3 or 4: Moderate Asthma

Daily symptoms

Nighttime symptoms: Three to four times a month (0 to 4 years old), >1/week but not nightly (5 to 11 years old)

PEF: 60% to 80% of predicted value (ages 5 and older)

FEV₁: 75% to 80% (ages 5 and older)

PEF variability: >30%

Interference with normal activity: Some limitation

Use of short-acting β -agonist for symptom control: Daily

Step 2: Mild Asthma

Symptoms >2 times/week but <1 time/day

Nighttime symptoms: One to two times a month (0 to 4 years old), three or four times a month (5 to 11 years old)

PEF or FEV₁: ≥80% of predicted value

PEF variability: 20% to 30%

Interference with normal activity: Minor limitation

Use of short-acting β-agonist for symptom control: >2 days/wk but not daily

Step 1: Intermittent Asthma

Symptoms ≤2 days/wk

Nighttime symptoms (awakenings): None (0 to 4 years old); ≤2 nights per month (5 to 11 years old)

PEF or FEV₁: ≥80% of predicted value

PEF variability: <20%

Interference with normal activity: None

Use of short-acting β-agonist for symptom control: <2 days/wk

*The presence of one clinical feature of severity is sufficient to place a patient in that category. An individual should be assigned to the most severe grade in which any feature occurs. The characteristics in this table are general and may overlap because asthma is highly variable. An individual's classification may change over time. Risk factors for each category are not presented in this table. See original reference for additional classification data. Asthma treatment should not be based on this table.

From National Asthma Education and Prevention Program: *Guidelines for the diagnosis and management of asthma: summary report 2007*, from <http://www.nhlbi.nih.gov/guidelines/asthma/index.htm>.

Asthma is the most common chronic disease of childhood, the primary cause of school absences, and the third leading cause of hospitalizations in children younger than 15 years old (Trent, Zimbro, and Rutledge, 2015). Although the onset of asthma may occur at any age, 80% to 90% of children have their first symptoms before 4 or 5 years old. Boys are affected more frequently than girls until adolescence, when the trend reverses. Asthma prevalence, morbidity, and mortality are increasing in the United States, especially among African Americans (Akinbami, Moorman, and Liu, 2011). Morbidity and mortality increases may result from worsening air pollution, more premature infants with chronic lung disease, poor access to medical care, under diagnosis, and under treatment.

Etiology

Studies of children with asthma indicate that allergies influence both the persistence and the severity of the disease. In fact, atopy, or the genetic predisposition for the development of an immunoglobulin E (IgE)-mediated response to common aeroallergens, is the strongest identifiable predisposing factor for developing asthma (Loutsios, Farahi, Porter, et al, 2014). However, 20% to 40% of children with asthma have no evidence of allergic disease. In addition to allergens, other substances and conditions can serve as triggers that may exacerbate asthma (Box 21-15). Evidence shows that viral respiratory infections, including RSV infection, may also have a significant role in the development and expression of asthma (Knudson and Varga, 2015).

Box 21-15

Triggers Tending to Precipitate or Aggravate Asthma Exacerbations

- Allergens
 - Outdoor: Trees, shrubs, weeds, grasses, molds, pollens, air pollution, spores
 - Indoor: Dust or dust mites, mold, cockroach antigen
 - Irritants: Tobacco smoke, wood smoke, odors, sprays
 - Exposure to occupational chemicals
 - Exercise
 - Cold air
 - Changes in weather or temperature
 - Environmental change: Moving to new home, starting new school, and so on
 - Colds and infections
 - Animals: Cats, dogs, rodents, horses
 - Medications: Aspirin, NSAIDs, antibiotics, beta-blockers
 - Strong emotions: Fear, anger, laughing, crying
 - Conditions: Gastroesophageal reflux, tracheoesophageal fistula
 - Food additives: Sulfite preservatives
 - Foods: Nuts, milk or other dairy products
 - Endocrine factors: Menses, pregnancy, thyroid disease
- NSAID, Nonsteroidal antiinflammatory drug.*

Pathophysiology

There is general agreement that inflammation contributes to heightened airway reactivity in asthma. It is unlikely that asthma is caused by either a single cell or a single inflammatory mediator; rather, it appears that asthma results from complex interactions among inflammatory cells, mediators, and the cells and tissues present in the airways (Liu, Covar, Spahn, et al, 2016). However, recognition of the importance of inflammation has made the use of antiinflammatory agents a key component of asthma therapy.

Another important component of asthma is bronchospasm and airflow obstruction. The mechanisms responsible for the obstructive symptoms in asthma include (1) inflammatory response to stimuli; (2) airway edema and accumulation and secretion of mucus; (3) spasm of the smooth muscle of the bronchi and bronchioles, which decreases the caliber of the bronchioles; and (4) airway remodeling, which causes permanent cellular changes (Liu, Covar, Spahn, et al, 2016) (Fig. 21-7).

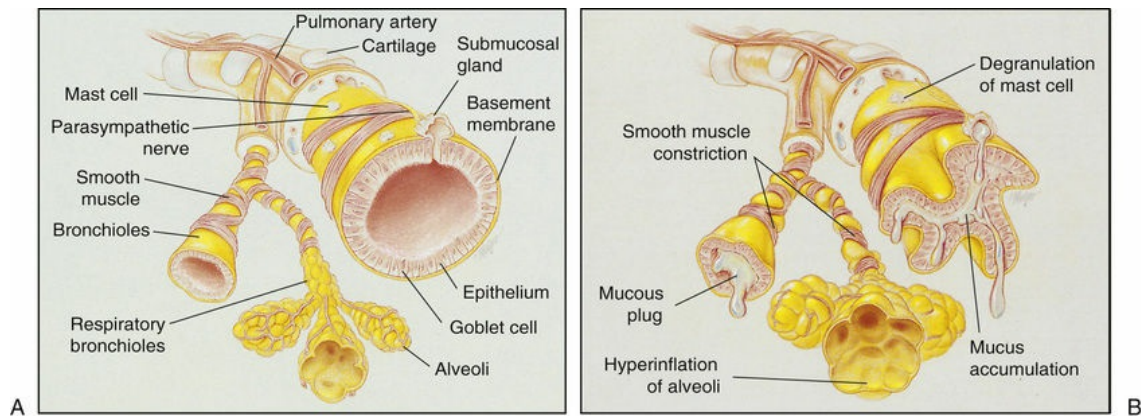

FIG 21-7 Airway obstruction caused by asthma. **A**, A normal lung. **B**, Bronchial asthma: Thick mucus, mucosal edema, and smooth muscle spasm causing obstruction of small airways; breathing becomes labored, and expiration is difficult. (Modified from Des Jardins T, Burton GG: *Clinical manifestations and assessment of respiratory disease*, ed 3, St Louis, 1995, Mosby.)

Airflow is determined by the size of the airway lumen, degree of bronchial wall edema, mucus production, smooth muscle contraction, and muscle hypertrophy. Bronchial constriction is a normal reaction to foreign stimuli; but with asthma, it is abnormally severe, producing impaired respiratory function. Because the bronchi normally dilate and elongate during inspiration and contract and shorten on expiration, the respiratory difficulty is more pronounced during the expiratory phase of respiration.

Increased resistance in the airway causes forced expiration through the narrowed lumen. The volume of air trapped in the lungs increases as airways are functionally closed at a point between the alveoli and the lobar bronchi. This trapping of gas forces the individual to breathe at higher and higher lung volumes. Consequently, the person with asthma fights to inspire sufficient air. This expenditure of effort for breathing causes fatigue, decreased respiratory effectiveness, and increased oxygen consumption. The inspiration occurring at higher lung volumes hyperinflates the alveoli and reduces the effectiveness of the cough. As the severity of obstruction increases, there is a reduced alveolar ventilation with carbon dioxide retention; hypoxemia; respiratory acidosis; and, eventually, respiratory failure.

Chronic inflammation may also cause permanent damage (airway remodeling) to airway structures, which cannot be prevented by and is not responsive to current treatments (Sferrazza Papa, Pellegrino, and Pellegrino, 2014).

Diagnostic Evaluation

The classic manifestations of asthma are dyspnea, wheezing, and coughing. An attack may develop gradually or appear abruptly and may be preceded by a URI. The age of the child is often a significant factor because the first attack frequently occurs before 5 years old, with some children manifesting clinical signs and symptoms in infancy. In infancy, an attack usually follows a respiratory infection. Some children may experience a prodromal itching at the front of the neck or over the upper part of the back just before an attack, especially if the attack is related to allergies (Box 21-16).

Nursing Alert

Shortness of breath with air movement in the chest restricted to the point of absent breath sounds (silent chest) accompanied by a sudden rise in respiratory rate is an ominous sign indicating ventilatory failure and imminent respiratory arrest.

Box 21-16

Clinical Manifestations of Asthma

Cough

Hacking, paroxysmal, irritative, and nonproductive

Becomes rattling and productive of frothy, clear, gelatinous sputum

Respiratory-Related Signs

Shortness of breath

Prolonged expiratory phase

Audible wheeze

May have a malar flush and red ears

Lips deep, dark red color

May progress to cyanosis of nail beds or circumoral cyanosis

Restlessness

Apprehension

Prominent sweating as the attack progresses

Older children sitting upright with shoulders in a hunched-over position, hands on the bed or chair, and arms braced (tripod)

Speaking with short, panting, broken phrases

Chest

Hyperresonance on percussion

Coarse, loud breath sounds

Wheezes throughout the lung fields

Prolonged expiration

Crackles

Generalized inspiratory and expiratory wheezing; increasingly high pitched

With Repeated Episodes

Barrel chest

Elevated shoulders

Use of accessory muscles of respiration

Facial appearance—flattened malar bones, dark circles beneath the eyes, narrow nose, prominent upper teeth

The diagnosis is determined primarily on the basis of clinical manifestations, history, physical examination, and, to a lesser extent, laboratory tests. Generally, chronic cough in the absence of infection or diffuse wheezing during the expiratory phase of respiration is sufficient to establish a diagnosis.

Pulmonary function tests (PFTs) provide an objective method of evaluating the presence and degree of lung disease, as well as the response to therapy. Spirometry can generally be performed reliably on children by 5 or 6 years old. The National Asthma Education and Prevention Program

recommends that spirometry testing be done at the time of initial assessment of asthma, after treatment is initiated and symptoms have stabilized, and at least every 1 to 2 years to assess the maintenance of airway function ([National Asthma and Education Prevention Program, 2012](#)).

Another measurement to consider is the **peak expiratory flow rate (PEFR)**, which measures the maximum flow of air (in liters per minute) that can be forcefully exhaled in 1 second using a **peak expiratory flow meter (PEFM)**. The reliability of the PEFM is controversial, because it relies on the child's ability to use the PEFM and willingness to participate. Because of this, some institutions no longer rely on the PEFR results to guide asthma management. The child's technique on doing the PEFR should be examined on an ongoing basis and reeducation provided when needed. Families are encouraged to record PEFM at regular intervals and to bring a record of this to any medical appointments for health care providers to review trends. Each child needs to establish his or her personal best value during a 2- to 3-week period when the child's asthma is stable. After the personal best value has been established, the child's current PEFR on any occasion can be compared with the personal best value. In some cases, a low PEFR may not truly mean that the child's asthma is poorly controlled. Each individual child's PEFR varies according to age, height, sex, and race.

Nursing Care Guidelines

Interpreting Peak Expiratory Flow Rates*

- **Green (80% to 100% of personal best)** signals all clear. Asthma is under reasonably good control. No symptoms are present, and the routine treatment plan for maintaining control can be followed.
- **Yellow (50% to 79% of personal best)** signals caution. Asthma is not well controlled. An acute exacerbation may be present. Maintenance therapy may need to be increased. Call the practitioner if the child stays in this zone.
- **Red (<50% of personal best)** signals a medical alert. Severe airway narrowing may be occurring. A short-acting bronchodilator should be administered. Notify the practitioner if the peak expiratory flow rate (PEFR) does not return immediately and stay in yellow or green zones.

*These zones are guidelines only. Specific zones and management should be individualized for each child.

Bronchoprovocation testing, direct exposure of the mucous membranes to a suspected antigen in increasing concentrations helps to identify inhaled allergens. Exposure to methacholine (methacholine challenge), histamine, or cold or dry air may be performed to assess airway responsiveness or reactivity. Exercise challenges may be used to identify children with exercise-induced bronchospasm (EIB). These tests should be done under close observation in a qualified laboratory or clinic.

Skin prick testing (SPT) and serological testing (with quantification of sIgE) for allergen-specific immunoglobulin E (sIgE) may be used to identify environmental allergens that trigger asthma ([Sicherer, Wood, and American Academy of Pediatrics Section on Allergy and Immunology, 2012](#)). It is recommended that all patients with year-round asthma symptoms be tested with skin tests or laboratory blood analysis to determine sensitization to perennial allergens (e.g., house dust mites, cats, dogs, cockroaches, molds, and fungus) ([Liu, Covar, Spahn, et al, 2016](#)).

In addition to these tests, other tests may be performed, including laboratory tests (complete blood count with differential) and chest radiographs. The presence of eosinophilia of greater than 500/mm³ suggests the presence of an allergic or inflammatory disorder. Frontal and lateral radiographs may show infiltrates and hyperexpansion of the airways, with the anteroposterior diameter on physical examination indicating an increased diameter (suggestive of barrel chest). Radiography may also assist in ruling out a respiratory tract infection or other conditions, such as aspiration or CF.

Therapeutic Management

The overall goals of asthma management are to maintain normal activity levels, maintain normal pulmonary function, prevent chronic symptoms and recurrent exacerbations, provide optimum drug therapy with minimum or no adverse effects, and assist the child in living as normal and happy a life as possible. This includes facilitating the child's social adjustments in the family, school, and community and normal participation in recreational activities and sports. To accomplish these goals, several treatment principles need to be followed (Brown, Gallagher, Fowler, et al, 2010):

- Regular visits to the health care provider is necessary to evaluate therapeutic response and revise plan of care if needed.
- Prevention of exacerbations includes avoiding triggers, avoiding allergens, and using medications as needed.
- Therapy includes efforts to reduce underlying inflammation and relieve or prevent symptomatic airway narrowing.
- Therapy includes education, environmental control, pharmacologic management, and the use of objective measures to monitor the severity of disease and guide the course of therapy.
- Managing asthma should be fostered in the child as the child increases in age and maturity.

Allergen Control

Nonpharmacologic therapy is aimed at the prevention and reduction of exposure to airborne allergens and irritants. House dust mites and other components of house dust are frequent agents identified in children who are allergic to inhalants. The cockroach, another common household inhabitant, is an important allergen in many locations. Exterminating live cockroaches, carefully cleaning kitchen floors and cabinets, putting food away after eating, and taking trash out in the evening are essential measures to control cockroaches. The mouse allergen is the most recent allergen to be identified in the homes of inner-city children with asthma. The role of cat and dog dander in allergen-induced asthma has also been studied. Although some studies suggest sensitized persons should carefully evaluate having such pets in the household, the overall data are inconsistent on the effect of cat or dog exposure and subsequent asthma development (Chen, Tischer, Schnappinger, et al, 2010). Additional sources of respiratory irritants include ozone, particulate matter produced by tobacco smoke, wood-burning stoves, cleaning products, pesticides, mold spores, nitrogen dioxide, and sulfur dioxide; these are believed to contribute to asthma morbidity in children and should be avoided or minimized (Liu, Covar, Spahn, et al, 2016). Living in homes close to busy roads, damp homes with mold, and exposure to tobacco smoke are significant contributing factors in the development of asthma in infants and small children (Heinrich, 2011).

Skin testing identifies specific allergens so steps can be taken to eliminate or avoid them. Often, simply removing the offending environmental allergens or irritants (e.g., removing carpeting from the home of a child sensitive to mold and dust particles) will decrease the frequency of asthma episodes. Dehumidifiers or air conditioners may control nonspecific factors that trigger an episode, such as extremes of temperature.

Drug Therapy

Pharmacologic therapy is used to prevent and control asthma symptoms, reduce the frequency and severity of asthma exacerbations, and reverse airflow obstruction. A stepwise approach is recommended based on the severity of the child's asthma. Because inflammation is considered an early and persistent feature of asthma, therapy is directed toward long-term suppression of inflammation. The National Asthma Education and Prevention Program (2012) highlights that asthma control has two domains:

- Reducing impairment (associated with the frequency and intensity of symptoms and functional limitations experienced by the patient)
- Reducing risk (preventing future attacks, ED visits, and decline in lung function, as well as watching for medication side effects)

Asthma medications are categorized into two general classes: **long-term control medications (preventive medications)** to achieve and maintain control of inflammation, and **quick-relief medications (rescue medications)** to treat symptoms and exacerbations.

Quick-relief and long-term medications are often used in combination. Inhaled corticosteroids,

cromolyn sodium, long-acting β_2 -agonists (LABAs), methylxanthines, and leukotriene modifiers are used as long-term control medications. Short-acting β_2 -agonists, anticholinergics, and systemic corticosteroids are used as quick-relief medications.

Many asthma medications are given by inhalation with a nebulizer or a **metered-dose inhaler (MDI)**. The MDI is always attached to a spacer, which can be equipped with a mask or a mouthpiece. Pharmaceutical companies are currently mandated to produce inhalers that do not contain chlorofluorocarbons (CFCs) as the propellant, because CFCs have been linked to damage and depletion of the earth's ozone level. Several currently available CFC-free MDI devices use dry powder (and are called *dry powder inhalers*); these include the Diskus inhaler and the Turbuhaler. These devices are breath activated, and the child needs to inhale as quickly and deeply as possible to use them effectively. The Diskhaler and Aerosolizer are similar; but with the Aerosolizer, the medication must be loaded into the inhaler before use. Children who have difficulty using MDIs or other inhalers can receive their asthma medications via a nebulizer, which administers the medication via compressed air or oxygen. Children are instructed to breathe normally with the mouth open to provide a direct route to the trachea.

Corticosteroids are antiinflammatory drugs used to treat reversible airflow obstruction, control symptoms, and reduce bronchial hyperresponsiveness in chronic asthma. Inhaled corticosteroids are used as first-line therapy in children older than 5 years of age. Clinical studies of corticosteroids have indicated significant improvement of all asthma parameters, including decreases in symptoms, emergency visits, and medication requirements ([Bekmezian, Fee, and Weber, 2015](#)).

Corticosteroids may be administered parenterally, orally, or by inhalation. Oral medications are metabolized slowly, with an onset of action up to 3 hours after administration and peak effectiveness occurring within 6 to 12 hours. Oral systemic steroids may be given for short periods of time (e.g., 3- or 10-day "bursts") to gain prompt control of inadequately controlled persistent asthma or to manage severe persistent asthma. These drugs should be given in the lowest effective dose. These medications have few side effects (cough, dysphonia, and oral thrush), and strong evidence indicates that they improve the long-term outcomes for children of all ages with mild or moderate persistent asthma. Some studies have monitored children for 6 years after starting inhaled corticosteroids, and they indicate that when used at recommended doses, they do not have long-term significant effects on growth, bone mineral density, or suppression of the adrenal-pituitary axis ([Liu, Covar, Spahn, et al, 2016](#)). However, primary care providers should frequently monitor (at least every 3 to 6 months) the growth of children and adolescents taking corticosteroids to assess the systemic effects of these drugs and make appropriate reductions in dosages or changes to other types of asthma therapy when necessary. Inhaled corticosteroids include budesonide and fluticasone.

β -Adrenergic agonists (short acting) (primarily albuterol, levalbuterol [Xopenex], and terbutaline) are used for treatment of acute exacerbations and for the prevention of EIB. These drugs bind with the β -receptors on the smooth muscle of airways, where they activate adenylate cyclase and convert adenosine monophosphate (AMP) to cyclic AMP (cAMP). The increased cAMP enhances binding of intracellular calcium to the cell membrane, reducing the availability of calcium and thus allowing smooth muscle to relax. Other effects of the drug help stabilize mast cells to prevent release of mediators. Most β -adrenergics used in asthma therapy affect predominantly the β_2 -receptors, which help eliminate bronchospasm. β_1 -receptor effects, such as increased heart rate and gastrointestinal disturbances, have been minimized. Albuterol is given orally (liquid or pill) or via a nebulizer or inhaler. Levalbuterol is given via nebulizer or MDI. Terbutaline is given orally, via nebulizer, subcutaneously, or intravenously. The inhaled drugs have a more rapid onset of action than oral forms. Inhalation also reduces troublesome systemic side effects, including irritability, tremor, nervousness, and insomnia.

Salmeterol (Serevent) is a LABA (bronchodilator) that is used twice a day (no more frequently than every 12 hours). This drug is added to antiinflammatory therapy and used for long-term prevention of symptoms, especially nighttime symptoms, and EIB. Salmeterol can be used with children from 4 years old and older, and it is not used to treat acute symptoms or exacerbations. LABA (e.g., salmeterol) should be added to a low- or medium-dosage inhaled corticosteroid among children with persistent asthma not controlled with inhaled corticosteroid treatment alone, in order to decrease asthma symptoms and the need for a short-acting β_2 -agonist ([Miraglia del Giudice, Matera, Capristo, et al, 2013](#)). LABAs can only be used as an adjuvant therapy in patients who are currently receiving but are not adequately controlled on a long-term asthma control medication.

LABAs can increase the risk of severely worsening asthma symptoms, potentially leading to hospitalizations and death (US Food and Drug Administration, 2011).

Theophylline is a methylxanthine drug used for decades to relieve symptoms and prevent asthma attacks; however, it is now used primarily in the ICU when the child is not responding to maximum therapy (Dalabih, Harris, Bondi, et al, 2012). Adding theophylline to inhaled glucocorticoids can be more effective than increasing the steroid dose alone. Therapeutic levels should be obtained with this drug because it has a narrow therapeutic window.

Cromolyn sodium is a medication used in maintenance therapy for asthma in children older than 2 years old. It stabilizes mast cell membranes; inhibits activation and release of mediators from eosinophil and epithelial cells; and inhibits the acute airway narrowing after exposure to exercise, cold dry air, and sulfur dioxide. It does not result in immediate relief of symptoms and has minimal side effects (occasional coughing on inhalation of the powder formulation). It is now only available as an oral preparation or via nebulizer. **Nedocromil sodium** inhibits the bronchoconstrictor response to inhaled antigens and inhibits the activity of and release of inflammatory cell types, such as histamine, leukotrienes, and prostaglandins. The drug has few side effects and is used for maintenance therapy in asthma; it is not effective for reversal of acute exacerbations and is not used in children younger than 5 years old. Cromolyn or nedocromil can be taken 10 to 20 minutes prior to exercise or other trigger exposure to help prevent an asthma exacerbation.

Leukotrienes are mediators of inflammation that cause increases in airway hyperresponsiveness. Leukotriene modifiers (e.g., zafirlukast [Accolate], zileuton [Zyflo], and montelukast sodium [Singulair]) block inflammatory and bronchospasm effects. These drugs are not used to treat acute episodes but are given orally in combination with β -agonists and steroids to provide long-term control and prevent symptoms in mild persistent asthma. Montelukast is approved for children 12 months old and older, zileuton is approved for children 12 years old and older, and zafirlukast is approved for children 5 years old and older.

Anticholinergics (atropine and ipratropium [Atrovent]) help relieve acute bronchospasm. However, these drugs have adverse side effects that include drying of respiratory secretions, blurred vision, and cardiac and CNS stimulation. The primary anticholinergic drug used is ipratropium, which does not cross the blood–brain barrier and therefore elicits no CNS effects. Ipratropium, when used in combination with albuterol, can be effective during acute severe asthma in improving lung function in children coming to the ED (Liu, Covar, Spahn, et al, 2016).

Omalizumab (Xolair) is a **monoclonal antibody** that blocks the binding of IgE to mast cells. Blocking this interaction inhibits the inflammation that is associated with asthma. It is used in patients with moderate to severe persistent asthma who have confirmed perennial aeroallergen sensitivity, have total serum IgE levels between 30 and 700 international units/mL and have had poor control of symptoms on inhaled steroids. Many patients with asthma are atopic and possess specific IgE antibodies to allergens responsible for airway inflammation. Xolair has been approved for use in children 12 years old and older in the United States. The drug is administered once or twice a month by subcutaneous injection. Efficacy of omalizumab is not immediate and can take up to 16 weeks (Humbert, Busse, and Hanania, 2014). In early 2007, the US Food and Drug Administration added a “black box warning” to the drug, which highlights the risk of anaphylaxis. Since that time, the US Food and Drug Administration reported an increase in cardiovascular and cerebrovascular adverse events related to its use (US Food and Drug Administration, 2011).

Some children with severe asthma and a history of severe life-threatening episodes may need a primary care practitioner prescription for an EpiPen (subcutaneous injectable epinephrine).

Exercise

Exercise-induced bronchospasm (EIB) is an acute, reversible, usually self-terminating airway obstruction that develops during or after vigorous activity, reaches its peak 5 to 10 minutes after stopping the activity, and usually stops in another 20 to 30 minutes. Patients with EIB have cough, shortness of breath, chest pain or tightness, wheezing, and endurance problems during exercise, but an exercise challenge test in a laboratory is necessary to make the diagnosis.

The problem is rare in activities that require short bursts of energy (e.g., baseball, sprints, gymnastics, skiing) and more common in those that involve endurance exercise (e.g., soccer, basketball, distance running). Swimming is well tolerated by children with EIB because they are breathing air fully saturated with moisture and because of the type of breathing required in swimming.

Children with asthma are often excluded from exercise by parents, teachers, and practitioners, as well as by the children themselves because they are reluctant to provoke an attack. However, this practice can seriously hamper peer interaction and physical health. Exercise is advantageous for children with asthma, and most children can participate in activities at school and in sports with minimal difficulty, provided their asthma is under control. Evaluate participation on an individual basis. Appropriate prophylactic treatment with β -adrenergic agents or cromolyn sodium before exercise usually permits full participation in strenuous exertion.

Breathing Exercises

Breathing exercises and physical training help produce physical and mental relaxation, improve posture, strengthen respiratory musculature, and develop more efficient patterns of breathing. For motivated children, breathing exercises and controlled breathing are of value in preventing overinflation and improving efficiency of the cough. However, these exercises are not recommended during acute, uncomplicated exacerbation of asthma.

Hyposensitization

The role of hyposensitization in childhood asthma is somewhat controversial. In the past, immunotherapy was used for seasonal allergies and when single substances were identified as the offending allergen. It is not recommended for allergens that can be eliminated, such as foods, drugs, and animal dander. Immunotherapy is considered for asthma patients in the following situations (Kwong and Leibel, 2013):

- Patient's preference
- Poor adherence to therapy
- Incomplete response to allergen avoidance
- Significant medication side effects or adverse effect
- Multiple and/or high dose medication requirements

Injection therapy is usually limited to clinically significant allergens. The initial dose of the offending allergen(s), based on the size of the skin reaction, is injected subcutaneously. The amount is increased at weekly intervals until a maximum tolerance is reached, after which a maintenance dose is given at 4-week intervals. This may be extended to 5- or 6-week intervals during the off-season for seasonal allergens. Successful treatment is continued for a minimum of 3 years and then stopped. If no symptoms appear, acquired immunity is assumed; if symptoms recur, treatment is reinstated. Hyposensitization injections should be administered only with emergency equipment and medications readily available in the event of an anaphylactic reaction.

Status Asthmaticus

Status asthmaticus is a medical emergency that can result in respiratory failure and death if untreated. Children who continue to display respiratory distress despite vigorous therapeutic measures, especially the use of sympathomimetics (e.g., albuterol, epinephrine), are in status asthmaticus. The condition may develop gradually or rapidly, often coincident with complicating conditions, such as pneumonia or a respiratory virus, that can influence the duration and treatment of the exacerbation.

Nursing Alert

A child with asthma who sweats profusely, remains sitting upright, and refuses to lie down is in severe respiratory distress. Also, a child who suddenly becomes agitated or an agitated child who suddenly becomes quiet may have serious hypoxia and requires immediate intervention.

Therapy for status asthmaticus is aimed at improving ventilation, decreasing airway resistance, relieving bronchospasm, correcting dehydration and acidosis, allaying child and parent anxiety related to the severity of the event, and treating any concurrent infection. Humidified oxygen is recommended and should be given to maintain SaO₂ greater than 90%. Inhaled aerosolized short-acting β_2 -agonists are recommended for all patients. Three treatments of β_2 -agonists spaced 20 to 30 minutes apart are usually given as initial therapy, and continuous administration of β_2 -agonists via

nebulizer may be initiated. A systemic corticosteroid (oral, IV, or IM) is given to decrease the effects of inflammation. An anticholinergic agent (such as ipratropium bromide) may be added to the aerosolized solution of the β_2 -agonist. Anticholinergics have been shown to result in additional bronchodilation in patients with severe airflow obstruction. An IV infusion is often initiated to provide a means for hydration and to administer medications. Correction of dehydration, acidosis, hypoxia, and electrolyte disturbance is guided by frequent determination of arterial pH, blood gases, and serum electrolytes.

Additional therapies in acute asthma attacks include the use of IV magnesium sulfate, a potent muscle relaxant that decreases inflammation and improves pulmonary function and peak flow rate among patients with moderate to severe asthma when treated in the ED or ICU. Heliox may be administered to decrease airway resistance and thereby decrease the work of breathing; heliox can be delivered via a nonrebreathing face mask from premixed tanks, which may be blended in a stand-alone unit or within a ventilator. Heliox may be used in acute exacerbations as an adjunct to β_2 -agonist and IV corticosteroid therapy to improve pulmonary function until the two latter medications have time to take full effect in decreasing bronchospasm; whereas the effects of heliox are usually seen within 20 minutes of administration, other drugs may take longer to exert the desired effect. Ketamine, a dissociative anesthetic, is believed to cause smooth muscle relaxation and decrease airway resistance caused by severe bronchospasm in acute asthma; it may be administered as an adjunct to other therapies mentioned previously, although evidence on the use of this in asthma is limited. Antibiotics should not be used to treat stable asthma except when a bacterial infection is present; however, macrolide antibiotics can be considered in patients with refractory asthma or with a presumed *M. pneumoniae*- or *C. pneumoniae*-related infection (Rollins, Good, and Martin, 2014).

A child suspected of having status asthmaticus is usually seen in the ED and is often admitted to a pediatric ICU for close observation and continuous cardiorespiratory monitoring. A key component in the prevention of morbidity is helping the child, parents, teachers, coaches, and other adults recognize features of deteriorating respiratory status, use the correct rescue drugs effectively, and immediately place the child with deteriorating respiratory status into the care of health care professionals instead of waiting to see if the asthma gets better on its own. For the child going into early status asthmaticus, immediate medical care is required to irreversible respiratory failure and possible death (see the [Nursing Care Plan](#) box).

Nursing Care Plan

The Child with Asthma

Case Study

Jeremy is a 17-year-old male with a history of asthma. His asthma symptoms have been controlled with use of a long-acting inhaler twice daily but an increase in seasonal allergies and a recent upper respiratory infection (URI) has caused an exacerbation of his symptoms. Jeremy rarely uses his peak expiratory flow meter (PEFM), instead he waits until his symptoms become severe before starting to use his rescue medications. He now presents to his primary care provider with his mother to seek further treatment as his symptoms are not resolving with his current treatment.

Assessment

Based on these events, what are the most important subjective and objective data that should be assessed?

Acute Asthma Exacerbation Defining Characteristics

Dyspnea

Shortness of breath

Diminished breath sounds and/or adventitious breath sounds (wheezing)

Increased respiratory rate

Use of accessory muscles (retractions)

Dry cough

Chest tightness or chest pain

Nursing Diagnosis

Impaired breathing pattern

Ineffective airway clearance

Ineffective health management

Nursing Interventions

What are the most appropriate nursing interventions for a child with acute respiratory tract infection?

| Nursing Interventions | Rationale |
|--|---|
| Monitor airway, breathing, and circulation (ABCs) closely. | To provide supportive measures as needed to maintain airway, breathing, and circulation |
| Allow patient to assume position of comfort. | To promote maximum ventilator function |
| Administer humidified oxygen to maintain oxygen saturation (SaO ₂) above 90%. | To enhance oxygenation of tissues |
| Administer rescue medications (as prescribed) that can include inhalers, nebulization, and/or oral or intravenous (IV) steroids. | To open constricted airways and allow air exchange and to enhance tissue oxygenation |
| Assess patient's response to rescue medications. | To determine need for more aggressive interventions |
| Assist patient in recognizing factors that trigger asthma symptoms. | To avoid factors that exacerbates asthma |
| Assist patient to understand the purpose and use of peak expiratory flow meter (PEFM). | To allow early recognition of asthma symptoms before acute exacerbation |
| Observe technique for use of PEFM, inhaler, and/or nebulizer. | To ensure appropriate technique to maximize accuracy and effectiveness |

Expected Outcomes

Adolescent will breathe easily with nonlabored respirations at a rate within normal limits for age.

Adolescent will maintain patent airway.

Adolescent will verbalize understanding of health maintenance measures (i.e., avoiding triggers, use of peak flow meter, use of inhalers).

Case Study (Continued)

Jeremy had no improvement with the nebulized treatment provided in the primary care office and his symptoms worsened. He was transferred to a nearby hospital for further evaluation. Upon arrival to the emergency department (ED), Jeremy is unable to answer questions, refuses to lie down, and displays short rapid breaths with significant retractions. His mother is concerned about what is happening to him.

Assessment

What are the most important signs and symptoms based on this scenario?

Status Asthmaticus Defining Characteristics

Inability to speak in full sentences

Agitation, confusion

Rapidly progressive shortness of breath

Tachypnea and tachycardia

Chest tightness

Retractions

Cyanosis

Nursing Diagnosis

Impaired breathing pattern

Ineffective airway clearance

Impaired gas exchange

Readiness for enhanced knowledge (family)

Nursing Interventions

What are the most appropriate nursing interventions for this child?

| Nursing Interventions | Rationale |
|--|--|
| Monitor airway, breathing, and circulation, airway, breathing (CAB) closely. | To provide supportive measures as needed to maintain airway, breathing, and circulation, airway, and breathing |
| Allow patient to assume position of comfort. | To promote maximum ventilator function |
| Administer humidified oxygen to maintain oxygen saturation (SaO ₂) above 90%. | To enhance oxygenation of tissues |
| Administer short acting β-agonist medications continuously via nebulizer (as prescribed). | To open constricted airways and allow air exchange and to enhance tissue oxygenation |
| Obtain blood specimen for electrolytes, complete blood count, renal function tests, and arterial blood gases (ABGs). | To determine current status of patient and institute therapy based on results |
| Obtain intravenous (IV) access and administer corticosteroid, hydration, and electrolytes as prescribed. | To decrease inflammation and correct dehydration, acidosis, and electrolyte disturbances |
| Educate family about status asthmaticus and treatment underway to resolve condition. | To promote understanding of characteristics and treatment for status asthmaticus |
| Arrange for social worker to meet with family to assess emotional and financial needs. | To identify and modify stressors associated with acute exacerbation of illness and sudden hospitalization |
| Transfer patient from the emergency department (ED) to the pediatric intensive care unit (ICU). | To allow for continuous cardiorespiratory monitoring and further treatment |

Expected Outcome

Adolescent will breathe easily with nonlabored respirations at a rate within normal limits for age.

Adolescent will maintain patent airway.

Adolescent will maintain adequate gas exchange.

Family will verbalize understanding of condition and treatment.

Prognosis

Although deaths from asthma have been relatively uncommon since the 1980s, the rate of death from asthma increased steadily in the United States until it peaked in the mid-1990s. Asthma-related deaths decreased 2000 to 2009, 84 deaths were noted among children in the United States in 2000 compared to 33 deaths among children in the United States in 2009 (Hasegawa, Tsugawa, Brown, et al, 2013). The rate of hospitalization due to asthma decreased significantly from 2000 to 2009 in children younger than 18 years old; however, the use of invasive and noninvasive mechanical ventilation significantly increased during that time (Hasegawa, Tsugawa, Brown, et al, 2013). African-American children have 2 to 7 times more hospitalizations, emergency department visits, and deaths than those of white and Hispanic children (Liu, Covar, Spahn, et al, 2016). Most asthma deaths in children occur in the home, school, or community before lifesaving medical care can be administered.

Some children's asthma symptoms may improve at puberty, but up to two thirds of children with asthma continue to have symptoms through puberty and into adulthood. The prognosis for control or disappearance of symptoms varies in children from those who have rare and infrequent attacks to those who are constantly wheezing or are subject to status asthmaticus. Risk factors that may predict the persistence of symptoms into childhood (from infancy) include atopy, male gender, exposure to environmental tobacco, and maternal history of asthma. Many children who outgrow their exacerbations continue to have airway hyperresponsiveness and cough as adults.

The younger child and adolescent age group appear to be the most vulnerable, with the greatest increase occurring in children younger than 4 years old and 12 to 17 years old (Hasegawa, Tsugawa, Brown, et al, 2013). No reliable data exist to explain this increase. Factors that have been postulated include exposure of atopic persons to more allergens (particularly in large urban centers), change in severity of the disease, abuse of drug therapy (toxicity), failure of families and practitioners to recognize the severity of asthma, and psychological factors, such as denial and refusal to accept the disease. On the other hand, studies have shown that children living in rural areas and farming communities have a decreased incidence of asthma and allergy (Liu, Covar, Spahn, et al, 2016).

Risk factors for asthma-related deaths include early onset, frequent attacks, difficult-to-manage

disease, adolescence, history of respiratory failure, psychological problems (refusal to take medications), dependency on or misuse of asthma drugs (high use), presence of physical stigmata (barrel chest, intercostal retractions), and abnormal PFT results.

Nursing Care Management

Acute Asthma Care

Children who are admitted to the hospital with acute asthma are ill, anxious, and uncomfortable. The importance of continual observation and assessment cannot be overemphasized.

When β_2 -agonists, supplemental oxygen, and corticosteroids are given, the child is monitored closely and continuously for relief of respiratory distress and signs of side effects. Pulse oximetry is monitored along with rate and depth of breathing, auscultation of air movement, and any signs of respiratory distress (e.g., nasal flaring, tachypnea, retractions). The child on supplemental oxygen requires intermittent or continuous oxygenation monitoring depending on severity of respiratory compromise and initial oxygenation status. The child in status asthmaticus should be placed on continuous cardiorespiratory (including blood pressure) and pulse oximetry monitoring. Oral fluid intake may be limited during the acute phase; IV fluid replacement may be required to provide adequate tissue hydration.

Older children may be more comfortable standing, sitting upright, or leaning slightly forward. Shortness of breath makes talking difficult. The calm, efficient presence of a nurse helps reassure children that they are safe and will be cared for during this stressful period. It is important to assure children that they will not be left alone and that their parents are allowed to remain with them. Parents need reassurance and want to be informed of their child's condition and therapies. They may believe that they have in some way contributed to the child's condition or could have prevented the episode. Reassurance regarding their efforts expended on the child's behalf and their parenting capabilities can help alleviate their stress. Efforts to reduce parental apprehension will also reduce the child's distress. Anxiety is easily communicated to the child from parents and other family members. Some institutions use an asthma scoring tool to evaluate symptom severity and wean the frequency of inhaled bronchodilator administration. Many asthma scoring tools assesses the child's respiratory rate, oxygen requirements, auscultation findings, retractions, and degree of dyspnea. Nurses and other members of the health care team can use this tool to evaluate how the child is responding to the medications and other therapies.

Provide Long-Term Asthma Care

Nursing care of children with asthma involves both acute and long-term care. Nurses who are involved with children in the home, hospital, school, outpatient clinic, or practitioner's office play an important role in helping children and their families learn to live with the condition. The disease can be managed so that it does not require hospitalization or interfere with family life, physical activity, or school attendance. The nursing process in the care of the child with asthma is outlined in the Nursing Care Plan box.

Nurses may perform a variety of functions in asthma care. These may include asthma education in the primary care setting and in schools and other community settings, care of the child with asthma in the acute care setting, ambulatory care, care coordination, and intensive care. Nurses also obtain information on how asthma affects the child's everyday activities and self-concept, the child's and family's adherence to the prescribed therapy, and their personal treatment goals. Every effort is made to build a partnership between the child and family and the health care team, and effective communication is an essential part of this partnership. In particular, the child and family's satisfaction with asthma control and with the quality of care should be assessed. The nurse should also assess the child and family's perception of the severity of the disease and their level of social support.

One of the major emphases of nursing care is outpatient management by the family. Parents are taught how to prevent exacerbations, to recognize and respond to symptoms of bronchospasm, to maintain health and prevent complications, and to promote normal activities. The nurse should determine any cultural or ethnic beliefs or practices that influence self-management and that may necessitate modifications in educational approaches to meet the family's needs. Inconsistent home care, on the part of either the child or the parents, often leads to unnecessary ED visits for management (Volpe, Smith, and Sultan, 2011). Parents and older children often need education

reinforced about the maintenance aspect of asthma management; children benefit from drug therapy even when asthma manifestations are not evident.

Avoid Allergens

One goal of asthma management is avoidance of an exacerbation. Parents need to know how to avoid allergens that precipitate asthma episodes. The nurse assists the parent in modifying the environment to reduce contact with the offending allergen(s). Parents are cautioned to avoid exposing a sensitive child to excessive cold, wind, and other extremes of weather; smoke (open fire or tobacco); sprays; scents; and other irritants. Foods known to provoke symptoms should be eliminated from the diet.

Approximately 2% to 6% of children with asthma are sensitive to aspirin; therefore, nurses should caution parents to use other analgesic/antipyretic drugs for discomfort or fever and to read package labeling. Although aspirin is rarely given to children in the United States, salicylate compounds are in other common medicines such as Pepto-Bismol. Children with aspirin-induced asthma may also be sensitive to nonsteroidal antiinflammatory drugs (NSAIDs) and tartrazine (yellow dye number 5, a common food coloring).

Nursing Alert

Parents are encouraged to avoid administering aspirin to any child unless specifically recommended by and under the supervision of a health practitioner due to the risk of Reye syndrome. Acetaminophen is safe for children and is the analgesic of choice.

Relieve Bronchospasm

Teach parents and older children to recognize early signs and symptoms of an impending attack so that it can be controlled before symptoms become distressing. Most children can recognize prodromal symptoms well before an attack (about 6 hours) and implement preventive therapy. Objective signs that parents may observe include rhinorrhea, cough, low-grade fever, irritability, itching (especially in front of the neck and chest), apathy, anxiety, sleep disturbance, abdominal discomfort, and loss of appetite.

Children who use a nebulizer, MDI, Diskus, or Turbuhaler to deliver drugs need to learn how to use the device correctly (Fig. 21-8). The MDI device (Fig. 21-9) delivers medication directly to the airways; therefore, the child needs to learn to breathe slowly and deeply for better distribution to narrowed airways (see [Family-Centered Care](#) box).

Family-Centered Care

Use of a Metered-Dose Inhaler*

Steps for Checking How Much Medicine Is in the Canister

1. If the canister is new, it is full.
2. Check product label to see how many inhalations should be in each canister.
3. Some metered-dose inhaler (MDI) containers and dry powder inhalers have a dose-counting device to specify the remaining number of doses available in the canister.
4. If a dose-counting device is not available, each use should be counted and recorded.
5. Do not place inhalers with hydrofluoroalkanes in water to check fill, because it will destroy them.

Steps for Using the Inhaler Without a Chamber

1. Shake the MDI well for 5 seconds.
2. Remove the cap and hold inhaler upright.

3. Attach spacer, as appropriate.
4. Keep chin up and breathe out slowly.
5. With the inhaler in an upright position, insert the mouthpiece and seal lips around it forming an airtight seal.
6. At the end of a normal expiration, depress the top of the inhaler canister firmly to release the medication (into the mouth) and breathe in slowly (about 3 to 5 seconds). Relax the pressure on the top of the canister.
7. Hold the breath for at least 5 to 10 seconds to allow the aerosol medication to reach deeply into the lungs.
8. Remove the inhaler and breathe out slowly through the nose.
9. Wait 1 minute between puffs (if an additional puff is needed) when using a bronchodilator.

. Replace the cap on the MDI.

. If using a corticosteroid, rinse mouth or take a drink to remove residual medication (which can cause a yeast infection to develop).

Steps for Using the Inhaler with an AeroChamber (see Figure 21-9)

1. Remove the cap and hold inhaler upright.
2. Shake the inhaler.
3. Attach the AeroChamber. It comes with a mouthpiece attached for older children or a mask for younger children.
4. Apply the AeroChamber mask to child's face and make sure there is a good seal. For older children, insert the mouthpiece and seal lips around it to form an airtight seal.
5. Have child breathe slow, regular breaths. Depress the top of the inhaler canister firmly to release the medication (into the AeroChamber) as the child breathes slowly in and out. Relax the pressure on the top of the canister.
6. Hold the AeroChamber in place over the child's face until six breaths have been taken. Give one puff at a time and wait 1 minute in between puffs.
7. Remove the inhaler and AeroChamber. Apply to cap to the MDI.

Common Problems for Children Using Inhalers

- Child refuses or resists treatment.
- Inhalation is too rapid.
- Child is unable to coordinate the spray with inhalation.
- Breath is not held long enough after inhalation.

*Inhaled dry powder such as budesonide (Pulmicort) requires a different inhalation technique. To use a dry powder inhaler, the base of the device is turned until a click is heard. It is important to close the mouth tightly around the mouthpiece of the inhaler and inhale rapidly.

FIG 21-8 Children with asthma may take a nebulized aerosol treatment with (A) a mask or (B) mouthpiece. (Courtesy of Texas Children's Hospital, Houston, TX.)

FIG 21-9 Child using metered-dose inhaler (MDI) with spacer and face mask.

A spacer or AeroChamber device should be used with MDI inhalers. These devices allow the parent or child to deliver the medication from the MDI and slowly inhale it. Spacers also help prevent yeast infections in the mouth when corticosteroids are inhaled via an MDI.

The child and parents also need to be cautioned about the adverse effects of prescribed drugs and the dangers of overuse of β_2 -agonists. They should know that it is important to use these drugs when needed but not indiscriminately or as a substitute for avoiding the symptom-provoking allergen.

Nursing Alert

Long-acting β_2 -agonist (LABA) inhalers (salmeterol) should be used only as directed (usually every 12 hours) and not more frequently. They are not intended to relieve acute asthmatic symptoms.

The family may be asked to obtain a PEFM and learn to use this device to monitor the child's asthma if the child is 5 years old and older. A written asthma action plan that includes the three peak flow meter zones and the child's asthma medications may be obtained from the child's primary care provider. A home asthma action plan may reduce the risk of asthma death by 70% (Liu, Covar, Spahn, et al, 2016). Medications used for asthma exacerbations are also included in the asthma plan. This action plan should be used to make decisions about asthma management at home and at school. The nurse may assist the child and family in understanding the written action plan, emphasizing that the child and family determine the success of the plan, not the health professionals. Teach parents how to read labels on prepared foods and snacks to determine the presence of allergens.

The child should be protected from a respiratory tract infection that can trigger an attack or aggravate the asthmatic state, especially in young children whose airways are mechanically smaller and more reactive. Annual influenza vaccinations are recommended for all children older than 6 months old. Pneumococcal vaccines should also be maintained. Equipment used for the child, such as nebulizers, must be kept absolutely clean to decrease the chances of contamination with bacteria and fungi.

Teach breathing exercises and controlled breathing for motivated children, and the nurse should provide information concerning activities that promote diaphragmatic breathing, side expansion, and improved mobility of the chest wall. Play techniques that can be used for younger children to extend their expiratory time and increase expiratory pressure include blowing cotton balls or a ping-pong ball on a table, blowing a pinwheel, blowing bubbles, or preventing a tissue from falling by blowing it against the wall.

Self-care and asthma self-management programs are important in helping the child and family cope with asthma. Self-contained programs and brochures for patient education are available from the Asthma and Allergy Foundation of America* and the American Lung Association.† The National Heart, Lung, and Blood Institute‡ provides fact sheets and educational materials for asthma education in the school setting. Practice parameters and guidelines designed for health care practitioners are available from the American Academy of Allergy Asthma and Immunology website.§

Support Child or Adolescent and Family

The nurse working with children with asthma can provide support in a number of ways. Many children voice frustration because their exacerbations interfere with their daily activities and social lives. Children need education on their condition and reassurance from the health team that they can learn to control and cope with their asthma and live a normal life.

Children in disruptive family situations (divorce, separation, violence, custodial battles) may disregard their daily asthma medication regimen or may be at higher risk as a result of neglect by adults who are in charge of their care. Adolescents struggling with a sense of identity and body image often regard asthma as a condition that will “go away,” especially if there is a time lapse between symptoms, and may abandon the therapeutic regimen. Referral for counseling and guidance is appropriate where the child's or adolescent's life is potentially in harm's way and the therapeutic regimen for asthma is abandoned due to personal or family crises.

Cystic Fibrosis

CF is a life-shortening disease, inherited as an autosomal recessive trait. The affected child inherits the defective gene from both parents, with an overall risk of one in four if both parents carry the gene. The condition has a frequency of 1 in 3500 live births among Caucasians (Egan, Green, and Voynow, 2016). The mutated gene responsible for CF is located on the long arm of chromosome 7. This gene codes a protein of 1480 amino acids called the **cystic fibrosis transmembrane conductance regulator (CFTR)**. The CFTR protein is related to a family of membrane-bound glycoproteins. The glycoproteins constitute a cAMP-activated chloride channel and regulate other chloride and sodium channels at the surfaces of the epithelial cells.

Pathophysiology

CF is characterized by several clinical features, which are increased viscosity of mucous gland secretions, a striking elevation of sweat electrolytes, an increase in several organic and enzymatic

constituents of saliva, and abnormalities in autonomic nervous system function. Although both sodium and chloride are affected, the defect appears to be primarily a result of abnormal chloride movement; the CFTR appears to function as a chloride channel. Children with CF demonstrate an increase in sodium and chloride in both saliva and sweat. This characteristic is the basis for the sweat chloride diagnostic test. The sweat electrolyte abnormality is present from birth, continues throughout life, and may be unrelated to the severity of the disease or the extent to which other organs are involved.

The primary factor, and the one that is responsible for many of the clinical manifestations of the disease, is mechanical obstruction caused by the increased viscosity of mucous gland secretions (Fig. 21-10). Instead of forming a thin, freely flowing secretion, the mucous glands produce a thick mucoprotein that accumulates and dilates them. Small passages in organs (such as the pancreas and bronchioles) become obstructed as secretions precipitate or coagulate to form concretions in glands and ducts. The earliest postnatal manifestation of CF is often **meconium ileus** in the newborn, in which the small intestine is blocked with thick, puttylike, tenacious, mucilaginous meconium.

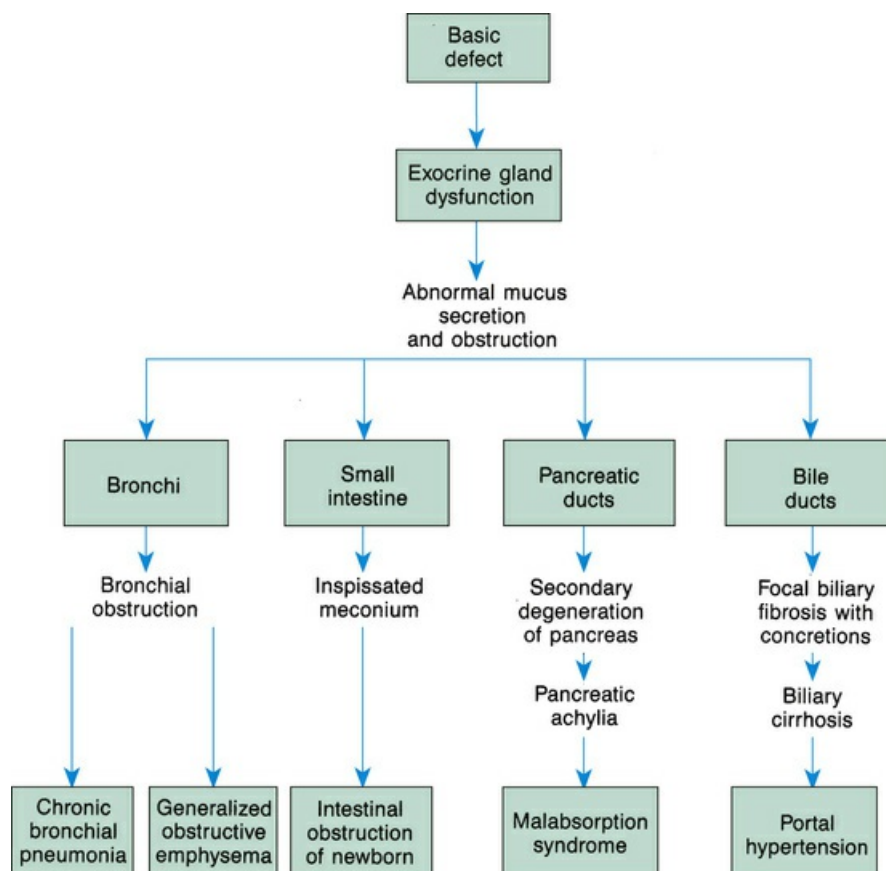

FIG 21-10 Various effects of exocrine gland dysfunction in cystic fibrosis (CF).

In the pancreas, the thick secretions block the ducts, eventually causing **pancreatic fibrosis**. This blockage prevents essential pancreatic enzymes from reaching the duodenum, which causes marked impairment in the digestion and absorption of nutrients. The disturbed function is reflected in bulky stools that are frothy from undigested fat (**steatorrhea**) and foul smelling from putrefied protein (**azotorrhea**).

The incidence of diabetes mellitus (cystic fibrosis–related diabetes [CFRD]) is greater in CF children than in the general population, which may be caused by changes in pancreatic architecture and diminished blood supply over time. CFRD is reported to be the most common complication associated with CF; by age 30 years, approximately 50% of people with CF will develop diabetes, which is associated with increased morbidity (sixfold) and mortality and poor lung function (O’Riordan, Dattani, and Hindmarsh, 2010). The primary characteristic of CFRD is severe insulin deficiency as a result of β -cell dysfunction; however, CFRD also may demonstrate fluctuating

insulin resistance, especially during acute illness. Thus, CFRD has characteristics of both type 1 diabetes mellitus and type 2 diabetes mellitus but is considered to be its own entity (Moran, Brunzell, Cohen, et al, 2010; O'Riordan, Dattani, and Hindmarsh, 2010). The positive correlation between nutritional status and optimal pulmonary function in patients with CF has been described; the presence of adequate insulin appears to be a key factor in maintaining an adequate nutritional status. Experts continue to recommend a high-fat, high-calorie diet in CF patients, and at this time there is no evidence to support a change in this diet for patients with CFRD (Ode and Moran, 2013).

A common gastrointestinal complication associated with CF is **prolapse of the rectum**, which occurs in infancy and childhood and is related to large, bulky stools; malnutrition; and increased intra-abdominal pressure secondary to paroxysmal cough. Affected children of all ages are subject to intestinal obstruction from heavy or impacted feces. Gum-like masses in the cecum can obstruct the bowel and produce a partial or complete obstruction, a condition that is referred to as **distal intestinal obstruction syndrome**.

Pulmonary complications are present in almost all children with CF, but the onset and extent of involvement are variable. Symptoms are produced by stagnation of mucus in the airways, with eventual bacterial colonization leading to destruction of lung tissue. The abnormally viscous and tenacious secretions are difficult to expectorate and gradually obstruct the bronchi and bronchioles, causing scattered areas of bronchiectasis, atelectasis, and hyperinflation. The stagnant mucus also offers a favorable environment for bacterial growth.

The reproductive systems of both males and females with CF are affected. Fertility can be inhibited by highly viscous cervical secretions, which act as a plug, blocking sperm entry. Women with CF who become pregnant have an increased incidence of premature labor and delivery and infant low birth weight. Favorable nutritional status and pulmonary function are positively correlated with favorable pregnancy outcomes. Most men (95%) with CF are sterile, which may be caused by blockage of the vas deferens with abnormal secretions or by failure of normal development of the wolffian duct structures (vas deferens, epididymis, and seminal vesicles), resulting in decreased or absent sperm production.

Growth and development are often affected in children with moderate to severe forms of CF. Physical growth may be restricted as a result of decreased absorption of nutrients, including vitamins and fat; increased oxygen demands for pulmonary function; and delayed bone growth. The usual pattern is one of growth failure (failure to thrive) with increased weight loss despite an increased appetite and gradual deterioration of the respiratory system. Clinical manifestations of CF are listed in [Box 21-17](#).

Box 21-17

Clinical Manifestations of Cystic Fibrosis

Meconium Ileus*

Abdominal distention

Vomiting

Failure to pass stools

Rapid development of dehydration

Gastrointestinal Manifestations

Large, bulky, loose, frothy, extremely foul-smelling stools

Voracious appetite (early in disease)

Loss of appetite (later in disease)

Weight loss

Marked tissue wasting

Failure to grow

Distended abdomen

Thin extremities

Sallow skin

Evidence of deficiency of fat-soluble vitamins A, D, E, and K

Anemia

Pulmonary Manifestations

Initial signs:

Wheezy respirations

Dry, nonproductive cough

Eventually:

Increased dyspnea

Paroxysmal cough

Evidence of obstructive emphysema and patchy areas of atelectasis

Progressive involvement:

Overinflated, barrel-shaped chest

Cyanosis

Clubbing of fingers and toes

Repeated episodes of bronchitis and bronchopneumonia

*In about 10% of cases.

Diagnostic Evaluation

Traditionally, the diagnosis of CF was based on the presence of one or more characteristic features (chronic sinopulmonary disease, gastrointestinal or nutritional abnormalities, salt loss syndromes, genital abnormalities in males), a history of CF in a sibling or a positive newborn screen plus laboratory confirmation of an abnormality in the CFTR gene or protein. However, more than 2000 mutations have now been identified in the CFTR gene, not all of which result in CF ([Barrio, 2015](#)).

Newer diagnostic methods make it possible to screen newborns for CF. Universal newborn screening for CF is now available in all states in the United States. The newborn screening test consists of an immunoreactive trypsinogen (IRT) analysis performed on a dried spot of blood, which may be followed by direct analysis of DNA for the presence of the $\Delta F508$ mutation or other mutations on the same dried blood spot. A positive screen indicates persistent

hypertrypsinogenemia and does not diagnose CF but identifies infants at risk of CF. Further testing is needed to confirm or rule out CF. Benefits of early screening and detection include preventing under nutrition of identified infants to optimize lung function. A disadvantage of newborn screening is parental anxiety associated with a false-positive result. Children who were identified and treated early in infancy with aggressive nutritional support had improved height and weight well into adolescence. An in utero diagnosis of CF is also possible based on detection of two CF mutations in the fetus.

The consistent finding of abnormally high sodium and chloride concentrations in the sweat is a unique characteristic of CF. Parents may report that their infant tastes “salty” when they kiss him or her. The quantitative sweat chloride test (pilocarpine iontophoresis) remains the best diagnostic tool for CF and involves stimulating the production of sweat with a special device (involves stimulation with 3-mA electric current), collecting the sweat on filter paper, and measuring the sweat electrolytes. The quantitative analysis requires a sufficient volume of sweat (>75 mg). Two separate samples are collected to ensure the reliability of the test for any individual. Normally, sweat chloride content is less than 40 mEq/L, with a mean of 18 mEq/L. A chloride concentration greater than 60 mEq/L in a child 6 months old or older is diagnostic of CF, a concentration between 40 and 59 mmol/L is indeterminate and a repeat test should be performed in 1 to 2 months (Nicholson, 2013). In some situations, DNA testing may be substituted for the sweat test and may be performed when the sweat test indicates the possible presence of CF. The presence of a mutation known to cause CF on each CFTR gene predicts with a high degree of certainty that the individual has CF; however, multiple CFTR mutations may also be present and detected with DNA assay.

Chest radiography reveals characteristic patchy atelectasis and obstructive emphysema. PFTs are sensitive indexes of lung function, providing evidence of obstructive airway disease. Other diagnostic tools that may aid in diagnosis include stool fat or enzyme analysis. Stool analysis requires a 72-hour sample with accurate recording of food intake during that time. Radiographs, including a contrast enema, are used for diagnosis of meconium ileus.

Therapeutic Management

Improved survival among patients with CF during the past two decades is attributable largely to antibiotic therapy and improved nutritional and respiratory management. Goals of CF therapy are to (1) prevent or minimize pulmonary complications, (2) prevent chronic pseudomonas infection, (3) ensure adequate nutrition for growth, (4) encourage appropriate physical activity, and (5) promote a reasonable quality of life for the child and the family. A multidisciplinary approach to treatment is needed to accomplish these goals.

Management of Pulmonary Problems

Management of pulmonary problems is directed toward prevention and treatment of pulmonary infection by improving ventilation, removing mucopurulent secretions, and administering antimicrobial agents. Many children develop respiratory symptoms by 3 years old. The large amounts and viscosity of respiratory secretions in children with CF contribute to the likelihood of respiratory tract infections. Recurrent pulmonary infections in children with CF result in greater damage to the airways; small airways are destroyed, causing bronchiectasis.

The most common pathogens responsible for pulmonary infections are *Pseudomonas aeruginosa*, *Burkholderia cepacia*, *S. aureus*, *H. influenzae*, *Escherichia coli*, and *Klebsiella pneumoniae*. *P. aeruginosa* and *B. cepacia* are particularly pathogenic for children with CF, and infections with these organisms are difficult to eradicate. In addition, children with CF who are chronically colonized with these organisms have poorer survival rates than children who are not colonized. Colonization and infection with methicillin-resistant *Staphylococcus aureus* (MRSA) has emerged as a critical factor in lung infection and pulmonary function in patients with CF (Muhlebach, Miller, LaVange, et al, 2011). Patients with MRSA require multiple antibiotic regimens. Fungal colonization with *Candida* or *Aspergillus* organisms in the respiratory tract is also common in CF patients.

Airway clearance therapies (ACTs) are an essential part of CF management and include percussion and postural drainage, positive expiratory pressure (PEP), active-cycle-of-breathing technique, autogenic drainage, oscillatory PEP, high-frequency chest compressions (HFCCs), and exercise. Studies have demonstrated that no particular ACT has any advantage over the other in relation to outcomes of sputum production; however, it is recommended that individualized assessment occur to determine the best ACT for each patient.

ACTs such as percussion and postural drainage are usually performed on average twice daily (on rising and in the evening) and more frequently if needed, especially during pulmonary infection. Percussion and postural drainage is especially useful for infants and young children. Patients with CF have been found to regress when conventional percussion and postural drainage is discontinued.

The **Flutter mucus clearance device** is a small handheld plastic pipe with a stainless-steel ball on the inside that facilitates removal of mucus (Fig. 21-11). It has the advantage of increasing sputum expectoration and being used without an assistant. Handheld percussors may be used to loosen secretions. Another method to clear mucus is HFCC in which the child temporarily wears a mechanical vest device that provides high-frequency chest wall oscillation.

FIG 21-11 Top, Flutter device components showing the pipe stem, cone with steel ball, and perforated top. Bottom, The Acapella device. (From Marks JH: Airway clearance devices in cystic fibrosis, *Paediatr Respir Rev* 8(1):17-23, 2007.)

The active cycle of breathing technique is a series of breathing techniques to help clear secretions. Forced expiration, or “huffing,” with the glottis partially closed helps move secretions from the small airways so that subsequent coughing can move secretions forcefully from the large airways. This maneuver enhances the pulmonary function of patients with CF. Autogenic drainage involves a variety of breathing techniques, which older children can use to force mucus in lower lobes up into the airways so that it can be successfully expelled. Another mucus-clearing technique involves use of a PEP mask; this technique involves breathing into a mask attached to a one-way valve, which creates resistance—as the patient exhales, the airway is kept open by the pressure, and mucus is forced into the upper airway for expulsion.

Bronchodilator medication delivered in an aerosol opens bronchi for easier expectoration and is administered before percussion and postural drainage when the patient exhibits evidence of reactive airway disease or wheezing. Another aerosolized medication is recombinant human deoxyribonuclease (DNase, known generically as dornase alfa [Pulmozyme]), which decreases the viscosity of mucus. It is well tolerated and has no major adverse effects; minor reactions are voice alterations and laryngitis. This medication, given daily via nebulization generally before or with percussion and postural drainage, has resulted in improvements in spirometry, PFTs, dyspnea scores, and perceptions of well-being and has reduced the viscosity of sputum.

Nebulized hypertonic saline (7%) has been shown to be effective in improving airway hydration and increases mucus clearance in patients with CF; this treatment, however, causes bronchospasm and may not be recommended for patients with severe disease (Furnari, Termini, Traverso, et al, 2012). The use of hypertonic saline with hyaluronic acid can decrease the incidence of bronchoconstriction, cough, and throat irritation (Furnari, Termini, Traverso, et al, 2012).

Physical exercise is an important adjunct to daily ACT. Exercise stimulates mucus excretion and provides a sense of well-being and increased self-esteem. Any aerobic exercise that the patient enjoys should be encouraged. The ultimate aim of exercise is to increase lung vital capacity, remove secretions, increase pulmonary blood flow, and maintain healthy lung tissue for effective ventilation.

Pulmonary infections are treated as soon as they are recognized. In CF patients, characteristic

signs of pulmonary infection—fever, tachypnea, and chest pain—may be absent. Therefore, a careful history and physical examination are essential. The presence of anorexia, weight loss, and decreased activity alerts the practitioner to pulmonary infection and the need for an antibiotic regimen. Aerosolized antibiotics (such as tobramycin, aztreonam, and colistin) are beneficial for patients with frequent pulmonary exacerbations and are administered in 2- to 4-week cycles or on an ongoing basis to prevent colonization with *P. aeruginosa*.

IV antibiotics may be administered at home as an alternative to hospitalization. The use of peripherally inserted central catheters (PICCs) for the administration of antibiotics in children with CF is a viable option with limited complications and fewer needle punctures to obtain blood specimens and to maintain often lengthy treatment with parenteral antibiotics. Alternatively, an implanted vascular access device offers the advantage of access for blood draws and antibiotic infusion. When pulmonary function does not improve with outpatient management, hospitalization may be recommended for continued antibiotic therapy and vigorous ACT. Periodic hospitalizations for preventive IV antibiotic therapy and percussion and postural drainage occur less frequently than in the past due to limited evidence to support this practice and concern about making organisms more multidrug resistant. Oxygen administration is used for children with acute episodes but must be used cautiously because many children with CF have chronic carbon dioxide retention, and the unsupervised use of oxygen can be harmful (see [Oxygen Therapy, Chapter 20](#)). With repeated infection and inflammation, bronchial cysts and emphysema may develop. These cysts may rupture, resulting in a pneumothorax.

Nursing Alert

Signs of a pneumothorax are usually nonspecific and include tachypnea, tachycardia, dyspnea, pallor, and cyanosis. A subtle drop in oxygen saturation (SaO₂; measured by pulse oximetry) may be an early sign of pneumothorax.

Blood streaking of the sputum is usually associated with increased pulmonary infection and often requires no specific treatment. Hemoptysis indicates a potentially life-threatening event seen more commonly in older patients with advanced disease, and needs to be treated immediately. Sometimes bleeding can be controlled with bed rest, IV antibiotics, replacement of acute blood loss, IV conjugated estrogens (Premarin) or vasopressin (Pitressin), and correction of any coagulation defects with vitamin K or fresh-frozen plasma. If hemoptysis persists, the site of bleeding should be localized via bronchoscopy and cauterized or embolized. In severe cases, a lung resection may be required.

Nasal polyposis can develop in two thirds of patients with CF and occur due to chronic inflammation. Treatment of nasal polyps includes intranasal corticosteroids, decongestants, and mucolytics. If these measures are ineffective, surgical interventions may be necessary. Saline irrigations are often prescribed to remove thick nasal secretions and to treat chronic sinusitis associated with CF.

Because pulmonary damage in patients with CF is believed to be caused by the inflammatory process that occurs with frequent infections, the use of corticosteroids has been studied; however, treatment with corticosteroids for prolonged periods found only a modest efficacy and numerous side effects including linear growth restriction, glucose tolerance abnormalities, and cataract formation. Antiinflammatory medications such as ibuprofen are becoming more important in the treatment of CF, but careful monitoring for adverse effects (gastrointestinal bleeding) is essential.

Management of Gastrointestinal Problems

The principal treatment for pancreatic insufficiency is replacement of pancreatic enzymes, which are administered with meals and snacks to ensure that digestive enzymes are mixed with food in the duodenum. Enteric-coated products prevent the neutralization of enzymes by gastric acids, thus allowing activation to occur in the alkaline environment of the small bowel. The amount of enzymes depends on the severity of the insufficiency, the child's response to enzyme replacement, and the practitioner's philosophy. Usually 1 to 5 capsules are administered with a meal, and a smaller amount is taken with snacks. Capsules can be swallowed whole or taken apart and the contents sprinkled on a small amount of food, such as cereal or fruit, to be taken at the beginning of the meal. The amount of enzyme is adjusted to achieve normal growth and a decrease in the

number of stools to one or two per day. Pancreatic enzymes should be taken before a meal or snack or within 30 minutes of eating. The enteric-coated beads should not be chewed or crushed because destroying the enteric coating can lead to inactivation of the enzymes and excoriation of oral mucosa. The powder form is used with infants and young children but should be used cautiously because inhalation of the powder may precipitate acute bronchospasm and, if mixed with food, predigests the food, making it unpalatable. The mouth must be rinsed after enzymes are administered to avoid break down of the oral mucosa or a breastfeeding mother's nipples.

Children with CF require a well-balanced, high-protein, high-caloric diet (because of their impaired intestinal absorption). In fact, they often require up to 150% of the recommended daily allowances to meet their needs for growth. Breastfeeding with enzyme supplementation should be continued as long as possible and, when necessary, supplemented with a higher-calorie-per-ounce formula. For formula-fed infants, commercial cow's milk-based formulas are usually adequate, although frequently a partially hydrolysed formula with medium-chain triglycerides (e.g., Pregestimil, Alimentum) may be recommended. Because the uptake of fat-soluble vitamins is decreased, water-miscible forms of these vitamins (A, D, E, and K) are given along with multivitamins and the enzymes. When high-fat foods are eaten, the child is encouraged to add extra enzymes.

Growth failure despite adequate nutritional support may indicate deterioration of pulmonary status. Patients with CF may experience frequent anorexia as a result of the copious amounts of mucus produced and expectorated, persistent cough, effects of medications, fatigue, and sleep disruption. They may be placed on oral nutritional supplements, nighttime supplemental gastrostomy or NG tube feedings, or rarely, parenteral alimentation in an effort to build up nutritional reserves if there has been a history of inability to maintain weight.

Meconium ileus and meconium ileus equivalent, or total or partial intestinal obstruction, can occur at any age. Constipation is often the result of a combination of malabsorption (either from inadequate pancreatic enzyme dosage or a failure to take the enzymes), decreased intestinal motility, and abnormally viscous intestinal secretions. These problems usually do not require surgical interventions and may be treated with MiraLAX or Colyte (osmotic solutions given orally or by NG tubes), other laxatives, stool softeners, or rectal administration of meglumine diatrizoate (Gastrografin).

Rectal prolapse occurs in a small number of infants with CF, due to steatorrhea, malnutrition, and repetitive coughing (Egan, Green, and Voynow, 2016). The first episode of rectal prolapse is frightening to both the parents and child. Its reduction usually requires immediate guidance and intervention, which is managed by simply guiding the rectum back into place with a gloved, lubricated finger. Further management usually involves attempting to decrease the bulk of daily stools through enzyme replacement.

Children with CF often experience transient or chronic gastroesophageal reflux, which should be treated with the appropriate histamine-receptor antagonist and gastrointestinal motility drug, dietary modifications, and an upright position after feedings and meals (Hazle, 2010).

Management of Endocrine Problems

The management of CFRD is critical in the therapeutic treatment of the child with CF. CFRD presents a combination of insulin resistance and insulin deficiency, with unstable glucose homeostasis in the presence of acute lung infection and treatment. Children with CFRD require close monitoring of blood glucose and administration of insulin, diet and exercise management, and quarterly glycosylated hemoglobin (A1C) measurements. Children with CF may be at increased risk for glucose management problems as a result of decreased nutrient absorption, anorexia, and severity of pulmonary illness. The prevalence of CFRD increases with age, and there is increased morbidity and mortality among children with CFRD compared to those without. Microvascular complications, such as retinopathy and nephropathy, may occur in children and adolescents with CFRD (O'Riordan, Dattani, and Hindmarsh, 2010). However, ketoacidosis is reported to be rare in individuals with CFRD (Egan, Green, and Voynow, 2016). Children with CFRD should perform self-blood glucose monitoring (SBGM) three times daily and should be on an insulin regimen. Target glucose levels should be the same as for any other patient with diabetes. There is no evidence that oral glycemic agents are effective. During acute CF exacerbations, the nondiabetic child should be monitored closely for hyperglycemia; glycosylated hemoglobin is reportedly a poor predictor of CFRD, so an oral glucose tolerance test is the preferred screening tool (Moran, Brunzell,

Cohen, et al, 2010).

Bone health is of concern in children and adults with CF. The pancreatic insufficiency of CF and chronic steroid use present potential risks for less than optimum bone growth in such children. Assessment of bone health by history and bone mass density evaluation should be considered in assessing the child's (8 years old and older) health status to detect and prevent osteoporosis and osteopenia.

Prognosis

The median survival age for the CF patient is 40 years, and approximately 50% of patients are 18 and older (Cystic Fibrosis Foundation, 2015). Lung, heart, pancreas, and liver transplantation have increased survival rates among some CF patients. Heart/lung and double-lung procedures have been successfully performed in children with advanced pulmonary vascular disease and hypoxia. The obstacles surrounding this technique are availability of donated organs; complications from surgery; pulmonary infections; and recurrence of obstructive bronchiolitis, which decreases transplanted lung function.

There is increasing focus on the use of CFTR pharmacotherapy to act as correctors and potentiators to override the CFTR defect and maintain adequate airway surface liquid layer, as well as to correct abnormal chloride and sodium channels to reduce mucus production. Ataluren (PTC124) and an agent labeled VX-809 are currently being examined (Panesar, 2011). These pharmacotherapeutic approaches have been shown to offer clinical benefits for persons with delta F508 mutation (Cuthbert, 2011; Kim Chiaw, Eckford, and Bear, 2011). With advances in technology, parents and adolescents are challenged to set future goals that may include college, careers, social relationships, and marriage. Concurrently, they are faced with increasing morbidity and higher rates of CF complications as they grow older.

Nursing Care Management

Assessment of the child with CF involves comprehensive assessment of all affected systems with special focus on the pulmonary and gastrointestinal systems. Pulmonary assessment is the same as that described for asthma, with special attention to lung sounds, observation of cough, and evidence of decreased activity or fatigue. Gastrointestinal assessment primarily involves observing the frequency and nature of the stools and abdominal distention. The nurse should also be alert to evidence of growth failure (e.g., weight loss, muscle wasting, pallor, anorexia, decreased activity [from baseline norm]). Family members are interviewed to determine the child's eating and eliminating habits and to confirm a history of frequent respiratory tract infections or bowel obstruction in infancy.

The nurse assesses the newborn for feeding and stooling patterns, which may indicate a potential problem, such as meconium ileus. The nurse also participates in diagnostic testing, such as the initial newborn screening, DNA analysis, or sweat chloride test.

The uncertainty, fear, and initial shock associated with the diagnosis are overwhelming to parents. They must face the impact of the chronic, life-threatening nature of the disease and the prospect of intensive treatment, for which they must assume a major part of the responsibility and for which they may be ill prepared. They often fear that they will be unable to provide the care the child needs. One of the most difficult aspects of the diagnosis is the implications inherent in its etiology (i.e., the recognition that each parent contributed the gene responsible for the defect).

Hospital Care

Most patients with CF require hospitalization only for treatment of pulmonary infection, uncontrolled diabetes, or a coexisting medical problem that cannot be treated on an outpatient basis. Therefore, when patients with CF are hospitalized, implement standard precautions with meticulous hand washing to decrease the nosocomial spread of organisms to the CF patient and between hospitalized CF patients (especially when MRSA is prevalent). Contact precautions may be required for specific infections or to prevent transmission of infection between patients. Some institutions issue contact precautions on all patients admitted with CF for their protection.

When the child with CF is hospitalized for diagnosis or treatment of pulmonary complications, aerosol therapy, and percussion and postural drainage are instituted or continued. Respiratory therapists often initiate, supervise, and provide these treatments; however, it is the nurse's responsibility to monitor the patient's tolerance to the procedure and evaluate the effectiveness of

the procedure in relation to treatment goals. The nurse may at times administer aerosol therapy, perform chest percussion and postural drainage, assist with ACTs (such as the mechanical vest), and teach breathing exercises. Planning percussion and postural drainage so that it does not coincide with meals is difficult in the hospital situation but is essential to the effectiveness of this treatment.

Nursing assessments, including observation of respiratory pattern, work of breathing, and lung auscultation, are vital assessments. Noninvasive pulse oximetry provides valuable data about the patient's oxygenation status. Supplemental oxygen therapy is administered to the child with mild or moderate respiratory distress, and the child requires frequent assessment of the tolerance to the procedure.

One of the nursing challenges in the care of the child with CF is encouraging adherence to the therapeutic medication regimen, which often involves a significant number of medications; pancreatic enzymes; vitamins A, D, E, and K; oral antifungals for *Candida* infection; antihistamines; antiinflammatory agents; and oral antibiotics. This may be overwhelming to the child. Factor in multiple inhaled bronchodilators, chest percussion and postural drainage and aerosol treatments, blood glucose monitoring and insulin administration, various other medications, and increased mucus production during the acute phase, and it is common for the child with CF to rebel and be reluctant to adhere to the prescribed regimen. Gentle coaxing, positive reinforcement, and frank negotiation may be required to enlist cooperative for effective therapy compliance.

The diet for the child with CF represents another challenge; careful planning with a registered pediatric dietitian and the child's input may help decrease the loss of appetite and weight loss that are often part of the condition. With infection and increased lung involvement, the child's appetite diminishes, and eventually it can become a challenge to provide appropriate nutrition. When dietary intake fails to meet the child's needs for growth, supplements are considered by mouth. Enteric feedings may be needed via an NG or gastrostomy tube during the night to minimize the disruption of daily activities, including school. A low-profile gastrostomy tube affords the child few activity restrictions and minimum disruption of body image in comparison to NG tube or conventional gastrostomy tube. The child and parents are encouraged to not perceive this therapy as a last-ditch effort but as an adjunct therapy to maintain optimum growth and prevent excessive weight loss.

Depression, anxiety, and disturbed self-image may occur in children and adolescents with CF. Older adolescents and young adults with severe symptoms may be especially prone to depression as a result of the realization of the poor prognosis and the reality of unmet life expectations and goals.

Providing support to both the child and the family is essential. Skilled nursing care and sympathetic attention to the emotional needs of the child and family help them cope with the stresses associated with repeated respiratory tract infections and hospitalizations.

Home Care

Most children and adolescents with CF can be managed at home. The goals of care include normalization and daily activities, including school and peer involvement. The care plan should be flexible so that family activities are disrupted as little as possible. Parents may initially require assistance finding and contacting durable medical equipment companies that will provide home care equipment. They also need opportunities to learn how to use the equipment and to solve problems that they may encounter while delivering therapy at home (see [Chapter 19](#)).

Patients and family members need education about the preferred diet of nutritious meals with tolerated fat, increased protein and carbohydrate, and the administration of pancreatic enzymes and nutritional supplements. It is important to stress to parents that the enzymes, in the amount regulated to the child's needs, should be administered at the beginning of all meals and snacks. For enteral feeds administered overnight, enzymes are generally administered at the start and finish of the feeds.

One of the most important aspects of educating parents for home care is teaching techniques for the removal of mucus (ACT, vest, forced expiration) and breathing exercises. The success of a therapy program depends on conscientious performance of these treatments regularly as prescribed. The number of times these therapies are performed each day is determined on an individual basis, and often parents readily learn to adjust the number and intensity of the treatments to the child's needs. For pulmonary infection, home IV antibiotics may be prescribed

pending verification of insurance coverage and availability of an agency with adequate staff to perform multiple daily home antibiotic infusions. With use of the venous access devices (such as PICC lines and implanted ports), the parents and child can be taught the technique of direct administration into the IV line.

Families also need information about medications and possible side effects. Children receiving multiple antibiotics may require serum drug levels to ensure therapeutic dosing as well as other laboratory testing.

If the child has CFRD, education on self-blood glucose monitoring, insulin therapy, diet control, and possible complications related to these may be needed. Follow up with a pediatric endocrinologist is recommended.

Children and adolescents with CF should receive routine primary care with special attention to diet, growth and development, and immunizations. Care providers should be alert to any weight loss or flattening in the growth curve associated with loss of appetite, which could indicate a pulmonary exacerbation in children with CF (Hazle, 2010). Anticipatory guidance concerning issues of discipline, how to incorporate aspects of the treatment regimen into the school environment, and delayed pubertal development are also important considerations for the primary care provider.

Home palliative care for the child or adolescent with CF who is in the terminal stages may be carried out with the assistance of palliative care or hospice as appropriate (see Chapter 17).

The nurse can assist the family in contacting resources that provide help to families with affected children. Various special child health services, many local clinics, private agencies, service clubs, and other community groups often offer equipment and medications either free or at reduced rates. The Cystic Fibrosis Foundation* has chapters throughout the United States that provide education and services to families and professionals.

Family Support

One of the most challenging aspects of providing care for the family of a child or adolescent with CF is meeting the emotional needs of the child and family. The diagnosis, treatment, and prognosis for CF are often associated with many problems and frustrations and may evoke feelings of guilt and self-recrimination in parents.

The long-range problems for an infant, child, or adolescent with CF are those encountered in any chronic illness (see Chapter 17). Both the child and the family must make many adjustments, the success of which depends on their ability to cope and on the quality and quantity of support they receive from outside sources. It is often the nurse who assesses the home situation, organizes and coordinates these services, and collects the data needed to evaluate the effectiveness of the services.

The persistent need for treatment several times a day places tremendous strain on the family. When the child is young, a family member must perform postural drainage and other ACTs. Children often balk at these treatments, and the parents are placed in the position of insisting on adherence. The stress and anxiety related to this routine may produce feelings of resentment in both the child and the family members. When possible, occasional trusted respite care should be available to allow parents to leave the situation for short periods without undue anxiety about the child's welfare.

The affected child or adolescent may become resentful about the disease, its relentless routine of therapy, and the necessary curtailment it places on activities and relationships. The child's activities are interrupted or built around treatments, medications, and diet. This imposes hardships and influences the child's quality of life. The child should be encouraged to attend school, seek employment when old enough, and join age-appropriate peer groups to foster a life that is as normal and productive as possible. Sports are often an important part of the child and adolescent's life; interaction with peers includes valuable life experiences, especially to adolescents. The child or adolescent with CF should be encouraged to participate in sports activities in as much as physical and pulmonary health allows. Exercise is encouraged to increase pulmonary vital capacity, promote muscle development, and enhance cardiovascular function.

As the disease progresses, however, family stress should be expected, and the patient may become angry and may resist medical therapy. It is important for the nurse to recognize the family's changing needs and the grief they may experience as the CF worsens. Families should be made aware of resources for counseling. Patients need to be guided into activities that enable them to express anger, sorrow, and fear without guilt.

Transition to Adulthood

As life expectancy continues to rise for children and adolescents with CF, issues related to marriage, sexuality, childbearing, and career choice become more pressing. Male patients must be informed at some point that they will often be unable to produce offspring. It is important that the distinction be made between sterility and impotence. Normal sexual relationships can be expected. Female patients may be able to bear children but should be informed of the possible deleterious effects on the respiratory system created by the burden of pregnancy. They also need to know that their children will be carriers of the CF gene. Adolescent females may need counseling concerning the use of oral contraceptives and other contraceptive options (Hazle, 2010).

Adolescents with CF are encouraged to take personal ownership and management of the illness to maximize their life's potential. Many adolescents and young persons with the illness enroll in college or vocational and technical training school and complete degrees either by distance learning or by attending a local school. Young people should set life goals and live normal lives to the extent their illness allows.

Anticipatory grieving and other aspects related to care of a child with a terminal illness are also part of nursing care. For example, it is important to prepare the child and family members for end-of-life decisions and care when appropriate. Families may need information about specific interventions such as hospice (see Chapter 17).

Obstructive Sleep-Disordered Breathing

Pediatric obstructive sleep-disordered breathing reportedly affects approximately 600,000 children 5 to 19 years old in the United States (Weiss and Owens, 2014). Obstructive sleep-disordered breathing is an abnormal respiratory pattern or abnormal deoxygenation associated with hypoventilation that results in repetitive partial or complete airway obstruction of the upper airway during sleep. The most severe form of this condition is **obstructive sleep apnea syndrome (OSAS)**. Common symptoms include nightly snoring, labored breathing during sleep, interrupted or disturbed sleep patterns, sleep enuresis, and daytime neurobehavioral problems (Marcus, Brooks, Draper, et al, 2012). OSAS is to be distinguished from primary snoring, which is snoring without obstructive apnea, frequent sleep arousals, or abnormalities in gas exchange. Children with OSAS usually do not exhibit daytime sleepiness as do adults, with the possible exception of obese children. If left untreated, obstructive sleep-disordered breathing may result in complications such as growth failure, cor pulmonale, hypertension, poor learning, behavioral problems, attention-deficit/hyperactivity disorder, and death.

The diagnosis of obstructive sleep-disordered breathing is made by a sleep study (polysomnography), which provides evidence of sleep disturbance, respiratory pauses, and changes in oxygenation. The six-channel polysomnography can be performed in children of all ages with videotaping or audiotaping, and abbreviated (vs. full night sleep study) polysomnography may be useful; however, this latter method does not predict the severity of OSAS (Marcus, Brooks, Draper, et al, 2012). Polysomnography can distinguish between OSAS and primary snoring (Owens, 2016).

Obstructive sleep disordered breathing in children has been associated with enlarged tonsils, obesity, chronic nasal congestion, asthma, prematurity, cerebral palsy, muscular dystrophy, Down syndrome, craniofacial anomalies, and nasal septal deviation (Weiss and Owens, 2014).

A common treatment for sleep-disordered breathing in children is adenotonsillectomy, provided there is evidence of adenotonsillar hypertrophy (Marcus, Brooks, Draper, et al, 2012; Owens, 2016). However, evidence indicates that this procedure may not be as successful in children with obesity as previously reported (Witmans and Young, 2011). A weight-management plan is implemented for obese children with OSAS.

CPAP and bilevel (cycles between high and low pressure) positive airway pressure (BiPAP) may be helpful in older children with sleep-disordered breathing whose condition persists after surgical intervention. CPAP or BiPAP is a long-term therapy with frequent assessments to evaluate the required amount of pressure and the overall effectiveness of the intervention.

Nursing care of the child with sleep-disordered breathing involves early detection by observation of the infant's or child's sleep patterns, active participation in the diagnostic polysomnography, observation of oxygenation and vital signs, application of CPAP when indicated, and monitoring the patient's response to diagnostic therapy. Counseling families of children with sleep-disordered breathing may involve dietary counseling for exercise programs and weight management, use of

the CPAP or BiPAP equipment, and direct postoperative care after the surgical intervention of tonsillectomy or adenoidectomy. Some children may resist wearing the CPAP or BiPAP devices and will need encouragement to do this. The nurse can help identify the most appropriate mask that can be tolerated by the child and can provide education about use of the CPAP or BiPAP at home.

Respiratory Emergency

Respiratory Failure

Effective pulmonary gas exchange requires clear airways, normal lungs and chest wall, and adequate pulmonary circulation. Anything that affects these functions or their relationships can compromise respiration. In general, the term **respiratory insufficiency** is applied to two situations: (1) when there is increased work of breathing but gas exchange function is near normal and (2) when normal blood gas tensions cannot be maintained and hypoxemia and acidosis develop secondary to carbon dioxide retention.

Respiratory failure is defined as the inability of the respiratory system to maintain adequate oxygenation of the blood with or without carbon dioxide retention. This process involves pulmonary dysfunction that generally results in impaired alveolar gas exchange, which can lead to hypoxemia or hypercapnia. Respiratory failure is the most common cause of cardiopulmonary arrest in children. **Respiratory arrest** is the complete cessation of respiration. **Apnea** is the cessation of breathing for more than 20 seconds or for a shorter period when associated with hypoxemia or bradycardia (Kline-Tilford, Sorce, Levin, et al, 2013). Apnea can be (1) central, in which both airflow and chest wall movement are absent; (2) obstructive, in which airflow is absent but chest wall motion is present; and (3) mixed, in which both central and obstructive components are present.

Respiratory dysfunction may have an abrupt or an insidious onset. Respiratory failure can occur as an emergency situation or may be preceded by gradual and progressive deterioration of respiratory function. Most clinical manifestations are nonspecific and are affected by variations among individual patients and differences in the severity and duration of inadequate gas exchange.

Diagnostic Evaluation

The diagnosis of respiratory failure is determined by the combined application of three sources of information:

1. Presence or history of a condition that might predispose the patient to respiratory failure
2. Observation of respiratory failure
3. Measurement of ABGs, including pH

Nursing observation and judgment are vital to the recognition and early management of respiratory failure. Nurses must be able to assess a situation and initiate appropriate action within moments. Signs of respiratory failure are listed in [Box 21-18](#).

Box 21-18

Clinical Manifestations of Respiratory Failure

Cardinal Signs

Restlessness

Tachypnea

Tachycardia

Diaphoresis

Early but Less Obvious Signs

Mood changes, such as euphoria or depression

Headache

Altered depth and pattern of respirations

Hypertension

Exertional dyspnea

Anorexia

Increased cardiac output and renal output

CNS symptoms (decreased efficiency, impaired judgment, anxiety, confusion, restlessness, irritability, depressed level of consciousness)

Flaring nares

Chest wall retractions

Expiratory grunt

Wheezing or prolonged expiration

Signs of More Severe Hypoxia

Hypotension or hypertension

Altered vision

Somnolence

Stupor

Coma

Dyspnea

Depressed respirations

Bradycardia

Cyanosis, peripheral or central

CNS, Central nervous system.

Therapeutic Management

The interventions used in the management of respiratory failure are often dramatic, requiring special skills and emergency procedures. If respiratory arrest occurs, the primary objectives are to recognize the situation and immediately initiate resuscitative measures, such as opening the airway, positioning, administering supplemental oxygen and positive pressure ventilation, and cardiopulmonary resuscitation (CPR). When the situation is not an arrest, the suspicion of respiratory failure is confirmed by assessment; the severity may be defined by ABG analysis. Interventions such as administering supplemental oxygen, positioning, stimulation, suctioning, CPAP, BiPAP, or early intubation may avert an arrest. When the severity is established, an attempt is made to determine the underlying cause by thorough evaluation.

The principles of management are to (1) maintain ventilation and maximize oxygen delivery, (2) correct hypoxemia and hypercapnia, (3) treat the underlying cause, (4) minimize extrapulmonary organ failure, (5) apply specific and nonspecific therapy to control oxygen demands, and (6) anticipate complications. Monitoring the patient's condition closely is critical.

Nursing Care Management

For families whose child has a respiratory arrest, support is aimed at keeping the family informed

of the child's status and helping them cope with a near-death experience or an actual death (see [Chapter 17](#)). Knowing that their child requires CPR is a frightening and often overwhelming experience for parents. Uncertainty regarding the outcome is a primary concern. Traditionally, family members are not allowed to be present during resuscitation efforts. However, studies indicate that family presence during emergencies alleviates the family's anger about being separated from the patient during a crisis, reduces their anxiety, eliminates doubts about what was done to help the patient, and facilitates the grieving process if the patient dies ([Meert, Clark, and Eggly, 2013](#)).

Regardless of whether an institution permits parental presence during CPR, nurses must consider the needs, fears, and concerns of family members during this situation. If family presence is not permitted during CPR, nurses should arrange for someone to remain with the family. After the child's recovery or death, the family will continue to need support and thorough medical information regarding lifesaving measures, the prognosis if the child survives, and the cause of death if the child dies.

Cardiopulmonary Resuscitation

Cardiac arrest in children occurs more frequently due to prolonged hypoxemia secondary to inadequate oxygenation, ventilation, and circulation (shock) than due to a cardiac condition. Some causes of cardiac arrest include injuries, suffocation (e.g., FB aspiration), smoke inhalation, anaphylaxis, apparent life-threatening event, or infection. Respiratory arrest is associated with a better survival rate than cardiac arrest. After cardiac arrest occurs, the outcome of resuscitative efforts is poor.

Apnea signals the need for rapid, vigorous action to prevent cardiac arrest. In such situations, nurses must initiate action immediately and notify emergency personnel. In the hospital, emergency equipment must be available and easily accessible in all patient care areas. The status of emergency equipment must be checked at least once daily.

Outside the hospital, the first action in an emergency is to quickly assess the extent of any injury and determine whether the child is unconscious. A child who is struggling to breathe but conscious should be transported immediately to an advanced life support (ALS) facility, with the child maintaining whatever position affords the most comfort. Transportation by an emergency medical service (EMS) is recommended. Services in most large communities can institute ALS immediately or en route to a medical facility.

An unconscious child is managed with care to prevent additional trauma if a head or spinal cord injury has been sustained (see [Spinal Cord Injury, Chapter 30](#)).

Resuscitation Procedure

In 2010, the American Heart Association implemented some changes in CPR guidelines. It stipulates that compressions only (no breaths) should be used when the rescuer is "untrained or trained and not proficient" ([Travers, Rea, Bobrow, et al, 2010](#)). However, if there is a respiratory arrest and the cause is asphyxia, then ventilations should be provided. Historically, the sequence for CPR was A-B-C (airway, breathing or ventilation, and chest compressions [or circulation]), but the 2010 guidelines have changed this recommended sequence to C-A-B to reduce the amount of time to the initiation of chest compressions ([Fig. 21-12](#)). Some modifications were also made to the depth of compressions, which now should be at least one third of the anteroposterior diameter of the chest (4 cm in infants and 5 cm in older children). The American Heart Association stipulates that having rescuers stop to detect a pulse is not reliable and wastes time. Instead, rescuers should start CPR if the child is unresponsive and not breathing or not breathing normally or if they failed to detect a pulse within 10 seconds. The "look, listen, and feel for breathing" practice is no longer recommended. In 2015, the American Heart Association implemented a few changes in CPR guidelines. Chest compressions should be at a rate of 100 to 120 per minute and chest compression depth should be at least 2 inches (5 cm) but not greater than 2.4 inches (6cm). Each breath should be delivered at a rate of 1 breath every 6 seconds. The automatic external defibrillator (AED) is used as a part of the treatment of cardiorespiratory arrest in children older than 1 year of age.

| Component | RECOMMENDATIONS | | |
|--|--|---|--|
| | Adults | Children | Infants |
| Recognition | Unresponsive (for all ages) | | |
| | No breathing or no normal breathing (ie, only gasping) | No breathing or only gasping | |
| | No pulse palpated within 10 seconds for all ages (HCP only) | | |
| CPR sequence* | C-A-B | | |
| Compression rate | 100 to 120 per minute | | |
| Compression depth | At least 2 inches (5 cm) but not more than 2.4 inches (6 cm) | At least $\frac{1}{3}$ AP diameter About 2 inches (5 cm) | At least $\frac{1}{3}$ AP diameter About $1\frac{1}{2}$ inches (4 cm) |
| Chest wall recoil | Allow complete recoil between compressions HCPs rotate compressors every 2 minutes | | |
| Compression interruptions | Minimize interruptions in chest compressions Attempt to limit interruptions to <10 seconds | | |
| Airway | Head tilt/chin lift (HCP suspected trauma: jaw thrust) | | |
| Compression-to-ventilation ratio (until advanced airway placed) | 30:2 1 or 2 rescuers | 30:2 Single rescuer 15:2 2 HCP rescuers | |
| Ventilations: when rescuer untrained or trained and not proficient | Compressions only | | |
| Ventilations with advanced airway (HCP) | 1 breath every 6 seconds (10 breaths/min) Asynchronous with chest compressions About 1 second per breath Visible chest rise | | |
| Defibrillation | Attach and use AED as soon as available. Minimize interruptions in chest compressions before and after shock; resume CPR beginning with compressions immediately after each shock. | | |

*Excluding the newly born, in whom the etiology of an arrest is nearly always asphyxial.
NOTE: Newborn/neonatal information not included.

FIG 21-12 Summary of basic life support maneuvers for infants, children, and adults. AED, Automatic external defibrillator; AP, anterior-posterior; CPR, cardiopulmonary resuscitation; HCP, health care provider. (Adapted from American Academy of Pediatrics, Committee on Infectious Diseases, Pickering L, editor: *Red book: 2009 report of the Committee on Infectious Diseases*, ed 28, Elk Grove Village, IL, 2009, Author.)

The American Heart Association stipulates that a manual defibrillator is preferred to an AED for defibrillation of infants. If a manual defibrillator is not available, an AED equipped with a pediatric dose attenuator is preferred. If neither is available, an AED without a pediatric dose attenuator may be used (Travers, Rea, Bobrow, et al, 2010). There is still limited evidence to support the safety of AED use in infants, but it may be safe and effective in this group. Appropriate-sized pediatric pads must be used for small children. Health care providers are advised to give children 1 year and older a defibrillatory shock after providing approximately five cycles of CPR (≈ 2 minutes of cycles of 30 compressions and two ventilations by the lone rescuer), provided the AED is sensitive to pediatric rhythms, the device is capable of delivering a pediatric dose of 2 to 4 joules/kg, and a shockable rhythm (usually ventricular fibrillation) is present. In a hospital situation in which weight-based defibrillation dosing is possible, manual defibrillation is the mode of choice instead of AED. When using an AED, health care providers are advised to give adults and children older than 8 years old a defibrillatory shock within 5 minutes of collapse outside the hospital and within 3 minutes in the hospital.

If two rescuers are present, one rescuer should begin CPR while the second rescuer activates the EMS system by calling 9-1-1 and obtaining an AED. Pediatric rescuers provide five cycles of basic life support (≈ 2 minutes) before activating EMS; each cycle consists of 30 chest compressions and two ventilations. Because pediatric arrests are most commonly caused by respiratory arrest, maintaining ventilation is key.

Pulse Check

During an emergent situation, palpating the pulse can be a challenge. The patient should be reassessed for a pulse every 2 minutes of CPR. The pulse should not be assessed for longer than 10

seconds. The carotid is the most central and accessible artery in children older than 1 year of age, but the femoral pulse may also be used. An infant's short and often fat neck makes the carotid pulse difficult to palpate. Therefore, in an infant, it is preferable to use the brachial pulse, located on the inner side of the upper arm midway between the elbow and the shoulder (Fig. 21-13). Absence of a carotid or brachial pulse is considered sufficient indication to begin external cardiac massage. Lay rescuers are not taught to check the pulse but are taught to look for signs of circulation (e.g., normal breathing, coughing, or air movement) in response to rescue breaths.

FIG 21-13 Locating the brachial pulse in an infant. (Adapted from American Academy of Pediatrics, Committee on Infectious Diseases, Pickering L, editor: *Red book: 2009 report of the Committee on Infectious Diseases*, ed 28, Elk Grove Village, IL, 2009, Author.)

Chest Compression

External chest compression consists of serial, rhythmic compressions of the chest to maintain circulation to vital organs until the child achieves spontaneous vital signs or ALS can be provided. Chest compressions are always interspersed with ventilation of the lungs; however, laypersons who witness an adult cardiac arrest should perform continuous chest compressions (push hard, push fast) without ventilations (Berg, Hemphill, Abella, et al, 2010). For optimal compressions, it is essential that the child's spine is supported on a firm surface during compressions of the sternum and that sternal pressure is forceful but not traumatic. The child's head is positioned for optimal airway opening using the head tilt/chin lift maneuver if the cervical spine is stable and no neck injuries are present. It is essential to prevent overextension of the head of small infants because this tends to close the flexible trachea.

The placement of the fingers for compression in infants is at a point on the lower sternum just below the intersection of the sternum and an imaginary line drawn between the nipples (Fig. 21-14). Compressions on the child 1 to 8 years old are applied to the lower half of the sternum (Fig. 21-15). Sternal compression to infants is applied with two fingers on the sternum, exerting a firm downward thrust; for children, pressure is applied with the heel of one hand or two hands, depending on the child's size. American Heart Association guidelines include the addition of the two-thumb encircling hands technique for chest compressions for infants when two health care providers are present (Travers, Rea, Bobrow, et al, 2010). In the two-thumb technique, one of the two rescuers places both thumbs side by side over the lower half of the infant's sternum; the remaining fingers encircle the infant's chest and support the back. The two-thumb technique is not taught to lay rescuers and is not practical for a health care provider working alone.

FIG 21-14 Combining chest compressions with breathing in infant.

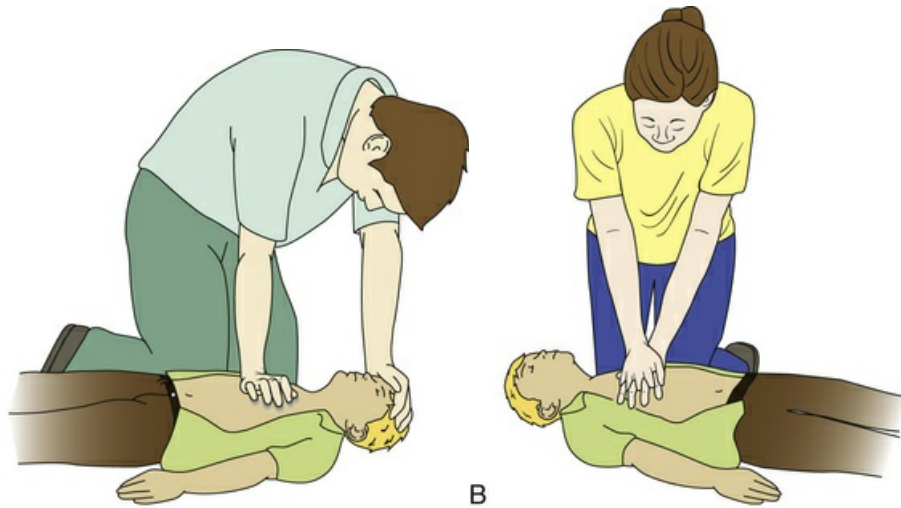

FIG 21-15 Chest compressions in child: one hand for a smaller child (A) and two hands for a larger child (B).

Lone-rescuer CPR is continued at the ratio of two breaths to 30 compressions for all ages until signs of recovery appear. These signs include palpable peripheral pulses, return of pupils to normal size, the disappearance of mottling and cyanosis, and possibly return of spontaneous respiration. When two rescuers are present, they should deliver two breaths to each 15 compressions.

Open the Airway

For effective CPR the victim is placed on the back on a firm, flat surface using appropriate precautions. With loss of consciousness, the tongue, which is attached to the lower jaw, may relax and fall back, obstructing the airway. To open the airway, the head is positioned with a head tilt/chin lift maneuver (if stable cervical spine) by the lay rescuer. Health professionals should open the airway using either a head tilt/chin lift or jaw thrust (if an unstable cervical spine) maneuver. A head tilt is accomplished by placing one hand on the victim's forehead and applying firm, backward pressure with the palm to tilt back the head. The fingers of the free hand are placed under the bony portion of the lower jaw near the chin to lift and bring the chin forward (chin lift). This supports the jaw and helps tilt the head back (Fig. 21-16).

FIG 21-16 Open the airway using the head tilt/chin lift maneuver, and check breathing.

The jaw thrust is accomplished by grasping the angles of the victim's lower jaw and lifting with both hands, one on each side, displacing the mandible upward and outward. The jaw thrust is recommended only for health care workers. In suspected neck injuries, the jaw thrust method should be used while the cervical spine is completely immobilized. After a patent airway has been restored by removal of foreign material and secretions (if indicated) and if the child is not breathing, maintenance of the airway is continued, and rescue breathing is initiated.

Give Breaths

To ventilate the lungs in the infant (from birth to 1 year old), the bag valve mask (BVM) or operator's mouth is placed in such a way that both the mouth and the nostrils are covered (Fig. 21-17) using the E-C technique. With the BVM, the thumb and index finger of the nondominant hand secure the mask on the patient's face (forming a C), while the first three fingers of the same hand are used to lift the jaw (forming an E). If no BVM is available, children (older than 1 year old) are ventilated through the mouth while the nostrils are pinched for airtight contact.

FIG 21-17 Mouth-to-mouth and nose breathing for an infant.

The volume of air in an infant's lungs is small, and the air passages are considerably smaller, with resistance to flow potentially higher than in adults. The rescuer should deliver small puffs of air and assess the rise of the chest to ensure that overinflation does not occur. A gentle rise of the chest is a sufficient indicator of adequate inflation and indicates that the airway is clear. Breaths should be given over 1 second with sufficient volume to make the chest rise. If the chest does not rise, reposition the head or jaw and try again.

Medications

Medications are an important adjunct to CPR, especially cardiac arrest, and are used during and after resuscitation in children. Medications are used to (1) correct hypoxemia, (2) increase perfusion pressure during chest compression, (3) stimulate spontaneous or more forceful myocardial contraction, (4) accelerate cardiac rate, (5) correct metabolic acidosis, and (6) suppress ventricular ectopy. In 2015, the American Heart Association changed the guidelines to report that bystanders may administer naloxone for suspected life-threatening opioid associated emergencies.

Appropriate fluid therapy is initiated immediately in the hospital or by EMS personnel during transport (see [Parenteral Fluid Therapy, Chapter 20](#), and [Shock, Chapter 23](#)). A complete supply of emergency medications is kept and maintained in all EMS vehicles and on all hospital units. The supply is checked on a regular basis (usually once a day at minimum). When administering drugs during CPR (or a "code"), use a saline flush or other compatible flush solution between medications to prevent drug interactions. Document all drugs, dosages, and the time and route of administration.

Airway Obstruction

Attempts at clearing the airway should be considered for (1) children in whom aspiration of an FB is witnessed or strongly suspected and (2) unconscious, nonbreathing children whose airways remain obstructed despite the usual maneuvers to open them. When aspiration is strongly suspected, the child is encouraged to continue coughing as long as the cough remains forceful. In a conscious choking child, attempt to relieve the obstruction only if:

- The child is unable to make any sounds.
- The cough becomes ineffective.
- There is increasing respiratory difficulty with stridor.

Nursing Alert

Blind finger sweeps are avoided in all infants and children.

Infants

A combination of back blows (over the spine between the shoulder blades) and chest thrusts (on the sternum, the same location as for chest compressions) is recommended to relieve the FB obstruction in infants (Fig. 21-18). A choking infant is placed face down over the rescuer's arm with the head lower than the trunk and the head supported. For additional support, the rescuer should support the arm firmly against the thigh. Up to five quick, sharp back blows are delivered between the infant's shoulder blades with the heel of the rescuer's hand. Less force is required than would be applied to an adult. After delivery of the back blows, the rescuer's free hand is placed flat on the infant's back so that the infant is "sandwiched" between the two hands, making certain the neck and chin are well supported. While the rescuer maintains support with the infant's head lower than the trunk, the infant is turned and placed supine on the rescuer's thigh, where up to five quick downward chest thrusts are applied in rapid succession in the same location as external chest compressions described for CPR. Back blows and chest thrusts are continued until the object is removed or the infant becomes unconscious. If the infant does lose consciousness, CPR should be initiated.

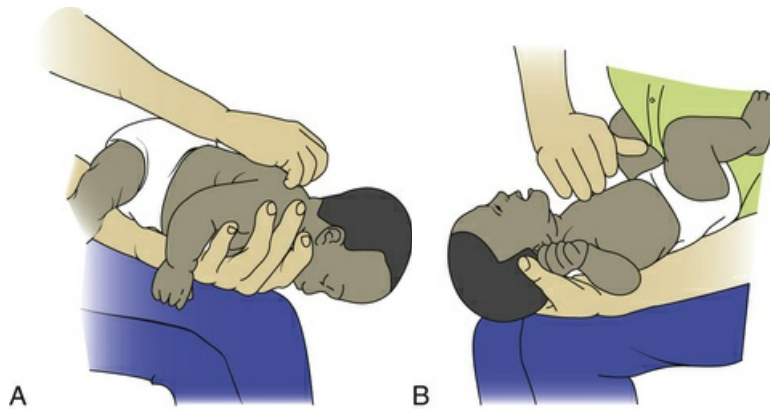

FIG 21-18 Relief of foreign body (FB) obstruction in infant. **A**, Back blows. **B**, Chest thrusts.

Children

A series of **subdiaphragmatic abdominal thrusts (Heimlich maneuver)** is recommended for children older than 1 year of age. The maneuver creates an artificial cough that forces air—and with it, the FB—out of the airway. The procedure is carried out with the child in a standing, sitting, or lying position (Fig. 21-19). In a conscious choking child, upward thrusts are delivered to the upper abdomen with the fisted hand at a point just below the rib cage. To prevent damage to the internal organs, the rescuer's hands should not touch the xiphoid process of the sternum or the lower margins of the ribs. Up to five thrusts are repeated in rapid succession until the FB is expelled.

FIG 21-19 Abdominal thrusts in standing child for relief of foreign body (FB) obstruction.

It is neither necessary nor desirable to squeeze or compress the arms during the procedure. It is not a punch or a bear hug. The child may vomit after relief of the obstruction and should be positioned to prevent aspiration. After breathing is restored, the child should receive medical attention and be assessed for complications. If the child is coughing, allow him or her to relieve the obstruction this way.

The success of the technique is primarily a result of the obstruction occurring at the end of a maximum respiration. The victim is most likely to choke on food during inspiration; therefore, the tidal volume plus expiratory reserve volume is present in the lungs. When pressure is exerted on the diaphragm by the maneuver, the food bolus is ejected with considerable force by this trapped air.

If the victim is breathing or resumes effective breathing after emergency interventions, place him or her in the recovery position—move the head, shoulders, and torso simultaneously and turn onto the side. The leg not in contact with the ground may be bent and the knee moved forward to stabilize the victim (Fig. 21-20). The victim should not be moved in any way if trauma is suspected and should not be placed in the recovery position if rescue breathing or CPR is required.

FIG 21-20 Recovery position for a child after a respiratory emergency.

NCLEX Review Questions

1. A 12-year-old child is in the urgent care clinic with a complaint of fever, headache, and sore throat. A diagnosis of group A beta-hemolytic streptococcus (GABHS) pharyngitis is established with a rapid-strep test, and oral penicillin is prescribed. The nurse knows which of the following statements about GABHS is correct?
 - a. Children with a GABHS infection are less likely to contract the illness again after the antibiotic regimen is completed.
 - b. A follow-up throat culture is recommended following the completion of antibiotic therapy.
 - c. Children with a GABHS infection are at increased risk for the development of rheumatic fever (RF) and glomerulonephritis.
 - d. Children with a GABHS infection are at increased risk for the development of rheumatoid arthritis in adulthood.
2. A 5-year-old is recovering from a tonsillectomy and adenoidectomy and is being discharged home with his mother. Home care instructions should include which of the following? Select all that apply.
 - a. Observe the child for continuous swallowing.
 - b. Encourage the child to take sips of cool, clear liquids.
 - c. Administer codeine elixir as necessary for throat pain.
 - d. Observe the child for restlessness or difficulty breathing.
 - e. Encourage the child to cough every 4 to 5 hours to prevent pneumonia.
 - f. Administer an analgesic such as acetaminophen for pain.
3. A 3-month-old infant is seen in the clinic with the following symptoms: irritability, crying, refusal to nurse for more than 2 to 3 minutes, rhinitis, and a rectal temperature of 101.8° F (38.8° C). The labor, delivery, and postpartum history for this term infant is unremarkable. The nurse anticipates a diagnosis of:
 - a. Acute otitis media (AOM)
 - b. Otitis media with effusion (OME)
 - c. Otitis externa
 - d. Respiratory syncytial virus (RSV)
4. A 5-year-old is seen in the urgent care clinic with the following history and symptoms: sudden onset of severe sore throat after going to bed, drooling and difficulty swallowing, axillary temperature of 102.2° F (39.0° C), clear breath sounds, and absence of cough. The child appears anxious and is flushed. Based on these symptoms and history, the nurse anticipates a diagnosis of:
 - a. Group A beta-hemolytic streptococcus (GABHS) pharyngitis
 - b. Acute tracheitis
 - c. Acute epiglottitis
 - d. Acute laryngotracheobronchitis (LTB)
5. A 2-month-old formerly healthy infant born at term is seen in the urgent care clinic with intercostal retractions, respiratory rate of 62, heart rate of 128, refusal to breastfeed, abundant nasal secretions, and a pulse oximeter reading of 88% in room air. The diagnosis of respiratory syncytial virus (RSV) is made, and a bronchodilator is administered. The infant's oxygen saturation (SaO₂) remains 95% in room air, and the respiratory rate is 54, with intercostal retractions; heart rate is 120 bpm. After 2 hours of observation and an intravenous (IV) bolus of fluids, the infant is being discharged home. The nurse provides which of the following home care instructions for this infant? Select all that apply.
 - a. Continue breastfeeding infant.
 - b. Discontinue breastfeeding and administer Pedialyte for 24 hours.
 - c. Observe infant for labored breathing or apnea (cessation of breathing).

- d. Instill normal saline drops in both nares and suction thoroughly before feeding and before placing to sleep.
- e. Place infant to sleep on his side with the head of bed slightly elevated to facilitate breathing.
- f. Keep the infant out of daycare or nursery.

Correct Answers

1. c; 2. a, b, d, f; 3. a; 4. c; 5. a, c, d, f

The Child with Gastrointestinal Dysfunction

Cheryl C. Rodgers, Kristina D. Wilson

Distribution of Body Fluids

The distribution of body fluids, or total body water (TBW), involves the presence of intracellular fluid (ICF) and extracellular fluid (ECF). Water is the major constituent of body tissues, and the TBW in an individual ranges from 75% (in term newborns) to 45% (in late adolescence) of total body weight.

The ICF refers to the fluid contained within the cells, whereas the ECF is the fluid outside the cells. The ECF is further broken down into several components: intravascular (contained within the blood vessels), interstitial (surrounding the cell; the location of most ECF), and transcellular (contained within specialized body cavities, such as cerebrospinal, synovial, and pleural fluid). In the newborn about 50% of the body fluid is contained within the ECF, whereas 30% of a toddler's body fluid is contained within the ECF.

Under normal conditions, the amount of water ingested closely approximates the amount of urine excreted in a 24-hour period. Maintenance water requirement is the volume of water needed to replace obligatory fluid loss such as that from insensible water loss (IWL; through the skin and respiratory tract), evaporative water loss, and losses through urine and stool formation. The amount and type of these losses may be altered by disease states such as fever (with increased sweating), diarrhea, gastric suction, and pooling of body fluids in a body space (often referred to as *third spacing*).

Nurses should be alert for altered fluid requirements in various conditions:

Increased requirements:

- Fever (add 12% per rise of 1° C)
- Vomiting, diarrhea
- High-output kidney failure
- Diabetes insipidus
- Diabetic ketoacidosis
- Burns
- Shock
- Tachypnea
- Radiant warmer (preterm infant)
- Phototherapy (infants)
- Postoperative bowel surgery (e.g., gastroschisis)

Decreased requirements:

- Heart failure

- Syndrome of inappropriate antidiuretic hormone (SIADH)
- Mechanical ventilation
- After surgery
- Oliguric renal failure
- Increased intracranial pressure

Basal maintenance calculations for required body water are based on the body's requirements for water in a normometabolic state at rest; estimated fluid requirements are then increased or decreased from these parameters based on increased or decreased water losses, such as with elevated body temperature (increased) or heart failure (decreased). Daily maintenance fluid requirements for infants, toddlers, and older children are listed in [Table 22-1](#).

TABLE 22-1
Daily Maintenance Fluid Requirements*

| Body Weight | Amount of Fluid per Day |
|-------------|--|
| 1 to 10 kg | 100 ml/kg |
| 11 to 20 kg | 1000 ml plus 50 ml/kg for each kg >10 kg |
| >20 kg | 1500 ml plus 20 ml/kg for each kg >20 kg |

*Not appropriate for neonatal use.

Maintenance fluids contain both water and electrolytes and can be estimated from the child's age, body weight, degree of activity, and body temperature. Basal metabolic rate (BMR) is derived from standard tables and adjusted for the child's activity, temperature, and disease state. For example, for afebrile patients at rest, the maintenance water requirement is approximately 100 ml for each 100 kcal expended. Children with fluid losses or other alterations require adjustment of these basic needs to accommodate abnormal losses of both water and electrolytes as a result of a disease state. For example, insensible losses increase when basal expenditure increases by fever or hypermetabolic states. Hypometabolic states, such as hypothyroidism and hypothermia, decrease the BMR.

The percentage of TBW varies among individuals and in adults and older children; it is related primarily to the amount of body fat. Consequently, females, who have more body fat than males, and obese people tend to have less water content in relation to weight.

Changes in Fluid Volume Related to Growth

The fetus is composed primarily of water with little tissue substance. As the organism grows and develops, a progressive decrease occurs in TBW, with the fastest rate of decline taking place during fetal life. The changes in water content and distribution that occur with age reflect the changes that take place in the relative amounts of bone, muscle, and fat making up the body. At maturity, the percentage of TBW is somewhat higher in the male than in the female and is probably a result of the differences in body composition, particularly fat and muscle content.

Another important aspect of growth change as it corresponds to water distribution is related to the ICF and ECF compartments. In the fetus and prematurely born infants, the largest proportion of body water is contained in the ECF compartment. As growth and development proceed, the proportion within the ECF compartment decreases as the ICF and cell solids increase. The ECF diminishes rapidly from approximately 40% of body weight at birth to less than 30% at 1 year of age. The different effects on males and females become apparent at puberty.

Water Balance in Infants

Compared with older children and adults, infants and young children have a greater need for water and are more vulnerable to alterations in fluid and electrolyte balance. Infants have a greater fluid

intake and output relative to size. Water and electrolyte disturbances occur more frequently and more rapidly, and children adjust less promptly to these alterations.

The fluid compartments in infants vary significantly from those in adults, primarily because of an expanded extracellular compartment. The ECF compartment constitutes more than half of the TBW at birth and has a greater relative content of extracellular sodium and chloride. Infants lose a large amount of fluid at birth and maintain a larger amount of ECF than adults until about 2 to 3 years old. This contributes to greater and more rapid water loss during this age period.

Fluid losses create compartment deficits that reflect the duration of dehydration. In general, approximately 60% of fluid is lost from the ECF, and the remaining 40% comes from the ICF. The amount of fluid lost from the ECF increases with acute illness and decreases with chronic loss.

Fluid losses may be divided into insensible, urinary, and fecal losses and vary with the patient's age. Approximately two thirds of **insensible water losses (IWLs)** occur through the skin, and the remaining one third is lost through the respiratory tract. Environmental heat and humidity, skin integrity, body temperature, and respiratory rate influence insensible fluid loss. Infants and children have a much greater tendency to become highly febrile than do adults. Fever increases IWL approximately 7 ml/kg/24 hr for each degree rise in temperature above 37.2° C (99° F). Fever and increased surface area relative to volume both contribute to greater insensible fluid losses in young patients.

Body Surface Area

The infant's relatively greater body surface area (BSA) allows larger quantities of fluid to be lost through the skin. It is estimated that the BSA of preterm neonates is five times more, and that of newborns is two to three times more, than that of older children or adults. The proportionately longer gastrointestinal (GI) tract in infancy is also a source of fluid loss, especially from diarrhea.

Basal Metabolic Rate

The rate of metabolism in infancy is significantly higher than in adulthood because of the larger BSA in relation to the mass of active tissue. Consequently, infants have a greater production of metabolic wastes that the kidneys must excrete. Any condition that increases metabolism causes greater heat production, insensible fluid loss, and an increased need for water for excretion. The BMR in infants and children is higher to support cellular and tissue growth.

Kidney Function

The infant's kidneys are functionally immature at birth and are therefore inefficient in excreting waste products of metabolism. Of particular importance for fluid balance is the inability of the infant's kidneys to concentrate or dilute urine, to conserve or excrete sodium, and to acidify urine. Therefore, the infant is less able to handle large quantities of solute-free water than older children and is more likely to become dehydrated when given concentrated formulas or overhydrated when given excessive water or dilute formula.

Fluid Requirements

Infants ingest and excrete a greater amount of fluid per kilogram of body weight than do older children. Because electrolytes are excreted with water and infants have a limited ability for conservation, maintenance requirements include both water and electrolytes. The daily exchange of ECF in infants is much greater than that of older children, which leave infants with little fluid volume reserve in dehydrated states. Fluid requirements depend on hydration status, size, environmental factors, and underlying disease.

Disturbances of Fluid and Electrolyte Balance

Disturbances of fluids and their solute concentration are closely interrelated. Alterations in fluid volume affect the electrolyte component, and changes in electrolyte concentration influence fluid movement. Because intracellular water and electrolytes move to and from the ECF compartment, any imbalance in the ICF is reflected by an imbalance in the ECF. Disturbances in the ECF involve either an excess or a deficit of fluid or electrolytes. Of these, fluid loss occurs more frequently.

Depletion of ECF, usually caused by gastroenteritis, is one of the most common problems encountered in infants and children. Until modern techniques for fluid replacement were perfected,

gastroenteritis was one of the chief causes of infant mortality. Fluid and electrolyte problems related to specific diseases and their management are discussed throughout the book where appropriate. The major fluid disturbances, their usual causes, and clinical manifestations are listed in Table 22-2. Problems of fluid and electrolyte disturbance always involve both water and electrolytes; therefore, replacement includes administration of both, calculated on the basis of ongoing processes and laboratory serum electrolyte values.

TABLE 22-2
Disturbances of Select Fluid and Electrolyte Balance

| Mechanisms and Situations | Manifestations | Management and Nursing Care |
|--|---|--|
| Water Depletion | | |
| Failure to absorb or reabsorb water Complete or sudden cessation of intake or prolonged diminished intake: <ul style="list-style-type: none"> Neglect of intake by self or caregiver—confused, psychotic, unconscious, or helpless Loss from GI tract—vomiting, diarrhea, NG suction, fistula Disturbed body fluid chemistry: Inappropriate ADH secretion Excessive renal excretion: Glycosuria (diabetes) Loss through skin or lungs: <ul style="list-style-type: none"> Excessive perspiration or evaporation—febrile states, hyperventilation, increased ambient temperature, increased activity (BMR) Impaired skin integrity—transudate from injuries Hemorrhage Iatrogenic: <ul style="list-style-type: none"> Overzealous use of diuretics Improper perioperative fluid replacement Use of radiant warmer or phototherapy | General symptoms depend to some extent on proportion of electrolytes lost with water Thirst Variable temperature—increased (infection) Dry skin and mucous membranes Poor skin turgor Poor perfusion (decreased pulse, prolonged capillary refill time) Weight loss Fatigue Diminished urinary output Irritability and lethargy Tachycardia Tachypnea Altered level of consciousness, disorientation Laboratory findings: <ul style="list-style-type: none"> High urine specific gravity Increased hematocrit Variable serum electrolytes Low serum bicarbonate (HCO₃) Variable urine volume Increased BUN Increased serum osmolality | Provide replacement of fluid losses commensurate with volume depletion. Provide maintenance fluids and electrolytes. Determine and correct cause of water depletion. Measure fluid intake and output. Monitor vital signs. Monitor urine specific gravity. Monitor body weight. Monitor serum electrolytes. |
| Water Excess | | |
| Water intake in excess of output: <ul style="list-style-type: none"> Excessive oral intake Hypotonic fluid overload Plain water enemas Failure to excrete water in presence of normal intake: <ul style="list-style-type: none"> Kidney disease Syndrome of inappropriate syndrome of inappropriate anti-diuretic hormone Heart failure Malnutrition | Edema: <ul style="list-style-type: none"> Generalized Pulmonary (moist rales or crackles) Intracutaneous (noted especially in loose areolar tissue) Elevated central venous pressure Hepatomegaly Slow, bounding pulse Weight gain Lethargy Increased spinal fluid pressure CNS manifestations (seizures, coma) Laboratory findings: <ul style="list-style-type: none"> Low urine specific gravity Decreased serum electrolytes Decreased hematocrit Variable urine volume | Limit fluid intake. Administer diuretics. Monitor vital signs. Monitor neurologic signs as necessary. Determine and treat cause of water excess. Analyze serum electrolyte measurements. Implement seizure precautions. |
| Sodium Depletion (Hyponatremia) | | |
| Prolonged low-sodium diet Decreased sodium intake Fever Excess sweating Increased water intake without electrolytes Tachypnea (infants) Cystic fibrosis Burns and wounds Vomiting, diarrhea, NG suction, fistulas Adrenal insufficiency Renal disease DKA Malnutrition | Associated with water loss: <ul style="list-style-type: none"> Same as with water loss—dehydration, weakness, dizziness, nausea, abdominal cramps, apprehension Mild—apathy, weakness, nausea, weak pulse Moderate—decreased blood pressure, lethargy Laboratory findings: <ul style="list-style-type: none"> Sodium concentration <130 mEq/L (may be normal if volume loss) Urine specific gravity depends on water deficit or excess | Determine and treat cause of sodium deficit. Administer IV fluids with appropriate saline concentration. Monitor fluid intake and output. |
| Sodium Excess (Hypernatremia) | | |
| High salt intake—enteral or IV Renal disease Fever Insufficient breast milk intake in neonate (dehydration hypernatremia) High IWL: <ul style="list-style-type: none"> Increased temperature Increased humidity Hyperventilation Diabetes insipidus Hyperglycemia | Intense thirst Dry, sticky mucous membranes Flushed skin Temperature possibly increased Hoarseness Oliguria Nausea and vomiting Possible progression to disorientation, seizures, muscle twitching, nuchal rigidity, lethargy at rest, hyperirritability when aroused Laboratory findings: <ul style="list-style-type: none"> Serum sodium concentration ≥150 mEq/L High plasma volume Alkalosis | Determine and treat cause of sodium excess. Administer IV fluids as prescribed. Measure fluid intake and output. Monitor laboratory data. Monitor neurologic status. Ensure adequate intake of breast milk and provide lactation assistance with new mother/baby pair before hospital discharge. |
| Potassium Depletion (Hypokalemia) | | |
| Starvation Clinical conditions associated with poor food intake Malabsorption IV fluid without added potassium GI losses—diarrhea, vomiting, fistulas, NG suction Diuresis Administration of diuretics Administration of corticosteroids Diuretic phase of nephrotic syndrome Healing stage of burns Potassium-losing nephritis Hyperglycemic diuresis (e.g., diabetes mellitus) Familial periodic paralysis IV administration of insulin in DKA Alkalosis | Muscle weakness, cramping, stiffness, paralysis, hyporeflexia Hypotension Cardiac arrhythmias, gallop rhythm Tachycardia or bradycardia Ileus Apathy, drowsiness Irritability Fatigue Laboratory findings: <ul style="list-style-type: none"> Decreased serum potassium concentration ≤3.5 mEq/L Abnormal ECG—notched or flattened T waves, decreased ST segment, premature ventricular contractions | Determine and treat cause of potassium deficit. Monitor vital signs, and ECG. Administer supplemental potassium. Assess for adequate renal output before administration. For IV replacement, administer potassium slowly. Always monitor ECG for IV bolus potassium replacement. For oral intake, offer high-potassium fluids and foods. Evaluate acid-base status. |
| Potassium Excess (Hyperkalemia) | | |
| Renal disease Renal failure Adrenal insufficiency (Addison disease) Associated with metabolic acidosis Too rapid administration of IV potassium chloride | Muscle weakness, flaccid paralysis Twitching Hyperreflexia Bradycardia Ventricular fibrillation and cardiac arrest | Determine and treat cause of potassium excess. Monitor vital signs, including ECG. Administer exchange resin, if prescribed. Administer IV fluids as prescribed. Administer IV insulin (if ordered) to facilitate movement of |

| | | |
|---|--|--|
| Transfusion with old donor blood Severe dehydration Crushing injuries Burns Hemolysis Dehydration Potassium-sparing diuretics Increased intake of potassium (e.g., salt substitutes) | Oliguria Apnea—respiratory arrest Laboratory findings: • High serum potassium concentration ≥ 5.5 mEq/L • Variable urine volume • Flat P wave on ECG, peaked T waves, widened QRS complex, increased PR interval | potassium into cells. Monitor potassium levels. Evaluate acid-base status. |

Water Intoxication

Water intoxication, or water overload, is observed less often than dehydration. However, it is important that nurses and others who care for children be alert to this possibility in certain situations. Children who ingest excessive amounts of electrolyte-free water develop a concurrent decrease in serum sodium accompanied by central nervous system (CNS) symptoms. There is a large urinary output, and because water moves into the brain more rapidly than sodium moves out, the child may also exhibit irritability, somnolence, headache, vomiting, diarrhea, or generalized seizures. The affected child usually appears well hydrated but may be edematous or even dehydrated.

Fluid intoxication can occur during acute intravenous (IV) fluid replacement, too rapid dialysis, tap water enemas, feeding of incorrectly mixed formula, or excess water ingestion (Greenbaum, 2016). Patients with CNS infections occasionally retain excessive amounts of water. Administration of inappropriate hypotonic solutions (e.g., 0.45% sodium chloride) may cause a rapid reduction in sodium and result in symptoms of water overload.

Infants are especially vulnerable to fluid overload. Their thirst mechanism is not well developed; therefore, they are unable to “turn off” fluid intake appropriately. A decreased glomerular filtration rate does not allow for repeated excretion of a water load, and antidiuretic hormone levels may not be maximally reduced. Consequently, infants are unable to excrete a water overload effectively.

Administration of inappropriately prepared formula is one of the more common causes of water intoxication in infants (Greenbaum, 2016). Families who cannot afford to buy enough formula may dilute the formula to increase the volume or even substitute water for the formula. A family may run out of formula and dilute the remaining amount to make it last until they are able to purchase more. In addition, water is sometimes used for pacification. Water intoxication can also occur in infants who receive overly vigorous hydration during a febrile illness.

A number of clinicians have reported water intoxication in children after swimming lessons, in water births, and with excessive enema administration. Although they hold their breath while swimming, some children apparently swallow a large amount of water during repeated submersion. Anticipatory guidance to parents should include a discussion of swimming instruction and advice to stop a lesson if the child swallows unusual amounts of water or exhibits any symptoms of hyponatremia (see Table 22-2).

Dehydration

Dehydration is a common body fluid disturbance in the nursing care of infants and children; it occurs whenever the total output of fluid exceeds the total intake, regardless of the underlying cause. Although dehydration can result from impaired oral intake, more often it is a result of abnormal losses, such as those that occur in vomiting or diarrhea, when oral intake only partially compensates for the abnormal losses. Other significant causes of dehydration include diabetic ketoacidosis and extensive burns.

Types of Dehydration

Because sodium is the primary osmotic force that controls fluid movement between the major fluid compartments, dehydration is often described according to plasma sodium concentrations (i.e., isotremic, hyponatremic, or hypernatremic). Other osmotic forces, however, such as glucose in diabetic ketoacidosis and protein in nephrotic syndrome, may also play a dominant role.

Isotonic (isosmotic or isonatremic) dehydration occurs in conditions in which electrolyte and water deficits are present in approximately balanced proportions. This is the primary form of dehydration occurring in children. The observable fluid losses are not necessarily isotonic, but losses from other avenues make adjustments so that the sum of all losses, or the net loss, is isotonic. Because no osmotic force is present to cause a redistribution of water between the ICF and the ECF,

the major loss is sustained from the ECF compartment. This significantly reduces the plasma volume and the circulating blood volume, which affects the skin, muscles, and kidneys. Shock is the greatest threat to life in isotonic dehydration, and the child with isotonic dehydration displays symptoms characteristic of hypovolemic shock. Plasma sodium remains within normal limits, between 130 and 150 mEq/L.

Hypotonic (hyposmotic or hyponatremic) dehydration occurs when the electrolyte deficit exceeds the water deficit. Because ICF is more concentrated than ECF in hypotonic dehydration, water transfers from the ECF to the ICF to establish osmotic equilibrium. This movement further increases the ECF volume loss, and shock is a frequent result. Because there is a greater proportional loss of ECF in hypotonic dehydration, the physical signs tend to be more severe with smaller fluid losses than with isotonic or hypertonic dehydration. Plasma sodium concentrations are typically less than 130 mEq/L.

Hypertonic (hyperosmotic or hypernatremic) dehydration results from water loss in excess of electrolyte loss and is usually caused by a proportionately larger loss of water or a larger intake of electrolytes. This type of dehydration is the most dangerous and requires more specific fluid therapy. This sometimes occurs in infants with diarrhea who are given fluids by mouth that contain large amounts of solute, or in children receiving high-protein nasogastric (NG) tube feedings that place an excessive solute load on the kidneys. In hypertonic dehydration, fluid shifts from the lesser concentration of the ICF to the ECF. Plasma sodium concentration is greater than 150 mEq/L.

Because the ECF volume is proportionately larger, hypertonic dehydration consists of a greater degree of water loss for the same intensity of physical signs. However, neurologic disturbances, such as seizures, are more likely to occur. Cerebral changes are serious and may result in permanent damage. These include disturbances of consciousness, poor ability to focus attention, lethargy, increased muscle tone with hyperreflexia, and hyperirritability to stimuli (tactile, auditory, bright lights).

Degree of Dehydration

Diagnosis of the type and degree of dehydration is necessary to develop an effective plan of therapy. The degree of dehydration has been described as a percentage of body weight dehydrated: mild—less than 3% in older children or less than 5% in infants; moderate—5% to 10% in infants and 3% to 6% in older children; and severe—more than 10% in infants and more than 6% in older children (Greenbaum, 2016). Water constitutes 60% to 70% of an infant's weight. However, adipose tissue contains little water and is highly variable in individual infants and children. A more accurate means of describing dehydration is to reflect acute loss (time frame of ≤ 48 hours) in milliliters per kilogram of body weight. For example, a loss of 50 ml/kg is considered to be a mild fluid loss, but a loss of 100 ml/kg produces severe dehydration.

A detailed history is the first step when assessing for dehydration. Parent reports of fluid intake, urine output, diarrhea, and emesis can aid in the identification of dehydration. In addition, parents are asked about tears; a child who is able to produce tears is less likely to have moderate or severe dehydration (Churgay and Aftab, 2012a). Clinical signs provide clues to the extent of dehydration (Table 22-3). Weight is the most important determinant of the percent of total body fluid loss in infants and younger children. However, often the pre-illness weight is unknown. Other predictors of fluid loss include a changing level of consciousness (irritability to lethargy), altered response to stimuli, decreased skin elasticity and turgor, prolonged capillary refill (>2 seconds), increased heart rate, and sunken eyes and fontanels. The earliest detectable sign is usually tachycardia followed by dry skin and mucous membranes, sunken fontanels, signs of circulatory failure (coolness and mottling of extremities), loss of skin elasticity, and prolonged capillary filling time (Table 22-4). There is evidence that the clinical signs of prolonged capillary refill time, abnormal skin turgor, and abnormal respiratory pattern are most useful in predicting dehydration in children (Churgay and Aftab, 2012a).

TABLE 22-3
Evaluating Extent of Dehydration

| Clinical Signs | LEVEL OF DEHYDRATION | | |
|----------------------|----------------------|----------|-------------|
| | Mild | Moderate | Severe |
| Weight loss—infants | 3% to 5% | 6% to 9% | $\geq 10\%$ |
| Weight loss—children | 3% to 4% | 6% to 8% | 10% |

| | | | |
|-----------------------|-------------------------|---|--|
| Pulse | Normal | Slightly increased | Very increased |
| Respiratory rate | Normal | Slight tachypnea (rapid) | Hyperpnea (deep and rapid) |
| Blood pressure | Normal | Normal to orthostatic (>10 mm Hg change) | Orthostatic to shock |
| Behavior | Normal | Irritable, more thirsty | Hyperirritable to lethargic |
| Thirst | Slight | Moderate | Intense |
| Mucous membranes* | Normal (moist) | Dry | Parched |
| Tears | Present | Decreased | Absent, sunken eyes |
| Anterior fontanel | Normal | Normal to sunken | Sunken |
| External jugular vein | Visible when supine | Not visible except with supraclavicular pressure | Not visible even with supraclavicular pressure |
| Skin* | Capillary refill >2 sec | Slowed capillary refill (2 to 4 seconds [decreased turgor]) | Very delayed capillary refill (>4 seconds) and tenting; skin cool, acrocyanotic or mottled |
| Urine | Decreased | Oliguria | Oliguria or anuria |

*These signs are less prominent in patients who have hyponatremia.

Data from Jospe N, Forbes G: Fluids and electrolytes—clinical aspects. *Pediatr Rev* 17(11):395–403, 1996; Steiner MJ, DeWalt DA, Byerley JS: Is this child dehydrated? *JAMA* 291(22):2746–2754, 2004.

TABLE 22-4
Clinical Manifestations of Dehydration

| Manifestation | Isotonic (Loss of Water and Sodium) | Hypotonic (Loss of Sodium in Excess of Water) | Hypertonic (Loss of Water in Excess of Sodium) |
|------------------------|-------------------------------------|---|---|
| Skin | | | |
| Color | Gray | Gray | Gray |
| Temperature | Cold | Cold | Cold or hot |
| Turgor | Poor | Very poor | Fair |
| Texture | Dry | Clammy | Thickened, doughy |
| Mucous membranes | Dry | Slightly moist | Parched |
| Tearing and salivation | Absent | Absent | Absent |
| Eyeball | Sunken | Sunken | Sunken |
| Fontanel | Sunken | Sunken | Sunken |
| Body temperature | Subnormal or elevated | Subnormal or elevated | Subnormal or elevated |
| Pulse | Rapid | Very rapid | Moderately rapid |
| Respirations | Rapid | Rapid | Rapid |
| Behavior | Irritable to lethargic | Lethargic or comatose; seizures | Marked lethargy with extreme hyperirritability on stimulation |

Compensatory mechanisms attempt to maintain fluid volume by adjusting to these losses. Interstitial fluid moves into the vascular compartment to maintain the blood volume in response to hemoconcentration and hypovolemia, and vasoconstriction of peripheral arterioles helps maintain pumping pressure. When fluid losses exceed the body's ability to sustain blood volume and blood pressure, circulation is seriously compromised, and the blood pressure falls. This results in tissue hypoxia with accumulation of lactic acid, pyruvate, and other acid metabolites, which contribute to the development of metabolic acidosis.

Renal compensation is impaired by reduced blood flow through the kidneys, and little urine is formed. Increased serum osmolality stimulates the secretion of ADH to conserve fluid and initiates the renin/angiotensin mechanisms in the kidney, causing further vasoconstriction. Aldosterone is released to promote sodium retention and conserve water in the kidneys. If dehydration increases in severity, urine formation is greatly diminished, and metabolites and hydrogen ions that are normally excreted by this route are retained.

Shock, a common manifestation of severe depletion of ECF volume, is preceded by tachycardia and signs of poor perfusion and tissue oxygenation (e.g., low pulse oximeter readings). Peripheral circulation is poor as a result of reduced blood volume; therefore, the skin is cool and mottled, with decreased capillary filling. Impaired kidney circulation often leads to oliguria and azotemia. Although low blood pressure may accompany other symptoms of shock, in infants and young children, it is usually a late sign and may herald the onset of cardiovascular collapse.

Diagnostic Evaluation

To initiate a therapeutic plan, several factors must be determined:

- The degree of dehydration based on physical assessment
- The type of dehydration based on the pathophysiology of the specific illness responsible for the dehydrated state
- Specific physical signs other than general signs
- Initial plasma sodium concentrations
- Serum bicarbonate concentration (HCO_3^-)
- Any associated electrolyte (especially serum potassium) and acid-base imbalances (as indicated)

Initial and regular ongoing evaluations assess the patient's progress toward equilibrium and the effectiveness of therapy.

In the examination of an infant or younger child, one of the most important determinants of the extent of dehydration is body weight because this can assist in determining the percentage of total

body fluid lost; however, since the pre-illness weight is often unknown, clinical manifestations must be evaluated. Important clinical manifestations include changing sensorium (irritability to lethargy); decreased response to stimuli; integumentary changes (decreased elasticity and turgor); prolonged capillary refill; increased heart rate; sunken eyes; and, in infants, sunken fontanel. Using multiple predictors increases the sensitivity of assessing the fluid deficit. Objective signs of dehydration are present at a fluid deficit of less than 5%.

Laboratory data are useful only when results are significantly abnormal. Urine specific gravity and blood urea nitrogen (BUN) measurements are unreliable assessments for determining dehydration in children (Churgay and Aftab, 2012a). However, a serum bicarbonate level (>17 mEq/L) reduces the chances of dehydration, whereas a bicarbonate level of less than 13 mEq/L increases the chance of dehydration requiring IV intervention (Churgay and Aftab, 2012a). Shock, tachycardia, and very low blood pressure are common features of severe depletion of ECF volume (see Shock, Chapter 23).

Therapeutic Management

Medical management is directed at correcting the fluid imbalance and treating the underlying cause. When the child is alert, awake, and not in danger, correction of dehydration may be attempted with oral fluid administration. Mild cases of dehydration can be managed at home by this method. Several commercial rehydration fluids are available for use. Oral rehydration management consists of replacement of fluid loss over 4 to 6 hours, replacement of continuing losses, and provision for maintenance fluid requirements. In general, a mildly dehydrated child may be given 50 ml/kg of oral rehydration solution (ORS), whereas the child with moderate dehydration may be given 100 ml/kg of ORS. The child with fluid losses from diarrhea or vomiting may be given an additional 10 ml/kg for each stool or vomitus (Churgay and Aftab, 2012b). Amounts and rates are determined from body weight and the severity of dehydration and are increased if rehydration is incomplete or if excess losses continue, until the child is well hydrated and the basic problem is under control.

The child may not be thirsty even though dehydrated and may refuse oral fluids initially for fear of continued emesis (if occurring) or because of decreased strength, oral stomatitis, or thrush. In such children, rehydration may proceed by administering 2 to 5 ml of ORS by a syringe or small medication cup every 2 to 3 minutes until the child is able to tolerate larger amounts; if the child has emesis, restarting small amounts (5 to 10 ml) of ORS after 10 minutes and administering every 5 minutes or so may help overcome fluid deficit, and the emesis will often lessen over time (Churgay and Aftab, 2012b). Oral rehydration therapy (ORT) is effective for treating mild or moderate dehydration in children, is less expensive, and involves fewer complications than parenteral therapy (Kleinman and Greer, 2014). ORSs enhance and promote the reabsorption of sodium and water. ORSs are available in the United States as commercially prepared solutions and are successful in treating the majority of infants with dehydration (see Diarrhea, later in chapter, for a complete discussion of fluid replacement therapy).

Nursing Tip

Enhance the flavor of an oral rehydration solution (ORS) such as Pedialyte (unflavored) by adding 1 tsp of unsweetened powder Kool-Aid to each 60 to 90 ml of ORS. Older children may take a small popsicle orally instead of fluids that require drinking. Many commercially available popsicles are relatively inexpensive, contain small amounts of sucrose, and contain approximately 40 to 50 ml of fluid. Frozen oral hydration may be accepted by some children when conventional ORS is rejected.

Parenteral fluid therapy.

Parenteral fluid therapy is initiated whenever the child is unable to ingest sufficient amounts of fluid and electrolytes to meet ongoing daily physiologic losses, replace previous deficits, and replace ongoing abnormal losses. Patients who usually require IV fluids are those with severe dehydration, those with uncontrollable vomiting, those who are unable to drink for any reason (e.g., extreme fatigue, coma), and those with severe gastric distention.

Because dehydration (volume depletion) constitutes a great threat to life, the first priority is the restoration of circulation by rapid expansion of the ECF volume to treat or prevent shock. IV administration of fluid begins immediately, although the exact nature of the dehydration and the

serum electrolyte values may not initially be known. The solution selected is based on what is known regarding the probable type and cause of the dehydration. This usually involves an isotonic solution such as 0.9% sodium chloride or lactated Ringer solution, both of which are close to the body's serum osmolality of 285 to 300 mOsm/kg and do not contain dextrose (which is contraindicated in the early treatment stages of diabetic ketoacidosis).

Parenteral rehydration therapy has three phases. The initial therapy is used to expand volume quickly to ensure tissue perfusion (Greenbaum, 2016). During initial therapy, an isotonic electrolyte solution is used at a rate of 20 ml/kg, given as an IV bolus over 5 to 20 minutes, and repeated as necessary after assessment of the child's response to therapy (Friedman, 2010). Subsequent therapy is used to replace deficits, meet maintenance water and electrolyte requirements, and catch up with ongoing losses. Water and sodium requirements for the deficit, maintenance, and ongoing losses are calculated at 8-hour intervals, taking into consideration the amount of fluids given with the initial boluses and the amount administered during the first 24-hour period. With improved circulation during this phase, water and electrolyte deficits can be evaluated, and acid-base status can be corrected either directly through the administration of fluids or indirectly through improved renal function. Potassium is withheld until kidney function is restored and assessed and circulation has improved.

The final phase of therapy allows the patient to return to normal and begin oral feedings, with a gradual correction of total body deficits. The potassium loss in ICF is replaced slowly by way of the ECF. The body fat and protein stores are replaced through diet. If the child is unable to eat or if feeding aggravates a chronic condition, IV maintenance fluids are provided.

Although the initial phase of fluid replacement is rapid in both isotonic and hypotonic dehydration, it is contraindicated in hypertonic dehydration because of the risk of water intoxication, especially in the brain cells, specifically the central pontine cells. Central pontine myelinolysis may occur with an overcorrection of fluid deficit and an overly rapid correction of serum sodium concentration (Alleman, 2014). There is an apparent lag time for sodium to reach a steady state when diffusing in and out of brain cells, water diffuses almost instantaneously. Consequently, rapid administration of fluid causes equally rapid diffusion of water into the dehydrated brain cells, causing marked cerebral edema. Because ECF volume is maintained relatively well in hypertonic as opposed to the other types of dehydration, shock is not a usual manifestation.

Nursing Care Management

Nursing observation and intervention are essential for detection and therapeutic management of dehydration. A variety of circumstances cause fluid losses in infants and small children, and changes can take place quickly. An important nursing responsibility is observation for signs of dehydration. Nursing assessment should begin with observation of general appearance and proceed to more specific observations. Ill children usually have drawn expressions, have dry mucous membranes and lips, and "look sick." Loss of appetite is one of the first behaviors observed in most childhood illnesses, and the infant's or child's activity level is diminished from baseline or usual activities. The child is irritable, seeks the parent's comfort and attention, and displays purposeless movements and inappropriate responses to people and familiar objects. In some cases, the child may not protest advances by the health care worker and procedures such as taking vital signs or starting an IV infusion. These are signs that the child truly feels bad and that the condition is serious and immediate intervention is necessary. As the child's illness and level of dehydration become more severe, irritability progresses to lethargy and even unconsciousness.

Assess capillary filling time by pinching the abdominal skin, chest, arm, or leg and measuring the time it takes for the blood to return. Capillary filling time in mild dehydration is less than 2 seconds, increasing to more than 4 seconds in severe dehydration. The technique is effective in children of all ages. However, it can be altered in the presence of heart failure, which affects circulation time, and hypertonic dehydration, in which fluid loss is primarily intracellular. Additional clinical signs observed in children with dehydration include cool mottled extremities, sunken eyes, tachypnea, and changes in sensorium.

When caring for the ill child, assess the vital signs as often as every 15 to 30 minutes and record weight frequently during the initial phase of therapy. It is important to use the same scale each time the child is weighed and to predetermine the weight of any equipment or devices that must remain attached during the weighing process, including arm boards, and any clothing the child might be

wearing. Take routine weights at the same time each day. Accurate intake and output measurements are essential to the assessment of fluid balance. Measurement from all sources including urine, stools, vomitus, fistulas, NG suction, sweat, and drainage from wounds, must be taken into consideration.

For nursing interventions, see the discussion under specific disorders in this chapter.

Edema

Edema represents an abnormal accumulation of fluid within the interstitial tissue and subsequent tissue and develops when there is a defect in the normal cardiovascular circulation or a failure in the lymphatic drainage systems. Edema results from anything that (1) alters the retention of sodium, such as renal disease or hormonal influences; (2) affects the formation or destruction of plasma proteins, such as starvation or liver disease; or (3) alters membrane permeability, such as nephrotic syndrome or trauma.

Edema may be localized to a small or large area or it can be generalized. A severe, generalized accumulation of great amounts of fluid in all body tissues is termed *anasarca*. Several types of edema include:

- Peripheral edema, or localized or generalized palpable swelling of the interstitial space
- Ascites, or the accumulation of fluid in the abdominal cavity (usually associated with renal or liver abnormalities)
- Pulmonary edema, which occurs when interstitial volume increases
- Cerebral edema, which is a particularly threatening form of edema caused by trauma, infection, or other etiologic factors, including vascular overload or injudicious IV administration of hypotonic solutions
- Overall fluid gain, which is especially seen in patients with kidney disease

Assessment

Generalized edema resulting from any of the above types is manifested by swelling in the extremities, face, perineum, and torso. Loss of normal skin creases may be assessed. Daily weights are more sensitive indicators of water gain or loss and should be obtained. Abdominal girth measurement changes may also be an indicator of edema in children. Pitting edema may occur and can be assessed by pressing the fingertip against a bony prominence for 5 seconds. If the tissue rebounds immediately on removing the finger, the patient does not have pitting edema. A quick way to determine the severity is to measure the degree of pitting edema (Fig. 22-1).

FIG 22-1 Assessment of pitting edema. A, +1. B, +2. C, +3. D, +4.

Therapeutic Management

The primary goal in the management of edema is treatment of the underlying disease process, which is discussed elsewhere in relation to the specific disorder. However, an essential aspect in the management of any fluid overload is early recognition in which nurses play a vital role. The management of edema is discussed throughout the text with specific conditions.

Gastrointestinal Dysfunction

The primary function of the GI tract is the digestion and absorption of nutrients. The extensive surface area of the GI tract and its digestive function represent the major means of exchange between the human organism and the environment. Thus any dysfunction of the GI tract can cause significant problems with the exchange of fluids, electrolytes, and nutrients.

Disorders of Motility

Diarrhea

Diarrhea is a symptom that results from disorders involving digestive, absorptive, and secretory functions. Diarrhea is caused by abnormal intestinal water and electrolyte transport. Worldwide, there are an estimated 1.7 billion episodes of diarrhea each year (Walker, Rudan, Liu, et al, 2013). The incidence and morbidity of diarrhea are more prominent in low-income countries, such as areas of Asia and Africa (Walker, Rudan, Liu, et al, 2013), and among children younger than 5 years old (Liu, Johnson, Cousens, et al, 2012). In the United States, approximately 370 children younger than 5 years old die of diarrhea and dehydration each year (Esposito, Holman, Haberling, et al, 2011).

Diarrheal disturbances involve the stomach and intestines (gastroenteritis), the small intestine (enteritis), the colon (colitis), or the colon and intestines (enterocolitis). Diarrhea is classified as acute or chronic.

Acute diarrhea is defined as a sudden increase in frequency and a change in consistency of stools, often caused by an infectious agent in the GI tract. It may be associated with upper respiratory or urinary tract infections, antibiotic therapy, or laxative use. Acute infectious diarrhea (infectious gastroenteritis) is caused by a variety of viral, bacterial, and parasitic pathogens (Table 22-5).

TABLE 22-5
Infectious Causes of Acute Diarrhea

| Agents | Pathology | Characteristics | Comments |
|--|---|--|---|
| Viral | | | |
| Rotavirus Incubation: 48 hours Diagnosis: EIA | Fecal–oral transmission Seven groups (A to G): Most group A virus replicates in mature villus epithelial cells of small intestine, leads to (1) imbalance in ratio of intestinal fluid absorption to secretion and (2) malabsorption of complex carbohydrates | Mild to moderate fever Vomiting followed by onset of watery stools Fever and vomiting generally abate in approximately 2 days, but diarrhea persists 5 to 7 days | Most common cause of diarrhea in children younger than 5 years old; infants 6 to 12 months old most vulnerable; affects all ages; usually milder in children older than 3 years old Immunocompromised children at greater risk for complications Peak occurrences in winter months Important cause of nosocomial infections Two preventive vaccines available |
| Norwalk-like organisms Also called <i>caliciviruses</i> Incubation: 12 to 48 hours Diagnosis: EIA | Fecal–oral; contaminated water Pathology similar to that of rotavirus; affects villus epithelial cells of small intestine, leading to (1) imbalance in ratio of intestinal fluid absorption to secretion and (2) malabsorption of complex carbohydrates | Abdominal cramps, nausea, vomiting, malaise, low-grade fever, watery diarrhea without blood; duration 2 to 3 days; tends to resemble so-called food poisoning symptoms with nausea predominating | Affects all ages Multiple strains often named for the location of outbreak (e.g., Norwalk, Sapporo, Snow Mountain, Montgomery) |
| Bacterial | | | |
| <i>Escherichia coli</i> Incubation: 3 to 4 days; variable depending on strain Diagnosis: Sorbitol MacConkey agar positive for blood, but fecal leukocytes absent or rare | <i>E. coli</i> strains produce diarrhea as a result of enterotoxin production, adherence, or invasion (enterotoxigenic-producing <i>E. coli</i> , enterohemorrhagic <i>E. coli</i> , enteroaggregative <i>E. coli</i>) | Watery diarrhea 1 to 2 days, then severe abdominal cramping and bloody diarrhea Can progress to hemolytic uremic syndrome | Foodborne pathogen Traveler's diarrhea Highest incidence in summer Cause of nursery epidemics Symptomatic treatment Antibiotics may worsen course Avoid antimotility agents and opioids |
| <i>Salmonella</i> groups (nontyphoidal) Gram-negative rods, nonencapsulated nonsporulating Incubation: 6 to 72 hours Diagnosis: Gram stain, stool culture | Invasion of mucosa in the small and large intestine, edema of the lamina propria, focal acute inflammation with disruption of the mucosa and microabscesses | Nausea, vomiting, colicky abdominal pain, bloody diarrhea, fever; symptoms variable (mild to severe) May have headache and cerebral manifestations (e.g., drowsiness confusion, meningismus, seizures) Infants may be afebrile and nontoxic May result in life-threatening septicemia and meningitis Nausea and vomiting typically of short duration; diarrhea may persist as long as 2 to 3 weeks Typically shed virus for average of 5 weeks; cases reported up to 1 year | Incidence highest in summer months; foodborne outbreaks common Usually transmitted person to person but may transmit via undercooked meats or poultry; about half the cases caused by poultry and poultry products In children, related to pets (e.g., dogs, cats, hamsters, turtles) Communicable as long as organisms are excreted Antibiotics not recommended in uncomplicated cases Antimotility agents also not recommended — prolong transit time and carrier state Incidence decreasing over past 10 years |
| <i>Salmonella typhi</i> Produces enteric fever: Systemic syndrome Incubation Usually 7 to 14 days but could be 3 to 30 days depending on size of inoculum Diagnosis: Positive blood cultures; also sometimes positive stool and urine cultures Late stage: Positive bone marrow culture | Bloodstream invasion; after ingestion, organism attaches to microvilli of ileal brush borders, and bacteria invade the intestinal epithelium via Peyer patches Next, organism is transported to intestinal lymph nodes and enters bloodstream via thoracic ducts, and circulating organism reaches reticuloendothelial cells, causing bacteremia | Manifestations dependent on age Abdominal pain, diarrhea, nausea, vomiting, high fever, lethargy Must be treated with antibiotics | Incidence much lower in developed countries; about 400 cases per year in United States; 65% of US cases acquired via international cases Ingestion of foods and water contaminated with human feces is most common mode of transmission Congenital and intrapartum transmission possible Three vaccines available |

| | | | |
|--|--|--|--|
| <p>Shigella groups Gram-negative nonmotile anaerobic bacilli Incubation: 1 to 7 days Diagnosis: Stool culture loaded with polymorphonuclear leukocytes</p> | <p>Enterotoxins: Invades the epithelium with superficial mucosal ulcerations</p> | <p>Children appear sick Symptoms begin with fever, fatigue, anorexia Crampy abdominal pain preceding watery or bloody diarrhea Symptoms usually subside in 5 to 10 days</p> | <p>Most cases in children younger than 9 years old, with about one third of cases in children 1 to 4 weeks old Antibiotics shorten illness and lower mortality All patients at risk for dehydration Acute symptoms may persist for 1 week Antidiarrheal medications not recommended, because they may predispose patient to toxic megacolon</p> |
| <p>Yersinia enterocolititis Incubation: Dose dependent, 1 to 3 weeks Diagnosis: Stool culture, ELISA Patients have leukocytosis, elevated sedimentation rate</p> | <p>Pathology poorly understood; possibly caused by production of enterotoxin</p> | <p>Mucoid diarrhea, sometimes bloody; abdominal pain suggestive of appendicitis; fever, vomiting</p> | <p>Seen more frequently in the winter months Transmitted by pets and food Antibiotics usually do not alter the clinical course in uncomplicated cases; antibiotics used in complicated infections and compromised hosts</p> |
| <p>Campylobacter jejuni Microaerophilic, motile, gram-negative bacilli Incubation: 1 to 7 days Ability to cause illness appears dose related Diagnosis: Stool culture, sometimes blood culture Commonly found in GI tract of wild or domestic animals</p> | <p>Not fully understood, possibly (1) adherence to intestinal mucosa by toxin, (2) invasion of the mucosa in the terminal ileum and colon, (3) translocation in which the organisms penetrate the mucosa and replicate in the lamina propria</p> | <p>Fever, abdominal pain, diarrhea that can be bloody, vomiting Watery, profuse, foul-smelling diarrhea Clinically similar to infection by Salmonella or Shigella organisms Fecal-oral transmission</p> | <p>Most infections in humans relate to consumption of contaminated foods or water, such as undercooked meats, particularly chicken Also acquired from contaminated household pets (e.g., dogs, cats, hamsters) Bimodal peaks in infants younger than 1 year old and again at 15 to 29 years old Antibiotics do not prolong the carriage of bacteria and may eliminate organism more quickly Erythromycin is the drug of choice Antimotility agents are not recommended because they tend to prolong symptoms</p> |
| <p>Vibrio cholerae Gram-negative, motile, curved bacillus living in bodies of salt water Incubation: 1 to 3 days Diagnosis: Stool culture</p> | <p>Enters via oral route in contaminated food or water; if survives acid stomach environment, travels to the small intestine, adheres to the mucosa, and produces toxin</p> | <p>Onset abrupt; vomiting, watery diarrhea without cramping or tenesmus Dehydration can occur quickly</p> | <p>More prevalent in developing countries Rehydration most important treatment Antibiotics can shorten diarrhea Despite continued efforts, still no vaccine</p> |
| <p>Clostridium difficile Gram-positive anaerobic bacillus with the ability to produce spores Diagnosis: By detecting C. difficile toxin in stool culture</p> | <p>Produces two important toxins (A and B) Toxin binds to the enterocyte surface receptor, resulting in altered permeability, protein synthesis, and direct cytotoxicity</p> | <p>Mostly mild watery diarrhea lasting a few days Some prolonged diarrhea and illness May cause pseudomembranous colitis Some individuals extremely ill with high fever, leukocytosis, hypoalbuminemia</p> | <p>Associated with alteration of normal intestinal flora by antibiotics Adults tend to have more severe symptoms than children Treatment with antibiotics (metronidazole) in mildly to moderately symptomatic patients; for nonresponders, give vancomycin Resistant strains have developed Relapse common</p> |
| <p>Clostridium perfringens Anaerobic, gram-positive, spore-producing bacilli Incubation: 8 to 24 hours</p> | <p>Toxins produced in the intestine after ingestion of organism</p> | <p>Acute onset—watery diarrhea, crampy abdominal pain Fever, nausea, and vomiting are rare Duration of illness usually 24 hours</p> | <p>Transmitted by contaminated food products, most often meats and poultry Usually self-limiting and medical intervention not needed Oral rehydration usually sufficient Antibiotics serve no purpose and should not be used</p> |
| <p>Clostridium botulinum Gram-positive anaerobic spore-producing bacilli Incubation: 12 to 26 hours (range, 6 hours to 8 days) Diagnosis: To detect toxin, submit blood and stool culture to special laboratory (usually state health department)</p> | <p>Botulism caused by binding of toxin to the neuromuscular junction</p> | <p>Clinical presentation related to age and the strain of the botulism GI—abdominal pain, cramping, and diarrhea Other strains—respiratory compromise, CNS symptoms</p> | <p>Transmitted in contaminated food products Can be acquired via wound infection Treatment is supportive care and neutralization of the toxin</p> |
| <p>Staphylococcus organisms Gram-positive nonmotile, aerobic or facultative anaerobic bacteria Incubation: Generally short, 1 to 8 hours Diagnosis: Identify organism in food, blood, pus, aspirate</p> | <p>Direct tissue invasion and production of toxin</p> | <p>Clinical presentation dependent on site of entry in food poisoning, profuse diarrhea, nausea, and vomiting</p> | <p>Transmitted in inadequately cooked or refrigerated foods Self-limiting Symptomatic treatment</p> |

CNS, Central nervous system; EIA, enzyme immunoassay; ELISA, enzyme-linked immunosorbent assay; GI, gastrointestinal.

Chronic diarrhea is an increase in stool frequency and increased water content with a duration of more than 14 days. It is often caused by chronic conditions, such as malabsorption syndromes, inflammatory bowel disease (IBD), immunodeficiency, food allergy, lactose intolerance, or chronic nonspecific diarrhea (CNSD), or as a result of inadequate management of acute diarrhea.

Intractable diarrhea of infancy is a syndrome that occurs in the first few months of life, persists for longer than 2 weeks with no recognized pathogens, and is refractory to treatment. The most common cause is acute infectious diarrhea that was not managed adequately.

Chronic nonspecific diarrhea (CNSD), also known as *irritable colon of childhood* and *toddlers' diarrhea*, is a common cause of chronic diarrhea in children 6 to 54 months old. These children have loose stools, often with undigested food particles, and diarrhea lasting longer than 2 weeks' duration. Children with CNSD grow normally and have no evidence of malnutrition, no blood in their stool, and no enteric infection. Poor dietary habits and food sensitivities have been linked to chronic diarrhea. The excessive intake of juices and artificial sweeteners such as sorbitol, which is a substance found in many commercially prepared beverages and foods, may be a factor.

Etiology

Most pathogens that cause diarrhea are spread by the fecal-oral route through contaminated food or water or are spread from person to person where there is close contact (e.g., daycare centers).

Lack of clean water, crowding, poor hygiene, nutritional deficiency, and poor sanitation are major risk factors, especially for bacterial or parasitic pathogens. Infants are often more susceptible to frequent and severe bouts of diarrhea because their immune system has not been exposed to many pathogens and has not acquired protective antibodies. Worldwide, the most common causes of acute gastroenteritis are infectious agents, viruses, bacteria, and parasites.

Rotavirus is the most important cause of serious gastroenteritis among children, with 28% of all cases causing fatality (Walker, Rudan, Liu, et al, 2013). The virus is spread through the fecal–oral route or by person-to-person contact, and almost all children are infected with rotavirus at least once by 5 years old (Yen, Tate, Patel, et al, 2011). Rotavirus is the most common cause of diarrhea-associated hospitalization, with an estimated 2.3 million hospitalizations occurring worldwide in children younger than 5 years old (Yen, Tate, Patel, et al, 2011).

Salmonella, *Shigella*, and *Campylobacter* organisms are the most frequently isolated bacterial pathogens in the United States (Scallan, Mahon, Hoekstra, et al, 2013). These organisms are gram-negative bacteria and can be contracted through raw or undercooked food, contaminated food or water, or through the fecal–oral route. Among children younger than 5 years old, *Salmonella* occurs in approximately 617 out of 100,000 children; *Campylobacter* occurs in 409 out of 100,000 children; and *Shigella* occurs in 312 out of 100,000 children (Scallan, Mahon, Hoekstra, et al, 2013). (See also **Intestinal Parasitic Diseases, Chapter 6.**)

Antibiotic administration is frequently associated with diarrhea because antibiotics alter the normal intestinal flora, resulting in an overgrowth of other bacteria. *Clostridium difficile* is the most common bacterial overgrowth and accounts for approximately 20% of all antibiotic-associated diarrhea (Barakat, El-Kady, Mostafa, et al, 2011). Antibiotic-associated diarrhea can also be caused by *Klebsiella oxytoca*, *Clostridium perfringens*, and *Staphylococcus aureus* pathogens (Barakat, El-Kady, Mostafa, et al, 2011).

Pathophysiology

Invasion of the GI tract by pathogens results in increased intestinal secretion as a result of enterotoxins, cytotoxic mediators, or decreased intestinal absorption secondary to intestinal damage or inflammation. Enteric pathogens attach to the mucosal cells and form a cuplike pedestal on which the bacteria rest. The pathogenesis of the diarrhea depends on whether the organism remains attached to the cell surface, resulting in a secretory toxin (noninvasive, toxin-producing, noninflammatory type diarrhea), or penetrates the mucosa (systemic diarrhea). Noninflammatory diarrhea is the most common diarrheal illness, resulting from the action of enterotoxin that is released after attachment to the mucosa. The most serious and immediate physiologic disturbances associated with severe diarrheal disease are dehydration, acid-base imbalance with acidosis, and shock that occurs when dehydration progresses to the point that circulatory status is seriously impaired.

Diagnostic Evaluation

Evaluation of the child with acute gastroenteritis begins with a careful history that seeks to discover the possible cause of diarrhea, to assess the severity of symptoms and the risk of complications, and to elicit information about current symptoms indicating other treatable illnesses that could be causing the diarrhea. The history should include questions about recent travel, exposure to untreated drinking or washing water sources, contact with animals or birds, daycare center attendance, recent treatment with antibiotics, or recent diet changes. History questions should also explore the presence of other symptoms, such as fever and vomiting, frequency and character of stools (e.g., watery, bloody), urinary output, dietary habits, and recent food intake.

Extensive laboratory evaluation is not indicated in children who have uncomplicated diarrhea and no evidence of dehydration, because most diarrheal illnesses are self-limiting. Laboratory tests are indicated for children who are severely dehydrated and receiving IV therapy. Watery, explosive stools suggest glucose intolerance; foul-smelling, greasy, bulky stools suggest fat malabsorption. Diarrhea that develops after the introduction of cow's milk, fruits, or cereal may be related to enzyme deficiency or protein intolerance. Neutrophils or red blood cells in the stool indicate bacterial gastroenteritis or IBD. The presence of eosinophils suggests protein intolerance or parasitic infection. Stool cultures should be performed only when blood, mucus, or polymorphonuclear leukocytes are present in the stool, when symptoms are severe, when there is a history of travel to a developing country, and when a specific pathogen is suspected. Gross blood or occult blood may

indicate pathogens, such as *Shigella*, *Campylobacter*, or hemorrhagic *Escherichia coli* strains. An enzyme-linked immunosorbent assay (ELISA) may be used to confirm the presence of rotavirus or *Giardia* organisms. If there is a history of recent antibiotic use, test the stool for *C. difficile* toxin. When bacterial and viral culture results are negative and when diarrhea persists for more than a few days, examine stools for ova and parasites. A stool specimen with a pH of less than 6 and the presence of reducing substances may indicate carbohydrate malabsorption or secondary lactase deficiency. Stool electrolyte measurements may help identify children with secretory diarrhea.

The serum bicarbonate (HCO_3^-) may be useful when combined with other clinical signs. In the presence of metabolic acidosis an anion gap may be helpful to distinguish between types of metabolic imbalance. Obtain a complete blood count (CBC), serum electrolytes, creatinine, and BUN in the child who has moderate to severe dehydration or who requires hospitalization. The hemoglobin, hematocrit, creatinine, and BUN levels are usually elevated in acute diarrhea and should normalize with rehydration.

Therapeutic Management

The major goals in the management of acute diarrhea include assessment of fluid and electrolyte imbalance, rehydration, maintenance fluid therapy, and reintroduction of an adequate diet. Treat infants and children with acute diarrhea and dehydration first with **oral rehydration therapy (ORT)**. ORT is one of the major worldwide health care advances. It is more effective, safer, less painful, and less costly than IV rehydration. The American Academy of Pediatrics, World Health Organization, and Centers for Disease Control and Prevention all recommend ORT as the treatment of choice for most cases of dehydration caused by diarrhea (Churgay and Aftab, 2012b). **Oral rehydration solutions (ORSs)** enhance and promote the reabsorption of sodium and water, and studies indicate that these solutions greatly reduce vomiting, volume loss from diarrhea, and the duration of the illness. ORSs, including reduced osmolarity ORS, are available in the United States as commercially prepared solutions and are successful in treating the majority of infants with dehydration. Guidelines for rehydration recommended by the American Academy of Pediatrics are given in Table 22-6.

TABLE 22-6
Treatment of Acute Diarrhea

| Degree of Dehydration | Signs and Symptoms | Rehydration Therapy* | Replacement of Stool Losses | Maintenance Therapy |
|-----------------------|--|---|--|---|
| Mild (5% to 6%) | Increased thirst Slightly dry buccal mucous membranes | ORS, 50 ml/kg within 4 hours | ORS, 10 ml/kg (for infants) or 150 to 250 ml at a time (for older children) for each diarrheal stool | Breastfeeding, if established, should continue; give regular infant formula if tolerated. If lactose intolerance suspected, give undiluted lactose-free formula (or half-strength lactose-containing formula for brief period only); infants and children who receive solid food should continue their usual diet. |
| Moderate (7% to 9%) | Loss of skin turgor, dry buccal mucous membranes, sunken eyes, sunken fontanel | ORS, 100 ml/kg within 4 hours | Same as above | |
| Severe (>9%) | Signs of moderate dehydration plus one of following: rapid, thready pulse; cyanosis; rapid breathing; lethargy; coma | IV fluids (Ringer lactate), 40 ml/kg until pulse and state of consciousness return to normal; then 50 to 100 ml/kg or ORS | Same as above | |

*If no signs of dehydration are present, rehydration therapy is not necessary. Proceed with maintenance therapy and replacement of stool losses.

IV, Intravenous; ORS, oral rehydration solution.

Modified from King CK, Glass R, Bresee JS, et al: Managing acute gastroenteritis among children: oral rehydration, maintenance, and nutritional therapy, *MMWR Recommend Rep* 52(RR-16):1–16, 2003.

After rehydration, ORS may be used during maintenance fluid therapy by alternating the solution with a low-sodium fluid, such as breast milk, lactose-free formula, or half-strength lactose-containing formula. In older children, ORS can be given and a regular diet continued. Ongoing stool losses should be replaced on a 1 : 1 basis with ORS. If the stool volume is not known, approximately 10 ml/kg (4 to 8 oz) of ORS should be given for each diarrheal stool.

Solutions for oral hydration are useful in most cases of dehydration, and vomiting is not a contraindication. Give a child who is vomiting an ORS at frequent intervals and in small amounts. For young children, the caregiver may give the fluid with a spoon or small syringe in 5- to 10-ml increments every 1 to 5 minutes. An ORS may also be given via NG or gastrostomy tube infusion. Infants without clinical signs of dehydration do not need ORT. They should, however, receive the same fluids recommended for infants with signs of dehydration in the maintenance phase and for ongoing stool losses. Probiotics when used in conjunction with ORS reduces the duration of antibiotic-associated diarrhea in children by 1 day (Churgay and Aftab, 2012b).

Early reintroduction of nutrients is desirable and has gained more widespread acceptance. Continued feeding or early reintroduction of a normal diet after rehydration has no adverse effects and actually lessens the severity and duration of the illness and improves weight gain when compared with the gradual reintroduction of foods (Churgay and Aftab, 2012b; Bhutta, 2016). Infants who are breastfeeding should continue to do so, and ORS should be used to replace ongoing losses in these infants. Formula-fed infants should resume their formulas; if it is not tolerated, a lactose-free formula may be used for a few days. In toddlers there is no contraindication to continuing soft or pureed foods. In older children, a regular diet, including milk, can generally be offered after rehydration has been achieved.

Nursing Alert

Encouraging intake of clear fluids by mouth, such as fruit juices, carbonated soft drinks, and gelatin, does not help diarrhea. These fluids usually have high carbohydrate content, very low electrolyte content, and high osmolality. Have patients avoid caffeinated beverages because caffeine is a mild diuretic and may lead to increased loss of water and sodium. Chicken or beef broth is not given because it contains excessive sodium and inadequate carbohydrate. A BRAT diet (bananas, rice, applesauce, and toast or tea) is contraindicated for the child and especially for infants with acute diarrhea, because this diet has little nutritional value (low in energy and protein), is high in carbohydrates, and is low in electrolytes (Churgay and Aftab, 2012b).

In cases of severe dehydration and shock, IV fluids are initiated whenever the child is unable to ingest sufficient amounts of fluid and electrolytes to (1) meet ongoing daily physiologic losses, (2) replace previous deficits, and (3) replace ongoing abnormal losses. Select the IV solution for fluid replacement on the basis of what is known regarding the probable type and cause of the dehydration. The type of fluid normally used is a saline solution containing 5% dextrose in water. Sodium bicarbonate may be added, because acidosis is usually associated with severe dehydration. Although the initial phase of fluid replacement is rapid in both isotonic and hypotonic dehydration, rapid replacement is contraindicated in hypertonic dehydration because of the risk of water intoxication.

After the severe effects of dehydration are under control, begin specific diagnostic and therapeutic measures to detect and treat the cause of the diarrhea. The use of antibiotic therapy in children with acute gastroenteritis is controversial. Antibiotics may shorten the course of some diarrheal illnesses (e.g., those caused by *Shigella* organisms). However, most bacterial diarrheas are self-limiting, and the diarrhea often resolves before the causative organism can be determined. Antibiotics may prolong the carrier period for bacteria such as *Salmonella*. Antibiotics may be considered, in patients who are younger than 3 months old, on immunosuppressive medication, or who have clinical signs of shock, severe malnutrition, dysentery, suspected cholera, or suspected giardiasis (Dekate, Jayashree, and Singhi, 2013) (see [Intestinal Parasitic Diseases, Chapter 6](#)). Antimotility drugs such as loperamide are not recommended in children. Because of the self-limiting nature of vomiting and its tendency to improve when dehydration is corrected, the use of antiemetic agents have historically not been recommended; however, ondansetron has few side effects and may be administered if vomiting persists and interferes with ORT (Bhutta, 2016).

Nursing Care Management

The management of most cases of acute diarrhea takes place in the home with education of the caregiver. Teach caregivers to monitor for signs of dehydration (especially the number of wet diapers or voidings) and the amount of fluids taken by mouth and to assess the frequency and amount of stool losses. Education relating to ORT, including the administration of maintenance fluids and replacement of ongoing losses, is important (see [Critical Thinking Case Study](#)). ORS should be administered in small quantities at frequent intervals. Vomiting is not a contraindication to ORT unless it is severe. Information concerning the introduction of a normal diet is essential. Parents need to know that a slightly higher stool output initially occurs with continuation of a normal diet and with ongoing replacement of stool losses. The benefits of a better nutritional outcome with fewer complications and a shorter duration of illness outweigh the potential increase in stool frequency. Address parents' concerns to ensure adherence to the treatment plan.

Critical Thinking Case Study

Diarrhea

A mother brings her 8-month-old infant, Mary, to the primary care clinic. The mother reports that Mary has had a “cold” for about 2 days, and this morning she began to vomit and has had diarrhea for the past 8 hours. The mother states that Mary is still breastfeeding, but she is not taking as much fluid as usual, and she is having three times as many stools as usual (the stools are watery). When the nurse practitioner examines Mary, she notes that her temperature is 38° C (100.4° F), her pulse and blood pressure are in the normal range, her mucous membranes are moist, and she has tears when she cries. The nurse practitioner also notes that Mary’s weight has not changed from what it was when she was seen in the clinic 2 weeks ago for her well-child visit. What interventions should the nurse practitioner include in her initial management of Mary?

Questions

1. Evidence: Is there sufficient evidence for the nurse and nurse practitioner to draw any conclusions for her initial plan of management?
2. Assumptions: Describe some underlying assumptions about the following:
 - a. Clinical manifestations of various levels of dehydration
 - b. Management of acute diarrhea
 - c. Breastfeeding and the management of acute diarrhea
 - d. Use of antidiarrheal medications for acute diarrhea
3. What nursing interventions should the nurse and nurse practitioner implement at this time?
4. Does the evidence support the nurse and nurse practitioner’s conclusion?

If the child with acute diarrhea and dehydration is hospitalized, the nurse must obtain an accurate weight and carefully monitor intake and output. The child may be placed on parenteral fluid therapy with nothing by mouth (NPO) for 12 to 48 hours, but small amounts of oral fluids may be started unless there are other illness factors which preclude ORT. Monitoring the IV infusion is an important nursing function. The nurse must ensure that the correct fluid and electrolyte concentration is infused, that the flow rate is adjusted to deliver the desired volume in a given time, and that the IV site is maintained.

Accurate measurement of output is essential to determine whether renal blood flow is sufficient to permit the addition of potassium to the IV fluids. The nurse is responsible for examination of stools and collection of specimens for laboratory examination (see [Collection of Specimens, Chapter 20](#)). Take care when obtaining and transporting stools to prevent possible spread of infection. Transport stool specimens to the laboratory in appropriate containers and media according to hospital policy.

Diarrheal stools are highly irritating to the perianal skin, and extra care is needed to protect the skin of the diaper region from excoriation (see [Diaper Dermatitis, Chapter 10](#)). Avoid taking the temperature rectally because it stimulates the bowel, increasing passage of stool.

Support for the child and family involves the same care and consideration given to all hospitalized children (see [Chapter 19](#)). Keep parents informed of the child’s progress and instruct them in the use of frequent and proper hand washing and the disposal of soiled diapers, clothes, and bed linens. Everyone caring for the child must be aware of “clean” areas and “dirty” areas, especially in the hospital, where the sink in the child’s room is used for many purposes. Discard soiled diapers and linens in receptacles close to the bedside.

Prevention

The best intervention for diarrhea is prevention. The fecal–oral route spreads most infections, and parents need information about preventive measures, such as personal hygiene, protection of the water supply from contamination, and careful food preparation.

Nursing Alert

To reduce the risk of bacteria transmitted via food, encourage parents to:

- Quickly freeze or refrigerate all ground meat and other perishable foods.
- Never thaw food on the counter or let it sit out of the refrigerator for more than 2 hours.
- Wash hands, utensils, and work areas with hot, soapy water after contact with raw meat to keep bacteria from spreading.
- Check ground meat with a fork to make certain no pink is showing before taking a bite.
- Cook all dishes made with ground meat until brown or gray inside or to an internal temperature of 71° C (160° F).

Meticulous attention to perianal hygiene, disposal of soiled diapers, proper hand washing, and isolation of infected persons also minimize the transmission of infection (see [Infection Control, Chapter 6](#)).

Parents need information about preventing diarrhea while traveling. Caution them against giving their children adult medications that are used to prevent traveler's diarrhea. The best measure during travel to areas where water may be contaminated is to allow children to drink only bottled water and carbonated beverages (from the container through a straw supplied from home). Children should also avoid tap water, ice, unpasteurized dairy products, raw vegetables, unpeeled fruits, meats, and seafood.

Constipation

Constipation is an alteration in the frequency, consistency, or ease of passing stool. It is defined as a decrease in bowel movement frequency or increased stool hardness for more than 2 weeks ([Greenwald, 2010](#)). Constipation is an alteration in the frequency, consistency, or ease of passing stool. The frequency of bowel movements varies by age, but most children have an average of 1.7 stools per day at 2 years old and an average of 1.2 stools per day at 4 years old or older ([Petersen, 2014](#)). Constipation is often associated with painful bowel movements, blood-streaked or retained stool, abdominal pain, lack of appetite, and stool incontinence (i.e., soiling) ([Rogers, 2012](#)). The frequency of bowel movements is not considered a diagnostic criterion because it varies widely among children. Having extremely long intervals between defecation is **obstipation**. Constipation with fecal soiling is **encopresis**.

Constipation may arise secondary to a variety of organic disorders or in association with a wide range of systemic disorders. Structural disorders of the intestine (such as strictures, ectopic anus, and Hirschsprung disease, may be associated with constipation. Systemic disorders associated with constipation include hypothyroidism, hypercalcemia resulting from hyperparathyroidism or vitamin D excess, and chronic lead poisoning. Constipation is also associated with use of drugs, such as antacids, diuretics, antiepileptics, antihistamines, opioids, and iron supplementation. Spinal cord lesions may be associated with loss of rectal tone and sensation. Affected children are prone to chronic fecal retention and overflow incontinence.

The majority of children have **idiopathic** or **functional constipation** because no underlying cause can be identified. Chronic constipation may occur as a result of environmental or psychosocial factors, or a combination of both. Transient illness, withholding and avoidance secondary to painful or negative experiences with stooling, and dietary intake with decreased fluid and fiber all play a role in the etiology of constipation.

Newborn Period

Normally, newborn infants pass a first meconium stool within 24 to 36 hours of birth. Any newborn that does not do so should be assessed for evidence of intestinal atresia or stenosis, Hirschsprung disease, hypothyroidism, meconium plug, or meconium ileus. **Meconium plug** is caused by meconium that has reduced water content and is usually evacuated after digital examination but may require irrigations with a hypertonic solution or contrast medium. **Meconium ileus**, the initial manifestation of cystic fibrosis, is the luminal obstruction of the distal small intestine by abnormal meconium. Treatment is the same as for a meconium plug; early surgical intervention may be needed to evacuate the small intestine.

Infancy

The onset of constipation frequently occurs during infancy and may result from organic causes, such as Hirschsprung disease, hypothyroidism, and strictures. It is important to differentiate these conditions from functional constipation. Constipation in infancy is often related to dietary practices. It is less common in breastfed infants, who have softer stools than bottle-fed infants. Breastfed infants may also have decreased stools because of more complete use of breast milk with little residue. When constipation occurs with a change from human milk or modified cow's milk to whole cow's milk, simple measures such as adding or increasing the amount of vegetables and fruit in the infant's diet and increasing fluids such as sorbitol-rich juices usually corrects the problem. When a bottle-fed infant passes a hard stool that results in an anal fissure, stool-withholding behaviors may develop in response to pain on defecation (see [Critical Thinking Case Study](#)).

Critical Thinking Case Study

Constipation

Harry, an 8-month-old infant, is seen by the pediatric nurse practitioner for his well-child visit. Harry's mother states that he usually has one hard stool every 4 or 5 days, which causes discomfort when the stool is passed. He has also had one episode of diarrhea and two episodes of ribbon-like stools. Abdominal distention and vomiting have not accompanied the constipation, and Harry's growth has been appropriate for his age. Currently, his diet consists of cow's milk-based formula only. Harry's mother reports that the infrequent passage of hard stools began approximately 6 weeks ago when she stopped breastfeeding. Which interventions should the nurse practitioner include in the initial management of Harry's problem?

Questions

1. Evidence: Is there sufficient evidence for the nurse and nurse practitioner to draw any conclusions about the management of Harry's problem?
2. Assumptions: Describe some underlying assumptions about:
 - a. Causes of constipation in infants
 - b. Factors associated with functional constipation in infants
 - c. Management of functional constipation in infants
3. What interventions should the nurse and nurse practitioner implement at this time?
4. Does the evidence support these interventions?

Childhood

Most constipation in early childhood is due to environmental changes or normal development when a child begins to attain control over bodily functions. A child who has experienced discomfort during bowel movements may deliberately try to withhold stool. Over time, the rectum

accommodates to the accumulation of stool, and the urge to defecate passes. When the bowel contents are ultimately evacuated, the accumulated feces are passed with pain, thus reinforcing the desire to withhold stool.

Constipation in school-age children may represent an ongoing problem or a first-time event. The onset of constipation at this age is often the result of environmental changes, stresses, and changes in toileting patterns. A common cause of new-onset constipation at school entry is fear of using the school bathrooms, which are noted for their lack of privacy. Early and hurried departure for school immediately after breakfast may also impede bathroom use.

Therapeutic Management

Treatment of constipation depends on the cause and duration of symptoms. A complete history and physical examination are essential to determine appropriate management. The management of simple constipation consists of a plan to promote regular bowel movements. Often this is as simple as changing the diet to provide more fiber and fluids, eliminating foods known to be constipating, and establishing a bowel routine that allows for regular passage of stool. An increase in dietary fiber is recommended as a treatment for constipation in the healthy child. The amount of fiber for different aged children varies by various authorities but the formula of “age + 5 g” daily intake of fiber is recommended for children 3 years old and older (Kranz, Brauchla, Slavin, et al, 2012). Stool-softening agents such as docusate or lactulose may also be helpful. Polyethylene glycol (PEG) 3350 without electrolytes (MiraLAX) is a chemically inert polymer that has been introduced as a new laxative in recent years. Children tolerate it well because it can be mixed in a beverage of choice. If other symptoms (such as vomiting, abdominal distention, or pain) and evidence of growth failure are associated with the constipation, the condition should be investigated further.

Management of chronic constipation requires an organized and ongoing approach. The goals for management include restoring regular evacuation of stool, shrinking the distended rectum to its normal size, and promoting a regular toileting routine. This requires a combination of therapies, including bowel cleansing to remove the impaction, maintenance therapy to prevent stool retention, modification of diet, bowel habit training, and behavioral modification.

Nursing Care Management

Constipation tends to be self-perpetuating. A child who has difficulty or discomfort when attempting to evacuate the bowels has a tendency to retain the bowel contents, which initiate a vicious cycle. Nursing assessment begins with an accurate history of bowel habits; diet; events associated with the onset of constipation; drugs or other substances that the child may be taking; and the consistency, color, frequency, and other characteristics of the stool. If there is no evidence of a pathologic condition, the nurse's major task is to educate the parents regarding normal stool patterns and to participate in the education and treatment of the child.

Dietary modifications are essential in preventing constipation. Fiber is an important part of the diet. Parents benefit from guidance about foods high in fiber (Table 22-7) and ways to promote healthy food choices in children. Parents need reassurance concerning the prognosis for establishing normal bowel habits. It is important to discuss attitudes and expectations regarding toilet habits and the treatment plan.

TABLE 22-7
Fiber Content of Select Foods

| Food | Serving Size | Grams of Fiber |
|---|----------------------|----------------|
| Apple, raw, with skin | 1 apple | 3.3 |
| Bananas, ripe, raw | 1 small-sized banana | 3.1 |
| Beans, baked, canned | 1 cup | 10.4 |
| Beans, pinto, mature seeds* | 1 cup | 15.4 |
| Beets* | 1 cup | 3.4 |
| Blackberries, raw | 1 cup | 7.6 |
| Blueberries, raw | 1 cup | 3.5 |
| Bread, mixed grain (includes whole grain) | 1 slice | 1.6 |
| Broccoli* | 1 cup | 5.1 |
| Brussels sprouts* | 1 cup | 4.1 |
| Carrots* | 1 cup | 4.7 |
| Cereals, ready-to-eat, General Mills, Cheerios | 1 cup | 3.6 |
| Cereals, ready-to-eat, General Mills, Raisin Nut Bran | 1 cup | 5.1 |
| Cereals, ready-to-eat, Kellogg's All Bran, original | $\frac{1}{2}$ cup | 8.8 |
| Cereals, ready-to-eat, Kellogg's Raisin Bran | 1 cup | 7.3 |
| Collards* | 1 cup | 5.3 |
| Dates, deglet noor | 1 cup | 14.2 |

| | | |
|---|--------|------|
| Lentils, mature seeds* | 1 cup | 15.6 |
| Lima beans, large, mature* | 1 cup | 13.2 |
| Oat bran, cooked | 1 cup | 5.7 |
| Pears, raw | 1 pear | 5.1 |
| Peas, green, frozen* | 1 cup | 8.8 |
| Raisins, seedless | 1 cup | 5.4 |
| Spinach* | 1 cup | 4.3 |
| Vegetables, mixed, frozen* | 1 cup | 8.0 |
| Wheat flour, whole grain | 1 cup | 14.6 |
| Wheat flour, white, all-purpose, enriched | 1 cup | 3.5 |

*Cooked, boiled, drained, no salt.

Modified from USDA National Nutrient Database for Standard Reference, Release 27, <http://ndb.nal.usda.gov/ndb/nutrients/index>.

Hirschsprung Disease (Congenital Aganglionic Megacolon)

Hirschsprung disease is a congenital anomaly that results in mechanical obstruction from inadequate motility of part of the intestine. It accounts for about one fourth of all cases of neonatal intestinal obstruction. The incidence is 1 in 5000 live births (Liang, Ji, Yuan, et al, 2014). It is four times more common in males than in females and follows a familial pattern in a small number of cases. A recent meta-analysis of mutations in the *RET* protooncogene confirmed a significant association between *RET* polymorphisms and Hirschsprung disease (Liang, Ji, Yuan, et al, 2014).

Pathophysiology

The pathology of Hirschsprung disease relates to the absence of ganglion cells in the affected areas of the intestine, resulting in a loss of the rectosphincteric reflex and an abnormal microenvironment of the cells of the affected intestine. The term *congenital aganglionic megacolon* describes the primary defect, which is the absence of ganglion cells in the myenteric plexus of Auerbach and the submucosal plexus of Meissner (Fig. 22-2). In 80% of cases, the aganglionosis is restricted to the internal sphincter, rectum, and a few centimeters of the sigmoid colon and is termed *short-segment disease* (Liang, Ji, Yuan, et al, 2014).

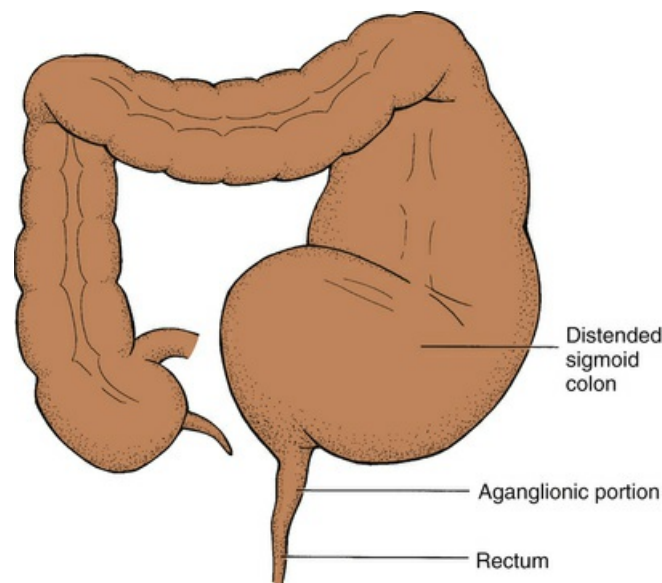

FIG 22-2 Hirschsprung disease.

The absence of ganglion cells in the affected bowel results in a lack of enteric nervous system stimulation, which decreases the internal sphincter's ability to relax. Unopposed sympathetic stimulation of the intestine results in increased intestinal tone. In addition to the contraction of the abnormal bowel and the resulting lack of peristalsis, there is a loss of the rectosphincteric reflex. Normally, when a stool bolus enters the rectum, the internal sphincter relaxes and the stool is evacuated. In Hirschsprung disease, the internal sphincter does not relax. In most cases, the aganglionic segment includes the rectum and some portion of the distal colon. However, the entire colon or part of the small intestine may be involved; this is considered long-segment Hirschsprung disease. Occasionally, skip segments or total intestinal aganglionosis may occur. Rarely, total

colonic aganglionosis, in which there is no innervation of the large and small intestine from the anus to the ileocecal valve, will occur in 2% to 13% of cases with Hirschsprung disease (Moore, 2012).

Diagnostic Evaluation

Most children with Hirschsprung disease are diagnosed in the first few months of life. Clinical manifestations vary according to the age when symptoms are recognized and the presence of complications, such as enterocolitis (Box 22-1). A neonate usually is seen with distended abdomen, feeding intolerance with bilious vomiting, and delay in the passage of meconium. Typically, 99% of normal term infants pass meconium in the first 48 hours of life, but fewer than 10% of infants with Hirschsprung disease do so (Gourlay, 2013).

Box 22-1

Clinical Manifestations of Hirschsprung Disease

Newborn Period

Failure to pass meconium within 24 to 48 hours after birth

Refusal to feed

Bilious vomiting

Abdominal distention

Infancy

Failure to thrive

Constipation

Abdominal distention

Episodes of diarrhea and vomiting

Signs of enterocolitis

Explosive, watery diarrhea

Fever

Appears significantly ill

Childhood

Constipation

Ribbonlike, foul-smelling stools

Abdominal distention

Visible peristalsis

Easily palpable fecal mass

Undernourished, anemic appearance

In infants and children, the history is an important part of diagnosis and typically includes a chronic pattern of constipation. On examination, the rectum is empty of feces, the internal sphincter is tight, and leakage of stool and accumulated gas may occur if the aganglionic segment is short. To confirm the diagnosis, rectal biopsy is performed either surgically to obtain a full-thickness biopsy specimen or by suction biopsy for histologic evidence of the absence of ganglion cells.

Therapeutic Management

The majority of children with Hirschsprung disease require surgery rather than medical therapy with frequent enemas (Gourlay, 2013). After the child is stabilized with fluid and electrolyte replacement, if needed, surgery is performed, with a high rate of success. Surgical management consists primarily of the removal of the aganglionic portion of the bowel to relieve obstruction, restore normal motility, and preserve the function of the external anal sphincter. The transanal Soave endorectal pull-through procedure is often performed and consists of pulling the end of the normal bowel through the muscular sleeve of the rectum, from which the aganglionic mucosa has been removed. With earlier diagnosis, the proximal bowel may not be extremely distended, thus allowing for a primary pull-through or one-stage procedure and eliminating the need for a temporary colostomy. Simpler operations, such as an anorectal myomectomy, may be indicated in very short-segment disease.

After the pull-through procedure, the majority of children achieve fecal continence. However, some children may experience anal stricture, recurrent enterocolitis, prolapse, and perianal abscess, and incontinence may occur and require further therapy, including dilations or bowel retraining therapy (Fiorino and Liacouras, 2016).

Nursing Care Management

The nursing concerns depend on the child's age and the type of treatment. If the disorder is diagnosed during the neonatal period, the main objectives are to help the parents adjust to a congenital defect in their child, foster infant–parent bonding, prepare them for the medical-surgical intervention, and prepare the parents to assume care of the child after surgery.

The child's preoperative care depends on the age and clinical condition. A child who is malnourished may not be able to withstand surgery until his or her physical status improves. Often this involves symptomatic treatment with enemas; a low-fiber, high-calorie, high-protein diet. Physical preoperative preparation includes the same measures that are common to any surgery (see [Surgical Procedures, Chapter 20](#)). In newborns, whose bowels are presumed sterile, no additional preparation is necessary. However, in other children, preparation for the pull-through procedure involves emptying the bowels with repeated saline enemas and decreasing bacterial flora with oral or systemic antibiotics and colonic irrigations using antibiotic solution. Enterocolitis is the most serious complication of Hirschsprung disease. Emergency preoperative care includes frequent monitoring of vital signs and blood pressure for signs of shock; monitoring fluid and electrolyte replacements, as well as plasma or other blood derivatives; and observing for symptoms of bowel perforation, such as fever, increasing abdominal distention, vomiting, increased tenderness, irritability, dyspnea, and cyanosis.

Because progressive distention of the abdomen is a serious sign, the nurse measures abdominal circumference with a paper tape measure, usually at the level of the umbilicus or at the widest part of the abdomen. The point of measurement is marked with a pen to ensure reliability of subsequent measurements. Abdominal measurement can be obtained with the vital sign measurements and is recorded in serial order so that any change is obvious. To reduce stress to the acutely ill child when frequent measurements of abdominal circumference are needed, the tape measure can be left in place beneath the child rather than removed each time.

Postoperative care.

Postoperative care is the same as that for any child or infant with abdominal surgery (see [Surgical Procedures, Chapter 20](#)). The nurse involves the parents in the care of the child, allowing them to help with feedings and observe for signs of wound infection or irregular passage of stool. Some children will require daily anal dilations in the postoperative period to avoid anastomotic strictures; parents are often taught to perform the procedure in the home (Temple, Shawyer, and Langer, 2012). Although less common, a diverting colostomy may be performed in some children with Hirschsprung disease. Parents are taught how to care for the colostomy and how to provide

skin care to prevent skin breakdown.

Vomiting

Vomiting is the forceful ejection of gastric contents through the mouth. It is a well-defined, complex, coordinated process that is under CNS control and is often accompanied by nausea and retching. Vomiting has many causes including acute infectious diseases, increased intracranial pressure, toxic ingestions, food intolerances and allergies, mechanical obstruction of the GI tract, metabolic disorders, nephrologic disease, and psychogenic problems (Singhi, Shah, Bansal, et al, 2013). Vomiting is common in childhood, is usually self-limiting, and requires no specific treatment. However, complications may occur, including acute fluid volume loss (dehydration) and electrolyte disturbances, malnutrition, aspiration, and Mallory-Weiss syndrome (small tears in the distal esophageal mucosa).

Characteristics of the emesis and pattern of vomiting help determine the cause. The color and consistency of the emesis vary according to the cause. Green bilious vomiting suggests bowel obstruction. Curdled stomach contents, mucus, or fatty foods that are vomited several hours after ingestion suggest poor gastric emptying or high intestinal obstruction. Gastric irritation by certain medicines, foods, or toxic substances may cause vomiting. Forceful vomiting is associated with pyloric stenosis. Cyclic vomiting is a rare disorder characterized by bouts of vomiting that can last from hours to several days with an unknown etiology (Cuvellier and Lépine, 2010). Vomiting is a well-recognized response to psychological stress due to a rise in adrenaline levels that stimulate the chemoreceptor trigger zone.

Associated symptoms also help identify the cause. Fever and diarrhea accompanying vomiting suggest an infection. Constipation associated with vomiting suggests an anatomic or functional obstruction. Localized abdominal pain and vomiting often occur with appendicitis, pancreatitis, or peptic ulcer disease (PUD).

Therapeutic Management

Management is directed toward detection and treatment of the cause of the vomiting and prevention of complications, such as dehydration and malnutrition. If vomiting leads to dehydration, oral rehydration or parenteral fluids may be required. Antiemetic drugs may be indicated (see [Translating Evidence into Practice](#) box). Adverse effects with earlier-generation antiemetics (such as promethazine and metoclopramide) include somnolence, nervousness, irritability, and dystonic reactions and should not be routinely administered to children (Singhi, Shah, Bansal, et al, 2013). Ondansetron (Zofran) is an antiemetic with limited adverse effects and is beneficial when the child is not able to tolerate anything orally or in the case of postoperative vomiting, chemotherapy-induced vomiting, cyclic vomiting syndrome, or acute motion sickness (Singhi, Shah, Bansal, et al, 2013). For children who are prone to motion sickness, it is helpful to administer an appropriate dose of dimenhydrinate (Dramamine) before a trip.

Translating Evidence Into Practice

Use of Antiemetics in Children with Acute Gastroenteritis

Ask the Question

In children with acute gastroenteritis (AGE), should antiemetics be used?

Search for the Evidence

Search Strategies

Search criteria included English-language publications within the past 4 years (2011 to 2015), research-based articles (level 3 or higher) regarding antiemetic efficacy among children with AGE.

Databases Used

PubMed/Medline, CINAHL, Cochrane, Google Scholar, National Guideline Clearinghouse (AHRQ), American Academy of Pediatrics, National Institute of Health and Clinical Excellence, European Society for Paediatric Gastroenterology, Hepatology, and Nutrition, Joanna Briggs Institute

Critically Analyze the Evidence

GRADE criteria: Evidence quality moderate; recommendation strong (Balshem, Hefland, Schunemann, et al, 2011)

A review of the literature revealed two systematic reviews and two randomized control trials from 2011 to 2015 that evaluated the efficacy of antiemetics in the treatment of children with AGE.

- A Cochrane review in 2011 revealed seven randomized controlled trials (1020 patients) evaluating the safety and efficacy of antiemetics to treat gastroenteritis-induced vomiting in children (Fedorowicz, Jagannath, and Carter, 2011). Ondansetron was found more effective than placebo in studies evaluating hospital admission rates, need for intravenous (IV) rehydration therapy, and resolution of vomiting. When comparing placebo, dimenhydrinate was found more effective in one study, and metoclopramide was more effective in another single study.
- A systematic review from 1980 to 2012 revealed 10 studies (1479 participants) evaluating the evidence of safety and effectiveness of antiemetics (dexamethasone, dimenhydrinate, granisetron, metoclopramide, and ondansetron for gastroenteritis-induced vomiting in children and adolescents (Carter and Fedorowicz, 2012). There is clear evidence from nine studies that ondansetron is more effective than placebo is resolving vomiting, reducing the need for IV rehydration therapy, and reducing the hospital admission rate. A single study showed a reduction in mean vomiting days among children receiving dimenhydrinate versus placebo and among granisetron versus placebo. Studies of metoclopramide were underpowered, and a single study of dexamethasone versus placebo showed no statistically significant difference in vomiting.
- A study of 144 children diagnosed with acute gastroenteritis were randomized to receive dimenhydrinate or placebo in a pediatric emergency department (Gouin, Vo, Roy, et al, 2012). No statistically significant difference regarding the frequency of vomiting was noted between the two groups.
- A study of 76 children diagnosed with acute gastroenteritis were randomized to receive an orally disintegrating ondansetron tablet or domperidone suspension (dosing based on body weight) then evaluated for vomiting for the next 24 hours (Rerksuppaphol and Rerksuppaphol, 2013). Sixty-two percent of patients in the ondansetron group and 44% of patients in the domperidone group had no vomiting after treatment, although no statistically significant difference was noted ($p = 0.16$).

Apply the Evidence: Nursing Implications

Ondansetron reduces the duration of vomiting in children with AGE and ondansetron and domperidone relieves the incidence of vomiting in children with AGE. There is limited evidence for dimenhydrinate and metoclopramide, and no evidence for the use of cyclizine, and dexamethasone in children with AGE who are vomiting. The number of children requiring IV rehydration and hospital admission for AGE is reduced with administration of ondansetron.

Nursing Care Management

The major emphasis of nursing care of the vomiting infant and child is on observation and reporting of vomiting behavior and associated symptoms and on the implementation of measures to reduce the vomiting. Accurate assessment of the type of vomiting, appearance of the emesis, and the child's behavior in association with the vomiting helps to establish a diagnosis.

The cause of the vomiting determines the nursing interventions. When the vomiting is a manifestation of improper feeding methods, establishing proper techniques through teaching and example ordinarily corrects the situation. If vomiting is a probable sign of GI obstruction, food is usually withheld or special feeding techniques are implemented. The nurse should direct efforts toward maintaining hydration and preventing dehydration in a vomiting child.

The thirst mechanism is the most sensitive guide to fluid needs, and *ad libitum* administration of a glucose-electrolyte solution to an alert child restores water and electrolytes satisfactorily. It is important to include carbohydrate to spare body protein and to avoid ketosis resulting from exhaustion of glycogen stores. Small, frequent feedings of fluids or foods are preferred and more effective. After vomiting has stopped, offer more liberal amounts of fluids followed by gradual resumption of the regular diet.

Position the vomiting infant or child on the side or semi-reclining to prevent aspiration and observed for evidence of dehydration. It is important to emphasize the need for the child to brush the teeth or rinse the mouth after vomiting to dilute hydrochloric acid that comes in contact with the teeth. Carefully monitor fluid and electrolyte status to prevent an electrolyte disturbance.

Gastroesophageal Reflux

Gastroesophageal reflux (GER) is defined as the transfer of gastric contents into the esophagus. This phenomenon is physiologic, occurring throughout the day, most frequently after meals and at night; therefore, it is important to differentiate GER from **gastroesophageal reflux disease (GERD)**. GERD represents symptoms or tissue damage that result from GER. The peak incidence of GER occurs at 4 months old and generally resolves spontaneously in most infants before 12 months old (Khan and Orenstein, 2016a). GER becomes a disease when complications (such as failure to thrive, respiratory problems, or dysphagia) develop.

Certain conditions predispose children to a high prevalence of GERD, including neurologic impairment, hiatal hernia, and morbid obesity (Singhal and Khaitan, 2014). Sandifer syndrome is an uncommon condition, usually occurring in young children, that is characterized by repetitive stretching and arching of the head and neck that can be mistaken for a seizure. This maneuver likely represents a physiologic neuromuscular response attempting to prevent acid refluxate from reaching the upper portion of the esophagus (Goldani, Nunes, and Ferreira, 2012).

Infants who are prone to develop GER include preterm infants and infants with bronchopulmonary dysplasia. Children who have had tracheoesophageal or esophageal atresia repairs, neurologic disorders, scoliosis, asthma, cystic fibrosis, or cerebral palsy are also prone to developing GER. The clinical manifestations of GER are listed in [Box 22-2](#).

Box 22-2

Clinical Manifestations and Complications of Gastroesophageal Reflux

Symptoms in Infants

Spitting up, regurgitation, vomiting (may be forceful)

Excessive crying, irritability, arching of the back with neck extension, stiffening

Weight loss, failure to thrive

Respiratory problems (cough, wheeze, stridor, gagging, choking with feedings)

Hematemesis

Apnea or apparent life-threatening event

Symptoms in Children

Heartburn

Abdominal pain

Noncardiac chest pain

Chronic cough

Dysphagia

Nocturnal asthma

Recurrent pneumonia

Complications

Esophagitis

Esophageal stricture

Laryngitis

Recurrent pneumonia

Anemia

Barrett esophagus

Adapted from Rudolph CD, Mazur LJ, Liptak GS, et al: Guidelines for evaluation and treatment of gastroesophageal reflux in infants and children: recommendations of the North American Society for Pediatric Gastroenterology and Nutrition, *J Pediatr Gastroenterol Nutr* 32(Suppl 2):S1–S31, 2001.

Pathophysiology

Although the pathogenesis of GER is multifactorial, its primary causative mechanism likely involves inappropriate transient relaxation of the lower esophageal sphincter (LES). Factors that increase abdominal pressure (such as coughing and sneezing, scoliosis, and overeating) may contribute to GER. Esophageal symptoms are caused by inflammation from the acid in the gastric refluxate, whereas reactive airway disease may result from stimulation of airway reflexes by the acid refluxate.

Diagnostic Evaluation

The history and physical examination are usually sufficiently reliable to establish the diagnosis of GER. However, the upper GI series is helpful in evaluating the presence of anatomic abnormalities (e.g., pyloric stenosis, malrotation, annular pancreas, hiatal hernia, esophageal stricture). The 24-hour intraesophageal pH monitoring study is the gold standard in the diagnosis of GER ([Wilshire and Watson, 2013](#)). Endoscopy with biopsy may be helpful to assess the presence and severity of esophagitis, strictures, and Barrett esophagus and to exclude other disorders, such as Crohn disease. **Scintigraphy** detects radioactive substances in the esophagus after a feeding of the compound and assesses gastric emptying. It can differentiate between aspiration of gastric contents from reflux and aspiration from poor oropharyngeal muscle coordination.

Therapeutic Management

Therapeutic management of GER depends on its severity. No therapy is needed for the infant who is thriving and has no respiratory complications. Avoidance of certain foods that exacerbate acid reflux (e.g., caffeine, citrus, tomatoes, alcohol, peppermint, and spicy or fried foods) can improve mild GER symptoms. Lifestyle modifications in children (e.g., weight control if indicated; small, more frequent meals) and feeding maneuvers in infants (e.g., thickened feedings, upright

positioning) can help as well.

Feedings thickened with 1 teaspoon to 1 tablespoon of rice cereal per ounce of formula may be recommended. This may benefit infants who are underweight as a result of GERD; however, the additional calories are not beneficial among infants who are overweight. These infants may benefit from pre-thickened formulas that are now commercially available. Constant NG feedings may be necessary for infants with severe reflux and failure to thrive until surgery can be performed. Elevating the head of the bed after feedings and weight loss can reduce GER symptoms. Prone positioning of infants also decreases episodes of GER but due to the risk of sudden infant death syndrome, all infants should sleep in the supine position (Khan and Orenstein, 2016a). The American Academy of Pediatrics continues to recommend supine positioning for sleep (see Chapter 9).

Pharmacologic therapy may be used to treat infants and children with GERD. Both H₂-receptor antagonists (cimetidine [Tagamet], ranitidine [Zantac], or famotidine [Pepcid]) and proton pump inhibitors (PPIs; esomeprazole [Nexium], lansoprazole [Prevacid], omeprazole [Prilosec], pantoprazole [Protonix], and rabeprazole [AcipHex]) reduce gastric hydrochloric acid secretion and may stimulate some increase in LES tone. Use of metoclopramide remains controversial; there is no sufficient evidence to support the effectiveness with GER, and several side effects have been noted among infants; however, the medication is still commonly prescribed.

Surgical management of GER is reserved for children with severe complications, such as recurrent aspiration pneumonia, apnea, severe esophagitis, or failure to thrive, and for children who have failed to respond to medical therapy. The **Nissen fundoplication** (Fig. 22-3) is the most common surgical procedure (Wilshire and Watson, 2013). This surgery involves passage of the gastric fundus behind the esophagus to encircle the distal esophagus. Complications following fundoplication include breakdown of the wrap, small bowel obstruction, gas-bloat syndrome, infection, retching, and dumping syndrome (Wilshire and Watson, 2013).

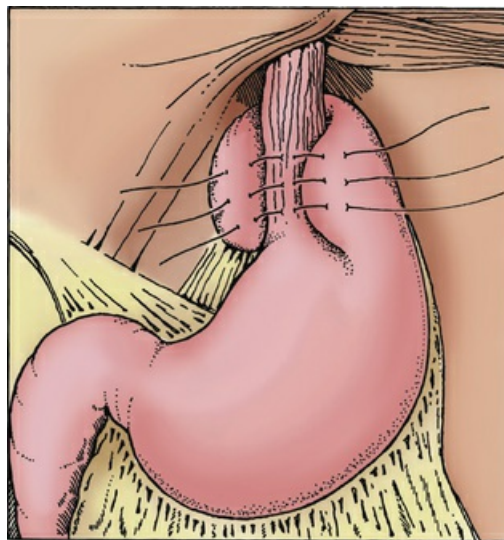

FIG 22-3 Nissen fundoplication sutures passing through esophageal musculature.

Nursing Care Management

Nursing care is directed at identifying children with symptoms suggestive of GER; educating parents regarding home care, including feeding, positioning, and medications when indicated; and caring for the child undergoing surgical intervention. For the majority of infants, parental reassurance of the benign nature of the condition and its relationship to physiologic maturity is the most important intervention. To help parents cope with the inconvenience of dealing with a child who spits up or regurgitates frequently, simple tips such as using bibs and protective clothes during feeding and prone positioning when holding the infant after feeding are beneficial.

It is important to educate and reassure parents about positioning. In the past, recommendations encouraged upright positioning during sleeping for both infants and older children. The supine

position for sleeping continues to be the recommended infant sleeping position. Parents should not place infants on their sides as an alternative to fully supine sleeping, and avoidance of soft bedding and soft objects in the bed is important. Rescheduling of the family's routine may be required to accommodate more frequent feeding times. If parents use thickened formula, they should also enlarge the nipple opening for easier sucking. Usually, breastfeeding may continue, and the mother may provide more frequent feeding times or express the milk for thickening with rice cereal. Parents should avoid feeding the child spicy foods or any foods that they find aggravate symptoms in general and avoid caffeine, chocolate, tobacco smoke, and alcohol when breastfeeding. Other practical advice includes advising the parents to avoid vigorous play after feedings and to avoid feeding just before bedtime.

When regurgitation is severe and growth is a problem, continuous NG tube feedings may decrease the amount of emesis and provide constant buffering of gastric acid. Special preparation of caregivers is required when this type of nutritional therapy is indicated.

The nurse can support the family by providing information about all aspects of treatment. Parents often require specific information about the medications given for GER. PPIs are most effective when administered 30 minutes before breakfast so that the peak plasma concentrations occur with mealtime. If they are given twice a day, the second best time for administration is 30 minutes before the evening meal. Parents need to be reassured that they may not see results right away because it takes several days of administration to achieve a steady state of acid suppression. A number of new formulations available in PPIs allow for more efficient administration. Some preparations are available in dissolvable pills. There are powder and granule preparations as well. Many pharmacies will compound the medication in a liquid form for administration.

Postoperative nursing care after the Nissen fundoplication is similar to that for other types of abdominal surgery (see [Chapter 20](#)).

Recurrent and Functional Abdominal Pain

Recurrent abdominal pain (RAP) is a complaint of childhood that is often attributed to psychogenic causes, although it can be a symptom of either psychosomatic or organic disease. RAP is characterized by three or more separate episodes of abdominal pain at least 3 months before diagnosis that interferes with daily activities ([Bufler, Gross, and Uhlig, 2011](#)). The disorder affects school-age children 4 to 18 years old but is more common in children approximately 11 years old, and it occurs more often in girls than in boys ([Chiou, How, and Ong, 2013](#)). The Rome III diagnostic criteria recognize four distinct entities of RAP in childhood: (1) functional dyspepsia, (2) irritable bowel syndrome (IBS), (3) abdominal migraine, and (4) childhood functional abdominal pain ([Bufler, Gross, and Uhlig, 2011](#)). Most children with RAP suffer from functional abdominal pain (FAP).

Etiology and Pathophysiology

Only a minority of children and adolescents with RAP have an organic basis for their pain. Organic causes include IBD, PUD, lactose intolerance, pelvic inflammatory disease, urinary tract infection, and pancreatitis. Psychogenic causes of abdominal pain (such as school phobia, depression, acute reactive anxiety, and conversion reaction) account for a small number of cases.

In cases in which no organic disorder is identifiable, the abdominal pain of RAP has been attributed to dysfunction. Dysfunctional conditions causing RAP include constipation, chronic stool retention, overeating, irritable colon, and intestinal gas with heightened awareness of intestinal motility or dysmotility. Normally, intestinal contents arrive at the distal portion of the intestine with a relatively high fluid content, and fluid is extracted in the distal colon and rectum. If the normally relaxed distal intestine fails to relax and prevents the flow of its contents toward the rectum, the resulting excessive distention and spasms of the distal intestinal musculature produce pressure on nerve endings, causing pain.

The symptoms of RAP may result from multiple causes, and it is important to assess a number of factors that could place a child at risk for this condition. These include (1) somatic predisposition, dysfunction, or disorder; (2) lifestyle and habit, including routines, diet, and life tempo; (3) temperament and learned response patterns, such as the child's behavior style, personality, and learned coping skills; and (4) milieu and critical events (i.e., the child's intimate surroundings [familial, social, and cultural norms] and unexpected sources of stress or gratification).

Diagnostic Evaluation

Diagnosis is based on a complete family history, the child's health history, physical examination, and laboratory tests. The family history may provide evidence of a hereditary disorder or mimicry of adult symptoms. The child is evaluated for evidence of an organic basis for symptoms, such as pain that radiates to the back, pain that awakens the child from sleep, persistent right upper or right lower quadrant pain, unexplained or recurrent fever, weight loss, GI blood loss, significant vomiting, chronic severe diarrhea, or family history of IBD. Pain is assessed for location, quality, frequency, duration, any associated symptoms, alleviating factors, and exacerbating factors.

Therapeutic Management

Treatment involves providing reassurance and reducing or eliminating symptoms. Hospitalization may be necessary, and the child frequently shows improvement in the hospital environment. Initial efforts are directed toward ruling out organic causes of the pain, relieving discomfort, and attempting to determine the situations that precipitate attacks.

Emphasize a high-fiber diet, psyllium bulk agents, lubricants (such as mineral oil), and bowel training for pain associated with bowel patterns. Treatment may also include acid-reduction therapy for pain associated with dyspepsia; antispasmodic agents, smooth muscle relaxants, or low doses of psychotropic agents for pain. Dietary modifications may include removal of dairy products, fructose, and gluten for 2 to 3 weeks to rule out lactose intolerance, sensitivity to high sugar content, and celiac disease. Other treatments include cognitive-behavior therapy and biofeedback.

Nursing Care Management

The nurse can be instrumental in assessment and management of RAP in children. Many techniques used in a routine assessment elicit information that might help identify factors that contribute to the child's symptoms. Evaluate the child's social and psychological adjustment and obtain the details of the pain directly from the child. Questions that provide clues to parent-child relationships and the way that the family deals with angry feelings provide information for diagnosis and management. Relationships with peers, school problems, and other concerns of the child need to be explored. Note any evidence of depression.

Once the diagnosis has been established, the parents and the child need an explanation of the pain, which can be compared to a skeletal muscle cramp, "charley horse," or headache for easier comprehension. Reassurance that the symptoms are not unique to their child and that the pain is rarely associated with a severe disease can help relieve parental fears and anxieties.

Discuss a high-fiber diet with the child and family and emphasize bowel training. The child is encouraged to establish a pattern of sitting on the toilet for 10 to 15 minutes immediately after breakfast to take advantage of the increased colonic activity following meals. If necessary, have the child use stimulatory suppositories to induce early morning defecation.

After the parents are reassured that there is no organic cause for the pain, they need guidance on what to do during a pain episode. Often they feel helpless and anxious, which tends to compound the child's distress. The simple measure of having the child rest in a peaceful, quiet environment and providing comfort will often relieve the symptoms in a short time. Application of a heating pad may also ease the discomfort (see [Nonpharmacologic \[Pain\] Management, Chapter 5](#)). If pain is not relieved by these simple measures, teach parents how to administer antispasmodics if prescribed. For example, if pain is precipitated by meals, having the child take the medication 20 to 30 minutes before mealtime may prevent an episode.

The most valuable assistance that the nurse can provide is support and reassurance to the family. When open communication is established and families are able to see a relationship between stress-provoking situations and the child's symptoms, the chance for remedial action is enhanced. Follow-up care and continued support are essential because the symptoms tend to remit and exacerbate; therefore, the availability of a supportive health professional can be a source of comfort to the child and family.

Irritable Bowel Syndrome

IBS is classified as a functional GI disorder. Children with IBS often have alternating diarrhea and constipation, flatulence, bloating or a feeling of abdominal distention, lower abdominal pain, a

feeling of urgency when needed to defecate, and a feeling of incomplete evacuation of the bowel. These symptoms should be present for 6 months or longer and present for at least 3 days per month over the last 3 months (Wadlund, 2012). IBS has been identified as a cause of RAP in 21% to 45% of school-age children (Rajindrajith and Devanarayana, 2012). Typically there are no abnormal physical findings on exam. Many children with symptoms appear active and healthy and have normal growth.

The cause of IBS is not clear, but it is believed to involve a combination of autonomic and psychological factors. Children with IBS are evaluated to rule out organic causes of their symptoms, such as IBD, lactose intolerance, and parasitic infections. The long-range goal of treatment is development of regular bowel habits and relief of symptoms.

Nursing Care Management

The disorder is stressful to children and parents, and the primary nursing goal is family support and education. The nurse provides support and reassurance that although the symptoms are difficult to deal with, the disorder is not generally a threat to the child's health.

Inflammatory Disorders

Acute Appendicitis

Appendicitis, inflammation of the **vermiform appendix** (blind sac at the end of the cecum), is the most common cause of emergency abdominal surgery in childhood. In the United States, 70,000 cases are diagnosed each year (Pepper, Stanfill, and Pearl, 2012). The average age of children with appendicitis is 10 years old, with boys and girls equally affected before puberty (Pepper, Stanfill, and Pearl, 2012). Classically, the first symptom of appendicitis is periumbilical pain followed by nausea, right lower quadrant pain, and later vomiting with fever (Balachandran, Singhi, and Lal, 2013). Perforation of the appendix can occur within approximately 48 hours of the initial complaint of pain and occurs in 20% to 40% of children with appendicitis (Wheeler, 2011). Complications from appendiceal perforation include major abscess, phlegmon, enterocutaneous fistula, peritonitis, and partial bowel obstruction (Pepper, Stanfill, and Pearl, 2012). A **phlegmon** is an acute suppurative inflammation of subcutaneous connective tissue that spreads.

Etiology

The cause of appendicitis is obstruction of the lumen of the appendix, usually by hardened fecal material (fecalith). Swollen lymphoid tissue, frequently occurring after a viral infection, can also obstruct the appendix. Another rare cause of obstruction is a parasite such as *Enterobius vermicularis*, or pinworms, which can obstruct the appendiceal lumen.

Pathophysiology

With acute obstruction, the outflow of mucus secretions is blocked, and pressure builds within the lumen, resulting in compression of blood vessels. The resulting ischemia is followed by ulceration of the epithelial lining and bacterial invasion. Subsequent necrosis causes perforation or rupture with fecal and bacterial contamination of the peritoneal cavity. The resulting inflammation spreads rapidly throughout the abdomen (**peritonitis**), especially in young children, who are unable to localize infection. Progressive peritoneal inflammation results in functional intestinal obstruction of the small bowel (**ileus**) because intense GI reflexes severely inhibit bowel motility. Because the peritoneum represents a major portion of total body surface, the loss of ECF to the peritoneal cavity leads to electrolyte imbalance and hypovolemic shock.

Diagnostic Evaluation

Diagnosis is not always straightforward. Fever, vomiting, abdominal pain, and an elevated white blood cell (WBC) count are associated with appendicitis but are also seen in IBD, pelvic inflammatory disease, gastroenteritis, urinary tract infection, right lower lobe pneumonia, mesenteric adenitis, Meckel diverticulum, and intussusception. Prolonged symptoms and delayed diagnosis often occur in younger children, in whom the risk of perforation is greatest because of their inability to verbalize their complaints.

The diagnosis is based primarily on the history and physical examination. Pain, the cardinal feature, is initially generalized (usually periumbilical); however, it usually descends to the lower right quadrant. The most intense site of pain may be at **McBurney point**. Rebound tenderness is not a reliable sign and is extremely painful to the child. Referred pain, elicited by light percussion around the perimeter of the abdomen, indicates peritoneal irritation. Movement, such as riding over bumps in an automobile or wheelchair, aggravates the pain. In addition to pain, significant clinical manifestations include fever, a change in behavior, anorexia, and vomiting (Box 22-3).

Box 22-3

Clinical Manifestations of Appendicitis

- Right lower quadrant abdominal pain
- Fever

- Rigid abdomen
- Decreased or absent bowel sounds
- Vomiting (typically follows onset of pain)
- Constipation or diarrhea
- Anorexia
- Tachycardia
- Rapid, shallow breathing
- Pallor
- Lethargy
- Irritability
- Stooped posture

Laboratory studies usually include a CBC; urinalysis (to rule out a urinary tract infection); and, in adolescent females, serum human chorionic gonadotropin (to rule out an ectopic pregnancy). A WBC count greater than 10,000/mm³ and a C-reactive protein (CRP) are common but are not necessarily specific for appendicitis. An elevated percentage of bands (often referred to as “a shift to the left”) may indicate an inflammatory process. CRP is an acute-phase reactant that rises within 12 hours of the onset of infection.

Computed tomography (CT) scan has become the imaging technique of choice, although ultrasonography may also be helpful in diagnosing appendicitis. A CT scan result is considered positive in the presence of enlarged appendiceal diameter; appendiceal wall thickening; and periappendiceal inflammatory changes, including fat streaks, phlegmon, fluid collection, and extraluminal gas (Balachandran, Singhi, and Lal, 2013). The accuracy of CT scan is 96% for diagnosing appendicitis (Pepper, Stanfill, and Pearl, 2012).

Nursing Alert

Signs of peritonitis, in addition to fever, include sudden relief from pain after perforation; subsequent increase in pain (usually diffuse and accompanied by rigid guarding of the abdomen); progressive abdominal distention; tachycardia; rapid, shallow breathing as the child refrains from using abdominal muscles; pallor; chills; irritability; and restlessness.

Therapeutic Management

Treatment of appendicitis before perforation is surgical removal of the appendix (**appendectomy**). Usually antibiotics are administered preoperatively. IV fluids and electrolytes are often required before surgery, especially if the child is dehydrated as a result of the marked anorexia characteristic of appendicitis.

The operation is usually performed through a right lower quadrant incision (open appendectomy). Laparoscopic surgery is commonly used to treat nonperforated acute appendicitis. Advantages of laparoscopic appendectomy include reduced time in surgery and anesthesia, and reduced risk of postoperative wound infection (Wray, Kao, Millas, et al, 2013).

Ruptured Appendix

Management of the child diagnosed with peritonitis caused by a ruptured appendix often begins preoperatively with IV administration of fluid and electrolytes, systemic antibiotics, and NG suction. Postoperative management includes IV fluids, continued administration of antibiotics, and NG suction for abdominal decompression until intestinal activity returns. Sometimes surgeons close the wound after irrigation of the peritoneal cavity. Other times, the wound is left open (delayed

closure) to prevent wound infection.

Prognosis

Complications are uncommon after a simple appendectomy, and recovery is usually rapid and complete. The mortality rate from perforating appendicitis has improved from nearly certain death a century ago to 1% or less at the present time (Wray, Kao, Millas, et al, 2013). Complications, however, including wound infection and intraabdominal abscess, are not uncommon. Early recognition of the illness is important to prevent complications.

Nursing Care Management

Because abdominal pain is a common childhood complaint, the nurse needs to make some preliminary assessment of the severity of pain (see [Pain Assessment, Chapter 5](#)). One of the most reliable estimates is the degree of change in behavior. Younger, nonverbal children will assume a rigid, motionless, side-lying posture with the knees flexed on the abdomen, and there is decreased range of motion of the right hip. Older children may exhibit all of these behaviors while complaining of abdominal pain and refusing to play.

Nursing Alert

In any instance in which severe abdominal pain is observed, the nurse must be aware of the danger of administering laxatives or enemas. Such measures stimulate bowel motility and increase the risk of perforation.

Postoperative Care

Postoperative care for the nonperforated appendix is the same as for most abdominal procedures. Care of the child with a ruptured appendix and peritonitis involves more complex care, and the course of recovery is considerably longer. The child is maintained on IV fluids and antibiotics, is allowed nothing by mouth (NPO), and the NG tube is kept on low continuous gastric decompression until there is evidence of intestinal activity. Listening for bowel sounds and observing for other signs of bowel activity (e.g., passage of flatus or stool) are part of the routine assessment. A drain is often placed in the wound during surgery, and frequent dressing changes with meticulous skin care are essential to prevent excoriation of the area surrounding the surgical site. If the wound is left open, moist dressings (usually saline-soaked gauze) and wound irrigations with antibacterial solution are used to provide optimum healing environment.

Management of pain is an essential part of the child's care. Because pain is continuous during the first few postoperative days, analgesics are given regularly to control pain. Procedures are performed when the analgesics are at peak effect. Psychological care of the child and parents is similar to that used in other emergency situations. Parents and older children need to express their feelings and concerns regarding the events surrounding the illness and hospitalization. The nurse can provide education and psychosocial support to promote adequate coping and alleviate anxiety for both the child and the family (see [Nursing Care Plan](#)).

Nursing Care Plan

The Child with Appendicitis

Case Study

Lisa is a 10-year-old girl who has a 2-day history of generalized periumbilical pain and anorexia. Today she developed a fever and vomiting, so her parents took her to her pediatrician. On examination, Lisa was febrile with abdominal pain midway between the anterior superior iliac crest and umbilicus. The pain intensifies with any activity or deep breathing. Blood work was performed and a complete blood count (CBC) with differential shows a white blood cell (WBC) count of $21,000/\text{mm}^3$, 79% bands, 14% lymphocytes, 6% eosinophils, and a normal hemoglobin and platelet count. With Susie's history and physical findings, she was referred to a local emergency room.

Assessment

Based on Lisa's history, what are the most important signs and symptoms that you need to be aware of?

Appendicitis Defining Characteristics

History of abdominal pain for 2 days that started around the umbilicus and has now progressed to the lower right abdomen (McBurney's point)

Fever

Anorexia

Nausea and vomiting

Elevated WBC count ($>10,000/\text{mm}^3$) along with a high percentage of bands (left shift)

Elevated C-reactive protein (CRP)

Nursing Diagnosis

Pain, acute

Body temperature, imbalanced

Infection

Nausea

Risk for electrolyte imbalance

Risk for fluid volume deficit

Knowledge deficit

Nursing Interventions

What are the most appropriate nursing interventions for a child with appendicitis?

| Nursing Interventions | Rationale |
|---|---|
| Close monitoring of the patient's status. Follow clinical and laboratory findings. Blood studies included CBC, CRP, and electrolytes. | To identify infection, signs of inflammation, changes in fluid and electrolyte status which require additional treatment |
| Close monitoring of diagnostic evaluation studies (i.e., computed tomography [CT] scan and/or ultrasound). | To confirm diagnosis of appendicitis |
| Administer intravenous (IV) fluids. | To correct fluid deficit and electrolyte imbalances |
| Administer analgesics as ordered. | To reduce pain |
| Administer antiemetics as ordered. | To reduce nausea and alleviate vomiting |
| Monitor temperature and vital signs. | To observe for signs of infection |
| Administer antipyretic medication as indicated. | To reduce fever |
| Administer antibiotics as ordered. | To treat infection |
| Maintain nothing by mouth (NPO) status. | To keep stomach empty in anticipation of possible surgery |
| Identify patient and family stressors that may accompany a diagnosis of appendicitis. | Providing financial and emotion support for family can help decrease some of the stressors associated with this condition |
| Review disease, medication, dietary restrictions. | Understanding the medical condition and therapies allows family to make informed decisions about care |

Expected Outcomes

The child will exhibit decreased pain

The child will exhibit no evidence of nausea or vomiting

The child's body temperature is within normal limits

Sufficient fluid and electrolytes are maintained

Patient/family indicate understanding of appendicitis and treatment

Case Study (Continued)

Results of the CT scan demonstrate a ruptured appendix. Lisa is now being prepared for surgery. The nurse performing the assessment finds Lisa's temperature to be elevated. Lisa reports the pain had initially resolved but she now reports increasing pain (rated 9 out of 10) and nausea.

Assessment

What concerns you most based on the scenario?

Lisa's appendix has ruptured and the reoccurrence of pain and fever is likely related to an infection or possible abscess.

What immediate steps should be taken to further evaluate Lisa's status?

Check CBC and differential

Document temperature and vital signs (pulse, respirations, blood pressure)

Assess and document location and rating of pain

Administer antipyretic agent, analgesic, antiemetic, and IV fluids

The following laboratory results have returned from Lisa's blood work:

CBC: WBC 24,000/mm³, bands 81%, lymphocytes 12%, eosinophils 5%, normal hemoglobin and normal platelets

Electrolytes and kidney function: Potassium 3.4, sodium 135, blood urea nitrogen (BUN) 25, serum creatinine 1.2

Nursing Diagnosis

Pain, acute

Body temperature, imbalanced

Infection

Nausea

Risk for electrolyte imbalance

Risk for fluid volume deficit

Nursing Interventions

What are the most appropriate nursing interventions for Lisa before and after surgery?

| Nursing Interventions | Rationale |
|---|---|
| Administer antibiotics as ordered. IV antibiotics are given for a minimum of 3 days postoperatively in children with complicated appendicitis then transitioned to oral antibiotics at discharge. | To treat infection |
| Administer analgesics as ordered. | To reduce pain |
| Administer antiemetics as ordered. | To reduce nausea and alleviate vomiting |
| Monitor temperature and vital signs. | To observe for signs of infection and shock |
| Administer IV fluids and monitor electrolytes. | To correct fluid deficit and electrolyte imbalances |
| Follow laboratory findings. Blood studies including CBC, CRP, and intraoperative cultures if obtained. | To identify infection, and signs of inflammation |
| Advance diet as tolerated postoperatively. | To maintain nutritional status |

Expected Outcome

The child will exhibit no signs of infection

The child's pain will be controlled initially with IV analgesics then transitioned to oral analgesics

The child will exhibit no evidence of nausea or vomiting

The child will tolerate a regular diet

The child's body temperature is within normal limits

Sufficient fluid and electrolytes are maintained

Case Study (Continued)

Lisa's parents are anxious and upset with the urgent need for surgery and hospitalization. You are concerned that they do not understand what is happening to their daughter.

Assessment

What are the most important aspects of Lisa's care to discuss with her parents at this time?

Family's Knowledge of Illness-Defining Characteristics

- Understands definition of appendicitis and ruptured appendix
- Describes rationale for urgent surgery
- Describes rationale for subsequent hospitalization and need for IV antibiotics
- Expresses fears and concerns
- Shows appropriate reactions to child's illness

Nursing Diagnosis

Readiness for enhanced knowledge related to parents' interest in Lisa's health status.

Nursing Interventions

What are the most appropriate nursing interventions for this diagnosis?

| Nursing Interventions | Rationale |
|--|--|
| Review disease and treatment prior to surgery. | Understanding the medical condition and therapies allow families to make informed decisions about care |
| Review disease and treatment after surgery. | To increase knowledge and compliance with treatment plan to control pain, treat infection, maintain adequate fluid and electrolyte balance, and maximize nutrition |
| Arrange for social worker to meet with family to assess emotional and financial needs. | To identify and modify stressors associated with urgent and prolonged hospitalization |
| As child nears discharge, arrange for discussions with parents to discuss home care. | Family must be aware of necessary treatment and monitoring in order to be compliant with care |

Expected Outcome

Parents indicate understanding of appendicitis and treatment

Parents verbalize understanding the signs and symptoms of infection and understand the actions to treat infection.

Parents verbalize understanding of the plan for managing postsurgical treatment at home.

Meckel Diverticulum

Meckel diverticulum is a remnant of the fetal omphalomesenteric duct, which connects the yolk sac with the primitive midgut during fetal life (Kotecha, Bellah, Pena, et al, 2012). Normally, the structure is obliterated between the fifth and ninth week of gestation, when the placenta replaces the yolk sac as the source of nutrition for the fetus. Failure of obliteration may result in an omphalomesenteric fistula (a fibrous band connecting the small intestine to the umbilicus), umbilical cyst, vitelline duct remnant, mesodiverticular bands, or Meckel diverticulum (Pepper, Stanfill, and Pearl, 2012).

Meckel diverticulum is a true diverticulum because it arises from the antimesenteric border of the small intestine and includes all layers of the intestinal wall. The position of the diverticulum varies, but it is usually found within 40 to 50 cm (16 to 20 inches) of the ileocecal valve. Meckel diverticulum is often referred to by the “rule of twos” because it occurs in 2% of the population, has a 2 : 1 male to female ratio, is located within 2 feet of the ileocecal valve, is commonly 2 cm in diameter and 2 inches in length, contains two types of ectopic tissue (pancreatic and gastric), and is more common before the age of 2 (Pepper, Stanfill, and Pearl, 2012).

Pathophysiology

Bleeding, obstruction, or inflammation causes the symptomatic complications of Meckel diverticulum. Bleeding, which is the most common problem in children, is caused by peptic ulceration or perforation because of the unbuffered acidic secretion. Several mechanisms may cause obstruction such as intussusception or entanglement of the small intestine (Pepper, Stanfill, and Pearl, 2012).

Diagnostic Evaluation

Diagnosis is usually based on the history, physical examination, and radiographic studies. Meckel diverticulum is often a diagnostic challenge. A technetium-99 pertechnetate scan (Meckel scan) is the most effective diagnostic testing, especially for a bleeding diverticulum, with sensitivity ranging from 65% to 85% (Pepper, Stanfill, and Pearl, 2012). CT, magnetic resonance imaging (MRI), and mesenteric angiography may be used to investigate complications of Meckel diverticulum but each test has associated risks, such as the use of contrast for CT scans, exposure to radiation for MRI scans, and the blood loss for tagged red blood cells with mesenteric angiography (Pepper, Stanfill, and Pearl, 2012). Laboratory studies such as a CBC and a basic metabolic panel are usually part of the general workup to rule out any bleeding disorder and to evaluate for dehydration.

The most common clinical presentation in children includes painless rectal bleeding, abdominal pain, or signs of intestinal obstruction (Box 22-4). Bleeding, which may be mild or profuse, often appears as bright red or “currant jelly-like” stools; bleeding may be significant enough to cause hypotension.

Box 22-4

Clinical Manifestations of Meckel Diverticulum

Abdominal Pain

Similar to appendicitis

May be vague and recurrent

Bloody Stools*

Painless

Bright or dark red with mucus (currant jelly-like stool)

In infants, rectal bleeding sometimes accompanied by pain

Sometimes

Severe anemia

Shock

*Often a presenting sign.

Therapeutic Management

The standard treatment for symptomatic Meckel diverticulum is surgical removal. When severe hemorrhage increases the surgical risk, interventions to correct hypovolemic shock (such as blood replacement, IV fluids, and oxygen) may be necessary. Antibiotics may be used preoperatively to control infection. If intestinal obstruction has occurred, appropriate preoperative measures are used to reverse electrolyte imbalances and prevent abdominal distention.

Prognosis

If symptomatic Meckel diverticulum is diagnosed and treated early, full recovery is likely. The mortality rate of untreated Meckel diverticulum is 0.001% (Zani, Easton, Rees, et al, 2008). Because of the potential for surgical complications, resection of asymptomatic Meckel diverticulum remains controversial.

Nursing Care Management

Nursing objectives are the same as for any child undergoing surgery (see Chapter 20). When intestinal bleeding is present, specific preoperative considerations include frequent monitoring of vital signs including blood pressure, keeping the child on bed rest, and recording the approximate amount of blood lost in stools.

Postoperatively, the child requires IV fluids and an NG tube for decompression and evacuation of gastric secretions. Because the onset of illness is usually rapid, psychological support is important, as in other acute conditions, such as appendicitis. It is important to remember that massive rectal bleeding is usually traumatic to both the child and the parents and may significantly affect their emotional reaction to hospitalization and surgery.

Inflammatory Bowel Disease

Inflammatory bowel disease (IBD) should not be confused with IBS. IBD is a term used to refer to two major forms of chronic intestinal inflammation: Crohn disease and ulcerative colitis. Crohn disease and ulcerative colitis have similar epidemiologic, immunologic, and clinical features, but they are distinct disorders (Table 22-8).

TABLE 22-8
Clinical Manifestations of Inflammatory Bowel Diseases

| Characteristics | Ulcerative Colitis | Crohn Disease |
|---------------------------|--------------------|--------------------|
| Rectal bleeding | Common | Uncommon |
| Diarrhea | Often severe | Moderate to severe |
| Pain | Less frequent | Common |
| Anorexia | Mild or moderate | May be severe |
| Weight loss | Moderate | May be severe |
| Growth restriction | Usually mild | May be severe |
| Anal and perianal lesions | Rare | Common |
| Fistulas and strictures | Rare | Common |
| Rashes | Mild | Mild |
| Joint pain | Mild to moderate | Mild to moderate |

Approximately 1 million people in the United States have IBD, with 10% of these being children (D'Auria and Kelly, 2013). Over the past 30 years, the incidence of Crohn disease has risen, but the incidence of ulcerative colitis in children has remained stable (Aloi, D'Arcangelo, Pofi, et al, 2013). Both Crohn disease and ulcerative colitis have been noted to be more aggressive if the onset occurs in childhood (Aloi, D'Arcangelo, Pofi, et al, 2013).

Etiology

Despite decades of research, the etiology of IBD is not completely understood, and there is no known cure. There is evidence to indicate a multifactorial etiology. Research is focused on theories of defective immunoregulation of the inflammatory response to bacteria or viruses in the GI tract in individuals with a genetic predisposition (Szigethy, McLafferty, and Goyal, 2011). In Crohn disease the chronic immune process is characterized by a T-helper 1 cytokine profile, whereas in ulcerative colitis the response is more humoral and mediated by T-helper 2 cells; however, recent studies have shown a subset of T cells (Th17) that are critical in inflammation for both forms of IBD (Szigethy, McLafferty, Goyal, 2011). Development of IBD also may have a genetic influence. Family-based genetic studies have linked chromosome 6 in ulcerative colitis with the NOD2 gene in Crohn disease (Szigethy, McLafferty, and Goyal, 2011).

Pathophysiology

The inflammation found with ulcerative colitis is limited to the colon and rectum, with the distal colon and rectum the most severely affected. Inflammation affects the mucosa and submucosa and involves continuous segments along the length of the bowel with varying degrees of ulceration, bleeding, and edema. Thickening of the bowel wall and fibrosis are unusual, but long-standing disease can result in shortening of the colon and strictures. Extraintestinal manifestations are less common in ulcerative colitis than in Crohn disease. Toxic megacolon is the most dangerous form of severe colitis.

The chronic inflammatory process of Crohn disease involves any part of the GI tract from the mouth to the anus but most often affects the terminal ileum. The disease involves all layers of the bowel wall (transmural) in a discontinuous fashion, meaning that between areas of intact mucosa, there are areas of affected mucosa (skip lesions). The inflammation may result in ulcerations; fibrosis; adhesions; stiffening of the bowel wall; stricture formation; and fistulas to other loops of bowel, bladder, vagina, or skin.

Diagnostic Evaluation

The diagnosis of ulcerative colitis and Crohn disease comes from the history, physical examination, laboratory evaluation, and other diagnostic procedures. Laboratory tests include a CBC to evaluate anemia and an erythrocyte sedimentation rate (ESR) or CRP to assess the systemic reaction to the inflammatory process. Levels of total protein, albumin, iron, zinc, magnesium, vitamin B₁₂, and fat-soluble vitamins may be low in children with Crohn disease. Stools are examined for blood, leukocytes, and infectious organisms. A serologic panel is often used in combination with clinical findings to diagnose IBD and to differentiate between Crohn disease and ulcerative colitis.

In patients with Crohn disease, an upper GI series with small bowel follow-through assists in assessing the existence, location, and extent of disease. Upper endoscopy and colonoscopy with biopsies are an integral part of diagnosing IBD (Ellis and Cole, 2011). Endoscopy allows direct visualization of the surface of the GI tract so that the extent of inflammation and narrowing can be evaluated. CT and ultrasonography also may be used to identify bowel wall inflammation, intraabdominal abscesses, and fistulas. Colonoscopy can confirm the diagnosis and evaluate the

extent of the disease. Discrete ulcers are commonly seen in patients with Crohn disease, whereas microulcers and diffuse abnormalities and inflammation are seen in patients with ulcerative colitis (Grossman and Baldassano, 2016). Crohn disease lesions may pierce the walls of the small intestine and colon, creating tracts called *fistulas* between the intestine and adjacent structures, such as the bladder, anus, vagina, or skin.

Therapeutic Management

The natural history of the disease continues to be unpredictable and characterized by recurrent flare-ups that can severely impair patients' physical and social functioning (D'Auria and Kelly, 2013). The goals of therapy are to control the inflammatory process to reduce or eliminate the symptoms, obtain long-term remission, promote normal growth and development, and allow as normal a lifestyle as possible. Treatment is individualized and managed according to the type and the severity of the disease, its location, and the response to therapy. Crohn disease is more disabling, has more serious complications, and is often less amenable to medical and surgical treatment than is ulcerative colitis. Because ulcerative colitis is confined to the colon, a colectomy may cure ulcerative colitis.

Medical Treatment

The goal of any treatment regimen is first to induce remission of acute symptoms and then to maintain remission over time. 5-Aminosalicylates (5-ASAs) are effective in the induction and maintenance of remission in mild to moderate ulcerative colitis. Mesalamine, olsalazine, and balsalazide are now preferred over sulfasalazine because of reduced side effects (headache, nausea, vomiting, neutropenia, and oligospermia). Suppository and enema preparations of mesalamine are used to treat left-sided colitis. These drugs decrease inflammation by inhibiting prostaglandin synthesis. 5-ASAs can be used to induce remission in mild Crohn disease. Corticosteroids, such as prednisone and prednisolone, are indicated in induction therapy in children with moderate to severe ulcerative colitis and Crohn disease. These drugs inhibit the production of adhesion molecules, cytokines, and leukotrienes. Although these drugs reduce the acute symptoms of IBD, they have side effects that relate to long-term use, including growth suppression (adrenal suppression), weight gain, and decreased bone density. High doses of IV corticosteroids may be administered in acute episodes and tapered according to clinical response. Budesonide, a synthetic corticosteroid, is designed for controlled release in the ileum and is indicated for ileal and right-sided colitis; budesonide has fewer side effects than prednisone and prednisolone (Szigethy, McLafferty, and Goyal, 2011). Rectal steroid therapy (enemas and foam-based preparations) are available for both induction and maintenance therapy in left-sided colitis (Szigethy, McLafferty, and Goyal, 2011).

Immunomodulators, such as azathioprine and its metabolite 6-mercaptopurine (6-MP), are used to induce and maintain remission in children with IBD who are steroid resistant or steroid dependent and in treating chronic draining fistulas. They block the synthesis of purine, thus inhibiting the ability of DNA and RNA to hinder lymphocyte function, especially that of T cells. Side effects include infection, pancreatitis, hepatitis, bone marrow toxicity, arthralgia, and malignancy. Methotrexate is also useful in inducing and maintaining remission in Crohn disease patients who are unresponsive to standard therapies. Cyclosporine and tacrolimus have both been effective in inducing remission in severe steroid-dependent ulcerative colitis. 6-MP or azathioprine is then used to maintain remission. Patients taking immunomodulating medications require regular monitoring of their CBC and differential to assess for changes that reflect suppression of the immune system because many of the side effects can be prevented or managed by dose reduction or discontinuation of medication.

Antibiotics, such as metronidazole and ciprofloxacin, may be used as an adjunctive therapy to treat complications, such as perianal disease or small bowel bacterial overgrowth in Crohn disease. Side effects of these drugs are peripheral neuropathy, nausea, and a metallic taste.

Biologic therapies act to regulate inflammatory and antiinflammatory cytokines. With the emergence of the biologic agents, specifically the use of tumor necrosis factor- α (TNF- α) agents, progress has been made in targeting specific pathogenetic mechanisms and achieving a more prolonged clinical response (Szigethy, McLafferty, and Goyal, 2011). TNF- α is believed to influence active inflammation.

Nutritional Support

Nutritional support is important in the treatment of IBD. Growth failure is a common serious complication, especially in Crohn disease. Growth failure is characterized by weight loss, alteration in body composition, restricted height, and delayed sexual maturation. Malnutrition causes the growth failure, and its etiology is multifactorial. Malnutrition occurs as a result of inadequate dietary intake, excessive GI losses, malabsorption, drug/nutrient interaction, and increased nutritional requirements. Inadequate dietary intake occurs with anorexia and episodes of increased disease activity. Excessive loss of nutrients (protein, blood, electrolytes, and minerals) occurs secondary to intestinal inflammation and diarrhea. Carbohydrate, lactose, fat, vitamin, and mineral malabsorption, as well as vitamin B₁₂ and folic acid deficiencies, occur with disease episodes and with drug administration and when the terminal ileum is resected. Finally, nutritional requirements are increased with inflammation, fever, fistulas, and periods of rapid growth (e.g., adolescence).

The goals of nutritional support include correction of nutrient deficits and replacement of ongoing losses, provision of adequate energy and protein for healing, and provision of adequate nutrients to promote normal growth. Nutritional support includes both enteral and parenteral nutrition. A well-balanced, high-protein, high-calorie diet is recommended for children whose symptoms do not prohibit an adequate oral intake. There is little evidence that avoiding specific foods influences the severity of the disease. Supplementation with multivitamins, iron, and folic acid is recommended.

Special enteral formulas, given either by mouth or continuous NG infusion (often at night), may be required. Elemental formulas are completely absorbed in the small intestine with almost no residue. A diet consisting only of elemental formula not only improves nutritional status but also induces disease remission, either without steroids or with a diminished dosage of steroids required. An elemental diet is a safe and potentially effective primary therapy for patients with Crohn disease. Unfortunately, remission is not sustained when NG feedings are discontinued unless maintenance medications are added to the treatment regimen.

Total parenteral nutrition (TPN) has also improved nutritional status in patients with IBD. Short-term remissions have been achieved after TPN, although complete bowel rest has not reduced inflammation or added to the benefits of improved nutrition by TPN. Nutritional support is less likely to induce a remission in ulcerative colitis than in Crohn disease. Improvement of nutritional status is important, however, in preventing deterioration of the patient's health status and in preparing the patient for surgery.

Surgical Treatment

Surgery is indicated for ulcerative colitis when medical and nutritional therapies fail to prevent complications. Surgical options include a **subtotal colectomy** and **ileostomy** that leaves a rectal stump as a blind pouch. A reservoir pouch is created in the configuration of a **J** or **S** to help improve continence postoperatively. An ileoanal pull-through preserves the normal pathway for defecation. Pouchitis, an inflammation of the surgically created pouch, is the most common late complication of this procedure. In many cases, ulcerative colitis can be cured with a total colectomy.

Surgery may be required in children with Crohn disease when complications cannot be controlled by medical and nutritional therapy. Segmental intestinal resections are performed for small bowel obstructions, strictures, or fistulas. Partial colonic resection is not curative, and the disease often recurs (Ellis and Cole, 2011).

Prognosis

IBD is a chronic disease. Relatively long periods of quiescent disease may follow exacerbations. The outcome is influenced by the regions and severity of involvement, as well as by appropriate therapeutic management. Malnutrition, growth failure, and bleeding are serious complications. The overall prognosis for ulcerative colitis is good.

The development of colorectal cancer (CRC) is a long-term complication of IBD. In ulcerative colitis, the median duration of a CRC diagnosis was 23.5 years with a range of 11 to 48 years (Latella, 2012). Because the risk for CRC occurs 10 years after diagnosis, surveillance colonoscopy with multiple biopsies should begin approximately 10 years after diagnosis of ulcerative colitis or Crohn disease (Latella, 2012). In Crohn disease, however, surgical removal of the affected colon does not prevent cancer from developing elsewhere in the GI tract.

Nursing Care Management

The nursing considerations in the management of patients with IBD extend beyond the immediate period of hospitalization. These interventions involve continued guidance of families in terms of (1) managing diet; (2) coping with factors that increase stress and emotional lability; (3) adjusting to a disease of remissions and exacerbations; and (4) when indicated, preparing the child and parents for the possibility of diversionary bowel surgery.

Because nutritional support is an essential part of therapy, encouraging the anorexic child to consume sufficient quantities of food is often a challenge. Successful interventions include involving the child in meal planning; encouraging small, frequent meals or snacks rather than three large meals a day; serving meals around medication schedules when diarrhea, mouth pain, and intestinal spasm are controlled; and preparing high-protein, high-calorie foods such as eggnog, milkshakes, cream soups, puddings, or custard (if lactose is tolerated). Using bran or a high-fiber diet for active IBD is questionable. Bran, even in small amounts, has been shown to worsen the condition. Occasionally, the occurrence of aphthous stomatitis further complicates adherence to dietary management. Mouth care before eating and the selection of bland foods help relieve the discomfort of mouth sores.

When NG feedings or TPN is indicated, nurses play an important role in explaining the purpose and the expected outcomes of this therapy. The nurse should acknowledge the anxieties of the child and family members and give them adequate time to demonstrate the skills necessary to continue the therapy at home if needed (see [Critical Thinking Case Study](#)).

Critical Thinking Case Study

Inflammatory Bowel Disease

Susan, a 13-year-old girl, was admitted to the hospital because of bloody diarrhea, abdominal pain, and weight loss. After a thorough evaluation, including laboratory tests, radiographic studies, and GI endoscopy procedures, the diagnosis of Crohn disease was made. Medical treatment, including corticosteroid drugs and nutritional support, was implemented during this hospitalization.

Susan has improved considerably and is to be discharged home this week. Enteral formula administered by continuous nighttime nasogastric (NG) tube infusion will be continued at home, and both Susan and her family are eager to learn how to perform these feedings. You are the nurse responsible for Susan's discharge planning. Which interventions relating to these feedings should you include in Susan's preparations for discharge?

Questions

1. Evidence: Are there sufficient data to formulate any specific interventions for discharge?
2. Assumptions: Describe some underlying assumptions about:
 - a. The goals of nutritional support for children with Crohn disease
 - b. Teaching required by an adolescent or family member who is administering NG tube feedings at home
 - c. Psychosocial issues related to Crohn disease
3. What are the priorities for discharge planning at this time?
4. Does the evidence support your conclusion?

The importance of continued drug therapy despite remission of symptoms must be stressed to the child and family members. Failure to adhere to the pharmacologic regimen can result in exacerbation of the disease (see [Compliance, Chapter 20](#)). Unfortunately, exacerbation of IBD can

occur even if the child and family are compliant with the treatment regimen; this is difficult for the child and family to cope with.

Emotional Support

The nurse should attend to the emotional components of the disease and assess any sources of stress. Frequently, the nurse can help children adjust to problems of growth restriction, delayed sexual maturation, dietary restrictions, feelings of being “different” or “sickly,” inability to compete with peers, and necessary absence from school during exacerbations of the illness (see [Impact of the Child's Chronic Illness, Chapter 17](#)).

If a permanent colectomy-ileostomy is required, the nurse can teach the child and family how to care for the ileostomy. The nurse can also emphasize the positive aspects of the surgery, particularly accelerated growth and sexual development, permanent recovery, the eliminated risk of colonic cancer in ulcerative colitis, and the normality of life despite bowel diversion. Introducing the child and parents to other ostomy patients, especially those who are the same age, is effective in fostering eventual acceptance. Whenever possible, offer continent ostomies as options to the child, although they are not performed in all centers in the United States.

Because of the chronic and often lifelong nature of the disease, families benefit from the educational services provided by organizations such as the Crohn's and Colitis Foundation of America.* If diversionary bowel surgery is indicated, the United Ostomy Associations of America[†] and the Wound, Ostomy and Continence Nurses Society[‡] are available to assist with ileostomy care and provide important psychological support through their self-help groups. Adolescents often benefit by participating in peer-support groups, which are sponsored by the Crohn's and Colitis Foundation of America.

Peptic Ulcer Disease

PUD is a chronic condition that affects the stomach or duodenum. Ulcers are described as gastric or duodenal and as primary or secondary. A **gastric ulcer** involves the mucosa of the stomach; a **duodenal ulcer** involves the pylorus or duodenum. Most **primary ulcers** are idiopathic or associated with *Helicobacter pylori* infection and tend to be chronic, occurring more frequently in the duodenum ([Blanchard and Czinn, 2016](#)). Secondary ulcers result from the stress of a severe underlying disease or injury (e.g., severe burns, sepsis, increased intracranial pressure, severe trauma, multisystem organ failure) and are more frequently gastric with an acute onset ([Blanchard and Czinn, 2016](#)).

About 1.8% to 5% of children in North America are diagnosed with PUD ([Sullivan, 2010](#)). Primary ulcers are more common in children older than 10 years old, and secondary ulcers are more common in infants and children with underlying disease, and children taking nonsteroidal antiinflammatory drugs (NSAIDs), corticosteroids, or sodium valproate medications ([Sullivan, 2010](#)).

Etiology

The exact cause of PUD is unknown, although infectious, genetic, and environmental factors are important. There is an increased familial incidence, likely due to *H. pylori*, which is known to cluster in families ([Sullivan, 2010](#)). *H. pylori* is a microaerophilic, gram-negative, slow-growing, spiral-shaped, and flagellated bacterium known to colonize the gastric mucosa in about half of the population of the world ([Ertem, 2012](#)). *H. pylori* synthesizes the enzyme urease, which hydrolyses urea to form ammonia and carbon dioxide. Ammonia then absorbs acid to form ammonium, thus raising the gastric pH. *H. pylori* may cause ulcers by weakening the gastric mucosal barrier and allowing acid to damage the mucosa. It is believed that it is acquired via the fecal–oral route, and this hypothesis is supported by finding viable *H. pylori* in feces.

In addition to ulcerogenic drugs, both alcohol and smoking contribute to ulcer formation. There is no conclusive evidence to implicate particular foods, such as caffeine-containing beverages or spicy foods, but polyunsaturated fats and fiber may play a role in ulcer formation. Psychological factors may play a role in the development of PUD, and stressful life events, dependency, passiveness, and hostility have all been implicated as contributing factors.

Pathophysiology

Most likely, the pathology is caused by an imbalance between the destructive (cytotoxic) factors and defensive (cytoprotective) factors in the GI tract. The toxic mechanisms include acid, pepsin, medications such as aspirin and NSAIDs, bile acids, and infection with *H. pylori*. The defensive factors include the mucus layer, local bicarbonate secretion, epithelial cell renewal, and mucosal blood flow. Prostaglandins play a role in mucosal defense because they stimulate both mucus and alkali secretion. The primary mechanism that prevents the development of peptic ulcer is the secretion of mucus by the epithelial and mucous glands throughout the stomach. The thick mucus layer acts to diffuse acid from the lumen to the gastric mucosal surface, thus protecting the gastric epithelium. The stomach and the duodenum produce bicarbonate, decreasing acidity on the epithelial cells and thereby minimizing the effects of the low pH. When abnormalities in the protective barrier exist, the mucosa is vulnerable to damage by acid and pepsin. Exogenous factors, such as aspirin and NSAIDs, cause gastric ulcers by inhibition of prostaglandin synthesis.

Zollinger-Ellison syndrome is rare but may occur in children who have multiple, large, or recurrent ulcers. This syndrome is characterized by hypersecretion of gastric acid, intractable ulcer disease, and intestinal malabsorption caused by a gastrin-secreting tumor of the pancreas.

Diagnostic Evaluation

Diagnosis is based on the history of symptoms, physical examination, and diagnostic testing. The focus is on symptoms such as epigastric abdominal pain, nocturnal pain, oral regurgitation, heartburn, weight loss, hematemesis, and melena (Box 22-5). History should include questions relating to the use of potentially causative substances such as NSAIDs, corticosteroids, alcohol, and tobacco. Laboratory studies may include a CBC to detect anemia, stool analysis for occult blood, liver function tests (LFTs), sedimentation rate, or CRP to evaluate IBD; amylase and lipase to evaluate pancreatitis; and gastric acid measurements to identify hypersecretion. A lactose breath test may be performed to detect lactose intolerance.

Box 22-5

Characteristics of Peptic Ulcers

Neonates

Usually gastric and secondary ulcers

Commonly a history of prematurity, respiratory distress, sepsis, hypoglycemia, or an intraventricular hemorrhage

Perforation may lead to massive bleeding

Infants to 2-Year-Old Children

Most likely to have a secondary ulcer located equally in the stomach or duodenum

Primary ulcers less common and usually located in stomach

Likely to be noticed in relation to illness, surgery, or trauma

Hematemesis, melena, or perforation

2- to 6-Year-Old Children

Primary or secondary ulcers

Located equally in stomach and duodenum

Perforation more likely in secondary ulcers

Periumbilical pain, poor eating, vomiting, irritability, nighttime waking, hematemesis, melena

Children Older than 6 Years Old

Usually primary and most often duodenal ulcers

More typical of adult type

Chance of recurrence greater

Often associated with *Helicobacter pylori*

Epigastric pain or vague abdominal pain

Nighttime waking, hematemesis, melena, and anemia possible

Radiographic studies such as an upper GI series may be performed to evaluate obstruction or malrotation, although rarely helpful in identifying ulcers in children. Fiber optic endoscopy is the most reliable procedure to detect PUD in children. A biopsy can determine the presence of *H. pylori*. A blood test can also identify the presence of the antigen to this organism. The C¹³ urea breath test measures bacterial colonization in the gastric mucosa and is often performed to determine the presence of antibodies to *H. pylori*. Polyclonal and monoclonal stool antigen tests are an accurate, noninvasive method both for the initial diagnosis of *H. pylori* and for the confirmation of its eradication after treatment (Ertem, 2012).

Therapeutic Management

The major goals of therapy for children with PUD are to relieve discomfort, promote healing, prevent complications, and prevent recurrence. Management is primarily medical and consists of administration of medications to treat the infection and to reduce or neutralize gastric acid secretion. Antacids are beneficial medications to neutralize gastric acid. Histamine (H₂) receptor antagonists (antisecretory drugs) act to suppress gastric acid production. Cimetidine (Tagamet), ranitidine (Zantac), and famotidine (Pepcid) are examples of these medications. These medications have few side effects.

PPIs (such as omeprazole, lansoprazole, pantoprazole, and esomeprazole) act to inhibit the hydrogen ion pump in the parietal cells, thus blocking the production of acid. These agents have been shown to be effective in children and adolescents but not in infants (van der Pol, Smits, van Wijk, et al, 2011).

Mucosal protective agents, such as sucralfate and bismuth-containing preparations, may be prescribed for PUD. Sucralfate is an aluminum-containing agent that forms a protective barrier over ulcerated mucosa to protect against acid and pepsin. Bismuth compounds are sometimes prescribed for the relief of ulcers, but they are used less frequently than PPIs. Although these compounds inhibit the growth of microorganisms, the mechanism of their activity is poorly understood. In combination with antibiotics, bismuth is effective against *H. pylori*. Although concern has been expressed about the use of bismuth salts in children because of potential side effects, none of these side effects has been reported when these compounds have been used in the treatment of *H. pylori* infection. These agents are available in both pill and liquid forms. Because they block the absorption of other medications, they should be given separately from other medications.

Triple-drug therapy is the standard first-line treatment regimen for *H. pylori* and has demonstrated 90% effectiveness in eradication of *H. pylori* (Ertem, 2012). Examples of drug combinations used in triple therapy are (1) bismuth, clarithromycin, and metronidazole; (2) lansoprazole, amoxicillin, and clarithromycin; and (3) metronidazole, clarithromycin, and omeprazole.

Common side effects of medications include diarrhea, nausea, and vomiting. In addition to medications, children with PUD should have a nutritious diet and avoid caffeine. Warn adolescents about gastric irritation associated with alcohol use and smoking.

Children with an acute ulcer who have developed complications, such as massive hemorrhage, require emergency care. The administration of IV fluids, blood, or plasma depends on the amount of blood loss. Replacement with whole blood or packed cells may be necessary for significant loss.

Surgical intervention may be required for complications, such as hemorrhage, perforation, or gastric outlet obstruction. Ligation of the source of bleeding or closure of a perforation is

performed. A vagotomy and pyloroplasty may be indicated in children with recurring ulcers despite aggressive medical treatment (Sullivan, 2010).

Prognosis

The long-term prognosis for PUD is variable. Many ulcers are successfully treated with medical therapy; however, primary duodenal peptic ulcers often recur. Complications such as GI bleeding can occur and extend into adult life. The effect of maintenance drug therapy on long-term morbidity remains to be established with further studies.

Nursing Care Management

The primary nursing goal is to promote healing of the ulcer through compliance with the medical regimen. If an analgesic/antipyretic is needed, acetaminophen, not aspirin or NSAIDs, is used. Critically ill neonates, infants, and children in intensive care units should receive H₂ blockers to prevent stress ulcers.

Drug Alert

Critically ill children receiving intravenous (IV) histamine (H₂) blockers should have their gastric pH values checked at frequent intervals.

For nonhospitalized children with chronic illnesses, consider the role stress plays. In children, many ulcers occur secondary to other conditions, and the nurse should be aware of family and environmental conditions that may aggravate or precipitate ulcers. Children may benefit from psychological counseling and from learning how to cope constructively with stress.

Hepatic Disorders

Acute Hepatitis

Etiology

Hepatitis is an acute or chronic inflammation of the liver that can result from infectious or noninfectious reasons. Viruses such as the hepatitis viruses, Epstein-Barr virus (EBV), and cytomegalovirus (CMV) are common causes of many types of hepatitis. Other causes of hepatitis are nonviral (abscess, amebiasis), autoimmune, metabolic, drug-induced, anatomic (choledochal duct cyst and biliary atresia [BA]), hemodynamic (shock, congestive heart failure), and idiopathic (sclerosing cholangitis and Reye syndrome). Determining the cause of acute or chronic hepatitis is important in determining the treatment and prognosis for the child (Clemente and Schwarz, 2011). Table 22-9 compares the features of hepatitis A virus (HAV), hepatitis B virus (HBV), and hepatitis C virus (HCV).

TABLE 22-9
Comparison of Types A, B, and C Hepatitis

| Characteristics | Type A | Type B | Type C |
|----------------------------|---|---|---|
| Incubation period | 15 to 50 days; average 28 days | 45 to 160 days; average 120 days | 2 to 24 weeks, average 7 to 9 weeks |
| Period of communicability | Believed to be latter half of incubation period to the first week after the onset of clinical illness | Variable Virus in blood or other body fluids during late incubation period and acute stage of disease; may persist in carrier state for years to lifetime | Begins before onset of symptoms May persist in carrier state for years |
| Mode of transmission | Principal route: Fecal-oral Rarely: Parenteral | Principal route: Parenteral Less frequent route: Oral, sexual, any body fluid Perinatal transfer: Transplacental blood (last trimester); at delivery; or during breastfeeding, especially if mother has cracked nipples | Principal route: Parenteral Non-parenteral spread possible |
| Clinical Features | | | |
| Onset | Usually rapid, acute | More insidious | Usually insidious |
| Fever | Common and early | Less frequent | Less frequent |
| Anorexia | Common | Mild to moderate | Mild to moderate |
| Nausea and vomiting | Common | Sometimes present | Mild to moderate |
| Rash | Rare | Common | Sometimes present |
| Arthralgia | Rare | Common | Rare |
| Pruritus | Rare | Sometimes present | Sometimes present |
| Jaundice | Present (many cases anicteric) | Present | Present |
| Immunity | Present after one attack; no crossover to type B or C | Present after one attack; no crossover to type A or C | Present after one attack; no crossover to type A or B |
| Carrier state | No | Yes | Yes |
| Chronic infection | No | Yes | Yes |
| Prophylaxis | | | |
| Immune globulin (IG) | Passive immunity Successful, especially in early incubation period and preexposure prophylaxis | Passive immunity Inconsistent benefits; probably of no use | Not currently recommended by CDC |
| HAV vaccine | Two inactivated vaccines approved for all children 12 to 23 months old: Havrix and Vaqta; given in a two-dose schedule (6 months between doses) | | |
| HBV immune globulin (HBIG) | No benefit | Post-exposure protection possible if given immediately after definite exposure | No benefit |
| HBV vaccine | No benefit | Provides active immunity Universal vaccination recommended for all newborns | No benefit |
| Mortality rate | 0.1% to 0.2% | 0.5% to 2.0% in uncomplicated cases; may be higher in complicated cases | 1% to 2% in uncomplicated cases; may be higher in complicated cases |

CDC, Centers for Disease Control and Prevention; HAV, hepatitis A virus; HBV, hepatitis B virus.

Hepatitis A

Hepatitis A incidence in the United States has declined 92% since the introduction of a vaccine in 1995 with approximately 21,000 cases annually in the United States (Matheny and Kingery, 2012). The virus is spread directly or indirectly by the fecal-oral route by ingestion of contaminated foods, direct exposure to infected fecal material, or close contact with an infected person. The virus is particularly prevalent in developing countries with poor living conditions, inadequate sanitation, crowding, and poor personal hygiene practices. The spread of HAV has been associated with improper food handling and high-risk areas, such as households with infected persons, residential centers for the disabled, and daycare centers. The average incubation period is about 28 days, with a range of 15 to 50 days (Matheny and Kingery, 2012). Fecal shedding of the virus can occur for 2 weeks before and for 1 week after the onset of jaundice. During this time, although the individual is asymptomatic, the virus is most likely to be transmitted. Infants with HAV infection are likely to be asymptomatic (anicteric hepatitis). Children often have diarrhea, and their symptoms are frequently

attributed to gastroenteritis. Younger children rarely develop jaundice; however, 70% of older children and adults infected with HAV develop clinical signs with icteric hepatitis (Matheny and Kingery, 2012). The prognosis of HAV infection is usually good, and complications are rare.

Hepatitis B

Although the incidence of HBV is declining after the introduction of a universal immunization program, approximately 1.25 million people in the United States are infected with HBV (Jensen and Balistreri, 2016). Hepatitis B can be an acute or chronic infection, ranging from an asymptomatic, limited infection to fatal, fulminant (rapid and severe) hepatitis (Clemente and Schwarz, 2011). There are no environmental or animal reservoirs for HBV. Humans are the main source of infections. HBV may be transmitted parenterally, percutaneously, or transmucosally. Hepatitis B surface antigen (HBsAg) has been found in all body fluids, including feces, bile, breast milk, sweat, tears, vaginal secretions, and urine, but only blood, semen, and saliva have been found to contain infectious HBV particles. HBV infection from human bites has been documented, but transmission from feces has not. HBV has been acquired after blood transfusion, but the likelihood of this has been reduced through blood product screening procedures. Adults whose occupations are associated with considerable exposure to blood or blood products, such as health care workers, are at an increased risk of contracting HBV.

Most HBV infection in children is acquired perinatally. Transmission from mother to infant during the perinatal period (e.g., blood exposure during delivery) results in chronic infection in up to 90% of infants if the mother is positive for HBsAg and HBeAg (Paganelli, Stephenne, and Sokal, 2012). HBsAg has been inconsistently detected in breast milk, but no increased risk of transmission has been found and breastfeeding is currently recommended after infant immunization (Clemente and Schwarz, 2011). Infants and children who are not infected during the perinatal period remain at high risk for acquiring person-to-person transmission from their mother, with a 30% incidence of transmission during the first 5 years of life (Clemente and Schwarz, 2011).

HBV infection occurs in children and adolescents in specific high-risk groups, which are (1) individuals with hemophilia or other disorders who have received multiple transfusions, (2) children and adolescents involved in IV drug abuse, (3) institutionalized children, (4) preschool children in endemic areas, and (5) individuals engaged in sexual activity with an infected partner. The incubation period for HBV infection ranges from 45 to 160 days with an average of 120 days (Jensen and Balistreri, 2016). HBV infection can cause a carrier state and lead to chronic hepatitis with eventual cirrhosis or hepatocellular carcinoma in adulthood.

Hepatitis C

HCV is the most common cause of chronic liver disease with an estimated 4 million people in the United States (Jensen and Balistreri, 2016). HCV is transmitted parenterally through exposure to blood and blood products from HCV-infected persons, whereas perinatal transmission is the most common mode of transmission of children (Jensen and Balistreri, 2016). Recent improvements in donor screening and inactivation procedures for blood products, such as the factor concentrates used for hemophilia patients, have significantly reduced the risk of transmission through blood products.

The clinical course is variable. The incubation period for HCV ranges from 2 to 24 weeks, with an average of 7 to 9 weeks (Jensen and Balistreri, 2016). The natural history of the disease in children is not well defined. Some children may be asymptomatic, but hepatitis C can become a chronic condition and can cause cirrhosis and hepatocellular carcinoma. About 85% of individuals infected with HCV develop chronic disease (Jensen and Balistreri, 2016).

Hepatitis D

Hepatitis D occurs rarely in children and must occur in individuals already infected with HBV (Clemente and Schwarz, 2011). Hepatitis D virus (HDV) is a defective RNA virus that requires the helper function of HBV. The incubation period is 2 to 8 weeks but with co-infection of HBV, the incubation period is similar to an HBV infection (Jensen and Balistreri, 2016). HDV infection occurs through blood and sexual contact and commonly occurs among drug abusers, individuals with hemophilia, and persons immigrating from endemic areas.

Hepatitis E

Hepatitis E was formerly known as non-A, non-B hepatitis. Transmission may occur through the fecal–oral route or from contaminated water. The incubation period ranges from 15 to 60 days, with an average of 40 days (Jensen and Balistereri, 2016). This illness is uncommon in children, does not cause chronic liver disease, is not a chronic condition, and has no carrier state. However, it can be a devastating disease among pregnant women, with an unusually high fatality rate.

Pathophysiology

Pathologic changes occur primarily in the parenchymal cells of the liver and result in variable degrees of swelling; infiltration of liver cells by mononuclear cells; and subsequent degeneration, necrosis, and fibrosis. Structural changes within the hepatocyte account for altered liver functions, such as impaired bile excretion, elevated transaminase levels, and decreased albumin synthesis. The disorder may be self-limiting with regeneration of liver cells without scarring, leading to a complete recovery. However, some forms of hepatitis do not result in complete return of liver function. These include fulminant hepatitis, which is characterized by a severe, acute course with massive destruction of the liver tissue causing liver failure and high mortality within 1 to 2 weeks, and subacute or chronic active hepatitis, which is characterized by progressive liver destruction, uncertain regeneration, scarring, and potential cirrhosis.

The progression of liver disease is characterized pathologically by four stages: (1) stage one is characterized by mononuclear inflammatory cells surrounding small bile ducts; (2) in stage two, there is proliferation of small bile ductules; (3) stage three is characterized by fibrosis or scarring; and (4) stage four is cirrhosis.

Clinical Manifestations

The clinical manifestations and course of uncomplicated acute viral hepatitis are similar for most of the hepatitis viruses. Usually the prodromal, or anicteric, phase (absence of jaundice) lasts 5 to 7 days. Anorexia, malaise, lethargy, and easy fatigability are the most common symptoms. Fever may be present, especially in adolescents. Nausea, vomiting, and epigastric or right upper quadrant abdominal pain or tenderness may occur. Arthralgia and skin rashes may occur and are more likely in children with hepatitis B than those with hepatitis A. The transaminases, rather than bilirubin, are often elevated in acute hepatitis, and hepatomegaly may be present. Some mild cases of acute viral hepatitis do not cause symptoms or can be mistaken for influenza.

In young children, most of the prodromal symptoms disappear with the onset of jaundice, or the icteric phase. Many children with acute viral hepatitis, however, never develop jaundice. If jaundice occurs, it is often accompanied by dark urine and pale stools. Pruritus may accompany jaundice and can be bothersome for children.

Children with chronic active hepatitis may be asymptomatic but more commonly have nonspecific symptoms of malaise, fatigue, lethargy, weight loss, or vague abdominal pain. Hepatomegaly may be present, and the transaminases are often very high, with mild to severe hyperbilirubinemia.

Fulminant hepatitis is due primarily to HBV or HCV. Many children with fulminant hepatitis develop characteristic clinical symptoms and rapidly develop manifestations of liver failure, including encephalopathy, coagulation defects, ascites, deepening jaundice, and an increasing WBC count. Changes in mental status or personality indicate impending liver failure. Although children with acute hepatitis may have hepatomegaly, a rapid decrease in the size of the liver (indicating loss of tissue due to necrosis) is a serious sign of fulminant hepatitis. Complications of fulminant hepatitis include GI bleeding, sepsis, renal failure, and disseminated coagulopathy.

Diagnostic Evaluation

Diagnosis is based on the history; physical examination; and serologic markers for hepatitis A, B, and C. No LFT is specific for hepatitis, but serum aspartate aminotransferase (AST) and serum alanine aminotransferase (ALT) levels are markedly elevated. Serum bilirubin levels peak 5 to 10 days after clinical jaundice appears. Histologic evidence from liver biopsy may be required to establish the diagnosis and to assess the severity of the liver disease. Serologic markers indicate the antibodies or antigens formed in response to the specific virus and confirm the diagnosis. Serum immunologic tests are not available to detect HAV antigen, but there are two HAV antibody tests: anti-HAV immunoglobulin G (IgG) and immunoglobulin M (IgM). Anti-HAV antibodies are present at the onset of the disease and persist for life. A positive anti-HAV antibody test can

indicate acute infection, immunity from past infection, passive antibody acquisition (e.g., from transfusion, serum immunoglobulin infusion), or immunization. To diagnose an acute or recent HAV infection, a positive anti-HAV IgM test result that is present with the onset of the disease and that persists for only 2 or 3 days is required.

Diagnosis of hepatitis B is confirmed by the detection of various hepatitis virus antigens and the antibodies that are produced in response to the infection. These antibodies and antigens and their significance include:

HBsAg: Hepatitis B surface antigen (found on the surface of the virus), indicating ongoing infection or carrier state

Anti-HBs: Antibody to surface antigen HBsAg, indicating resolving or past infection

HBcAg: Hepatitis B core antigen (found on the inner core of the virus), detected only in the liver

Anti-HBc: Antibody to core antigen HBcAg, indicating ongoing or past infection

HBeAg: Hepatitis B antigen (another component of the HBV core), indicating active infection

Anti-HBe: Antibody to HBeAg, indicating resolving or past infection

IgM anti-HBc: IgM antibody to core antigen

Tests are available for detection of all the HBV antigens and antibodies except HBcAg. HBsAg is detectable during acute infection. Presence of HBsAg indicates that the individual has been infected with the hepatitis virus. If the infection is self-limiting, HBsAg disappears in most patients before serum anti-HBs can be detected (termed the *window phase of infection*). IgM anti-HBc is highly specific in establishing the diagnosis of acute infection, as well as during the window phase in older children and adults. However, IgM anti-HBc usually is not present in perinatal HBV infection. Clinical improvement is usually associated with a decrease in or disappearance of these antigens followed by the appearance of their antibodies. For example, anti-HBc of the IgM class often occurs early in the disease followed by a rise in anti-HBc of the IgG class. Because the antibodies persist indefinitely, they are used to identify the carrier state (individuals with HBV who have no clinical disease but are able to transmit the organism). Persons with chronic HBV infection have circulating HBsAg and anti-HBc, and on rare occasions, anti-HBsAg is present. Both anti-HBs and anti-HBc are detected in persons with resolved infection, but anti-HBs alone are present in individuals who have been immunized with the HBV vaccine.

HCV RNA is the earliest serologic marker for HCV. HCV-RNA can be detected during the incubation period before symptoms of HCV disease are expressed. A positive HCV-RNA result indicates active infection, and persistence of HCV-RNA indicates chronic infection. A negative test result correlates with resolution of the disease. HCV-RNA is also used to determine patient response to antiviral therapy for HCV.

The history of all patients should include questions to seek evidence of (1) contact with a person known to have hepatitis, especially a family member; (2) unsafe sanitation practices, such as contaminated drinking water; (3) ingestion of certain foods, such as clams or oysters (especially from polluted water); (4) multiple blood transfusions; (5) ingestion of hepatotoxic drugs, such as salicylates, sulfonamides, antineoplastic agents, acetaminophen, and anticonvulsants; and (6) parenteral administration of illicit drugs or sexual contact with a person who uses these drugs.

Therapeutic Management

The goals of management include early detection, support and monitoring of the disease, recognition of chronic liver disease, and prevention of spread of the disease. Special high-protein, high-carbohydrate, low-fat diets are generally not of value. The use of corticosteroids alone or with immunosuppressive drugs is not advocated in the treatment of chronic viral hepatitis. However, steroids have been used to treat chronic autoimmune hepatitis. Hospitalization is required in the event of coagulopathy or fulminant hepatitis.

Therapy for hepatitis depends on the severity of inflammation and the cause of the disorder. HAV is treated primarily with supportive care. The US Food and Drug Administration approved several medications for treatment of children with HBV and HCV. Human interferon alpha is being

used successfully in the treatment of chronic hepatitis B and C in children. Lamivudine is used for the treatment of HBV. It is well tolerated with no significant side effects and is approved for children older than 3 years old (Paganelli, Stephenne, and Sokal, 2012). Combined therapy with lamivudine and interferon alpha reduces the rate of antiviral resistance compared with lamivudine monotherapy (Paganelli, Stephenne, and Sokal, 2012). Adefovir is used to treat HBV in children older than 12 years old. Entecavir is a recently approved treatment for HBV in adolescents 16 years old or older (Paganelli, Stephenne, and Sokal, 2012). Pegylated interferon, interferon alpha-2b, and ribavirin have been approved for use in the treatment of HCV infections in children 3 years old or older (Jensen and Balistereri, 2016). Products such as telbivudine and tenofovir are under current investigation in clinical trials, largely with adult patients.

Prevention

Proper hand washing and standard precautions prevent the spread of viral hepatitis. Prophylactic use of standard immune globulin is effective in preventing hepatitis A in situations of preexposure (e.g., anticipated travel to areas where HAV is prevalent) or within 2 weeks of exposure.

Hepatitis B immune globulin (HBIG) is effective in preventing HBV infection after one-time exposures such as accidental needle punctures or other contact of contaminated material with mucous membranes and should be given to newborns whose mothers are HBsAg positive. HBIG is prepared from plasma that contains high titers of antibodies against HBV. HBIG should be given within 72 hours of exposure.

Vaccines have been developed to prevent HAV and HBV infection (see Table 22-9). HBV vaccination is recommended for all newborns and children who did not receive the vaccination as a newborn (see Immunizations, Chapter 6). Because HDV cannot be transmitted in the absence of HBV infection, it is possible to prevent HDV infection by preventing HBV infection. Routine serologic testing for anti-HCV of children older than 12 months who were born to women previously identified as being infected with HCV is also recommended (Jensen and Balistereri, 2016).

Prognosis

The prognosis for children with hepatitis is variable and depends on the type of virus and the child's age and immunocompetency. Hepatitis A and E are usually mild, brief illnesses with no carrier state. Hepatitis B can cause a wide spectrum of acute and chronic illness. Infants are more likely than older children to develop chronic hepatitis. Hepatocellular carcinoma during adulthood is a potentially fatal complication of chronic HBV infection. Hepatitis C frequently becomes chronic, and cirrhosis may develop in these children.

Nursing Care Management

Nursing objectives depend largely on the severity of the hepatitis, the medical treatment, and factors influencing the control and transmission of the disease. Because children with mild viral hepatitis are frequently cared for at home, it is often the nurse's responsibility to explain any medical therapies and infection control measures. When further assistance is needed for parents to comply with instructions, a public health nursing referral is necessary.

Encourage a well-balanced diet and a schedule of rest and activity adjusted to the child's condition. Because the child with HAV is not infectious within 1 week after the onset of jaundice, the child may feel well enough to resume school shortly thereafter. Caution parents about administering any medication to the child because normal doses of many drugs may become dangerous because of the liver's inability to detoxify and excrete them.

Standard precautions are followed when children are hospitalized. However, these children are not usually isolated in a separate room unless they are fecally incontinent or their toys and other personal items are likely to become contaminated with feces. Discourage children from sharing their toys.

Hand washing is the single most effective measure in prevention and control of hepatitis in any setting. Parents and children need an explanation of the usual ways in which hepatitis is spread (fecal-oral route and parenteral route). Parents should also be aware of the recommendation for universal vaccination against HBV for newborns and adolescents (see Chapter 6).

In young people with HBV infection who have a known or suspected history of illicit drug use, the nurse has the responsibility of helping them realize the associated dangers of drug abuse,

stressing the parenteral mode of transmission of hepatitis, and encouraging them to seek counseling through a drug program.

Cirrhosis

Cirrhosis occurs at the end stage of many chronic liver diseases, including BA and chronic hepatitis. Infectious, autoimmune, toxic injury, and chronic diseases such as hemophilia and cystic fibrosis can cause severe liver damage. A cirrhotic liver is irreversibly damaged.

Clinical manifestations of cirrhosis include jaundice, poor growth, anorexia, muscle weakness, and lethargy. Ascites, edema, GI bleeding, anemia, and abdominal pain may be present in children with impaired intrahepatic blood flow. Pulmonary function may be impaired because of pressure against the diaphragm caused by hepatosplenomegaly and ascites. Dyspnea and cyanosis may occur, especially on exertion. Intrapulmonary arteriovenous shunts may develop, which can also cause hypoxemia. Spider angiomas and prominent blood vessels on the upper torso are often present.

Diagnostic Evaluation

The diagnosis of cirrhosis is based on (1) the history, especially in regard to prior liver disease, such as hepatitis; (2) physical examination, particularly hepatosplenomegaly; (3) laboratory evaluation, especially LFTs such as bilirubin and transaminases, ammonia, albumin, cholesterol, and prothrombin time; and (4) liver biopsy for characteristic changes. Doppler ultrasonography of the liver and spleen is useful to confirm ascites, to evaluate blood flow through the liver and spleen, and to determine patency and size of the portal vein if liver transplantation is considered.

Therapeutic Management

Unfortunately, there is no successful treatment to arrest the progression of cirrhosis. The goals of management include monitoring liver function and managing specific complications such as esophageal varices and malnutrition. Assessment of the child's degree of liver dysfunction is important so that the child can be evaluated for transplantation at the appropriate time.

Liver transplantation has improved the prognosis substantially for many children with cirrhosis. The combination of new immunosuppressive medications and new surgical techniques has resulted in 83% to 91% 1-year survival rates in many large hospital centers (Kamath and Olthoff, 2010). The policy governing the allocation of livers for transplantation by the United Network for Organ Sharing allows pediatric patients younger than 12 years old, those with acute fulminant liver failure, or those with chronic liver disease to be placed at the top of the network's transplantation lists (Kamath and Olthoff, 2010). Although this change has benefited many pediatric patients, the shortage of available donors for children continues to dictate transplantation decisions, and many children continue to die while waiting for a suitable donor.

Nutritional support is an important therapy for children with cirrhosis and malnutrition. Supplements of fat-soluble vitamins are often required, and mineral supplements may be indicated. In some instances, aggressive nutritional support in the form of enteral feedings or PN may be necessary.

Esophageal and gastric varices can be life-threatening complications of portal hypertension. Acute hemorrhage is managed with IV fluids, blood products, vitamin K if needed to correct coagulopathy, vasopressin or somatostatin, and gastric lavage. If acute hemorrhage persists, the most common secondary approach is endoscopic sclerotherapy or endoscopic banding ligation (El-Tawil, 2012). Balloon tamponade with a Sengstaken-Blakemore tube may be indicated for the unstable patient with acute hemorrhage (El-Tawil, 2012). Ascites can be managed by sodium and fluid restrictions and diuretics. Severe ascites with respiratory compromise can be managed with albumin infusions or by paracentesis.

Although the full mechanism of hepatic encephalopathy is unknown, failure of the damaged liver to remove endogenous toxins, such as ammonia, plays a role. Treatment is directed at limiting the ammonia formation and absorption that occur in the bowel, especially with the drugs neomycin and lactulose. Because ammonia is formed in the bowel by the action of bacteria on ingested protein, neomycin reduces the number of intestinal bacteria so that less ammonia is produced. The fermentation of lactulose by colonic bacteria produces short-chain fatty acids that lower the colonic pH, thereby inhibiting bacterial metabolism. This decreases the formation of ammonia from

bacterial metabolism of protein.

Prognosis

The success of liver transplantation has revolutionized the approach to liver cirrhosis. Liver failure and cirrhosis are indications for transplantation. Careful monitoring of the child's condition and quality of life are necessary to evaluate the need for and timing of transplantation.

Nursing Care Management

Several factors influence nursing care of the child with cirrhosis, including the cause of the cirrhosis, the severity of complications, and the prognosis. The prognosis is often poor unless successful liver transplantation occurs. Therefore, nursing care of the child is similar to that for any child with a life-threatening illness (see [Chapter 17](#)). Hospitalization is required when complications such as hemorrhage, severe malnutrition, or hepatic failure occur. Nursing assessments are directed at monitoring the child's condition, and interventions are aimed at treatment of specific complications. If liver transplantation is an option, the family needs support and assistance to cope (see [Family-Centered Care](#) box).

Family-Centered Care

End-Stage Liver Disease

In many cases, the child with liver disease and the family must cope with an uncertain progression of the disease. The only hope for long-term survival may be liver transplantation. Transplantation can be successful, but the waiting period may be long because there are many more children in need of organs than there are donors. The procedure is expensive and is performed only at designated medical centers, which are often far from the family's home. The nurse should recognize the unique stresses of coping with end-stage liver disease and waiting for transplantation and assist the family in coping with these stressors. The assistance of social workers and support from other parents can be beneficial.

Biliary Atresia

Biliary atresia (BA), or extrahepatic biliary atresia (EHBA), is a progressive inflammatory process that causes both intrahepatic and extrahepatic bile duct fibrosis, resulting in eventual ductal obstruction. The incidence of BA is approximately 1 in 10,000 to 15,000 live births ([Hassan and Balistreri, 2016](#)). Associated malformations include polysplenia, intestinal atresia, and malrotation of the intestine. BA, if untreated, usually leads to cirrhosis, liver failure, and death ([Box 22-6](#)).

Box 22-6

Clinical Manifestations of Extrahepatic Biliary Atresia

Jaundice

- Earliest manifestation and most striking feature of disorder
- First observed in sclera
- Usually not apparent until 2 to 3 weeks old after resolution of neonatal jaundice

Dark yellow urine

Stools lighter than expected or white or tan

Hepatomegaly and abdominal distention common

Splenomegaly occurs later

Poor fat metabolism results in:

- Poor weight gain
- Failure to thrive

Pruritus

Irritability; difficulty comforting infant

Etiology and Pathophysiology

The exact cause of BA is unknown, although immune- or infection-mediated mechanisms may be responsible for the progressive process that results in complete obliteration of the bile ducts. BA is not seen in fetuses or stillborn or newborn infants. This suggests that BA is acquired late in gestation or in the perinatal period and is manifested a few weeks after birth. The majority of cases of BA (85%) have a complete obliteration of the extrahepatic biliary tree at or above the porta hepatis (Hassan and Balistreri, 2016).

Many infants with BA are full term and appear healthy at birth. If jaundice persists beyond 2 weeks old, especially if the direct (conjugated) serum bilirubin is elevated, the nurse should suspect BA. The urine may be dark, and the stools often become progressively acholic or gray, indicating absence of bile pigment. Hepatomegaly is present early in the course of the disease, and the liver is firm on palpation.

Diagnostic Evaluation

Early diagnosis is critical to the child with EHBA; the outcome in children surgically treated before 2 months old is much better than in patients with delayed treatment. The diagnosis of BA is suspected on the basis of the history, physical findings, and laboratory studies. Laboratory tests include a CBC, electrolytes, bilirubin levels, and liver function studies. Additional laboratory analyses, including α_1 -antitrypsin level, TORCH titers and other intrauterine infections (see [Maternal Infections, Chapter 8](#)), hepatitis serology, and urine CMV may be indicated to rule out other conditions that cause persistent cholestasis and jaundice. Abdominal ultrasonography allows inspection of the liver and biliary system. The patency of the extrahepatic biliary system will be demonstrated by a nuclear scintiscan using technetium-99m iminodiacetic acid (^{99m}Tc IDA) or hepatobiliary iminodiacetic acid (HIDA) scan. If there is no evidence of radioactive material excreted into the duodenum, BA is the most probable diagnosis. Because the nuclear scan may take up to 5 days for the results, a percutaneous liver biopsy is probably the most useful method of diagnosing BA (Hassan and Balistreri, 2016). The definitive diagnosis of BA is further established during an exploratory laparotomy and an intraoperative cholangiogram that demonstrates complete obstruction at some level of the biliary tree.

Therapeutic Management

The primary surgical treatment of BA is hepatic portoenterostomy (Kasai procedure) in which a segment of intestine is anastomosed to the resected porta hepatis to attempt bile drainage. A Roux-en-Y jejunal limb is then anastomosed to the porta hepatis (a Y-shaped anastomosis performed to provide bile drainage without reflux). After the Kasai procedure, approximately one third of infants become jaundice free and regain normal liver function. Another one third of infants demonstrate liver damage; however, they may be supported by medical and nutritional interventions. A final third require liver transplantation.

Medical management of BA is primarily supportive. It includes nutritional support with infant formulas that contain medium-chain triglycerides and essential fatty acids. Supplementation with fat-soluble vitamins (A, D, E, and K); a multivitamin; and minerals, including iron, zinc, and

selenium, is usually required. Aggressive nutritional support in the form of continuous gastrostomy feedings or TPN may be indicated for moderate to severe growth failure; the enteral solution should be low in sodium. Phenobarbital may be prescribed after hepatic portoenterostomy to stimulate bile flow, and ursodeoxycholic acid may be used to decrease cholestasis and the intense pruritus from jaundice. In cases of advanced liver dysfunction, management is the same as in infants with cirrhosis.

Prognosis

Untreated BA results in progressive cirrhosis and death in most children by 10 years old (Baumann and Ure, 2012). The Kasai procedure improves the prognosis but is not a cure. Biliary drainage can often be achieved if the surgery is done before the intrahepatic bile ducts are destroyed, and the success rate decreases to 20% if surgery is performed in an infant greater than 3 months old (Baumann and Ure, 2012). Long-term survival rates of 75% to 90% have been reported in children who receive the Kasai procedure (Baumann and Ure, 2012). However, even with successful bile drainage, many children ultimately develop liver failure and require liver transplantation.

Advances in surgical techniques and the use of immunosuppressive and antifungal drugs have improved the success of transplantation to survival rates of 80% to 90% (Baumann and Ure, 2012). The major obstacle continues to be a shortage of suitable infant donors.

Nursing Care Management

Nursing interventions for the child with BA include support of the family before, during, and after surgical procedures and education regarding the treatment plan. In the postoperative period of a hepatic portoenterostomy, nursing care is similar to that following any major abdominal surgery. Teaching includes the proper administration of medications. Administration of nutritional therapy, including special formulas, vitamin and mineral supplements, gastrostomy feedings, or parenteral nutrition, is an essential nursing responsibility. Growth failure in such infants is common, and increased metabolic needs combined with ascites, pruritus, and nutritional anorexia constitute a challenge for care. The nurse teaches caregivers how to monitor and administer nutritional therapy in the home. Pruritus may be a significant problem that is addressed by drug therapy or comfort measures such as baths in colloidal oatmeal compounds and trimming of fingernails. The risk of complications of BA, such as cholangitis, portal hypertension, GI bleeding, and ascites, should be explained to the caregivers.

These children and their families require special psychosocial support. The uncertain prognosis, discomfort, and waiting for transplantation produce considerable stress. In addition, extended hospitalizations, pharmacologic therapy, and nutritional therapy can impose significant financial burdens on the family, as with any chronic condition. The Children's Liver Association for Support Services* and the American Liver Foundation† provide educational materials, programs, support systems for parents of children with liver disease.

Structural Defects

Cleft Lip and Cleft Palate

Clefts of the lip (CL) and palate (CP) are facial malformations that occur during embryonic development and are the most common congenital deformities in the United States. They may appear separately or, more often, together.

The palate can be divided into the primary and secondary palates. The primary palate consists of the medial portion of the upper lip and the portion of the alveolar ridge that contains the central and lateral incisors. The secondary palate consists of the remaining portion of the hard palate and all of the soft palate. CL may vary from a small notch in the upper lip to a complete cleft extending into the base of the nose, including the lip and the alveolar ridge (Fig. 22-4). CL can be unilateral or bilateral. Deformed dental structures are associated with CL. Isolated CP occurs in the midline of the secondary palate and may also vary from a bifid uvula (the mildest form of CP) to a complete cleft extending from the soft palate to the hard palate.

FIG 22-4 A, Cleft lip (CL) repair at 16 weeks old. Note the elbow restraints. B, CL 3 weeks after surgical repair. (Photos courtesy of E. Danks.)

Cleft lip and palate (CL/P) is more common than CP alone and varies by ethnicity. The occurrence is 1 in 750 births in whites, 1 in 500 births in Asians, 1 in 300 births in American Indians, and 1 in 2500 births in African Americans (Tinanoff, 2016). CL/P tends to be more common in males, and isolated CP occurs more frequently in females.

Etiology

Cleft deformities may be an isolated anomaly, or they may occur with a recognized syndrome. CL/P and CP are distinct from isolated CP. Clefts of the secondary palate alone are more likely to be associated with syndromes than are isolated CL or CL/P.

Most cases of CL and CP have multifactorial inheritance, which is generally caused by a combination of genetic and environmental factors. Researchers do not yet know which gene(s) are responsible for clefting or to what extent environmental factors impact the developing structures. Exposure to teratogens such as alcohol, cigarette smoking, anticonvulsants, steroids, and retinoids are associated with higher rates of oral clefting. Folate deficiency is also a risk factor for clefting.

Pathophysiology

Cleft deformities represent a defect in cell migration that results in a failure of the maxillary and premaxillary processes to come together between the fourth and tenth weeks of embryonic development. Although often appearing together, CL and CP are distinct malformations embryologically, occurring at different times during the developmental process. Merging of the primary palate (upper lip and alveolus bilaterally) is completed by the seventh week of gestation. Fusion of the secondary palate (hard and soft palate) takes place later, between the seventh and tenth weeks of gestation. In the process of migrating to a horizontal position, the palates are separated by the tongue for a short time. If there is delay in this movement or if the tongue fails to descend soon enough, the remainder of development proceeds, but the palate never fuses.

Diagnostic Evaluation

CL and CL/P are apparent at birth. CP is less obvious than CL and may not be detected immediately without a thorough assessment of the mouth. CP is identified through visual examination of the oral cavity or when the examiner places a gloved finger directly on the palate. Clefts of the hard and soft palate form a continuous opening between the mouth and the nasal cavity. The severity of the CP has an impact on feeding; the infant is unable to create suction in the oral cavity that is necessary for feeding. However, in most cases, the infant's ability to swallow is normal.

Prenatal diagnosis with fetal ultrasonography is not reliable until the soft tissues of the fetal face can be visualized at 13 to 14 weeks. About 20% to 30% of infants with CL and CL/P are prenatally diagnosed through ultrasonography (Robbins, Damiano, Druschel, et al, 2010), although infants with CP only are rarely diagnosed prenatally.

Therapeutic Management

Treatment of the child with CL and CP involves the cooperative efforts of a multidisciplinary health care team, including pediatrics, plastic surgery, orthodontics, otolaryngology, speech/language pathology, audiology, nursing, and social work. Management is directed toward closure of the cleft(s), prevention of complications, and facilitation of normal growth and development in the child.

Surgical Correction of Cleft Lip

CL repair typically occurs at most centers between 2 and 3 months old. The two most common procedures for repair of CL are the Fisher repair and the Millard rotational advancement technique. Surgeons often use a combination of techniques to address individual differences. Improved surgical techniques and postoperative wound care have minimized scar retraction, and in the absence of infection or trauma, most heal very well (see Fig. 22-4). Nasoalveolar molding may also be used to bring the cleft segments closer together before definitive CL repair, reducing the need for CL revision. Optimal cosmetic results, however, may be difficult to obtain in severe defects. Additional revisions may be necessary at a later age.

Surgical Correction of Cleft Palate

CP repair typically occurs before 12 months of age to enhance normal speech development (Tinanoff, 2016). The most common techniques to repair CP include the Veau-Wardill-Kilner V-Y pushback procedure and the Furlow double-opposing Z-plasty. Approximately 20% to 30% of children with repaired CP will need a secondary surgery to improve velopharyngeal closure for speech. Secondary procedures may include palatal lengthening, pharyngeal flap, sphincter pharyngoplasty, or posterior pharyngeal wall augmentation. If the child is not a candidate for surgical revision to improve velopharyngeal function, prosthetic management should be considered.

Prognosis

Children with CL may require multiple surgeries to achieve optimal aesthetic outcomes but are not at risk for increased speech problems. Although some children with CP and CL/P do not require speech therapy, many have some degree of speech impairment that requires speech therapy at some point throughout childhood. Articulation errors result from a history of velopharyngeal dysfunction, incorrect articulatory placement, improper tooth alignment, and varying degrees of hearing loss. Improper drainage of the middle ear as a result of inefficient function of the eustachian tube relating to the history of CP contributes to recurrent otitis media, which leads to conductive hearing loss in many children with CP; many children with clefts will have pressure-equalization tubes placed. Extensive orthodontics and prosthodontics may be needed to correct malposition of the teeth and maxillary arches. Academic achievement, social adjustment, and behavior should be monitored, particularly in children with syndromic cleft conditions.

Nursing Care Management

The immediate nursing problems for an infant with CL/P deformities are related to feeding. Parents of newborns with clefts place high priority on learning how to feed their infants and identify when they are sick, but they also express interest in learning about the infant's "normal" features. Whenever possible, they should be referred to a comprehensive CP team.

Feeding

Feeding the infant with a cleft presents a challenge to nurses and parents. Growth failure in infants with CL/P or CP has been attributed to preoperative feeding difficulties. After surgical repair, most infants who have isolated CL, CP, or CL/P with no associated syndromes gain weight or achieve adequate weight and height for age.

CL may interfere with an infant's ability to achieve an adequate anterior lip seal. An infant with an isolated CL typically has no difficulty breastfeeding because the breast tissue is able to conform to the cleft. If bottle fed, an infant with an isolated CL may have greater success using bottles with a wide base of the nipple, such as a Playtex nurser or a NUK (orthodontic) nipple. Cheek support (squeezing the cheeks together to decrease the width of the cleft) may be useful in improving lip seal during feeding.

Infants with CP and CL/P are often unable to feed using conventional methods before surgical management. La Leche League International reports that "over time, lactation consultants have found that feeding exclusively at the breast is a difficult goal for all but a few infants with uncorrected cleft palates" (Cleft Palate Foundation, 2009). CP reduces the infant's ability to suck, which interferes with breastfeeding and traditional bottle feeding. Modifications to positioning, bottle selection, and feeder supportive techniques can help infants with CP feed efficiently. Begin by positioning an infant with CP in an upright position with the head supported by the caregiver's hand or cradled in the arm; this position allows gravity to assist with the flow of the liquid so that it is swallowed instead of resulting in a loss of liquid through the nose.

Suction is almost certainly impaired in infants with CP because the velum is unable to elevate and separate the oral nasal cavities while generating adequate negative intraoral pressure. Several types of bottles work well with infants unable to generate adequate suction, including the Special Needs Feeder (formerly Haberman), the Pigeon bottle, and the Mead-Johnson Cleft Palate Nurser. The Special Needs Feeder and the Pigeon bottles use a one-way flow valve that allows the infant to feed successfully by compressing the nipple with either the intact segments of the palate and the mandible or tongue. With the one-way flow valve in place, the liquid flows into the oral cavity

rather than back into the bottle chamber when the nipple is compressed. The Special Needs Feeder also has a large nipple chamber that allows the feeder to provide extra assistance by squeezing the chamber if needed. The tip of the Special Needs Feeder has a slit cut, which allows the feeder to control the flow of liquid by positioning the slit vertically or horizontally within the mouth, which can reduce choking and gagging. The Pigeon bottle comes with two nipple sizes—standard and small, each with a Y-cut nipple that increases the flow of liquid. The third bottle, the Mead Johnson Cleft Palate Nurser, is a squeezable bottle with a long, thin X-cut nipple; this bottle requires the feeder to rhythmically squeeze the bottle throughout the feeding and does not require the infant to actively compress the nipple during the feeding.

Infants with clefts tend to swallow excessive air during feedings, so it is important to pause during feedings and burp the infant. Some CP specialists advocate for the use of feeding obturators to assist with feeding; these devices may increase compression surfaces within the oral cavity but do not improve feeding efficiency or growth within the first year of life (Jindal and Khan, 2013).

Regardless of the feeding method used, the mother should begin feeding the infant as soon as possible, preferably after the initial nursery feeding. When maternal feeding is initiated early, the mother can help to determine the method best suited to her and the infant and can become adept in the technique before discharge from the hospital.

Preoperative Care

In preparation for surgical repair, parents may be taught to use alternative feeding systems (e.g., syringes) several days before surgery. For CL, many surgeons allow babies to return to their typical feeding system. However, for CP, some surgeons require that the child be off the bottle and drinking from an open cup or sippy cup.

Postoperative Care

The major efforts in the postoperative period are directed toward protecting the operative site. For CL, parents may be advised to apply petroleum jelly to the operative site for several days after surgery. For CL, CP, or CL/P, elbow immobilizers may be used to prevent the infant from rubbing or disturbing the suture line; they are applied immediately after surgery and may be used for 7 to 10 days. Some centers advocate using a syringe for feeding for 7 to 10 days after CL or CP repair. Adequate analgesia is required to relieve postoperative pain and to prevent restlessness. Feeding is resumed when tolerated. An upright or infant seat position is helpful in the immediate postoperative period (especially for infants who have difficulty handling secretions). Avoid the use of suction or other objects in the mouth, such as tongue depressors, thermometers, pacifiers, spoons, and straws.

The older infant or child may be discharged on a blenderized or soft diet, and parents are instructed to continue the diet until the surgeon directs them otherwise. Parents are cautioned against allowing the child to eat hard items (e.g., toast, hard cookies, and potato chips) that can damage the repaired palate.

Long-Term Care

Children with CL/P often require a variety of services during recovery. Family members need support and encouragement by health professionals and guidance in activities that facilitate a normal outcome for their child. Parents frequently cite financial stress as a difficult issue. With the combined efforts of the family and the health team, most children achieve a satisfactory outcome. Many children with CL/P have surgical correction that creates a near normal-appearing lip and permits good function of the palate for speech and feeding. Parents need to understand the function of speech therapy and the purpose and care of all orthodontic appliances, as well as the importance of establishing good mouth care and proper brushing habits.

Throughout the child's development, an important goal is the development of a healthy personality and self-esteem. Many communities have CP parents' groups that offer help and support to families. Agencies that provide services and information for children with CL/P and their families include the American Cleft Palate–Craniofacial Association (<http://www.acpa-cpf.org>), the Cleft Palate Foundation (<http://www.cleftline.org>), Cleft Advocate (<http://www.cleftadvocate.org>), the March of Dimes (<http://www.marchforbabies.org>), and various state children's medical services.

Esophageal Atresia and Tracheoesophageal Fistula

Congenital esophageal atresia (EA) and tracheoesophageal fistula (TEF) are rare malformations that represent a failure of the esophagus to develop as a continuous passage and a failure of the trachea and esophagus to separate into distinct structures. These defects may occur as separate entities or in combination (Fig. 22-5); and without early diagnosis and treatment, they pose a serious threat to the infant's well-being.

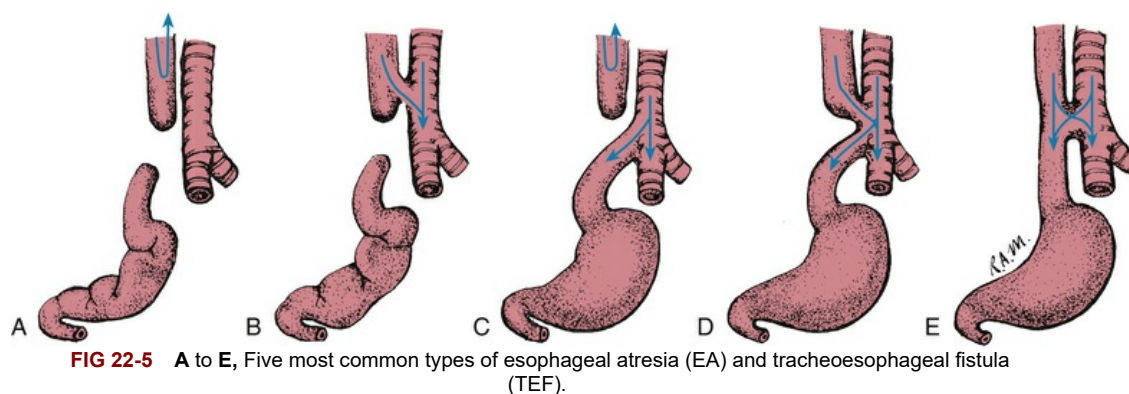

FIG 22-5 A to E, Five most common types of esophageal atresia (EA) and tracheoesophageal fistula (TEF).

The incidence of EA is estimated to be approximately 1 in 4000 live births (Kunisaki and Foker, 2012). There appears to be a slightly higher incidence in males, and the birth weight of most affected infants is significantly lower than average, with an unusually high incidence of preterm birth with EA and a subsequent increase in mortality. A history of maternal polyhydramnios is common.

Approximately 50% of the cases of EA/TEF are a component of VATER or VACTERL association, which are acronyms used to describe associated anomalies (VATER for vertebral defects, imperforate anus, tracheoesophageal fistula, and radial and renal dysplasia; and VACTERL for vertebral, anal, cardiac, tracheal, esophageal, renal, and limb) (Khan and Orenstein, 2016b). Cardiac anomalies may also occur with EA/TEF; therefore, all patients should undergo a workup for associated anomalies.

Pathophysiology

Anomalies involving the trachea and esophagus are caused by defective separation, incomplete fusion of the tracheal folds after this separation, or altered cellular growth during embryonic development. In the most frequently encountered form of EA and TEF (80% to 90% of cases), the proximal esophageal segment terminates in a blind pouch, and the distal segment is connected to the trachea or primary bronchus by a short fistula at or near the bifurcation (see Fig. 22-5, C). The second most common variety (7% to 8%) consists of a blind pouch at each end, widely separated and with no communication to the trachea (see Fig. 22-5, A). An H-type EA refers to an otherwise normal trachea and esophagus connected by a fistula (4% to 5%) (see Fig. 22-5, E). Extremely rare anomalies involve a fistula from the trachea to the upper esophageal segment (0.8%) (see Fig. 22-5, B) or to both the upper and lower segments (0.7% to 6%) (see Fig. 22-5, D).

Diagnostic Evaluation

Although the diagnosis is established on the basis of clinical signs and symptoms (Box 22-7), the exact type of anomaly is determined by radiographic studies. A radiopaque catheter is inserted into the hypopharynx and advanced until it encounters an obstruction. Chest radiographs are taken to ascertain esophageal patency or the presence and level of a blind pouch. Films that show air in the stomach indicate a connection between the trachea and the distal esophagus in types C, D, and E. Complete absence of air in the stomach is seen in types A and B. Occasionally fistulas are not patent, which makes their presence more difficult to diagnose. A careful bronchoscopic examination may be performed in an attempt to visualize the fistula.

Box 22-7

Clinical Manifestations of Tracheoesophageal Fistula

Excessive frothy mucus from nose and mouth

Three Cs of tracheoesophageal fistula (TEF):

Coughing

Choking

Cyanosis

Apnea

Increased respiratory distress during feeding

Abdominal distention

The presence of polyhydramnios (accumulation of 2000 mls of amniotic fluid) prenatally is a clue to the possibility of EA in the unborn infant, especially with defect type A, B, or C. With these types of EA/TEF, amniotic fluid normally swallowed by the fetus is unable to reach the GI tract to be absorbed and excreted by the kidneys. The result is an abnormal accumulation of amniotic fluid, or polyhydramnios.

Therapeutic Management

The treatment of patients with EA and TEF includes maintenance of a patent airway, prevention of pneumonia, gastric or blind pouch decompression, supportive therapy, and surgical repair of the anomaly.

When EA with a TEF is suspected, the infant is immediately deprived of oral intake, IV fluids are initiated, and the infant is positioned to facilitate drainage of secretions and decrease the likelihood of aspiration. Accumulated secretions are suctioned frequently from the mouth and pharynx. A double-lumen catheter should be placed into the upper esophageal pouch and attached to intermittent or continuous low suction. The infant's head is kept upright to facilitate removal of fluid collected in the pouch and to prevent aspiration of gastric contents. Broad-spectrum antibiotic therapy is often instituted if there is a concern about aspiration of gastric contents.

The surgery consists of a thoracotomy with division and ligation of the TEF and an end-to-end or end-to-side anastomosis of the esophagus. A chest tube may be inserted to drain intrapleural air and fluid. For infants who are not stable enough to undergo definitive repair or those with a lengthy gap (>3 to 4 cm) between the proximal and distal esophagus, a staged operation is preferred that involves gastrostomy, ligation of the TEF, and constant drainage of the esophageal pouch. A delayed esophageal anastomosis is usually attempted after several weeks to months. Thoracoscopic repair of EA/TEF is being used successfully, thus negating the need for a thoracotomy and minimizing associated postoperative complications and morbidities ([Guidry and McGahren, 2012](#); [Kunisaki and Foker, 2012](#)).

If an esophageal anastomosis cannot be accomplished, a gastrostomy is recommended; a cervical esophagostomy (to allow drainage of saliva through a stoma in the neck) was performed in cases of a long gap atresia but this is no longer recommended because it makes subsequent surgical repair more difficult ([Kunisaki and Foker, 2012](#)).

A primary anastomosis may be impossible because of insufficient length of the two segments of esophagus. This occurs if the distance between the two segments is 3 to 4 cm (1.2 to 1.6 inches) ([Khan and Orenstein, 2016b](#)). In these cases, an esophageal replacement procedure using a part of the colon or gastric tube interposition may be necessary to bridge the missing esophageal segment. Further surgical techniques may be performed later to facilitate esophageal lengthening.

Tracheomalacia may occur as a result of weakness in the tracheal wall that exists when a dilated

proximal pouch compresses the trachea early in fetal life. It may also occur as a result of inadequate intratracheal pressure causing abnormal tracheal development. Clinical signs of tracheomalacia include a barking cough, stridor, wheezing, recurrent respiratory tract infections, cyanosis, and sometimes apnea.

Prognosis

The survival rate is nearly 100% in otherwise healthy children. Most deaths are the result of extreme prematurity or other lethal associated anomalies. Potential complications after the surgical repair of EA and TEF depend on the type of defect and surgical correction. Complications of repair include an anastomotic leak, strictures caused by tension or ischemia, esophageal motility disorders causing dysphagia, respiratory compromise, and gastroesophageal reflux. Anastomotic esophageal strictures may cause dysphagia, choking, and respiratory distress. The strictures are often treated with routine esophageal dilation. Feeding difficulties are often present for months or years after surgery, and the infant must be monitored closely to ensure adequate weight gain, growth, and development. In some cases, laparoscopic fundoplication may be required. At times, the infant must be fed via gastrostomy or jejunostomy to provide adequate caloric intake.

Nursing Care Management

Nursing responsibility for detection of this serious malformation begins immediately after birth. For an infant with the classic signs and symptoms of EA, the major concern is the establishment of a patent airway and prevention of further respiratory compromise. Cyanosis is usually a result of laryngeal spasm caused by overflow of saliva into the larynx from the proximal esophageal pouch or aspiration; it normally resolves after removal of the secretions from the oropharynx by suctioning. The passage of a small-gauge orogastric feeding tube via the mouth into the stomach during the initial nursing physical assessment is helpful to determine the presence of EA or other obstructive defects.

Nursing Alert

Any infant who has an excessive amount of frothy saliva in the mouth or difficulty with secretions and unexplained episodes of apnea, cyanosis, or oxygen desaturation should be suspected of having an esophageal atresia (EA) or tracheoesophageal fistula (TEF) and referred immediately for medical evaluation.

Preoperative Care

The nurse carefully suction the mouth and nasopharynx and places the infant in an optimum position to facilitate drainage and avoid aspiration. The most desirable position for a newborn who is suspected of having the typical EA with a TEF (e.g., type C) is supine (or sometimes prone) with the head elevated on an inclined plane of at least 30 degrees. This positioning minimizes the reflux of gastric secretions at the distal esophagus into the trachea and bronchi, especially when intraabdominal pressure is elevated.

It is imperative to immediately remove any secretions that can be aspirated. Until surgery, the blind pouch is kept empty by intermittent or continuous suction through an indwelling double-lumen catheter passed orally or nasally to the end of the pouch. In some cases, a percutaneous gastrostomy tube is inserted and left open so that any air entering the stomach through the fistula can escape, thus minimizing the danger of gastric contents being regurgitated into the trachea. The gastrostomy tube is emptied by gravity drainage. Feedings through the gastrostomy tube and irrigations with fluid are contraindicated before surgery in the infant with a distal TEF.

Nursing interventions include respiratory assessment, airway management, thermoregulation, fluid and electrolyte management, and parenteral nutrition (PN) support.

Often the infant must be transferred to a hospital with a specialized care unit and pediatric surgical team. The nurse advises the parents of the infant's condition and provides them with necessary support and information.

Postoperative Care

Postoperative care for these infants is the same as for any high-risk newborn. Adequate

thermoregulation is provided, the double-lumen NG catheter is attached to low-suction or gravity drainage, PN is provided, and the gastrostomy tube (if applicable) is returned to gravity drainage until feedings are tolerated. If a thoracotomy is performed and a chest tube is inserted, attention to the appropriate function of the closed drainage system is imperative. Pain management in the postoperative period is important even if only a thoracoscopic approach is used. In the first 24 to 36 hours, the nurse should provide pain management for the neonate just as for an adult undergoing a similar procedure (see [Pain in Neonates, Chapter 5](#)). Tracheal suction should only be done using a premeasured catheter and with extreme caution to avoid injury to the suture line.

If tolerated, gastrostomy feedings may be initiated and continued until the esophageal anastomosis is healed. Before oral feedings are initiated and the chest tube (if applicable) is removed, a contrast study or esophagram will verify the integrity of the esophageal anastomosis.

The nurse must carefully observe the initial attempt at oral feeding to make certain the infant is able to swallow without choking. Oral feedings are begun with sterile water, followed by frequent small feedings of breast milk or formula. Until the infant is able to take a sufficient amount by mouth, oral intake may need to be supplemented by bolus or continuous gastrostomy feedings. Ordinarily, infants are not discharged until they can take oral fluids well. The gastrostomy tube may be removed before discharge or maintained for supplemental feedings at home.

Special Problems

Upper respiratory tract complications are a threat to life in both the preoperative and the postoperative periods. In addition to pneumonia, there is a constant danger of respiratory distress resulting from atelectasis, pneumothorax, and laryngeal edema. Any persistent respiratory difficulty after removal of secretions is reported to the surgeon immediately. The infant is monitored for anastomotic leaks, such as purulent chest tube drainage, an increased WBC count, and temperature instability.

For the infant who requires esophageal replacement, nonnutritive sucking is provided by a pacifier. Sometimes small amounts of water or formula are given orally, and although the liquid drains from the esophagostomy, this process allows the infant to develop mature sucking patterns. Other appropriate oral stimulation prevents feeding aversion. Infants who take nothing by mouth (NPO) for an extended period or who have not received oral stimulation have difficulty eating by mouth after corrective surgery and may develop oral hypersensitivity and feeding aversion. They require patient, firm guidance to learn the techniques of taking food into the mouth and swallow after repair. A referral to a multidisciplinary feeding behavior team may be necessary.

Some infants with EA/TEF may require periodic esophageal dilations on an outpatient basis. Discharge education should include instructions about feeding techniques in the child with a repaired esophagus, including a semi-upright feeding position, small feedings, and observation for adequacy of swallowing (regurgitation, cyanosis, choking). Tracheomalacia is often a complication, and parents are educated regarding the signs and symptoms of this condition, which include a barking cough, stridor, wheezing, recurrent respiratory tract infections, cyanosis, and sometimes apnea. GER may also occur when feedings resume and may contribute to reactive airway disease with wheezing and labored respirations as the prominent clinical manifestations. Problems with thriving and gaining weight may occur in the first 5 years of life in the child with EA/TEF, especially if the infant is born preterm, and the nurse should be alert to the achievement of developmental milestones that indicate a need for early intervention and multidisciplinary referral.

Preparing parents for discharge of their infant involves teaching the techniques that will continue at home. Parents learn signs of respiratory distress and esophageal stricture (poor feeding, choking, dysphagia, drooling, regurgitating undigested food). Discharge planning also includes obtaining the necessary equipment and home nursing services to provide home care.

Hernias

A **hernia** is a protrusion of a portion of an organ or organs through an abnormal opening. The danger of herniation arises when the organ protruding through the opening is constricted to the extent that circulation is impaired or when the protruding organs encroach on and impair the function of other structures.

The umbilical hernia is a common hernia observed in infants. An umbilical hernia usually is an isolated defect, but it may be associated with other congenital anomalies, such as Down syndrome

(trisomy 21) and trisomies 13 and 18. Inguinal hernias account for approximately 80% of all childhood hernias and occur more frequently in boys than in girls. An inguinal hernia that cannot be reduced easily is called an **incarcerated hernia**. A **strangulated inguinal hernia** is one in which the blood supply to the herniated organ is impaired. If left untreated, both incarcerated and strangulated hernias will progress to necrotic bowel.

Obstructive Disorders

Obstruction in the GI tract occurs when the passage of nutrients and secretions is impeded by a constricted or occluded lumen or when there is impaired motility (**paralytic ileus**). Obstructions may be congenital or acquired. Congenital obstructions (such as esophageal or intestinal atresia, imperforate anus, meconium plug, and meconium ileus) usually appear in the neonatal period. Other obstructions of congenital etiology (such as malrotation, Hirschsprung disease, pyloric stenosis, volvulus, incarcerated hernia, and Meckel diverticulum) appear after the first few weeks of life. Intestinal obstruction from acquired causes such as intussusception and tumors may occur in infancy or childhood. Intestinal obstructions from any cause are characterized by similar signs and symptoms (Box 22-8).

Box 22-8

Clinical Manifestations of Intestinal Obstruction

Colicky abdominal pain: From peristalsis attempting to overcome the obstruction

Abdominal distention: As a result of accumulation of gas and fluid above the level of the obstruction

Vomiting: Often the earliest sign of a high obstruction; a later sign of lower obstruction (may be bilious or feculent)

Constipation and obstipation: Early signs of low obstructions; later signs of higher obstructions

Dehydration: From losses of large quantities of fluid and electrolytes into the intestine

Rigid and board-like abdomen: From increased distention

Bowel sounds: Gradually diminish and cease

Respiratory distress: Occurs as the diaphragm is pushed up into the pleural cavity

Shock: Caused by plasma volume diminishing as fluids and electrolytes are lost from the bloodstream into the intestinal lumen

Sepsis: Caused by bacterial proliferation with invasion into the circulation

Hypertrophic Pyloric Stenosis

Hypertrophic pyloric stenosis (HPS) occurs when the circumferential muscle of the pyloric sphincter becomes thickened, resulting in elongation and narrowing of the pyloric channel. This produces an outlet obstruction and compensatory dilation, hypertrophy, and hyperperistalsis of the stomach. This condition usually develops in the first few weeks of life, causing nonbilious vomiting, which occurs after a feeding. If the condition is not diagnosed early, dehydration, metabolic alkalosis, and failure to thrive may occur. The precise etiology of HPS is unknown. Boys are affected four to six times more frequently than girls (Hunter and Liacouras, 2016). It is more common in white infants and is seen less frequently in African-American and Asian infants (Hunter and Liacouras, 2016).

Pathophysiology

The circular muscle of the pylorus thickens as a result of hypertrophy. This produces severe narrowing of the pyloric canal between the stomach and the duodenum, causing partial obstruction of the lumen (Fig. 22-6, A). Over time, inflammation and edema further reduce the size of the opening, resulting in complete obstruction. The hypertrophied pylorus may be palpable as an olive-like mass in the upper abdomen.

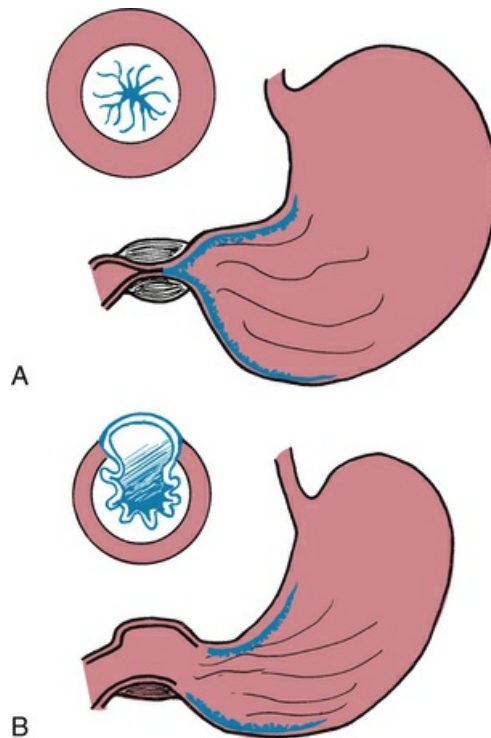

FIG 22-6 Hypertrophic pyloric stenosis (HPS). **A**, Enlarged muscular area nearly obliterates the pyloric channel. **B**, Longitudinal surgical division of the muscle down to the submucosa establishes an adequate passageway.

Pyloric stenosis is not a congenital disorder. It is believed that local innervation may be involved in the pathogenesis. In most cases, HPS is an isolated lesion; however, it may be associated with intestinal malrotation, esophageal and duodenal atresia, and anorectal anomalies.

Diagnostic Evaluation

The diagnosis of HPS is often made after the history and physical examination. The olive-like mass is easily palpated when the stomach is empty, the infant is quiet, and the abdominal muscles are relaxed. Vomiting usually occurs 30 to 60 minutes after feeding and becomes projectile as the obstruction progresses. Emesis is nonbilious in the early stages. These infants may become dehydrated and appear malnourished if an early diagnosis is not established.

If the diagnosis is inconclusive from the history and physical signs ([Box 22-9](#)), ultrasonography will demonstrate an elongated, sausage-shaped mass with an elongated pyloric channel. If ultrasonography fails to demonstrate a hypertrophied pylorus, ultrasonography will demonstrate an elongated mass surrounding a long pyloric canal. If the condition is not diagnosed early, laboratory findings reflect the metabolic alterations (hypochloremic metabolic alkalosis) created by severe depletion of both fluid and electrolytes from extensive and prolonged vomiting.

Box 22-9

Clinical Manifestations of Hypertrophic Pyloric Stenosis

Projectile vomiting

- May be ejected 3 to 4 feet from the child when in a side-lying position or 1 foot or more when in a supine position
- Usually occurs shortly after a feeding but may not occur for several hours

- May occur after each feeding or appear intermittently
- Nonbilious vomitus that may be blood tinged

Infant hungry, avid feeder; eagerly accepts a second feeding after vomiting episode

No evidence of pain or discomfort except that of chronic hunger

Weight loss

Signs of dehydration

Distended upper abdomen

Readily palpable olive-shaped tumor in the epigastrium just to the right of the umbilicus

Visible gastric peristaltic waves that move from left to right across the epigastrium

Therapeutic Management

Surgical relief of the pyloric obstruction by pyloromyotomy is the standard therapy for this disorder. Preoperatively, the infant must be rehydrated and metabolic alkalosis corrected with parenteral fluid and electrolyte administration. Replacement fluid therapy usually delays surgery for 24 to 48 hours. The stomach is decompressed with an NG tube if the infant continues with vomiting. In infants with no evidence of fluid and electrolyte imbalance, surgery is performed without delay.

The surgical procedure is often performed by laparoscope and consists of a longitudinal incision through the circular muscle fibers of the pylorus down to, but not including, the submucosa (pyloromyotomy, or the Fredet-Ramstedt operative procedure) (see [Fig. 22-6, B](#)). The procedure has a high success rate. Laparoscopic surgery through a single small incision often results in a shorter surgical time, more rapid postoperative feeding, and shorter hospital stay ([Hunter and Liacouras, 2016](#)).

Feedings are usually begun 4 to 6 hours postoperatively, beginning with small, frequent feedings of water or an electrolyte solution. If clear fluids are retained, about 24 hours after surgery formula is started in the same small increments. The amount and the interval between feedings are gradually increased until a full feeding schedule is reinstated, which usually takes about 48 hours.

Prognosis

The prognosis for infants and small children with HPS is excellent when the diagnosis is confirmed early, and the mortality rate is low (0 to 0.5%). A small percentage of children with HPS will have gastroesophageal reflux.

Nursing Care Management

Nursing care involves primarily observation for clinical features that help establish the diagnosis, careful regulation of fluid therapy, and reestablishment of normal feeding patterns. Assessment is based on observation of eating behaviors and evidence of other characteristic clinical manifestations, hydration, and nutritional status.

Preoperatively, the emphasis is placed on restoring hydration and electrolyte balance. Infants are usually given no oral feedings and receive IV fluids with glucose and electrolyte replacement based on laboratory serum electrolyte values and clinical appearance.

Observations also include assessment of vital signs, particularly those that might indicate fluid or electrolyte imbalances. These infants are prone to metabolic alkalosis from loss of hydrogen ions and depletion of potassium, sodium, and chloride. Assess the skin, mucous membranes, and daily weight for alterations in hydration status.

If stomach decompression is used preoperatively, the nurse is responsible for ensuring that the tube is patent and functioning properly and for measuring and recording the type and amount of drainage. Parental involvement is encouraged and promoted.

Postoperative vomiting is common, and most infants, even with successful surgery, exhibit some vomiting during the first 24 to 48 hours. IV fluids are administered until the infant is taking and retaining adequate amounts by mouth. Much of the same care that was instituted before surgery is continued postoperatively, including observation of vital signs, monitoring of IV fluids, and careful monitoring of fluid intake and output. In addition, the infant is observed for responses to the stress of surgery and for evidence of pain. Appropriate analgesics should be given around the clock because pain is continuous. The surgical incision(s) is inspected for drainage or erythema, and any signs of infection are reported to the surgeon. A surgical adhesive may be used for incision closure, and parents are instructed regarding the care of the incision and any dressings before discharge.

Feedings are usually instituted within 12 to 24 hours postoperatively, beginning with clear liquids advancing to formula or breast milk as tolerated. Observation and recording of feedings and the infant's responses to feedings are a vital part of postoperative care. Care of the operative site consists of observation for any drainage or signs of inflammation and care of the incision.

Intussusception

Intussusception is the most common cause of intestinal obstruction in children between 5 months old and 3 years old (Kennedy and Liacouras, 2016). Intussusception is more common in males than in females and is more common in children younger than 2 years old. Although specific intestinal lesions occur in a small percentage of the children, generally the cause is not known. More than 90% of intussusceptions do not have a pathologic lead point, such as a polyp, lymphoma, or Meckel diverticulum. The idiopathic cases may be caused by hypertrophy of intestinal lymphoid tissue secondary to viral infection.

Pathophysiology

Intussusception occurs when a proximal segment of the bowel telescopes into a more distal segment, pulling the mesentery with it. The mesentery is compressed and angled, resulting in lymphatic and venous obstruction. As the edema from the obstruction increases, pressure within the area of intussusception increases. When the pressure equals the arterial pressure, arterial blood flow stops, resulting in ischemia and the pouring of mucus into the intestine. Venous engorgement also leads to leaking of blood and mucus into the intestinal lumen, forming the classic currant jelly-like stools. The most common site is the ileocecal valve (ileocolic), where the ileum invaginates into the cecum and then further into the colon (Fig. 22-7). Other forms include ileoileal (one part of the ileum invaginates into another section of the ileum) and colocolic (one part of the colon invaginates into another area of the colon) intussusceptions, usually in the area of the hepatic or splenic flexure or at some point along the transverse colon.

Nursing Alert

The classic signs and symptoms of intussusception (abdominal pain, abdominal mass, bloody stools) is present in fewer than 30% of children (Kennedy and Liacouras, 2016). A more chronic case may be presented, characterized by diarrhea, anorexia, weight loss, occasional vomiting, and periodic pain. Because intussusception is potentially life threatening, be aware of such signs, and closely observe and refer these children for further medical evaluation.

FIG 22-7 Ileocecal intussusception.

Diagnostic Evaluation

Frequently, subjective findings lead to the diagnosis ([Box 22-10](#)), which can be confirmed by ultrasonography. A rectal examination reveals mucus, blood, and occasionally a low intussusception itself.

Box 22-10

Clinical Manifestations of Intussusception

- Sudden acute abdominal pain
- Child screaming and drawing the knees onto the chest
- Child appearing normal and comfortable between episodes of pain
- Vomiting
- Lethargy
- Passage of red, currant jelly–like stools (stool mixed with blood and mucus)
- Tender, distended abdomen
- Palpable sausage-shaped mass in upper right quadrant
- Empty lower right quadrant (Dance sign)
- Eventual fever, prostration, and other signs of peritonitis

Therapeutic Management

Conservative treatment consists of radiologist-guided pneumo-enema (air enema) with or without water-soluble contrast or ultrasound-guided hydrostatic (saline) enema, the advantage of the latter being that no ionizing radiation is needed ([Kennedy and Liacouras, 2016](#)). Recurrence of

intussusception after conservative treatment is rare; however this procedure should not be attempted with prolonged intussusception, signs of shock, peritoneal irritation, or intestinal perforation (Kennedy and Liacouras, 2016).

IV fluids, NG decompression, and antibiotic therapy may be used before hydrostatic reduction is attempted. If these procedures are not successful, the child may require surgical intervention. Surgery involves manually reducing the invagination and, when indicated, resecting any nonviable intestine.

Prognosis

Nonoperative reduction is successful in approximately 65% to 75% of cases (Gourlay, 2013). Surgery is required for patients in whom the hydrostatic enema is unsuccessful. With early diagnosis and treatment, serious complications and death are uncommon.

Nursing Care Management

The nurse can help establish a diagnosis by listening to the parent's description of the child's physical and behavioral symptoms. It is not unusual for parents to state that they thought something was seriously wrong before others shared their concerns. The description of the child's severe colicky abdominal pain combined with vomiting is a significant sign of intussusception.

As soon as a possible diagnosis of intussusception is made, the nurse prepares the parents for the immediate need for hospitalization, the nonsurgical technique of hydrostatic reduction, and the possibility of surgery. It is important to explain the basic defect of intussusception. A model of the defect is easily demonstrated by pushing the end of a finger on a rubber glove back into itself or using the example of a telescoping rod. The principle of reduction by hydrostatic pressure can be simulated by filling the glove with water, which pushes the "finger" into a fully extended position.

Physical care of the child does not differ from that for any child undergoing abdominal surgery. Even though nonsurgical intervention may be successful, the usual preoperative procedures, such as maintenance of NPO status, routine laboratory testing (CBC and urinalysis), signed parental consent, and preanesthetic sedation, are performed. Children with perforation will require IV fluids, systemic antibiotics, and bowel decompression before undergoing surgery. Fluid volume replacement and restoration of electrolytes may be required in such children before surgery. Before surgery, the nurse monitors all stools.

Nursing Alert

Passage of a normal brown stool usually indicates that the intussusception has reduced itself. This is immediately reported to the practitioner, who may choose to alter the diagnostic and therapeutic care plan.

Post-procedural care includes observations of vital signs, blood pressure, intact sutures and dressing, and the return of bowel sounds. After spontaneous or hydrostatic reduction, the nurse observes for passage of water-soluble contrast material (if used) and the stool patterns because the intussusception may recur. Children may be admitted to the hospital or monitored on an outpatient basis. A recurrence of intussusception is treated with the conservative reduction techniques described earlier, but a laparotomy is considered for multiple recurrences.

Malrotation and Volvulus

Malrotation of the intestine is caused by the abnormal rotation of the intestine around the superior mesenteric artery during embryologic development. Malrotation may manifest in utero or may be asymptomatic throughout life. Infants may have intermittent bilious vomiting, RAP, distention, or lower GI bleeding. Malrotation is the most serious type of intestinal obstruction because if the intestine undergoes complete volvulus (the intestine twisting around itself), compromise of the blood supply will result in intestinal necrosis, peritonitis, perforation, and death.

Diagnostic Evaluation

It is imperative that malrotation and volvulus be diagnosed promptly and surgical treatment instituted quickly. In addition to a history and physical, a plain abdominal radiograph and lateral

decubitus view are obtained; bowel distention will be present proximal to the distention on plain radiograph, and a lateral view will demonstrate air-fluid levels in the distended bowel (Bales and Liacouras, 2016). An upper GI series is the most accurate imaging study (Juang and Snyder, 2012).

Therapeutic Management

Surgery is indicated to remove the affected area. Because of the extensive nature of some lesions, short-bowel syndrome (SBS) is a postoperative complication.

Nursing Care Management

Preoperatively, the nursing care is the same as that provided to an infant or child with intestinal obstruction. IV fluids, NG decompression, and systemic antibiotics are implemented; in the rapidly deteriorating infant, fluid volume resuscitation and vasopressors may be required for preoperative stabilization. Postoperatively, the nursing care is similar to that provided to the infant or child who has undergone abdominal surgery.

Anorectal Malformations

Anorectal malformations are among the more common congenital malformations caused by abnormal development, with an incidence of approximately 1 in 4000 to 5000 births (Herman and Teitelbaum, 2012). These malformations may range from simple imperforate anal to include other associated complex anomalies of genitourinary (GU) and pelvic organs, which may require extensive treatment for fecal, urinary, and sexual function. Anorectal malformations may occur in isolation or as a part of the VACTERL association (see earlier in chapter). These anomalies are classified according to the newborn's gender and abnormal anatomic features, including GU defects.

Rectal atresia and stenosis occur when the anal opening appears normal, there is a midline intergluteal groove, and usually no fistula exists between the rectum and urinary tract. **Rectal atresia** is a complete obstruction (inability to pass stool) and requires immediate surgical intervention. **Rectal stenosis** may not become apparent until later in infancy when the infant has a history of difficult stooling, abdominal distention, and ribbonlike stools.

The anus and rectum originate from an embryologic structure called the **cloaca**. Lateral growth of the cloaca forms the urorectal septum that separates the rectum dorsally from the urinary tract ventrally. The rectum and urinary tract separate completely by the seventh week of gestation. A **persistent cloaca** is a complex anorectal malformation in which the rectum, vagina, and urethra drain into a common channel opening into the perineum (Fig. 22-8, A).

FIG 22-8 **A**, No visible external opening forms in high imperforate anus defect. Absence of the intergluteal cleft is also common, frequently associated with sacral agenesis. **B**, Imperforate anus in a girl, commonly associated with cloaca anomaly, which manifests as a single perineal opening on the perineum. (From Zitelli BJ, McIntire SC, Nowalk AJ: *Zitelli and Davis' atlas of pediatric physical diagnosis*, ed 6, St Louis 2012, Saunders/Elsevier.)

Imperforate anus includes several forms of malformation without an obvious opening (see Fig. 22-8, B). Frequently, a fistula (an abnormal communication) leads from the distal rectum to the

perineum or GU system (Fig. 22-9). The fistula may be evidenced when meconium is evacuated through the vaginal opening, the perineum below the vagina, the male urethra, or the perineum under the scrotum. The presence of meconium on the perineum does not indicate anal patency. A fistula may not be apparent at birth, but as peristalsis increases, meconium is forced through the fistula into the urethra or onto the newborn's perineum. Anorectal anomalies are classified according to gender and abnormal anatomic features, including GU and associated pelvic anomalies (Box 22-11).

FIG 22-9 Anorectal malformations. **A**, Typical cloaca (female). **B**, Low rectovaginal fistula (female). **C**, Rectourethral bulbar fistula (male).

Box 22-11

Classification of Anorectal Malformations

Male Defects

- Perineal fistula
- Rectourethral bulbar fistula
- Rectourethral prostatic fistula
- Rectovesicular (bladder neck) fistula
- Imperforate anus without fistula
- Rectal atresia and stenosis

Female Defects

- Perineal fistula
- Retrovestibular fistula
- Imperforate anus without fistula
- Rectal atresia and stenosis
- Cloaca

From Peña A, Hong A: Advances in the management of anorectal malformations, *Am J Surg* 180(5):370–376, 2000.

Diagnostic Evaluation

The diagnosis of an anorectal malformation is based on the physical finding of an absent anal opening. Other symptoms may include abdominal distention, vomiting, absence of meconium passage, or presence of meconium in the urine. Additional physical findings with an anorectal

malformation are a flat perineum and the absence of a midline intergluteal groove. The appearance of the perineum alone does not accurately predict the extent of the defect and associated anomalies. GU and spinal-vertebral anomalies associated with anorectal malformations should be considered when an anomaly is noted. EA with or without TEF, cardiac defects, and neural tube defects or vertebral anomalies may occur in association with anorectal malformations, and the infant should be carefully evaluated for the presence of these and other anomalies. Although rare, some anorectal malformations may not be diagnosed until later in infancy or early childhood.

A perineal fistula may be diagnosed by clinical observation. Abdominal and pelvic ultrasonography is performed to further evaluate the infant's anatomic malformation. An IV pyelogram and a voiding cystourethrogram are performed to evaluate associated anomalies involving the urinary tract. Other diagnostic examinations that may be performed include pelvic MRI, radiography, ultrasonography, and fluoroscopic examination of pelvic anatomic contents and lower spinal anatomy.

Therapeutic Management

The primary management of anorectal malformations is surgical. Once the defect has been identified, take steps to rule out associated life-threatening defects, which need immediate surgical intervention. Provided no immediate life-threatening problems exist, the newborn is stabilized and kept NPO for further evaluation. IV fluids are provided to maintain glucose and fluid and electrolyte balance. Current recommendation is that surgery be delayed at least 24 hours to properly evaluate for the presence of a fistula and possibly other anomalies (Herman and Teitelbaum, 2012).

The surgical treatment of anorectal malformations varies according to the defect but usually involves one or possibly a combination of several of the following procedures: anoplasty, colostomy, **posterior sagittal anorectoplasty (PSARP)** or other pull-through with colostomy, and colostomy (take-down) closure. The following Nursing Care Management discussion outlines some aspects of preoperative and postoperative care.

A primary laparoscopic repair (without colostomy) of anorectal malformations is being performed successfully in some centers. This minimizes surgical risks, associated morbidity, and postoperative pain management.

Nursing Care Management

The first nursing responsibility is assisting in identification of anorectal malformations. A newborn that does not pass stool within 24 hours after birth or has meconium that appears at a location other than the anal opening requires further assessment. Preoperative care includes diagnostic evaluation, GI decompression, bowel preparation, and IV fluids.

For the newborn with a perineal fistula, an anoplasty is performed, which involves moving the fistula opening to the center of the sphincter and enlarging the rectal opening. Postoperative nursing care after anoplasty is primarily directed toward healing the surgical site without other complications. A program of anal dilations is usually initiated when the child returns for the 2-week checkup. Feedings are started soon after surgical repair, and breastfeeding is encouraged because it causes less constipation.

In neonates with anomalies such as cloaca (female), rectourethral prostatic fistula (males), and vestibular fistula (females), a descending colostomy is performed to allow fecal elimination and avoid fecal contamination of the distal imperforate section and subsequent urinary tract infection in infants with urorectal fistulas. With a colostomy, postoperative nursing care is directed toward maintaining appropriate skin care at the stoma sites (both distal and proximal), managing postoperative pain, and administering IV fluids and antibiotics. Postoperative NG decompression may be required with laparotomy, and nursing care focuses on maintenance of appropriate drainage. See [Chapter 20](#) for colostomy care.

The PSARP is a common surgical procedure for the repair of anorectal malformations in infants approximately 1 to 2 months after the initial colostomy. Preoperative PSARP care often involves irrigation of the distal stoma to prevent fecal contamination of the operative site. During this time, parents must be given accurate yet simple information regarding the infant's appearance postoperatively and expectations as to their level of involvement in the child's care.

In the PSARP procedure, the repair is made via a posterior midline sacral approach to dissect the different muscle groups involved without damaging strategic innervation of pelvic structures so

that optimum postoperative bowel continence is achieved. A laparotomy may be required if the rectum is unidentifiable by the posterior approach. Additional management after successful repair involves a program of anal dilations, colostomy closure, and a bowel management program.

Parents are instructed in perineal and wound care or care of the colostomy as needed. Anal dilations may be necessary for some infants. Parents should observe stooling patterns and observe for signs of anal stricture or complications. Information on dietary modifications and administration of medications is included in counseling. Nurses have a vital role in helping families of a child with an anorectal malformation provide optimum care so that bowel management is successful and quality of life enhanced for the child and family.

Family Support, Discharge Planning, and Home Care

Long-term follow-up is essential for children with complex malformations. After the definitive pull-through procedure, toilet training is delayed, and complete continence is seldom achieved at the usual age of 2 to 3 years. Bowel habit training, bowel management irrigation programs, diet modification, and administration of stool softeners or fiber help children improve bowel function and social continence. Some children never achieve bowel continence and must rely on daily bowel irrigations. Support and reassurance are important during the slow progression to normal, socially acceptable function.

Malabsorption Syndromes

Chronic diarrhea and malabsorption of nutrients characterize malabsorption syndromes. An important complication of malabsorption syndromes in children is failure to thrive. Most cases are classified according to the location of the supposed anatomic or biochemical defect. The term **celiac disease** is often used to describe a symptom complex with four characteristics: (1) steatorrhea (fatty, foul, frothy, bulky stools), (2) general malnutrition, (3) abdominal distention, and (4) secondary vitamin deficiencies.

Digestive defects are conditions in which the enzymes necessary for digestion are diminished or absent, such as (1) cystic fibrosis, in which pancreatic enzymes are absent; (2) biliary or liver disease, in which bile flow is affected; or (3) lactase deficiency, in which there is congenital or secondary lactose intolerance.

Absorptive defects are conditions in which the intestinal mucosal transport system is impaired. This may occur because of a primary defect (e.g., celiac disease) or secondary to inflammatory disease of the bowel that results in impaired absorption because bowel motility is accelerated (e.g., ulcerative colitis). Obstructive disorders (e.g., Hirschsprung disease) also cause secondary malabsorption from enterocolitis.

Anatomic defects, such as extensive resection of the bowel or SBS, affect digestion by decreasing the transit time of substances and affect absorption by severely compromising the absorptive surface.

Celiac Disease (Gluten-Sensitive Enteropathy)

Celiac disease, also known as *gluten-induced enteropathy*, *gluten-sensitive enteropathy*, and *celiac sprue*, is a permanent intestinal intolerance to dietary gluten, a protein present in wheat, barley, rye, and oats that causes damage to the villi in the small intestine (Paul, Johnson, and Speed, 2013). The incidence is variable and has been reported in 1 in 141 people (Rubio-Tapia, Ludvigsson, Brantner, et al, 2012). The disease is seen more frequently in Europe and the United States; it is rarely reported in Asians or African Americans (Reilly and Green, 2012). As adults, it is more prevalent in women than men, but there is equal distribution of cases among children (Reilly and Green, 2012). Although the exact cause is unknown, it is generally accepted that celiac disease is an immunologically mediated small intestine enteropathy. The mucosal lesions contain features that suggest both humoral and cell-mediated immunologic overstimulation.

Pathophysiology

Celiac disease is characterized by villous atrophy in the small intestine in response to the protein gluten. When individuals are unable to digest the gliadin component of gluten (an accumulation of a toxic substance that is damaging to the mucosal cells), damage to the mucosa of the small intestine leads to villous atrophy, hyperplasia of the crypts, and infiltration of the epithelial cells with lymphocytes. Villous atrophy leads to malabsorption caused by the reduced absorptive surface area (Fig. 22-10).

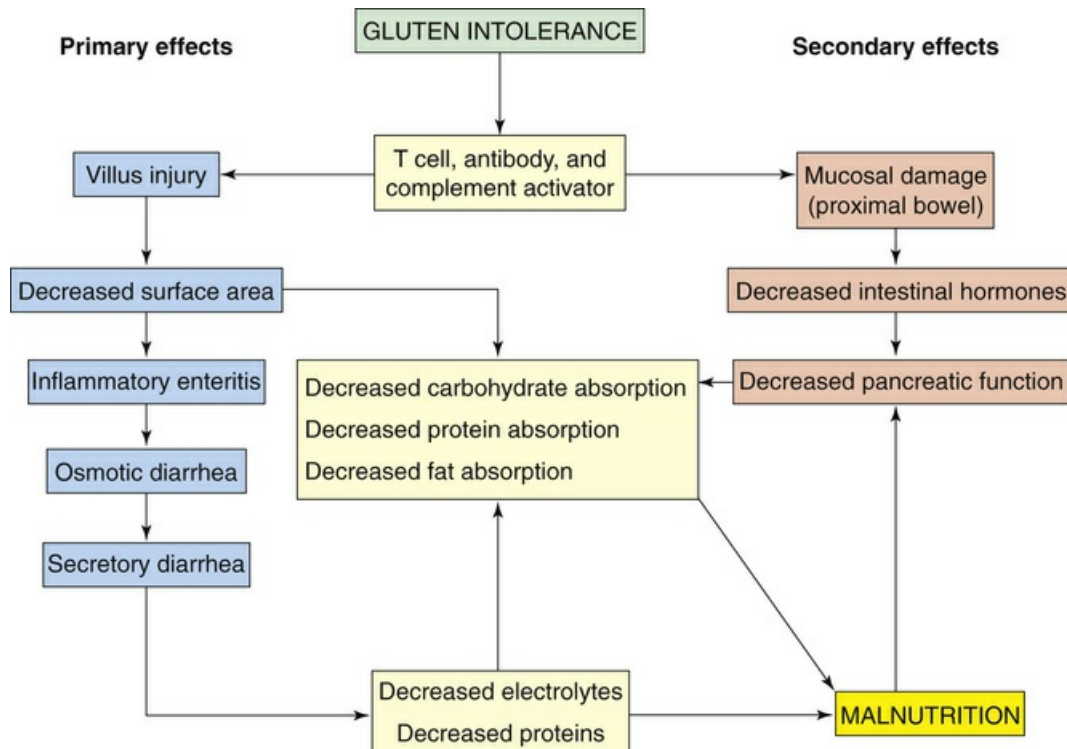

FIG 22-10 Pathophysiology of gluten-sensitive enteropathy.

Genetic predisposition is an essential factor in the development of celiac disease. Membrane receptors involved in preferential antigen presentation to CD4⁺ T cells play a crucial role in the immune response characteristic of celiac disease. Children with genetic susceptibilities, namely *HLA-DQ2* or *HLA-DQ8*, are more susceptible to being diagnosed with celiac disease (Paul, Johnson, and Speed, 2013).

Symptoms of celiac disease appear when solid foods such as beans and pasta are introduced into the child's diet, typically between 1 and 5 years old (Box 22-12). Intestinal symptoms are common in children diagnosed within the first 2 years of life. Other symptoms include failure to thrive, chronic diarrhea, abdominal distention and pain, muscle wasting, aphthous ulcers, and fatigue.

Box 22-12

Clinical Manifestations of Celiac Disease

Impaired Fat Absorption

Steatorrhea (excessively large, pale, oily, frothy stools)

Exceedingly foul-smelling stools

Impaired Nutrient Absorption

Malnutrition

Muscle wasting (especially prominent in legs and buttocks)

Anemia

Anorexia

Abdominal distention

Behavioral Changes

Irritability

Uncooperativeness

Apathy

Celiac Crisis*

Acute, severe episodes of profuse watery diarrhea and vomiting

May be precipitated by:

- Infections (especially gastrointestinal)
- Prolonged fluid and electrolyte depletion
- Emotional disturbance

*In very young children.

Diagnostic Evaluation

Gluten should not be excluded from the diet until the diagnostic evaluation is complete so that proper identification can occur. The first step is a serological blood test for tissue transglutaminase and antiendomysial antibodies in children 18 months old or older (Paul, Johnson, and Speed, 2013). Positive serological markers should be followed by an upper GI endoscopy with biopsy. The diagnosis of celiac disease is based on a biopsy of the small intestine demonstrating the characteristic changes of mucosal inflammation, crypt hyperplasia, and villous atrophy (Paul, Johnson, and Speed, 2013).

Therapeutic Management

Treatment of celiac disease consists primarily of dietary management. Although the diet is called "gluten free," it is actually *low* in gluten because it is impossible to remove every source of this protein. Because gluten is found primarily in wheat and rye but also in smaller quantities in barley and oats, these four foods are eliminated. Corn, rice, and millet become substitute grain foods.

Children with untreated celiac disease may have lactose intolerance, especially if their mucosal lesions are extensive. Lactose intolerance usually improves as the mucosa heals with gluten withdrawal. Specific nutritional deficiencies, such as iron, folic acid, and fat-soluble vitamin deficiencies, are treated with appropriate supplements.

Prognosis

Celiac disease is regarded as a chronic disease; its severity varies greatly among children. The most severe symptoms usually occur in early childhood and again in adult life. Most children who comply with dietary management are healthy and remain free of symptoms and complications; however, children should be evaluated annually for nutritional deficiencies, impaired growth, delayed puberty, and reduced bone mineral density (Paul, Johnson, and Speed, 2013).

Nursing Care Management

The main nursing consideration is helping the child adhere to the dietary regimen. Considerable time is involved in explaining the disease process to the child and parents, the specific role of gluten in aggravating the disorder, and the foods that must be restricted. It is difficult to maintain a diet indefinitely when the child has no symptoms and temporary transgressions result in no difficulties. However, the majority of individuals who relax their diet will experience a relapse of their disease.

Although the chief source of gluten is cereal and baked goods, grains are frequently added to processed foods as thickeners or fillers. To compound the difficulty, gluten is added to many foods

as hydrolyzed vegetable protein, which is derived from cereal grains. The nurse must advise parents of the necessity of reading all label ingredients carefully to avoid hidden sources of gluten.

Many of children's favorite foods contain gluten, including bread, cake, cookies, crackers, donuts, pies, spaghetti, pizza, prepared soups, some processed ice cream, many types of chocolate candy, milk preparations such as malts, hot dogs, luncheon meats, meat gravy, and some prepared hamburgers. Many of these products can be eliminated from an infant's or young child's diet fairly easily, but monitoring the diet of a school-age child or adolescent is more difficult. Luncheon preparation away from home is particularly difficult because bread, luncheon meats, and instant soups are not allowed. For families on restricted food budgets, the diet adds an additional financial burden because many inexpensive and convenient foods cannot be used.

In addition to restricting gluten, other dietary alterations may be necessary. For example, in some children who have more severe mucosal damage, the digestion of disaccharides is impaired, especially in relation to lactose. Therefore, these children often need a temporarily lactose-free diet, which necessitates eliminating all milk products. In general, dietary management includes a diet high in calories and proteins with simple carbohydrates such as fruits and vegetables but low in fats. Because the bowel is inflamed as a result of the pathologic processes in absorption, the child must avoid high-fiber foods, such as nuts, raisins, raw vegetables, and raw fruits with skin, until inflammation has subsided.

It is important to stress long-range complications and to remind parents of the child's physical status before dietary treatment and the dramatic improvement after treatment. The nurse can be instrumental in allowing the child to express concerns and frustration while focusing on ways in which the child can still feel normal. Encourage the child and parents to find new recipes using suitable ingredients, such as Mexican or Chinese dishes that use corn or rice. Consult a registered dietitian to provide children and their families with detailed dietary instructions and education.

Several resources are available to assist children and parents in all aspects of coping with celiac disease. The Celiac Sprue Association* provides support and guidance to families and supplies educational materials concerning a gluten-free diet, food sources, recipes, and travel information.

Short-Bowel Syndrome

SBS is a malabsorptive disorder that occurs as a result of decreased mucosal surface area, usually because of extensive resection of the small intestine. Malabsorption may be exacerbated by other factors, such as bacterial overgrowth and dysmotility. The most common causes of SBS in children are necrotizing enterocolitis, volvulus, jejunal atresias, and gastroschisis (Uko, Radhakrishnan, and Alkhouri, 2012). Less frequent causes include trauma to the GI tract and total colonic aganglionosis with extension into the small bowel (Soden, 2010).

The definition of SBS includes two important findings: (1) decreased intestinal surface area for absorption of fluid, electrolytes, and nutrients; and (2) a need for PN (Olieman, Penning, Ijsselstijn, et al, 2010). The prognosis for infants with SBS has improved dramatically with survival rates between 73% to 89%; however, children on PN have a lower survival rate at approximately 60% (Soden, 2010).

Management

The goals of therapy for infants and children with SBS include (1) preserve as much length of bowel as possible during surgery; (2) maintain optimum nutritional status, growth, and development while intestinal adaptation occurs; (3) stimulate intestinal adaptation with enteral feeding; and (4) minimize complications related to the disease process and therapy (Uko, Radhakrishnan, and Alkhouri, 2012).

Nutritional support is the long-term focus of care for children with SBS (Uko, Radhakrishnan, and Alkhouri, 2012). The initial phase of therapy includes PN as the primary source of nutrition. The second phase is the introduction of enteral feeding, which usually begins as soon as possible after surgery. Elemental formulas containing glucose, sucrose and glucose polymers, hydrolyzed proteins, and medium-chain triglycerides facilitate absorption. Usually these formulas are given by continuous infusion through an NG or gastrostomy tube. As the enteral feedings are advanced, the PN solution is decreased in terms of calories, amount of fluid, and total hours of infusion per day. If enteral feedings are tolerated, oral feedings should be attempted to minimize oral aversion and preserve oral skills (Goulet, Olieman, Ksiazyc, et al, 2013).

The final phase of nutritional support occurs when growth and development are sustained. When PN is discontinued, there is a risk of nutritional deficiency secondary to malabsorption of fat-soluble vitamins (A, D, E, and K) and trace minerals (iron, selenium, and zinc). Serum vitamin and mineral levels should be monitored closely and supplemented enterally, if needed. Pharmacologic agents have been used to reduce secretory losses. H₂ blockers, PPIs, and octreotide inhibit gastric or pancreatic secretion. Cholestyramine is often prescribed to improve diarrhea that is associated with bile salt malabsorption. Growth factors have also been used to hasten adaptation and to enhance mucosal growth, but these uses are still experimental and results are controversial (Uko, Radhakrishnan, and Alkhouri, 2012).

Numerous complications are associated with SBS and long-term PN. Infectious, metabolic, and technical complications can occur. Sepsis can occur after improper care of the catheter. The GI tract can also be a source of microbial seeding of the catheter. Bowel atrophy may foster increased intestinal permeability of bacteria. A lack of adequate sites for central lines may become a significant problem for the child in need of long-term PN. Hepatic dysfunction, hepatomegaly with abnormal LFTs, and cholestasis may also occur (Soden, 2010).

Bacterial overgrowth is likely to occur when the ileocecal valve is absent or when stasis exists as a result of a partial obstruction or a dilated segment of bowel with poor motility. Alternating cycles of broad-spectrum antibiotics are used to reduce bacterial overgrowth. This treatment may also decrease the risk of bacterial translocation and subsequent central venous catheter infections. Other complications of bacterial overgrowth and malabsorption include metabolic acidosis and gastric hypersecretion.

Many surgical interventions, including intestinal valves, tapering enteroplasty or stricturoplasty, intestinal lengthening, and interposed segments, have been used to slow intestinal transit, reduce bacterial overgrowth, or increase mucosal surface area. Intestinal transplantation has been performed successfully in children. Children with a permanent dependence on PN or severe complications of long-term PN are candidates for transplantation.

Prognosis

The prognosis for infants with SBS has improved with advances in PN and with the understanding of the importance of intraluminal nutrition. Improved supportive care for the management of therapy-related problems and the development of more specific immunosuppressive medications for transplantation have all contributed to improved management. The prognosis depends in part on the length of the residual small intestine. An intact ileocecal valve also improves the prognosis. Infants and children with SBS die from PN-related problems, such as fulminant sepsis or severe PN cholestasis.

Nursing Care Management

The most important components of nursing care are administration and monitoring of nutritional therapy. During PN therapy, care must be taken to minimize the risk of complications related to the central venous access device (i.e., catheter infections, occlusions, dislodgment, or accidental removal). Care of the enteral feeding tubes and monitoring of enteral feeding tolerance are also important nursing responsibilities.

When long-term PN is required, preparing the family for home care is a major nursing responsibility. Preparation for home nutritional support begins as early as possible to prevent a lengthy hospitalization with subsequent problems such as family dysfunction and developmental delays. Many infants and children can be successfully cared for at home with enteral nutrition and PN if the family is thoroughly prepared and provided with adequate support services. Most families benefit from home nursing care to assist with and supervise therapy. Careful follow-up by a multidisciplinary nutritional support service is essential. The nurse plays an active and important role in the success of a home nutrition program. Home infusion companies provide portable equipment, which enables the child and family to maintain a more normal lifestyle.

Many infants with SBS have an intestinal ostomy performed at the time of the initial bowel resection. Routine ostomy care is another important nursing responsibility. Because infants and children with SBS have chronic diarrhea, perineal skin irritation is often a problem after ostomy closure. Frequent diaper changes, gentle perineal cleansing, and protective skin ointments help prevent skin breakdown.

When hospitalization is prolonged, the child's developmental and emotional needs must be met.

This often requires special planning to promote normal family adjustment and adaptation of the hospital routines. Care of hospitalized children is discussed in [Chapter 19](#).

NCLEX Review Questions

1. A 16-month-old has a history of diarrhea for 3 days with poor oral intake. He received intravenous (IV) fluids, has tolerated some oral fluids in the emergency department (ED), and is being discharged home. Instructions for diet for this child should include:
 - a. BRAT (bananas, rice, applesauce, and toast) diet for 24 hours, then a soft diet as tolerated
 - b. Chicken or beef broth for 24 hours, then resume a soft diet
 - c. Offer a regular diet as child's appetite warrants
 - d. Keep on clear liquids and toast for 24 hours
2. A 5-month-old infant is seen in the well-child clinic for a complaint of vomiting and failure to grow. His birth weight was 7 pounds, and he now weighs 8 pounds, 10 ounces. The infant's mother reports that he is taking 4 to 7 ounces of formula every 4 to 5 hours, but he "spits up a lot after eating and then is hungry again." The child is noted to be alert but appears malnourished. The mother reports his stools are brown in color, and he has one to two bowel movements every day. Based on these findings, the nurse anticipates the infant has:
 - a. Meckel diverticulum
 - b. Hypertrophic pyloric stenosis (HPS)
 - c. Intussusception
 - d. Hirschsprung disease
3. Because many children with celiac disease require parenteral nutrition therapy, they are at risk for which of the following nutritional deficiencies when the PN is discontinued? Select all that apply.
 - a. Iron deficiency anemia
 - b. Folic acid deficiency
 - c. Zinc deficiency
 - d. Vitamin A, D, E, and K deficiency
 - e. Vitamin B₁₂ deficiency
4. A formerly preterm infant who had surgery for necrotizing enterocolitis is now 6 months old and has short bowel syndrome. He is unable to absorb most nutrients taken by mouth and is totally dependent on parenteral nutrition (PN), which he receives via a Broviac catheter. The clinic nurse following this infant is aware that this infant should be closely observed for the development of:
 - a. Gastroesophageal reflux (GER)
 - b. Chronic diarrhea
 - c. Cholestasis
 - d. Failure to thrive
5. The nurse caring for a 4-month-old infant with biliary atresia (BA) and significant urticaria can anticipate administering:
 - a. Diphenhydramine
 - b. Ursodiol (ursodeoxycholic acid)
 - c. Loratadine
 - d. Ranitidine (Zantac)
6. Hepatitis A virus (HAV) is transmitted by which of the following? Select all that apply.
 - a. Breast milk from mother with HAV
 - b. Ingestion of contaminated food
 - c. Fecal-oral route
 - d. Casual contact with infected person
 - e. Blood transfusion

Correct Answers

1. c; 2. b; 3. a, b, d; 4. c; 5. b; 6. b, c

UNIT 10

The Child with Problems Related to the Production and Circulation of Blood

OUTLINE

- 23 The Child with Cardiovascular Dysfunction
- 24 The Child with Hematologic or Immunologic Dysfunction
- 25 The Child with Cancer

The Child with Cardiovascular Dysfunction

Amy Delaney, Annette L. Baker, Heather Bastardi, Patricia O'Brien

Cardiovascular Dysfunction

Cardiovascular disorders in children are divided into two major groups, congenital heart disease and acquired heart disorders. **Congenital heart disease (CHD)** includes primarily anatomic abnormalities present at birth that result in abnormal cardiac function. The clinical consequences of congenital heart defects fall into two broad categories, heart failure (HF) and hypoxemia. **Acquired cardiac disorders** are disease processes or abnormalities that occur after birth and can be seen in the normal heart or in the presence of congenital heart defects. They result from various factors, including infection, autoimmune responses, environmental factors, and familial tendencies. The pathophysiology review found in Fig. 23-1 describes the flow of blood through the heart.

FIG 23-1 Diagram showing serially connected pulmonary and systemic circulatory systems and how to trace the flow of blood. Right heart chambers propel unoxygenated blood through the systemic circulation. LA, Left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle. (From McCance KL, Heuther SE: *Pathophysiology: the biological basis for disease in adults and children*, ed 6, St Louis, 2010, Mosby.)

History and Physical Examination

Taking an accurate health history is an important first step in assessing an infant or child for possible heart disease. Parents may have specific concerns, such as an infant with poor feeding or fast breathing, or a 7-year-old who can no longer keep up with friends on the soccer field. Others may not realize that their child has a medical problem because their baby has always been pale and fussy.

Asking details about the mother's health history, pregnancy, and birth history is important in assessing infants. Mothers with chronic health conditions, such as diabetes or lupus, are more likely to have infants with heart disease. Some medications, such as phenytoin (Dilantin), are teratogenic

to fetuses. Maternal alcohol use or illicit drug use increases the risk of congenital heart defects. Exposures to infections, such as rubella, early in pregnancy may result in congenital anomalies. Infants with low birth weight resulting from intrauterine growth restriction are more likely to have congenital anomalies. High-birth-weight infants have an increased incidence of heart disease.

A detailed family history is also important. There is an increased incidence of congenital cardiac defects if either parent or a sibling has a heart defect. Some diseases, such as Marfan syndrome, and some cardiomyopathies are hereditary. A family history of frequent fetal loss, sudden infant death, and sudden death in adults may indicate heart disease. Congenital heart defects are seen in many syndromes such as Down and Turner syndromes.

The physical assessment of suspected cardiac disease begins with observation of general appearance and then proceeds with more specific observations. The following lists are supplementary to the general assessment techniques described for physical examination of the chest and heart in [Chapter 4](#).

Inspection

Nutritional state: Failure to thrive or poor weight gain is associated with heart disease.

Color: Cyanosis is a common feature of CHD, and pallor is associated with poor perfusion.

Chest deformities: An enlarged heart sometimes distorts the chest configuration.

Unusual pulsations: Visible pulsations of the neck veins are seen in some patients.

Respiratory excursion: This refers to the ease or difficulty of respiration (e.g., tachypnea, dyspnea, expiratory grunt).

Clubbing of fingers: This is associated with cyanosis.

Palpation and Percussion

Chest: These maneuvers help discern heart size and other characteristics (e.g., thrills) associated with heart disease.

Abdomen: Hepatomegaly or splenomegaly may be evident.

Peripheral pulses: Rate, regularity, and amplitude (strength) may reveal discrepancies.

Auscultation

Heart rate and rhythm: Listen for fast heart rates (tachycardia), slow heart rates (bradycardia), and irregular rhythms.

Character of heart sounds: Listen for distinct or muffled sounds, murmurs, and additional heart sounds.

Diagnostic Evaluation

A variety of invasive and noninvasive tests may be used in the diagnosis of heart disease ([Table 23-1](#)). Some of the more common diagnostic tools that require nursing assessment and intervention are described in the following sections.

TABLE 23-1
Procedures for Cardiac Diagnosis

| Procedure | Description |
|---------------------------|--|
| Chest radiography (x-ray) | Provides information on heart size and pulmonary blood flow patterns |
| ECG | Graphic measure of electrical activity of heart |
| Holter monitor | 24-hour continuous ECG recording used to assess dysrhythmias |
| Echocardiography | Use of high-frequency sound waves obtained by a transducer to produce an image of cardiac structures |
| Trans thoracic | Done with transducer on chest |
| M-mode | One-dimensional graphic view used to estimate ventricular size and function |

| | |
|-------------------------|--|
| Two-dimensional | Real-time, cross-sectional views of heart used to identify cardiac structures and cardiac anatomy |
| Doppler | Identifies blood flow patterns and pressure gradients across structures |
| Fetal | Imaging fetal heart in utero |
| TEE | Transducer placed in esophagus behind heart to obtain images of posterior heart structures or in patients with poor images from chest approach |
| Cardiac catheterization | Imaging study using radiopaque catheters placed in a peripheral blood vessel and advanced into heart to measure pressures and oxygen levels in heart chambers and visualize heart structures and blood flow patterns |
| Hemodynamics | Measures pressures and oxygen saturations in heart chambers |
| Angiography | Use of contrast material to illuminate heart structures and blood flow patterns |
| Biopsy | Use of special catheter to remove tiny samples of heart muscle for microscopic evaluation; used in assessing infection, inflammation, or muscle dysfunction disorders; also to evaluate for rejection after heart transplant |
| EPS | Special catheters with electrodes employed to record electrical activity from within heart; used to diagnose rhythm disturbances |
| Exercise stress test | Monitoring of heart rate, BP, ECG, and oxygen consumption at rest and during progressive exercise on a treadmill or bicycle |
| Cardiac MRI | Noninvasive imaging technique; used in evaluation of vascular anatomy outside of heart (e.g., COA, vascular rings), estimates of ventricular mass and volume; uses for MRI are expanding |

BP, Blood pressure; COA, coarctation of the aorta; ECG, electrocardiography; EPS, electrophysiology; MRI, magnetic resonance imaging; TEE, transesophageal echocardiography.

Electrocardiogram

Electrocardiography (ECG or EKG) measures the electrical activity of the heart, provides a graphic display and supplies information on heart rate and rhythm, abnormal rhythms or conduction, ischemic changes, and other information. A standard ECG uses 12 leads to get different views of the heart. An ECG takes about 15 minutes to perform, infants and young children may be fussy with lead placement.

Bedside cardiac monitoring with a single lead of the ECG is commonly used in pediatrics, especially in the care of children with heart disease. An alarm can be set with parameters for individual patient requirements and will sound if the heart rate is above or below the set parameters. Gelfoam electrodes are commonly used and placed on the right side of the chest (above the level of the heart) and on the left side of the chest, and a ground electrode is placed on the abdomen. Bedside monitors are an adjunct to patient care and should never be substituted for direct assessment and auscultation of heart sounds. The nurse should assess the patient, not the monitor.

Nursing Alert

Electrodes for cardiac monitoring are often color coded: white for right, green (or red) for ground, and black for left. Always check to ensure that these colors are placed correctly.

Echocardiography

Echocardiography involves the use of ultra-high-frequency sound waves to produce an image of the heart's structure. A transducer placed directly on the chest wall delivers repetitive pulses of ultrasound and processes the returned signals (echoes). It is the most frequently used test for describing cardiac anatomy and detecting cardiac dysfunction in children. In many cases, a prenatal diagnosis of CHD can be made by fetal echocardiography.

Although the test is noninvasive, painless, and associated with no known side effects, it can be stressful for children. A full echocardiogram can take an hour and the child must lie quietly in the standard echocardiographic positions. Therefore, infants and young children may need a mild sedative; older children benefit from preparation for the test. The distraction of a video or movie is often helpful.

Cardiac Magnetic Resonance Imaging

Cardiac magnetic resonance imaging (MRI) is often used to define unresolved anatomic pathways when a child may have poor acoustic windows or a complex structure that is difficult to visualize by ultrasound alone. In today's practices, cardiac MRI is increasingly used in conjunction with other imaging modalities for assessment of blood flow, and evaluation of myocardial perfusion and viability (Prakash, Powell, Krishnamurthy, et al, 2004).

Cardiac catheterization is an invasive diagnostic procedure in which a radiopaque catheter is introduced through a large bore needle into a peripheral vessel (usually the femoral artery or vein in children) and then guided into the heart with the aid of fluoroscopy. After the tip of the catheter is within a heart chamber, measurements of pressures and saturations in the different cardiac chambers are obtained. Contrast material is injected, and images are taken of the circulation inside the heart (**angiography**). Types of cardiac catheterizations include:

Diagnostic catheterizations: These studies are used to diagnose congenital cardiac defects, particularly in symptomatic infants and before surgical repair. They can include right-sided

catheterizations, in which the catheter is introduced through a vein (usually the femoral vein) and threaded to the right atrium, and left-sided catheterizations, in which the catheter is threaded through an artery into the aorta and into the heart.

Interventional catheterizations (therapeutic catheterizations): A balloon catheter or other device is used to alter the cardiac anatomy. Examples include dilating stenotic valves or vessels or closing abnormal connections ([Table 23-2](#)).

TABLE 23-2
Current Interventional Cardiac Catheterization Procedures in Children

| Intervention | Diagnosis |
|---|---|
| Balloon atrioseptostomy: Use well established in newborns; may also be done under echocardiographic guidance | Transposition of great arteries Some complex single-ventricle defects |
| Balloon dilation: Treatment of choice | Valvular pulmonic stenosis Branch pulmonary artery stenosis Congenital valvular aortic stenosis Rheumatic mitral stenosis Recurrent coarctation of aorta Further follow-up required in: Native coarctation of aorta in patients older than 7 months Congenital mitral stenosis |
| Coil occlusion: Accepted alternative to surgery | PDA (<4 mm) |
| Transcatheter device closure: Several devices used in clinical trials | ASD |
| Amplatzer septal occluder: Approved for ASD closure | ASD |
| VSD devices: Used in clinical trials | VSDs |
| Stent placement | Pulmonary artery stenosis Coarctation of the aorta in adolescents Use to treat other lesions investigational |
| RF ablation | Some tachydyrhythmias |

ASD, Atrial septal defect; PDA, patent ductus arteriosus; RF, radiofrequency; VSD, ventricular septal defect.

Electrophysiology studies: Catheters with tiny electrodes that record the impulses of the heart directly from the conduction system are used to evaluate dysrhythmias. Other catheters can destroy abnormal pathways that cause rapid rhythms (called *ablation*).

Nursing Care Management

Cardiac catheterization has become a routine diagnostic and therapeutic procedure but it is not without risks, especially in neonates and seriously ill infants and children. Risks include exposure to radiation and anesthesia, hypothermia in young infants, arrhythmias, vascular injury and bleeding that may require transfusion, renal insufficiency caused by contrast material, allergic reactions, and, rarely, injury to the heart or central nervous system (CNS), stroke, or death ([Feltes, Bacha, Beekman, et al, 2011](#)).

Preprocedural Care

A complete nursing assessment is necessary to ensure a safe procedure with minimum complications. This assessment should include accurate height (essential for correct catheter selection) and weight. Obtaining a history of allergic reactions is important because some of the contrast agents are iodine based. Specific attention to signs and symptoms of infection is crucial. Severe diaper rash may be a reason to cancel the procedure if femoral access is required. Because assessment of pedal pulses is important after catheterization, the nurse should assess and mark the pulses (dorsalis pedis, posterior tibial) before the child goes to the catheterization room. Baseline oxygen saturation using pulse oximetry in children with cyanosis is also recorded.

Preparing the child and family for the procedure is the joint responsibility of the patient care team. School-age children and adolescents benefit from a description of the catheterization laboratory and a chronologic explanation of the procedure, emphasizing what they will see, feel, and hear. Older children and adolescents may bring earphones and favorite music so that they can listen to music during the catheterization procedure. Preparation materials such as picture books, videotapes, or tours of the catheterization laboratory may be helpful. Preparation should be geared to the child's developmental level. The child's caregivers often benefit from the same explanations. Additional information, such as the expected length of the catheterization, description of the child's appearance after catheterization, and usual post-procedure care, should be outlined (also see the [Prepare the Child and Family for Invasive Procedures](#) section later in this chapter).

Methods of sedation vary among institutions and may include oral or intravenous (IV) medications (see [Chapter 20](#)). The child's age, heart defect, clinical status, and type of

catheterization procedure planned are considered when sedation is determined. General anesthesia is needed for most interventional procedures. Children are allowed nothing by mouth (NPO) for 6 to 8 hours or more before the procedure. Infants and patients with polycythemia may need IV fluids to prevent dehydration and hypoglycemia.

Post-Procedural Care

Postcatheterization care may occur in a recovery unit, hospital room, or intensive care unit (ICU) depending on the patient's acuity and care needs. Some catheterizations may be done as outpatient procedures, but most patients having interventional procedures are observed overnight in the hospital. Patients are placed on a cardiac monitor and a pulse oximeter for the first few hours of recovery. The most important nursing responsibility is observation of the following for signs of complications:

- **Pulses**, especially below the catheterization site, for equality and symmetry (Pulse distal to the site may be weaker for the first few hours after catheterization but should gradually increase in strength.)
- **Temperature and color of the affected extremity** because coolness or blanching may indicate arterial obstruction
- **Vital signs**, which are taken as frequently as every 15 minutes, with special emphasis on heart rate, which is counted for 1 full minute for evidence of dysrhythmias or bradycardia
- **Blood pressure (BP)**, especially for hypotension, which may indicate hemorrhage from cardiac perforation or bleeding at the site of initial catheterization
- **Dressing**, for evidence of bleeding or hematoma formation in the femoral or antecubital area
- **Fluid intake**, both IV and oral, to ensure adequate hydration (Blood loss in the catheterization laboratory, the child's NPO status, and diuretic actions of dyes used during the procedure put children at risk for hypovolemia and dehydration.)
- **Blood glucose levels** for hypoglycemia, especially in infants, who should receive dextrose-containing IV fluids

Nursing Alert

If bleeding occurs, direct continuous pressure is applied 2.5 cm (1 inch) above the percutaneous skin site to localize pressure over the vessel puncture.

Depending on hospital policy, the child may be kept in bed with the affected extremity maintained straight for 4 to 6 hours after venous catheterization and 6 to 8 hours after arterial catheterization to facilitate healing of the cannulated vessel. If younger children have difficulty complying, they can be held in the parent's lap with the leg maintained in the correct position. The child's usual diet can be resumed as soon as tolerated, beginning with sips of clear liquids and advancing as the condition allows. The child is encouraged to void to clear the contrast material from the blood. Generally, there is only slight discomfort at the percutaneous site. To prevent infection, the catheterization area is protected from possible contamination. If the child wears diapers, the dressing can be kept dry by covering it with a piece of plastic film and sealing the edges of the film to the skin with tape. However, the nurse must be careful to continue observing the site for any evidence of bleeding (see [Family-Centered Care](#) box and [Critical Thinking Case Study](#)).

Family-Centered Care

After Cardiac Catheterization

Cover catheter insertion site with an adhesive bandage strip and change daily for 2 days.

Keep site clean and dry. Avoid tub baths and swimming for several days; patient may shower or have a sponge bath.

Observe site for redness, swelling, drainage, and bleeding. Monitor for fever. Notify practitioner if

these occur.

Encourage rest and quiet activities for the first 3 days and avoid strenuous exercise.

Discuss returning to school and resuming other activities with the practitioner.

Resume regular diet without restrictions.

Use acetaminophen for pain.

Keep follow-up appointments per practitioner's instruction.

Modified from Children's Hospital (Boston) Cardiovascular Program, 2012.

Critical Thinking Case Study

Cardiac Catheterization

Tommy, a 3-year-old boy with tetralogy of Fallot, has just returned to his hospital room from the cardiac catheterization recovery room. His mother calls you to the bedside to tell you that he is vomiting and bleeding. You arrive to find Tommy anxious, pale, crying, and sitting in a puddle of blood.

Questions

1. Evidence: Is there sufficient evidence to draw conclusions about Tommy's situation?
2. Assumptions: Describe an underlying assumption about each of the following:
 - a. Risks of cardiac catheterization
 - b. Association between vomiting and bleeding after cardiac catheterization
 - c. Concerns related to acute blood loss
3. What priorities for nursing care should be established for Tommy?
4. Does the evidence support your nursing interventions?

Congenital Heart Disease

The incidence of CHD in children is approximately 8 to 12 per 1000 live births (Park, 2014). CHD is the major cause of death (other than prematurity) in the first year of life. Although there are more than 35 well-recognized cardiac defects, the most common heart anomaly is ventricular septal defect (VSD).

The exact cause of most congenital cardiac defects is unknown. Most are thought to be a result of multiple factors, including a complex interaction of genetic and environmental influences. Some risk factors are known to be associated with increased incidence of congenital heart defects. Maternal risk factors include chronic illnesses (such as diabetes or poorly controlled phenylketonuria), alcohol consumption, and exposure to environmental toxins and infections. Family history of a cardiac defect in a parent or sibling increases the likelihood of a cardiac anomaly. In general, when one child is affected, the risk of recurrence in siblings is about 3%, and for those who have a child with hypoplastic left heart syndrome (HLHS) the risk of CHD in subsequent children is reported to be at 10% (Park, 2014).

Congenital heart anomalies are often associated with chromosomal abnormalities, specific syndromes, or congenital defects in other body systems. Down syndrome (trisomy 21) and trisomies 13 and 18 are highly correlated with congenital heart defects. Syndromes associated with heart defects include DiGeorge syndrome, a syndrome characterized by deletion of part of chromosome 22q11 (interrupted aortic arch, truncus arteriosus, tetralogy of Fallot, and posterior malaligned VSDs); Noonan syndrome (pulmonic valve anomalies and cardiomyopathy); Williams syndrome (aortic and pulmonic stenosis); and Holt-Oram syndrome (upper limb anomalies and atrial septal defect [ASD]). Extracardiac defects (such as tracheoesophageal fistula, renal abnormalities, and diaphragmatic hernia) are seen in association with heart anomalies.

Circulatory Changes at Birth

Blood carrying oxygen and nutritive materials from the placenta enters the fetal system through the umbilicus via the large umbilical vein. The blood then travels to the liver, where it divides. Part of the blood enters the portal and hepatic circulation of the liver, and the remainder travels directly to the inferior vena cava (IVC) by way of the ductus venosus. Oxygenated blood enters the heart by way of the IVC. Because of the higher pressure of blood entering the right atrium, it is directed posteriorly in a straight pathway across the right atrium and through the **foramen ovale** to the left atrium. In this way, the better-oxygenated blood enters the left atrium and ventricle to be pumped through the aorta to the head and upper extremities. Blood from the head and upper extremities entering the right atrium from the superior vena cava is directed downward through the tricuspid valve into the right ventricle. From there it is pumped through the pulmonary artery, where the major portion is shunted to the descending aorta via the **ductus arteriosus**. Only a small amount flows to and from the nonfunctioning fetal lungs (Fig. 23-2, A).

FIG 23-2 Changes in circulation at birth. **A**, Prenatal circulation. **B**, Postnatal circulation. Arrows indicate direction of blood flow. Although four pulmonary veins enter the left atrium (LA), for simplicity, this diagram shows only two. LV, Left ventricle; RA, right atrium; RV, right ventricle.

Before birth, the high pulmonary vascular resistance created by the collapsed fetal lung causes greater pressures in the right side of the heart and the pulmonary arteries. At the same time, the free-flowing placental circulation and the ductus arteriosus produce a low vascular resistance in the remainder of the fetal vascular system. With the cessation of placental blood flow from clamping of the umbilical cord and the expansion of the lungs at birth, the hemodynamics of the fetal vascular system undergo pronounced and abrupt changes (see Fig. 23-2, B).

With the first breath, the lungs are expanded, and increased oxygen causes pulmonary vasodilation. Pulmonary pressures start to fall as systemic pressures, given the removal of the placenta, start to rise. Normally, the foramen ovale closes as the pressure in the left atrium exceeds the pressure in the right atrium. The ductus arteriosus starts to close in the presence of increased oxygen concentration in the blood and other factors.

Altered Hemodynamics

To appreciate the physiology of heart defects, it is necessary to understand the role of pressure gradients, flow, and resistance within the circulation. As blood is pumped through the heart, it (1) flows from an area of high pressure to one of low pressure and (2) takes the path of least resistance. In general, the higher the pressure gradient, the faster the rate of flow; and the higher the resistance, the slower the rate of flow.

Normally, the pressure on the right side of the heart is lower than that on the left side, and the resistance in the pulmonary circulation is less than that in the systemic circulation. Vessels entering or exiting these chambers have corresponding pressures. Therefore, if an abnormal connection exists between the heart chambers (e.g., a septal defect), blood will necessarily flow from an area of higher pressure (left side) to one of lower pressure (right side). Such a flow of blood is termed a **left-to-right shunt**. Anomalies resulting in cyanosis may result from a change in pressure so that the blood is shunted from the right to the left side of the heart (**right-to-left shunt**) because of either increased pulmonary vascular resistance or obstruction to blood flow through the pulmonic valve and artery. Cyanosis may also result from a defect that allows mixing of oxygenated and deoxygenated blood within the heart chambers or great arteries, such as occurs in truncus arteriosus.

Classification of Defects

There are typically two classification systems used to categorize congenital heart defects.

Traditionally, cyanosis, a physical characteristic, has been used as the distinguishing feature, dividing anomalies into **acyanotic defects** and **cyanotic defects**. In clinical practice, this system is problematic because children with acyanotic defects may develop cyanosis. Also, more often, those with cyanotic defects may appear pink and have more clinical signs of HF.

A more useful classification system is based on hemodynamic characteristics (blood flow patterns within the heart). These blood flow patterns are (1) **increased pulmonary blood flow**; (2) **decreased pulmonary blood flow**; (3) **obstruction to blood flow** out of the heart; and (4) **mixed blood flow**, in which saturated and desaturated blood mix within the heart or great arteries. As a comparison, Fig. 23-3 outlines both classification systems. With the hemodynamic classification system, the clinical manifestations of each group are more uniform and predictable. Defects that allow blood flow from the higher pressure left side of the heart to the lower pressure right side (left-to-right shunt) result in increased pulmonary blood flow and cause HF. Obstructive defects impede blood flow out of the ventricles; whereas obstruction on the left side of the heart results in HF, severe obstruction on the right side causes cyanosis. Defects that cause decreased pulmonary blood flow result in cyanosis. Mixed lesions present a variable clinical picture based on the degree of mixing and amount of pulmonary blood flow; hypoxemia (with or without cyanosis) and HF usually occur together. Using this classification system, the clinical presentation and management of the most common defects are outlined in the following sections and Box 23-1.

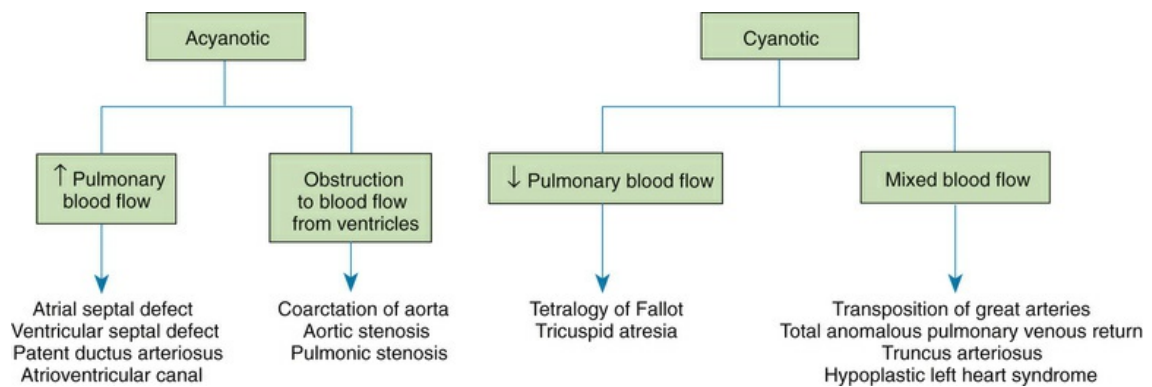

FIG 23-3 Comparison of acyanotic-cyanotic and hemodynamic classification systems of congenital heart disease (CHD).

Box 23-1

Defects with Increased Pulmonary Blood Flow

Atrial Septal Defect

Description: Abnormal opening between the atria, allowing blood from the higher pressure left atrium to flow into the lower pressure right atrium. There are three types of ASD:

Ostium primum (ASD 1): Opening at lower end of septum; may be associated with mitral valve abnormalities

Ostium secundum (ASD 2): Opening near center of septum

Sinus venosus defect: Opening near junction of superior vena cava and right atrium; may be associated with partial anomalous pulmonary venous connection

Pathophysiology: Because left atrial pressure slightly exceeds right atrial pressure, blood flows from the left to the right atrium, causing an increased flow of oxygenated blood into the right side of the heart. Despite the low pressure difference, a high rate of flow can still occur because of low pulmonary vascular resistance and the greater distensibility of the right atrium, which further reduces flow resistance. This volume is well tolerated by the right ventricle because it is delivered under much lower pressure than with a VSD. Although there is right atrial and ventricular enlargement, cardiac failure is unusual in an uncomplicated ASD. Pulmonary vascular changes usually occur only after several decades if the defect is left unrepaired.

Clinical manifestations: Patients may be asymptomatic. They may develop HF. There is a characteristic systolic murmur with a fixed split second heart sound. There may also be a diastolic murmur. Patients are at risk for atrial dysrhythmias (probably caused by atrial enlargement and stretching of conduction fibers) and pulmonary vascular obstructive disease and emboli formation later in life from chronically increased pulmonary blood flow.

Surgical treatment: Surgical patch closure (pericardial patch or Dacron patch) is done for moderate to large defects. Open repair with cardiopulmonary bypass is usually performed before school age. In addition, the sinus venosus defect requires patch placement, so the anomalous right pulmonary venous return is directed to the left atrium with a baffle. ASD 1 type may require mitral valve repair or, rarely, replacement of the mitral valve.

Nonsurgical treatment: ASD 2 closure with a device during cardiac catheterization is becoming commonplace and can be done as an outpatient procedure. The Amplatzer Septal Occluder is most commonly used. Smaller defects that have a rim around them for attachment of the device can be closed with a device; large, irregular defects without a rim require surgical closure. Successful closure in appropriately selected patients yields results similar to those from surgery but involves shorter hospital stays and fewer complications. Patients receive low-dose aspirin for 6 month (Park, 2014).

Prognosis: Operative mortality is very low (<0.5%).

Ventricular Septal Defect

Description: Abnormal opening between the right and left ventricles. May be classified according to location: membranous (accounting for 80%) or muscular. May vary in size from a small pinhole to absence of the septum, which results in a common ventricle. VSDs are frequently associated with other defects, such as pulmonary stenosis, transposition of the great vessels, PDA, atrial defects, and COA. Many VSDs (20% to 60%) close spontaneously. Spontaneous closure is most likely to occur during the first year of life in children having small or moderate defects. A left-to-right shunt is caused by the flow of blood from the higher pressure left ventricle to the lower pressure right ventricle.

Pathophysiology: Because of the higher pressure within the left ventricle and because the systemic arterial circulation offers more resistance than the pulmonary circulation, blood flows through the defect into the pulmonary artery. The increased blood volume is pumped into the lungs, which may eventually result in increased pulmonary vascular resistance. Increased pressure in the right ventricle as a result of left-to-right shunting and pulmonary resistance causes the muscle to hypertrophy. If the right ventricle is unable to accommodate the increased workload, the right atrium may also enlarge as it attempts to overcome the resistance offered by incomplete right ventricular emptying.

Clinical manifestations: HF is common. There is a characteristic loud holosystolic murmur heard best at the left sternal border. Patients are at risk for BE and pulmonary vascular obstructive disease.

Surgical treatment:

Palliative: Pulmonary artery banding (placement of a band around the main pulmonary artery to decrease pulmonary blood flow) may be done in infants with multiple muscular VSDs or complex anatomy. Improvements in surgical techniques and postoperative care make complete repair in infancy the preferred approach.

Complete repair (procedure of choice): Small defects are repaired with sutures. Large defects usually require that a knitted Dacron patch be sewn over the opening. CPB is used for both procedures. The approach for the repair is generally through the right atrium and the tricuspid valve. Postoperative complications include residual VSD and conduction disturbances.

Prognosis: Risks depend on the location of the defect, the number of defects, and the presence of

other associated cardiac defects. Single-membranous defects are associated with low mortality (<1%); multiple muscular defects can carry a higher risk for infants, as well as infants younger than 2 months old or associated other defects (Park, 2014).

Atrioventricular Canal Defect

Description: Incomplete fusion of the endocardial cushions. Consists of a low ASD that is continuous with a high VSD and clefts of the mitral and tricuspid valves, which create a large central AV valve that allows blood to flow between all four chambers of the heart. The directions and pathways of flow are determined by pulmonary and systemic resistance, left and right ventricular pressures, and the compliance of each chamber, although flow is generally from left to right. It is the most common cardiac defect in children with Down syndrome.

Pathophysiology: The alterations in hemodynamics depend on the severity of the defect and the child's pulmonary vascular resistance. Immediately after birth, while the newborn's pulmonary vascular resistance is high, there is minimum shunting of blood through the defect. When this resistance falls, left-to-right shunting occurs, and pulmonary blood flow increases. The resultant pulmonary vascular engorgement predisposes the child to development of HF.

Clinical manifestations: Patients usually have moderate to severe HF. There is a loud systolic murmur. There may be mild cyanosis that increases with crying. Patients are at high risk for developing pulmonary vascular obstructive disease.

Surgical treatment:

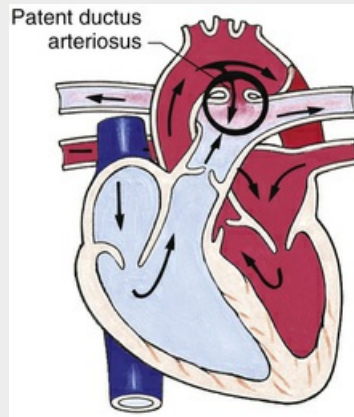

Palliative: Pulmonary artery banding is occasionally done in small infants with severe symptoms. Complete repair in infancy is most common.

Complete repair: Surgical repair consists of patch closure of the septal defects and reconstruction of the AV valve tissue (either repair of the mitral valve cleft or fashioning of two AV valves). Postoperative complications include heart block, HF, mitral regurgitation, dysrhythmias, and pulmonary hypertension.

Prognosis: Operative mortality has been 3% to 10%. Factors that increase surgical risk are younger age, severe AV valve regurgitation, hypoplasia of the left ventricle and severe failure

preoperatively, as well as other heart defects (Park, 2014). A potential later problem is mitral regurgitation, which may require valve replacement.

Patent Ductus Arteriosus

Description: Failure of the fetal ductus arteriosus (artery connecting the aorta and pulmonary artery) to close within the first weeks of life. The continued patency of this vessel allows blood to flow from the higher pressure aorta to the lower pressure pulmonary artery, which causes a left-to-right shunt.

Pathophysiology: The hemodynamic consequences of PDA depend on the size of the ductus and the pulmonary vascular resistance. At birth, the resistance in the pulmonary and systemic circulations is almost identical so that the resistance in the aorta and pulmonary artery is equalized. As the systemic pressure comes to exceed the pulmonary pressure, blood begins to shunt from the aorta across the duct to the pulmonary artery (left-to-right shunt). The additional blood is recirculated through the lungs and returned to the left atrium and left ventricle. The effects of this altered circulation are increased workload on the left side of the heart, increased pulmonary vascular congestion and possibly resistance, and potentially increased right ventricular pressure and hypertrophy.

Clinical manifestations: Patients may be asymptomatic or show signs of HF. There is a characteristic machinery-like murmur. A widened pulse pressure and bounding pulses result from runoff of blood from the aorta to the pulmonary artery. Patients are at risk for BE and pulmonary vascular obstructive disease in later life from chronic excessive pulmonary blood flow.

Medical management: Administration of indomethacin (a prostaglandin inhibitor) has proved successful in closing a PDA in preterm infants and some newborns.

Surgical treatment: Surgical division or ligation of the patent vessel is performed via a left thoracotomy. In a newer technique, video-assisted thoracoscopic surgery, a thoracoscope and instruments are inserted through three small incisions on the left side of the chest to place a clip on the ductus. The technique is used in some centers and eliminates the need for a thoracotomy, thereby speeding postoperative recovery.

Nonsurgical treatment: Coils to occlude the PDA are placed in the catheterization laboratory in many centers. Preterm or small infants (with small-diameter femoral arteries) and patients with large or unusual PDAs may require surgery.

Prognosis: Both surgical procedures can be done at low risk with zero percent mortality. PDA closure in very preterm infants has a higher mortality rate because of the additional significant medical problems. Complications are rare, but can include injury to the laryngeal nerve, paralysis

of the left hemidiaphragm, or injury to the thoracic duct (Park, 2014).

ASD, Atrial septal defect; *AV*, atrioventricular; *BE*, bacterial endocarditis; *COA*, coarctation of the aorta; *CPB*, cardiopulmonary bypass; *HF*, heart failure; *PDA*, patent ductus arteriosus; *VSD*, ventricular septal defect.

The outcomes of surgical treatment for patients with moderate to severe disease are variable. Patient risk factors for increased morbidity and mortality include prematurity or low birth weight, a genetic syndrome, multiple cardiac defects, a noncardiac congenital anomaly, and age at time of surgery (neonates are a higher risk group). For example, aortic stenosis or coarctation manifesting in the first week of life is more severe and carries a higher mortality than if it becomes apparent at 1 year of age. Outcomes for surgical repair of similar congenital heart defects also vary among treatment centers. In general, the outcomes of surgical procedures have steadily improved in the past decade, with mortality rates for many severe defects below 10% and a decrease in the incidence of complications and length of hospital stay.

Defects with Increased Pulmonary Blood Flow

In this group of cardiac defects, intracardiac communications along the septum or an abnormal connection between the great arteries allows blood to flow from the higher pressure left side of the heart to the lower pressure right side of the heart (Fig. 23-4). Increased blood volume on the right side of the heart increases pulmonary blood flow at the expense of systemic blood flow. Clinically, patients demonstrate signs and symptoms of HF. ASD, VSD, and patent ductus arteriosus are typical anomalies in this group (see Box 23-1).

FIG 23-4 Hemodynamics in defects with increased pulmonary blood flow. *LA*, Left atrium; *LV*, left ventricle; *RA*, right atrium; *RV*, right ventricle.

Obstructive Defects

Obstructive defects are those in which blood exiting the heart meets an area of anatomic narrowing (**stenosis**), causing obstruction to blood flow. The pressure in the ventricle and in the great artery before the obstruction is increased, and the pressure in the area beyond the obstruction is decreased. The location of the narrowing is usually near the valve (Fig. 23-5), as follows:

Valvular: At the site of the valve itself

Subvalvular: Narrowing in the ventricle below the valve (also referred to as the **ventricular outflow tract**)

Supravalvular: Narrowing in the great artery above the valve

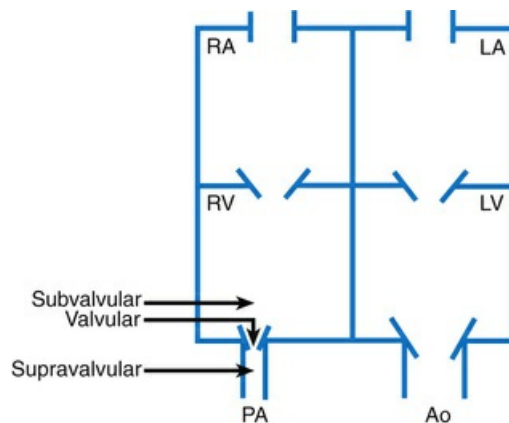

FIG 23-5 Obstruction to ventricular ejection can occur at the valvular level (shown), below the valve (subvalvular), or above the valve (supravalvular). Pulmonary stenosis is shown here. Ao, Aorta; LA, left atrium; LV, left ventricle; PA, pulmonary artery; RA, right atrium; RV, right ventricle.

Coarctation of the aorta (narrowing of the aortic arch), aortic stenosis, and pulmonic stenosis are typical defects in this group (Box 23-2). Hemodynamically, there is a pressure load on the ventricle and decreased cardiac output. Clinically, infants and children exhibit signs of HF. Children with mild obstruction may be asymptomatic. Rarely, as in severe pulmonic stenosis, hypoxemia may be seen.

Box 23-2

Obstructive Defects

Coarctation of the Aorta

Description: Localized narrowing near the insertion of the ductus arteriosus, which results in increased pressure proximal to the defect (head and upper extremities) and decreased pressure distal to the obstruction (body and lower extremities).

Pathophysiology: The effect of a narrowing within the aorta is increased pressure proximal to the defect (upper extremities) and decreased pressure distal to it (lower extremities).

Clinical manifestations: The patient may have high BP and bounding pulses in the arms, weak or absent femoral pulses, and cool lower extremities with lower BP. There are signs of HF in infants. In infants with critical coarctation, the hemodynamic condition may deteriorate rapidly with severe acidosis and hypotension. Mechanical ventilation and inotropic support are often necessary before surgery. Older children may experience dizziness, headaches, fainting, and

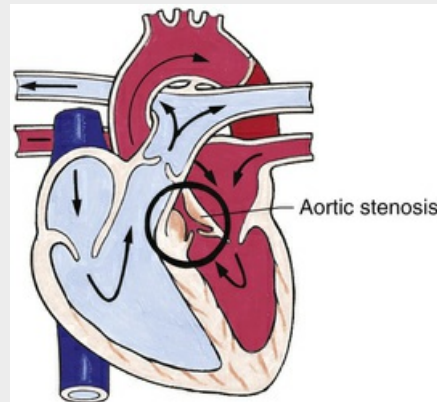

epistaxis resulting from hypertension. Patients are at risk for hypertension, ruptured aorta, aortic aneurysm, and stroke.

Surgical treatment: Surgical repair is the treatment of choice for infants younger than 6 months old and for patients with long-segment stenosis or complex anatomy; it may be performed for all patients with coarctation. Repair is by resection of the coarcted portion with an end-to-end anastomosis of the aorta or enlargement of the constricted section using a graft of prosthetic material or a portion of the left subclavian artery. Because this defect is outside the heart and pericardium, cardiopulmonary bypass is not required, and a thoracotomy incision is used. Postoperative hypertension is treated with IV sodium nitroprusside, esmolol, or milrinone followed by oral medications, such as ACE inhibitors or beta-blockers. Residual permanent hypertension after repair of COA seems to be related to age and time of repair. To prevent both hypertension at rest and exercise-provoked systemic hypertension after repair, elective surgery for COA is advised within the first 2 years of life. There is a 15% to 30% risk of recurrence in patients who underwent surgical repair as infants (Beekman, 2001). Percutaneous balloon angioplasty techniques have proved to be effective in relieving residual postoperative coarctation gradients.

Nonsurgical treatment: Balloon angioplasty is being performed as a primary intervention for COA in older infants and children. Balloon angioplasty has a higher associated rate of recoarctation than surgical repair and the rate of complication, particularly femoral artery injury is high during infancy.

Prognosis: Mortality is less than 5% in patients with isolated coarctation; the risk is increased in infants with other complex cardiac defects (Park, 2014).

Aortic Stenosis

Description: Narrowing or stricture of the aortic valve, causing resistance to blood flow in the left ventricle, decreased cardiac output, left ventricular hypertrophy, and pulmonary vascular congestion. The prominent anatomic consequence of AS is the hypertrophy of the left ventricular wall, which eventually leads to increased end-diastolic pressure, resulting in pulmonary venous and pulmonary arterial hypertension. Left ventricular hypertrophy also interferes with coronary artery perfusion and may result in myocardial infarction or scarring of the papillary muscles of the left ventricle, which causes mitral insufficiency. Valvular stenosis, the most common type, is usually caused by malformed cusps that result in a bicuspid rather than tricuspid valve or fusion of the cusps. Subvalvular stenosis is a stricture caused by a fibrous ring below a normal valve; supra-valvular stenosis occurs infrequently. Valvular AS is a serious defect for the following reasons: (1) the obstruction tends to be progressive; (2) sudden episodes of myocardial ischemia, or low cardiac output, can result in sudden death; and (3) surgical repair rarely results in a normal valve. This is one of the rare instances in which strenuous physical activity may be curtailed because of the cardiac condition.

Pathophysiology: A stricture in the aortic outflow tract causes resistance to ejection of blood from the left ventricle. The extra workload on the left ventricle causes hypertrophy. If left ventricular failure develops, left atrial pressure will increase; this causes increased pressure in the pulmonary veins, which results in pulmonary vascular congestion (pulmonary edema).

Clinical manifestations: Newborns with critical AS demonstrate signs of decreased cardiac output with faint pulses, hypotension, tachycardia, and poor feeding. Children show signs of exercise intolerance, chest pain, and dizziness when standing for a long period. A systolic ejection murmur may or may not be present. Patients are at risk for BE, coronary insufficiency, and ventricular dysfunction.

Valvular Aortic Stenosis

Surgical treatment: Aortic valvotomy is performed under inflow occlusion. Used rarely because balloon dilation in the catheterization laboratory is the first-line procedure. Newborns with critical AS and small left-sided structures may undergo a stage 1 Norwood procedure (see Hypoplastic Left Heart Syndrome, [Box 23-4](#)).

Prognosis: Aortic valve replacement offers a good treatment option and may lead to normalization of left ventricular size and function ([Arnold, Ley-Zaporozhan, Ley, et al, 2008](#)). Aortic valvotomy remains a palliative procedure, and approximately 25% of patients require additional surgery within 10 years for recurrent stenosis. A valve replacement may be required at the second procedure. An aortic homograft with a valve may also be used (extended aortic root replacement), or the pulmonary valve may be moved to the aortic position and replaced with a homograft valve (Ross procedure).

Nonsurgical treatment: The narrowed valve is dilated using balloon angioplasty in the catheterization laboratory. This procedure is usually the first intervention.

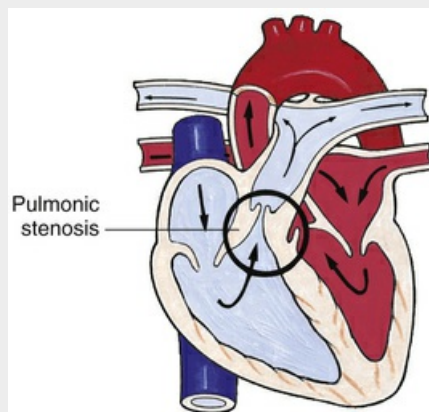

Prognosis: Complications include aortic insufficiency or valvular regurgitation, tearing of the valve leaflets, and loss of pulse in the catheterized limb.

Subvalvular Aortic Stenosis

Surgical treatment: Procedure may involve incising a membrane if one exists or cutting the fibromuscular ring. If the obstruction results from narrowing of the left ventricular outflow tract and a small aortic valve annulus, a patch may be required to enlarge the entire left ventricular outflow tract and annulus and replace the aortic valve; this is known as the *Konno procedure*.

Prognosis: Mortality from surgical repairs of subvalvular AS is less than 5% in major centers. About 20% of these patients will develop recurrent subaortic stenosis and will require additional surgery ([Schneider and Moore, 2008](#)).

Pulmonic Stenosis

Description: Narrowing at the entrance to the pulmonary artery. Resistance to blood flow causes right ventricular hypertrophy and decreased pulmonary blood flow. Pulmonary atresia is the extreme form of PS in that there is total fusion of the commissures and no blood flows to the lungs. The right ventricle may be hypoplastic.

Pathophysiology: When PS is present, resistance to blood flow causes right ventricular hypertrophy. If right ventricular failure develops, right atrial pressure will increase, and this may result in reopening of the foramen ovale, shunting of unoxygenated blood into the left atrium, and systemic cyanosis. If PS is severe, HF occurs, and systemic venous engorgement will be noted. An associated defect such as a PDA partially compensates for the obstruction by shunting blood from the aorta to the pulmonary artery and into the lungs.

Clinical manifestations: Patients may be asymptomatic; some have mild cyanosis or HF. Progressive narrowing causes increased symptoms. Newborns with severe narrowing are cyanotic. A loud systolic ejection murmur at the upper left sternal border may be present. However, in severely ill patients, the murmur may be much softer because of decreased cardiac output and shunting of blood. Cardiomegaly is evident on chest radiography. Patients are at risk for BE.

Surgical treatment: In infants, transventricular (closed) valvotomy (Brock procedure) is the surgical treatment. In children, pulmonary valvotomy with CPB is the surgical treatment. Need for surgical treatment is rare with widespread use of balloon angioplasty techniques.

Nonsurgical treatment: Balloon angioplasty in the cardiac catheterization laboratory to dilate the valve. A catheter is inserted across the stenotic pulmonic valve into the pulmonary artery, and a balloon at the end of the catheter is inflated and rapidly passed through the narrowed opening (see figure at right). The procedure is associated with few complications and has proved to be

highly effective. It is the treatment of choice for discrete PS in most centers and can be done safely in neonates.

Prognosis: The risk is low for both surgical and nonsurgical procedures; mortality is lower than 1% and slightly higher in neonates (Park, 2014). Both balloon dilation and surgical valvotomy leave the pulmonic valve incompetent because they involve opening the fused valve leaflets; however, these patients are clinically asymptomatic. Long-term problems with restenosis or valve incompetence may occur.

ACE, Angiotensin-converting enzyme; *AS*, aortic stenosis; *BE*, bacterial endocarditis; *BP*, blood pressure; *COA*, coarctation of the aorta; *CPB*, cardiopulmonary bypass; *HF*, heart failure; *IV*, intravenous; *PDA*, patent ductus arteriosus; *PS*, pulmonic stenosis.

Defects with Decreased Pulmonary Blood Flow

In this group of defects, there is obstruction of pulmonary blood flow and an anatomic defect (ASD or VSD) between the right and left sides of the heart (Fig. 23-6). Because blood has difficulty exiting the right side of the heart via the pulmonary artery, pressure on the right side increases, exceeding left-sided pressure. This allows desaturated blood to shunt right to left, causing desaturation in the left side of the heart and in the systemic circulation. Clinically, these patients have hypoxemia and usually appear cyanotic. Tetralogy of Fallot and tricuspid atresia are the most common defects in this group (Box 23-3).

FIG 23-6 Hemodynamic defects with decreased pulmonary blood flow. *LA*, Left atrium; *LV*, left ventricle; *RA*, right atrium; *RV*, right ventricle.

Box 23-3

Defects with Decreased Pulmonary Blood Flow

Tetralogy of Fallot

Description: The classic form includes four defects: (1) VSD, (2) PS, (3) overriding aorta, and (4) right ventricular hypertrophy. Tetralogy of Fallot occurs in 5% to 10% of all CHDs and is the most common cyanotic lesion (Park, 2014).

Pathophysiology: The alteration in hemodynamics varies widely, depending primarily on the degree of PS but also on the size of the VSD and the pulmonary and systemic resistance to flow. Because the VSD is usually large, pressures may be equal in the right and left ventricles. Therefore, the shunt direction depends on the difference between pulmonary and systemic vascular resistance. If pulmonary vascular resistance is higher than systemic resistance, the shunt is from right to left. If systemic resistance is higher than pulmonary resistance, the shunt is from left to right. PS decreases blood flow to the lungs and consequently the amount of oxygenated blood that returns to the left side of the heart. Depending on the position of the aorta, blood from both ventricles may be distributed systemically.

Clinical manifestations: Some infants may be acutely cyanotic at birth; others have mild cyanosis that progresses over the first year of life as the PS worsens. There is a characteristic systolic murmur that is often moderate in intensity. There may be acute episodes of cyanosis and hypoxia, called *blue spells* or *tet spells*. Anoxic spells occur when the infant's oxygen requirements exceed the blood supply, usually during crying or after feeding. Patients are at risk for emboli, seizures, and loss of consciousness or sudden death after an anoxic spell.

Surgical treatment:

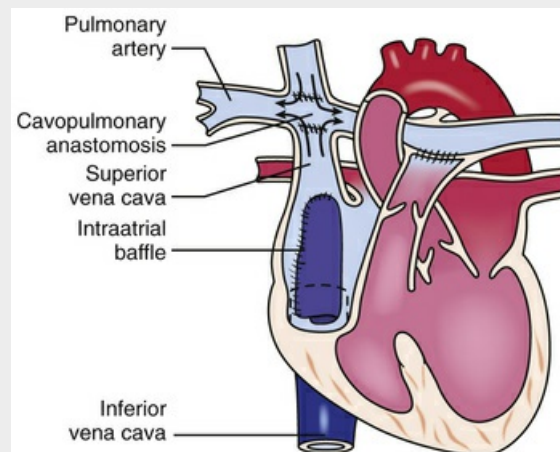

Palliative shunt: In infants who cannot undergo primary repair, a palliative procedure to increase pulmonary blood flow and increase oxygen saturation may be performed. The preferred procedure is a modified Blalock-Taussig shunt operation, which provides blood flow to the pulmonary arteries from the left or right subclavian artery via a tube graft (see Table 23-4). In general, however, shunts are avoided because they may result in pulmonary artery distortion.

Complete repair: Elective repair is usually performed in the first year of life. Indications for repair include increasing cyanosis and the development of hypercyanotic spells. Complete repair involves closure of the VSD and resection of the infundibular stenosis, with placement of a pericardial patch to enlarge the RVOT. In some

repairs, the patch may extend across the pulmonary valve annulus (transannular patch), making the pulmonary valve incompetent. The procedure requires a median sternotomy and the use of cardiopulmonary bypass.

Prognosis: The operative mortality for total correction of tetralogy of Fallot is less than 2% to 3% during the first 2 years of life (Park, 2014). Infants younger than 3 months old and children older than 4 years old, as well as those with other CHD or hypoplasia of the pulmonary annulus and trunk have a higher mortality rate. With improved surgical techniques, there is a lower incidence of dysrhythmias and sudden death; surgical heart block is rare. HF may occur postoperatively.

Tricuspid Atresia

Description: The tricuspid valve fails to develop; consequently there is no communication from the right atrium to the right ventricle. Blood flows through an ASD or a patent foramen ovale to the left side of the heart and through a VSD to the right ventricle and out to the lungs. The condition is often associated with PS and TGA. There is complete mixing of unoxygenated and oxygenated blood in the left side of the heart, which results in systemic desaturation, and varying amounts of pulmonary obstruction, which causes decreased pulmonary blood flow.

Pathophysiology: At birth, the presence of a patent foramen ovale (or other atrial septal opening) is required to permit blood flow across the septum into the left atrium; the PDA allows blood flow

to the pulmonary artery into the lungs for oxygenation. A VSD allows a modest amount of blood to enter the right ventricle and pulmonary artery for oxygenation. Pulmonary blood flow usually is diminished.

Clinical manifestations: Cyanosis is usually seen in the newborn period. There may be tachycardia and dyspnea. Older children have signs of chronic hypoxemia with clubbing.

Therapeutic management: For neonates whose pulmonary blood flow depends on the patency of the ductus arteriosus, a continuous infusion of prostaglandin E₁ is started at 0.1 mcg/kg/min until surgical intervention can be arranged.

Surgical treatment: Palliative treatment is the placement of a shunt (pulmonary-to-systemic artery anastomosis) to increase blood flow to the lungs. If the ASD is small, an atrial septostomy is performed during cardiac catheterization. Some children have increased pulmonary blood flow and require pulmonary artery banding to lessen the volume of blood to the lungs. A bidirectional Glenn shunt (cavopulmonary anastomosis) may be performed at 4 to 9 months as a second stage.

Modified Fontan procedure: Systemic venous return is directed to the lungs without a ventricular pump through surgical connections between the right atrium and the pulmonary artery. A fenestration (opening) is sometimes made in the right atrial baffle to relieve pressure. The patient must have normal ventricular function and a low pulmonary vascular resistance for the procedure to be successful. The modified Fontan procedure separates oxygenated and unoxygenated blood inside the heart and eliminates the excess volume load on the ventricle but does not restore normal anatomy or hemodynamics. This operation is also the final stage in the correction of many complex defects with a functional single ventricle, including HLHS.

Prognosis: Surgical mortality following the Fontan procedure is less than 3% (Park, 2014). The overall survival rate after the Fontan operation was above 95% at follow up of 50 months (Hirsch, Goldberg, Bove, et al, 2008). Postoperative complications include dysrhythmias, systemic venous hypertension, pleural and pericardial effusions, and ventricular dysfunction. Long-term concerns are the development of protein-losing enteropathy, atrial dysrhythmias, late ventricular dysfunction, and developmental delays.

ASD, Atrial septal defect; *CHD*, congenital heart disease; *HF*, heart failure; *HLHS*, hypoplastic left heart syndrome; *PDA*, patent ductus arteriosus; *PS*, pulmonic stenosis; *RVOT*, right ventricular outflow tract; *TGA*, transposition of the great arteries; *VSD*, ventricular septal defect.

Mixed Defects

Many complex cardiac anomalies are classified together in the mixed category (Box 23-4), because survival in the postnatal period depends on mixing of blood from the pulmonary and systemic circulations within the heart chambers. Hemodynamically, fully saturated systemic blood flow mixes with the desaturated pulmonary blood flow, causing a relative desaturation of the systemic blood flow. Pulmonary congestion occurs because the differences in pulmonary artery pressure and aortic pressure favor pulmonary blood flow. Cardiac output decreases because of a volume load on the ventricle. Clinically, these patients have a variable picture that combines some degree of desaturation (although cyanosis is not always visible) and signs of HF. Some defects, such as transposition of the great arteries, cause severe cyanosis in the first days of life and later cause HF. Others, such as truncus arteriosus, cause severe HF in the first weeks of life and mild desaturation.

Box 23-4

Mixed Defects

Transposition of the Great Arteries, or Transposition of the Great Vessels

Description: The pulmonary artery leaves the left ventricle, and the aorta exits from the right ventricle with no communication between the systemic and pulmonary circulations.

Pathophysiology: Associated defects, such as septal defects or PDA, must be present to permit blood to enter the systemic circulation or the pulmonary circulation for mixing of saturated and desaturated blood. The most common defect associated with TGA is a patent foramen ovale. At birth, there is also a PDA, although in most instances, this closes after the neonatal period. Another associated defect may be a VSD. The presence of a VSD increases the risk of HF because it permits blood to flow from the right to the left ventricle, into the pulmonary artery, and finally to the lungs. However, it also produces high pulmonary blood flow under high pressure, which can result in high pulmonary vascular resistance.

Clinical manifestations: These depend on the type and size of the associated defects. Newborns with minimum communication are severely cyanotic and have depressed function at birth. Those with large septal defects or a PDA may be less cyanotic but have symptoms of HF. Heart sounds vary according to the type of defect present. Cardiomegaly is usually evident a few weeks after birth.

Therapeutic management (to provide intracardiac mixing): The administration of IV prostaglandin E_1 may be initiated to keep the ductus arteriosus open to temporarily increase blood mixing and provide an oxygen saturation of 75% or to maintain cardiac output. During cardiac catheterization or under echocardiographic guidance, a balloon atrial septostomy (Rashkind procedure) may also be performed to increase mixing by opening the atrial septum.

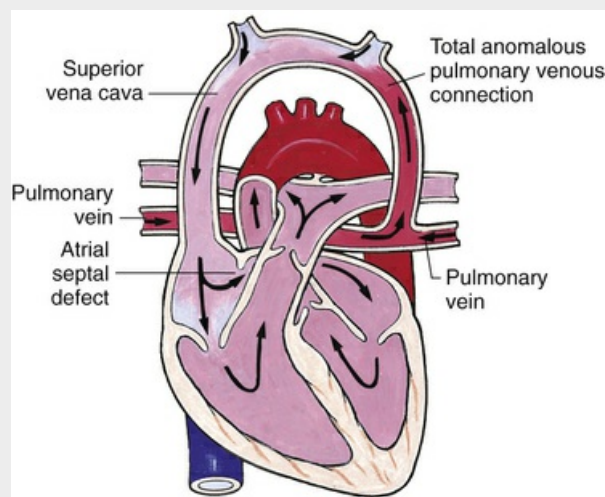

Surgical treatment: An arterial switch procedure is the procedure of choice performed in the first weeks of life. It involves transecting the great arteries and anastomosing the main pulmonary artery to the proximal aorta (just above the aortic valve) and anastomosing the ascending aorta to the proximal pulmonary artery. The coronary arteries are switched from the proximal aorta to the proximal pulmonary artery to create a new aorta. Reimplantation of the coronary arteries is critical to the infant's survival, and they must be reattached without torsion or kinking to provide the heart with its supply of oxygen. The advantage of the arterial switch procedure is the reestablishment of normal circulation, with the left ventricle acting as the systemic pump. Potential complications of the arterial switch include narrowing at the great artery anastomoses and coronary artery insufficiency.

Intraatrial baffle repairs: Intraatrial baffle repairs are rarely performed, although many adolescents and adults survive today with repairs that were done more than 15 years ago. An intraatrial baffle is created to divert venous blood to the mitral valve and pulmonary venous blood to the tricuspid valve using the patient's atrial septum (Senning procedure) or a prosthetic material (Mustard procedure). A disadvantage is the continuing role of the right ventricle as the systemic pump and the late development of right ventricular failure and rhythm disturbances. Other potential postoperative complications include loss of normal sinus rhythm, baffle leaks, and ventricular dysfunction.

Rastelli procedure: This procedure is the operative choice in infants with TGA, VSD, and severe PS. It involves closure of the VSD with a baffle so that left ventricular blood is directed through the VSD into the aorta. The pulmonic valve is then closed, and a conduit is placed from the right ventricle to the pulmonary artery to create a physiologically normal circulation. Unfortunately, this procedure requires multiple conduit replacements as the child grows.

Prognosis: Mortality rate varies dependent upon the anatomy and procedure performed. The operative mortality rate for neonates with TGA and intact ventricular septum is at 6% (Park, 2014). Potential long-term problems include suprapulmonic stenosis and neo-aortic dilation and regurgitation, as well as coronary artery obstruction.

Total Anomalous Pulmonary Venous Connection

Description: Rare defect characterized by failure of the pulmonary veins to join the left atrium. Instead, the pulmonary veins are abnormally connected to the systemic venous circuit via the right atrium or various veins draining toward the right atrium, such as the SVC. The abnormal attachment results in mixed blood being returned to the right atrium and shunted from the right

to the left through an ASD. TAPVC (also called *total anomalous pulmonary venous return* or *total anomalous pulmonary venous drainage*) is classified according to the pulmonary venous point of attachment as follows:

Supracardiac: Attachment above the diaphragm, such as to the SVC (most common form) (see [Fig. 23-10](#))

Cardiac: Direct attachment to the heart, such as to the right atrium or coronary sinus

Infradiaphragmatic: Attachment below the diaphragm, such as to the IVC (most severe form)

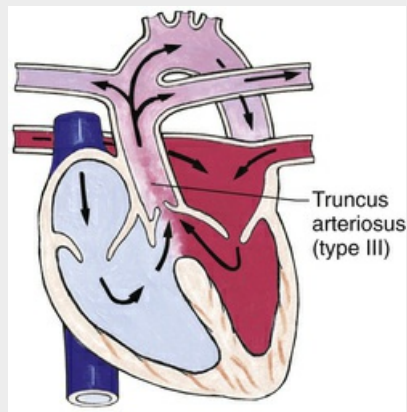

Pathophysiology: The right atrium receives all the blood that normally would flow into the left atrium. As a result, whereas the right side of the heart hypertrophies, the left side, especially the left atrium, may remain small. An associated ASD or patent foramen ovale allows systemic venous blood to shunt from the higher pressure right atrium to the left atrium and into the left side of the heart. As a result, the oxygen saturation of the blood in both sides of the heart (and ultimately in the systemic arterial circulation) is the same. If the pulmonary blood flow is large, pulmonary venous return is also large, and the amount of saturated blood is relatively high. However, if there is obstruction to pulmonary venous drainage, pulmonary venous return is impeded, pulmonary venous pressure rises, and pulmonary interstitial edema develops and eventually contributes to HF. Infradiaphragmatic TAPVC is often associated with obstruction to pulmonary venous drainage and is a surgical emergency.

Clinical manifestations: Most infants develop cyanosis early in life. The degree of cyanosis is inversely related to the amount of pulmonary blood flow—the more pulmonary blood, the less cyanosis. Children with unobstructed TAPVC may be asymptomatic until pulmonary vascular resistance decreases during infancy, increasing pulmonary blood flow with resulting signs of HF. Cyanosis becomes worse with pulmonary vein obstruction; when obstruction occurs, the infant's condition usually deteriorates rapidly. Without intervention, cardiac failure will progress to death.

Surgical treatment: Corrective repair is performed in early infancy. The surgical approach varies with the anatomic defect. In general, however, the common pulmonary vein is anastomosed to the back of the left atrium, the ASD is closed, and the anomalous pulmonary venous connection is ligated. The cardiac type is most easily repaired; the infradiaphragmatic type carries the highest morbidity and mortality because of the higher incidence of pulmonary vein obstruction. Potential postoperative complications include re-obstruction; bleeding; dysrhythmias, particularly heart block; PAH; and persistent heart failure.

Prognosis: Mortality is between 5% to 10% for infants without obstruction, and it can be as high as 20% for infants with infradiaphragmatic type ([Park, 2014](#)).

Truncus Arteriosus

Description: Failure of normal septation and division of the embryonic bulbar trunk into the pulmonary artery and the aorta, which results in development of a single vessel that overrides both ventricles. Blood from both ventricles mixes in the common great artery, which leads to desaturation and hypoxemia. Blood ejected from the heart flows preferentially to the lower-pressure pulmonary arteries so that pulmonary blood flow is increased and systemic blood flow is reduced. There are three types:

Type I: A single pulmonary trunk arises near the base of the truncus and divides into the left and right pulmonary arteries.

Type II: The left and right pulmonary arteries arise separately but in close proximity and at the same level from the back of the truncus.

Type III: The pulmonary arteries arise independently from the sides of the truncus.

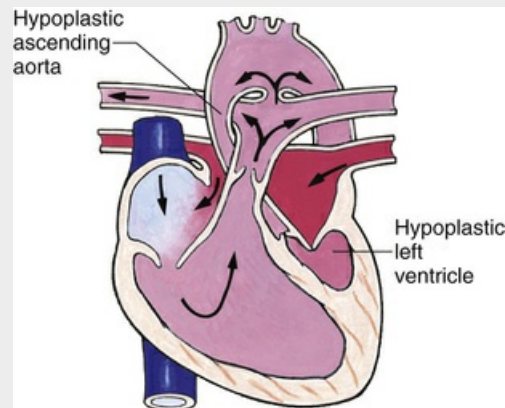

Pathophysiology: Blood ejected from the left and right ventricles enters the common trunk so that pulmonary and systemic circulations are mixed. Blood flow is distributed to the pulmonary and systemic circulations according to the relative resistances of each system. The amount of pulmonary blood flow depends on the size of the pulmonary arteries and the pulmonary vascular resistance. Generally, resistance to pulmonary blood flow is less than systemic vascular resistance, which results in preferential blood flow to the lungs. Pulmonary vascular disease develops at an early age in patients with truncus arteriosus.

Clinical manifestations: Most infants are symptomatic with moderate to severe HF and variable cyanosis, poor growth, and activity intolerance. There is a holosystolic murmur at the left sternal murmur with a diastolic murmur present if truncal regurgitation is present. Thirty-five percent of patients have 22q11 deletions (Goldmuntz, Clark, Mitchell, et al, 1998).

Surgical treatment: Early repair is performed in the first month of life. It involves closing the VSD so that the truncus arteriosus receives the outflow from the left ventricle and excising the pulmonary arteries from the aorta and attaching them to the right ventricle by means of a homograft. Currently, homografts (segments of cadaver aorta and pulmonary artery that are treated with antibiotics and cryopreserved) are preferred over synthetic conduits to establish continuity between the right ventricle and pulmonary artery. Homografts are more flexible and easier to use during the procedure and appear less prone to obstruction. Postoperative complications include persistent heart failure, bleeding, PAH, dysrhythmias, and residual VSD. Because conduits are not living tissue, they will not grow along with the child and may also become narrowed with calcifications. One or more conduit replacements will be needed in childhood.

Prognosis: Mortality is greater than 10%; future operations are required to replace the conduits.

Hypoplastic Left Heart Syndrome

Description: Underdevelopment of the left side of the heart, resulting in a hypoplastic left ventricle and aortic atresia. Most blood from the left atrium flows across the patent foramen ovale to the right atrium, to the right ventricle, and out the pulmonary artery. The descending aorta receives blood from the PDA supplying systemic blood flow.

Pathophysiology: An ASD or patent foramen ovale allows saturated blood from the left atrium to mix with desaturated blood from the right atrium and to flow through the right ventricle and out into the pulmonary artery. From the pulmonary artery, the blood flows both to the lungs and through the ductus arteriosus into the aorta and out to the body. The amount of blood flow to the pulmonary and systemic circulations depends on the relationship between the pulmonary and systemic vascular resistances. The coronary and cerebral vessels receive blood by retrograde flow through the hypoplastic ascending aorta.

Clinical manifestations: The patient has mild cyanosis and signs of HF until the PDA closes and then progressive deterioration with cyanosis and decreased cardiac output, leading to cardiovascular collapse. The condition is usually fatal in the first months of life without intervention.

Therapeutic management: Neonates require stabilization with mechanical ventilation and inotropic support preoperatively. A prostaglandin E₁ infusion is needed to maintain ductal patency and ensure adequate systemic blood flow.

Surgical treatment: A multiple-stage approach is used. The first stage is a Norwood procedure, which involves an anastomosis of the main pulmonary artery to the aorta to create a new aorta, shunting to provide pulmonary blood flow (usually with a modified Blalock-Taussig shunt), and creation of a large ASD. Postoperative complications include imbalance of systemic and pulmonary blood flow, bleeding, low cardiac output, and persistent heart failure. A new modification of the first stage repair is the use of a right ventricle-to-pulmonary artery homograft conduit instead of a shunt to supply pulmonary blood flow (Sano procedure). The second stage is often a bidirectional Glenn shunt procedure (see Fig. 23-10) or a hemi-Fontan operation. Both involve anastomosing the SVC to the right pulmonary artery so that SVC flow bypasses the right atrium and flows directly to the lungs. The procedure is usually done at 3 to 6 months of age to relieve cyanosis and reduce the volume load on the right ventricle. The final repair is a modified Fontan procedure (see Tricuspid Atresia, Box 23-3).

Transplantation: Heart transplantation in the newborn period is another option for these infants. Problems include the shortage of newborn organ donors, risk of rejection, long-term problems with chronic immunosuppression, and infection (see Heart Transplantation, later in the chapter).

Prognosis: For the first-stage repair, survival rates vary widely in different centers. Much progress has been made, and some experienced centers are reporting mortality rates of about 10% (Tweddell, Hoffman, Mussatto, et al, 2002). Long-term problems with repair include worsening ventricular function, tricuspid regurgitation, recurrent aortic arch narrowing, dysrhythmias, and developmental delays. There is a risk of mortality between surgical procedures. The mortality for the later two operations is less than 5%.

ASD, Atrial septal defect; *HF*, heart failure; *IV*, intravenous; *IVC*, inferior vena cava; *PAH*, pulmonary artery hypertension; *PDA*, patent ductus arteriosus; *PS*, pulmonic stenosis; *SVC*, superior vena cava; *TAPVC*, total anomalous pulmonary venous connection; *TGA*, transposition of the great arteries; *VSD*, ventricular septal defect.

Clinical Consequences of Congenital Heart Disease

Heart Failure

HF is the inability of the heart to pump an adequate amount of blood to the systemic circulation at normal filling pressures to meet the body's metabolic demands. In children, HF most frequently occurs secondary to structural abnormalities (e.g., septal defects) that result in increased blood volume and pressure within the heart. It can also result from myocardial failure in which the contractility or relaxation of the ventricle is impaired. This can occur with cardiomyopathy, dysrhythmias, or severe electrolyte disturbances. HF can also occur because of excessive demands on a normal heart muscle, such as sepsis or severe anemia.

Pathophysiology

HF is often separated into two categories, right-sided and left-sided failure. In **right-sided failure**, the right ventricle is unable to pump blood effectively into the pulmonary artery, resulting in increased pressure in the right atrium and systemic venous circulation. Systemic venous hypertension causes hepatosplenomegaly and occasionally edema. In **left-sided failure**, the left ventricle is unable to pump blood into the systemic circulation, resulting in increased pressure in the left atrium and pulmonary veins. The lungs become congested with blood, causing elevated pulmonary pressures and pulmonary edema.

Although each type of HF produces different signs and symptoms, clinically, it is unusual to observe solely right- or left-sided failure in children. Because each side of the heart depends on adequate function of the other side, failure of one chamber causes a reciprocal change in the opposite chamber.

If the abnormalities precipitating HF are not corrected, the heart muscle becomes damaged. Despite compensatory mechanisms, the heart is unable to maintain an adequate cardiac output. Decreased blood flow to the kidneys continues to stimulate sodium and water reabsorption, leading to fluid overload, increased workload on the heart, and congestion in the pulmonary and systemic circulations (Fig. 23-7).

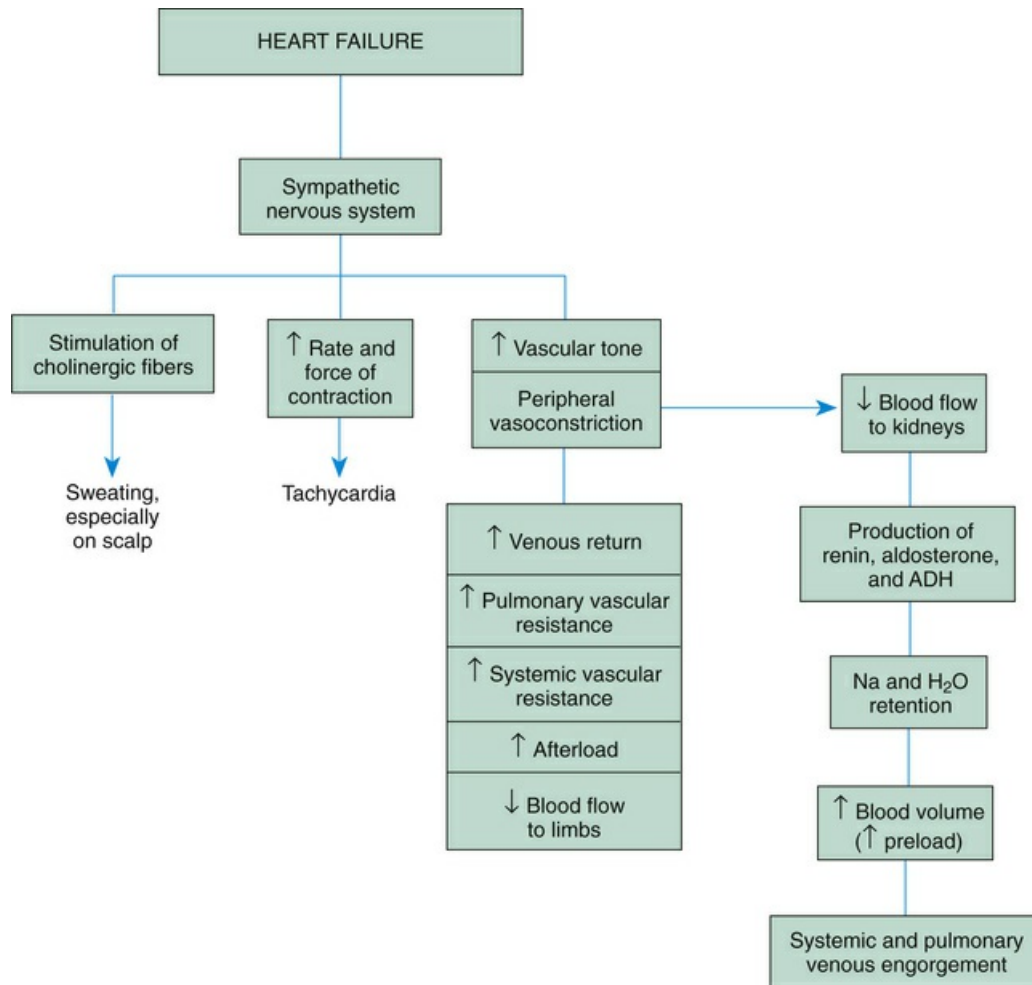

FIG 23-7 Pathophysiology of heart failure. *ADH*, Antidiuretic hormone.

Clinical Manifestations

The signs and symptoms of HF can be divided into three groups: (1) impaired myocardial function, (2) pulmonary congestion, and (3) systemic venous congestion (Box 23-5). Because these hemodynamic changes occur from different causes and at differing times, the clinical presentation may vary among children.

Box 23-5

Clinical Manifestations of Heart Failure

Impaired Myocardial Function

- Tachycardia
- Sweating (inappropriate)
- Decreased urinary output
- Fatigue
- Weakness
- Restlessness
- Anorexia

Pale, cool extremities
Weak peripheral pulses
Decreased blood pressure (BP)
Gallop rhythm
Cardiomegaly

Pulmonary Congestion

Tachypnea
Dyspnea
Retractions (infants)
Flaring nares
Exercise intolerance
Orthopnea
Cough, hoarseness
Cyanosis
Wheezing
Grunting

Systemic Venous Congestion

Weight gain
Hepatomegaly
Peripheral edema, especially periorbital
Ascites
Neck vein distention (children)

Diagnostic Evaluation

Diagnosis is made on the basis of clinical symptoms, such as tachypnea and tachycardia at rest, dyspnea, retractions, activity intolerance (especially during feeding in infants), feeding intolerance, weight gain caused by fluid retention, and hepatomegaly. Chest radiography demonstrates cardiomegaly and increased pulmonary blood flow. Ventricular hypertrophy, abnormal rhythm or decreased voltages appear on the ECG. An echocardiogram is done to determine the cause of HF, such as a congenital heart defect or poor ventricular function.

Therapeutic Management

The goals of treatment are to (1) improve cardiac function (increase contractility and decrease afterload), (2) remove accumulated fluid and sodium (decrease preload), (3) decrease cardiac demands, and (4) improve tissue oxygenation and decrease oxygen consumption. For most infants diagnosed with HF, the cause is CHD. Infants are stabilized on medical therapy and then referred for surgical repair. Today many children are being surgically repaired in the neonatal and early infancy stages before the onset of HF symptoms (Margossian, 2008). For children newly diagnosed with HF, the cause may be worsening ventricular function following a previous cardiac repair,

cardiomyopathy, arrhythmia, or other conditions. In addition to management of HF, the underlying cause is treated if possible.

Improve Cardiac Function

Three groups of drugs are used to enhance myocardial function in HF: (1) digitalis glycosides (digoxin), which improve contractility, (2) angiotensin-converting enzyme (ACE) inhibitors, which reduce the afterload on the heart and thus make it easier for the heart to pump, and (3) beta-blockers. Myocardial efficiency is improved through administration of digitalis glycosides. The beneficial effects are increased cardiac output, decreased heart size, decreased venous pressure, and relief of edema. In children, digoxin (Lanoxin) is used almost exclusively because of its more rapid onset. Note the dose is calculated in micrograms (1000 mcg = 1 mg). During initiation, the child is monitored by means of an ECG to observe for the desired effects (prolonged PR interval and reduced ventricular rate) and detect side effects, especially dysrhythmias.

Another group of drugs used in the treatment of HF, the ACE inhibitors, inhibit the normal function of the renin/angiotensin system in the kidney. The ACE inhibitors block the conversion of angiotensin I to angiotensin II so that, instead of vasoconstriction, vasodilation occurs. Vasodilation results in decreased pulmonary and systemic vascular resistance, decreased BP, and a reduction in afterload. It also reduces the secretion of aldosterone, which reduces preload by preventing volume expansion from fluid retention and decreases the risk of hypokalemia. Common medications used in children are captopril (Capoten), enalapril (Vasotec), and lisinopril. The principal side effects of ACE inhibitors are hypotension, cough, and renal dysfunction.

Beta-blockers, specifically carvedilol (Coreg), are the newest medications to be added to the treatment of some children with chronic HF. The α - and β -adrenergic receptors are blocked, causing decreased heart rate, decreased BP, and vasodilation. It has been shown to decrease morbidity and mortality in some adults with HF and is being used selectively in children. Side effects included dizziness, headache, and hypotension.

Cardiac resynchronization therapy (CRT) using biventricular pacing is an effective treatment in adult patients with HF and is beginning to be applied in the pediatric population. With pharmacologic therapies described earlier, CRT has the potential to improve cardiac function in this group of patients, including those with a single ventricle (Cecchin, Frangini, Brown, et al, 2009; Dubin, Janousek, Rhee, et al, 2005).

Nursing Alert

Because ACE inhibitors also block the action of aldosterone, the addition of potassium supplements or spironolactone (Aldactone) to the drug regimen of patients taking diuretics is usually not needed and may cause hyperkalemia.

Remove Accumulated Fluid and Sodium

Treatment consists of diuretics, possible fluid restriction, and possible sodium restriction. Diuretics are the mainstay of therapy to eliminate excess water and salt to prevent reaccumulation. The most frequently used agents are listed in Table 23-3. Because furosemide and the thiazides are potassium-losing diuretics, potassium supplements may be prescribed, and rich dietary sources of the electrolyte are encouraged.

Nursing Alert

A fall in the serum potassium level enhances the effects of digitalis, increasing the risk of digoxin toxicity. Increased serum potassium levels diminish digoxin's effect. Therefore, serum potassium levels must be carefully monitored.

TABLE 23-3
Diuretics Used in Heart Failure

| Actions | Comments | Nursing Care Management |
|--|---|--|
| Furosemide (Lasix): Blocks reabsorption of sodium and water in proximal renal tubule and interferes with reabsorption of sodium | Drug of choice in severe HF Causes excretion of chloride and potassium (hypokalemia may precipitate digitalis) | Begin to record output as soon as drug is given. Observe for dehydration caused by profound diuresis. Observe for side effects (nausea and vomiting, diarrhea, |

| | | |
|--|---|---|
| | toxicity) | ototoxicity, hypokalemia, dermatitis, postural hypotension). Encourage foods high in potassium or give potassium supplements. Monitor chloride and acid-base balance with long-term therapy. Observe for signs of digoxin toxicity. |
| Chlorothiazide (Diuril): Acts directly on distal tubules to decrease sodium, water, potassium, chloride, and bicarbonate absorption | Less frequently used drug Causes hypokalemia, acidosis from large doses | Observe for side effects (nausea, weakness, dizziness, paresthesia, muscle cramps, skin eruptions, hypokalemia, acidosis). Encourage foods high in potassium or give potassium supplements. |
| Spirolactone (Aldactone): Blocks action of aldosterone, which promotes retention of sodium and excretion of potassium | Weak diuretic Has potassium-sparing effect; frequently used with thiazides, furosemide Poorly absorbed from GI tract Takes several days to achieve maximum actions | Observe for side effects (skin rash, drowsiness, ataxia, hyperkalemia). Do not administer potassium supplements. |

GI, Gastrointestinal; HF, heart failure.

Fluid restriction may be required in the acute stages of HF and must be carefully calculated to avoid dehydrating the child, especially if cyanotic CHD and significant polycythemia are present. Infants rarely need fluid restrictions because HF makes feeding so difficult that they struggle to take maintenance fluids.

Sodium-restricted diets are used less often in children than in adults to control HF because of their potential negative effects on the child's appetite and ultimate growth. If salt intake is restricted, additional table salt and highly salted foods are avoided.

Decrease Cardiac Demands

To lessen the workload on the heart, metabolic needs are minimized by (1) providing a neutral thermal environment to prevent cold stress in infants, (2) treating any existing infections, (3) reducing the effort of breathing (by placement in semi-Fowler position), (4) using medication to sedate an irritable child, and (5) providing for rest and decreasing environmental stimuli.

Improve Tissue Oxygenation

The preceding measures serve to increase tissue oxygenation, either by improving myocardial function or by lessening tissue oxygen demands. In addition, supplemental cool humidified oxygen may be administered to increase the amount of available oxygen during inspiration. Oxygen administration is especially helpful in patients with pulmonary edema, intercurrent respiratory tract infections, and increased pulmonary vascular resistance (oxygen is a vasodilator that decreases pulmonary vascular resistance).

Nursing Alert

Oxygen is a drug and is administered only with an appropriate order. There are some uncommon circumstances in patients with complex hemodynamics in which oxygen can be detrimental.

An oxygen hood, nasal cannula, or face tent is used to deliver oxygen. Nasal cannulas are ideal for long-term oxygen administration because the child can be ambulatory and can easily eat and drink. Cool humidification is necessary to counteract the drying effect of oxygen. The amount of cool humidity is carefully regulated to prevent chilling.

Quality Patient Outcomes: Heart Failure

- Adequate cardiac output
- Decreased cardiac demands
- Improved respiratory function
- No evidence of fluid excess
- Adequate support and education

Nursing Care Management

The infant or child with HF may be acutely ill, and some may require intensive care until the symptoms improve. Expert nursing care is essential to reduce the cardiac demands that strain the

failing heart muscle. During this time, the child and family require emotional support. Although the objectives of nursing care are the same, interventions differ depending on the child's age (see [Nursing Care Plan](#) box).

Nursing Care Plan

The Child with Heart Failure

Case Study

George is a 2-week-old male with congenital heart disease (CHD). At birth he initially showed no signs or symptoms but within the first week he developed symptoms of heart failure (HF). He was found to have coarctation of the aorta and is now under the care of the cardiology team and scheduled for surgery. George is experiencing more signs of HF and the care is now focused on preventing further symptoms before he goes to surgery.

Assessment

What are the most important signs of HF that you need to look for in a young infant?

Heart Failure Defining Characteristics

Tachycardia

Tachypnea

Ineffective peripheral circulation, cool extremities

Hypotension

Rapid, weak peripheral pulses

Prolonged capillary refill, longer than 2 or 3 seconds

Narrow pulse pressure

Distended neck veins in older children

Cardiomegaly revealed on chest radiograph

Gallop rhythm

Edema

Rapid weight gain

Feeding difficulty

Irritability

Nursing Diagnosis

Decreased cardiac output related to inadequate volume of blood pumped by the heart per minute to meet the metabolic demands of the body.

Nursing Interventions and Rationales

What are the most appropriate nursing interventions for an infant in heart failure?

| Nursing Interventions | Rationales |
|---|--|
| Assess and record heart rate, respiratory rate, blood pressure (BP), and any signs or symptoms of decreased cardiac output every 2 to 4 hours and as necessary. | To detect change in vital signs and infant's physical status that reflect altered cardiac output and cardiogenic shock |
| Administer cardiac drugs on schedule. Assess and record any side effects or any signs and symptoms of toxicity. Follow hospital protocol for administration. | To avoid dangers inherent in failure to administer cardiac drugs as prescribed and to perform careful assessment before administration |
| Keep accurate record of intake and output. | To detect HF, which causes decreased urinary output |
| Weigh infant on same scale at same time of day as previously. Document results and compare to previous weight. | To monitor for weight increases, which may indicate excess fluid accumulation |
| Administer diuretics on schedule. Assess and record effectiveness and any side effects noted. | To eliminate excess water and salt because fluid retention commonly occurs with HF |
| Offer small, frequent feedings to infant's tolerance. | To increase caloric intake and compensate for fatigue during feeding and increased metabolic rate because of poor cardiac function |

Expected Outcome

George's cardiac function will be protected by decreasing cardiac demands, improving respiratory function, and preventing fluid excess.

Infant will have adequate cardiac output as evidenced by:

- Heart rate within acceptable range (state specific range)
- Respiratory rate within acceptable range (state specific range)
- Skin warm to touch
- Strong and equal peripheral pulses
- BP normal for age
- Brisk capillary refill within 2 or 3 seconds
- Lack of distended neck veins
- Normal sinus rhythm
- Lack of edema
- Adequate urinary output (1 to 2 ml/kg/hr)
- Age-appropriate weight gain on standardized growth curve
- Successful feeding

Case Study (Continued)

George's BP is increased and the pulses in his arms are bounding. You find weak femoral pulses and his extremities are cool to touch. George's breathing appears labored, and you note nasal flaring but no intercostal retractions at this time. His color is pale and slightly mottled.

Assessment

What are the most important signs and symptoms of impaired breathing in this infant?

Impaired Breathing Defining Characteristics

Tachypnea

Dyspnea

Retractions

Crackles

Shortness of breath

Cyanosis

Pallor

Mottling

Nasal flaring

Grunting

Head bobbing

Cough

Use of accessory muscles

Activity intolerance

Do the findings described in the case study concern you?

The effect of the coarctation of the aorta causes a narrowing within the aorta that increases pressure proximal to the defect (upper extremities) and a decreased pressure distal to it (lower extremities). It is not surprising to find high BP, bounding upper extremity pulses, and weak or even absent femoral pulses and cool extremities in these infants. You should follow his breathing patterns closely and observe for breathing changes.

How would you assess the effectiveness of these interventions?

Evaluate for changes in breathing patterns, respiratory rate, and labored breath sounds; observe for nasal flaring or change in color to dusky or blue.

Why are breathing pattern changes a concern?

Coarctation of the aorta can cause pulmonary congestion as a result of decreased cardiac output. Breathing difficulties can be a sign of progression of heart failure.

Nursing Diagnosis

Impaired breathing pattern related to pulmonary congestion, decreased cardiac output.

Nursing Interventions and Rationales

What are the most appropriate nursing interventions for this diagnosis?

| Nursing Interventions | Rationales |
|--|---|
| Assess and record oxygen saturation every 2 to 4 hours or more often as needed. | To evaluate pulmonary effectiveness |
| Elevate head of bed at a 30- to 45-degree angle. | To promote maximum chest expansion |
| Assess and record respiratory rate, breath sounds, and any signs or symptoms of ineffective pattern every 2 to 4 hours and as needed. | To detect indicators of worsening HF |
| Administer humidified oxygen in correct amount and route of delivery. Record percent of oxygen and route of delivery. Assess and record child's response to therapy. | To reduce respiratory distress by easing respiratory effort |
| Suction if infant has ineffective cough or is unable to manage secretions. Assess and record amount and characteristics of secretions. | To maintain patent airway to promote respiratory expansion |

Expected Outcome

George will have an effective breathing pattern and maintain stable respiratory pattern until surgery as evidenced by respiratory rate within acceptable limits for age.

Infant will have effective breathing pattern as evidenced by:

- Respiratory rate within acceptable range (state specific range)
- Clear and equal breath sounds bilaterally anteriorly and posteriorly
- Pink or tan color
- Absence of nasal flaring, retractions, cough, and head bobbing
- Unlabored breath sounds
- Tolerance of activities appropriate for age

Case Study (Continued)

George's parents ask you what you have found in your initial assessment. They ask about why he seems to be having problems breathing. What should you say to the parents?

Assessment

What are the most important aspects of George's care to discuss with his parents at this time?

Family's Knowledge of Illness-Defining Characteristics

- Understands definition of heart failure
- States four characteristics of signs of heart failure
- Describes medications the infant is taking
- Expresses fears and concerns
- Shows appropriate reactions to infant's illness

Nursing Diagnosis

Readiness for enhanced knowledge related to parents' interest in George's health status.

Nursing Interventions and Rationales

What are the most appropriate nursing interventions for this diagnosis?

| Nursing Interventions | Rationales |
|---|---|
| Educate family about characteristics of HF. Assess and record effectiveness of teaching session. | To promote understanding of measures to improve cardiac function and decrease demands |
| Educate family about George's daily care, such as medication administration. Assess and record results and family's participation in care. | To promote understanding and of disease and medication side effects |
| Educate family regarding illness factors which should prompt them to take George to the primary practitioner (fever, blue skin color, poor eating). | To prevent further compromise of cardiac and respiratory status. |

Expected Outcome

George's parents will understand the signs and symptoms of HF and will understand the actions being taken by the health care team.

Assist in Measures to Improve Cardiac Function

The nurse's responsibility in administering digoxin includes calculating and administering the correct dosage, observing for signs of toxicity, and instituting parental teaching regarding drug administration at home. The child's apical pulse is always checked before administering digoxin. As a general rule, the drug is not given if the pulse is below 90 to 110 beats/min in infants and young children or below 70 beats/min in older children (the cutoff point for adults is 60 beats/min). However, because the pulse rate varies in children in different age groups, the written drug order should specify at what heart rate the drug is withheld. The nurse should also use judgment in evaluating the pulse rate. If it is significantly lower than the previous recording, the dose should be withheld until the practitioner is notified.

The apical rate is taken because a pulse deficit (radial pulse rate lower than apical) may be present with decreased cardiac output. It is auscultated for 1 full minute to evaluate alterations in rhythm. If the child is monitored by means of an ECG, a rhythm strip is obtained and attached to the chart for rate and rhythm analysis, such as abnormal lengthening of the PR interval (>50% increase over predigitalization interval) and dysrhythmias.

Digoxin is a potentially dangerous drug because of its narrow margin of safety of therapeutic, toxic, and lethal doses. Many toxic responses are extensions of its therapeutic effects. Therefore, the nurse must maintain a high index of suspicion for signs of toxicity when administering digoxin (Box 23-6).

Box 23-6

Common Signs of Digoxin Toxicity in Children

Gastrointestinal

Nausea

Vomiting

Anorexia

Cardiac

Bradycardia

Dysrhythmias

Because digoxin toxicity can occur from accidental overdose, great care must be taken in properly calculating and measuring the dosage. When converting milligrams to micrograms to milliliters, the nurse carefully checks the placement of the decimal point, because an error causes a significant change in dosage. For example, 0.1 mg is 10 times the dosage of 0.01 mg.

Nursing Alert

Infants rarely receive more than 1 ml (50 mcg or 0.05 mg) of digoxin in one dose; a higher dose is an immediate warning of a dosage error. To ensure safety, compare the calculation with another staff member's calculation before giving the drug.

These same principles are taught to parents in preparation for discharge, although the correct dose in milliliters is usually specified on the container, thus reducing potential errors in calculation. The nurse watches the parent measure the elixir in the dropper and stresses the level mark as the meniscus of the fluid that is observed at eye level.

Parents are also advised of the signs of toxicity. According to the practitioner's preference, they may be taught to take the pulse before giving the drug. A return demonstration of the procedure from the parents or another principal caregiver is included as part of the teaching plan. Their level of anxiety in counting the pulse is assessed because overconcern about the heart rate may result in excessive withholding of the drug.

Monitor Afterload Reduction

For patients receiving ACE inhibitors for afterload reduction, the nurse should carefully monitor BP before and after dose administration, observe for symptoms of hypotension, and notify the practitioner if BP is low. Numerous medications affecting the kidney can potentiate renal dysfunction, so children taking multiple diuretics and an ACE inhibitor require careful assessment of serum electrolytes and renal function.

Decrease Cardiac Demands

The infant requires rest and conservation of energy for feeding. Every effort is made to organize nursing activities to allow for uninterrupted periods of sleep. Whenever possible, parents are encouraged to stay with their infant to provide the holding, rocking, and cuddling that help children sleep more soundly. To minimize disturbing the infant, changing bed linens and complete bathing are done only when necessary. Feeding is planned to accommodate the infant's sleep and wake patterns. The child is fed at the first sign of hunger, such as when sucking on fists, rather than waiting until he or she cries for a bottle because the stress of crying exhausts the limited energy supply. Because infants with HF tire easily and may sleep through feedings, smaller feedings every 3 hours may be helpful. Gavage feedings may be instituted to provide adequate nutrition and allow the infant to rest.

Every effort is made to minimize unnecessary stress. Older children need an explanation of what is happening to them to decrease anxiety about their illness and necessary treatments, such as cardiac monitoring, oxygen administration, and medications. Outlining a plan for the day, preparing the child for tests and procedures, providing quiet activities, and providing adequate rest periods are all helpful interventions with older children. Some infants and children require sedation during the acute phase of illness to allow them to rest.

Temperature is carefully monitored because hyperthermia or hypothermia increases the need for oxygen. Febrile states are reported to the physician because infection must be promptly treated. Maintaining body temperature is of special importance in children who are receiving cool, humidified oxygen and in infants, who tend to be diaphoretic and lose heat by way of evaporation.

Skin breakdown from edema is prevented with a change of position every 2 hours (from side to side while in semi-Fowler position) and use of a pressure-relieving mattress or bed. The skin, especially over the sacrum, is checked for evidence of redness from pressure.

Reduce Respiratory Distress

Careful assessment, positioning, and oxygen administration can reduce respiratory distress. Respirations are counted for 1 full minute during a resting state. Any evidence of increased respiratory distress is reported, because this may indicate worsening HF.

Infants are positioned to encourage maximum chest expansion, with the head of the bed elevated; they should sit up in an infant seat or be held at a 45-degree angle. Children prefer to sleep on several pillows and remain in a semi-Fowler or high-Fowler position during waking hours. Safety restraints, such as those used with infant seats, are applied low on the abdomen and loosely enough to provide both safety and maximum expansion.

The infant or child is often given humidified supplemental oxygen via oxygen hood or tent, nasal cannula, or mask. The child's response to oxygen therapy is carefully evaluated by noting respiratory rate, ease of respiration, color, and especially oxygen saturation as measured by oximetry.

Respiratory tract infections can exacerbate HF and should be appropriately treated and prevented if possible. The child should be protected from persons with respiratory tract infections and have a noninfectious roommate. Good hand washing is practiced before and after caring for any hospitalized child. Antibiotics may be given to combat respiratory tract infection. The nurse ensures that the drug is given at equally divided times over a 24-hour schedule to maintain high blood levels of the antibiotic.

Maintain Nutritional Status

Meeting the nutritional needs of infants with HF or serious cardiac defects is a nursing challenge. The metabolic rate of these infants is greater because of poor cardiac function and increased heart and respiratory rates. Their caloric needs are greater than those of the average infant because of their increased metabolic rate, yet their ability to take in adequate calories is hampered by their fatigue. Feeding for a fragile infant with serious CHD is similar to exercising for an adult, and these infants often do not have the energy or cardiac reserve to do extra work. The nurse seeks measures to enable the infant to feed easily without excess fatigue and to increase the caloric density of the formula.

The infant should be well rested before feeding and fed soon after awakening so as not to expend energy on crying. A 3-hour feeding schedule works well for many infants. (Feeding every 2 hours does not provide enough rest between feedings, and a 4-hour schedule requires an increased volume of feeding, which many infants are unable to take.) The feeding schedule should be individualized to the infant's needs. A feeding goal of 150 ml/kg/day and at least 120 kcal/kg/day is common for newborns with significant heart disease (Steltzer, Rudd, and Pick, 2005). A soft preemie nipple or a slit in a regular nipple to enlarge the opening decreases the infant's energy expenditure while sucking. Infants should be well supported and fed in a semiupright position. Infants may need to rest frequently and may need to have the jaw and cheeks stroked to encourage sucking. Generally, giving an infant about a half hour to complete a feeding is reasonable. Prolonging the feeding time can exhaust the infant and decrease the rest period between feedings.

Infants with feeding difficulties are often gavage fed using a nasogastric tube to supplement their oral intake and ensure adequate calories. If they are very stressed and fatigued, experiencing signs of respiratory distress, or tachypneic to 80 to 100 breaths/min, oral feedings may be withheld and all nutrition given by gavage feedings. Gavage feedings are usually a temporary measure until the infant's medical status improves and nutritional needs can be met through oral feedings. Some infants with severe HF, neurologic deficits, or significant gastroesophageal reflux may need placement of a gastrostomy tube to allow adequate nutrition.

The caloric density of formulas is frequently increased by concentration and then adding Polycose, medium-chain triglyceride oil, or corn oil. Infant formulas provide 20 kcal/oz, and the use of additives can increase the calories to 30 kcal/oz or more. This allows the infant to obtain more calories despite a smaller volume intake of formula. The caloric density of the formula needs to be increased slowly (by 2 kcal/oz/day) to prevent diarrhea or formula intolerance. Breastfeeding mothers are encouraged to provide the infant with alternating feedings of breast milk and high-calorie formulas. Some lactating mothers prefer to feed the child expressed breast milk that has been fortified with Similac or Enfamil powder, Polycose, or corn oil to increase caloric intake. A diet plan specific to the individual infant's needs is calculated and prescribed by the nutritionist in collaboration with the other health personnel. The nurse needs to reinforce this information with

the parents as necessary.

Assist in Measures to Promote Fluid Loss

When diuretics are given, the nurse records fluid intake and output and monitors body weight at the same time each day to evaluate benefit from the drug. Because profound diuresis may cause dehydration and electrolyte imbalance (loss of sodium, potassium, chloride, bicarbonate), the nurse observes for signs indicating either complication, as well as signs and symptoms suggesting reactions to the drugs. Diuretics should be given early in the day to children who are toilet trained to avoid the need to urinate at night. If potassium-losing diuretics are given, the nurse encourages foods high in potassium, such as bananas, oranges, whole grains, legumes, and leafy vegetables and administers prescribed supplements. Serum potassium levels are checked frequently.

Nursing Alert

Mix the elixir with fruit juice (red punch or grape juice works well) to disguise the bitter taste and to prevent intestinal irritation from a concentrated solution.

Fluid restriction is rarely necessary in infants because of their difficulty in feeding. However, if fluids are restricted, the nurse plans fluid intake schedules for a 24-hour period, allowing for most fluids during waking hours. Toddlers and preschoolers should be given small amounts of liquid in small cups so the containers appear full. Older children's cooperation is gained by placing them in charge of recording their fluid intake.

If salt is limited, the nurse discusses food sources of sodium with the family and discourages their bringing salt-containing treats to the child. At mealtimes, the child's tray is checked to make sure the appropriate diet is given.

Support Child and Family

HF is a serious complication of heart disease. Parents and older children are usually acutely aware of the critical nature of the condition. Because stress places additional demands on cardiac function, the nurse should focus on reducing anxiety through anticipatory preparation, frequent communication with the parent regarding the child's progress, and constant reassurance that everything possible is being done.

Home care involves many of the same interventions discussed in the Plan for Discharge and Home Care section. The nurse teaches the family about the medications that need to be administered and alerts them to the signs of worsening HF that require medical attention, such as increased sweating, decreased urinary output (noted in fewer wet diapers or infrequent use of the toilet), or poor feeding. Every effort is made to improve the family's adherence to the medication schedule by adapting the schedule to their usual home routines, avoiding medications during the night, making it as simple as possible, and using charts or visual aids to remember when to give medications (see [Chapter 20](#)). Written instructions regarding correct administration of digoxin are essential (see [Family-Centered Care](#) box), including an explanation regarding signs of toxicity.

If HF is the end stage of a severe heart defect, the nurse cares for this child as for any child who is terminally ill, using the principles discussed in [Chapter 17](#).

Hypoxemia

Hypoxemia refers to an arterial oxygen tension (or pressure, PaO₂) that is less than normal and can be identified by a decreased arterial saturation or a decreased PaO₂. **Hypoxia** is a reduction in tissue oxygenation that results from low oxygen saturations and PaO₂ and results in impaired cellular processes. **Cyanosis** is a blue discoloration in the mucous membranes, skin, and nail beds of the child with reduced oxygen saturation. It results from the presence of deoxygenated hemoglobin (hemoglobin not bound to oxygen) in a concentration of 5 g/dl of blood. Cyanosis is usually apparent when arterial oxygen saturations are 80% to 85%. Determination of cyanosis is subjective. It can vary depending on skin pigment, quality of light, color of the room, or clothing worn by the child. The presence of cyanosis may not accurately reflect arterial hypoxemia because both oxygen saturation and the amount of circulating hemoglobin are involved. Children with severe anemia may not be cyanotic despite severe hypoxemia because the hemoglobin level may be too low to

produce the characteristic blue color. Conversely, patients with polycythemia may appear cyanotic despite a near-normal PaO₂. Heart defects that cause hypoxemia and cyanosis result from desaturated venous blood (blue blood) entering the systemic circulation without passing through the lungs.

Clinical Manifestations

Over time, two physiologic changes occur in the body in response to chronic hypoxemia: polycythemia and clubbing. **Polycythemia**, an increased number of red blood cells, increases the oxygen-carrying capacity of the blood. However, anemia may result if iron is not readily available for the formation of hemoglobin. Polycythemia increases the viscosity of the blood and crowds out clotting factors. **Clubbing**, a thickening and flattening of the tips of the fingers and toes, is thought to occur because of chronic tissue hypoxemia and polycythemia (Fig. 23-8). Infants with mild hypoxemia may be asymptomatic except for cyanosis and exhibit near-normal growth and development. Those with more severe hypoxemia may exhibit fatigue with feeding, poor weight gain, tachypnea, and dyspnea. Severe hypoxemia resulting in tissue hypoxia is manifested by clinical deterioration and signs of poor perfusion.

FIG 23-8 Clubbing of the fingers.

Hypercyanotic spells, also referred to as **blue spells** or **tet spells** because they are often seen in infants with tetralogy of Fallot, may occur in any child whose heart defect includes obstruction to pulmonary blood flow and communication between the ventricles. The infant becomes acutely cyanotic and hyperpneic because sudden infundibular spasm decreases pulmonary blood flow and increases right-to-left shunting (the proposed mechanism in tetralogy of Fallot). Spells, rarely seen before 2 months of age, occur most frequently in the first year of life. They occur more often in the morning and may be preceded by feeding, crying, defecation, or stressful procedures. Because profound hypoxemia causes cerebral hypoxia, hypercyanotic spells require prompt assessment and treatment to prevent brain damage or possibly death.

Persistent cyanosis as a result of cyanotic heart defects places the child at risk for significant **neurologic complications**. Cerebrovascular accident (CVA; stroke), brain abscess, and developmental delays (especially in motor and cognitive development) may result from chronic hypoxia.

Diagnostic Evaluation

Cyanosis in a newborn can be the result of cardiac, pulmonary, metabolic, or hematologic disease, although cardiac and pulmonary causes occur most often. To distinguish between the two, a hyperoxia test is helpful. The infant is placed in a 100% oxygen environment, and blood parameters are monitored. A PaO₂ of 100 mm Hg or higher suggests lung disease, and a PaO₂ lower than 100 mm Hg suggests cardiac disease (Park, 2014). An accurate history, a chest radiograph, and especially an echocardiogram contribute to the diagnosis of cyanotic heart disease.

Therapeutic Management

Newborns generally exhibit cyanosis within the first few days of life as the ductus arteriosus, which provided pulmonary blood flow, begins to close. Prostaglandin E₁, which causes vasodilation and

smooth muscle relaxation, thus increasing dilation and patency of the ductus arteriosus, is administered intravenously to reestablish pulmonary blood flow. The use of prostaglandins has been lifesaving for infants with ductus-dependent cardiac defects. The increase in oxygenation allows the infant to be stabilized and have a complete diagnostic evaluation performed before further treatment is needed.

Hypercyanotic spells occur suddenly, and prompt recognition and treatment are essential. In the hospital setting, spells are often seen during blood drawing or IV insertion, when the child is highly agitated, or after cardiac catheterization. Treatment of a hypercyanotic spell is outlined in the [Nursing Care Guidelines](#) box. Morphine, administered subcutaneously or through an existing IV line, helps reduce infundibular spasm. A spell indicates the need for prompt surgical treatment if possible. In infants with defects not amenable to surgical repair, a shunt may be created surgically to increase blood flow to the lungs. Several commonly used shunt procedures are described in [Table 23-4](#) and [Fig. 23-9](#).

Nursing Care Guidelines

Treating Hypercyanotic Spells

Place infant in knee/chest position ([Fig. 23-10](#)).

Use a calm, comforting approach.

Administer 100% “blow-by” oxygen.

Give morphine subcutaneously or through an existing IV line.

Begin IV fluid replacement and volume expansion if needed.

Repeat morphine administration.

IV, Intravenous.

TABLE 23-4

Selected Shunt Procedures for Children with Cardiac Defects

| Shunt Type | Comments |
|---|--|
| Modified Blalock-Taussig shunt: Subclavian artery to pulmonary artery using Gore-Tex or Impra tube graft | Shunt flow sometimes excessive, requiring use of diuretics Possibility of thrombosis; aspirin usually prescribed postoperatively Easy to ligate at time of definitive correction Shunt size fixed and may become too small as child grows |
| Sano modification: Right ventricular to pulmonary artery using Gore-Tex | Prevents diastolic runoff of systemic blood into the pulmonary arteries Provides a higher diastolic BP and seemingly better coronary perfusion Used in place of the Modified Blalock-Taussig shunt in the Norwood procedure |
| Central shunt: Ascending aorta to main pulmonary artery using Gore-Tex graft | Length of shunt acts to restrict blood flow; possibility of symptoms of HF; diuretic therapy sometimes required Uncommon; used when modified Blalock-Taussig shunt cannot be used Easy to insert and remove at time of repair |
| Bidirectional Glenn shunt (cavopulmonary anastomosis): SVC to side of right pulmonary artery; blood flow to both lungs | Possibility of thrombosis; aspirin usually prescribed postoperatively Done as a second shunt; often used as a staging step to a Fontan procedure Can be incorporated into eventual modified Fontan procedure Relieves severe cyanosis and decreases volume overload on ventricle Carries risk of embolic events (mixing defect); aspirin often prescribed Pulmonary arteriovenous fistulas may occur months or years later, causing desaturation (uncommon finding) |

BP, Blood pressure; *HF*, heart failure; *SVC*, superior vena cava.

FIG 23-9 Schematic diagram of cardiac shunts.

FIG 23-10 Infant held in a knee/chest position.

The cyanotic infant and child are well hydrated to keep the hematocrit and blood viscosity within acceptable limits to reduce the risk of CVAs. The infant is monitored closely for anemia because of the risk of CVAs and the reduced arterial oxygen-carrying capacity that occurs. Iron supplementation and possibly blood transfusion are used as needed.

Respiratory tract infections or reduced pulmonary function from any cause can worsen hypoxemia in the cyanotic child. Aggressive pulmonary hygiene, chest physical therapy, administration of antibiotics, and use of oxygen to improve arterial saturations are important interventions.

Nursing Care Management

The general appearance of infants and children with significant cyanosis poses unique concerns. Blue lips and fingernails are obvious signs of their hidden cardiac defect. Clubbing and small, thin stature in older children further indicate severe heart disease. Adolescents are especially concerned about their body image; children with cyanosis are often teased about their appearance and singled out as different. Many children, when asked what surgery will do, reply, "Make me pink." Their joy and excitement after surgery are evident when they see their pink fingers. Parents are often fearful of their child's bluish color because cyanosis is usually associated with lack of oxygen and severe illness. They also must deal with comments from relatives, friends, and strangers about their child's abnormal color. They need a simple explanation of hypoxemia and cyanosis and reassurance that cyanosis does not imply a lack of oxygen to the brain. Their questions and fears need to be addressed in a calm, supportive manner, and positive aspects of their child's growth and

development are emphasized. They are taught the treatment for hypercyanotic spells (see [Nursing Care Guidelines](#) box).

Dehydration must be prevented in children with hypoxemia because it potentiates the risk of CVAs. Fluid status is carefully monitored, with accurate intake and output and daily weight measurements. Maintenance fluid therapy is the minimum requirement, supplemental fluids should be readily available, and gavage feeding or IV hydration is given to children unable to take adequate oral fluids. Fever, vomiting, and diarrhea can cause dehydration and require prompt treatment. Parents are instructed in the importance of adequate fluid intake and measures to prevent dehydration. An oral electrolyte solution should be available at home in the event that the infant is unable to tolerate the usual formula. The practitioner should be notified of fever, vomiting, diarrhea, or other problems.

Preventive measures and accurate assessment of respiratory infection are important nursing considerations. Any compromise in pulmonary function will increase the infant's hypoxemia. Good hand washing and protection from individuals with an obvious respiratory tract infection are important. Aggressive pulmonary hygiene, treatment with antibiotics or antiviral agents as indicated, and supplemental oxygen to decrease hypoxemia are necessary measures. Infants may need to be gavage fed or given parenteral hydration if respiratory distress prevents oral feeding.

Nursing Alert

Intracardiac shunting of blood from the right side (desaturated) to the left side of the heart allows air in the venous system to go directly to the brain, resulting in an air embolism. Therefore, all IV lines should have filters in place to prevent air from entering the system, the entire tubing should be checked for air, all connections should be taped securely, and any air should be removed.

Nursing Care of the Family and Child with Congenital Heart Disease

When a child is born with a severe cardiac anomaly, the parents are faced with the immense psychological and physical tasks of adjusting to the birth of a child with special needs. Family issues and nursing interventions to support the family are similar to those discussed in [Chapters 10](#) and [20](#). The following discussion is primarily directed (1) toward the family of an infant who has a serious heart defect and requires home care before definitive repair and (2) toward preparation and care of the child and family when invasive procedures (catheterization and surgery) are performed. For nursing care related to the child with hypoxemia and HF, the reader should refer to earlier discussions of these topics.

Nursing care of the child with a congenital heart defect begins as soon as the diagnosis is suspected. Prenatal diagnosis of congenital heart defects is becoming increasingly frequent. New demands are being placed on nurses to counsel and support families as they prepare for the birth of these infants.

Help the Family Adjust to the Disorder

When parents learn of the heart defect, they are initially in a period of shock followed by high anxiety and fear that the child will die. The family needs time to grieve before they can assimilate the meaning of the defect. Unfortunately, the demands for medical treatment may not allow this, instead necessitating that the parents immediately give informed consent for diagnostic-therapeutic procedures. The nurse can be instrumental in supporting parents in their loss, assessing their level of understanding, supplying information as needed, and helping other members of the health care team understand the parents' reactions (see [Family-Centered Care](#) box).

Family-Centered Care

Diagnosis of Heart Disease

Remember, we don't have your experience. We don't see children every day who have heart disease. We would have been upset finding out our child had to have his tonsils out. How could we ever be prepared for this? Please remember, we only know people who have trivial heart murmurs. How could we ever expect this to happen? And to us, this is the worst problem we've ever heard of.

We still fear most what we don't know and understand. Be honest with us. If you don't know either, tell us. But at least don't leave us wondering about what you know and we don't. Not knowing anything really can be worse than knowing something bad. Be honest but don't strip us of hope.

Please, remember we are trying to learn complex information in a moment of time. And trying to learn it in a context of great pain and emotional investment. This is our lives you're talking about. Please be thorough but keep it simple. Tell us again, maybe even again and again, when we can hear better.

From Schrey C, Schrey M: A parent's perspective: our needs and our message, *Crit Care Nurs Clin North Am* 6(1):113–119, 1994.

Severely ill newborns usually remain in the hospital. Parent–infant attachment is supported by encouraging parents to hold, touch, and look at their child and providing time and privacy for the parents to spend with their newborn. (See [Chapter 8](#) for suggestions on promoting attachment between parents and their hospitalized newborn.)

The effect of a child with a serious heart defect on the family is complex. No member, regardless of the degree of positive adjustment, is unaffected. Mothers frequently feel inadequate in their mothering ability because of the more complex care infants with congenital heart defects require. They often feel exhausted from the pressures of caring for these children and the other family members. Fathers and siblings may feel neglected and resentful, which is a reaction similar to the feelings toward family members with other chronic conditions (see [Chapter 17](#)). Often, parents do

not feel confident leaving the child in another person's care. This often sets up a trap for parents, especially mothers, who become locked into the child's care with no relief. Although the fears are justified, they can be minimized by gradually teaching someone (a reliable relative or neighbor) how to care for the child.

The need to maintain discipline and set consistent limits can be difficult for parents. Using behavior modification techniques, in the form of either concrete awards (e.g., a favorite activity) or social reinforcement (e.g., approval), can be effective. However, it is most beneficial if used *before* the child learns to control the family. To prevent later problems, it is necessary to begin discussions with parents while the child is in infancy regarding the need for discipline as the child gets older.

Another issue that may develop within family relationships is the child's overdependency. This is often the result of parental fear that the child may die. Parents need guidance to recognize the eventual hazards of continuing dependency and protectiveness as the child grows older, and the nurse can assist parents in learning ways to foster optimum development. Unless parents are shown what activities the child can do, they may focus on physical limitations and encourage dependency.

The child also needs opportunities for normal social interaction with peers. These children do not need to be prevented from playing with other children because of concern regarding overexertion. Children usually limit their activities if allowed to set their own pace. A child with CHD may constitute a long-term family crisis. Frequently, the continuing unremitting stresses of care—physical exhaustion, financial costs, emotional upset, fear of death, and concern for the child's future—are not fully appreciated by those caring for the family. Even when the child's condition is stabilized or corrected, the family may need to make adjustments in their lifestyle. Introducing them to other families with similarly affected children can help them adjust to the daily stresses.

Educate the Family About the Disorder

When parents are ready to hear about the heart condition, they require a clear explanation based on their level of understanding. A review of the basic structure and function of the heart is helpful before describing the defect. A simple diagram, pictures, or a model of the heart can help parents visualize the heart and the congenital defect. Parents appreciate receiving written information about the specific condition.* Health care professionals should take advantage of subsequent encounters to assess parental understanding of the condition and clarify information as needed.

Increasingly, families are using the Internet as a source of information about heart disease in children. They are also finding support through contacts with other parents and parent groups.† It is important for parents to realize that not all websites offer medically accurate information and that information from other parents might not be applicable to their own situation. Some children with rare, complex heart defects require individualized treatment plans, and general information on the Internet or in books may not apply to their child. Parents should use their health care team, in particular their cardiologist, to discuss information they have received from other sources.

Information given to the child must be tailored to the child's developmental age. As the child matures, the level of information is revised to meet the child's new cognitive level. Preschoolers need basic information about what they will experience more than what is actually occurring physiologically. School-age children benefit from a concrete explanation of the defect. Including the child at this age early in their own health care and education about their condition will improve self-care and their own accountability (Mickley, Burkhart, and Sigler, 2013). Preadolescents and adolescents often appreciate a more detailed description of how the defect affects their heart. Children of all ages need to express their feelings concerning the diagnosis.

Help the Family Manage the Illness at Home

Parents are the child's principal caregivers and need to develop a positive, supportive working relationship with the health care team. Because most children spend the majority of their time at home with episodic trips to the hospital, parents manage their child's illness on a daily basis. They monitor for signs of illness, give medications and treatments, bring their child to appointments, work with a variety of caregivers, and alert the team about problems. Successful relationships are partnerships between parents and caregivers that are built on mutual trust and respect. Good communication among the family, the cardiology specialists, and the primary care practitioner is essential. As children reach adolescence, they begin to take a larger role in managing their illness

and making decisions about their care.

Parents should be aware of the symptoms of their child's cardiac condition and signs of worsening clinical status. Parents of children who may develop HF should be familiar with the symptoms (see [Box 23-5](#)) and know when to contact the practitioner. Parents of children with cyanosis should be informed about fluid management and hypercyanotic spells (see earlier in this chapter). Parents should have an information sheet with their child's diagnosis, significant treatments such as surgical procedures, allergies, other health care problems, current medications, and health care providers' contact numbers available in case of emergencies and to share with other caregivers such as teachers, babysitters, and daycare providers.

The family also needs to be knowledgeable regarding the therapeutic management of the disorder and the role that surgery, other procedures, medications, and a healthy lifestyle play in maintaining good health. Medications play a critical role in managing some cardiac conditions, such as dysrhythmias, severe HF, anticoagulation for artificial valves, and antirejection medications after heart transplantation. Some patients must take multiple medications daily for their lifetime. Many medications can be dangerous if taken incorrectly and require close monitoring. Parents are taught the correct procedure for giving medications and cautioned to keep them in a safe area to prevent accidental ingestion.

Another area of parental concern is the child's level of physical activity. Most children do not need to restrict activity, and the best approach is to treat the child normally and allow self-limited activity. Exceptions to self-determined activity primarily involve strenuous recreational and competitive sports in children with specific cardiac problems. Activities and exercise restrictions should be discussed with the child's cardiologist. In 2013, the American Heart Association published guidelines for promotion of physical activity in children and adults with CHD. Regular exercise can assist the child with CHD in maintaining a healthy weight, foster normal development, help with self-esteem and help with acceptance into peer groups ([Longmuir, Brothers, de Ferranti, et al, 2013](#)).

Infants and children with CHD require good nutrition. Breastfeeding should be possible for many infants with CHD. Providing adequate nutrition to infants with HF or complex congenital defects is especially difficult because of their high caloric requirements and inability to suck effectively because of fatigue and tachypnea. Instructing parents in feeding methods that decrease the infant's work and giving high-calorie formula are important interventions (see earlier in the chapter for a discussion on feeding the infant with HF). Children with severe cardiac defects are often anorexic. Encouraging them to eat can be a tremendous challenge. Consultation with a dietitian is often helpful. The child should be given a choice of available high-nutrient foods.

Infants with heart disease should be immunized according to the current guidelines. Immunization schedules may need to be modified around times of acute illness or surgical procedures. Infants and children younger than 12 months old with hemodynamically significant CHD or those younger than 24 months old undergoing cardiac transplantation during RSV season should receive the vaccine for respiratory syncytial virus (RSV) monthly during RSV season (November to April in North America) for a total of five doses ([American Academy of Pediatrics Committee on Infectious Diseases and American Academy of Pediatrics Bronchiolitis Guidelines Committee, 2014](#)).

Infants and children who have serious heart disease are at risk for developmental delays. Multiple factors can influence neurodevelopmental outcomes, including genetics (chromosomal abnormalities and microdeletions), family background (parental intelligence quotient [IQ] and socioeconomic status), preoperative factors (including prematurity, cyanosis, shock), intraoperative factors (use of cardiopulmonary bypass, deep hypothermic circulatory arrest), and postoperative factors (hemodynamic instability, hypoxia, acidosis, cardiac arrest, stroke, ischemic events).

Research in the past decade has begun to identify specific risk factors and common developmental concerns for CHD. In complex CHD, altered flow of oxygen to the brain, both in utero and postnatally may impact brain development. One study demonstrated that the brain in utero of infants with complex CHD is delayed, thus the brain is less mature than is by gestational age in a certain population ([Licht, Shera, Clancy, et al, 2009](#)). The American Heart Association's 2012 Scientific Statement reinforces that children with CHD are at increased risk of developmental disorder or disabilities or developmental delay. The American Heart Association recommends that all children with CHD be developmentally screened, evaluated and reevaluated, because this may identify deficits and allow therapies and education to assist academic, behavioral, and psychosocial functioning.

Recent efforts to limit the time of deep hypothermic circulatory arrest and provide better

neuroprotection during infant surgery may improve outcomes in the future. Although most children with serious heart disease are within the normal range for IQ, there is a higher incidence of neurodevelopmental deficits in children after heart surgery than in the normal population, specifically in speech and language, fine motor skills, and cognitive processes (Majnemer and Limperopoulos, 1999). Severe neurologic problems such as cerebral palsy, epilepsy, and mental retardation are uncommon.

Prepare the Child and Family for Invasive Procedures

Chapter 20 provides an extensive discussion of the principles for preparing children for invasive procedures. The American Heart Association published a scientific statement, “Recommendations for Preparing Children and Adolescents for Invasive Cardiac Procedures” (LeRoy, Elixson, O'Brien, et al, 2003), which addresses issues specific to the child with heart disease. The following discussion highlights some important aspects of preparation for cardiac catheterization and cardiac surgery.

The expected outcomes for preprocedure preparation include reducing anxiety, improving patient cooperation with procedures, enhancing recovery, developing trust with caregivers, and improving long-term emotional and behavioral adjustments after procedures (LeRoy, Elixson, O'Brien, et al, 2003). Important factors to consider in planning preparation strategies are the child's cognitive development, previous hospital experiences, the child's temperament and coping style, the timing of preparation, and the involvement of the parents. The most beneficial preparation strategies usually combine information giving and coping skills training, such as conscious breathing exercises, distraction techniques, guided imagery, or other behavioral interventions.

Outpatient preoperative and precatheterization workups are common for most elective procedures. Children are then admitted on the morning of the procedure. Preprocedure teaching is often done in the clinic setting or at home and may include a tour of the ICU and inpatient facilities. Children of different ages and developmental levels require different amounts of information and different approaches. Whereas young children should be prepared close in time to the event, older children and adolescents may benefit from teaching several weeks in advance. Parents should be included in the preparation session to support their child and learn about upcoming events.

Topics to include in preoperative or precatheterization preparation include information on the environment, equipment, and procedures that the child will encounter during and after the procedure. Many information-giving techniques can be used, such as verbal and written information, hospital tours, preoperative classes, picture books, or videos. Information about what the child will see, hear, and feel should be included, especially for older children and adolescents. Some of the sensory experiences of being in an ICU or catheterization laboratory include sights (monitors, many people, a lot of equipment), sounds (beeping noises, alarms, voices), and sensations (lines and dressings, tape, discomfort, thirst). Familiar aspects of the environment, such as BP cuffs, stethoscopes, or oximeter probes, are reviewed, and new equipment, such as monitors, IV lines, and oxygen masks, are described. Comforting aspects of the environment, such as play areas, chairs for parents, and televisions, are emphasized. Many patients who will be sedated during catheterization or receive narcotic pain relievers after surgery will have minimal recall of that period and will not need detailed information about the equipment or procedures used. Information should be specific to the planned procedure for each patient.

A discussion of ways the child can cope with the experience should be included. For a young child, bringing a familiar stuffed animal or comfort object will help relieve anxiety, and advising an older child to bring headphones and favorite music to the catheterization laboratory will help distract him or her during the procedure. Recovery topics after catheterization include lying still to prevent bleeding at the catheter site, advancing diet, controlling pain, and monitoring. After surgery, the nurse reviews the importance of ambulation, coughing, deep breathing, drinking, and eating and describes pain management and monitoring routines. Simple coping strategies for use during painful procedures should be reviewed; these include distraction techniques such as counting, blowing, singing, and telling stories.

Children and their families should have a choice about an ICU tour. Exposure to the ICU environment can actually increase anxiety in some children, particularly young children, those with previous hospital experiences, and those who are highly anxious (LeRoy, Elixson, O'Brien, et al, 2003). Usually the day before the procedure is ample time to allow the child to ask questions and to prevent undue fantasizing about the experience. The child should be protected from the frightening sights in the unit; equipment not in view postoperatively, such as equipment located behind or

below the bed, needs less attention. The child and parents are encouraged to ask questions or to explore further any equipment in the room, but they should not be pushed to assimilate more information than they are able.

Preoperative physical care differs little, if any, from that for any other surgery and is discussed in [Chapter 20](#). The child should be assured that the parents will be there when the child wakes up; they should be allowed to accompany their child as far as possible to the operating suite (see [Surgical Procedures, Chapter 20](#)). After all of the equipment and procedures have been explained, it is important to talk about “getting well” and going home.

Provide Postoperative Care

Immediate postoperative care is usually provided by specially trained nurses in ICUs. Many of the procedures, such as arterial pressure and central venous pressure (CVP) monitoring, and the observations related to vital functions require advanced educational training (readers should refer to critical care texts for further information). However, nurses caring for the child before surgery and during the convalescent period need to be familiar with the major principles of care. Selected complications that may occur postoperatively are described in [Box 23-7](#).

Box 23-7

Selected Complications After Cardiac Surgery and Treatment Approaches

Cardiac

Heart failure: Digoxin, diuretics

Low cardiac output: Intravenous (IV) inotropes

Dysrhythmias: Identification, drug treatment, possible pacing, cardioversion

Tamponade (blood or fluid in the pericardial space constricting the heart): Prompt removal of fluid by pericardiocentesis

Respiratory

Atelectasis: Chest physical therapy, coughing, deep breathing, ambulation

Pulmonary edema: Diuretics

Pleural effusions: Diuretics, possible chest tube drainage

Pneumothorax: Possible chest tube drainage

Neurologic

Seizures: Assessment, antiepileptic drugs

Cerebrovascular accident (CVA; stroke), cerebral edema, neurologic deficits: Assessment and treatment

Infectious Disease

Infections (especially wound, pneumonia, otitis media, and sepsis): Antibiotics

Hematologic

Anemia: Iron supplementation, possible transfusion

Postoperative bleeding: Initially, clotting factors, blood products; may need repeat surgery to locate and ligate source of bleeding

Other

Postpericardiotomy syndrome (syndrome of fever, leukocytosis, friction rub, pericardial and pleural effusions, and lethargy seen about 7 to 21 days after cardiac surgery; possible viral or autoimmune etiologies): Antipyretics, diuretics, antiinflammatory medications

Observe Vital Signs

Vital signs and BP are recorded frequently until stable. Heart rate and respirations are counted for 1 full minute, compared with the ECG monitor, and recorded with activity. The heart rate is normally increased after surgery. The nurse observes cardiac rhythm and notifies the practitioner of any changes in regularity. Dysrhythmias may occur postoperatively secondary to anesthetics, acid-base and electrolyte imbalance, hypoxia, surgical intervention, or trauma to conduction pathways.

At least hourly, the lungs are auscultated for breath sounds. Diminished or absent sounds may indicate an area of atelectasis or a pleural effusion or pneumothorax, which necessitates further medical assessment. Temperature changes are typical during the early postoperative period. Hypothermia is expected immediately after surgery from hypothermia procedures, effects of anesthesia, and loss of body heat to the cool environment. During this period, the child is kept warm to prevent additional heat loss. Infants may be placed under radiant heat warmers. During the next 24 to 48 hours the body temperature may rise to 37.7° C (100° F) or slightly higher as part of the inflammatory response to tissue trauma. After this period, an elevated temperature is most likely a sign of infection and warrants immediate investigation for probable cause.

Intraarterial monitoring of BP is commonly done after open-heart surgery. A catheter is passed into the radial artery or other artery, and the other end is attached to an electronic monitoring system, which provides a continuous recording of the BP. The intraarterial line is maintained with a low-rate, constant infusion of heparinized saline to prevent clotting.

Several IV lines are inserted preoperatively, including a peripheral IV to give fluids and medications and a central venous line, usually in a large vessel in the neck, to measure CVP. Additional, intracardiac monitoring lines are sometimes placed intraoperatively in the right atrium, left atrium, or pulmonary artery. Intracardiac lines allow assessment of pressures inside the cardiac chambers, providing vital information about volume status, cardiac output, and ventricular function. All lines must be cared for using strict aseptic technique, and patients must be carefully assessed for bleeding at the time of line removal.

Maintain Respiratory Status

Infants usually require mechanical ventilation in the immediate postoperative period. Early extubation in the operating room or early postoperative period is becoming more common. Children, especially those not requiring cardiopulmonary bypass, may be extubated in the operating room or in the first few postoperative hours. Suctioning is performed only as needed and performed carefully to avoid vagal stimulation (which can trigger cardiac dysrhythmias) and laryngospasm, especially in infants. Suctioning is intermittent and maintained for no more than 5 seconds at a time to avoid depleting the oxygen supply. Supplemental oxygen is administered with a manual resuscitation bag before and after the procedure to prevent hypoxia. The heart rate is monitored after suctioning to detect changes in rhythm or rate, especially bradycardia. The child should always be positioned facing the nurse to permit assessment of the child's color and tolerance of the procedure.

When weaning and extubation are completed, humidified oxygen is delivered by mask, hood, or

nasal cannula to prevent drying of mucosa. The child is encouraged to turn and deep breathe at least hourly. Incentive spirometer used should be encouraged. Measures are used to enhance ventilation and decrease pain, such as splinting of the operative site and use of analgesics. Chest tubes are inserted into the pleural or mediastinal space during surgery or in the immediate postoperative period to remove secretions and air to allow reexpansion of the lung. Drainage is checked hourly for color and quantity. Immediately after surgery the drainage may be bright red, but afterward, it should be serous. The largest volume of drainage occurs in the first 12 to 24 hours and is greater in extensive heart surgery.

Nursing Alert

Chest tube drainage greater than 3 ml/kg/hr for more than 3 consecutive hours or 5 to 10 ml/kg in any 1 hour is excessive and may indicate postoperative hemorrhage. The surgeon should be notified immediately because cardiac tamponade can develop rapidly and is life threatening.

Chest tubes are usually removed on the first to third postoperative day. Removal of chest tubes is a painful, frightening experience. Analgesics such as morphine sulfate, often combined with midazolam (Versed), should be given before the procedure. Older children are forewarned that they will feel a sharp, momentary pain. After the suture is cut, the tubes are quickly pulled out at the end of full inspiration in the extubated patient to prevent intake of air into the pleural cavity. (In the intubated patient, the tubes are pulled out on inspiration because the lungs are stented open with the positive pressure ventilation.) A purse-string suture (placed when the tubes were inserted) is pulled tight to close the opening. A petrolatum-covered gauze dressing is immediately applied over the wound and securely taped on all four sides to the skin so that an airtight seal is formed. It is left on for 1 or 2 days. Breath sounds are checked to assess for a pneumothorax, a possible complication of chest tube removal. A chest radiograph is usually obtained after removal to evaluate for possible pneumothorax or pleural effusion.

Monitor Fluids

Intake and output of all fluids must be accurately calculated. Intake is primarily IV fluids; however, a record of fluid used to flush the arterial and CVP lines or to dilute medications is also kept. Output includes hourly recordings of urine (usually a Foley catheter is inserted and attached to a closed collecting device), drainage from chest and nasogastric tubes, and blood drawn for analysis. Renal failure is a potential risk from a transient period of low cardiac output.

Nursing Alert

The signs of renal failure are decreased urinary output (<1 ml/kg/hr) and elevated levels of blood urea nitrogen and serum creatinine.

Fluids are restricted during the immediate postoperative period to prevent hypervolemia, which places additional demands on the myocardium, predisposing the patient to cardiac failure. If the child is to be extubated within the first 24 to 48 hours, fluids are provided primarily intravenously. If the child is to be intubated longer, fluids may be given via a nasogastric or nasojejunal tube to optimize nutrition and gut motility. Approximately 4 hours after extubation, enteral fluids may be reinitiated in the setting of a stable hemodynamic and respiratory status. To monitor fluid retention, the child is weighed daily, and the same scale is used at approximately the same time each day to avoid errors in measurement. Fluid restriction may be imposed even when oral fluids are given. The nurse calculates the distribution over a 24-hour period based on the child's preoperative weight and drinking habits. The distribution should allow for most fluid to be given during the child's most wakeful and active periods.

Provide Rest and Progressive Activity

After heart surgery, rest should be provided to decrease the workload of the heart and promote healing. The simplest way to ensure individualized, efficient, high-quality care is to plan at the beginning of the shift the nursing procedures to be done, with periods of rest identified. The schedule should be shared with parents to allow them to visit at the most advantageous times, such

as after a rest period when no special treatments are anticipated.

A progressive schedule of ambulation and activity is planned, based on the child's preoperative activity patterns and postoperative cardiovascular and pulmonary function. Ambulation is initiated early, usually by the second postoperative day, when chest tubes, arterial lines, and assisted ventilatory equipment have been removed. Activity progresses from sitting on the edge of the bed and dangling the legs to standing up and sitting in a chair. Heart rate and respirations are carefully monitored to assess the degree of cardiac demand imposed by each activity. Tachycardia, dyspnea, cyanosis, desaturation, progressive fatigue, and dysrhythmias indicate the need to limit further energy expenditure.

Provide Comfort and Emotional Support

Heart surgery is both painful and frightening for children, and comfort is a primary nursing concern. Several types of incisions are used by the cardiac surgeon. A median sternotomy is most common, following the sternum down the center of the chest. A ministernotomy opens the lower sternum. A thoracotomy incision is most uncomfortable because it goes through muscle tissue. It allows access to the side of the chest through an incision from under the arm around the back to the scapula.

Most patients need IV analgesics for pain control during the immediate postoperative period. Patient-controlled analgesia may be used with children old enough to understand the concept. Nonsteroidal antiinflammatory drugs (NSAIDs) such as ketorolac (Toradol) may be used intravenously. Paralyzing agents may also be used with the analgesics for children who are hemodynamically unstable.

After extubation and removal of lines and tubes, pain can be satisfactorily controlled with oral medications such as ibuprofen, codeine with acetaminophen (Tylenol No. 3), or oxycodone and acetaminophen. Acetaminophen alone provides adequate pain relief for most children at discharge. Sternotomy incisions are usually well tolerated, with some discomfort when walking and coughing. Thoracotomy incisions are usually more painful because the incision is through muscle; a more aggressive pain management plan with around-the-clock medications for several days is often necessary to allow for adequate rest, ambulation, and pulmonary hygiene.

In addition to pharmacologic pain control, every effort is made to minimize the discomfort of procedures, such as using a firm pillow or favorite stuffed animal placed against the chest incision during movement and performing treatments *after* pain medication is given, preferably at a time that coincides with the drug's peak effect. Nonpharmacologic measures are used to lessen the perception of pain, and parents are encouraged to comfort their child as much as possible. (See also [Pain Assessment](#); [Pain Management](#), Chapter 5.)

Children may become depressed after surgery. This is thought to be caused by preoperative anxiety, postoperative psychological and physiologic stress, and sensory overstimulation. Typically, the child's disposition improves on leaving the ICU.

Children may also be angry and uncooperative after surgery as a response to the physical pain and to the loss of control imposed by the surgery and treatments. They need an opportunity to express feelings, either verbally or through activity. Children often regress in their behavior during the stress of surgery and hospitalization. They also may express feelings of anger or rejection toward their parents. The nurse can support the parents by being available for information and explaining all of the procedures to them. The first few postoperative days are particularly difficult because parents see their child in pain and realize the potential risks from surgery. They often are overwhelmed by the physical environment of the ICU and feel useless because they can do so little for their child. The nurse can minimize such feelings by including parents in caregiving activities and comfort and play activities, providing information about the child's condition, and being sensitive to their emotional and physical needs. The importance of their presence in making the child feel more secure is stressed even if they do not provide physical care.

Quality Patient Outcomes: Congenital Heart Disease

- Improved cardiac function
- Prevention of fluid and sodium overload

- Decreased cardiac demands
- Improved oxygenation
- Reduced respiratory distress

Plan for Discharge and Home Care

Ideally, discharge planning begins on admission for cardiac surgery and includes an assessment of the parents' adjustment to the child's altered state of health. Neonates need additional screening tests (e.g., newborn metabolic screen and hearing tests) and may need immunizations, as well as a car seat test before discharge ([American Academy of Pediatrics, 2012](#)). The family will need both verbal and written instructions on medication, nutrition, activity restrictions, return to school, wound care, and signs and symptoms of infection or complications (see [Family-Centered Care](#) box). Referrals to community agencies may be warranted to assist parents in the transition from the hospital to home and to reinforce the teaching.

Family-Centered Care

Topics to Include in Discharge Teaching After Cardiac Surgery

- Medication teaching
- Activity restrictions
- Diet and nutrition
- Wound care (including dressings, if any; suture removal; bathing)
- Bacterial (infective) endocarditis prophylaxis (see [Box 23-9](#))
- Follow-up appointments (cardiologist, primary care provider)
- Community agencies as needed (visiting nurse service, early developmental intervention)
- When to call practitioner; signs and symptoms of postoperative problems
- Review of cardiac defect and surgical repair

The parents will also need clear instructions on when to seek medical care for complications and how to contact the health care provider. Follow-up with the cardiologist and primary care provider is also arranged before discharge. Parents should have a summary, including their child's medical condition, medications, and health care providers available for emergencies. Appropriate identification, such as a Medic-Alert device, is indicated for children with a pacemaker or a heart transplant and for those receiving anticoagulation therapy or antidysrhythmic medication.

Although surgical correction of heart defects has improved dramatically, it is still not possible to completely repair many of the complex anomalies. For many children, repeat procedures are required to replace conduits or grafts or to manage complications, such as restenosis. Consequently, the long-term prognosis is uncertain, and full recovery is not always possible. For these families, medical follow-up and continued emotional support are essential. The nurse can often serve as an important primary health professional and as a resource for referrals when needed.

Acquired Cardiovascular Disorders

Infective Endocarditis

Infective endocarditis (IE) (also called *bacterial endocarditis* or *subacute bacterial endocarditis [SBE]* in the past) is an infection of the inner lining of the heart (endocardium), generally involving the valves. Though rare in children, it carries a mortality rate of 20% to 25% (Bragg and Alvarez, 2014). It is most often a sequela of bacteremia in children with acquired or congenital anomalies of the heart or great vessels, particularly those with valvular abnormalities, prosthetic valves, shunts, recent cardiac surgery with invasive lines, and rheumatic heart disease (RHD) with valve involvement. There is an increased incidence of IE in children without cardiac abnormalities, likely related to the increased use of indwelling central lines to treat other serious diseases (Bragg and Alvarez, 2014).

Pathophysiology

Organisms may enter the bloodstream from any site of localized infection. Endocarditis may occur from routine exposure to bacteremia associated with usual daily activities such as brushing teeth although it can also occur after procedures such as dental work, invasive procedures involving the gastrointestinal and genitourinary tracts, cardiac surgery, especially if synthetic material is used (valves, patches, conduits); or from long-term indwelling catheters. The most common causative agents are *Staphylococcus aureus* and *Streptococcus viridans*; other causative agents include gram-negative bacteria and fungi such as *Candida albicans*. The microorganisms grow on the endocardium, forming vegetations (verrucae), deposits of fibrin, and platelet thrombi. The lesion may invade adjacent tissues, such as the aortic and mitral valves, and may break off and embolize elsewhere, especially in the spleen, kidney, and CNS.

Diagnostic Evaluation

The diagnosis of IE is suspected on the basis of clinical manifestations (Box 23-8). The most commonly used diagnostic guidelines are the revised Duke criteria, which outline major and minor criteria consistent with IE (Li, Sexton, Mick, et al, 2000). Definitive diagnosis rests on growth and identification of the causative agent in the blood. At least three blood cultures are drawn at different times to aid in diagnosis. Vegetations on the valve and abnormal valve function can often be visualized by echocardiography. A diagnosis of culture-negative IE is made when the patient has echocardiographic or clinical evidence of IE but no organism can be cultured. Several laboratory findings may suggest IE including anemia, elevated erythrocyte sedimentation rate [ESR], leukocytosis, and microscopic hematuria.

Box 23-8

Clinical Manifestations of Infective Endocarditis

Onset usually insidious

Unexplained fever (low grade and intermittent)

Anorexia

Malaise

Weight loss

Characteristic findings caused by extracardiac emboli formation:

- Splinter hemorrhages (thin black lines) under the nails

- Osler nodes (red, painful intradermal nodes found on pads of phalanges)
- Janeway lesions (painless hemorrhagic areas on palms and soles)
- Petechiae on oral mucous membranes

May be present:

- Heart failure
- Cardiac dysrhythmias
- New murmur or change in previously existing one

Therapeutic Management

Treatment should be instituted immediately and consists of administration of high doses of appropriate antibiotics intravenously for 2 to 8 weeks. Blood cultures are taken periodically to evaluate the response to antibiotic therapy. Cardiac function is monitored by echocardiograms. Heart surgery to repair or replace the affected valve may be necessary.

Prevention involves administration of prophylactic antibiotic therapy to high-risk patients prior to dental procedures that are associated with the risk of entry of organisms (Box 23-9). Drugs of choice for prophylaxis, given 1 hour prior to the procedure, include amoxicillin, ampicillin, and clindamycin in penicillin allergic patients (Wilson, Taubert, Gewitz, et al, 2007).

Quality Patient Outcomes: Bacterial (Infective) Endocarditis

- Prevention in high-risk patients with antibiotic prophylaxis
- Early recognition and treatment

Box 23-9

Cardiac Conditions Associated with the Highest Risk of Adverse Outcome from Endocarditis

Prophylaxis with dental procedures recommended for*:

- Previous episode of infective endocarditis (IE)
- Prosthetic cardiac valve

Congenital heart disease (CHD), including only:

- Unrepaired cyanotic CHD, including palliative shunts and conduits
- Completely repaired congenital heart defect with prosthetic material

or device, whether placed by surgery or by catheter intervention, during the first 6 months after the procedure

Repaired CHD with residual defects at the site or adjacent to the site of a prosthetic patch or prosthetic device (which inhibits endothelialization)

Cardiac transplantation recipients who develop cardiac valvulopathy

*Except for the conditions listed, antibiotic prophylaxis is no longer recommended for any other form of CHD.

Adapted from Wilson W, Taubert K, Gewitz M, et al: Prevention of infective endocarditis: guidelines from the American Heart Association, *Circulation* 116(15):1736–1754, 2007.

Nursing Care Management

Nurses counsel parents of high-risk children concerning the signs and symptoms of endocarditis and the need for prophylactic antibiotic therapy before dental work. The family's dentist should be advised of the child's cardiac diagnosis as an added precaution to ensure preventive treatment. It is important that all children with congenital or acquired heart disease maintain the highest level of oral health to reduce the chance of bacteremia from oral infections.

Parents should also have a high index of suspicion regarding potential infections. Without unduly alarming them, the nurse stresses that any unexplained fever, weight loss, or change in behavior (lethargy, malaise, anorexia) must be brought to the practitioner's attention. Early diagnosis and treatment are important in preventing further cardiac damage, embolic complications, and growth of resistant organisms.

Treatment of endocarditis requires long-term parenteral drug therapy. In many cases, IV antibiotics may be administered at home with nursing supervision. Nursing goals during this period are (1) preparation of the child for IV infusion, usually with an intermittent-infusion device and several venipunctures for blood cultures; (2) observation for side effects of antibiotics, especially inflammation along venipuncture sites; (3) observation for complications, including embolism and HF; and (4) education regarding the importance of follow-up visits for cardiac evaluation, echocardiographic monitoring, and blood cultures. Some children may need preparation for surgery and later, postoperative care.

Acute Rheumatic Fever and Rheumatic Heart Disease

Acute rheumatic fever (ARF) is a result of an abnormal immune response to a group A strep (GAS) infection, usually pharyngitis, in a genetically susceptible host (Marijon, Mirabel, Celermajer, et al, 2012). It occurs most often in late school-age children and adolescents and is rare in adults. ARF is a self-limited illness that involves the joints, skin, brain, and heart but cardiac valve damage, which is referred to as **rheumatic heart disease (RHD)**, the most significant complication of ARF, occurs in more than half the cases. The mitral valve is most often affected. In developed countries, ARF and RHD have become uncommon. However, in developing countries, because of overcrowded living conditions and poor access to medical care, ARF and resulting RHD is the leading cause of HF in young people (Remenyi, Carapetis, Wyber, et al, 2013).

Etiology

Strong evidence supports a relationship between upper respiratory tract infection with GAS and subsequent development of ARF (usually within 2 to 6 weeks). Prevention or treatment of GAS infection prevents ARF. If the GAS infection is untreated, antibodies are produced to fight the infection, which can also act against the heart valves causing damage. If children have one strep infection, they are at greater risk for repeated infections and recurrent infections cause the cumulative valve damage of RHD.

Diagnostic Evaluation

Diagnosis is based on a set of guidelines, and later revisions, known as the *modified Jones criteria*

(Guidelines for the diagnosis of rheumatic fever, 1992; Ferrieri and Jones Criteria Working Group, 2002). The updated Jones criteria suggest that the presence of two major manifestations or one major and two minor manifestations, with supportive evidence of recent GAS infection, indicates a high probability of ARF (see [Nursing Care Guidelines](#) box).

Nursing Care Guidelines

Diagnosis of Initial Attack of Rheumatic Fever (Jones Criteria, 1992 Update)*

Major Manifestations

Carditis

- Tachycardia out of proportion to degree of fever
- Cardiomegaly
- New murmurs or change in preexisting murmurs
- Muffled heart sounds
- Pericardial friction rub
- Chest pain
- Changes in ECG (especially prolonged PR interval)

Polyarthritits

- Swollen, hot, red, painful joint(s)
- After 1 to 2 days, different joint(s) affected
- Favors large joints: Knees, elbows, hips, shoulders, wrists

Erythema Marginatum

- Erythematous macules with clear center and wavy, well-demarcated border
- Transitory
- Nonpruritic
- Primarily affects trunk and extremities (inner surfaces)

Chorea (St. Vitus Dance, Sydenham Chorea)

- Sudden aimless, irregular movements of extremities
- Involuntary facial grimaces
- Speech disturbances
- Emotional lability
- Muscle weakness (can be profound)
- Muscle movements exaggerated by anxiety and attempts at fine motor activity; relieved by rest

Subcutaneous Nodes

Nontender swelling

Located over bony prominences

May persist for some time and then gradually resolve

Minor Manifestations

Clinical Findings

Arthralgia

Fever

Laboratory Findings

Elevated acute-phase reactants

- ESR
- CRP
- Prolonged PR interval

Supporting Evidence of Antecedent Group A Streptococcal Infection

Positive throat culture or rapid streptococcal antigen test result

Elevated or rising streptococcal antibody titer

CRP, C-reactive protein; *ECG*, electrocardiogram; *ESR*, erythrocyte sedimentation rate.

*If supported by evidence of preceding group A streptococcal infection, the presence of two major manifestations or of one major and two minor manifestations indicates a high probability of acute rheumatic fever.

From Guidelines for the diagnosis of rheumatic fever, Jones criteria, 1992 update, Special Writing Group of the Committee on Rheumatic Fever, Endocarditis, and Kawasaki Disease of the Council on Cardiovascular Disease in the Young of the American Heart Association, *J Am Med Assoc* 268(15):2069–2073, 1992.

Children suspected of having ARF are tested for streptococcal antibodies. The most reliable and best standardized test is an elevated or rising **antistreptolysin O (ASO or ASLO) titer**, which occurs in 80% of children with ARF. Additional antistreptococcal antibody titers may be sent if ASO titers are negative. Acute-phase reactants, ESR, and C-reactive protein (CRP) are usually elevated as well. Echocardiograms play an important role in diagnosing RHD and monitoring deteriorating valve function.

Therapeutic Management

Primary prevention involves prompt diagnosis and treatment of strep throat infections so that ARF does not occur. Penicillin is the drug of choice or an alternative in penicillin-sensitive children (Gerber, Baltimore, Eaton, et al, 2009).

If children have ARF, antibiotics are given to treat the GAS infection and salicylates are used to control the inflammatory process, especially in the joints, and reduce the fever and discomfort. Supportive care involves bed rest initially and then quiet activities as symptoms subside. Good nutrition is important. Children who have had ARF are susceptible to recurrent infections that are likely to result in RHD and further damage to the heart valves. Prophylactic treatment against recurrence of ARF (secondary prevention) is started after the acute therapy. The treatment of choice is intramuscular injections of benzathine penicillin G every 28 days because it is most effective.

Alternative therapy includes oral doses of penicillin or erythromycin twice a day, or one daily dose of sulfadiazine. The duration of secondary prophylaxis is based on the presence of residual heart disease. In ARF occurs without carditis, prophylaxis is recommended for 5 years or until age 21 years, whichever is longer. In patients with carditis, 10 years is recommended or until 21 years old. In patients with RHD, prophylaxis can continue until the age of 40 years and may be indicated indefinitely depending on the individual's risk (Gerber, Baltimore, Eaton, et al, 2009).

Management of RHD may require surgical valve repair or replacement. Valve replacement with a mechanical valve requires lifelong anticoagulation with warfarin.

Quality Patient Outcomes: Acute Rheumatic Fever

- Group A strep (GAS) tonsillopharyngitis identified and treated
- Early recognition and treatment to prevent cardiac valve damage
- Recurrence prevented with prophylaxis compliance

Nursing Care Management

The objective of nursing care is, first, prevention. For the child with ARF, nursing care (1) encourages compliance with drug regimens, (2) facilitates recovery from the illness, and (3) provides emotional support. Nurses play an important role in prevention by educating parents about the complications of strep infections and working with patients and families to ensure follow up with antibiotic prophylaxis. Because compliance is a major concern in long-term drug therapy, every effort is made to encourage adherence to the therapeutic plan (see [Compliance, Chapter 20](#)). When compliance is poor, monthly injections may be substituted for daily oral administration of antibiotics, and children need preparation for this often-dreaded procedure.

Interventions for ARF are primarily concerned with providing rest, adequate nutrition, and management of cardiac symptoms or chorea. One of the most disturbing manifestations of ARF is **chorea**. The onset is gradual and may occur weeks to months after the illness. Sometimes mistaken for nervousness, clumsiness, or inattentiveness, it is usually a source of great frustration to the child because the movements, incoordination, and weakness severely limit physical ability. It is important that parents and teachers are aware of the involuntary, sudden nature of the movements and that the movements are transitory and will eventually disappear.

Children with RHD will need lifelong follow-up, education, and management of HF and monitoring for progressive valve disease. If surgery is required, preparation for the procedure is provided. An important aspect of postoperative care is education about anticoagulation medications and follow-up.

Hyperlipidemia (Hypercholesterolemia)

Hyperlipidemia is a general term for excessive lipids (fat and fatlike substances); **hypercholesterolemia** refers to excessive cholesterol in the blood. **Dyslipidemia** is a term used to describe all abnormalities in lipid metabolism, including low levels of high-density lipoprotein (HDL) or “good” cholesterol, high low-density lipoprotein (LDL) or “lousy” cholesterol or high triglycerides. Abnormal lipid or cholesterol levels play an important role in producing atherosclerosis (fatty plaque on the arteries), which eventually can lead to coronary artery disease, which is a primary cause of morbidity and mortality in the adult population. A presymptomatic phase of atherosclerosis begins in childhood/adolescence, providing the template for later clinical disease. Preventive cardiology focuses on the identification of high risk patients and management of lipid levels in childhood/adolescence.

Cholesterol is part of the lipoprotein complex in plasma that is essential for cellular metabolism. Triglycerides, natural fats synthesized from carbohydrates, are used for energy. Both are major lipids transported on **lipoproteins**, a combination of lipids and proteins, which include:

Low-density lipoproteins (LDLs): LDL is the major carrier of cholesterol to the cells. Cells use cholesterol for synthesis of membranes and steroid production. Elevated circulating LDL is a strong risk factor in cardiovascular disease. In addition, particle size and density of LDL may

affect overall risk, with small, dense particles associated with increased atherosclerosis.

High-density lipoproteins (HDLs): HDL cholesterol contains very low concentrations of triglycerides, relatively little cholesterol, and high levels of protein. They transport free cholesterol to the liver for excretion in the bile. High levels of HDL are thought to be protective against cardiovascular disease.

Very-low-density lipoproteins (VLDLs): Contain high concentration of triglycerides, some cholesterol and a little protein. Triglycerides are the main storage form of fuel or energy for the body.

Diagnostic Evaluation

Hyperlipidemia can have a genetic basis (familial homozygous or heterozygous), and/or a lifestyle component, or can be caused by secondary problems, such as hypothyroidism. Hyperlipidemia is diagnosed on the basis of analysis of blood. A complete lipid profile should be drawn after a 12-hour fast. In children with elevated cholesterol levels, a screening thyroid-stimulating hormone is measured at diagnosis in order to rule out hypothyroidism as a cause of secondary hypercholesterolemia. Additional blood work is individualized based on other risk factors. Lipid values may be affected by recent high fevers and therefore cholesterol values should not be drawn if a child has had a fever within the past 3 weeks. Diagnostic values for acceptable, borderline, and high total cholesterol and LDL cholesterol levels are listed in [Table 23-5](#).

TABLE 23-5
Classification of Cholesterol Levels in Children

| Category | Normal mg/dl | Borderline High mg/dl | Elevated g/dl |
|------------------------------------|--------------|-----------------------|---------------|
| Triglycerides | <170 | 170-199 | ≥200 |
| Low-density lipoprotein (LDL) | <110 | 110-120 | ≥130 |
| Non-high-density lipoprotein (HDL) | <120 | 120-144 | ≥145 |
| High-density lipoprotein (HDL)* | >45 | N/A | N/A |

*Borderline low HDL 40–45; Low HDL <40.

Data adapted from the Expert Panel on Integrated Guidelines for Cardiovascular health and risk reduction in children and adolescents. Daniels SR, Benuck I, Christakis DA, et al: Expert Panel on Integrated Guidelines for Cardiovascular health and risk reduction in children and adolescents: summary report, US Dept of Health and Human services, National Heart, Lung, and Blood Institute, NIH, Bethesda, MD, 2012.

The National Heart, Lung, and Blood Institute published comprehensive guidelines for cardiovascular health and risk reduction in children and adolescents in 2011. In contrast to prior guidelines, the National Heart, Lung, and Blood Institute guidelines now recommend universal screening for all children between the ages of 9 to 11 and again between the ages of 17 to 21. In addition, selective lipid screening continues to be recommended for children over 2 years old who have a family history of dyslipidemia or early heart disease in a first or second degree relative, as well as for those children who have individual coronary risk factors ([Expert Panel on Integrated Guidelines for Cardiovascular Health and Risk Reduction in Children and Adolescents](#); and [National Heart, Lung, and Blood Institute, 2011](#)) (see [Translating the Evidence into Practice](#) box). Although not without controversy, the goal of this new approach is to identify children earlier in order decrease coronary risk factors particularly in the current era of an increased prevalence of obesity in young people ([Daniels, 2012](#); [de Ferranti, Daniels, Gillman, et al, 2012](#); [McC Crindle, Kwiterovich, McBride, et al, 2012](#)). In addition to abnormal cholesterol levels, known risk factors that correlate with the development CHD include:

- Positive family history of elevated cholesterol and/or early heart disease
- Cigarette smoking
- Obesity
- Sedentary lifestyle
- Nutritional factors
- Older age
- Male gender
- Hypertension

- Type 1 or type 2 diabetes

Translating Evidence Into Practice

Rationale for Universal Cholesterol Screening for Children

Updated by *Olga A. Taylor*

Ask the Question

PICOT Question

Should cholesterol screening be performed in children?

Search for the Evidence

Search Strategies

The literature was searched to locate clinical research studies related to this issue. Selection criteria included English-language publications within the past 10 years, research-based articles (level 3 or lower), and infant and child populations.

Databases Used

PubMed, Cochrane Collaboration, MD Consult, Joanna Briggs Institute, National Guidelines Clearinghouse (AHRQ), TRIP Database Plus, PedsCCM, BestBETs

Critically Analyze the Evidence

- In late 2011, an expert panel of the National Heart, Lung, and Blood Institute made a recommendation that lipid screening be performed on all children 9 to 11 years old; this recommendation was based on evidence that as many as 30% to 60% of children with dyslipidemia might be missed when screening is performed by family history alone ([National Heart, Lung, and Blood Institute, 2011](#)). The expert panel's guidelines also include comprehensive screening and treatment guidelines for children with cardiovascular disease risk factors.
- Diagnosis of obesity is paramount in enhancing care of obese pediatric patients. Current laboratory (cholesterol or glucose) screening rates (10%) are inadequate in the outpatient setting ([Patel, Madsen, Maselli, et al, 2010](#)).
- Testing for cardiovascular risk factors: HDL cholesterol, LDL cholesterol, fasting glucose, HgbA1C, BP, thyroid stimulating hormone, and ALT should be considered in pediatric patients with increased waist circumference and even normal BMI ([l'Allemand-Jander, 2010](#)).
- In obese children, LDL cholesterol, HDL cholesterol, total cholesterol, and triglycerides are significantly different from subjects who are not obese ([Simsek, Balta, Balta, et al, 2010](#)).
- Serum triglyceride levels are a predictive risk factor of carotid intima-media thickness ([Simsek, Balta, Balta, et al, 2010](#)).
- In children and adolescents (12 to 19 years old) fasting non-HDL cholesterol levels were strongly associated with metabolic syndrome. A non-HDL cholesterol threshold of 120 mg/dl indicated borderline risk for metabolic syndrome, and a threshold of 145 mg/dl indicated high metabolic syndrome risk ([Li, Ford, McBride, et al, 2011](#)).
- Cholesterol levels in childhood are a major population predictor for adult cholesterol levels ([Daniels, Greer, and Committee on Nutrition, 2008](#)).
- Precursors of atherosclerosis are present in young people. The atherosclerotic process begins early in life with early phases characterized by the development of fatty streaks in the vessels (PDAY study) ([Enos, Holmes, and Beyers, 1953](#); [Strong, Malcom, McMahan, et al, 1999](#)).
- Atherosclerosis is related to the presence and degree of cardiovascular risk factors in adults

(Berenson, Srinivasan, Bao, et al, 1998).

- Most severely affected children come from families with a high incidence of early heart disease. Children whose genetic family history is unknown should also be screened (National Heart, Lung, and Blood Institute, 2011).
- Universal cholesterol screening in children would identify all individuals with dyslipidemia. Using solely the family history to identify subjects for cholesterol screening missed individuals with moderate dyslipidemia and those with potentially genetic dyslipidemia (Ritchie, Murphy, Ice, et al, 2010).

Apply the Evidence: Nursing Implications

There are strong recommendations (Guyatt, Oxman, Vist, et al, 2008) that lipid screening should be performed on all children 9 to 11 years old and again between 17 and 21 years old. Selective screening is still recommended over the age of 2 years old in children with affected first or second degree relatives or those with individual cardiac risk factors. The National Heart, Lung, and Blood Institute guidelines have been endorsed by the American Academy of Pediatrics (National Heart, Lung, and Blood Institute, 2011).

Quality and Safety Competencies: Evidence-Based Practice*

Knowledge

Differentiate clinical opinion from research and evidence-based summaries.

Describe use of cholesterol screening in children.

Skills

Base individualized care plan on patient values, clinical expertise, and evidence.

Integrate evidence into practice by using cholesterol screening in children.

Attitudes

Value the concept of evidence-based practice as integral to determining best clinical practice.

Appreciate strengths and weakness of evidence for using cholesterol screening in children.

ALT, Alanine aminotransferase; *BMI*, body mass index; *BP*, blood pressure; *HDL*, high-density lipoprotein; *HgbA1C*, hemoglobin A1C test; *LDL*, low-density lipoprotein.

*Adapted from the Quality and Safety Education for Nurses website at <http://www.qsen.org>.

In addition to the risk factors noted earlier, the American Heart Association and National Heart, Lung, and Blood Institute have identified children who are considered to be at higher-risk for atherosclerosis because of co-existing health problems including:

- Chronic inflammatory diseases
- Cancer survivors
- Transplant patients
- CHD
- A history of Kawasaki disease with coronary artery aneurysms

Therapeutic Management

The first step in the treatment of high cholesterol is focused on lifestyle modification. The National Heart, Lung, and Blood Institute guidelines advocate the benefits of a heart-healthy diet for all children (Box 23-10). In addition, children with known elevated cholesterol should have individual nutritional counseling, ideally by a dietician with expertise in pediatric lipids.

Box 23-10

Recommendations for Dietary/Lifestyle Management of Dyslipidemia for Children/Adolescents Older than 2 Years Old

For All Children/Adolescents

- Obtain 1 hour of moderate or vigorous physical activity at least 5 days a week
- Less than 2 hours per day of sedentary screen time
- Avoidance of first and secondhand smoke exposure
- Eat a diverse diet rich in fruits, vegetables, whole grains, lean meats, and fish
- Refer to registered dietician for individual nutritional counselling

Elevated Low-Density Lipoprotein Cholesterol

- 25% to 30% of calories from fat
- Less than 7% from saturated fats (approximately 12 to 15 gm/daily)

- Avoid trans fats
- Favor monounsaturated fats
- Less than 200 mg/day of dietary cholesterol

Elevated Triglycerides or Non-High-Density Lipoprotein Cholesterol

- Decrease intake of simple sugars
- Avoid white bread, white pasta, white potatoes, white rice, sugary cereals, cookies, cakes, candy
- No sugar-sweetened beverages
- Replace simple sugars with complex carbohydrates
- 25% to 30% of calories from fat
- Less than 7% from saturated fat
- Favor monounsaturated fats (beneficial effects on high-density lipoprotein [HDL] cholesterol)
- Use olive oil, canola oil, avocados, nuts, and fish
- Avoid trans fats
- Increase dietary fish intake for omega-3 fatty acids

Adapted from Expert Panel on Integrated Guidelines for Cardiovascular Health and Risk Reduction in Children and Adolescents; National Heart, Lung, and Blood Institute: Expert panel on integrated guidelines for cardiovascular health and risk reduction in children and adolescents: summary report, *Pediatrics* 128(Suppl 5):S213–S256, 2011.

Research continues to support the benefit of diets low in saturated fats. Current thinking favors a “Mediterranean”-type diet. Whole grains, fruits, and vegetables form the foundation of this diet. In addition, this diet recommends the use of monounsaturated fats, such as olive oil, canola oil, nuts, avocados, and fish, which have beneficial effects on HDL cholesterol values. Patients who have elevated triglycerides, particularly those with an elevated body mass index (BMI), should receive targeted counseling aimed at a low glycemic diet. Daily aerobic exercise of at least 60 minutes a day 5 days a week is also recommended for children. In addition, patients and parents should be counseled regarding the negative effects of smoking (both first- and secondhand).

For children with severe hypercholesterolemia who fail to respond to dietary modifications, drug therapy may be necessary. Pharmacologic therapy is recommended for children older than 10 years old who have LDL cholesterol greater than 190 mg/dl without other risk factors or over 160 mg/dl in patients with two or more other risk factors or with a family history of early heart disease in a first degree relative. In young people who are considered to have individual risk conditions (such as diabetes, chronic kidney disease, Kawasaki disease with aneurysms, or heart transplant recipients), the threshold for medication is lower and may be considered when LDL values are greater than 130 mg/dl.

The use of medication in a child/adolescent needs to be a cooperative decision with the parents. Parents and patients should understand the available data related to statin use in young people particularly because prospective, long-term evidence-based practice is not practical or available for this population. Options for lipid lowering medications include bile acid-binding resins, 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors (statins), ezetimibe, and fibrates. Nicotinic acid is generally not used in children/adolescents.

The most recent guidelines on lipid abnormalities in children recommend treatment with statins

if pharmacologic therapy is indicated after lifestyle modification has been attempted ([Expert Panel on Integrated Guidelines for Cardiovascular Health and Risk Reduction in Children and Adolescents](#); and [National Heart, Lung, and Blood Institute, 2011](#)). Statins are effective in lowering LDL cholesterol. To a lesser degree, they also help lower triglycerides levels and can raise HDL cholesterol somewhat. Statins work by inhibiting the enzyme necessary for cholesterol synthesis. Statins are most effective when taken in the evening and are started at the lowest possible dose in young people. Blood work should be followed closely in children and adolescents and usually includes a fasting lipid profile, liver function tests, and creatinine kinase repeated a month or so after initiation, and then twice yearly as well as with any dosage changes.

Patients beginning therapy with a statin should be counseled regarding rare but potentially serious side effects (such as rhabdomyolysis) as well as more minor potential side effects. Patients should discontinue their medication and contact their practitioner if they develop dark urine or new muscle aches. Statin medications are not safe during pregnancy; therefore, sexually active adolescents need to take adequate birth control measures. Very long-term studies are unlikely to be available over decades; however, in the shorter-term studies that have been completed, statins seem to have a similar safety profile for children as they do for adults ([McCrimble, Urbina, Dennison, et al, 2007](#)). Ezetimibe is sometimes given in combination with statins to further reduce LDL cholesterol, which it accomplishes by decreasing reabsorption of cholesterol from the gut. Another class of lipid lowering drugs includes bile acid binding resins. Bile acid binding resins act by binding bile acids in the intestinal lumen. Because the intestine does not absorb them, resin binders do not produce systemic toxicity and are safe for children. Cholestyramine (Questran) and colestipol (Colestid) are both powders that are mixed with water or juice just before ingestion. Unfortunately, the vast majority of patients do not get adequate reduction in LDL cholesterol from bile acid-binding resins alone. Many cannot tolerate the medication because of the taste; gritty texture; and side effects, the most significant being constipation, abdominal pain, gastrointestinal bloating, flatulence, and nausea. Lastly, it is not common to use medications to lower triglyceride values unless they are significantly elevated (>500 mg/dl), in which case, fibrates which decrease the production of triglycerides, may be considered.

Nursing Care Management

Nurses play an important role in the screening, education, and support of children with lipid abnormalities and their families. When a child is referred to a preventive cardiology clinic, it is essential that the family be adequately prepared for the first visit. Generally, the parents will be asked to keep a dietary history of the child before this visit. Sometimes they will need to complete a questionnaire regarding the child's normal dietary habits. Families should be instructed to keep their child fasting for at least 12 hours before lab work. In addition, parents should be aware that lipids should not be drawn within 3 weeks of a febrile illness because doing so can affect cholesterol values. It is important to schedule the blood test early in the morning and to arrange for nourishment immediately thereafter. At the visit, a full family history should be taken, including the health of both parents and all first-degree relatives. Specific questions should be asked regarding early heart disease, hypertension, strokes (CVAs), sudden death, hyperlipidemia, diabetes, and endocrine abnormalities.

Patients and parents should be educated about cholesterol and lipid abnormalities. This should include a brief introduction of the different lipoprotein categories, including an explanation of the components of the lipid profile. Also, lifestyle risk factors for heart disease, such as smoking and exercise, should be reviewed. For management to be effective, parents and patients need to understand that the rationale for dietary or pharmacologic intervention is prevention of future cardiovascular disease and is part of any treatment plan for lipid abnormalities.

A child with a lipid disorder should not be viewed as having a disease, and stringent dietary guidelines may become an issue of control and a source of great stress for many families. Rather, the positive aspects of healthy eating, regularly exercising, and avoiding smoking should be emphasized. Basic dietary changes should be encouraged for the whole family so that the affected child is not singled out. Cultural differences must be considered and recommendations individualized. Substitution rather than elimination needs to be emphasized. Visual aids (e.g., test tubes depicting the amount of fat in a hot dog or the number or packs of sugar in a glass of juice) are often helpful, especially for children. Diets should be flexible and individually tailored by a nutritionist who is experienced in lipid disorders. Dietary recommendations need to meet the

nutritional demands of growing children while providing benefit to the overall profile. Parents and patients are encouraged to participate in dietary and educational sessions, ask questions, and share ideas and experiences.

Parents often feel guilty about the hereditary component of hyperlipidemia. Many also believe they have failed if the diet alone is not making a significant difference in their child's lipid profile. They need to be reassured that a dietary approach alone is often not sufficient, especially for children with genetically elevated values.

Parents of children who require pharmacologic therapy need to understand the purpose, dosage, and possible side effects of the various drugs. Medication schedules should remain flexible and should not interfere with the child's daily activities. Follow-up phone calls by the nurse between visits allow parents to discuss their concerns and ask any questions that have arisen.

Cardiac Dysrhythmias

Dysrhythmias, or abnormal heart rhythms, can occur in children with structurally normal hearts, as features of some congenital heart defects, and in patients after surgical repair of congenital heart defects. They are also seen in patients with cardiomyopathy and with cardiac tumors. They can occur secondary to metabolic and electrolyte imbalances. They can be classified in several ways, including by heart rate characteristics (bradycardia and tachycardia) and by the origin of the dysrhythmia in the atria or ventricles. Some dysrhythmias are well tolerated and self-limiting. Others may cause decreased cardiac output with associated symptoms. Some dysrhythmias can cause sudden death. Treatment depends on the cause of the dysrhythmia and its severity.

Many advances have been made in the diagnosis and treatment of pediatric dysrhythmias in the past decade. Improvements in technology have allowed better diagnosis, the development of ablation techniques, and the expansion of pacemaker capabilities. New antidysrhythmic medications have proven safe and effective in children. Radiofrequency ablation has offered a cure for some dysrhythmias. Pediatric electrophysiology has become a highly specialized field, and students should consult more detailed sources for an in-depth discussion. The following sections address diagnostic studies and provide a general discussion of the most common tachycardia (supraventricular tachycardia [SVT]) and the most common bradycardia (complete heart block) that require treatment in the pediatric population.

Diagnostic Evaluation

Nurses must be familiar with the standards of normal heart rate for the particular age group (see inside back cover). An initial nursing responsibility is recognition of an abnormal heartbeat, either in rate or rhythm. When a dysrhythmia is suspected, the apical rate is counted for 1 full minute and compared with the radial rate, which may be lower because not all of the apical beats are felt. Consistently, high or low heart rates should be regarded as suspicious. The patient should be placed on a cardiac monitor with recording capabilities. A 12-lead ECG yields more information than the monitor recording and should be done as soon as possible.

The basic diagnostic procedure is the ECG, including 24-hour Holter monitoring.

Electrophysiologic cardiac catheterization allows for identification of the conduction disturbance and immediate investigation of drugs that may control the dysrhythmia. Another procedure that may be used is **transesophageal recording**. An electrode catheter is passed to the lower esophagus and, when in position at a point proximal to the heart, is used to stimulate and record dysrhythmias.

Dysrhythmias can be classified according to various criteria, such as effect on heart rate and rhythm, as follows:

Bradycardias: Abnormally slow rate

Tachycardias: Abnormally rapid rate

Conduction disturbances: Irregular heart rate

Bradycardias

Sinus bradycardia (slower than normal rate) in children can be attributed to the influence of the autonomic nervous system, as with hypervagal tone, or in response to hypoxia and hypotension.

Sinus bradycardias are also known to develop after some complex cardiac surgical repairs involving extensive atrial suture lines, such as atrial baffle repairs (Mustard and Senning repairs) and the Fontan procedure.

Complete atrioventricular (AV) block is also referred to as **complete heart block**. This can be either congenital (occurring in children with structurally normal hearts) or acquired after surgery to repair cardiac defects. AV blocks are most often related to edema around the conduction system and resolve without treatment. Temporary epicardial wires are placed in most patients at surgery; if a rhythm disturbance occurs, temporary pacing can be used. Several days after surgery, the health practitioner removes the wires by pulling slowly and deliberately down on them from the site of insertion.

Some children may need a permanent pacemaker. The pacemaker takes over or assists in the heart's conduction function. The implantation of a pacemaker, in the operating room or possibly the catheterization laboratory, is usually a low-risk procedure. The pacemaker is made up of two basic parts, the pulse generator and the lead. The pulse generator is composed of the battery and the electronic circuitry. The lead is an insulated, flexible wire that conducts the electrical impulse from the pulse generator to the heart. Two types of leads are available, transvenous and epicardial. After the lead has been attached to the heart, a small incision is made, and a pocket is formed under the muscle to house and protect the generator. Continuous ECG monitoring is necessary during the recovery phase to assess pacemaker function. The nurse should be aware of the programmed rate and expected individual generator variations. The pacemaker insertion site is monitored for signs of infection. Analgesics are given for pain.

Pacemaker functions have become more sophisticated, and some models can adjust the heart rate to activity demands or be programmed for overdrive pacing or cardioversion.

Discharge teaching includes information about the signs and symptoms of infection, general wound care, and activity restrictions. Parents, and patients if they are old enough, should be taught to take a pulse and know the settings of the pacemaker. If the patient's low rate is set at 80 beats/min and the heart rate is only 68 beats/min, there is a possible problem with the pacemaker that needs to be investigated. Instructions for telephone transmission of ECG readings are also given. Telephone transmission can be used to transmit ECG strips and to monitor battery life and pacemaker function. The pacemaker generator will have to be replaced periodically because of battery depletion. Children with pacemakers should wear a Medic-Alert device, and their parents should have a paper identification card with specific pacer data in case of an emergency. Cardiopulmonary resuscitation (CPR) instruction is suggested for parents.

Tachydysrhythmias

Sinus tachycardia (an abnormally fast heart rate) secondary to fever, anxiety, pain, anemia, dehydration, or any other etiologic factor requiring increased cardiac output should be ruled out before diagnosing an increased heart rate as pathologic. SVT is the most common tachydysrhythmia found in children and refers to a rapid regular heart rate of 200 to 300 beats/min. As many as 1 in 250 children experience SVT (Schlechte, Boramanand, and Funk, 2008). The onset of SVT is often sudden, the duration is variable, and the rhythm may end abruptly and convert back to a normal sinus rhythm. Clinical signs in infants and young children are: poor feeding, extreme irritability, and pallor. Children may experience palpitations, dizziness, chest pain, and diaphoresis. If SVT is sustained, signs of HF may be seen.

The treatment of SVT depends on the degree of compromise imposed by the dysrhythmia (see [Critical Thinking Case Study](#)). In some cases, vagal maneuvers, such as applying ice to the face, massaging the carotid artery (on one side of the neck only), or having an older child perform a Valsalva maneuver (e.g., exhaling against a closed glottis, blowing on a thumb as if it were a trumpet for 30 to 60 seconds), have terminated SVT. If vagal maneuvers fail or the child is hemodynamically unstable, adenosine (a drug that impairs AV conduction) may be used. Adenosine is given by rapid IV push with a saline bolus immediately after the drug because of its very short half-life. If this is unsuccessful or cardiac output is compromised, esophageal overdrive pacing or synchronized cardioversion (delivering an electrical shock to the heart) can be used in the intensive care setting. Sedation is needed for both procedures. Cardioversion should never be done in a conscious patient. More long-term pharmacologic treatment includes digoxin or possibly propranolol (Inderal) or amiodarone for severe or recurrent SVT.

Critical Thinking Case Study

Supraventricular Tachycardia

You are working in the emergency department when a father comes through the doors, crying, carrying his 1-month-old infant. The infant is awake and very irritable. The father reports that the infant has not been feeding well for the past 6 hours, and the father has noticed sweating (diaphoresis) with attempted feeds. No history of fever is noted. Further assessment reveals a diaphoretic, crying infant with a respiratory rate of 60 breaths/min, blood pressure of 60/40 mm Hg, and heart rate that is too fast to count by auscultation. When the infant is attached to the cardiorespiratory monitor, the heart rate is 220 beats/min, nonvariable, with an oxygen saturation of 97%. Capillary refill time is slightly prolonged at 3 seconds, and femoral pulses are palpable but weak.

Questions

1. Evidence: Is there sufficient evidence to draw conclusions about this infant?
2. Assumptions: Describe an underlying assumption about each of the following:
 - a. Symptoms associated with heart failure
 - b. An infant younger than 3 months with poor feeding
 - c. Tachyarrhythmias in infants
3. What priorities for nursing care should be established?
4. Does the evidence support your nursing interventions?

A primary focus of nursing care is education of the family regarding the symptoms of SVT and its treatment. SVT may occur again despite therapy. Parents should be taught to take a radial pulse for a full minute. If medication is prescribed, instructions regarding accurate dosage and the importance of administering the correct dose at specified intervals are stressed.

Radiofrequency ablation has become first-line therapy for some types of SVT. The procedure is done in the cardiac catheterization laboratory and begins with mapping of the conduction system to identify the dysrhythmia focus. A catheter delivering radiofrequency current is directed at the site, and the area is heated to destroy the tissue in the area. These are lengthy procedures, often lasting 6 to 8 hours, and sedation or general anesthesia is required. Preparation is similar to that for cardiac catheterization. Another procedure, cryoablation, is also used in treatment of SVT. Liquid nitrous oxide is used to cool a catheter to subfreezing temperatures, which then destroys the tissue of target by freezing.

Pulmonary Artery Hypertension

Pulmonary artery hypertension (PAH) is a disease of the entire pulmonary circulation. The pulmonary arteries are described as having vascular narrowing due to decreased vascular growth and surface area, as well as structure remodeling of the vessel wall (Abman and Ivy, 2011). This leads to an increase in pulmonary vascular resistance. These disorders are poorly understood, and until recently, there was no treatment beyond supportive care. PAH is a progressive, eventually fatal disease for which there is no known cure. It can be difficult to diagnose in the early stages. Often when patients become symptomatic and a diagnosis is made, their disease is rapidly progressing, treatment is unsuccessful, and death occurs within several years. There is also evidence of a genetic basis for some PAH (Newman, Phillips, and Loyd, 2008).

There are many possible causes of PAH. Cardiac causes occur primarily in patients with a large left-to-right shunt producing increased pulmonary blood flow. If these defects are not repaired

early, the high pulmonary flow will cause changes in the pulmonary artery vessels, and the vessels will lose their elasticity. Other causes of PAH include hypoxic lung diseases, thromboembolic diseases causing pulmonary vascular obstruction, collagen vascular diseases, exposure to toxic substances, and congenital heart defects with a large left-to-right shunt, from increased pulmonary blood flow. Many of the patients have no identifiable cause for PAH and have primary or idiopathic PAH.

Clinical Manifestations

The clinical manifestations include dyspnea with exercise, chest pain, and syncope. Dyspnea is the most common symptom and is caused by impaired oxygen delivery. Chest pain is the result of coronary ischemia in the right ventricle from severe hypertrophy. Syncope reflects a limited cardiac output leading to decreased cerebral blood flow. Right-sided heart dysfunction is steadily progressive, and when symptoms of venous congestion and edema are present, the prognosis is poor.

Therapeutic Management

Although no cure is known, several therapies have shown promise in slowing the progression of the disease and improving quality of life. In general, situations that may exacerbate the disease and cause hypoxia, such as exercise and high altitudes, are avoided. Supplemental oxygen, especially at night while sleeping, is commonly used to relieve hypoxia. Patients are at risk for thromboembolic events leading to pulmonary emboli, so anticoagulation with warfarin (Coumadin) is often prescribed.

A number of new drug therapies have been used in this patient population and have promise in improving quality of life and survival. Several studies and newer approaches in treatment emphasize combined therapy that targets each of the major pathways of the disease process rather than monotherapy approaches.

Vasodilator therapy (which relaxes vascular smooth muscle and reduces pulmonary artery pressure) can prolong survival of patients with PAH. Oral calcium channel blockers have been successful in some children. For patients who are nonresponders in vasodilator testing, a new oral drug, bosentan (an endothelin-receptor antagonist), is now available that reduces pulmonary artery pressure and resistance and is safe and well tolerated in children (Barst, Ivy, Dingemane, et al, 2003). It has been used in combination with IV prostacyclin.

Lung transplantation may be another treatment option for those with severe disease. Patients with pulmonary hypertension have had a higher mortality rate than after lung transplantation than other lung transplant patients. The management of PAH continues to evolve as new information is learned and new combination therapies are tested and evaluated.

Quality Patient Outcomes: Hypertension

- Underlying cause of hypertension identified
- Blood pressure (BP) control maintained
- Dietary practices and lifestyle changes effectively used to control hypertension
- Compliance with medication regimen, if prescribed

Cardiomyopathy

Cardiomyopathy refers to abnormalities of the myocardium in which the cardiac muscles' ability to contract is impaired. Cardiomyopathies are relatively rare in children. Possible etiologic factors include familial or genetic causes, infection, deficiency states, metabolic abnormalities, and collagen vascular diseases. Most cardiomyopathies in children are considered primary or idiopathic, in which the cause is unknown and the cardiac dysfunction is not associated with systemic disease. Some of the known causes of **secondary cardiomyopathy** are anthracycline toxicity (the antineoplastic agents, doxorubicin [Adriamycin] and daunomycin), hemochromatosis (from excessive iron storage), Duchenne muscular dystrophy, Kawasaki disease, collagen diseases, and

thyroid dysfunction.

Cardiomyopathies can be divided into three broad clinical categories according to the type of abnormal structure and dysfunction present: (1) dilated cardiomyopathy, (2) hypertrophic cardiomyopathy, and (3) restrictive cardiomyopathy.

Dilated cardiomyopathy is characterized by ventricular dilation and greatly decreased contractility, resulting in symptoms of HF. This is the most common type of cardiomyopathy in children. Its cause is often unknown. The clinical findings are of HF with tachycardia, dyspnea, hepatosplenomegaly, fatigue, and poor growth. Dysrhythmias may be present and may be more difficult to control with worsening HF.

Hypertrophic cardiomyopathy is characterized by an increase in heart muscle mass without an increase in cavity size, usually occurring in the left ventricle and associated with abnormal diastolic filling. It is a familial autosomal dominant genetic abnormality in most cases and is probably the most common genetically transmitted cardiovascular disease (Maron, 2001). The expression of clinical disease varies greatly among patients. Clinical symptoms usually appear in school-age period or adolescence and may include anginal chest pain, dysrhythmias, and syncope. One recent study confirmed that unexplained syncope in the childhood age group (younger than 18 years old) with known hypertrophic cardiomyopathy had a 60% cumulative risk of sudden death within 5 years of the syncopal event (Spirito, Autore, Rapezzi, et al, 2009). Presentation in infancy includes signs of HF and has a poor prognosis. The ECG demonstrates left ventricular hypertrophy, often with ST-T changes. The echocardiogram is most helpful and demonstrates asymmetric septal hypertrophy and an increase in left ventricular wall thickness, with a small left ventricle cavity.

Restrictive cardiomyopathy, which is rare in children, describes a restriction to ventricular filling caused by endocardial or myocardial disease or both. It is characterized by diastolic dysfunction and absence of ventricular dilation or hypertrophy. Symptoms are similar to those of HF (see earlier in this chapter).

Therapeutic Management

Treatment is directed toward correcting the underlying cause whenever feasible. However, in most affected children, this is not possible, and treatment is aimed at managing HF (see earlier in this chapter) and dysrhythmias. Digoxin, diuretics, and aggressive use of afterload reduction agents have been found to be helpful in managing symptoms in those with dilated cardiomyopathy. Practice guidelines for the management of HF in children have been outlined and provide an in-depth review of available therapies (Rosenthal, Chrisant, Edens, et al, 2004; Rossano and Shaddy, 2014). Digoxin and inotropic agents are usually not helpful in the other forms of cardiomyopathy because increasing the force of contraction may exacerbate the muscular obstruction and actually impair ventricular ejection. Beta-blockers (such as propranolol) and calcium channel blockers (such as verapamil) have been used to reduce left ventricular outflow obstruction and improve diastolic filling in those with hypertrophic cardiomyopathy.

Careful monitoring and treatment of dysrhythmias are essential. The placement of an automatic implantable cardioverter defibrillator (AICD) should be considered for patients at high risk of sudden death because of ventricular dysrhythmias. Anticoagulants may be given to reduce the risk of thromboemboli, a complication of the sluggish circulation through the heart. For worsening HF and signs of poor perfusion, IV inotropic or vasodilating drugs may be needed. Severely ill children may require mechanical ventilation, oxygen administration, and IV medications. Heart transplantation may be a treatment option for patients who have worsening symptoms despite maximum medical therapy.

Nursing Care Management

Because of the poor prognosis in many children with cardiomyopathy, nursing care is consistent with that for any child with a life-threatening disorder (see Chapter 17). One of the most difficult adjustments for the child may be the realization of failing health and the need for restricted activity. The child should be included in decisions regarding activity and allowed to discuss feelings, particularly if the disease follows a progressively fatal course. After symptoms of HF or dysrhythmias develop, the same nursing interventions are implemented as discussed earlier in the chapter. If heart transplantation is considered, the needs of the child and family are great in terms of psychological preparation and postoperative care. The nurse plays an important role in assessing the family's understanding of the procedure and long-term consequences. Children of school age

and older should be fully informed to give their assent to the procedure (see [Informed Consent, Chapter 20](#)).

Heart Transplantation

Heart transplantation has become a treatment option for infants and children with worsening HF and a limited life expectancy despite maximum medical and surgical management. Indications for heart transplantation in children are cardiomyopathy and end-stage CHD. It is also an option for patients with some forms of complex congenital cardiac defects, such as HLHS, for whom conventional surgical approaches have a high mortality rate.

The heart transplant procedure may be orthotopic or heterotopic. **Orthotopic heart transplantation** refers to removing the recipient's own heart and implanting a new heart from a donor who has had brain death but a healthy heart. The donor and recipient are matched by weight and blood type. **Heterotopic heart transplantation** refers to leaving the recipient's own heart in place and implanting a new heart to act as an additional pump, or "piggyback" heart; this type of transplant is rarely done in children.

Before transplantation, potential recipients undergo a careful cardiac evaluation to determine if there are any other medical or surgical options to improve the patient's cardiac status. Other organ systems are assessed to identify problems that might increase the risk of or preclude transplantation. A psychosocial evaluation of the patient and family is done to assess family function, support systems, and ability to comply with the complex medical regimen after the transplant. Support services to help the family successfully care for their child are provided when possible. Parents and older adolescents need extensive education about the risks and benefits of transplantation so that they can make an informed decision. Patients are listed on a national computer network organized by the United Network for Organ Sharing to match donors and recipients. (See also [Organ or Tissue Donation and Autopsy, Chapter 17](#).)

The total number of pediatric heart transplants has increased from 274 in 1998 to 372 in 2012 ([Scientific Registry of Transplant Recipients, 2012](#)). Primary diagnosis for the majority of candidates continues to be complex CHD and most (87.9%) candidates are status 1A at the time of transplant ([Scientific Registry of Transplant Recipients, 2012](#)). The 1-year graft survival rate for pediatric heart transplants performed in 2012 was 87.5% ([Scientific Registry of Transplant Recipients, 2012](#)).

Waiting list mortality remains high, particularly in the smallest children. Recent progress in suitable ventricular assist devices for use in children as a bridge to transplantation has made outcomes to survival for cardiac transplantation more successful ([Blume, Naftel, Bastardi, et al, 2006](#)). A multicenter study using the US Scientific Registry of Transplant Recipients was recently conducted ([Almond, Thiagarajan, Piercy, et al, 2009](#)). Among 3098 children listed for a heart transplant between 1999 and 2006, the median age was 2 years. Sixty percent of patients were listed as a top status (30% ventilated and 18% on supportive measures), and of those children, 17% died, 63% received transplants, 8% recovered, and 12% remained listed. These numbers concluded that US waiting time remains high in the current era, and high-risk groups in these categories could benefit from emerging cardiac assist devices, such as extracorporeal membrane oxygenation and ventricular assist devices.

The posttransplant course is complex. Although heart function is greatly improved or normal after transplantation, the risk of rejection is serious. The leading cause of death in the first 3 years after heart transplantation is rejection, with the greatest risk in the first 6 months ([Blume, 2003](#)). Rejection of the heart is diagnosed primarily by endomyocardial biopsy in older children. Serial echocardiograms are often used in infants and young children to reduce the need for invasive biopsies. Immunosuppressants must be taken for life and have many systemic side effects. Triple-drug therapy for immunosuppression with a calcineurin inhibitor (cyclosporine or tacrolimus), steroids, and mycophenolate mofetil or azathioprine is most commonly used in pediatric patients. Steroids are weaned in the first year and may be discontinued in some patients; many pediatric centers are avoiding long-term steroids by utilizing induction therapy protocols of high dose steroids and thymoglobulin at the time of transplant ([Thrush and Hoffman, 2014](#)).

Infection is always a risk. Potential long-term problems that may limit survival include chronic rejection, causing coronary artery disease; renal dysfunction and hypertension resulting from cyclosporine administration; lymphoma; and infection. Coronary artery disease is the leading cause of death among late survivors of heart transplantation ([Boucek, Aurora, Edwards, et al, 2007](#)). In the short term, after successful transplantation, children are able to return to full participation in age-appropriate activities and appear to adapt well to their new lifestyle. Transplantation is not a cure

because patients must live with the lifetime consequences of chronic immunosuppression.

Nursing Care Management

Successfully caring for a child after a heart transplant requires the expertise and dedication of many members of the health care team. Nurses play vital roles in assessment, coordination of care, psychosocial support, and patient and family education. The heart transplant recipient must be carefully monitored for signs of rejection, infection, and the side effects of the immunosuppressant medications. The patient's and family's psychosocial well-being also needs to be assessed to identify issues such as increased family stress, depression, substance abuse, and school problems.

Noncompliance with an intense medication regimen, especially during adolescence, can lead to serious medical problems and can be fatal. Immunosuppressants and nursing implications are discussed in [Chapter 26](#) in relation to renal transplantation. Care of the immunosuppressed child is reviewed in [Chapter 25](#). Psychosocial concerns and appropriate interventions for the child with a life-threatening disorder are presented in [Chapter 17](#).

The first 6 months to 1 year after the transplant are most intense because the risk of complications is greatest and the patient and family are adjusting to a new lifestyle. Patients are monitored closely by the health care team, with frequent visits and laboratory tests. Care is usually shared between local health care providers and the transplant center. Many patients are able to return to school and other age-appropriate activities within 2 to 3 months after the transplant.

Vascular Dysfunction

Systemic Hypertension

Hypertension is defined as the consistent elevation of BP beyond values considered to be the upper limits of normal. The two major categories are **essential hypertension** (no identifiable cause) and **secondary hypertension** (subsequent to an identifiable cause). In recent years, there has been increasing incidence in this disorder in adolescents and children, which is most likely related to the obesity epidemic. Hypertension in children and adolescents is defined as having a systolic or diastolic BP that consistently falls at or over the 95th percentile. This group is further delineated as follows:

Stage 1 hypertension includes patients who have BP readings between the 95th and 99th percentiles.

Stage 2 hypertension includes patients with BP readings over the 99th percentile plus 5 mm Hg.

An additional group includes children and adolescents who have prehypertension (or high-normal BP). This prehypertensive group includes those with BP readings that fall consistently between the 90th and 95th percentiles. *The Fourth Report on the Diagnosis, Evaluation, and Treatment of High Blood Pressure in Children and Adolescents* outlines in detail the identification, testing, and treatment recommendations for young people with high BP ([National High Blood Pressure Education Program Working Group on High Blood Pressure in Children and Adolescents, 2004](#)). These recommendations were reiterated in the more recent Expert Panel on Integrated Guidelines for Cardiovascular Health and Risk Reduction ([Expert Panel on Integrated Guidelines for Cardiovascular Health and Risk Reduction in Children and Adolescents; and National Heart, Lung, and Blood Institute, 2011](#)).

Etiology

Most instances of hypertension in young children occur secondary to a structural abnormality or an underlying pathologic process, although this is being challenged by screening programs of relatively healthy children. The most common cause of secondary hypertension is renal disease followed by cardiovascular, endocrine, and some neurologic disorders. As a rule, the younger the child and the more severe the hypertension, the more likely it is to be secondary.

The causes of essential hypertension are undetermined, but evidence indicates that both genetic and environmental factors play a role. The incidence of hypertension has been shown to be higher in children whose parents are hypertensive. African Americans have a higher incidence of hypertension than whites, and in African Americans it develops earlier, is frequently more severe, and results in death at an earlier age. Environmental factors that contribute to the risk of developing hypertension include obesity, salt ingestion, smoking, and stress.

Diagnostic Evaluation

BP assessment should be a routine part of annual assessment in healthy children older than 3 years old. BP readings should also be done in those children younger than 3 years old who have high-risk family histories or those with individual risk factors, including CHD, kidney disease, malignancy, transplant, certain neurologic problems, or systemic illnesses known to cause hypertension. Although clinical manifestations associated with hypertension depend largely on the underlying cause, some observations can provide clues to the examiner that an elevated BP may be a factor ([Box 23-11](#)). In infants and very young children who cannot communicate symptoms, observation of behavior may provide clues, although gross behavioral changes may not be apparent until complications are present.

Box 23-11

Clinical Manifestations of Hypertension

Adolescents and Older Children

Frequent headaches

Dizziness

Changes in vision

Infants or Young Children

Irritability

Head banging or head rubbing

Waking up screaming in the night

No definitive cutoff values are used in the diagnosis of hypertension in the pediatric patient. The Expert Panel on Integrated Guidelines for Cardiovascular Health and Risk Reduction in Children and Adolescents ([National Heart, Lung, and Blood Institute, 2011](#)) endorsed the National Heart, Lung, and Blood Institute's *Fourth Report on the Diagnosis, Evaluation, and Treatment of High Blood Pressure in Children and Adolescents* ([National High Blood Pressure Education Program Working Group on High Blood Pressure in Children and Adolescents, 2004](#)). Both documents provide normative data for children. BP tables include the 50th, 90th, 95th, and 99th percentiles for BP readings based on age, gender, and height percentiles. These guidelines are based on auscultatory readings, and therefore this is currently the preferred method of assessment. These charts take into account differences in body height but not weight or BMI. It is therefore important to note that a child who is large for his or her age may normally have a higher BP than a child of average size. Before a diagnosis is made, BP should be measured on at least three separate occasions. An ambulatory BP monitor may be ordered if "white-coat hypertension" is suspected. These are useful in that they provide BP readings over a 24-hour period. There are different normative values for ambulatory BP readings ([Urbina, Alpert, Flynn, et al, 2008](#)).

A careful medical history and family history should be obtained to screen for other relatives with hypertension or other cardiovascular risk factors. In children with suspected hypertension, initial laboratory data include a urinalysis, renal function studies (such as creatinine and blood urea nitrogen), a lipid profile, complete blood count, and electrolytes. Depending on the severity of hypertension, additional testing may be indicated. Testing may include a retinal examination, renal ultrasonography to measure kidney size and Doppler flow to detect the likelihood of a renal etiology. In addition, an ECG and an echocardiogram help to evaluate the presence of end-organ involvement, such as left ventricular hypertrophy. Further testing for a secondary cause of hypertension may be indicated in children with significant hypertension and normal initial screening test findings.

Oral contraceptives can be a cause of hypertension because of their pressor effects. A trial off of oral contraceptives may be indicated; however, other options of contraceptives should be discussed before this decision is made (see [Chapter 16](#)).

Therapeutic Management

Therapy for secondary hypertension involves diagnosis and treatment of the underlying cause. Children and adolescents with consistently elevated BP readings from no known cause or those with secondary hypertension not amenable to surgical correction may be treated with a combination of lifestyle and pharmacologic interventions. Dietary practices and lifestyle changes are important in the control of hypertension both for children and for adults. Nonpharmacologic measures, such as weight control in overweight patients, increased exercise, limited salt intake (such as recommended in the Dietary Approaches to Stop Hypertension [DASH] diet), and avoidance of stress and smoking, carry no risk and should be instituted as first-line therapy except in severe cases in which pharmacologic therapy may be indicated as well.

Drug therapy is instituted with caution in children with significant elevations of BP despite lifestyle modification. The treatment should begin with one drug with additional drug added if control is not obtained. The classes of oral antihypertensive drugs used in children include the β -

blockers, ACE inhibitors, calcium channel blockers, angiotensin-receptor blockers, and diuretics. The goal is to achieve a normotensive state without accompanying drug side effects.

Nursing Care Management

BP measurement should be a part of the routine assessment of children older than 3 years old and patients younger than 3 years old who are considered to be at high risk for hypertension. To obtain an accurate reading, care is taken to quiet the child or relax the adolescent while the measurement is recorded to avoid false readings caused by excitement. BP should be measured in the sitting position with the arm at the level of the heart. Initial evaluation should also include four extremity pressures (in the supine position) to rule out coarctation of the aorta. The chief cause of falsely elevated BP readings is the use of improperly fitting, narrow cuffs. Therefore, attention to correct measurement technique is essential (see [Blood Pressure, Chapter 4](#)).

Education aimed at understanding hypertension and its implication over the life span is essential in promoting patient and family compliance with both nonpharmacologic and pharmacologic therapies (see [Compliance, Chapter 20](#)).

Ambulatory/home BP measurements can facilitate surveillance in youngsters being assessed for hypertension or can document the effectiveness of therapy for those being treated for chronic hypertension. In addition, a family member can be instructed in how to take and record accurate BP measurements, thus decreasing the number of trips to a health care facility. This individual needs to have parameters, above which they should contact the practitioner. In addition, the school nurse can often be a valuable resource in monitoring BP. The nurse plays an important role in assessing individual families and providing targeted information regarding nonpharmacologic modes of intervention, such as diet, weight loss, smoking cessation, and exercise programs. A DASH diet—low in sodium, red meats, and sugar and high in fruits, vegetables, whole grains, beans, nuts, low-fat dairy, fish, and poultry—is recommended for children/adolescents with elevated BP/hypertension. The child should be referred to a nutritionist with expertise in working with children and adolescents with hypertension. Exercise regimens should be individualized but should emphasize the benefits of regular aerobic exercise (ideally 300 minutes of aerobic exercise weekly). School-aged children and young adolescents generally prefer team sports rather than individual training, which they may view as a burden rather than an enjoyable activity. If peers and family members can be encouraged to participate in any of the management strategies, the child's compliance is likely to be greater.

If drug therapy is prescribed, the nurse needs to provide information to the family regarding the reasons for it, how the drug works, and possible side effects. General instructions for antihypertensive drugs include:

- Rise slowly from a horizontal position and avoid sudden position changes.
- Take drugs as prescribed.
- Maintain adequate hydration.
- Notify the practitioner if unpleasant side effects occur but do not discontinue the drug.
- Avoid alcohol and stay on the prescribed diet.

The need for regular follow-up is stressed, especially because antihypertensive therapy can sometimes be safely discontinued if BP remains under control over time.

Kawasaki Disease

Kawasaki disease is an acute systemic vasculitis of unknown cause. It is seen in every racial group, with 75% of the cases occurring in children younger than 5 years old. The peak incidence is in the toddler age group. The acute disease is self-limited; however, without treatment, approximately 20% to 25% of children develop coronary artery dilation or aneurysm formation. Infants younger than 1 year old are at the greatest risk for heart involvement, although an increased incidence has also been reported in older children, perhaps because of later diagnosis in many.

The etiology of Kawasaki disease is unknown. The illness is not spread by person-to-person contact; however, several factors support an infectious etiologic trigger, possible in a genetically susceptible host. It is often seen in geographic and seasonal outbreaks, with an increased incidence reported in the late winter and early spring ([Newburger, de Ferranti, Fulton, et al, 2015](#); [Newburger, Takahashi, Gerber, et al, 2004](#)).

Pathophysiology

The principal area of concern in Kawasaki disease is the cardiovascular system. During the initial stage of the illness, extensive inflammation of the arterioles, venules, and capillaries is evident, resulting in many of the clinical symptoms. In addition, segmental damage to the medium-sized muscular arteries, mainly the coronary arteries, can occur, resulting in the formation of coronary artery aneurysms in some children. Death is very rare in Kawasaki disease (<0.17% of cases) and is usually the result of myocardial ischemia from coronary thrombosis during the first few months of illness or years later from severe scar formation and stenosis in coronary aneurysms (Wilder, Palinkas, Kao, et al, 2007).

Clinical Manifestations

Because no specific diagnostic test exists for Kawasaki disease, the diagnosis is established on the basis of clinical findings and associated laboratory results (Box 23-12). These criteria should be used as guidelines. It is important to note that many children with Kawasaki disease do not fulfill standard diagnostic criteria, and infants in particular often have an incomplete presentation. It is therefore important to consider Kawasaki disease as a possible diagnosis in any infant or child with prolonged fever that is unresponsive to antibiotics and is not attributable to another cause.

Box 23-12

Diagnostic Criteria for Kawasaki Disease

Child must have fever for more than 5 days along with four of five clinical criteria* (diagnosis may be made on day 4 by an experienced clinician if child has all the clinical criteria):

1. Changes in the extremities: In the acute phase edema, erythema of the palms and soles; in the subacute phase, periungual desquamation (peeling) of the hands and feet
2. Bilateral conjunctival injection (inflammation) without exudation
3. Changes in the oral mucous membranes, such as erythema of the lips, oropharyngeal reddening; or “strawberry tongue” (large papillae are exposed)
4. Polymorphous rash
5. Cervical lymphadenopathy (one lymph node >1.5 cm)

*Incomplete Kawasaki disease should be considered in situation of prolonged fever (see algorithm for incomplete Kawasaki disease from American Heart Association guidelines). Kawasaki disease can be diagnosed with fewer clinical criteria when coronary artery changes are noted.

Kawasaki disease manifests in three phases: acute, subacute, and convalescent. The **acute phase** begins with an abrupt onset of a high fever that is unresponsive to antibiotics and antipyretics. The remaining diagnostic symptoms evolve over the next week or so. Symptoms may come and go and do not need to be present simultaneously for diagnosis, although the fever is generally persistent throughout. During this stage, the child is typically *very* irritable. The **subacute phase** begins with resolution of the fever and lasts until all clinical signs of Kawasaki disease have disappeared. During this phase, coronary artery aneurysms may be noticed or previously dilated vessels may continue to increase in size. Irritability persists during this phase. In the **convalescent phase**, all of the clinical signs of Kawasaki disease have resolved, but the laboratory values have not returned to normal. This phase is complete when all blood values are normal (6 to 8 weeks after onset). At the end of this stage, the child has regained his or her usual temperament, energy, and appetite.

Cardiac Involvement

Long-term complications of Kawasaki disease include the development of coronary artery aneurysms, potentially disrupting blood flow. Children with large (giant) aneurysms have the potential for myocardial infarction, which can result from thrombotic occlusion of a coronary

aneurysm or late-stenosis of the same vessel.

Affected coronary arteries dilate progressively, reaching their maximal diameter approximately 1 month from the onset of fever. Over time, as the damaged vessel tries to heal, stenosis of the aneurysm may develop and may lead to myocardial ischemia. Most of the morbidity and mortality occur in children affected with the largest aneurysms (giant aneurysms >8 mm or z-score >10). Symptoms of acute myocardial infarction in young children can be confusing and may include abdominal pain, vomiting, restlessness, inconsolable crying, pallor, and shock, as well as chest pain or pressure (noted more in older children). In the initial phase of the illness, children with Kawasaki disease may have signs or symptoms related to inflammation of the myocardium, including myocarditis, valvulitis, or arrhythmias.

Echocardiograms are accurate in assessing coronary artery dilation and are used to monitor coronary artery dimensions, myocardial function, and valvar function. A baseline echocardiogram should be obtained at the time of diagnosis and is used for comparison with future studies, which are obtained at 1 week after the initial diagnosis and again at 4 to 6 weeks later. Additional echocardiograms should be done (often as frequently as twice a week) in situations where a child has coronary artery dilation or obvious aneurysm formation or when response to treatment is incomplete.

Therapeutic Management

The current treatment of children with Kawasaki disease includes high-dose intravenous immunoglobulin (IVIG) along with salicylate therapy. IVIG has been demonstrated to be effective at reducing the incidence of coronary artery abnormalities when given within the first 10 days of the illness and ideally in the first 7 days of illness. A single, large infusion of 2 g/kg over 10 to 12 hours is recommended. Retreatment with IVIG and/or other antiinflammatory drugs may be given to patients with an incomplete response to the initial IVIG (continued or recrudescing fever) or those with coronary artery dilation.

Aspirin is used in an antiinflammatory dose (80 to 100 mg/kg/day in divided doses every 6 hours) to control fever and symptoms of inflammation. However, after the fever has subsided, aspirin can be reduced to an antiplatelet dose (3 to 5 mg/kg/day). Low-dose aspirin is continued in patients without echocardiographic evidence of coronary abnormalities until the platelet count has returned to normal (6 to 8 weeks). If the child develops coronary abnormalities, salicylate therapy is continued indefinitely. Additional anticoagulation (e.g., clopidogrel [Plavix], enoxaparin [Lovenox], or warfarin) may be indicated in children who have medium-sized or giant coronary artery aneurysms.

Prognosis

Most children with Kawasaki disease recover fully after treatment. However, when cardiovascular complications occur, serious morbidity may result. The prognosis for patients is strongly related to the extent of coronary damage, with patients who have giant aneurysms being at the highest risk for complications and those with normal coronary dimensions having an excellent long-term prognosis.

Quality Patient Outcomes: Kawasaki Disease

- Early diagnosis and treatment
- Prevention of cardiovascular complications

Nursing Care Management

In the initial phase, the nurse must monitor the child's cardiac status carefully. Intake and output and daily weight measurements are recorded. Although the child may be reluctant to eat and therefore may be partially dehydrated, fluids need to be administered with care because of the usual finding of myocarditis. The child should be assessed frequently for signs of HF, including decreased urinary output, gallop rhythm (an additional heart sound), tachycardia, and respiratory distress.

Administration of IVIG should follow the same guidelines as for any blood product, with

frequent monitoring of vital signs. Patients must be watched for allergic reactions. Cardiac status must be monitored because of the large volume being administered to patients who may have diminished left ventricular function.

The majority of nursing care in the hospital focuses on symptomatic relief. To minimize skin discomfort, cool cloths; unscented lotions; and soft, loose clothing are helpful. During the acute phase, mouth care, including lubricating ointment to the lips, is important for mucosal inflammation. Clear liquids and soft foods can be offered.

Patient irritability is perhaps the most challenging problem. These children need a quiet environment that promotes adequate rest. Their parents need to be supported in their efforts to comfort an often inconsolable child. They may need time away from their child, and nurses can often provide respite care for the family. Parents need to understand that irritability is a hallmark of Kawasaki disease and that it will resolve. They need not feel guilty or embarrassed about their child's behavior.

Discharge Teaching

Parents need accurate information about the course of the illness, including the importance of follow-up monitoring and when they should contact their practitioner. Irritability is likely to persist for up to 2 months after the onset of symptoms. Periungual desquamation (peeling of the hands and feet) begins in the second and third weeks. Usually the fingertips peel first followed by the feet. The peeling is painless, but the new skin may be tender. Arthritis is always temporary but may involve the larger weight-bearing joints and may persist for several weeks. Affected children are typically most stiff in the mornings, during cold weather, and after naps. Passive range-of-motion exercises in the bathtub are often helpful in increasing flexibility. Any live immunizations (e.g., measles, mumps, and rubella; varicella) should be deferred for 11 months after the administration of IVIG because the body might not produce the appropriate amount of antibodies to provide lifelong immunity. The decision to give the varicella (chickenpox) vaccine while the child is receiving aspirin therapy is made individually by the practitioner. Daily temperatures should be recorded in the first week or two after discharge, and the occurrence of fever should be communicated to the health care provider.

At discharge, the ultimate cardiac sequelae is generally not fully known yet because vessels may be evolving. Parents of children with large aneurysms should be educated as to the unlikely but real possibility of myocardial infarction, as well as the signs and symptoms of cardiac ischemia in a child. CPR should be taught to parents of children with severe coronary artery aneurysms.

Long-Term Follow-Up

The frequency and type of follow-up is based on the presence or absence of coronary damage. The long-term outlook for children without aneurysms is excellent. Increased incidence of early heart disease in this population has not been observed with over 40 years of follow-up. In order to keep the coronary arteries as healthy as possible, it is recommended that these children follow the national guidelines, which recommend screening for the presence of coronary risk factors as they grow older. They should have a cholesterol screen performed at routine physical exams; routine BP monitoring and education recommending a heart-healthy lifestyle, including exercise, a heart-healthy diet; and avoidance of smoking.

In patients with aneurysms, follow-up focuses on the prevention and early detection of coronary ischemia. Noninvasive modalities of coronary imaging (such as echocardiography, EKGs, and stress testing to assess for reversible ischemia) are used as much as possible with other forms of imaging such as cardiac computed tomography angiography, MRI and cardiac catheterization recommended based on the individual situation.

In addition to regular monitoring, patients with coronary aneurysms may require long-term antiplatelet or anticoagulation and possibly β -blocker therapy or other therapies, depending on the severity of coronary involvement.

Shock

Shock, or **circulatory failure**, is a complex clinical syndrome characterized by inadequate tissue perfusion to meet the metabolic demands of the body, resulting in cellular dysfunction and eventual organ failure. Although the causes are different, the physiologic consequences are the

same and include hypotension, tissue hypoxia, and metabolic acidosis. Circulatory failure in children is a result of hypovolemia, altered peripheral vascular resistance, or pump failure. Types of shock are listed in [Box 23-13](#).

Box 23-13

Types of Shock

Hypovolemic

Characteristics

Reduction in size of vascular compartment

Falling BP

Poor capillary filling

Low CVP

Most Frequent Causes

Blood loss (hemorrhagic shock): Trauma, gastrointestinal bleeding, intracranial hemorrhage

Plasma loss: Increased capillary permeability associated with sepsis and acidosis, hypoproteinemia, burns, peritonitis

Extracellular fluid loss: Vomiting, diarrhea, glycosuric diuresis, sunstroke

Distributive

Characteristics

Reduction in peripheral vascular resistance

Profound inadequacies in tissue perfusion

Increased venous capacity and pooling

Acute reduction in return blood flow to the heart

Diminished cardiac output

Most Frequent Causes

Anaphylaxis (anaphylactic shock): Extreme allergy or hypersensitivity to a foreign substance

Sepsis (septic shock, bacteremic shock, endotoxic shock): Overwhelming sepsis and circulating bacterial toxins

Loss of neuronal control (neurogenic shock): Interruption of neuronal transmission (spinal cord injury)

Myocardial depression and peripheral dilation: Exposure to anesthesia or ingestion of barbiturates, tranquilizers, opioids, antihypertensive agents, or ganglionic blocking agents

Cardiogenic

Characteristic

Decreased cardiac output

Most Frequent Causes

After surgery for CHD

Primary pump failure: Myocarditis, myocardial trauma, biochemical derangements, heart failure

Dysrhythmias: SVT, AV block, and ventricular dysrhythmias; secondary to myocarditis or biochemical abnormalities (occasionally)

AV, Atrioventricular; *BP*, blood pressure; *CHD*, congenital heart disease; *CVP*, central venous pressure; *SVT*, supraventricular tachycardia.

Pathophysiology

A healthy child's circulatory system is able to transport oxygen and metabolic substrates to body tissues, which require a constant source for these essential needs. The cardiac output and distribution to the various body tissues can change rapidly in response to intrinsic (myocardial and intravascular) or extrinsic (neuronal) control mechanisms. In shock states, these mechanisms are altered or challenged.

Reduced blood flow, as in hypovolemic shock, causes diminished venous return to the heart, low CVP, low cardiac output, and hypotension. Vasomotor centers in the medulla are signaled, causing a compensatory increase in the force and rate of cardiac contraction and constriction of arterioles and veins, thereby increasing peripheral vascular resistance. Simultaneously, the lowered blood volume leads to the release of large amounts of catecholamines, antidiuretic hormone, adrenocorticosteroids, and aldosterone in an effort to conserve body fluids. This causes reduced blood flow to the skin, kidneys, muscles, and viscera to shunt the available blood to the brain and heart. Consequently, the skin feels cold and clammy, there is poor capillary filling, and glomerular filtration rate and urinary output are significantly reduced.

As a result of impaired perfusion, oxygen is depleted in the tissue cells, causing them to revert to anaerobic metabolism, producing lactic acidosis. The acidosis places an extra burden on the lungs as they attempt to compensate for the metabolic acidosis by increasing the respiratory rate to remove excess carbon dioxide. Prolonged vasoconstriction results in fatigue and atony of the peripheral arterioles, which leads to vessel dilation. Venules, which are less sensitive to vasodilator substances, remain constricted for a time, causing massive pooling in the capillary and venular beds, which further depletes blood volume.

Complications of shock create further hazards. CNS hypoperfusion may eventually lead to cerebral edema, cortical infarction, or intraventricular hemorrhage. Renal hypoperfusion causes renal ischemia with possible tubular or glomerular necrosis and renal vein thrombosis. Reduced blood flow to the lungs can interfere with surfactant secretion and result in acute respiratory distress syndrome, which is characterized by sudden pulmonary congestion and atelectasis with formation of a hyaline membrane. Gastrointestinal tract bleeding and perforation are always possibilities after splanchnic ischemia and necrosis of intestinal mucosa. Metabolic complications of shock may include hypoglycemia, hypocalcemia, and other electrolyte disturbances.

Diagnostic Evaluation

The etiology of shock can be discerned from the history and the physical examination. The severity of the shock is determined by measurements of vital signs, including CVP and capillary filling (Box 23-14). Shock can be regarded as a form of compensation for circulatory failure. Because of the progressive nature of shock, it can be divided into the following three stages or phases:

- 1. Compensated shock:** Vital organ function is maintained by intrinsic compensatory mechanisms; blood flow is usually normal or increased but generally uneven or maldistributed in the microcirculation.
- 2. Decompensated shock:** Efficiency of the cardiovascular system gradually diminishes until perfusion in the microcirculation becomes marginal despite compensatory adjustments. The outcomes of circulatory failure that progress beyond the limits of compensation are tissue hypoxia, metabolic acidosis, and eventual dysfunction of all organ systems.

3. **Irreversible, or terminal, shock:** Damage to vital organs, such as the heart or brain, is of such magnitude that the entire organism will be disrupted regardless of therapeutic intervention. Death occurs even if cardiovascular measurements return to normal levels with therapy.

Box 23-14

Clinical Manifestations of Shock

Compensated

Apprehensiveness

Irritability

Unexplained tachycardia

Normal blood pressure (BP)

Narrowing pulse pressure

Thirst

Pallor

Diminished urinary output

Reduced perfusion of extremities

Decompensated

Confusion and somnolence

Tachypnea

Moderate metabolic acidosis

Oliguria

Cool, pale extremities

Decreased skin turgor

Poor capillary filling

Irreversible

Thready, weak pulse

Hypotension

Periodic breathing or apnea

Anuria

Stupor or coma

At all stages, the principal differentiating signs are observed in the (1) degree of tachycardia and perfusion to the extremities, (2) level of consciousness, and (3) BP. Additional signs or modifications of these more universal signs may be present depending on the type and cause of the shock. Initially, the child's ability to compensate is effective; therefore, early signs are subtle. As the shock state advances, signs are more obvious and indicate early decompensation.

Additional signs may be present, depending on the type and cause of the shock. In early septic shock, there are chills, fever, and vasodilation, with increased cardiac output that results in warm, flushed skin (hyperdynamic, or “hot,” shock). A later and ominous development is disseminated intravascular coagulation (DIC) (see [Chapter 24](#)), the major hematologic complication of septic shock. Anaphylactic shock is frequently accompanied by urticaria and angioneurotic edema, which is life threatening when it involves the respiratory passages (see [Anaphylaxis](#), later).

Laboratory tests that assist in assessment are: blood gas measurements, pH, and sometimes liver function tests. Coagulation tests are evaluated when there is evidence of bleeding, such as oozing from a venipuncture site, bleeding from any orifice, or petechiae. Cultures of blood and other sites are indicated when there is a high suspicion of sepsis. Renal function tests are performed when impaired renal function is evident.

Therapeutic Management

Treatment of shock consists of three major interventions: (1) ventilation, (2) fluid administration, and (3) improvement of the pumping action of the heart (vasopressor support). The first priority is to establish an airway and administer oxygen. After the airway is ensured, circulatory stabilization is the major concern. Establishment of adequate IV access, ideally with multilumen central lines, is essential to deliver fluids and medications.

Ventilatory Support

The lung is the organ that is most sensitive to shock. Decreased distribution or redistribution of blood flow to respiratory muscles plus the increased work of breathing can rapidly lead to respiratory failure. Critically ill patients are unable to maintain an adequate airway. To place the lung at rest and improve ventilation, tracheal intubation is initiated early with positive-pressure ventilation. Supplemental oxygen is always given as soon as possible. Blood gases and pH are monitored frequently.

Increased extravascular lung water caused by edema contributes to the development of respiratory complications. Therapy is directed toward maintaining normal arterial blood gas measurements, normal acid-base balance, and circulation. Efforts are made to remove fluid and prevent its accumulation with the use of diuretics.

Cardiovascular Support

In most cases, rapid restoration of blood volume is all that is needed for resuscitation of the child in shock. An isotonic crystalloid solution (normal saline or Ringer lactate) is the fluid of choice; colloids (such as albumin) are also used. Successful resuscitation is reflected by an increase in BP and a reduction in heart rate; increased cardiac output results in improved capillary circulation and skin color. CVP measurements of right atrial pressure help guide fluid therapy, and urinary output measurement is an important indicator of adequacy of circulation. Correction of acidosis, hypoxemia, hypoglycemia, hypothermia, and any metabolic derangements is mandatory.

Temporary pharmacologic support may be required to enhance myocardial contractility, reverse metabolic or respiratory acidosis, and maintain arterial pressure. The principal agents used to improve cardiac output and circulation are catecholamines, such as dopamine (Intropin) and epinephrine (Adrenalin). Vasodilators that are sometimes used include nitroprusside (Nipride) and milrinone.

Quality Patient Outcomes: Shock

- Oxygen content of blood optimized
- Cardiac output improved
- Oxygen demand reduced
- Metabolic abnormalities corrected
- Type of shock identified and treated

Nursing Care Management

The child who is in shock requires intensive observation and care. *The initial action is to ensure adequate tissue oxygenation.* The nurse should be prepared to administer oxygen by the appropriate route and to assist with any intubation and ventilatory procedures indicated. Other procedures and activities that require immediate attention are establishing an IV line, weighing the child, obtaining baseline vital signs, placing an indwelling catheter, obtaining blood gases and other measurements, and administering medications as indicated. The child is best positioned flat with the legs elevated.

Nursing Alert

Early clinical signs of shock include apprehension, irritability, normal BP, narrowing pulse pressure (difference between diastolic and systolic BP), thirst, pallor, diminished urinary output, unexplained mild tachycardia, and decreased perfusion of the hands and feet.

The nurse's responsibilities are to monitor the IV infusion, intake and output, vital signs (including CVP), and general systems assessments on a routine basis. IV medications are titrated according to patient responses, and vital signs are taken every 15 minutes during the critical periods and thereafter as needed. Urinary output is measured hourly; blood gases, hematocrit, pH, and electrolytes are monitored frequently to assess the child's status and the efficacy of therapy. An apnea and cardiac monitor is attached and monitored continuously. In the initial stages of acute shock, more than one nurse is often needed to manage all of the necessary activities that must be carried out simultaneously (see [Emergency Treatment](#) box).

Emergency Treatment

Shock

Ventilation

Establish airway; be prepared for intubation.

Administer oxygen, usually 100% by mask.

Fluid Administration

Restore fluid volume as ordered.

Cardiovascular Support

Administer vasopressors (epinephrine 1 : 1000, 0.01 mg/kg subcutaneously; maximum dose of 0.5 mg; may repeat if needed).

General Support

Keep child flat with legs raised above level of heart.

Keep child warm and calm.

Throughout the intense activity, support for the family must not be overlooked. Someone should contact family members at frequent intervals to inform them about what is being done and whether there is any progress. Ideally, someone should remain with the parents to serve as a liaison between them and the intensive care team. However, this is not always feasible in such a critical situation. As soon as possible, the family should be allowed to see the child. A member of the clergy or a social worker may be called to help provide comfort and support.

Anaphylaxis

Anaphylaxis is the acute clinical syndrome resulting from the interaction of an allergen and a

patient who is hypersensitive to that allergen. When the antigen enters the circulatory system, a generalized reaction rapidly takes place. Vasoactive amines (principally histamine or a histamine-like substance) are released and cause vasodilation, bronchoconstriction, and increased capillary permeability.

Severe reactions are immediate in onset; are often life threatening; and frequently involve multiple systems, primarily the cardiovascular, respiratory, gastrointestinal, and integumentary systems. Exposure to the antigen can be by ingestion, inhalation, skin contact, or injection. Examples of common allergens associated with anaphylaxis include drugs (e.g., antibiotics, chemotherapeutic agents, radiologic contrast media), latex, foods, venom from bees or snakes, and biologic agents (antisera, enzymes, hormones, blood products).

Nursing Alert

Penicillin allergy is associated with immediate onset (within 1 hour of administration) or accelerated onset (1 to 72 hours after administration) of skin eruption, especially an urticarial rash, or more serious symptoms such as laryngeal edema or anaphylactic shock.

Clinical Manifestations

The onset of clinical symptoms usually occurs within seconds or minutes of exposure to the antigen, and the rapidity of the reaction is directly related to its intensity: the sooner the onset, the more severe the reaction. The reaction may be preceded by symptoms of uneasiness, restlessness, irritability, severe anxiety, headache, dizziness, paresthesia, and disorientation. The patient may lose consciousness. Cutaneous signs of flushing and urticaria are common early signs followed by angioedema, most notable in the eyelids, lips, tongue, hands, feet, and genitalia.

Bronchiolar constriction may follow, causing narrowing of the airway; pulmonary edema and hemorrhage also may occur. Laryngeal edema with severe acute upper airway obstruction may be life threatening and requires rapid intervention. Shock occurs as a result of mediator-induced vasodilation, which causes capillary permeability and loss of intravascular fluid into the interstitial space. Sudden hypotension and impaired cardiac output with poor perfusion are seen.

Therapeutic Management

Successful outcome of anaphylactic reactions depends on rapid recognition and institution of treatment. The goals of treatment are to provide ventilation, restore adequate circulation, and prevent further exposure by identifying and removing the cause when possible.

A mild reaction with no evidence of respiratory distress or cardiovascular compromise can be managed with subcutaneous administration of antihistamines, such as diphenhydramine (Benadryl) and epinephrine.

Moderate or severe distress presents a potentially life-threatening emergency. Establishing an airway is the first concern, as with all shock states. Epinephrine is given subcutaneously or intravenously as an antihistamine and to support the cardiovascular system and increase BP. Other routes for giving epinephrine are intramuscular and via the airway, either nebulized or injected through an endotracheal tube. In severe anaphylaxis, epinephrine by any route is better than none. Fluids are given to restore blood volume. Additional vasopressors may be given to improve cardiac output.

Prevention of a reaction is preferable. Preventing exposure is more easily accomplished in children known to be at risk, including those with (1) a history of previous allergic reaction to a specific antigen; (2) a history of atopy; (3) a history of severe reactions in immediate family members; and (4) a reaction to a skin test, although skin tests are not available for all allergens. Desensitization may be recommended in certain cases.

Quality Patient Outcomes: Anaphylaxis

- Early recognition of symptoms
- Airway patency maintained

- Adequate circulation restored and maintained
- Further exposure to allergic agent prevented

Nursing Care Management

When an anaphylactic reaction is suspected, both immediate intervention and preparation for medical therapy are nursing responsibilities. Placing the child in a head-elevated position ensures ventilation, unless contraindicated by hypotension, to facilitate breathing and administer oxygen. If the child is not breathing, CPR is initiated and emergency medical services are summoned.

If the cause can be determined, measures are implemented to slow the spread of the offending substance. An IV infusion is established immediately. Emergency medications are given intravenously whenever possible; however, epinephrine may be given subcutaneously (see [Emergency Treatment](#) box). Vital signs and urinary output are monitored frequently. Medications are administered as prescribed, with regular assessment to monitor effectiveness and to detect signs of side effects of medication and fluid overload.

To prevent an anaphylactic reaction, parents are always asked about possible allergic responses to foods, latex, medications, and environmental conditions. These are displayed prominently on the patient's chart. The specific allergen is noted, as are the type and severity of the reaction. Parents are excellent historians, especially when the child has displayed a pronounced reaction to a substance. Drugs, including related drugs (e.g., penicillin, nafcillin), and other items, such as latex, that have produced a reaction previously are *never* used. If the child is allergic to insect venom, the family is instructed to purchase an emergency kit to be kept with the child at all times. Both the family and the child, if the child is old enough, are taught how to use the equipment. The patient should carry medical identification at all times.

Septic Shock

Sepsis and septic shock are caused by infectious organisms. Normally, an infection triggers an inflammatory response in a local area, which results in vasodilation, increased capillary permeability, and eventually elimination of the infectious agent. The widespread activation and systemic release of inflammatory mediators is called the **systemic inflammatory response syndrome (SIRS)**. [Box 23-15](#) provides the exact definitions for SIRS, infection, sepsis, and severe sepsis. SIRS can occur in response to both infectious and noninfectious (e.g., trauma, burns) causes. When caused by infection, it is called **sepsis**. Septic shock is defined as sepsis with organ dysfunction and hypotension.

Box 23-15

Definitions of Systemic Inflammatory Response Syndrome, Infection, Sepsis, and Severe Sepsis

Systemic inflammatory response syndrome (SIRS): The presence of at least two of the following four criteria, one of which must be abnormal temperature or leukocyte count:

1. Core temperature of more than 38.5° C (101.3° F) or less than 36° C (96.8° F)
2. Tachycardia, defined as a mean heart rate more than two standard deviations above normal for age in the absence of external stimulus, chronic drugs, or painful stimuli; or otherwise unexplained persistent elevation over a 0.5- to 4-hour period; or, for children younger than 1 year old: bradycardia, defined as a mean heart rate less than the 10th percentile for age in the absence of external vagal

stimulus, β -blocker drugs, or CHD; or otherwise unexplained persistent depression over a 0.5-hour period

3. Mean respiratory rate more than two standard deviations above normal for age or mechanical ventilation for an acute process not related to underlying neuromuscular disease or the receipt of general anesthesia
4. Leukocyte count elevated or depressed for age (not secondary to chemotherapy-induced leukopenia) or more than 10% immature neutrophils

Infection: A suspected or proven (by positive culture, tissue stain, or PCR test) infection caused by any pathogen; or a clinical syndrome associated with a high probability of infection. Evidence of infection includes positive findings on clinical examination, imaging, or laboratory tests (e.g., white blood cells in a normally sterile body fluid, perforated viscus, chest radiograph consistent with pneumonia, petechial or purpuric rash, or purpura fulminans).

Sepsis: SIRS in the presence of or as a result of suspected or proven infection.

Severe sepsis: Sepsis plus cardiovascular organ dysfunction or ARDS or two or more other organ dysfunctions.

ARDS, Acute respiratory distress syndrome; *CHD*, congenital heart disease; *PCR*, polymerase chain reaction.

From Goldstein B, Giroir B, Randolph A, et al: International Pediatric Sepsis Consensus Conference: definitions for sepsis and organ dysfunction in pediatrics, *Pediatr Crit Care Med* 6(1):2–8, 2005; used with permission.

Most of the physiologic effects of shock occur because the exaggerated immune response triggers more than 30 different mediators that result in diffuse vasodilation, increased capillary permeability, and maldistribution of blood flow. This impairs oxygen and nutrient delivery to the cells, resulting in cellular dysfunction. If the process continues, multiple-organ dysfunction occurs and may result in death. Table 23-6 includes the age-specific vital signs and laboratory values reflective of septic shock in children. Although the incidence of shock continues to be on the increase, survival rate due to early detection and treatment improves (Martin, 2012).

TABLE 23-6

Age-Specific Vital Signs and Laboratory Variables in Septic Shock*

| Age Group | HEART RATE (beats/min) | | Respiratory Rate (breaths/min) | Leukocyte Count (Leukocytes \times 103/mm ³) | Systolic Blood Pressure (mm Hg) |
|-----------------------|------------------------|-------------|--------------------------------|--|---------------------------------|
| | Tachycardia | Bradycardia | | | |
| 0 days to 1 week old | >180 | <100 | >50 | >34 | <65 |
| 1 week to 1 month old | >180 | <100 | >40 | >19.5 or <5 | <75 |
| 1 month to 1 year old | >180 | <90 | >34 | >17.5 or <5 | <100 |
| 2 to 5 years old | >140 | N/A | >22 | >15.5 or <6 | <94 |
| 6 to 12 years old | >130 | N/A | >8 | >13.50 or <4.5 | <105 |
| 13 to <18 years old | >110 | N/A | >4 | >11 or <4.5 | <117 |

*Lower values for heart rate, leukocyte count, and systolic blood pressure are for fifth percentile, and upper values for heart rate, respiratory rate, or leukocyte count are for 95th percentile.

N/A, Not applicable.

From Goldstein B, Giroir B, Randolph A, et al: International Pediatric Sepsis Consensus Conference: definitions for sepsis and organ dysfunction in pediatrics, *Pediatr Crit Care Med* 6(1):2–8, 2005; used with permission.

Three stages have been identified in septic shock. In early septic shock, the patient has chills, fever, and vasodilation with increased cardiac output, which results in warm, flushed skin that reflects vascular tone abnormalities and hyperdynamic, warm, or hyperdynamic-compensated responses. BP and urinary output are normal. The patient has the best chance for survival in this

stage. The second stage—the normodynamic, cool, or hyperdynamic-decompensated stage—lasts only a few hours. The skin is cool, but pulses and BP are still normal. Urinary output diminishes, and the mental state becomes depressed. With advancing disease, certain signs of circulatory decompensation that deteriorate to signs of circulatory collapse are indistinguishable from late shock of any cause. In the hypodynamic, or cold, stage of shock, cardiovascular function progressively deteriorates even with aggressive therapy. The patient has hypothermia, cold extremities, weak pulses, hypotension, and oliguria or anuria. Patients are severely lethargic or comatose. Multiorgan failure is common. This is the most dangerous stage of shock.

Management of septic shock involves measures to provide hemodynamic stability and adequate oxygenation to the tissues and the use of antimicrobials to treat the infectious organism. As with other forms of shock, hemodynamic stability is achieved with fluid volume resuscitation and inotropic agents as needed. Providing adequate oxygenation often requires intubation and mechanical ventilation, supplemental oxygen, sedation, and paralysis to decrease the work of breathing. Septic shock involves activation of complement proteins that promote clumping of the granulocytes in the lung. The granulocytes can release chemicals that can cause direct lung injury to the pulmonary capillary endothelium. This causes a fluid leak into the alveoli, which causes stiff, noncompliant lungs. DIC and multiorgan dysfunction may also occur and require prompt assessment and management.

Newer therapies are being developed to modify the host immune response by attempting to block various mediators, thereby interrupting the inflammatory cascade.

Early identification of the symptoms of septic shock is critical to patient survival. A high index of suspicion is required in all critically ill patients who are at greater risk for sepsis because of multiple invasive lines and devices, poor nutrition, and impaired immune function. Subtle alterations in tissue perfusion and unexplained tachypnea and tachycardia often are early warning signs. Identification of the infectious agent and prompt treatment are also critical to patient survival. Broad-spectrum antibiotics should be given, and the site of infection should be removed if possible (e.g., drain abscesses, remove indwelling lines). Patients should be managed in an ICU in which continuous monitoring and sophisticated cardiac and respiratory support are available. Multidisciplinary collaboration is essential in managing these critically ill patients.

Toxic Shock Syndrome

Toxic shock syndrome (TSS) is a relatively rare condition caused by the toxins produced by the *Staphylococcus* bacteria. First described in 1978, TSS can cause acute multisystem organ failure and a clinical picture that resembles septic shock. TSS became well known in 1980 because of the striking relationship between the disease and tampon use (Nakase, 2000). An aggressive health education campaign about the dangers of prolonged tampon use and a change in the chemical composition of tampons have markedly reduced the incidence of TSS in menstruating women. Cases of TSS have also been reported in men, older women, and children.

Diagnostic Evaluation

Diagnosis is established on the basis of the criteria established by the Centers for Disease Control and Prevention's toxic case definition (Box 23-16). A history of tampon use contributes to the diagnosis. Additional laboratory tests include cultures from blood, the vagina, the cervix, and any discharge. Other laboratory tests are those that facilitate the management of shock.

Box 23-16

Criteria for Definition of Toxic Shock Syndrome

Toxic Shock Syndrome (Other Than Streptococcal)

2011 Case Definition

Clinical Criteria

An illness with the following clinical manifestations:

- Fever: Temperature $\geq 102.0^{\circ}$ F ($\geq 38.9^{\circ}$ C)

- Rash: Diffuse macular erythroderma
- Desquamation: 1 to 2 weeks after onset of rash
- Hypotension: Systolic blood pressure (BP) ≤ 90 mm Hg for adults or less than fifth percentile by age for children younger than 16 years old
- Multisystem involvement (three or more of the following organ systems):
 - Gastrointestinal: Vomiting or diarrhea at onset of illness
 - Muscular: Severe myalgia or creatine phosphokinase level at least twice the upper limit of normal
 - Mucous membrane: Vaginal, oropharyngeal, or conjunctival hyperemia
 - Renal: Blood urea nitrogen or creatinine at least twice the upper limit of normal for laboratory or urinary sediment with pyuria (≥ 5 leukocytes per high-power field) in the absence of urinary tract infection
 - Hepatic: Total bilirubin, alanine aminotransferase enzyme, or aspartate aminotransferase enzyme levels at least twice the upper limit of normal for laboratory
 - Hematologic: Platelets $< 100,000/\text{mm}^3$
 - Central nervous system (CNS): disorientation or alterations in consciousness without focal neurologic signs when fever and hypotension are absent

Laboratory Criteria for Diagnosis

Negative results on the following tests, if obtained:

- Blood or cerebrospinal fluid (CSF) cultures blood culture may be positive for *Staphylococcus aureus*
- Negative serologies for Rocky Mountain spotted fever, leptospirosis, or measles

Case Classification

Probable

A case that meets the laboratory criteria and in which four of the five clinical criteria described in the following section are present

Confirmed

A case that meets the laboratory criteria and in which all five of the clinical criteria described below are present, including desquamation, unless the patient dies before desquamation occurs:

1. Fever of 38.9°C (102°F) or higher

2. Presence of diffuse macular erythroderma
3. Desquamation, particularly of palms and soles, 1 to 2 weeks after onset of illness
4. Hypotension, defined as a systolic BP of 90 mm Hg or less for adults and below the fifth percentile for children younger than 16 years old; or an orthostatic drop in diastolic BP of 15 mm Hg or more with a change from lying to sitting; or orthostatic syncope; or orthostatic dizziness
5. Involvement of three or more of the following organ systems: Gastrointestinal (GI), muscular, mucous membrane, renal, hepatic, hematologic, or CNS

Toxic shock syndrome (TSS) is probable when four of the five major criteria are fulfilled. In addition, if blood and CSF cultures are obtained, they must be negative for any organisms other than *S. aureus*. Serologic tests for Rocky Mountain spotted fever, leptospirosis, and measles also must be negative.

Centers for Disease Control and Prevention: *National Notifiable Diseases Surveillance System (NNDSS): Toxic shock syndrome (other than Streptococcal (TSS) 2011 case definition, 2011*, <http://wwwn.cdc.gov/nndss/script/casedef.aspx?CondYrID=869&DatePub=1/1/2011>.

Therapeutic Management

The management of patients with TSS is the same as management of shock of any cause and may range from supportive care in mild cases to hospitalization and intensive care in severe cases. Appropriate parenteral antibiotics are usually administered after cultures are obtained.

Nursing Care Management

Because the disease is relatively rare, the major efforts of nursing are directed toward prevention. The association between the disease and the use of tampons provides some direction for education. Avoiding the use of tampons offers the most certain preventive measure, although this approach is probably unacceptable to most adolescent girls, who prefer the freedom, comfort, and inconspicuousness that tampons afford.

Adolescent girls who use tampons can be taught general hygiene measures, such as good hand washing and careful insertion to avoid vaginal abrasion. It is wise to modify their use, alternating with sanitary napkins—perhaps using the napkins during the night, when at home during the day, and when flow is slight. Young girls are advised not to use super-absorbent tampons and not to leave any tampon in the body for more than 4 to 6 hours.

NCLEX Review Questions

1. You are working with a new graduate on the pediatric unit and your patient is returning from the cardiac catheterization lab. You feel the graduate understands the important nursing interventions when she says which of the following? Select all that apply.
 - a. "Check pulses especially below the catheterization site, for equality and symmetry."
 - b. "Check vital signs, which may be taken as frequently as every 30 to 45 minutes, with special emphasis on the heart rate, which is counted for 1 full minute for evidence of dysrhythmias or bradycardia."
 - c. "Special attention needs to be given to the BP, especially for hypertension, which may indicate hemorrhage or bleeding from the catheterization site."
 - d. "Check the dressing for evidence of bleeding or hematoma formation in the femoral or antecubital area."
 - e. "Allow the child to ambulate because this will prevent skin breakdown from lying so long in one place."
2. You are working with a family with a child who has a congenital heart defect. Future surgery is planned, and you are teaching the parent how to reduce cardiac demands. The parent needs more teaching when she says which of the following?
 - a. "I will wake my child for feeding every 2 hours so he can get enough calories to gain weight."
 - b. "When I give the digoxin, I will listen to the pulse for 1 full minute."
 - c. "I should protect my child from people who have respiratory infections."
 - d. "I will count the number of wet diapers to be sure my child is not getting too much or too little fluid."
3. Which heart defect and hemodynamic change pairing is correct?
 - a. Aortic stenosis and obstruction to blood flow out of the heart
 - b. Ventricular septal defect (VSD) and decreased pulmonary blood flow
 - c. Tricuspid atresia and increased pulmonary blood flow
 - d. Atrioventricular (AV) canal and mixed blood flow, in which saturated and desaturated blood mix within the heart or great arteries
4. You are discharging a 5-week-old infant with a congenital heart defect who will be going home on digoxin. Which of the following answers by the father indicate the need for more teaching? Select all that apply.
 - a. "I know I give the drug carefully by slowly directing it to the side and back of the mouth."
 - b. "I give the medication every 12 hours, and I can place it in a bit of formula so that I know the baby will take it."
 - c. "If I miss a dose, I don't give an extra dose, but I give the next dose as ordered."
 - d. "If the baby vomits, I should give a second dose."
 - e. "If more than two doses have been missed, I should call the doctor."
5. You are working in the pediatric clinic, and a child presents with symptoms that are suspicious of the acute phase of Kawasaki disease. Which of the following symptoms are included? Select all that apply.
 - a. Periungual desquamation (peeling that begins under the fingertips and toes) of the hands and feet is present.
 - b. The bulbar conjunctivae of the eyes become reddened, with clearing around the iris.
 - c. A temporary arthritis is evident, which may affect the larger weight-bearing joints.
 - d. Inflammation of the pharynx and the oral mucosa develops, with red, cracked lips and the characteristic "strawberry tongue."
 - e. Loud pansystolic murmur along with ECG changes are present.

Correct Answers

1. a, d; 2. a; 3. a; 4. b, d; 5. b, d

The Child with Hematologic or Immunologic Dysfunction

Rosalind Bryant

Hematologic and Immunologic Dysfunction

Several tests can be performed to assess hematologic function, including additional procedures to identify the cause of the dysfunction. The following discussion is limited to a description of the most common and one of the most valuable tests, the **complete blood count (CBC)**. Other procedures, such as those related to iron, coagulation, and immune status, are discussed throughout the chapter as appropriate. The nurse should be familiar with the significance of the findings from the CBC (Table 24-1).

TABLE 24-1
Tests Performed as Part of a Complete Blood Count

| Test (Average Value) | Description, Comments |
|---|--|
| RBC count (4.5 to 5.5 million/mm ³) | Number of RBCs/mm ³ of blood Indirectly estimates Hgb content of blood Reflects function of bone marrow |
| Hgb determination (11.5 to 15.5 g/dl) | Amount of Hgb (g)/dl of whole blood Total blood Hgb primarily depends on number of circulating RBCs but also on amount of Hgb in each cell |
| Hct (35% to 45%) | Percent volume of packed RBCs in whole blood Indirectly measures Hgb content Is approximately three times Hgb content |
| RBC indices | |
| MCV (77 to 95 fl) | Average or mean volume (size) of a single RBC MCV value is expressed as femtoliter (fl) or cubic micron (mm ³) |
| MCH (25 to 33 pg/cell) | Average or mean quantity (weight) of Hgb in a single RBC MCH value is expressed as picogram (pg) or micromicrogram (mmcg) Whereas MCV and MCH depend on accurate counts of RBCs, MCHC does not; therefore, MCHC is often more reliable All indices depend on average cell measurements and do not show individual RBC variations (anisocytosis) |
| MCHC (31% to 37% Hgb [g]/dl RBC) | Average concentration of Hgb in a single RBC MCHC values are expressed as percent Hgb (g)/cell or Hgb (g)/dl RBC |
| RBC volume distribution width (13.4% ± 1.2%) | Average size of RBCs Differentiates some types of anemia |
| Reticulocyte count (0.5% to 1.5% erythrocytes) | Percent reticulocytes in RBCs Index of production of mature RBCs by bone marrow Decreased count indicates depressed bone marrow function Increased count indicates erythropoiesis in response to some stimulus When reticulocyte count is extremely high, other forms of immature RBCs (normoblasts, even erythroblasts) may be present Indirectly estimates hypochromic anemia Usually elevated in patients with chronic hemolytic anemia |
| WBC count (4.5 to 13.5 × 10 ³ cells/mm ³) | Number of WBCs/mm ³ of blood Total number of WBCs less important than differential count |
| Differential WBC count | Inspection and quantification of WBC types present in peripheral blood Values are expressed as percentages; to obtain absolute number of any type of WBC, multiply its respective percentage by total number of WBCs |
| Neutrophils (polys) (54% to 62%) (3 to 5.8 × 10 ³ cells/mm ³) | Primary defense in bacterial infection; capable of phagocytizing and killing bacteria |
| Bands (3% to 5%) (0.15–0.4 × 10 ³ cells/mm ³) | Immature neutrophil Increased numbers in bacterial infection Also capable of phagocytosis and killing |
| Eosinophils (1% to 3%) (0.05 to 0.25 × 10 ³ cells/mm ³) | Named for their staining characteristics with eosin dye Increased in allergic disorders, parasitic diseases, certain neoplasms, and other diseases |
| Basophils (0.075%) (0.015 to 0.030 × 10 ³ cells/mm ³) | Named for their characteristic basophilic stippling Contain histamine, heparin, and serotonin; believed to cause increased blood flow to injured tissues while preventing excessive clotting |
| Lymphocytes (25% to 33%) (1.5 to 3.0 × 10 ³ cells/mm ³) | Involved in development of antibody and delayed hypersensitivity |
| Monocytes (3% to 7%) | Large phagocytic cells that are involved in early stage of inflammatory reaction |
| ANC (>1000/mm ³) | Percent neutrophils/bands times WBC count Indicates body's capability to handle bacterial infections |
| Platelet count (150 to 400 × 10 ³ /mm ³) | Number of platelets/mm ³ of blood Cellular fragments that are necessary for clotting to occur |
| Stained peripheral blood smear | Visual estimation of amount of Hgb in RBCs and overall size, shape, and structure of RBCs Various staining properties of RBC structures may be evidence of immature forms of erythrocytes Shows variation in size and shape of RBCs: microcytic, macrocytic, poikilocytic (variable shapes) |

ANC, Absolute neutrophil count; *Hct*, hematocrit; *Hgb*, hemoglobin; *MCH*, mean corpuscular hemoglobin; *MCHC*, mean corpuscular hemoglobin concentration; *MCV*, mean corpuscular volume; *RBC*, red blood cell; *WBC*, white blood cell.

As with any disorder, the history and physical examination are essential to identify hematologic dysfunction, and the nurse is often the first person to suspect a problem based on information from these sources. Comments by the parent regarding the child's lack of energy, food diary of poor sources of iron, frequent infections, and bleeding that is difficult to control offer clues to the more common disorders affecting the blood. A careful physical appraisal, especially of the skin, can reveal findings (e.g., pallor, petechiae, bruising) that may indicate minor or serious hematologic conditions. Nurses need to be aware of the clinical manifestations of blood diseases to assist in recognizing symptoms and establishing a diagnosis.

Nursing Tip

A common term used in describing an abnormal complete blood count (CBC) is **shift to the left**, which refers to the presence of immature neutrophils in the peripheral blood from hyperfunction

of the bone marrow, as seen during a bacterial infection.

Red Blood Cell Disorders

Anemia

The term **anemia** describes a condition in which the number of red blood cells (RBCs) or the hemoglobin (Hgb or Hb) concentration is reduced below normal values for age. This diminishes the oxygen-carrying capacity of the blood, causing a reduction in the oxygen available to the tissues. The anemias are the most common hematologic disorder of infancy and childhood and are not diseases but an indication or manifestation of an underlying pathologic process.

Classification

Anemias can be classified using two basic approaches: **etiology** or **physiology**, manifested by erythrocyte or Hgb depletion, and **morphology**, the characteristic changes in RBC size, shape, or color (Box 24-1). Although the morphologic classification is useful in terms of laboratory evaluation of anemia, the etiology provides direction for planning nursing care. For example, anemia with reduced Hgb concentration may be caused by a dietary depletion of iron, and the principal intervention is replenishing iron stores. The classification of anemias is found in Fig. 24-1.

Box 24-1

Red Blood Cell Morphology

Size (Cell Size)

Variation in RBC sizes (anisocytosis)

- Normocytes (normal cell size)
- Microcytes (smaller than normal cell size)
- Macrocytes (larger than normal cell size)

Shape (Cell Shape)

Variation in RBC shapes (poikilocytosis)

- Spherocytes (globular cells)
- Drepanocytes (sickle-shaped cells)
- Numerous other irregularly shaped cells

Color (Cell Staining Characteristics)

Variation in hemoglobin concentration in the RBC

- Normochromic (sufficient or normal amount of hemoglobin per RBC)
- Hypochromic (reduced amount of hemoglobin per RBC)
- Hyperchromic (increased amount of hemoglobin per RBC)

RBC, Red blood cell.

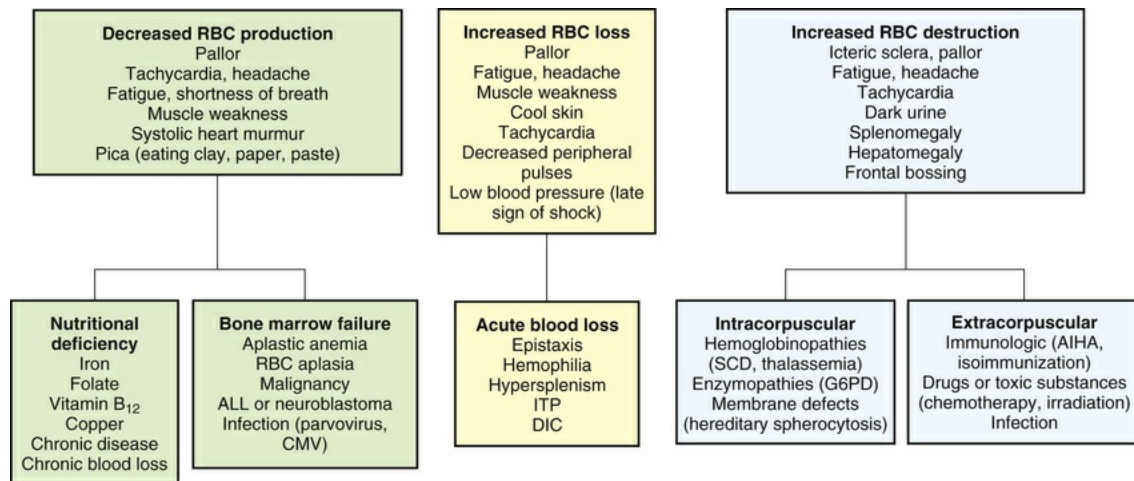

FIG 24-1 Classifications of anemias. *AIHA*, Autoimmune hemolytic anemia; *ALL*, acute lymphoid leukemia; *CMV*, cytomegalovirus; *DIC*, disseminated intravascular coagulation; *G6PD*, glucose-6-phosphate dehydrogenase; *ITP*, idiopathic thrombocytopenic purpura; *RBC*, red blood cell; *SCD*, sickle cell disease.

Consequences of Anemia

The basic physiologic defect caused by anemia is a decrease in the oxygen-carrying capacity of blood and consequently a reduction in the amount of oxygen available to the cells. When the anemia has developed slowly, the child usually adapts to the declining Hgb level.

The effects of anemia on the circulatory system can be profound. Because the viscosity of blood depends almost entirely on the concentration of RBCs, the resulting hemodilution of severe anemia decreases peripheral resistance, causing greater quantities of blood to return to the heart. The increased circulation and turbulence within the heart may produce a murmur. Because the cardiac workload is greatly increased, especially during exercise, infection, or emotional stress, cardiac failure may ensue.

Children seem to have a remarkable ability to function well despite low levels of Hgb. **Cyanosis**, which results from an increased quantity of deoxygenated Hgb in arterial blood, is typically not evident. Growth retardation, resulting from decreased cellular metabolism, and coexisting anorexia is a common finding in chronic severe anemia. It is frequently accompanied by delayed sexual maturation in the older child.

Diagnostic Evaluation

In general, anemia may be suspected based on findings on the history and physical examination, such as a lack of energy, easy fatigability, and pallor. Unless the anemia is severe, one of the first clues to the disorder may be alterations in the CBC, such as decreased RBCs, and decreased Hgb and hematocrit (Hct) levels (see Fig. 24-1). Although anemia is sometimes defined as an Hgb level below 10 or 11 g/dl, this arbitrary cutoff is inappropriate for all children, since Hgb levels normally vary with age (see Table 24-1).

Other tests specific to a particular type of anemia are used to determine the underlying cause of anemia. These are discussed in relation to the particular disorder.

Therapeutic Management

The objective of medical management is to reverse the anemia by treating the underlying cause. In nutritional anemias, the specific deficiency is replaced. In blood loss from acute hemorrhage, RBC transfusion may be given. In patients with severe anemia, supportive medical care may include oxygen therapy, bed rest, and replacement of intravascular volume with intravenous (IV) fluids. In addition to these general measures, the nurse may implement more specific interventions, depending upon the cause. The next sections will discuss these interventions.

Nursing Care Management

The assessment of anemia includes the basic techniques that are applicable to any condition. The

age of the infant or child provides some clues regarding the possible etiology of the anemia. For example, iron-deficiency anemia occurs more frequently in toddlers between 12 and 36 months old and during the growth spurt of adolescence.

Racial or ethnic background is significant. For example, the anemias related to abnormal Hgb levels are found in Southeast Asians and persons of African or Mediterranean ancestry. These same groups may be genetically deficient in the enzyme lactase after the period of infancy. Affected individuals are unable to tolerate lactose in the diet, with consequent intestinal irritation and chronic blood loss.

Special emphasis is placed on a careful history to elicit any information that might help identify the cause of the anemia. For example, a statement such as “My child drinks lots of milk” is a frequent finding in toddlers with iron-deficiency anemia. An episode of diarrhea may have precipitated temporary lactose intolerance in a young child.

Stool examination for occult (microscopic) blood (Hemoccult test) can identify chronic intestinal bleeding that result from a primary or secondary lactase deficiency. It is also important to understand the significance of various blood tests (see [Table 24-1](#)).

Prepare the Child and Family for Laboratory Tests

Usually, several blood tests are ordered, but because they are generally done sequentially rather than at one time, the child is subjected to multiple finger or heel punctures or venipunctures. Laboratory technicians frequently are not aware of the trauma that repeated punctures represent to a child. These invasive procedures need not be painful (see [Blood Specimens, Chapter 20](#)) with the topical application of an eutectic mixture of local anesthetics (EMLA; lidocaine and prilocaine) or 4% lidocaine (ELA-Max or LMX) before needle punctures (see [Pain Management, Chapter 5](#)). Therefore, the nurse is responsible for preparing the child and family for the tests by:

- Explaining the significance of each test, particularly why the tests are not all done at one time
- Encouraging parents or another supportive person to be with the child during the procedure
- Allowing the child to play with the equipment on a doll or participate in the actual procedure (e.g., by holding the Band-Aid)

Older children may appreciate the opportunity to observe the blood cells under a microscope or in photographs. This experience is especially important if a serious blood disorder, such as aplastic anemia, is suspected because it serves as a foundation for explaining the pathophysiology of the disorder.

Bone marrow aspiration is not a routine hematologic test but is essential for definitive diagnosis of the certain anemias such as severe aplastic anemia.

Nursing Tip

The following are suggested explanations for teaching children about blood components:

Red blood cells: Carry the oxygen you breathe from your lungs to all parts of your body

White blood cells: Help keep germs from causing infection

Platelets: Small parts of cells that help make bleeding stop by forming a clot (scab) over the hurt area

Plasma: The liquid portion of blood, which has clotting factors that help make bleeding stop

Decrease Tissue Oxygen Needs

Because the basic pathologic process in anemia is a decrease in oxygen-carrying capacity, an important nursing responsibility is to minimize tissue oxygen needs by continual assessment of the child's energy level. Assess the child's level of tolerance for activities of daily living and play, and make adjustments to allow as much self-care as possible without undue exertion. During periods of rest, the nurse measures vital signs and observes behavior to establish a baseline of nonexertion energy expenditure. During periods of activity, the nurse repeats these measurements and observations to compare them with resting values.

Nursing Tip

Signs of exertion include tachycardia, palpitations, tachypnea, dyspnea, shortness of breath, hyperpnea, dizziness, lightheadedness, diaphoresis, and change in skin color. The child looks fatigued (e.g., sagging, limp posture; slow, strained movements; inability to tolerate additional activity; difficulty sucking in infants).

Prevent Complications

Children with anemia are prone to infection because tissue hypoxia causes cellular dysfunction that weakens the body's defense against infectious agents. Take all of the usual precautions to prevent infection, such as practicing thorough hand washing, selecting an appropriate room in a noninfectious area, restricting visitors or hospital personnel with active infection, and maintaining adequate nutrition. The nurse also observes for signs of infection, particularly temperature elevation and leukocytosis. However, an elevated white blood cell (WBC) count sometimes occurs in anemia without the presence of systemic or local infection.

Iron-Deficiency Anemia

Anemia caused by an inadequate supply of dietary iron is the most prevalent and preventable nutritional disorder in the United States and globally. The prevalence of iron-deficiency anemia has decreased during infancy in the United States, probably in part because of families' participation in the Women, Infants, and Children (WIC) program, which provides iron-fortified formula for the first year of life and routine screening of Hgb levels during early childhood (Baker, Greer, and Committee on Nutrition American Academy of Pediatrics, 2010; Lerner and Sills, 2011; Powers and Buchanan, 2014). Preterm infants are especially at risk because of their reduced fetal iron supply. Children 12 to 36 months old are at risk for anemia as a result of primarily cow milk intake and not eating an adequate amount of iron-containing food (Baker, Greer, and Committee on Nutrition American Academy of Pediatrics, 2010; Eussen, Alles, Uijterschout, et al, 2015; Paoletti, Bogen, and Ritchey, 2014). Adolescents are also at risk because of their rapid growth rate combined with poor eating habits, menses, obesity, or strenuous activities.

Pathophysiology

Iron-deficiency anemia can be caused by any number of factors that decrease the supply of iron, impair its absorption, increase the body's need for iron, or affect the synthesis of Hgb. Although the clinical manifestations and diagnostic evaluation are similar regardless of the cause, the therapeutic and nursing care management depends on the specific reason for the iron deficiency. The following discussion is limited to iron-deficiency anemia resulting from inadequate iron in the diet.

During the last trimester of pregnancy, iron is transferred from the mother to the fetus. Most of the iron is stored in the circulating erythrocytes of the fetus, with the remainder stored in the fetal liver, spleen, and bone marrow. These iron stores are usually adequate for the first 5 to 6 months in a full-term infant but for only 2 to 3 months in preterm infants and multiple births. If dietary iron is not supplied to meet the infant's growth demands after the fetal iron stores are depleted, iron-deficiency anemia results. Physiologic anemia should not be confused with iron-deficiency anemia resulting from nutritional causes.

Although infants with iron-deficiency anemia are underweight, many are overweight because of excessive milk ingestion (known as **milk babies**). These children become anemic for two reasons: (1) milk, a poor source of iron, is given almost to the exclusion of solid foods, and (2) increased fecal loss of blood occurs in 50% of iron-deficient infants fed cow's milk.

Therapeutic Management

After the diagnosis of iron-deficiency anemia is made, therapeutic management focuses on increasing the amount of supplemental iron the child receives. This is usually done through dietary counseling and the administration of oral iron supplements.

In formula-fed infants, the most convenient and best sources of supplemental iron are iron-fortified commercial formula and iron-fortified infant cereal. Iron-fortified formula provides a relatively constant and predictable amount of iron and is not associated with an increased incidence of gastrointestinal (GI) symptoms, such as colic, diarrhea, or constipation. Infants younger than 12

months old should *not* be given fresh cow's milk because it may increase the risk of GI blood loss occurring from exposure to a heat-labile protein in cow's milk or cow's milk–induced GI mucosal damage resulting from a lack of cytochrome iron (heme protein) (Kett, 2012; Subramaniam and Girish, 2015; Ziegler, 2011). If GI bleeding is suspected, several stool analyses for occult blood known as *guaiac tests* are performed to identify any intermittent blood loss.

The addition of iron-rich foods to the diet may not provide sufficient supplemental quantities of the mineral as the sole treatment of iron-deficiency anemia. If dietary sources of iron cannot replenish the body stores, oral iron supplements are prescribed. Ferrous iron, more readily absorbed than ferric iron, results in higher Hgb levels. Ascorbic acid (vitamin C) appears to facilitate absorption of iron and may be given as vitamin C–enriched foods and juices with the iron preparation.

If the Hgb level fails to rise after 1 month of oral therapy, it is important to assess for persistent bleeding, iron malabsorption, noncompliance, improper iron administration, or other causes of the anemia. Parenteral (IV or intramuscular [IM]) iron administration is safe and effective but painful, expensive, and occasionally associated with regional lymphadenopathy, transient arthralgias or serious allergic reaction (Andrews, Ullrich, and Fleming, 2009; Bregman and Goodnough, 2014; Lerner and Sills, 2011). Therefore, parenteral iron is reserved for children who have iron malabsorption, chronic hemoglobinuria, or intolerance to oral preparations. Transfusions are indicated for the most severe anemia and in cases of serious infection, cardiac dysfunction, or surgical emergency when anesthesia is required. Packed RBCs (2 to 3 ml/kg), not whole blood, are used to minimize the chance of circulatory overload. Supplemental oxygen is administered when tissue hypoxia is severe.

Prognosis

The prognosis for a child with iron deficiency anemia is very good. However, evidence indicates that if the iron-deficiency anemia is severe and long-standing, cognitive, behavioral, and motor impairment and even death may result (Andrews, Ullrich, and Fleming, 2009; Jauregui-Lobera, 2014; Lokeshwar, Mehta, Mehta, et al, 2011; Scott, Chen-Edinboro, Caulfield, et al, 2014). However, there is lack of convincing evidence that iron treatment of young children with iron deficiency anemia has an effect on psychomotor development or cognitive function (McDonagh, Blazina, Dana, et al, 2015; Thompson, Biggs, and Pasricha, 2013; Wang, Zhan, Gong et al, 2013). Therefore, there is need for further large long-term follow-up randomized interventional studies to be conducted in this area.

Quality Patient Outcomes: Iron Deficiency Anemia

- Early recognition of signs and symptoms of iron deficiency anemia
- Appropriate quantity of milk, use of iron-fortified infant formula, and introduction of solid foods
- Adherence to oral iron supplement with appropriate administration
- Hemoglobin increase within 1 month and anemia resolved within 6 months

Nursing Care Management

An essential nursing responsibility is instructing parents in the administration of iron. Oral iron should be given as prescribed in two divided doses between meals, when the presence of free hydrochloric acid is greatest, because more iron is absorbed in the acidic environment of the upper GI tract. A citrus fruit or juice taken with the medication aids in absorption.

Drug Alert

Cow's milk contains substances that bind the iron and interfere with absorption. Iron supplements should not be administered with milk or milk products (Carley, 2003; Powers and Buchanan, 2014).

An adequate dosage of oral iron turns the stools a tarry green or black color. The nurse advises

parents of this normally expected change and inquires about its occurrence on follow-up visits. Absence of the greenish black stool may be a clue to poor compliance (e.g., in schedule, in dosage, in administration, in side effects). If compliance is an issue, make every effort to institute strategies to improve adherence to the medication regimen, such as changing the schedule to more convenient times.

Drug Alert

Liquid preparations of iron may temporarily stain the teeth. If possible, the medication should be taken through a straw or given through a syringe or medicine dropper placed toward the back of the mouth. Brushing the teeth after administration of the drug lessens the discoloration.

Nursing Alert

Because iron ingestion in excessive quantities is toxic or even fatal, parents should be instructed to keep no more than a month's supply in the home and store it safely away from the reach of children.

If parenteral iron preparations are prescribed, iron dextran must be injected deeply into a large muscle mass using the Z-track method. The injection site is *not* massaged after injection to minimize skin staining and irritation. Because no more than 1 ml should be given in one injection site, the IV route should be considered to avoid multiple injections. Careful observation with IV iron administration is required because of the risk of anaphylaxis, so a test dose is recommended before use. Several IV iron preparations (e.g., ferumoxytol, ferric carboxymaltose, iron sucrose complex, iron isomaltoside) show promise in complete replacement of iron with little toxicity (Auerbach, 2011; Bregman and Goodnough, 2014; Smith, 2012).

Diet

A primary nursing objective is to prevent nutritional anemia through family education. The nurse must reinforce the importance of administering iron supplementation to exclusively breastfed infants by 4 months of age because breast milk is a low iron source (Baker, Greer, and Committee on Nutrition American Academy of Pediatrics, 2010; Lokeshwar, Mehta, Mehta, et al, 2011; Ziegler, Nelson, and Jeter, 2011). The American Academy of Pediatrics recommends that preterm, marginally low and low-birth-weight infants, or infants with inadequate iron stores at birth receive iron supplements at approximately 2 months old (Berglund, Westrup, and Domellof, 2010).

In formula-fed infants, the nurse discusses with parents the importance of using iron-fortified formula and of introducing solid foods at the appropriate age during the first year of life. Traditionally, cereals are one of the first semisolid foods to be introduced into the infant's diet at approximately 6 months old (Baker, Greer, and Committee on Nutrition American Academy of Pediatrics, 2010; Lerner and Sills, 2011; Lokeshwar, Mehta, Mehta, et al, 2011). The best solid-food source of iron is commercial iron-fortified cereals. It may be difficult at first to teach the infant to accept foods other than milk. The same principles are applied as those for introducing new foods (see Nutrition, Chapter 7), especially feeding the solid food before the milk. Predominantly milk-fed infants rebel against solid foods, and parents are cautioned about this and the need to be firm in not relinquishing control to the child. It may require intense problem solving on the part of both the family and the nurse to overcome the child's resistance.

A difficulty encountered in discouraging the parents from feeding milk to the exclusion of other foods is dispelling the popular myth that milk is a "perfect food." Many parents believe that milk is best for infants and equate weight gain with "healthiness." Although milk is an excellent food, it is deficient in iron, vitamin C, zinc, and fluoride. Sources of each of these nutrients and the role they play in preventing deficiencies need to be discussed with the family, especially the person responsible for feeding the infant. Also stress that overweight is not synonymous with good health.

Diet education of teenagers is difficult, especially because teenage girls are particularly prone to following weight-reduction diets. Emphasizing the effect of anemia on appearance (pallor) and energy level (difficulty maintaining popular activities) may be useful.

Sickle Cell Anemia

Sickle cell anemia (SCA) is one of a group of diseases collectively termed **hemoglobinopathies** in which normal adult Hgb (Hgb A [HbA]) is partly or completely replaced by abnormal sickle Hgb (HbS). **Sickle cell disease (SCD)** refers to a group of hereditary disorders, all of which are related to the presence of HbS. Although the term *SCD* is sometimes used to refer to SCA, this use is incorrect. The correct terms for SCA are homozygous sickle cell disease (HgbSS) and **homozygous SCD**.

The following are the most common forms of SCD in the United States:

- **SCA**, the homozygous form of the disease (HgbSS), in which valine, an amino acid, is substituted for glutamic acid at the sixth position of the β chain
- **Sickle cell–C disease**, a heterozygous variant of SCD (HgbSC) is characterized by the presence of both HgbS and HgbC, in which lysine is substituted for glutamic acid at the sixth position of the β chain
- **Sickle thalassemia disease**, a combination of sickle cell trait and β -thalassemia trait ($S\beta$ thal). In the β^+ (beta plus) form, some normal HbA can be produced. In the β^0 (beta zero) form, there is no ability to produce HbA.

Of the SCDs, SCA is the most common form in African Americans followed by sickle cell–C disease and sickle thalassemia. Numerous other sickle syndromes exist in which HbS is paired with other mutant globin.

SCD is one of the most common genetic diseases worldwide, affecting approximately 100,000 Americans, including other nationalities, such as Africans, Hispanics, Italians, Greeks, Iranians, Turks, and individuals of Arab, Caribbean, Asian Indian descent, and other ethnic groups. The incidence of the disease varies in different geographic locations. Among African Americans, the incidence of sickle cell trait is about 8%, whereas among inhabitants of West Africa, the incidence is reported to be as high as 40%. The high incidence of sickle cell trait in West Africans is believed by some to be the result of selective protection afforded trait carriers against one type of malaria.

The gene that determines the production of HbS is situated on an autosome and, when present, is always detectable and therefore dominant. Heterozygous persons who have both normal HbA and abnormal HbS are said to have **sickle cell trait**. Persons who are homozygous have predominantly HbS and have SCA. The inheritance pattern is essentially that of an autosomal recessive disorder. Therefore, when both parents have sickle cell trait, there is a 25% chance with each pregnancy of producing an offspring with SCA.

Although the defect is inherited, the sickling phenomenon is usually not apparent until later in infancy because of the presence of fetal Hgb (HbF). As long as the child has predominantly HbF, sickling does not occur because there is less HbS. Newborns with SCA are generally asymptomatic because of the protective effect of HbF (60% to 80% HbF), but this rapidly decreases during the first year, so these children are at risk for sickle cell–related complications ([Driscoll, 2007](#); [Ellison, 2012](#); [Heeney and Dover, 2009](#); [Meier and Miller, 2012](#)).

Pathophysiology

The clinical features of SCA are primarily the result of (1) obstruction caused by the sickled RBCs with other cells, (2) vascular inflammation, and (3) increased RBC destruction ([Fig. 24-2](#)). The abnormal adhesion, entanglement, and enmeshing of rigid sickle-shaped cells accompanied by the inflammatory process intermittently blocks the microcirculation causing vasoocclusion ([Fig. 24-3](#)). The resultant absence of blood flow to adjacent tissues causes local hypoxia, leading to tissue ischemia and infarction (cellular death). Most of the complications seen in SCA can be traced to this process and its impact on various organs of the body ([Box 24-2](#)).

FIG 24-2 Clinical features of sickle cell anemia (SCA) from red blood cell (RBC) obstruction and destruction. CVA, cerebrovascular accident.

FIG 24-3 **A**, Normal red blood cells (RBCs) flowing freely in a blood vessel. The *inset* shows a cross-section of a normal RBC with normal hemoglobin. **B**, Abnormal, sickled RBCs clumping and blocking blood flow in a blood vessel. (Other cells also may play a role in this clumping process.) The *inset* shows a cross-section of a sickle cell with abnormal hemoglobin. (From National Heart, Lung, and Blood Institute: *What is sickle cell anemia?* Bethesda, MD, August 2008, Author.)

Box 24-2

Clinical Manifestations of Sickle Cell Anemia

General

Possible growth retardation

Chronic anemia (hemoglobin level of 6 to 9 g/dl)

Possible delayed sexual maturation

Marked susceptibility to sepsis

Vasooclusive Crisis

Pain in area(s) of involvement

Manifestations related to ischemia of involved areas

Extremities: Painful swelling of hands and feet (sickle cell dactylitis, or hand/foot syndrome), painful joints

Abdomen: Severe pain resembling acute surgical condition

Cerebrum: Stroke, visual disturbances

Chest: Symptoms resembling pneumonia, protracted episodes of pulmonary disease

Liver: Obstructive jaundice, hepatic coma

Kidney: Hematuria

Genitalia: Priapism (painful penile erection)

Sequestration Crisis

Pooling of large amounts of blood

Hepatomegaly

Splenomegaly

Circulatory collapse

Effects of Chronic Vasoocclusive Phenomena

Heart: Cardiomegaly, systolic murmurs

Lungs: Altered pulmonary function, susceptibility to infections, pulmonary insufficiency

Kidneys: Inability to concentrate urine, enuresis, progressive renal failure

Liver: Hepatomegaly, cirrhosis, intrahepatic cholestasis

Spleen: Splenomegaly, susceptibility to infection, functional reduction in splenic activity progressing to autosplenectomy

Eyes: Intraocular abnormalities with visual disturbances; sometimes progressive retinal detachment and blindness

Extremities: Avascular necrosis of hip or shoulder; skeletal deformities, especially lordosis and kyphosis; chronic leg ulcers; susceptibility to osteomyelitis

Central nervous system (CNS): Hemiparesis, seizures

The clinical manifestations of SCA vary greatly in severity and frequency. The most acute symptoms of the disease occur during periods of exacerbation called **crises**. There are several types

of episodic crises, including vasoocclusive, acute splenic sequestration, aplastic, hyperhemolytic, cerebrovascular accident (CVA), chest syndrome, and infection. The crises may occur individually or concomitantly with one or more other crises. The **vasoocclusive crisis (VOC)**, preferably called a “painful episode,” is characterized by ischemia causing mild to severe pain that may last from minutes to days or longer. **Sequestration crisis** is a pooling of a large amount of blood usually in the spleen and infrequently in the liver that causes a decreased blood volume and ultimately shock. **Aplastic crisis** is diminished RBC production, usually triggered by viral infection that may result in profound anemia. **Hyperhemolytic crisis** is an accelerated rate of RBC destruction characterized by anemia, jaundice, and reticulocytosis.

Another serious complication is **acute chest syndrome (ACS)**, which is clinically similar to pneumonia. It is the presence of a new pulmonary infiltrate and may be associated with chest pain, fever, cough, tachypnea, wheezing, and hypoxia. A **cerebrovascular accident (CVA, stroke)** is a sudden and severe complication, often with no related illnesses. Sickled cells block the major blood vessels in the brain, resulting in cerebral infarction, which causes variable degrees of neurologic impairment. The current treatment for SCD children who have experienced a stroke is chronic transfusion therapy. Repeat CVAs causing progressively greater brain damage occur in approximately 70% of untreated children who have experienced one stroke (Heeney and Dover, 2009; Wang and Dwan, 2013).

Diagnostic Evaluation

Universal screening of newborns for SCD has become standard in all 50 United States and territories (McCavit, 2012; McGann, Nero, and Ware, 2013; Meier and Miller, 2012). However, global newborn screening varies by country and is not a common practice in most countries where SCD is a public health concern (Aygun and Odame, 2012; Huttler, Maestre, Lantigua, et al, 2015). The screening provides early identification of these children before complications develop. At birth, infants have up to 80% of HbF, which does not carry the defect. Because levels of HbS are low at birth, Hgb electrophoresis or other tests that measure Hgb concentrations are indicated. Early diagnosis (before 3 months of age) enables initiation of appropriate interventions to minimize complications. The family is taught to administer prophylactic antibiotics and identify early signs of infection to seek medical therapy as soon as possible.

Although SCD is usually reported during the prenatal or neonatal periods, it may not be recognized until the toddler and preschool period during a crisis precipitated by an acute respiratory tract or GI infection. However, early diagnosis (before the age of 2 months) facilitates initiation of appropriate interventions to minimize complications. There are several specific tests that detect the presence of the abnormal Hgb in the heterozygous or the homozygous form of SCD. For screening purposes, the sickle-turbidity test (Sickledex) is used because it can be performed on blood from a finger or heel stick and yields accurate results in 3 minutes. If the test result is positive, however, Hgb electrophoresis is necessary to distinguish between children with the trait and those with the disease. **Hemoglobin electrophoresis** referred to as “fingerprinting” of the protein is a specially prepared blood test that separates various hemoglobins by high-voltage. The blood test is accurate, rapid, and specific for detecting the homozygous and heterozygous forms of the disease, as well as the percentages of the various types of Hgb. The hemoglobin electrophoresis is used as the initial screening test increasingly in centers within the United States.

Therapeutic Management

The aims of therapy are to prevent the sickling phenomena, which are responsible for the pathologic sequelae, and treat the medical emergencies of sickle cell crisis. The successful achievement of the aims depends on prompt nursing interventions, medical therapies, patient and family preventive measures, and use of innovative treatments.

Medical management of a crisis is usually directed toward supportive, symptomatic and specific treatments. The main objectives are to provide (1) rest to minimize energy expenditure and to improve oxygen utilization; (2) hydration through oral and IV therapy; (3) electrolyte replacement because hypoxia results in metabolic acidosis, which also promotes sickling; (4) analgesia for the severe pain from vasoocclusion; (5) blood replacement to treat anemia and to reduce the viscosity of the sickled blood; and (6) antibiotics to treat any existing infection.

Administration of pneumococcal, *Haemophilus influenzae* and meningococcal vaccines is recommended for these children because of their susceptibility to infection as a result of functional

asplenia. In addition to routine immunizations, children with SCD should receive a yearly influenza vaccination (see Immunizations, [Chapter 7](#)). Oral penicillin prophylaxis is recommended by 2 months old to reduce the chance of pneumococcal sepsis (see [Translating Evidence into Practice](#) box).

Translating Evidence Into Practice

Sickle Cell Anemia and Penicillin Prophylaxis

Ask the Question

PICOT Question

In children with **sickle cell anemia** (SCA), does prophylaxis with penicillin reduce the risk of pneumococcal infection?

Critically Analyze the Evidence

- [Hirst and Owusu-Ofori \(2014\)](#) conducted an updated systematic Cochrane review of three trials that showed a reduced rate of infection in children with **sickle cell disease** (SCD) homozygous sickle cell disease (HgbSS or HgbS β 0Thal) receiving prophylactic penicillin. Two trials looked at whether treatment was effective. The third trial followed from one of the early trials and looked at when it was safe to stop treatment. Adverse drug effects were rare and minor. Penicillin given prophylactically significantly reduces the risk of pneumococcal infection in children with SCD younger than 5 years old and is associated with minimal adverse reactions. Supporting the same conclusion that there is strong evidence that daily oral penicillin prophylaxis greatly reduces the risk of pneumococcal infection in children with SCA younger than 3 years old was reported in a systematic review ([Gwaram and Gwaram, 2014](#)).
- Researchers combined the clinical experiences of three sickle cell programs in the eastern United States in an attempt to determine the age and disease-specific risk of *Streptococcus pneumoniae* bacteremia and meningitis in children with SCD at a time when penicillin prophylaxis was routine. Forty-seven pneumococcal infections (44 bacteremia; 3 meningitis) among 40 patients with SCD were observed. Most children in whom infections developed were taking prophylactic penicillin and received Pneumovax at 24 months old. The observed severe pneumococcal infection rate in HgbSS children younger than 5 years old was less than that reported before penicillin prophylaxis in this specific population ([Hord, Byrd, Stowe, et al, 2002](#)).
- Administration of oral prophylactic penicillin was compared with the 14-valent pneumococcal vaccine in preventing pneumococcal infection in 242 children between the ages of 6 months and 3 years with HgbSS. In the first 5 years of the trial, there were 11 pneumococcal infections in the pneumococcal vaccine group and higher infection rates in those given the vaccine before 1 year of age. No pneumococcal isolates were found in the group receiving penicillin, although four pneumococcal isolates were found in this group within 1 year of stopping the penicillin prophylaxis at 3 years old. This study supported the use of penicillin prophylaxis to prevent pneumococcal infection in children younger than 3 years old ([John, Ramlal, Jackson, et al, 1984](#)).
- In a multicenter, randomized, double-blind, placebo-controlled clinical trial, 105 children received penicillin twice daily; a control group of 110 children received a placebo twice daily. The trial was terminated 8 months early when an 84% reduction in the incidence of pneumococcal infections was observed in the group treated with penicillin compared with the placebo group. There were no deaths in the penicillin group, but three deaths from infection occurred in the placebo group.

Researchers stressed the importance of screening children during the neonatal period and prescribing prophylactic penicillin to decrease the morbidity and mortality associated with pneumococcal infection (Gaston, Verter, Woods, et al, 1986).

- Zarkowsky, Gallagher, Gill, et al (1986) conducted a retrospective analysis of 178 episodes of bacteremia in children with sickle hemoglobinopathies that occurred during 13,771 patient-years of follow-up ($n = 3451$). The predominant pathogen in patients younger than 6 years old was *S. pneumoniae* (66%), and gram-negative organisms were responsible for 50% of the bacteremias in patients 6 years old and older. The incidence of pneumococcal bacteremia in children with SCA younger than 3 years old was 6.1 events per 100 patient-years. The results of this study supported prophylactic administration of penicillin for prevention of pneumococcal bacteremia in children younger than 3 years old.
- A cohort study of 315 patients with HgbSS who lived in Jamaica was conducted between June 1973 and December 1981. The patients were divided into three groups to determine whether interventions such as penicillin prophylaxis, parental education in early diagnosis of acute splenic sequestration, and close monitoring in a sickle cell clinic improved survival. A significant decline in deaths from acute splenic sequestration and pneumococcal septicemia and meningitis was found. The research indicated that early detection of SCD and prophylactic measures could significantly reduce deaths associated with HgbSS (Lee, Thomas, Cupidore, et al, 1995).
- Riddington and Owusu-Ofori (2002) conducted a systematic review of randomized controlled trials evaluating the effectiveness of prophylactic antibiotic administration in preventing pneumococcal infection in children with SCD. The review of published research found that penicillin prophylaxis significantly reduced the risk of pneumococcal infection in children with HgbSS with minimal adverse reactions.
- McCavit, Gilbert, and Buchanan (2013) conducted a cross-sectional electronic survey of 106 pediatric hematologists with expertise in SCD regarding their practices related to penicillin prophylaxis in children with SCD after 5 years old. Eighty-four percent of pediatric hematologist from 76 centers completed the survey, and 76% routinely recommended cessation of penicillin prophylaxis after 5 years old.

Apply the Evidence: Nursing Implications

There is **good evidence** with a **strong recommendation** (Guyatt, Oxman, Vist, et al, 2008) that penicillin prophylaxis significantly reduces the risk of pneumococcal infection in children with SCA. The epidemiologic studies strongly suggest that all children with SCA should be started on prophylactic penicillin at 2 months old. Parents and children with SCA should be instructed in the importance of taking the prophylactic penicillin twice daily and seeking medical attention immediately for acute illness, especially if the temperature exceeds 38.3° C (101° F), regardless of the use of prophylaxis.

Quality and Safety Competencies: Evidence-Based Practice*

Knowledge

Differentiate clinical opinion from research and evidence-based summaries.

Summarize the epidemiologic studies that strongly suggest that children with SCA should be started on prophylactic penicillin.

Skills

Base individualized care plan on patient values, clinical expertise, and evidence.

Integrate evidence into practice by making sure infants with SCD are started on penicillin at 2 months old.

Attitudes

Value the concept of evidence-based practice as integral to determining best clinical practice.

Appreciate strengths and weakness of evidence for preventing pneumococcal infection in children with SCD.

Oxygen therapy is of little therapeutic value unless the patient has hypoxia (Heeney and Dover, 2009). Severe hypoxia must be prevented because it causes massive systemic sickling that can be fatal. Oxygen administration is usually not effective in reversing sickling or reducing pain because the oxygen is unable to reach the enmeshed sickled erythrocytes in clogged vessels. In addition, prolonged administration of oxygen can depress bone marrow, further aggravating the anemia.

Another important component of care is the use of blood transfusions. Exchange RBC transfusion (erythrocytapheresis) is the replacement of sickle cells with normal RBCs. Exchange transfusion is a successful, rapid method of reducing the number of circulating sickle cells and therefore slowing down the vicious circle of hypoxia, thrombosis, tissue ischemia, and injury. Therapy including simple and exchange transfusions are used in life-threatening ACS and after acute overt stroke to prevent reoccurrence and further tissue damage (Velasquez, Mariscalco, Goldstein, et al, 2009; Meier and Miller, 2012; Wang and Dwan, 2013). A transcranial Doppler (TCD) test identifies the child with SCA or HgbS-B° thalassemia who is at high risk for developing a CVA by monitoring the intracranial vascular flow (Driscoll, 2007; Kwiatkowski, Yim, Miller, et al, 2011; Meier and Miller, 2012). The TCD is performed yearly for children from 2 to 16 years old. The recommended treatment for children with confirmed abnormal TCD is chronic transfusion therapy (Armstrong-Wells, Grimes, Sidney, et al, 2009; Kwiatkowski, Yim, Miller, et al, 2011; Wang and Dwan, 2013). The duration of transfusion is indefinite, although current studies are addressing whether patients may be transitioned safely to hydroxyurea to prevent stroke (McCavit, 2012). Multiple transfusions carry the risk of transmission of viral infection, hyperviscosity, transfusion reactions, alloimmunization, and hemosiderosis (Driscoll, 2007; Heeney and Dover, 2009; Jordan, Casella, and DeBaun, 2012; Yawn, Buchanan, Afenyi-Annan, et al, 2014). After a CVA, blood transfusions are usually given every 3 to 4 weeks to help prevent a repeat stroke. To reduce iron overload from

chronic transfusion therapy, chelation therapy may be started (see later in chapter).

In children with recurrent life-threatening splenic sequestration, splenectomy may be a lifesaving measure. However, the spleen usually atrophies on its own through progressive fibrotic changes (**functional asplenia**) by 6 years of age in children with SCA. Prophylactic penicillin and pneumococcal vaccines have decreased the incidence of pneumococcal sepsis in children with SCD. Packed RBC transfusions are recommended not only for treatment of splenic sequestration but also stroke and used preoperatively accompanied with maintenance IV hydration for most surgical procedures in children with SCD.

VOC, the most common, severe, painful episode, is considered the clinical hallmark of SCD that is usually accompanied by increasing health care cost because of prolonged hospitalization (Ballas, 2011; McCavit, 2012; Raphael, Mei, Mueller, et al, 2012; Yawn, Buchanan, Afenyi-Annan, et al, 2014). The chronic nature of this pain can greatly affect the child's development. A multidisciplinary team (e.g., physician, psychologist, child life specialist, family, nurse, social worker) approach is best for vasoocclusive pain management that includes pharmacologic treatments, hydration, physical therapy, and non-pharmacologic and complementary treatment (e.g., prayer, spiritual healing, massage, heating pads, herbs, relaxation, breathing exercises, distraction, music, guided imagery, self-motivation, acupuncture, and biofeedback) (Ballas, 2011; Brandow, Weisman, and Panepinto, 2011; Meier and Miller, 2012; Redding-Lallinger and Knoll, 2006). When mild to moderate VOC is reported, nonsteroidal antiinflammatory medication (e.g., ibuprofen, ketorolac) or nonopioids (e.g., acetaminophen) are used initially. If these drugs are not effective alone, an opioid may be added. The dosages of both drugs are titrated (adjusted) to a therapeutic level. Opioids such as immediate- and sustained-release morphine, oxycodone, hydrocodone, hydromorphone (Dilaudid), and methadone are administered intravenously or orally for severe pain and are given around the clock. In conjunction with the opioid, IV ketorolac for a maximum of a 5-day course is commonly used to enhance the pain management effect. Patient-controlled analgesia (PCA) has been used successfully for sickle cell–related pain. PCA reinforces the patient's role and responsibility in managing the pain and provides flexibility in dealing with pain, which may vary in severity over time (see [Pain Management, Chapter 5](#)).

Drug Alert

Meperidine (Demerol) is not recommended. Normeperidine, a metabolite of meperidine, is a central nervous system (CNS) stimulant that produces anxiety, tremors, myoclonus, and generalized seizures when it accumulates with repetitive dosing. Patients with SCD are particularly at risk for normeperidine-induced seizures (Ellison, 2012; Howard and Davies, 2007; National Institutes of Health, National Heart, Lung, and Blood Institute, Division of Blood Disease and Resources, 2002).

Prognosis

The prognosis varies, but most patients live into the fifth decade. The greatest risk is usually in children younger than 5 years old, and the majority of deaths in these children are caused by overwhelming infection. Consequently, SCA is a chronic illness with a potentially terminal outcome. Physical and sexual maturation are delayed in adolescents with SCA. Although adults achieve normal height, weight, and sexual function, the delay may present problems to adolescents (Heeney and Dover, 2009; Redding-Lallinger and Knoll, 2006).

Individuals with SCD who have higher levels of HbF tend to have a milder disease with fewer complications than those with lower levels (Driscoll, 2007; Meier and Miller, 2012). Hydroxyurea is a US Food and Drug Administration–approved medication that increases the production of HbF, reduces endothelial adhesion of sickle cells, improves the sickle cell hydration and cell size, increases nitric oxide production (a vasodilator), and lowers leukocyte and reticulocyte counts (McGann and Ware, 2011; National Institutes of Health, National Heart, Lung, and Blood Institute, Division of Blood Disease and Resources, 2002; Yawn, Buchanan, Afenyi-Annan, et al, 2014). Long-term follow-up of patients taking hydroxyurea alone revealed a 40% reduction in mortality and decreased frequency of VOC, ACS, hospital admissions, and need for transfusions, thus making SCD crises milder (Anderson, 2006; Strouse, Lanzkron, Beach, et al, 2008; Voskaridou, Christoulas, Bilalis, et al, 2010). Pediatric studies have shown that hydroxyurea can be safely used in children (Wang, Ware, Miller, et al, 2011; Zimmerman, Schultz, Davis, et al, 2004).

Allogeneic hematopoietic stem cell transplantation (HSCT) offers a curative treatment for children with SCD with overall survival 92% to 95% and event-free survival of 82% to 86% (Bernaudin, Socie, Kuentz, et al, 2007; Haining, Duncan, and Lehmann, 2009; Hsieh, Fitzhugh, Weitzel, et al, 2014; Locatelli and Pagliara, 2012).

Since SCD is an autosomal recessive disorder, curative strategies for correction, replacement, addition, or modulation of the globin gene continue to evolve in the basic and clinical research settings (Meier and Miller, 2012).

Quality Patient Outcomes: Sickle Cell Disease

- Early recognition of signs and symptoms of sickle cell anemia (SCA)
- Tissue deoxygenation minimized
- Sickle cell crisis prevented or quickly managed
- Pain appropriately managed
- Stroke prevented
- Prophylactic penicillin regimen followed
- Hypoxia prevented when surgery is necessary
- Pneumococcal, *H. influenzae* type b, and meningococcal vaccines administered

Nursing Care Management

Educate the Family and Child

Family education begins with an explanation of the disease and its consequences (see [Nursing Care Plan](#) box). After this explanation, the most important issues to teach the family are to (1) seek early intervention for problems, such as fever of 38.5° C (101.3° F) or greater; (2) give penicillin as ordered; (3) recognize signs and symptoms of stroke, splenic sequestration, as well as respiratory problems that can lead to hypoxia; and (4) treat the child normally. The nurse tells the family that the child is normal but can get sick in ways that other children cannot.

Nursing Care Plan

The Child with Sickle Cell Anemia

Case Study

Donny is a 2-year-old male with sickle cell anemia (HgbSS). He returns to the hematology clinic this morning after being seen last night in the emergency department (ED) for pain. His mother states he is having more pain in his feet over the past several hours and he no longer wants to walk. The mother has been giving Donny the pain medications as prescribed by the ED doctor, but she feels his pain is getting worse. On examination, you find that his feet and hands are swollen and he cries out when you touch them.

Assessment

What are the most important signs of acute pain that you need to look for in a young child with sickle cell disease (SCD)?

Sickle Cell Vasoocclusive Pain: Defining Characteristics

Pain can be in any location in the body; can be rapid in onset and severe, may be localized or generalized

Low-grade fever may be present

Localized swelling over joints with arthralgia can occur

Nursing Diagnosis

Acute pain related to tissue anoxia (vasoocclusive episode or crisis)

Nursing Interventions and Rationales

What are the most appropriate nursing interventions for a child with SCD experiencing pain?

| Nursing Interventions | Rationales |
|---|--|
| Discuss schedule of medication around the clock with parents. | To control pain |
| Encourage high level of fluid intake. | To ensure hydration |
| Recognize that various analgesics, including opioids and medication schedules, may need to be tried. | To ensure satisfactory pain relief |
| Reassure child and family that analgesics, including opioids, are medically indicated, that high doses may be needed, and that children rarely become addicted. | To avoid needless suffering because of unfounded fears |
| Apply heat application or massage to affected area. Avoid applying cold compresses. | To prevent vasoconstriction that may enhance sickling |

Case Study (Continued)

Donny's pain is not being controlled by oral pain medications, and the plan is to begin intravenous (IV) pain medications to control his pain. What is the most appropriate IV medication for Donny at this time?

A dose of morphine (0.1 to 0.2 mg/kg/dose) is given every 10 minutes for three doses.

What important nursing interventions should be implemented at this time?

Give both the morphine and ketorolac. If pain is still not relieved after three doses of morphine, then switch to patient-controlled analgesia (PCA) and admit. Give ketorolac 1mg/kg for first dose, then 0.5 mg/kg /dose IV every 6 hours; not to exceed 5 days (maximum of 30 mg/dose).

| Nursing Interventions | Rationales |
|---|--|
| Administer morphine and ketorolac safely. | To prevent adverse effects and overdose |
| Monitor for side effects of morphine; assess respiratory status closely and prevent constipation. | To prevent discomfort and adverse effects following administration |
| Monitor for side effects of ketorolac; assess for bleeding (gastrointestinal [GI] or renal) closely. | To reduce unfounded fears |
| Educate parents on the safety and effectiveness of morphine and ketorolac as pain-relieving medications. | To ensure satisfactory pain relief |
| Reassess the child's pain level after administering morphine and ketorolac continue to assess frequently. | To assure optimal pain relief |
| Recognize that various analgesics and doses may need to be tried. | |

Case Study (Continued)

Because Donny is only 2 years old, what kind of pain assessment tool is most appropriate for a child this age?

Because Donny is in a great deal of pain, the FLACC Pain Assessment Tool is an appropriate observational tool to use at this time. The FLACC is an interval scale that includes the five categories of behavior: facial expression (F), leg movement (L), activity (A), cry (C), and consolability (C). See Chapter 5 for more discussion of this tool.

How frequently should Donny's pain be assessed?

Donny's pain should be assessed frequently to determine whether the IV morphine is providing enough pain relief. Morphine (0.1 to 0.2 mg/kg/dose) is given every 10 minutes for three doses. After this initial

intervention, pain assessment will help determine what to do next. Donny may require additional medications to control his pain. If the IV morphine provided relief, then discharge on oral morphine (0.2 to 0.5 mg/kg) or convert to home opioid equivalent with ibuprofen every 6 hours. Instruct to continue around the clock medications at home, emphasize increased fluid intake, and start bowel regimen to prevent constipation. If pain is still not under control after three doses of IV morphine, then initiate morphine PCA and admit to hospital.

PCA: Loading dose of 0.1 mg/kg (maximum 8 mg); basal rate of 0.01 mg/kg and intermittent dose 0.035 mg/kg (maximum 8 mg) with the interval lockout \approx 10 minutes. A 4-hour limit 0.5 to 0.75 mg/kg with IV fluids at $\frac{1}{2}$ maintenance rate is administered unless history of **acute chest syndrome** (ACS), then IV is at maintenance rate.

Once the pain is controlled (e.g., decrease swelling, using extremities, no crying when touch extremities), then gradually decrease IV analgesic. If drinking orally, at least maintenance and half fluids daily, and then may convert to home oral opioid equivalent with ibuprofen every 6 hours and discharge home. If pain remains under control and Donny is drinking fluids adequately at home, instruct the parents to continue home oral opioid every 24 hours, then stop opioid and continue to observe for any signs of pain. Continue ibuprofen for 24 hours after stopping the opioid and then stop ibuprofen with no signs of pain observed.

Expected Outcome

Donny's pain will be controlled in a timely manner.

Case Study (Continued)

Donny is not eating or drinking this morning and appears lethargic in the examination room. When you question his mother regarding the last time he drank something, she remembers it was over 12 hours ago.

Assessment

What are the most important signs and symptoms of dehydration in a child with SCD?

Deficient Fluid Volume: Defining Characteristics

Dry mucous membranes

Loss of skin turgor

Sunken eyes

No or diminished tears

Sunken fontanel

Dark urine

Rapid, thready pulse

Rapid breathing

Nursing Diagnosis

Deficient fluid volume

Nursing Interventions and Rationales

What are the most appropriate nursing interventions for dehydration in a young child with sickle cell anemia (SCA) who is experiencing a vasoocclusive crisis (VOC)?

| Nursing Interventions | Rationales |
|--|--|
| Calculate recommended daily fluid intake (1600 ml/m ² /day) and base child's fluid requirements on this amount. | To ensure adequate hydration |
| Increase fluid intake above minimum requirements during physical exercise or emotional stress and during a crisis. | To compensate for additional fluid needs |
| Give parents written instructions regarding specific quantity of fluid required daily. | To encourage compliance |
| Encourage child to drink. | To ensure adequate hydration |
| Increase fluid intake above minimum requirements during physical exercise or emotional stress and during a crisis. | To compensate for additional fluid needs |

Expected Outcome

Donny will receive appropriate hydration and will demonstrate electrolyte and fluid stability.

Case Study (Continued)

Donny's parents ask you what you have found in your initial assessment. They ask why he has swollen hands and feet and how that causes pain from SCD. They are very worried and think it is their fault that this happened.

Assessment

What are the most important aspects of Donny's care to discuss with his parents at this time? What should be included regarding SCD in a young child?

Family's Knowledge of Illness: Defining Characteristics

Lack of understanding

Inability to identify signs and symptoms of painful crises

Inability to follow disease management guidelines

Difficulty describing treatment plan

Nursing Diagnosis

Readiness for enhanced knowledge related to parents' interest in Donny's health status.

Nursing Interventions and Rationales

What are the most appropriate nursing interventions to help a family manage a young child with SCD?

| Nursing Interventions | Rationales |
|---|---|
| Explain signs of developing complications, such as fever, pallor, respiratory distress, persistent headaches, and pain. Discuss dactylitis in the young child. | To ensure prompt and appropriate treatment |
| Reinforce basic information regarding trait transmission and refer to genetic counseling services if appropriate. | To allow for informed decision making |
| Provide information on what to do when complications occur, such as fever, pallor, respiratory distress, persistent headaches, and pain. | To ensure prompt and appropriate treatment |
| Stress importance of adequate nutrition; routine immunizations, including pneumococcal and meningococcal vaccinations; protection from known sources of infection; and frequent health evaluation and regularly scheduled comprehensive evaluation. | To encourage preventive measures and decrease risk for infection exposure |

Expected Outcome

Donny's parents will understand the signs and symptoms of SCD and will understand the actions being taken by the health care team. His parents will be prepared to manage his disease at home.

Nursing Tip

One simple yet graphic way to demonstrate the effect of sickling is to roll rounded objects, such as marbles or beads, through a tube to simulate normal circulation and then roll pointed objects, such as screws or jacks, through the tube. The effect of sickling and clumping of the pointed objects is especially noticeable at a bend or slight narrowing of the tube.

The nurse emphasizes the importance of adequate hydration to prevent sickling and delay the

vasoocclusion and hypoxia–ischemia cycle. It is not sufficient to advise parents to “force fluids” or “encourage drinking.” They need specific instructions on how many daily glasses or bottles of fluid are required. Many foods are also a source of fluid, particularly soups, flavored ice pops, ice cream, sherbet, gelatin, and puddings.

Increased fluids combined with impaired kidney function result in the problem of **enuresis**. Parents who are unaware of this fact frequently use the usual measures to discourage bedwetting, such as limiting fluids at night, and may resort to punishment and shame to force bladder control. The nurse should discuss this problem with the parents, stressing that the child's ability to concentrate urine is impaired. Reminding the child to urinate frequently during the day and prior to bedtime may be helpful and waking the child during the night if the child's sleep pattern is not disturbed. Enuresis is treated as a complication of the disease, such as joint pain or some other symptom, to alleviate parental pressure on the child.

Promote Supportive Therapies During Crises

The success of many of the medical therapies relies heavily on nursing implementation. Management of pain is an especially difficult problem and often involves experimenting with various analgesics, including opioids, and schedules before relief is achieved. Unfortunately, these children tend to be undermedicated, that result in “clock watching” and demands for additional doses sooner than might be expected. Often this incorrectly raises suspicions of drug addiction, when in fact the problem is one of improper dosage (see [Family-Centered Care](#) box). In choosing and scheduling analgesics, the goal should be *prevention* of pain.

Family-Centered Care

Fear of Addiction

Although the pain during a sickle cell crisis is usually severe and opioids are needed, many families fear that their child will become addicted to the narcotic. Unfortunately, misinformed health professionals may foster this unfounded fear, which results in needless suffering. Extremely few children who receive opioids for severe pain become behaviorally addicted to the drug ([American Pain Society, 2015](#); [Howard and Davies, 2007](#); [National Institutes of Health, National Heart, Lung, and Blood Institute, Division of Blood Disease and Resources, 2002](#)). Families and older children, especially adolescents, need to be reassured that opioids are medically indicated, high doses may be needed, and children rarely become addicted.

Nursing Tip

Advise parents to be particularly alert to situations in which dehydration may be a possibility (e.g., hot weather, playing sports) and to recognize early signs of reduced fluid intake, such as decreased urinary output (e.g., fewer wet diapers) and increased thirst.

Any pain program should be combined with psychological support to help the child deal with the depression, anxiety, and fear that may accompany the disease. This includes regular visits with the child to discuss any concerns during the hospitalization and positive reinforcement of coping skills, such as successful methods of dealing with the pain and compliance with treatment prescriptions. To reduce the negative connotation associated with the term *crisis*, it is best to say *pain episode*.

If blood transfusions or exchange transfusions are given, the nurse has the responsibility of observing for signs of transfusion reaction (see [Table 24-3](#) later in this chapter). Because hypervolemia from too-rapid transfusion can increase the workload of the heart, the nurse also must be alert to signs of cardiac failure.

In splenic sequestration, gently measure the size of the spleen, because increasing splenomegaly is an ominous sign (see [Abdomen, Chapter 4](#)). A decrease in spleen size denotes response to therapy. The nurse also closely monitors vital signs and blood pressure to detect impending shock. Anemia is typically not a presenting complication in VOC but is a critical problem in other types of crises. The nurse monitors for evidence of increasing anemia and institutes appropriate nursing interventions (see earlier in chapter). Oxygen is not beneficial in vasoocclusive episodes unless

hypoxemia is present (Heeney and Dover, 2009). It does not reverse sickled RBCs, and if used in a nonhypoxic patient, it will decrease erythropoiesis (Vichinsky and Styles, 1996). Because prolonged use of oxygen can aggravate the anemia, report any signs of lack of therapeutic benefit, such as restlessness, increased pallor, and continued pain.

Record intake, especially of IV fluids, and output. The child's weight should be taken on admission, because it serves as a baseline for evaluating hydration. Because diuresis can result in electrolyte loss, the nurse observes for signs of hypokalemia and should be familiar with normal serum electrolyte values to report changes.

Recognize Other Complications

Nurses also need to be aware of the signs of ACS and CVA, which are both potentially fatal complications.

Nursing Alert

Report signs of the following immediately:

Acute chest syndrome (ACS):

- Severe chest, back, or abdominal pain
- Fever of 38.5° C (101.3° F) or higher
- Cough
- Dyspnea, tachypnea
- Retractions
- Declining oxygen saturation (oximetry)

Cerebrovascular accident (CVA):

- Severe, unrelieved headaches
- Severe vomiting
- Jerking or twitching of the face, legs, or arms
- Seizures
- Strange, abnormal behavior
- Inability to move an arm or leg
- Stagger or an unsteady walk
- Stutter or slurred speech

- Weakness in the hand, foot, or leg
- Changes in vision

Support the Family

Families need the opportunity to discuss their feelings regarding transmitting a potentially fatal, chronic illness to their child. Because of the widely publicized prognosis for children with SCA, many parents express their fear of the child's death. Three manifestations of SCD that may appear in the first 2 years of life (dactylitis, severe anemia, leukocytosis) can be predictors of disease severity (Miller, Sleeper, Pegelow, et al, 2000). The nurse should care for the family as for any family with a child who has a chronic and life-threatening illness and give consideration to the siblings' reactions, the stress on the marital relationship, and the childrearing attitudes displayed toward the child (see Chapter 17). Several resources are available to families with a sickling disorder.*

The nurse advises parents to inform all treating personnel of the child's condition. The use of medical identification, such as a bracelet, is another way of ensuring awareness of the disease.

If family members have the SCD trait or SCA, genetic counseling is necessary. A primary consideration in genetic counseling is informing parents of the 25% chance with each pregnancy of having a child with the disease when both parents carry the trait.

Beta-Thalassemia (Cooley Anemia)

Worldwide, thalassemia is a common genetic disorder, affecting as many as 15 million people (Yaish, 2015). The term **thalassemia**, which is derived from the Greek word *thalassa*, meaning "sea," is applied to a variety of inherited blood disorders characterized by deficiencies in the rate of production of specific globin chains in Hgb. The name appropriately refers to people living near the Mediterranean Sea, namely Italians, Greeks, Syrians, Asians, Africans, and their descendants. Evidence suggests that the high incidence of the disorders among these groups is a result of the selective advantage the trait in protecting against malaria, as is postulated in SCD. The disorder has a wide geographic distribution, probably as a result of genetic migration through intermarriage or possibly as a result of spontaneous mutation.

Beta-thalassemia is the most common of the thalassemiias and occurs in four forms:

- Two heterozygous forms, **thalassemia minor**, an asymptomatic silent carrier, and **thalassemia trait**, which produces a mild microcytic anemia
- **Thalassemia intermedia**, which may involve either homozygous or heterozygous abnormalities and is manifested as splenomegaly and moderate to severe anemia
- A homozygous form, **thalassemia major** (also known as **Cooley anemia**), which results in a severe anemia that would lead to cardiac failure and death in early childhood without transfusion support

Pathophysiology

Normal postnatal Hgb is composed of two α - and two β -polypeptide chains. In β -thalassemia, there is a partial or complete deficiency in the synthesis of the β -chain of the Hgb molecule. Consequently, there is a compensatory increase in the synthesis of α -chains, and γ -chain production remains activated, resulting in defective Hgb formation. This unbalanced polypeptide unit is very unstable; when it disintegrates, it damages RBCs, causing severe anemia.

To compensate for the hemolytic process, an overabundance of erythrocytes is formed unless the bone marrow is suppressed by transfusion therapy. Excess iron from packed RBC transfusions and from the rapid destruction of defective cells is stored in various organs (**hemosiderosis**).

Diagnostic Evaluation

The onset of clinical manifestations in thalassemia major may be insidious and not recognized until the late infancy or early toddlerhood. The clinical effects of thalassemia major are primarily attributable to defective synthesis of HbA, structurally impaired RBCs, and shortened life span of erythrocytes (Box 24-3).

Box 24-3

Clinical Manifestations of Beta-Thalassemia

Anemia (Before Diagnosis)

Pallor

Unexplained fever

Poor feeding

Enlarged spleen or liver

Progressive Anemia

Signs of chronic hypoxia

Headache

Precordial and bone pain

Decreased exercise tolerance

Listlessness

Anorexia

Other Features

Small stature

Delayed sexual maturation

Bronzed, freckled complexion (if not receiving chelation therapy)

Bone Changes (Older Children If Untreated)

Enlarged head

Prominent frontal and parietal bossing

Prominent malar eminences

Flat or depressed bridge of the nose

Enlarged maxilla

Protrusion of the lip and upper central incisors and eventual malocclusion

Generalized osteoporosis

Hematologic studies reveal the characteristic changes in RBCs (e.g., microcytosis, hypochromia, anisocytosis, poikilocytosis, target cells, and basophilic stippling of various stages). Low Hgb and Hct levels are seen in severe anemia, although they are typically lower than the reduction in RBC count because of the proliferation of immature erythrocytes. Hgb electrophoresis confirms the diagnosis and is helpful in distinguishing the type of the thalassemia because it analyzes the

quantity and kind of hemoglobin variants found in the blood.

Therapeutic Management

The objectives of supportive therapy are to maintain sufficient Hgb levels to prevent bone marrow expansion and bony deformities and to provide sufficient RBCs to support normal growth and normal physical activity. Transfusions are the foundation of medical management with the goal of maintaining the Hgb level above 9.5 g/dl, an aim that may require transfusions as often as every 3 to 5 weeks. The advantages of this therapy include (1) improved physical and psychological well-being because of the ability to participate in normal activities, (2) decreased cardiomegaly and hepatosplenomegaly, (3) fewer bone changes, (4) normal or near-normal growth and development until puberty, and (5) fewer infections.

One of the potential complications of frequent blood transfusions is iron overload (hemosiderosis). Because the body has no effective means of eliminating the excess iron, the mineral is deposited in body tissues. To minimize the development of hemosiderosis, oral iron chelators (deferasirox, deferiprone) have shown in short-term studies to be a safe equivalent to **deferoxamine (Desferal)**, a parenteral iron-chelating agent, and more tolerable by patients and families (Bakai and Pennell, 2014; Cappellini, Porter, El-Beshlawy, et al, 2010; Meerpohl, Schell, Rucker, et al, 2014; Vichinsky, Bernaudin, Forni, et al, 2011).

In some children with severe splenomegaly who require repeated transfusions, a splenectomy may be necessary to decrease the disabling effects of abdominal pressure and to increase the life span of supplemental RBCs. Over time, the spleen may accelerate the rate of RBC destruction and thus increase transfusion requirements. After a splenectomy, children generally require fewer transfusions, although the basic defect in Hgb synthesis remains unaffected. A major postsplenectomy complication is severe and overwhelming infection. Therefore, these children are often on prophylactic antibiotics with close medical supervision for many years and should receive the pneumococcal and meningococcal vaccines in addition to the regularly scheduled immunizations (see Immunizations, Chapter 7).

Nursing Tip

Ensure that the family and patient understand the need to notify the health professional of all fevers of 38.5° C (101.3° F) or greater because of the risk of sepsis in a child with asplenia.

Prognosis

Most children treated with blood transfusion and early chelation therapy survive well into adulthood. The most common causes of death are heart disease, postsplenectomy sepsis, and multiple-organ failure secondary to hemochromatosis (Cunningham, Sankaran, Nathan, et al, 2009; Yaish, 2015). A curative treatment for some children is HSCT. Children younger than 16 years old who undergo allogeneic HSCT have a high rate of complication-free survival; approximately 80% to 97% of these children are cured (Isgro, Gaziev, Sodani, et al, 2010; Lucarelli, Isgro, Sodani, et al, 2012).

Nursing Care Management

The objectives of nursing care are to (1) promote compliance with transfusion and chelation therapy, (2) assist the child in coping with the anxiety-provoking treatments and the effects of the illness, (3) foster the child's and family's adjustment to a chronic illness, and (4) observe for complications of multiple blood transfusions. Basic to each of these goals is explaining to parents and older children the defect responsible for the disorder, its effect on RBCs, and the potential effects of untreated iron overload (e.g., delayed growth and maturation and heart disease). Because this condition is prevalent among families of Mediterranean descent, the nurse also inquires about the family's previous knowledge about thalassemia. All families with a child with thalassemia should be tested for the trait and referred for genetic counseling.

As with any chronic illness, the family's needs must be met for optimal adjustment to the stresses imposed by the disorder (see Chapter 19). Sources of information for the family include the Cooley's Anemia Foundation* and the Northern California Comprehensive Thalassemia Center. Genetic counseling for the parents and fertile offspring is mandatory, and both prenatal diagnosis using amniocentesis or fetal blood sampling and screening for thalassemia trait are available.

Aplastic Anemia

Aplastic anemia (AA) is a rare and life-threatening disorder, which can be satisfactorily treated in about 90% of cases (Miano and Dufour, 2015). It refers to a bone marrow failure condition in which the formed elements of the blood are simultaneously depressed. To diagnose AA, the peripheral blood smear demonstrates pancytopenia with at least two of the following present: profound anemia, leukopenia, and thrombocytopenia. Whereas, **hypoplastic anemia** is characterized by a profound depression of RBCs but normal or slightly decreased WBCs and platelets.

Etiology

AA can be primary (**congenital**, or present at birth) or secondary (**acquired**). The best-known congenital disorder of which AA is an outstanding feature is **Fanconi syndrome**, a rare hereditary disorder characterized by pancytopenia, hypoplasia of the bone marrow, and patchy brown discoloration of the skin resulting from the deposit of melanin. It is associated with multiple congenital anomalies of the musculoskeletal and genitourinary systems. The syndrome appears to be inherited as an autosomal recessive trait with varying penetrance; therefore, affected siblings may demonstrate several different combinations of defects.

Several etiologic factors contribute to the development of acquired AA; however, most of the cases are considered idiopathic (Box 24-4). The following discussion focuses on severe acquired AA, which carries a poorer prognosis and follows a more rapidly fatal course than the primary types.

Box 24-4

Common Causes of Acquired Aplastic Anemia

- Human parvovirus infection, hepatitis, or overwhelming infection
- Irradiation
- Immune disorders, such as eosinophilic fasciitis and hypogammaglobulinemia
- Drugs, such as certain chemotherapeutic agents, anticonvulsants, and antibiotics
- Industrial and household chemicals, including benzene and its derivatives, which are found in petroleum products, dyes, paint remover, shellac, and lacquers
- Infiltration and replacement of myeloid elements, such as in leukemia or the lymphomas
- Idiopathic (In most cases, no identifiable precipitating cause can be found.)

Diagnostic Evaluation

The onset of clinical manifestations, which include anemia, leukopenia, and decreased platelet count, is usually insidious. Definitive diagnosis is determined from bone marrow examination, which demonstrates the conversion of red bone marrow to yellow, fatty bone marrow. Severe AA is based on Camitta's criteria that include less than 25% bone marrow cellularity with at least two of the following findings: absolute granulocyte count less than $500/\text{mm}^3$, platelet count less than $20,000/\text{mm}^3$, and absolute reticulocyte count less than $40,000/\text{mm}^3$ (Miano and Dufour, 2015; Passweg and Marsh, 2010). Moderate AA is defined as more than 25% bone marrow cellularity with the presence of mild or moderate cytopenia (Miano and Dufour, 2015; Shimamura and Guinan, 2009).

Therapeutic Management

The objectives of treatment are based on the recognition that the underlying disease process is failure of the bone marrow to carry out its hematopoietic functions. Therefore, therapy is directed at restoring function to the marrow and involves two main approaches: (1) immunosuppressive therapy (IST) to remove the presumed immunologic functions that prolong aplasia or (2) replacement of the bone marrow through transplantation. Bone marrow transplantation is the treatment of choice for severe AA when a suitable donor exists (see later in chapter).

Antilymphocyte globulin (ALG) or **antithymocyte globulin (ATG)** is the principal drug treatment used for AA. The rationale for using ATG is based on the theory that AA may be a result of autoimmunity. IST is a combination of ATG and cyclosporine that suppress T cell–dependent autoimmune responses by recognizing human lymphocyte cell surface antigen and decreasing the lymphocytes without causing bone marrow suppression (Peinemann and Labeit, 2014). Cyclosporine is administered orally for several weeks to months. ATG usually is administered intravenously over 12 to 16 hours for 4 days after a test dose to check for hypersensitivity. Response to IST is typically delayed and responses generally do not start before 3 to 4 months (Samarasinghe and Webb, 2012). An IST course may be repeated, depending on the reduction in circulating lymphocytes and the patient's response. Because of the hypersensitivity response associated with ATG (i.e., fever, chills, myalgias), methylprednisolone is given intravenously to prevent these side effects. Growth factors, given parenterally, may be used to prevent neutropenic infection and enhance bone marrow production (Passweg and Marsh, 2010). Androgens may be used with ATG to stimulate erythropoiesis if the AA is unresponsive to initial therapies.

HSCT should be considered early in the course of the disease if a compatible donor can be found. Transplantation is more successful when performed before multiple transfusions have sensitized the child to leukocyte and **human leukocyte antigens (HLAs)**. HSCT is associated with an approximately 90% survival rate in patients who receive a bone marrow transplant from an HLA-identical sibling (Hord, 2011; Scheinberg, 2012).

Nursing Care Management

The care of the child with AA is similar to that of the child with leukemia (see [Chapter 25](#)) and includes preparing the child and family for the diagnostic and therapeutic procedures, preventing complications from the severe pancytopenia, and emotionally supporting them in the face of a potentially fatal outcome. Information and support are available from the Aplastic Anemia and MDS International Foundation, Inc.*

The aspects of nursing care are discussed in the section on leukemia (see [Chapter 25](#)), therefore only interventions specific to AA are presented here. The drug ATG is usually administered by way of a central vein. If not, vigilant care must be directed to the IV infusion to prevent extravasation. Meticulous care of the venous access is essential because of the child's susceptibility to infection. Chemotherapeutic agents have been used in the treatment of relapsed patients with AA after unresponsive IST. Many of the side effects associated with chemotherapy such as nausea and vomiting, alopecia, and mucositis are experienced by children receiving treatment for AA. Specialized care is required for AA children who have HSCT that is discussed in [Chapter 25](#).

Defects in Hemostasis

Hemostasis is the process that stops bleeding when a blood vessel is injured. Vascular and plasma clotting factors, as well as platelets, are required. A complex system of clotting, anticlotting, and clot breakdown (**fibrinolysis**) mechanisms exists in equilibrium to ensure clot formation only in the presence of blood vessel injury and to limit the clotting process to the site of vessel wall injury. Dysfunction in these systems leads to bleeding or abnormal clotting. Although the coagulation process is complex, clotting depends on three factors: (1) vascular influence, (2) platelet role, and (3) clotting factors.

Hemophilia

The term **hemophilia** refers to a group of bleeding disorders resulting from congenital deficiency or dysfunction or absence of specific coagulation proteins or factors (Montgomery, Gill, and DiPaola, 2009; Sharathkumar and Pipe, 2008). Although the symptomatology is similar regardless of which clotting factor is deficient, the identification of specific factor deficiencies allows definitive treatment with replacement agents.

In about 80% of all cases of hemophilia, the inheritance pattern is demonstrated as X-linked recessive. The two most common forms of the disorder are **factor VIII deficiency** (hemophilia A, or classic hemophilia) and **factor IX deficiency** (hemophilia B, or Christmas disease) with prevalence of approximately 1 in 5000 and 1 in 20,000 to 30,000 live births, respectively (McLean, Fiebelkorn, Temte, et al, 2013; Sharathkumar and Carcao, 2011; Zimmerman and Valentino, 2013). **Von Willebrand disease (vWD)** is another hereditary bleeding disorder characterized by a deficiency, abnormality, or absence of the protein called *von Willebrand factor (vWF)*. The following discussion is primarily concerned with factor VIII deficiency, which accounts for 80% of all hemophilia cases.

Pathophysiology

The basic defect of hemophilia A is a deficiency of **factor VIII (antihemophilic factor [AHF])**. Factor VIII is produced by the liver and is necessary for the formation of thromboplastin in phase I of blood coagulation (Fig. 24-4). The less factor VIII that is found in the blood, the more severe the disease. Individuals with hemophilia have two of the three factors required for coagulation: vascular influence and platelets. Therefore, they may bleed for longer periods but not at a faster rate.

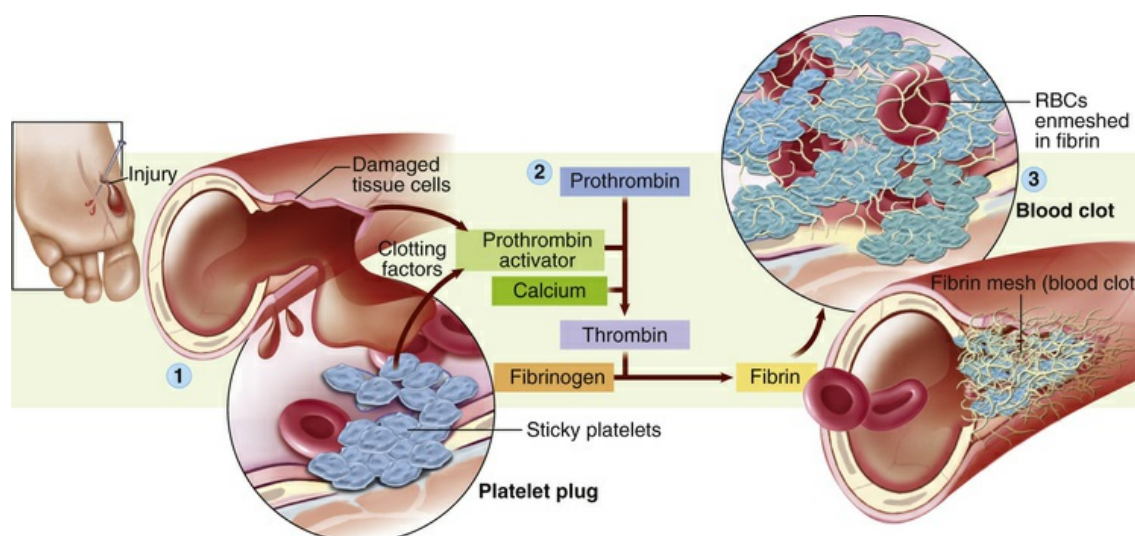

FIG 24-4 Blood clotting. The extremely complex clotting mechanism can be distilled into three basic steps: (1) release of clotting factors from both injured tissue cells and sticky platelets at the injury site (which form a temporary platelet plug); (2) a series of chemical reactions that eventually result in the formation of thrombin; and (3) formation of fibrin and trapping of red blood cells (RBCs) to form a clot. (From Thibodeau GA: *The human body in health and disease*, ed 5, St Louis, 2010, Mosby.)

Subcutaneous and IM hemorrhages are common. Hemarthrosis, which refers to bleeding into a joint cavities, especially the knees, elbows and ankles, is the most frequent form of internal bleeding. Bony changes and crippling deformities occur after repeated bleeding episodes over several years. Early signs of hemarthrosis are a feeling of stiffness, tingling, or achiness in the affected joint, followed by decrease in joint movement. Obvious affected joint signs and symptoms are increased warmth, redness, and swelling and severe pain with loss of movement. Bleeding in the neck, mouth, or thorax is serious because the airway can become obstructed. Intracranial hemorrhage can have fatal consequences and is one of the major causes of death. Hemorrhage anywhere along the GI tract can lead to anemia, and bleeding into the retroperitoneal cavity is especially hazardous because of the large space for blood to accumulate. Hematomas in the spinal cord can cause paralysis.

Diagnostic Evaluation

The diagnosis is usually made from a history of bleeding episodes, evidence of X-linked inheritance (only one third of the cases are new mutations), and laboratory findings. To understand the significance of various tests of hemostasis, it is helpful to recall the usual mechanism to control bleeding (e.g., the function of platelets and clotting factors). The test specific for hemophilia plasma includes factor VIII and factor IX assay, procedures normally performed in specialized laboratories. Other tests are those that depend on specific factors for a reaction to occur, especially the partial thromboplastin time (PTT). Carrier detection is possible in classic hemophilia using deoxyribonucleic acid (DNA) testing and is an important consideration in families in which female offspring may have inherited the trait.

Therapeutic Management

The primary therapy for hemophilia is replacement of the missing clotting factor. The products available are **factor VIII concentrates**, either produced through genetically engineering (recombinant form) or derived from pooled plasma, which are reconstituted with sterile water immediately before use. A synthetic form of vasopressin, **1-deamino-8-d-arginine vasopressin (DDAVP)**, increases plasma factor VIII activity and is the treatment of choice in mild hemophilia and vWD types I and IIA only if the child shows an appropriate response. After DDAVP administration, a threefold to fourfold rise in factor VIII level activity should occur. It is not effective in the treatment of severe hemophilia A, severe vWD, or any form of hemophilia B. Aggressive factor concentrate replacement therapy is initiated to prevent chronic crippling effects from joint bleeding.

Other drugs may be included in the therapy plan, depending on the source of the hemorrhage. Corticosteroids are given for hematuria, acute hemarthrosis, and chronic synovitis. Nonsteroidal antiinflammatory drugs (NSAIDs), such as ibuprofen, are effective in relieving pain caused by synovitis; however, they are occasionally used with caution because they inhibit platelet function (Curry, 2004; Hermans, De Moerloose, Fisher, et al, 2011). Oral administration of ϵ -aminocaproic acid (Amicar) prevents clot destruction. Its use is limited to mouth trauma or surgery with a dose of factor concentrate given first.

A regular program of exercise and physical therapy is an important aspect of management. Physical activity within reasonable limits strengthens muscles around joints and may decrease the number of spontaneous bleeding episodes.

Treatment without delay results in more rapid recovery and a decreased likelihood of complications; therefore, most children are treated at home. The family is taught the technique of venipuncture and to administer the AHF to children older than 2 to 3 years old. The child learns the procedure for self-administration at 8 to 12 years old. Home treatment is highly successful, and the rewards, in addition to the immediacy, are less disruption of family life, fewer school or work days missed, and enhancement of the child's self-esteem and independence.

Prophylactic therapy is periodic factor replacement for children with severe hemophilia to prevent bleeding complications, including arthropathy and spontaneous life-threatening bleeding events (Coppola, Tagliaferri, Di Capua, et al, 2012; Montgomery, Gill, and DiPaola, 2009; Scott and Montgomery, 2011; Zimmerman and Valentino, 2013). Primary prophylaxis involves the infusion of factor VIII concentrate on a regular basis before the onset of joint damage. Secondary prophylaxis involves the infusion of factor VIII concentrate on a regular basis after the child experiences his or her first joint bleed. The administration of infusions differs among treatment centers and may range

from every other day to three times a week for several weeks to promote healing. On-demand factor replacement may be a cost-effective alternative to primary prophylaxis, but prophylaxis decreases the development of joint disease and preserves joint function compared with on-demand factor replacement treatment (Iorio, Marchesini, Marcucci, et al, 2011; Manco-Johnson, Abshire, Shapiro, et al, 2007). Prompt appropriate treatment of hemorrhage and prophylactic therapy are key to excellent care and prevention of long-term morbidity in patients with hemophilia (Lillicrap, 2013; Montgomery, Gill, and DiPaola, 2009).

Prognosis

Although there is no cure for hemophilia, its symptoms can be controlled and its potentially crippling deformities greatly reduced or even avoided. Today many children with hemophilia function with minimal or no joint damage. They have an average life expectancy and are normal in every respect but one—they have a tendency to bleed, which is a significant inconvenience but not necessarily a life-threatening event.

Gene therapy may prove to be a treatment option in the future. Techniques are under development to introduce factor VIII and factor IX genes into hepatocytes, fibroblast, endothelial cells using adeno-associated viral vectors, and other novel ideas for genetic correction (Branchford, Monahan, and Di Paola, 2013; Nienhuis, 2008; Walsh and Batt, 2013). Problems exist with appropriate selection of the vector, identification of the cell for gene expression, and control of side effects (Mátrai, Chuah, and VandenDriessche, 2010; Montgomery, Gill, and DiPaola, 2009; Sharathkumar and Carcoa, 2011).

Quality Patient Outcomes: Hemophilia

- Early recognition of signs and symptoms of hemophilia
- Bleeding episodes prevented
- Bleeding episodes treated early with factor replacement
- Adherence to prophylactic factor replacement program when indicated
- Hemarthrosis prevented when possible with limited joint damage
- Exercise program and physical therapy ongoing

Nursing Care Management

The earlier a bleeding episode is recognized, the more effectively it can be treated. Signs that indicate internal bleeding are especially important to recognize. Children are aware of internal bleeding and are reliable in telling the examiner the location of an internal bleed. In addition to the manifestations described (Box 24-5), the nurse maintains a high level of suspicion when a child with hemophilia shows signs such as headache, slurred speech, loss of consciousness (from cerebral bleeding), and black, tarry stools (from GI bleeding).

Box 24-5

Clinical Manifestations of Hemophilia

- Prolonged bleeding anywhere from or in the body
- Hemorrhage from any trauma: Loss of deciduous teeth, circumcision, cuts, epistaxis, injections
- Excessive bruising, even from a slight injury, such as a fall
- Subcutaneous and intramuscular (IM) hemorrhages
- Hemarthrosis (bleeding into the joint cavities), especially the knees, ankles, and elbows

- Hematomas: Pain, swelling, and limited motion
- Spontaneous hematuria

Prevent Bleeding

The goal of prevention of bleeding episodes is directed toward decreasing the risk of injury. Prevention of bleeding episodes is geared mostly toward appropriate exercises to strengthen muscles and joints and to allow age-appropriate activity. During infancy and toddlerhood, the normal acquisition of motor skills creates innumerable opportunities for falls, bruises, and minor wounds. Restraining the child from mastering motor development can bring more serious long-term problems than allowing the behavior. However, the environment should be made as safe as possible, with close supervision during playtime to minimize incidental injuries.

For older children, the family usually needs assistance in preparing for school. A nurse who knows the family can be instrumental in discussing the situation with the school nurse and in jointly planning an appropriate activity schedule. Because almost all individuals with hemophilia are boys, the physical limitations in regard to active sports may be a difficult adjustment, and activity restrictions must be tempered with sensitivity to the child's emotional and physical needs. Use of protective equipment, such as helmets, face masks, shin/wrist/forearm guards, kneepads, and other equipment appropriate for the type of athletic activity, is encouraged to prevent injury. Children and adolescents with severe hemophilia may participate in noncontact sports, such as aerobic exercise, stretching exercises, swimming, walking, jogging, tennis, golf, fishing, and bowling (Blaney, Forsyth, Zourikian, et al, 2010;). However, the use of prophylaxis to prevent joint hemorrhage or use of exercise during low-impact athletic participation remains unknown (Broderick, Herbert, Latimer, et al, 2012; Michael, Mulder, and Strike, 2014; Ross, Goldenberg, Hund, et al, 2009).

To prevent oral bleeding, some readjustment in terms of dental hygiene may be needed to minimize trauma to the gums, such as use of a water irrigating device, softening the toothbrush in warm water before brushing, or using a sponge-tipped disposable toothbrush. A regular toothbrush should be soft bristled and small.

Because any trauma can lead to a bleeding episode, all persons caring for these children must be aware of their disorder. These children should wear medical identification, and older children should be encouraged to recognize situations in which disclosing their condition is important, such as during dental extraction or injections. Health personnel need to take special precautions to prevent the use of procedures that may cause bleeding, such as IM injections. The subcutaneous route is substituted for IM injections whenever possible. Venipunctures for blood samples are usually preferred for these children. There is usually less bleeding after the venipuncture than after finger or heel punctures. Neither aspirin nor any aspirin-containing compound should be used. Acetaminophen is a suitable aspirin substitute, especially for controlling pain at home.

Recognize and Control Bleeding

As noted, the earlier a bleeding episode is recognized, the more effectively it can be treated. Factor replacement therapy should be instituted according to established medical protocol, and supportive measures may be implemented, such as **RICE**, which stands for *rest, ice, compression, and elevation*. When parents and older children are taught such measures beforehand, they can be prepared to initiate immediate treatment. Plastic bags of ice or cold packs should be kept in the freezer for such emergencies. However, such measures do not take the place of factor replacement.

Prevent Crippling Effects of Bleeding

As a result of repeated episodes of hemarthrosis, incompletely absorbed blood in the joints, and limitation of motion, bone and muscle changes occur that result in flexion contractures and joint fixation. During bleeding episodes, the joint is elevated and immobilized. Active range-of-motion exercises are usually instituted after the acute phase. This allows the child to control the degree of exercise according to the level of discomfort. If an exercise program is instituted in the home, a physical therapist or public health nurse may need to supervise compliance with the regimen. Rarely, orthopedic intervention (such as casting, application of traction, or aspiration of blood) may be necessary to preserve joint function. Diet is also an important consideration because excessive body weight can increase the strain on affected joints, especially the knees, and predispose the child

to hemarthrosis. Consequently, calories need to be supplied in accordance with energy requirements.

Support the Family and Prepare for Home Care

Genetic counseling is essential as soon as possible after diagnosis. Unlike many other disorders in which both parents carry the trait, the feeling of responsibility for this condition usually rests with the mother. Unless she has an opportunity to discuss her feelings, the couple's relationship can suffer. Technology is now available to identify classic hemophilia carriers using DNA testing and may reduce the anxiety regarding childbearing in women who may be at risk of carrying the defective gene. Factor concentrates have greatly changed the outlook for these children by minimizing bleeding and allowing the child to live a normal, unrestricted life. Children are taught to take responsibility for their disease at an early age. They learn their limitations, preventive measures, and self-administration of the prophylactic AHF.

The needs of families who have children with hemophilia are best met through a comprehensive team approach of physicians (pediatrician, hematologist, orthopedist), nurse practitioner, nurse, social worker, and physical and psychological therapist. Parent-group discussions are beneficial in meeting the needs that are often best met by similarly affected families. For example, with the improved prognosis for these children, parents and adolescents with hemophilia face vocational and financial problems in addition to concern over future childbearing. This can be disastrous in terms of the cost of treatment, which can exceed \$100,000 a year. Financial support is particularly important. The National Hemophilia Foundation* and the Canadian Hemophilia Society† provide numerous services and publications for both health providers and families.

Children who have become infected with human immunodeficiency virus (HIV) through transfusions and factor replacement products are faced with the consequences of this dreaded disease. Consequently, they need the support of health professionals, especially in the areas of safe sexual practices to avoid disease transmission and public education regarding acquired immune deficiency syndrome (AIDS) and ways to deal with public reactions to persons who have AIDS.

Immune Thrombocytopenia (Idiopathic Thrombocytopenic Purpura)

Idiopathic thrombocytopenic purpura (ITP), the formerly used term because purpura is an infrequent sign at presentation, is now referred to as *immune thrombocytopenia* (Rodeghiero, Stasi, Gernsheimer, et al, 2009). ITP is an acquired hemorrhagic disorder characterized by (1) **thrombocytopenia**, (2) absence or minimal signs of bleeding (easy bruising, mucosal bleeding, petechiae) in most childhood cases, and (3) normal bone marrow with normal or increased number of immature platelets (**megakaryocytes**) and **eosinophils**. Although all causes of ITP are not known, it is understood that ITP involves the evolution of antibodies against multiple platelet antigens, leading to reduced platelet survival and impaired platelet production (Consolini, 2011; McCrae, 2011). ITP is the most common thrombocytopenia of childhood, with the majority of cases in children younger than 10 years old with the peak incidence between 1 to 5 years old (Consolini, 2011; McCrae, 2011; Montgomery and Scott, 2011).

The disease occurs in one of two forms: (1) an acute, self-limiting course or (2) a chronic condition (>12 months' duration). The acute form occurs most commonly after upper respiratory tract infections; after the childhood diseases measles, rubella, mumps, and chickenpox; or after infection with human parvovirus.

Diagnostic Evaluation

The diagnosis is suspected on the basis of clinical manifestations (Box 24-6). In ITP, the platelet count is reduced to less than 20,000/mm³; therefore, tests that depend on platelet function, such as the tourniquet test, bleeding time, and clot retraction, are abnormal. There is no definitive test that establishes a diagnosis of ITP; several tests are usually performed to rule out other disorders in which thrombocytopenia is a manifestation, such as systemic lupus erythematosus, lymphoma, or leukemia.

Box 24-6

Clinical Manifestations of Immune Thrombocytopenia (Idiopathic Thrombocytopenic Purpura)

Easy Bruising

- Petechiae
- Ecchymoses
- Most often over bony prominences

Bleeding from Mucous Membranes

- Epistaxis
- Bleeding gums
- Internal hemorrhage evidenced by the following:
 - Hematuria
 - Hematemesis
 - Melena
 - Hemarthrosis
 - Menorrhagia
 - Hematomas over lower extremities

Therapeutic Management

Management of ITP is primarily supportive, because the disease is self-limiting in the majority of cases. Activity is restricted at the onset while the platelet count is low and while active bleeding or progression of lesions is occurring. Treatment for acute presentation is symptomatic and has included prednisone, intravenous immunoglobulin (IVIG), and anti-D antibody. These are not curative therapies. **Anti-D antibody** is a plasma-derived immunoglobulin that causes a transient hemolytic anemia in Rh (D)-positive patients with ITP. With the clearance of antibody-coated RBCs, there is prolonged survival of platelets resulting from the blockade of the Fc receptors of the reticuloendothelial cells. The platelet count usually increases approximately 48 hours after an infusion of anti-D antibody; therefore, it is not appropriate therapy for patients who are actively bleeding. The benefits of choosing anti-D antibody IV therapy over prednisone or IVIG are that anti-D antibody can be given in one dose over 5 to 10 minutes and is significantly less expensive than IVIG. Historically, patients who are treated with prednisone may first undergo a bone marrow examination to rule out leukemia, which is controversial because leukemia rarely manifests with low platelet count alone (Montgomery and Scott, 2011; Wilson, 2009). Therefore, the use of anti-D antibody and IVIG alleviates the need for a bone marrow examination. Before receiving the initial dose of anti-D antibody, patients must meet certain criteria (Box 24-7). Premedication with acetaminophen 5 to 10 minutes before the infusion is recommended.

Nursing Tip

After administration of anti-D antibody, observe the child for a minimum of 1 hour and maintain a patent IV line. Obtain baseline vital signs measurements before the infusion and again 5, 20, and 60

minutes after beginning the infusion. If fever, chills, and headache occur during or shortly after the infusion, the nurse should administer acetaminophen, diphenhydramine (Benadryl), and/or hydrocortisone (Solu-Cortef) as ordered and observe the patient for an additional hour after the reaction.

Box 24-7

Criteria for Anti-D Antibody Therapy

- Age between 1 and 19 years old; Rh(D)-positive blood type
- Normal WBC count and hemoglobin level for age; platelet count of 20,000/mm³
- No active mucosal bleeding
- No history of reaction to plasma products
- No known immunoglobulin A deficiency
- No concurrent infection
- Absence of Evans syndrome (characterized by the combination of ITP and autoimmune hemolytic anemia)
- No suspicion of lupus erythematosus or other collagen vascular disorder
- No splenectomy

ITP, Idiopathic thrombocytopenic purpura; *WBC*, white blood cell.

Splenectomy is for patients who have chronic ITP that is not responsive to pharmacologic management and have increased risk of severe hemorrhage. It is an option associated with long-term remission for these children and reduces the risk of hemorrhage (McCrae, 2011; Montgomery and Scott, 2011; Wilson, 2009). Before splenectomy is considered, it is recommended to wait until the child is older than 5 years of age because of the increased risk of bacterial infection. Administration of pneumococcal, meningococcal, and *H. influenzae* vaccines are recommended before splenectomy (see Immunizations, Chapter 7). The child also receives penicillin prophylaxis after splenectomy. The length of prophylactic therapy is controversial, but in general, a minimum of 3 years of therapy is recommended.

Prognosis

The majority of children have a self-limited course without major complications. Some children may develop chronic ITP and require ongoing therapy. A splenectomy may modify the disease process, and the child may be asymptomatic.

Quality Patient Outcomes: Idiopathic Thrombocytopenic Purpura

- Serious bleeding episode prevented
- Activities that increase risk for serious bleeding avoided
- Treatment administered without serious side effects

Nursing Care Management

Nursing care is largely supportive and should include teaching regarding possible side effects of therapy and limitation in activities while the child's platelet count is less than 50,000/mm³

(Consolini, 2011). Children with ITP should not participate in *any* contact sports, bike riding, skateboarding, in-line skating, gymnastics, climbing, or running. Parents are encouraged to engage their children in quiet activities and to prevent any injuries, especially to the child's head. Instruct the parents to obtain prompt medical evaluation if the child sustains head or abdominal trauma. As in any condition with an uncertain outcome, the family needs emotional support.

Disseminated Intravascular Coagulation

Disseminated intravascular coagulation (DIC), also known as **consumption coagulopathy**, is characterized by diffuse fibrin deposition in the microvasculature, consumption of coagulation factors, and endogenous generation of thrombin and plasmin. DIC is a secondary disorder of coagulation that occurs as a complication of a number of pathologic processes, such as hypoxia, acidosis, shock, endothelial damage (e.g., burns), and many severe systemic diseases (e.g., congenital heart disease, necrotizing enterocolitis, gram-negative bacterial sepsis, rickettsial infections, and some severe viral infections). The hallmarks of this disorder are bleeding and clotting that occurs simultaneously.

Pathophysiology

DIC occurs when the first stage of the coagulation process is abnormally stimulated. Although no well-defined sequence of events occurs, two distinct phases can be identified. First, when the clotting mechanism is triggered in the circulation, thrombin is generated in greater amounts than can be neutralized by the body. Consequently, there is rapid conversion of fibrinogen to fibrin, with aggregation and destruction of platelets. Local and widespread fibrin deposition occurs in blood vessels that causes obstruction of blood flow with eventual necrosis of tissues. Concurrently, the fibrinolytic mechanism is activated, which causes extensive destruction of clotting factors. With a deficiency of clotting factors, the child is vulnerable to uncontrollable hemorrhage into vital organs. An additional complication is damage and hemolysis of RBCs.

Diagnostic Evaluation

DIC is suspected when the patient has an increased tendency to bleed (Box 24-8). Hematologic findings include prolonged prothrombin time, PTT, thrombin time, and increased D-dimer antigen (byproduct of fibrinolytic process). There is a profoundly depressed platelet count, fragmented RBCs, and depleted fibrinogen.

Box 24-8

Clinical Manifestations of Disseminated Intravascular Coagulation

Petechiae

Purpura

Bleeding from openings in the skin

- Venipuncture site
- Surgical incision

Bleeding from umbilicus, trachea (newborn)

Evidence of gastrointestinal (GI) bleeding

Hypotension

Organ dysfunction from infarction and ischemia

Therapeutic Management

Treatment of DIC is directed toward control of the underlying or initiating cause, which in most instances stops the coagulation problem spontaneously. Platelets and fresh-frozen plasma may be needed to replace lost plasma components, especially in children whose underlying disease remains uncontrolled. Extremely ill newborn infants may require exchange transfusion with fresh blood. The administration of IV heparin to inhibit thrombin formation is most often restricted to patients who have no response to treatment of the underlying disease or replacement of coagulation factors and platelets.

Nursing Care Management

The goals of nursing care are to be aware of the possibility of DIC in severely ill children and to recognize signs that might indicate its presence. The skills needed to monitor IV infusion and blood transfusions and to administer heparin are the same as for any child receiving these therapies. (See [Chapter 17](#) for care of children with life-threatening illnesses.)

Epistaxis (Nosebleeding)

Isolated and transient episodes of epistaxis, or nosebleeding, are common in childhood. The nose, especially the septum, is a highly vascular structure, and bleeding usually results from direct trauma, including blows to the nose, foreign bodies, and nose picking, or from mucosal inflammation associated with allergic rhinitis and upper respiratory tract infections. The bleeding usually stops with minimal pressure and requires no medical evaluation or therapy.

Recurrent epistaxis and severe bleeding may indicate an underlying disease, particularly vascular abnormalities, leukemia, thrombocytopenia, and clotting factor deficiency diseases (e.g., hemophilia, vWD). Nosebleeds are sometimes associated with administration of aspirin, even in normal amounts. Persistent episodes of epistaxis require medical evaluation.

Nursing Care Management

In the event of a nosebleed, an essential intervention is to remain calm. Otherwise, the child will become more agitated, the blood pressure will increase, and the child will not cooperate. Although in most instances a nosebleed is not serious, it can be upsetting to family members as well. They need reassurance that the loss of blood is not serious and that the bleeding usually stops in less than 10 minutes with nasal pressure.

To control the bleeding, the child is instructed to sit up and lean forward (not to lie down or hold head backwards) to avoid aspiration of blood. Most of the nosebleeding originates in the anterior part of the nasal septum and can be controlled by applying pressure to the soft lower portion of the nose with the thumb and forefinger (see [Emergency Treatment](#) box). During this time, the child breathes through the mouth.

Emergency Treatment

Epistaxis

- Have child sit up and lean forward (not lie down).
- Apply continuous pressure to nose with thumb and forefinger for at least 10 minutes.
- Insert cotton or wadded tissue into each nostril and apply ice or cold cloth to bridge of nose if bleeding persists.
- Keep child calm and quiet.

In the event that hemorrhage continues, the child should be evaluated by a practitioner, who may pack the nose with epinephrine-soaked gauze. After a nosebleed, a water-soluble jelly can be inserted into each nostril to prevent crusting of old blood and to lessen the likelihood of the child's picking at the nose and restarting the hemorrhage. If a child has numerous nosebleeds, factors

believed to increase the likelihood of bleeds are eliminated, such as discouraging nose picking or altering the household humidity by placing a cool-mist humidifier in the child's room. Repeated bleeding episodes lasting longer than 30 minutes may be an indication to refer the child for evaluation for the possibility of a bleeding disorder.

Immunologic Deficiency Disorders

A number of disorders can cause profound, often life-threatening alterations within the body's immune system. The most serious are those conditions that completely depress immunity, such as severe combined immunodeficiency disease (SCID). However, the one disorder that generates the most anxiety, within both the family and the community at large, is HIV infection and the subsequent development of AIDS.

Several classifications of immune dysfunction exist. AIDS, SCID, and **Wiskott-Aldrich syndrome (WAS)** are syndromes wherein the body is unable to mount an immune response. The immune response can also be misdirected. In **autoimmune disorders**, antibodies, macrophages, and lymphocytes attack healthy cells.

Human Immunodeficiency Virus Infection and Acquired Immune Deficiency Syndrome

HIV infection and AIDS have generated intense medical investigation and constitute one of world's most serious medical, public health, and social challenges of our time (Ezekowitz, 2009; Joint United Nations Programme on HIV/AIDS (UNAIDS), 2013). Research has led to early diagnosis and improved medical treatments for HIV infection, changing this disease from a rapidly fatal one to a chronic disease.

Epidemiology

The first AIDS cases in the pediatric population in the United States were identified in children born to HIV-infected mothers and in children who received blood products. More than 90% of these children acquired the disease perinatally from their mothers. Smaller numbers of children were infected through the transfusion of contaminated blood or blood products before establishment of screening blood products routinely for HIV. Currently, the principal modes of HIV transmission to the pediatric population are mother-to-child transmission and adolescent risky behaviors, such as sexual activity and IV drug use (Siberry, 2014; Simpkins, Siberry, and Hutton, 2009; Joint United Nations Programme on HIV/AIDS (UNAIDS), 2013).

The estimated number of children with perinatally acquired AIDS peaked in 1992; subsequent years have seen significant declines. This trend is a result of implementation of recommended HIV counseling and voluntary testing practices and the use of highly active antiretroviral therapy (HAART) to prevent perinatal transmission. HAART, typically a combination of two nucleoside analog reverse transcriptase inhibitors and a non-nucleoside reverse transcriptase inhibitor protease inhibitor or integrase inhibitor, is the current standard in the United States for the treatment of HIV-infected pregnant women, and it has significantly reduced the transmission of HIV (Hayden, 2013; Siberry, 2014; Siegfried, van der Merwe, Brocklehurst, et al, 2011; Simpkins, Siberry, and Hutton, 2009). Routine HIV counseling and voluntary testing using the opt-in (must agree) or opt-out approach (right of refusal) is the recommended standard of care for pregnant women in the United States (Centers for Disease Control and Prevention, 2006; 2014b; American Academy of Pediatrics Committee on Pediatric AIDS, 2008; Siberry, 2014; Simpkins, Siberry, and Hutton, 2009).

Etiology

HIV is a retrovirus that is transmitted by lymphocytes and monocytes. It is found in the blood, semen, vaginal secretions, and breast milk. It has an incubation or latency period of months to years (Yogev and Chadwick, 2011). There are different strains of HIV. Whereas HIV-2 is prevalent in Africa, HIV-1 is the dominant strain in the United States and elsewhere. **Horizontal transmission** of HIV occurs through intimate sexual contact or parenteral exposure to blood or body fluids containing visible blood. **Perinatal (vertical) transmission** occurs when an HIV-infected pregnant woman passes the infection to her infant. There is no evidence that *casual* contact between infected and uninfected individuals can spread the virus.

Pathophysiology

The HIV virus primarily infects a specific subset of T lymphocytes, the CD₄⁺ T cells, but it can also

invade cells of the monocyte-macrophage lineage. The virus takes over the machinery of the CD₄⁺ lymphocyte, using it to replicate itself, rendering the CD₄⁺ cell dysfunctional. The CD₄⁺ lymphocyte count gradually decreases over time, at some point, physical symptoms appear. The count eventually reaches a critical level below which there is substantial risk of opportunistic illnesses, followed by death.

Clinical Manifestations

Common clinical manifestations of HIV infection in children are varied (Box 24-9). The diagnosis of AIDS is associated with certain illnesses or conditions. The most common AIDS-defining conditions observed among American children are listed in Box 24-10. Other problems in these children may include short stature, malnutrition, and cardiomyopathy. CNS abnormalities resulting from HIV infection may include neuropsychologic deficits; developmental disabilities; and deficits in motor skills, communication, and behavioral functioning.

Box 24-9

Common Clinical Manifestations of Human Immunodeficiency Virus Infection in Children

- Lymphadenopathy
- Hepatosplenomegaly
- Oral candidiasis
- Chronic or recurrent diarrhea
- Failure to thrive
- Developmental delay
- Parotitis

Box 24-10

Common Defining Conditions for Acquired Immune Deficiency Syndrome in Children

- *Pneumocystis carinii* pneumonia (PCP)
- Lymphoid interstitial pneumonitis (LIP)
- Recurrent bacterial infections
- Wasting syndrome
- Candidal esophagitis
- Human immunodeficiency virus (HIV) encephalopathy
- Cytomegalovirus disease
- *Mycobacterium avium-intracellulare* complex infection
- Pulmonary candidiasis
- Herpes simplex disease

- Cryptosporidiosis

Diagnostic Evaluation

For children 18 months of age and older, the HIV enzyme-linked immunosorbent assay (ELISA) and Western blot immunoassay are performed to determine HIV infection. In infants born to HIV-infected mothers, results of these assays are positive because of the presence of maternal antibodies derived transplacentally. Maternal antibodies may persist in the infant up to 18 months of age. Therefore, other diagnostic tests are used—most commonly the HIV polymerase chain reaction (PCR) for detection of proviral DNA. A controlled-center study tested recombinase polymerase amplification (RPA) as a novel technology that is ideal for early infant diagnosis of HIV-1, because it amplifies target DNA in less than 20 minutes at a constant temperature without the need for complex thermocycling equipment needed for the PCR assay (Boyde, Lehman, Lillis, et al, 2013). RPA may become a beneficial yet inexpensive test for early diagnosis of HIV-infected individuals worldwide. There is a need for further research to compare of RPA assay to the gold standard PCR-based assay in a real-world setting. With these techniques, almost all infected infants can be diagnosed between 1 and 6 months old (Siberry, 2014; Yogev and Chadwick, 2011).

HIV testing is entering a new era in the United States because of Food and Drug Administration approval of (1) combination tests that detect both HIV antigen and antibody, and (2) tests that accurately differentiate HIV-1 from HIV-2 antibodies (Centers for Disease Control and Prevention, 2014a). With the identification of HIV antigen, individuals may be diagnosed with HIV infection prior to development of symptoms.

The Centers for Disease Control and Prevention (1994) has developed a classification system to describe the spectrum of HIV disease in children (Table 24-2). The system indicates the severity of clinical signs and symptoms and the degree of immunosuppression. The non-symptomatic category includes either no signs and symptoms or one of the conditions listed in the mildly symptomatic category. Mildly symptomatic category includes signs and symptoms, such as lymphadenopathy, parotitis, hepatosplenomegaly, dermatitis, and recurrent or persistent sinusitis or otitis media. Moderately symptomatic category includes signs and symptoms such as lymphoid interstitial pneumonitis (LIP) and a variety of organ-specific dysfunctions or infections. Severely symptomatic category includes signs and symptoms, such as AIDS-defining illnesses with the exception of LIP. Children with LIP have a better prognosis than those with other AIDS-defining illnesses. In children whose HIV infection is not yet confirmed, the letter *E* (vertically exposed) is placed in front of the classification. The immune categories are based on CD₄⁺ lymphocyte counts and percentages. Age adjustment of these numbers is necessary because normal counts, which are relatively high in infants, decline steadily until 6 years of age, which is when they reach adult norms.

TABLE 24-2
Pediatric Human Immunodeficiency Virus Infection Classification*

| Immunologic Category | N: No Signs or Symptoms | A: Mild Signs or Symptoms | B: Moderate Signs or Symptoms [†] | C: Severe Signs or Symptoms [†] |
|----------------------------------|-------------------------|---------------------------|--|--|
| No evidence of suppression | N1 | A1 | B1 | C1 |
| Evidence of moderate suppression | N2 | A2 | B2 | C2 |
| Severe suppression | N3 | A3 | B3 | C3 |

*Children whose human immunodeficiency virus (HIV) infection status is not confirmed are classified by using this table with the letter *E* (for perinatally exposed) placed before the appropriate classification code (e.g., EN2).

[†]Both category C and lymphoid interstitial pneumonitis (LIP) in category B are reportable to state and local health departments as acquired immune deficiency syndrome (AIDS).

From Centers for Disease Control and Prevention: 1994 Revised classification system for human immunodeficiency virus infection in children less than 13 years of age, *MMWR Recomm Rep* 43(RR-12):1–10, 1994.

Therapeutic Management

The goals of therapy for HIV infection include slowing the growth of the virus, preventing and treating opportunistic infections, and providing nutritional support and symptomatic treatment. **Antiretroviral drugs** work at various stages of the HIV life cycle to prevent reproduction of functional new virus particles. Although not a cure, these drugs can suppress viral replication, prevent further deterioration of the immune system, and delay disease progression. Classes of antiretroviral agents include nucleoside reverse transcriptase inhibitors (e.g., zidovudine, didanosine, stavudine, lamivudine, abacavir), nonnucleoside reverse transcriptase inhibitors (e.g.,

nevirapine, delavirdine, efavirenz), nucleotide reverse transcriptase inhibitors (e.g., adefovir), and protease inhibitors (e.g., indinavir, saquinavir, ritonavir, nelfinavir, amprenavir). Combinations of antiretroviral drugs are used to stall the emergence of drug resistance. Antiretroviral therapy regimens and guidelines are continually evolving. Therapy is lifelong, making adherence difficult. Laboratory markers (CD_4^+ lymphocyte count, viral load) assist in monitoring both disease progression and response to therapy.

Pneumocystis carinii pneumonia (PCP) is the most common opportunistic infection of children infected with HIV. It occurs most frequently between 3 and 6 months old. All infants born to HIV-infected women should receive prophylaxis by 6 weeks old until HIV infection is reasonably excluded (Siberry, 2014; Simpkins, Siberry, and Hutton, 2009). Trimethoprim/sulfamethoxazole (TMP-SMZ) is the agent of choice. If adverse effects are experienced with TMP-SMZ, dapsone or pentamidine can be used.

Prophylaxis is often employed for other opportunistic infections, such as disseminated *Mycobacterium avium-intracellulare* complex, candidiasis, or herpes simplex. Intravenous gamma globulin (IVGG) has been helpful in preventing recurrent or serious bacterial infections in some HIV-infected children.

Immunization against common childhood illnesses, including the pneumococcal and influenza vaccines, is recommended for all children exposed to and infected with HIV (American Academy of Pediatrics Committee on Pediatric AIDS, 2000b; Leggat, Iyer, Ohtola, et al, 2015; Simpkins, Siberry, and Hutton, 2009). Varicella (chickenpox) vaccine and measles, mumps, and rubella (MMR) vaccine can be administered if there is no evidence of severe immunocompromise. Because antibody production to vaccines may be poor or decrease over time, immediate prophylaxis after exposure to several vaccine-preventable diseases (e.g., measles, varicella) is warranted. It should be recognized that children receiving IVGG prophylaxis may not respond to the MMR vaccine if given in close proximity to the IVGG dose (McLean, Fiebelkorn, Temte, et al, 2013).

HIV infection often leads to marked failure to thrive and multiple nutritional deficiencies. Nutritional management may be difficult because of recurrent illness, diarrhea, and other physical problems. The nurse should implement intensive nutritional interventions if the child's growth begins to slow or weight begins to decrease.

Prognosis

Early recognition and improved medical care have changed HIV disease from a rapidly fatal illness to a chronic disease. After the introduction of combination antiretroviral therapy, the numbers of new AIDS cases and deaths declined substantially. In the United States, from 2009 to 2013, the annual estimated number and rate of deaths of HIV-infected children younger than 13 years old has remained stable (Centers for Disease Control and Prevention, 2015; Simpkins, Siberry, and Hutton, 2009). In contrast, adolescents and young adults (13 to 24 years old) with AIDS that represent a minority of cases in the US ($\approx 5\%$) constitute one of the fastest growing groups of newly infected persons in the country (Simpkins, Siberry, and Hutton, 2009; Yogev and Chadwick, 2011).

Quality Patient Outcomes: Human Immunodeficiency Virus

- Early recognition of human immunodeficiency virus (HIV) infection
- HIV infection slowed or maintained
- Growth and development promoted
- No infectious complications or cancer development
- Adherence to antiretroviral therapy
- Prolonged survival
- Quality of life supported

Nursing Care Management

Education concerning transmission and control of infectious diseases, including HIV infection, is essential for children with HIV infection and anyone involved in their care. The basic tenets of standard precautions should be presented in an age-appropriate manner, with careful consideration of the educational levels of the individuals (see [Infection Control, Chapter 20](#)). Safety issues, including appropriate storage of special medications and equipment (e.g., needles and syringes), are emphasized.

Unfortunately, relatives, friends, and others in the general public may be fearful of contracting HIV infection, and criticism and ostracism of the child and family may occur. In an effort to protect the child and deal with fears of the community, the family may limit the child's activities outside the home. Although certain precautions are justified in limiting exposure to sources of infections, they must be tempered with concern for the child's normal developmental needs. Both the family and the community need ongoing education about HIV to dispel many of the myths that have been perpetuated by uninformed persons.*

Prevention is a key component of HIV education. Educating adolescents about HIV is essential in preventing HIV infection in this age group. Education should include the routes of transmission, the hazards of IV and other recreational drug use, and the value of sexual abstinence and safe sex practices. Such education should be a part of anticipatory guidance provided to all adolescent patients. Nurses should also encourage adolescents at risk to undergo HIV counseling and testing. In addition to identifying infected teenagers and getting them into care, such counseling affords adolescents an opportunity to learn about, and possibly change, their risky behaviors.

Because approximately 20% to 25% of individuals living with HIV infection are unaware of their positive status, US Preventive Services Task Force recommended clinicians screen for HIV infection in persons 15 to 64 years old and all of those individuals who are at increased risk regardless of age ([Moyer and US Preventive Services Task Force, 2013](#)). US Preventive Services Task Force's recommendation was supported by a report on two health care settings that screened 32,534 individuals from 2011 to 2013 of which 148 tested HIV-positive with 120 (81%) linked to HIV medical care ([Lin, Dietz, Rodriguez, et al, 2014c](#)). Early detection of HIV-infected individuals and linking them to medical care and counseling through screening programs in the health care setting provides effective treatment and decreases the transmission of HIV ([Suthar, Ford, Bachanas, et al, 2013](#)).

The multiple complications associated with HIV disease are potentially painful ([Ezekowitz, 2009](#)). Aggressive pain management is essential for these children to have an acceptable quality of life. Their pain may be caused by infections (e.g., otitis media, dental abscess), encephalopathy (e.g., spasticity), adverse effects of medications (e.g., peripheral neuropathy), or an unknown source (e.g., deep musculoskeletal pain). Pain is not only related to the disease processes but also to various treatments these children often undergo, including venipunctures, lumbar punctures, biopsies, and endoscopies. Ongoing assessment of pain is crucial and is most easily accomplished in older children who are able to communicate. Nonverbal and developmentally delayed children are more difficult to assess. The nurse should be alert for signs of pain, such as emotional detachment, lack of interactive play, irritability, and depression. Effective pain management depends on the appropriate use of pharmacologic agents, including EMLA or LMX cream, acetaminophen, NSAIDs, muscle relaxants, and opioids. Tolerance to opioids may indicate increased dosing; monitored use ensures safety. Nonpharmacologic interventions (e.g., guided imagery, hypnosis, relaxation, and distraction techniques) are useful adjuncts.

Common psychosocial concerns include disclosing the diagnosis to the child, making custody plans when the parent is infected, and anticipating the loss of a family member. Other stressors may include financial difficulties, HIV-associated stigma, attempts to keep the diagnosis secret, infection of other family members, and any losses associated with HIV. Most mothers of these children are single mothers who are also HIV infected. As primary caretakers, they often attend to the needs of their child first, neglecting their own health in the process. The nurse should encourage the mother to receive regular health care. As an integral part of the multidisciplinary team, the nurse is necessary for the successful management of the complex medical and social problems of these families.

Children with HIV infection attend daycare centers and schools. It is well established that the risk of HIV transmission in these settings is minimal. These institutions are required to follow Centers for Disease Control and Prevention and Occupational Safety and Health Administration guidelines

for infection control measures. Standard precautions describing proper management of blood and body fluids should also be followed. It is recommended that school personnel receive current HIV information and include it in the health education curriculum for kindergarten through twelfth grade ([American Academy of Pediatrics Committee on Pediatric AIDS and Committee on Infectious Diseases, 1999](#); [American Academy of Pediatrics Committee on Pediatric AIDS, 2000a](#)). School nurses play a vital role in educating the school staff, students, and parents. They are also invaluable in monitoring the needs of known affected children.

Confidentiality is another major issue in daycare or school attendance. Parents and legal guardians have the right to decide whether they inform the daycare or school of their child's HIV diagnosis. Unfortunately, myths about HIV infection continue to exist, and the family often wishes to avoid any potential criticism or ostracism of the child.

Severe Combined Immunodeficiency Disease

SCID is a defect characterized by absence of both humoral and cell-mediated immunity. The terms **Swiss-type lymphopenic agammaglobulinemia** that refers to the autosomal recessive form of the disease and **X-linked lymphopenic agammaglobulinemia** have been used to describe this disorder, which, as the names imply, can follow either mode of inheritance.

The most common manifestation is susceptibility to infection early in life, most often in the first month. The disorder in children is characterized by chronic infections, failure to completely recover from infections, frequent reinfection, and infection with unusual agents. Failure to thrive is a consequence of the persistent illnesses.

Diagnosis is usually based on a history of recurrent, severe infections from early infancy; a familial history of the disorder; and specific laboratory findings, which include lymphopenia, lack of lymphocyte response to antigens, and absence of plasma cells in the bone marrow. Documentation of immunoglobulin deficiency is difficult during infancy because of the normally delayed response of infants in producing their own immunoglobulins and maternal transfer of immunoglobulin G (IgG).

Therapeutic Management

The definitive treatment for SCID is HSCT. If the condition is diagnosed at birth or within the first 3 months of life, more than 95% of cases can be treated successfully with HLA-identical or T-cell depleted haploidentical donor (usually a parent), or a matched unrelated donor bone marrow stem cells transplant ([Bonilla and Geha, 2009](#); [Buckley, 2011](#)). Other approaches to management of SCID include providing passive immunity with IVIG infusions and maintaining child in a sterile environment. PCP prophylaxis is used to augment the humoral immunity until the transplant is performed. Several investigators are attempting gene therapy with some success, offering hope that gene therapy may eventually be the treatment of choice for cases of SCID ([Bonilla and Geha, 2009](#); [Buckley, 2011](#)).

Nursing Care Management

Nursing care focuses on preventing infection and supporting the child and family. The care is consistent with that needed for HSCT for any condition (see earlier in this chapter). Because the prognosis for SCID is very poor if a compatible bone marrow donor is not available, nursing care is directed at supporting the family in caring for a child with a life-threatening illness (see [Chapter 17](#)). Genetic counseling is essential because of the modes of transmission in either form of the disorder.

Wiskott-Aldrich Syndrome

WAS is a congenital X-linked recessive disorder characterized by a triad of abnormalities: thrombocytopenia, eczema, and immunodeficiency of selective functions of B lymphocytes and T lymphocytes. An abnormal gene has been identified on the proximal arm of the X chromosome and designated the WAS protein ([Bonilla and Geha, 2009](#); [Buckley, 2011](#)). At birth, the presenting feature may be increased bleeding at the circumcision site or bloody diarrhea as a result of thrombocytopenia. As the child grows older, recurrent infection and eczema become more severe, and the bleeding becomes less frequent.

Eczema is typical of the allergic type and readily becomes superinfected. Chronic infection with herpes simplex is a frequent problem and may lead to chronic keratitis of the eye with loss of vision. Chronic pulmonary disease, sinusitis, and otitis media result from repeated infections. In children who survive the bleeding episodes and overwhelming infections, malignancy presents an additional risk to survival. Medical treatment involves:

- Counteracting the bleeding tendencies with platelet transfusions
- Administering IVIG to provide passive immunity
- Administering prophylactic antibiotics to prevent and control infection
- Providing aggressive local therapy for the eczema

WAS is usually cured with HSCT and should be performed as early as possible ([Albert, Notarangelo and Ochs, 2011](#); [Buckley, 2011](#); [Mahlaoui, Pellier, Mignot, et al, 2013](#)). Several clinical trials focused on replacing the WAS gene are being conducted to determine the most effective vector ([Albert, Notarangelo, and Ochs, 2011](#)).

Nursing Care Management

Because of the poor prognosis for these children, the main nursing consideration is supporting the family in the care of a fatally ill child (see [Chapter 17](#)). Physical care should be directed at controlling the problems imposed by the disorder. The measures used to control bleeding are similar to those for hemophilia and vWD (see previous discussions). Another major goal is prevention or control of infection. Because eczema is a troublesome problem, nursing measures specific to this condition are especially important. The genetic implications of this X-linked recessive disorder differ little from those of any other X-linked disease.

Technologic Management of Hematologic and Immunologic Disorders

Blood Transfusion Therapy

Technologic advances in blood banking and transfusion medicine enable the administration of only the blood component needed by the child, such as packed RBCs in anemia or platelets for bleeding disorders. Regardless of the blood component administered, the nurse must be aware of the possible transfusion reactions. [Table 24-3](#) summarizes the major complications of transfusions, the signs and symptoms typically associated with each, and nursing responsibilities. General guidelines that apply to all transfusions include:

- Take vital signs, including blood pressure, *before* administering blood to establish baseline data for pretransfusion and posttransfusion comparison; 15 minutes after initiation; hourly while blood is infusing; and on completion of transfusion.
- Check the identification of the recipient along with his/her blood type and group against the donor, regardless of the blood product being used.
- Administer the first 50 ml of blood or initial 20% of the volume (whichever is smaller) *slowly* and stay with the child.
- Administer with normal saline on a piggyback setup or have normal saline available.
- Administer blood through an appropriate filter to eliminate particles in the blood and prevent the precipitation of formed elements; gently shake the container frequently.
- Use blood within 30 minutes of its arrival from the blood bank; if it is not used, return it to the blood bank—do not store it in the regular unit refrigerator.
- Infuse a unit of blood (or the specified amount) within 4 hours. If the infusion will exceed this time, the blood should be divided into appropriately sized quantities by the blood bank and the unused portion refrigerated under controlled conditions.
- If a reaction of any type is suspected, stop the transfusion, take vital signs, maintain a patent IV line with normal saline and new tubing, notify the practitioner, and do not restart the transfusion until the child's condition has been medically evaluated.

TABLE 24-3
Nursing Care of the Child Receiving Blood Transfusions

| Complication | Signs and Symptoms | Precautions and Nursing Responsibilities |
|--|--|--|
| Immediate Reactions | | |
| Hemolytic reactions Most severe type but rare | Sudden, severe headache Chills | Identify donor and recipient blood types and groups before transfusion is begun; verify with another nurse or practitioner. |
| Incompatible blood | Shaking | Transfuse blood slowly for the first 15 to 20 minutes or initial 20% of blood volume; remain with patient. |
| Incompatibility in multiple transfusions | Fever Pain at needle site and along venous tract Nausea and vomiting Sensation of tightness in chest Red or black urine Flank pain Progressive signs of shock or renal failure | Stop transfusion immediately in event signs or symptoms occur, maintain patent IV line, and notify practitioner. Save donor blood to recrossmatch with patient's blood. Monitor for evidence of shock. Insert urinary catheter and monitor hourly outputs. Send samples of patient's blood and urine to laboratory for presence of hemoglobin (indicates intravascular hemolysis). Observe for signs of hemorrhage resulting from DIC. Support medical therapies to reverse shock. |
| Febrile reactions | Fever | May give acetaminophen for prophylaxis. |
| Leukocyte or platelet antibodies | Chills | Leukocyte-poor RBCs are less likely to cause reaction. Stop transfusion immediately; report to practitioner for evaluation. |
| Plasma protein antibodies | | |
| Allergic reactions | Urticaria | Give antihistamines for prophylaxis to children with tendency to allergic reactions. |
| Recipient reaction to allergens in donor's blood | Pruritus Flushing Asthmatic wheezing Laryngeal edema | Stop transfusion immediately. Administer epinephrine for wheezing or anaphylactic reaction. |
| Circulatory overload | Precordial pain | Transfuse blood slowly. |
| Too rapid transfusion (even a small quantity) | Dyspnea | Prevent overload by using packed RBCs or administering divided amounts of blood. |
| Transfusion of excessive quantity of blood (even slowly) | Rales Cyanosis Dry cough Distended neck veins Hypertension | Use infusion pump to regulate and maintain flow rate. Stop transfusion immediately if there are signs of overload. Place child upright with feet in dependent position to increase venous resistance. |
| Air emboli | Sudden difficulty in breathing | Normalize pressure before container is empty when infusing blood under pressure. |
| May occur when blood is transfused under pressure | Sharp pain in chest Apprehension | Clear tubing of air by aspirating air with syringe at nearest Y connector if air is observed in tubing; disconnect tubing and allow blood to flow until air has escaped only if a Y connector is not available. |
| Hypothermia | Chills | Allow blood to warm at room temperature (<1 hour). |
| | Low temperature Irregular heart rate Possible cardiac arrest | Use approved mechanical blood warmer or electric warming coil to warm blood rapidly; never use microwave oven. Take temperature if patient complains of chills; if subnormal, stop transfusion. |
| Electrolyte disturbances | Nausea, diarrhea | Use washed RBCs or fresh blood if patient is at risk. |
| Hyperkalemia (in | Muscular weakness | |

| | | |
|--|--|--|
| massive transfusions or in patients with renal problems) | Flaccid paralysis Paresthesia of extremities Bradycardia Apprehension Cardiac arrest | |
| Delayed Reactions | | |
| Transmission of infection Hepatitis HIV infection Malaria Syphilis Other bacterial or viral infection | Signs of infection (e.g., jaundice) Toxic reaction: High fever, severe headache or substernal pain, hypotension, intense flushing, vomiting or diarrhea | Blood is tested for antibodies to HIV, hepatitis C virus, and hepatitis B core antigen; in addition, blood is tested for hepatitis B surface antigen and alanine aminotransferase, and a serologic test is performed for syphilis. Units that test positive are destroyed. Individuals at risk for carrying certain viruses are deterred from donation. Report any sign of infection, and if it occurs during transfusion, stop transfusion immediately, send sample for culture and sensitivity testing, and notify practitioner. |
| Alloimmunization Antibody formation Occurs in patients receiving multiple transfusions | Increased risk of hemolytic, febrile, and allergic reactions | Use limited number of donors. Observe carefully for signs of reactions. |
| Delayed hemolytic reaction | Destruction of RBCs and fever 5 to 10 days after transfusion | Observe for posttransfusion anemia and decreasing benefit from successive transfusion. |

DIC, Disseminated intravascular coagulation; *HIV*, human immunodeficiency virus; *RBC*, red blood cell.

Although hemolytic reactions are rare, ABO incompatibility remains the most common cause of death from blood transfusion, and human error (e.g., administration of the wrong type to the patient or mislabeling of the blood product) is usually responsible (Lavoie, 2011; Tondon, Pandey, Mickey, et al, 2010). Hemolysis can also cause the release of large quantities of phospholipids, which are capable of stimulating DIC. Acute kidney shutdown and eventual renal failure are a result of renal vasoconstriction from antigen–antibody complexes derived from the RBC surface.

Blood is usually administered to children by infusion pump; therefore, the usual precautions and management related to pumps apply. When the blood infusion begins with a standard transfusion set, the filter chamber is filled to allow the total filter to be used. The drip chamber is partially filled with blood to permit counting of the drops. In adjusting the flow rate, it is important to remember that blood administration sets do not use microdrops (60 drops/ml) but regular drops (usually 10 to 15 drops/ml). The nurse must consider this when calculating the flow rate.

Apheresis

Apheresis is the removal of blood from an individual, separation of the blood into its components, retention of one or more of these components, and reinfusion of the remainder of the blood into the individual. Apheresis is most often used to remove large quantities of platelets from healthy adult donors. These transfusion products have greatly prolonged the survival of patients with hematologic and oncologic diseases.

NCLEX Review Questions

1. A child is admitted to the pediatric unit. The mother reports that the doctor says her son is anemic. What laboratory findings/manifestations would the nurse expect to see to confirm iron deficiency anemia?
 - a. Cyanosis, due to inadequate oxygen saturation of existing hemoglobin
 - b. A decreased reticulocyte count
 - c. A total iron-binding capacity (TIBC) that is elevated above the normal range
 - d. Decreased blood pressure changes, which are an early sign because of the compensatory mechanisms
2. A child with sickle cell anemia (SCA) is admitted in a vasoocclusive crisis (VOC). Which of the following interventions should the nurse expect to see ordered? Select all that apply.
 - a. Cold compresses to painful joints
 - b. IV fluids started, and oral fluids encouraged
 - c. Meperidine ordered every 4 hours for pain
 - d. High-calorie, high-protein diet
 - e. Antibiotics ordered for any existing infection
3. You are working with a recent graduate on the pediatric unit. You are assigned to take care of an adolescent with β -thalassemia. The nurse needs more information about this disease if she states which of the following? Select all that apply.
 - a. "We need to check the patient's iron level to make sure he is not anemic."
 - b. "I believe this is most common in those of Hispanic descent, although this patient is Mediterranean."
 - c. "The doctor will be prescribing deferasirox (Exjade) or deferoxamine (Desferal) for chelation therapy."
 - d. "This patient looks much younger than I would expect. I guess he's just a late bloomer."
 - e. "I think a transfusion will be ordered, because his hemoglobin level is 9.0."
4. Which is the most accurate genetic explanation for a family with hemophilia?
 - a. It is a Y-linked dominant disorder.
 - b. It is equally distributed among males and females.
 - c. It is an X-linked recessive disorder.
 - d. It is an autosomal recessive disorder.
5. You are discharging a patient with hemophilia. Which of the following responses by the parents indicate an understanding of this disorder? Select all that apply.
 - a. "My child should remain active to decrease joint problems, and most children with hemophilia can participate in the same activities as peers."
 - b. "Care should be taken to avoid bleeding of gums, and softening the toothbrush in warm water before brushing or using a sponge-tipped disposable toothbrush may be helpful."
 - c. "Signs of internal bleeding should be recognized, such as headache, slurred speech, loss of consciousness (from cerebral bleeding), and black, tarry stools (from gastrointestinal bleeding)."
 - d. "If there is bleeding in a joint, elevation, ice, and rest should help and may prevent the need for factor VIII replacement."
 - e. "All of my son's teachers need to be aware of what to do if he gets a bloody nose."

Correct Answers

1. c; 2. b, d, e; 3. a, b, d; 4. c; 5. b, c, e

The Child with Cancer

Cheryl C. Rodgers

Cancer in Children

Few situations in nursing exceed the challenges of caring for a child with cancer. Despite the dramatic improvements in survival rates for these children, the family's needs are tremendous as they cope with a serious physical illness and the fear that the child will not be cured. Nurses should base support of patients and their families on the premise that communication promotes understanding and clarity. With understanding, fear diminishes and hope emerges, and in the presence of hope, anything is possible.

Epidemiology

Childhood cancer is rare; approximately 16,400 cases of cancer are diagnosed in children younger than 20 years old in the United States each year (Scheurer, Lupo, and Bondy, 2016). Despite the relatively low incidence, approximately 1300 children younger than 15 years old die from their disease each year, making cancer the leading cause of death from disease in this age group (Scheurer, Lupo, and Bondy, 2016). The incidence of cancer in children and adolescents is approximately 18 cases per 100,000 children (Henley, Singh, King, et al, 2015).

The incidence of specific subtypes of childhood cancer can vary according to age, sex, and race. For example, males have a higher overall incidence of cancer compared with females, with a ratio of 1.1 : 1 (Scheurer, Lupo, and Bondy, 2016). This is due to the higher incidence of acute lymphoblastic leukemia (ALL), non-Hodgkin lymphoma (NHL), and central nervous system (CNS) tumors—the most common types of childhood cancer—in young boys. Unlike adults, Caucasian children have an overall higher incidence of cancer compared to African-American children. This is accounted for by the higher incidence in ALL, Ewing sarcoma, and melanoma in Caucasian children. The incidence of childhood cancer is more pronounced in children ages 0 to 4 years and adolescents ages 15 to 19 years; however, the types of cancers among these two groups are very distinct, with neuroblastoma and retinoblastoma occurring more commonly in young children and lymphoma and sarcoma occurring more commonly in adolescents (Scheurer, Lupo, and Bondy, 2016) (see [Research Focus](#) box).

Research Focus

Childhood Cancer Survival Rates

Childhood cancer survival has dramatically increased over the past five decades. In the 1960s, the overall survival rate of childhood cancer was 28% compared with 3-year survival rates now exceeding 80% (Scheurer, Lupo, and Bondy, 2016). There has been a lack of progress in survival among the adolescent group compared with progress in younger age-groups. The cancers demonstrating the greatest improvement in survival rates are acute lymphoblastic leukemia (ALL), non-Hodgkin lymphoma (NHL), and Wilms tumor. The typical definition of “cure” in childhood cancer includes completion of all therapy, clinical and radiologic evidence of no disease, and a period of 5 years since diagnosis.

Etiology

Often the first questions parents of newly diagnosed children with cancer ask is “How did my child get this, and did I do something to cause it?” Parents are also understandably concerned with the question of the likelihood that their other children will get cancer. Although there are numerous hypotheses concerning the origin of cancer, the most enduring theory is that some genetic alteration results in the unregulated proliferation of cells. Significant advances have been made in our understanding of cell proliferation, programmed cell death (apoptosis), genes that activate tumor growth (oncogenes), and genes that keep tumor growth in check (tumor suppressor genes). Cancer is the result of multiple genetic events but is not necessarily hereditary. Overall, the incidence of cancers caused by direct inheritance is low.

In the early 1970s, Alfred Knudson described the “two-hit hypothesis.” This explanation of cancer inheritance is best described in retinoblastoma. Like most genes, the retinoblastoma gene (*Rb*) is

present in two copies on each cell. It is a tumor suppressor gene, responsible for controlling cell growth. When just one of these copies is lost—the “first hit,” the cell remains normal. However, when the second copy is lost—the “second hit,” abnormal cell proliferation occurs and retinoblastoma develops (Knudson, Hethcote, and Brown, 1975). A child can inherit one altered copy of the retinoblastoma gene from a mother or father. Therefore, it takes only one more hit for retinoblastoma to develop. Perhaps the most well-known inherited cancer predisposition syndrome is Li-Fraumeni syndrome, which is mainly due to constitutional (in all cells) mutation in the tumor suppressor gene, *p53*. This syndrome is characterized by early incidence brain tumors, premenopausal breast cancer, soft tissue and bone sarcomas, leukemias, and lymphomas (Plon and Malkin, 2016).

Chromosome abnormalities have been identified in many childhood malignancies and are important in the development of various types of cancer. Chromosome abnormalities can be confined to the tumor or can be present in all cells; the latter are called *germ-line mutations*. Chromosome abnormalities can be due to translocations (a rearrangement of information between two chromosomes) or abnormal numbers of chromosomes. For example, many well-established chromosome translocations have been identified in childhood leukemia and some solid tumors.

Other genetic syndromes that can affect genes or chromosomes and are associated with a predisposition to cancer include Fanconi anemia, Bloom syndrome, Beckwith-Weidemann syndrome, neurofibromatosis type 1, ataxia-telangiectasia, and Klinefelter syndrome.

Children with immunodeficiencies, such as Wiskott-Aldrich syndrome or acquired immunodeficiency syndrome, or children whose immune system has been suppressed, such as following transplant procedures, are at a greater risk for developing various cancers. Of major concern is the increased risk of secondary cancers in some children successfully treated for their primary malignancy.

Risk Factors

Lifestyle-related behaviors are the main factors that increase the risk of cancer in adults, but they have little to no effect on childhood cancer. There is relatively little information to support a strong environmental role in the development of childhood cancer. However, some risk factors are well established. Known risk factors include exposure to ionizing radiation, carcinogenic drugs, immunosuppressive therapy, infections (such as Epstein Barr virus), race, and genetic conditions (Scheurer, Lupo, and Bondy, 2016).

Prevention

Knowledge of the risk factors that increase the likelihood of cancer holds the promise of prevention. Unfortunately, the known carcinogens are limited in children. Therefore, at present there is really no known prevention.

Health professionals, however, have two roles. One is aimed at preventing adult type of cancers by educating parents and children about the hazards of known carcinogens, particularly the effects of cigarette smoking and excessive exposure to sunlight. Lung cancer is the leading cause of death from cancer in adults, and malignant melanoma is the leading cause of death from diseases of the skin. In addition, to provide early detection of other types of cancer, males should learn testicular self-examination, and female adolescents should learn breast self-examination and seek periodic health examinations, including a Papanicolaou smear.

Second, health care professionals need to be aware of the cardinal symptoms of childhood cancer (Box 25-1). Unfortunately, fever and pain are manifestations of common childhood disorders and, without a high index of suspicion, may be attributed to minor ailments. The other signs are subtle and easily missed. If parents suspect an abnormality, their concerns must be taken seriously. The greatest weapons against all forms of cancer are early detection and treatment.

Box 25-1

Cardinal Symptoms of Cancer in Children

- Unusual mass or swelling
- Unexplained paleness and loss of energy

- Sudden tendency to bruise
- Persistent, localized pain or limping
- Prolonged, unexplained fever or illness
- Frequent headaches, often with vomiting
- Sudden eye or vision changes
- Excessive, rapid weight loss

Data from American Cancer Society: *How are childhood cancers found?*, 2015, <http://www.cancer.org/cancer/cancerinchildren/detailedguide/cancer-in-children-finding-childhood-cancers-early>.

Diagnostic Evaluation

The evaluation of a child suspected of having cancer may take several days to complete. Specific signs and symptoms depend on the type of cancer and its location. The essential components of a comprehensive evaluation for childhood cancer include complete history and review of symptoms, physical examination, laboratory tests, diagnostic imaging, diagnostic procedures (e.g., lumbar puncture [LP], bone marrow aspirate, and biopsy), and surgical pathology.

Laboratory Tests

Several laboratory tests must be performed to accurately diagnose and treat children with cancer. The majority of patients have a complete blood count, serum chemistries, liver function tests, coagulation studies, and urinalysis done on initial presentation. Frequent complete blood counts are necessary to monitor effects of therapy and in some hematologic malignancies, response to therapy. Blood chemistry yields important information with regard to kidney, liver, bone function, and electrolyte balance. These tests are important to help detect the extent of disease and also to monitor for side effects during therapy.

Diagnostic Procedures

A LP is a routine test employed in leukemia, brain tumors, and other cancers that may metastasize to the CNS. LPs are also used to administer intrathecal drugs in patients with various malignancies, such as leukemia.

A bone marrow aspirate test is performed by aspirating marrow with a large- or fine-bore needle. A bone marrow biopsy is performed by obtaining a piece of bone through a special type of needle. These tests are performed to determine the presence or absence of tumor or response to therapy in this specific location.

Diagnostic Imaging

Modern-day diagnostic imaging has greatly improved our ability to accurately diagnose childhood cancers. The most commonly employed modes of imaging include chest x-rays, computed tomography (CT), magnetic resonance imaging (MRI), positron emission tomography (PET), and metaiodobenzylguanidine (MIBG) scan, which is being used increasingly in certain types of pediatric malignancies, such as neuroblastoma and soft tissue tumors. Interventional radiology is playing an increasing role in the diagnosis and management of pediatric malignancies.

Pathologic Evaluation

A biopsy is necessary to establish the diagnosis of a malignancy. Besides determining what type of cancer the patient has, this tissue sample can also be sent for various biologic studies that define the patient's prognosis and allow health care providers to tailor therapy according to the risk group. For example, a bone marrow biopsy determines whether the patient has acute lymphocytic leukemia or acute myelocytic leukemia and also tells what specific subtype of leukemia the patient has and how aggressively it should be treated. Similarly, patients with neuroblastoma undergo a biopsy of the tumor to establish the diagnosis and to evaluate the tumor for *N-myc* amplification, which determines the type of treatment they receive.

Treatment Modalities

The use of multimodal therapy consisting of surgery, chemotherapy, and radiotherapy; enrollment of large numbers of children in cooperative group clinical trials or protocols; and improvements in supportive care have greatly increased the survival of children with cancer. Eighty percent of these patients are now expected to be cured of their disease.

Current efforts are aimed at increasing the survival of patients with high-risk tumors, decreasing the acute and long-term side effects of treatment, and studying the biology of the diseases to better identify patients who are at different risk levels for disease recurrence and can therefore benefit from risk-adapted therapies.

Surgery

The main goal of surgery, besides obtaining biopsies, is to remove all traces of the tumor and restore normal body functioning. Surgery is most successful when the tumor is encapsulated and localized (confined to the site of origin). It may be used for palliative care when the cancer is regional (metastasized to an area adjacent to the original site) or advanced (widespread throughout the body). Obviously the best prognosis is directly related to early detection of the tumor.

Because the majority of pediatric cancers respond well to chemotherapy, more conservative surgical excision is increasingly used in a variety of tumors in an attempt to preserve function and cosmesis. For example, in some types of bone cancer, such as osteosarcoma, patients are successfully treated with resection of the diseased portion of the bone rather than amputation. There is an increasing emphasis on the use of combination drug therapy and radiotherapy after limited surgical intervention.

Chemotherapy

Chemotherapy may be the primary form of treatment, or it may be an adjunct to surgery or radiotherapy. The majority of chemotherapy agents work by interfering with the function or production of nucleic acids, deoxyribonucleic acid (DNA), or ribonucleic acid (RNA). Although several drugs with antineoplastic capabilities have been effective in treating different forms of cancer, the remarkable survival rates have been the result of improved combination drug regimens. Combining drugs allows for optimum cell cycle destruction with minimum toxic effects and decreased resistance by the cancer cells to the agent.

In addition to more effective combinations of drugs, several advances in the administration of chemotherapy have permitted continuous or intermittent intravenous (IV) administration without multiple venipunctures. The use of venous access devices (e.g., catheters and implantable infusion ports) has greatly facilitated safe and effective drug administration with minimum discomfort for the child (see [Chapter 20](#)). Continuous infusions over an extended period using syringe pumps have made possible the administration of certain drugs (such as cytosine arabinoside) in higher doses with less toxicity than when the drug is administered intermittently.

Chemotherapeutic agents can be classified according to their primary mechanism of action. Alkylating agents replace a hydrogen atom of a molecule by an alkyl group. The irreversible combination of alkyl groups with nucleotide chains, particularly DNA, causes unbalanced growth of unaffected cell constituents so that the cell eventually dies. These agents have a steep dose-response curve and, for this reason, can be used in high-dose therapy regimens. Examples of alkylating agents include cyclophosphamide, ifosfamide, cisplatin (Platinol), and dacarbazine. Antimetabolites resemble essential metabolic elements needed for cell growth but are sufficiently altered in molecular structure to inhibit further synthesis of DNA or RNA; their maximum effect occurs in cells that are actively producing DNA. Examples of antimetabolites include methotrexate and mercaptopurine. Plant alkaloids arrest cells in metaphase (a phase of mitosis) by binding to microtubular protein needed for spindle formation. Examples include vincristine and vinblastine. Antitumor antibiotics are natural products that interfere with cell division by reacting with DNA in such a way as to prevent further replication of DNA and transcription of RNA. Examples include doxorubicin and daunomycin.

A number of agents are not categorized according to the preceding classifications. For example, L-asparaginase is an enzyme isolated from extracts of bacterial cultures of *Escherichia coli* or *Erwinia carotovora*. It hydrolyzes L-asparagine, an amino acid, to L-aspartic acid, which prevents the cell from synthesizing protein needed for DNA and RNA synthesis. Because L-asparagine is

synthesized by normal cells but must be exogenously supplied to certain leukemia and lymphoma cells, administration of the enzyme destroys the essential exogenous supply while sparing normal cells of untoward effects.

An understanding of the actions and side effects of these drugs is essential to nursing care of children with cancer. Unfortunately, almost all drugs are not selectively cytotoxic for malignant cells, and other cells with a high rate of proliferation (such as the bone marrow elements, hair, skin, and epithelial cells of the gastrointestinal tract) are also affected. Frequently the problems related to the destruction of these normal cells require more nursing care than the disease itself.

A number of targeted agents called *tyrosine kinase inhibitors* have been developed and are being used in a variety of pediatric and adult malignancies. Examples of some of these agents include imatinib, sunitinib, and sorafenib.

Precautions in Administering and Handling Chemotherapeutic Agents

Many chemotherapeutic agents are **vesicants** (sclerosing agents) that can cause severe cellular damage if even minute amounts of the drug infiltrate surrounding tissue. Only nurses experienced with chemotherapeutic agents should administer vesicants (Fig. 25-1). Guidelines are available and must be followed meticulously to prevent tissue damage to patients.

FIG 25-1 Nurses caring for children with cancer require expertise in the safe administration of chemotherapy.

In addition to extravasation, a potentially fatal complication is anaphylaxis, especially from L-asparaginase, bleomycin, cisplatin, and etoposide (VP-16). Hypersensitivity reactions to these chemotherapeutic agents are characterized by urticaria, angioedema, flushing, rashes, difficulty breathing, hypotension, and nausea or vomiting. Nursing responsibilities include prevention, recognition, and preparation for serious reactions. If a reaction is suspected, the nurse discontinues the drug, flushes and maintains the IV line with saline, and monitors the child's vital signs and subsequent responses.

Nursing Alert

When chemotherapeutic and immunologic agents with known anaphylactic potential are given, it is standard practice to observe the child for at least 1 hour after the infusion for signs of anaphylaxis (e.g., rash, urticaria, hypotension, wheezing, nausea, vomiting). Emergency equipment (especially blood pressure monitor, bag and valve mask, and suction) and emergency drugs (especially oxygen, epinephrine, antihistamine, aminophylline, corticosteroids, and vasopressors) must be readily available.

In addition to the many responsibilities during chemotherapy administration, nurses must also use safeguards to protect themselves. Handling chemotherapeutic agents may present risks to handlers and to their offspring, although the exact degree of risk is not known. The Oncology Nursing Society has published comprehensive guidelines for safe practice issues related to administration of chemotherapy.* They have also established safe management procedures for chemotherapy administered in the home.† Basic nursing guidelines are in the [Nursing Care Guidelines](#) box.

Nursing Care Guidelines

Handling Chemotherapeutic Agents

- Use great care and strict aseptic technique in handling chemotherapeutic agents to prevent any physical contact with the substance.
- Drugs are prepared in a properly ventilated room (which incorporates a protective front panel and vertical laminar airflow to reduce potential for inhalation during preparation).
- Wear disposable gloves and protective clothing and discard in special container after each use.
- Wear face and eye protection when splashing is possible, and wear a respirator when the risk of inhalation is possible.
- Use a sterile gauze pad when priming intravenous (IV) tubing, connecting and disconnecting tubing, inserting syringes into vials, breaking glass ampules, or performing any other procedure in which antineoplastic drugs may be inadvertently discharged.
- Dispose of all contaminated needles, syringes, IV tubing, and other contaminated equipment in a leak-proof and puncture-resistant container; do not recap or break needles.

Radiotherapy

Radiotherapy is frequently used in the treatment of childhood cancer, usually in conjunction with chemotherapy or surgery. It can be used for curative purposes or for palliation to relieve symptoms by shrinking the size of the tumor. Recent advances in radiotherapy have optimized its beneficial effects and minimized many of the undesirable side effects, although high-dose irradiation is associated with many serious late effects.

Ionizing radiation is cytotoxic in at least three different ways: (1) damaging the pyrimidine bases cytosine, thymine, and uracil needed for the synthesis of nucleic acids; (2) causing single-strand breaks in the DNA or RNA molecule; or (3) causing double helical-strand breaks in these molecules. The effect of disturbing cellular metabolic and reproductive functions is either sublethal or lethal damage. *Lethal damage* refers to the death of the cell. *Sublethal damage* refers to injured cells that may subsequently be repaired. Many of the acute side effects are the result of lethal damage to radiosensitive tissue, particularly proliferating cells such as those of the bone marrow, gastrointestinal tract, and hair follicles. Late effects are usually the result of cell death.

The acute untoward reactions from radiotherapy depend primarily on the area to be irradiated. Total-body irradiation is associated with the most severe reactions and is employed to prepare the immune system for blood or marrow transplantation (BMT). [Table 25-1](#) summarizes the acute effects of radiotherapy and nursing interventions that may be helpful in mitigating or preventing them. In limited areas of the country, proton beam radiation is available. Protons are positively charged subatomic particles that deposit energy differently than x-ray beams. There is no “exit dose” beyond the tumor involved in proton radiotherapy; therefore, the local control of the therapy is a huge benefit with no long-term effects to organs surrounding the target area ([Hill-Kayser, Tochner, Both, et al, 2013](#)). For example, some brain tumor patients receive radiation to the spine. With traditional forms of radiotherapy, long-term effects to nearby vital organs like the heart and lungs are possible; however, with proton therapy the heart and lungs would not be affected, greatly reducing long-term effects.

TABLE 25-1**Early Side Effects of Radiotherapy**

| Site | Effects | Nursing Interventions |
|------------------------|---|--|
| Gastrointestinal tract | Nausea and vomiting | Give antiemetic on schedule around the clock. Measure amount of emesis to assess for dehydration. |
| | Anorexia | Encourage fluids and foods best tolerated, usually light, soft diet and small, frequent meals. Monitor weight. |
| | Mucosal ulceration | Use frequent mouth rinses and oral hygiene to prevent mucositis. |
| | Diarrhea | Control with antispasmodics and kaolin pectin preparations. Observe for signs of dehydration. |
| Skin | Alopecia (within 2 weeks; hair may regrow by 3 to 6 months) | Introduce idea of wig. Stress necessity of scalp hygiene and need for head covering in sun and cold weather. |
| | Dry or moist desquamation | Do not refer to skin change as a "burn" (implies use of too much radiation). Avoid lotions and other creams to skin. Wash daily, using soap (e.g., Dove) sparingly. Do not remove skin marking for radiation fields. Avoid exposure to sun. For desquamation, consult practitioner for skin hygiene and care. |
| Head | Nausea and vomiting (from stimulation of vomiting center in brain) | Same as for gastrointestinal tract. |
| | Alopecia | Same as for skin. |
| | Mucositis | Encourage regular dental care, fluoride treatments. |
| | Potential effects: • Parotitis • Sore throat • Loss of taste | Provide analgesics as needed to relieve discomfort. |
| | Xerostomia (dry mouth) | Combat severe dryness of mouth with oral hygiene and liquid diet. |
| Urinary bladder | Rarely cystitis | Encourage liberal fluid intake and frequent voiding. Evaluate for hematuria. |
| Bone marrow | Myelosuppression | Observe for fever (temperature >101° F [38.3° C]). Initiate workup for sepsis as ordered. Administer antibiotics as prescribed. Avoid use of suppositories, rectal temperatures. Institute bleeding precautions. Observe for signs of anemia. |

Biologic Response Modifiers

Biologic response modifiers (BRMs) alter the relationship between tumor and host by therapeutically changing the host's biologic response to tumor cells. These agents or interventions may affect the host's immunologic mechanisms (immunotherapy); have direct antitumor activity; or stimulate cell growth, reducing the hematologic toxicity associated with chemotherapy (Fry, Sondel, and Mackall, 2016). Much of the current work in biotherapy is directed toward the use of monoclonal antibodies in the diagnosis and treatment of cancers. Through a complex process, special cells are fused to form a hybrid clone, or hybridoma, that produces antibodies that recognize a single specific antigen—hence the term *monoclonal antibody* (*mono* meaning "one" and *clone* meaning "exact duplicate"). These clones are then frozen, maintained in culture, or grown as tumors in mice to produce large quantities of the antibody. Monoclonal antibodies have several mechanisms of cytotoxic action, but their main effect is exerted on the small molecule inhibitors of the cell surface proteins (Fry, Sondel, and Mackall, 2016). A commonly used monoclonal antibody is rituximab, which directs its effect on the B-cell surface protein CD20 and is used for the treatment of NHL (Fry, Sondel, and Mackall, 2016).

Blood or Marrow Transplantation

Another approach to the treatment of childhood cancer is BMT. Candidates for transplantation are children who have diseases that require high doses of chemotherapy and/or replacement of dysfunctional bone marrow. The conditioning regimen consists of radiotherapy and/or high-dose chemotherapy to rid the body of malignant cells and suppress the immune system to prevent rejection of the transplanted marrow. Next, the marrow, stem cells, or cord blood obtained from a family member or volunteer donor (allogeneic) or the cells previously stored from the patient (autologous) are given to the patient by IV infusion. The newly transfused marrow or stem cells begin to produce functioning nonmalignant blood cells. In essence, the recipient accepts a new blood-forming organ.

The selection process for a suitable donor and the potential complications in transplantation are related to the human leukocyte antigen (HLA) system complex. Some of the major HLA antigens are A, B, C, D, DR, and DQ. There is a wide diversity for each of these HLA loci. For example, more than 20 different HLA-A antigens and more than 40 different HLA-B antigens can be inherited. The genes are inherited as a single unit, or haplotype. A child inherits one unit from each parent; thus a child and each parent have one identical and one nonidentical haplotype. Because the possible haplotype combinations among siblings follow the laws of Mendelian genetics, there is a one in four chance that two siblings have two identical haplotypes and are perfectly matched at the HLA loci.

The importance of HLA matching is to prevent the serious complication of graft-versus-host

disease (GVHD). Because the child's immune system is essentially rendered nonfunctional, the recipient is unlikely to reject the bone marrow. However, the donor's marrow may contain antigens not matched to the recipient's antigens, which begin attacking body cells. The more closely the HLA systems match, the less likely GVHD is to develop. However, GVHD can occur even with a perfect HLA match because of unidentified and thus unmatched histocompatibility antigens (Gottschalk, Naik, Hegde, et al, 2016).

Complications of Therapy

Although tremendous advances have been achieved through current modes of cancer therapy, the successes are not without consequences. Numerous side effects are expected with chemotherapy and radiotherapy. Other complications that are less common but generally more serious are described here.

Pediatric Oncologic Emergencies

Tumor Lysis Syndrome

Life-threatening conditions may develop in children with cancer as a result of the malignancy and/or aggressive treatment modalities. Acute tumor lysis syndrome has hallmark metabolic abnormalities that are the direct result of rapid release of intracellular contents during the lysis of malignant cells. This typically occurs in patients with ALL or Burkitt lymphoma during the initial treatment period but may occur spontaneously before onset of therapy. Tumor lysis syndrome may also occur in other malignancies that have a large tumor burden, are very sensitive to chemotherapy, or have a rapid proliferative rate. The hallmark metabolic abnormalities of tumor lysis syndrome include hyperuricemia, hypocalcemia, hyperphosphatemia, and hyperkalemia. The crystallization of uric acid that can occur in cases of hyperuricemia can lead to obstructive nephropathy, tubular injury, acute renal failure, and death (McCurdy and Shanholtz, 2012).

Risk factors for development of tumor lysis syndrome include high white blood cell count at diagnosis, large tumor burden, sensitivity to chemotherapy, and high proliferative rate. In addition to the described metabolic abnormalities, children may develop a spectrum of clinical symptoms, including flank pain, lethargy, nausea and vomiting, muscle cramps, pruritus, tetany, and seizures.

Management of tumor lysis syndrome consists of early identification of patients at risk, prophylactic measures, and early interventions. Patients at risk for tumor lysis syndrome should have serum chemistries and urine pH monitored frequently, strict record of intake and output, and aggressive IV fluids. Medications to reduce uric acid formation and promote excretion of byproducts of purine metabolism, such as allopurinol, are often used. If tumor lysis syndrome occurs, IV hydration continues and the specific metabolic abnormalities are treated. Hyperuricemia is now effectively treated with recombinant urate oxidase, or rasburicase. This medication converts uric acid to allantoin, which is more soluble in urine. Exchange transfusions are sometimes necessary to reduce the metabolic consequences of massive tumor lysis, especially in children with a high tumor burden.

Hyperleukocytosis

Hyperleukocytosis, which is defined as a peripheral white blood cell count greater than $100,000/\text{mm}^3$, can lead to capillary obstruction, microinfarction, and organ dysfunction. Children often experience respiratory distress and cyanosis. They also experience neurologic changes, including altered level of consciousness, visual disturbances, agitation, confusion, ataxia, and delirium. Management consists of rapid cytoreduction by chemotherapy, hydration, urinary alkalization, and allopurinol. Leukapheresis or exchange transfusion may be necessary.

Superior Vena Cava Syndrome

Space-occupying lesions located in the chest, especially from Hodgkin disease and NHL, may cause superior vena cava syndrome (SVCS), leading to airway compromise and potentially to respiratory failure. Children are initially seen with cyanosis of the face, neck, and upper chest; facial and upper extremity edema; and distended neck and chest veins. They may be anxious and have dyspnea, wheezing, or a frequent cough from airway obstruction. Management consists of airway protection and alleviation of respiratory distress. Rapid treatment is initiated, and symptoms typically

improve as the disease is effectively treated.

Spinal Cord Compression

Different malignancies can invade or impinge on the spinal cord, causing acute symptoms of cord compression. Children with primary CNS tumors can have tumors that originate or spread to the spinal cord. Other solid tumors, like neuroblastoma or rhabdomyosarcoma, can metastasize to the spinal cord and cause compression. Back pain is a common initial manifestation, but other symptoms can include sensation change, extremity weakness, loss of bowel and bladder function, and respiratory insufficiency. Careful physical examination is essential in early detection of symptoms, and MRI is the gold standard for diagnosis ([McCurdy and Shanholtz, 2012](#)). Treatment may include high-dose steroids to reduce associated edema and alleviate symptoms and rapid initiation of treatment such as emergent radiation or laminectomy if indicated.

Nursing Care Management

This section presents an overview of general nursing concepts that apply to most childhood cancers. Specific nursing care for children with a particular type of cancer is discussed under each disease section later in this chapter. This discussion focuses on the physical aspects of care. [Chapter 17](#) (chronic illness and terminal illness) presents the emotional aspects.

Quality Patient Outcomes: The Child with Cancer

- Child and family educated on disease and treatment
- Treatment administered on schedule with appropriate drug doses
- Side effects of treatment managed
- Treatment complications prevented
- Child and family coping skills supported
- Quality of life during treatment maintained
- Child and family adjusted to chronic illness
- Growth and development maintained during treatment

Signs and Symptoms of Cancer in Children

Early detection is critical to early treatment and eventual cure. Cancers in children are often difficult to recognize. Therefore, being alert to the persistence of unusual symptoms is essential (see [Box 25-1](#)). This section discusses some of the more significant clues to pediatric cancer.

Pain may be an early or late initial sign of cancer and requires a careful history of its onset, characteristics, location, intensity, and alleviating factors. Pain may be generalized or present at a specific location. For example, bone pain occurs in approximately 20% of children with leukemia. Pain, swelling, and tenderness at the tumor site may be the initial sign in solid tumors. In addition, a mass is a typical finding in children with solid tumors. An abdominal mass in a child must be evaluated for a malignancy, such as Wilms tumor or neuroblastoma.

Fever is a frequent occurrence during childhood and is caused by numerous illnesses, including cancer. The cause of fever in cancer patients is infection or the malignant process itself. A careful skin assessment will reveal signs and symptoms of a low platelet count. Ecchymosis and petechiae are most commonly found on the child's extremities and under constricting parts of clothing like waistbands. Spontaneous gum or nose bleeding may occur when the platelet count falls below 20,000/mm³.

The child with malignant invasion of the bone marrow often appears pale, with symptoms of lethargy, weight loss, and generalized malaise. These symptoms may be attributed to anemia caused by the replacement of normal cells with malignant cells in the bone marrow. The nurse should assess for signs and symptoms of anemia (see [Chapter 24](#)).

Swollen lymph glands are another common finding in children. However, enlarged, firm lymph nodes in a child with fever for more than 1 week, a recent history of weight loss, or an abnormal chest x-ray film may indicate a serious disease and should be evaluated further.

The presence of a white reflection as opposed to the normal red pupillary reflex in the pupil of a child's eye is the classic sign of retinoblastoma. Squinting, strabismus, or swelling can indicate other solid tumors of the eye.

The child with a brain tumor develops signs and symptoms according to the exact area of the brain involved. The nurse must perform a thorough neurological assessment to identify the specific area of tumor involvement.

Managing Side Effects of Treatment

Cancer care encompasses more than treatments aimed at eliminating the malignant cells. Because of the delicate balance between killing malignant cells and preserving functional cells, supportive therapy is frequently needed during those times that serious damage occurs to normal body tissues. A major concern for the child receiving treatment for cancer is the risk for the development of complications secondary to the treatment.

Infection

The nurse caring for the child with fever must be aware of the signs and symptoms of septic shock, as discussed in [Chapter 23](#). The child with fever who has an absolute neutrophil count (ANC) lower than $500/\text{mm}^3$ is at risk for the following (see [Nursing Care Guidelines](#) box):

- Overwhelming infection
- General malaise
- Invasion of organisms producing secondary infections

Nursing Care Guidelines

Calculating the Absolute Neutrophil Count

1. Determine the total percentage of neutrophils (“polys, or segs,” and “bands”).
2. Multiply white blood cell (WBC) count by percentage of neutrophils.

Example

WBC = $1000/\text{mm}^3$, neutrophils = 7%, nonsegmented neutrophils (bands) = 7%

Step 1: $7\% + 7\% = 14\%$

Step 2: $0.14 \times 1000 = 140/\text{mm}^3$ ANC

ANC, Absolute neutrophil count.

The child with fever is evaluated for potential sites of infection, such as from a needle puncture, mucosal ulceration, minor abrasion, or skin tears (e.g., a hangnail). Although the body may not be able to produce an adequate inflammatory response to the infection and the usual clinical signs of infection may be partially expressed or absent, fever will occur. Therefore, monitor the temperature closely. To identify the source of infection, the health care team takes blood, stool, urine, and nasopharyngeal cultures and chest x-ray films.

Once infection is suspected, broad-spectrum IV antibiotic therapy is begun before the organism is identified and may be continued for 7 to 10 days. If the child does not have a venous access device, a peripheral IV should be inserted to prevent the inconvenience of multiple venipunctures in administering antibiotic therapy.

The organisms most lethal to these children are (1) viruses, particularly varicella (chickenpox), herpes zoster, herpes simplex, respiratory syncytial virus, influenza, cytomegalovirus; (2) protozoan, *Toxoplasma gondii*; (3) fungi, especially *Pneumocystis jiroveci* (formally known as *carinii*) or *Candida albicans*; (4) gram-negative bacteria, such as *Pseudomonas aeruginosa*, *E. coli*, and *Klebsiella* organisms; and (5) gram-positive bacteria, especially *Staphylococcus* and *Enterococcus* species ([Ardura and Koh, 2016](#)). Prophylaxis against *Pneumocystis* pneumonia, such as trimethoprim-sulfamethoxazole, is routinely given to most children during treatment for cancer ([Ardura and Koh, 2016](#)).

Colony stimulating factors (CSFs), a family of glycoprotein hormones that regulate the reproduction, maturation, and function of blood cells, are now routinely used as supportive measures to prevent the side effects caused by low blood counts. CSFs promote stem cell

proliferation and stimulate a more rapid maturation of the cells, allowing them to enter the bloodstream earlier. G-CSF (filgrastim [Neupogen], pegfilgrastim [Neulasta]) directs granulocyte development and can decrease the duration of neutropenia. This reduces the incidence and duration of infection in children receiving treatment for cancer. G-CSF is also being used to decrease the bone marrow recovery time after BMT (Ardura and Koh, 2016). Prevention of infection continues as a priority after discharge from the hospital. Some institutions allow the child to return to school when the ANC is above 500/mm³. Other institutions place no restrictions on the child, regardless of the blood count. If the level falls below this value, cautious isolation from crowded areas, such as shopping centers or subways, is advisable. At all times, encourage family members to practice good hand washing to avoid introducing pathogens into the home (see [Critical Thinking Case Study](#) box).

Critical Thinking Case Study

Fever and Neutropenia

Billy, 9 years old, is undergoing chemotherapy for high-risk acute lymphoblastic leukemia (ALL) but has recently been hospitalized with a fever of 103° F (39.5° C). He last received chemotherapy 10 days ago with vincristine, doxorubicin, and PEG-L-asparaginase and is currently taking oral dexamethasone for 21 days. His current white blood cell count is 0.1/mm³, with an absolute neutrophil count (ANC) of 0. His platelet count is 31,000/mm³, and his hemoglobin is 8.1 g/dl. He has noticeable petechiae on his arms and legs with multiple bruises in various stages of healing.

After your morning report, you visit Billy, start your assessment, and note the following: Billy is an alert and oriented 9-year-old Caucasian boy. His tongue and oral mucosa are covered with a white plaque. Vital signs are as follows: Temperature, 102.6° F (39.2° C), axial; respiratory rate, 24 breaths/min; heart rate, 140 beats/min; and blood pressure, 100/56 mm Hg. Further observation of the patient and his surroundings reveals (1) a sign over his bed that reads “no needle punctures”; (2) he is currently getting 6 liters of oxygen via nasal cannula; (3) the Port-A-Cath is accessed with intravenous (IV) fluids infusing, and the dressing is clean and dry; and (4) a tympanic thermometer is in the room.

1. What evidence should you consider regarding this condition?
2. What additional information is required at this time?
3. List the nursing intervention(s) that have the highest priority.
4. Identify important patient-centered outcomes with reference to your nursing interventions.

Hemorrhage

Before the use of transfused platelets, hemorrhage was a leading cause of death in children with some types of cancer. Now most bleeding episodes can be prevented or controlled with judicious administration of platelet concentrates or platelet-rich plasma. Severe spontaneous internal hemorrhage varies but usually does not occur until the platelet count is 20,000/mm³ or less (Hockenberry, Kline, and Rodgers, 2016).

Platelet transfusions are generally reserved for active bleeding episodes that do not respond to local treatment and that may occur during induction or relapse therapy. Epistaxis and gingival bleeding are the most common. The nurse teaches parents and other children measures to control nose bleeding. Applying pressure at the site without disturbing clot formation is the general rule. Platelet concentrates normally do not have to be cross-matched for blood group or type. However, because platelets contain specific antigen components similar to blood group factors, children who receive multiple transfusions may become sensitized to a platelet group other than their own. Therefore, platelets are cross-matched with the donor's blood components whenever possible.

During bleeding episodes the parents and child need much emotional support (see [Critical Thinking Case Study](#) box). The sight of oozing blood is upsetting. Often parents request a platelet transfusion, unaware of the necessity of trying local measures first. The nurse can help calm their anxiety by explaining the reason for delaying a platelet transfusion until absolutely necessary.

Because compatible donors decrease the risk of antigen formation in the recipient, the nurse should encourage parents to locate suitable donors for eventual blood use.

Critical Thinking Case Study

Bleeding

Paul, 14 years old, is undergoing chemotherapy for non-Hodgkin lymphoma (NHL) but has recently been hospitalized with an infection. He last received chemotherapy 12 days ago. His current platelet count is 28,000/mm³. He has noticeable petechiae on his arms and legs with multiple bruises in various stages of healing. After your morning report, you visit Paul, start your assessment, and note the following: Paul is an alert and oriented 14-year-old Caucasian boy. The right sclera has a hemorrhage, and multiple petechiae and bruises are on the arms and legs. Petechiae are noted on the buccal mucosa and palate. Further observation of the patient and his surroundings reveals (1) a sign over his bed that reads “no needle punctures”; (2) he is currently getting 6 liters of oxygen via nasal cannula; (3) the Port-A-Cath is accessed with intravenous (IV) fluids infusing, and the dressing is clean and dry; and (4) a tympanic thermometer is in the room.

1. What evidence should you consider regarding this condition?
2. What additional information is required at this time?
3. List the nursing intervention(s) that have the highest priority.
4. Identify important patient-centered outcomes with reference to your nursing interventions.

Children at home who have low platelet counts (usually <100,000/mm³) should avoid activities that might cause injury or bleeding, such as riding bicycles or skateboards, roller skating or in-line skating, climbing trees or playground equipment, and contact sports such as football or soccer. Once the platelet count rises, these restrictions are not necessary. In addition, aspirin and aspirin-containing products are not used; for mild pain or significantly elevated temperature, acetaminophen is substituted.

Anemia

Initially anemia may be profound from complete replacement of the bone marrow by cancer cells. During induction therapy, blood transfusions with packed red blood cells may be necessary to raise the hemoglobin to levels approaching 10 g/dl. The usual precautions in caring for the child are instituted (see [Chapter 24](#)).

Anemia is also a consequence of drug-induced myelosuppression. Although not as severely affected as the white blood cells, erythrocyte production may be delayed. Because children have an amazing capacity to withstand low hemoglobin levels, the best approach is to allow the child to regulate activity with reasonable adult supervision. It may be necessary for the parents to alert the schoolteacher to the child's physical limitations, particularly in terms of strenuous activity.

Nausea and Vomiting

The nausea and vomiting that occur shortly after administration of chemotherapy and as a result of cranial or abdominal irradiation can be profound. 5-Hydroxytryptamine-3 receptor antagonists are the antiemetics of choice to manage nausea and vomiting caused by chemotherapy and radiotherapy ([Dupuis, Boodhan, Holdsworth, et al, 2013](#)). The advantage of these agents over conventional drugs is that they produce no extrapyramidal side effects. Multiple studies have shown ondansetron (Zofran) to be effective for patients receiving moderate to highly emetic chemotherapy, and ondansetron in combination with dexamethasone has been more effective than ondansetron alone ([Dupuis, Boodhan, Holdsworth, et al, 2013](#)).

For mild to moderate vomiting, phenothiazine-type drugs remain in use. Promethazine (Phenergan), prochlorperazine (Compazine), or trimethobenzamide (Tigan) may be effective agents. Synthetic cannabinoids are now being used in children undergoing chemotherapy, such as dronabinol. Dronabinol helps control nausea and vomiting and also is an effective appetite

stimulant (Feyer and Jordan, 2011).

The most beneficial regimen for antiemetic control has been the administration of the antiemetic before the chemotherapy begins (30 minutes to 1 hour before) and regular (not as-needed) administration for at least 24 hours after chemotherapy. The goal is to prevent the child from ever experiencing nausea or vomiting, because this can prevent the development of anticipatory symptoms (the conditioned response of developing nausea and vomiting before receiving the drug). Other nonpharmacologic interventions (similar to those discussed for pain management in Chapter 5) can be useful in controlling post-therapy and anticipatory nausea and vomiting. Giving the antineoplastic drug with a mild sedative at bedtime is also helpful for some children, and there is evidence that nighttime administration of drugs such as methotrexate and 6-mercaptopurine may be more effective cytotoxically than morning administration.

Altered Nutrition

Altered nutrition is a common side effect of treatment. Continued assessment of the child's nutritional status, child's intake, and energy expenditure must occur throughout treatment. The child's height, weight, and head circumference (for children younger than 3 years old) must be measured routinely during visits to the hospital or clinic. Energy reserves should be evaluated with routine skinfold measurements. Biochemical assays such as serum prealbumin, transferrin, and albumin may be helpful to evaluate nutritional status in some children, but a single assay should not be used alone for a nutritional evaluation (Lawson, Daley, Sams, et al, 2013). There are no specific criteria that mandate nutritional interventions in children undergoing cancer treatment. Instead each child should have an individualized nutritional care plan based on routine assessments.

Nutritional status is important to maintain because a compromised nutritional status can contribute to reduced tolerance to treatment, altered metabolism of chemotherapy drugs, prolonged episodes of neutropenia, and increased risk for infection.

Supportive nutrition measures include oral supplements with high-protein and high-calorie foods. Ways to increase calories include using whole milk, adding tofu (high in protein) to most meals, and serving full-fat instead of nonfat or low-fat items. Cooking with butter; putting sugar or cheese on foods; and making high-calorie snacks such as trail mix, peanut butter, or dried fruit readily available for the child are other ways to increase calories. Enteral feeding or parenteral hyperalimentation may be necessary when children are unable to maintain the necessary calories to prevent weight loss. Chapter 20 discusses these interventions in more detail.

Despite such approaches, some children still do not eat. Theories to explain persistent anorexia include (1) a physical effect related to the cancer that is nonspecific; (2) a conditioned aversion to food from nausea and vomiting during treatment; (3) a response to stress in the environment, related to eating or to the child's condition; (4) a result of depression; and (5) a control mechanism when so much else has been imposed on the child. When loss of appetite and weight decline persists, the nurse should investigate the family situation to determine whether any of these variables are contributing to the problem.

Mucosal Ulceration

One of the most distressing side effects of several chemotherapy drugs is gastrointestinal mucosal cell damage, which results in ulcers anywhere along the alimentary tract. Oral ulcers (stomatitis) are red, eroded, painful areas in the mouth or pharynx. Similar lesions may extend along the esophagus and occur in the rectal area. They greatly compound anorexia because eating is extremely uncomfortable.

Nursing Alert

Viscous lidocaine is not recommended for young children. If applied to the pharynx, it may depress the gag reflex, increasing the risk of aspiration. Seizures have also been associated with the use of oral viscous lidocaine, most likely as a result of the rapid absorption into the bloodstream via the oral lesions (Lutwak, Howland, Gambetta, et al, 2013).

Some interventions that are helpful when oral ulcers develop are feeding a bland, moist, soft diet; using a soft sponge toothbrush (Toothette) instead of a toothbrush; frequently rinsing the mouth

with chlorhexidine mouthwash or sodium bicarbonate and salt mouth rinses (using a solution of 1 tsp of baking soda and $\frac{1}{2}$ tsp of table salt in 1 quart of water); using sucralfate; and administering local anesthetics without alcohol, such as a solution of diphenhydramine and Maalox (aluminum and magnesium hydroxide) (Miller, Donald, and Hagemann, 2012). Although local anesthetics are effective in temporarily relieving the pain, many children dislike the taste and numb feeling they produce.

Nursing Alert

Avoid agents such as lemon glycerin swabs and hydrogen peroxide because of the drying effects on the mucosa. In addition, lemon may be very irritating, especially on eroded tissue.

Administering mouth care is particularly difficult in infants and toddlers. A satisfactory method of cleaning the gums is to wrap a piece of gauze around a finger; soak it in saline or plain water; and swab the gums, palate, and inner cheek surfaces with the finger. Children should perform mouth care routinely before and after any feeding and as often as every 2 to 4 hours to rid mucosal surfaces of debris, which becomes an excellent medium for bacterial and fungal growth.

Difficulty eating is a major problem with stomatitis and may warrant hospitalization if the child refuses fluids. The child usually chooses the foods that are best tolerated. Drinking can usually be encouraged if a straw is used to bypass the ulcerated oral mucosa. The nurse should encourage parents to relax any eating pressures because the anorexia accompanying stomatitis is well justified. In addition, because it is a temporary condition, once the ulcers heal, the child can resume good food habits. Ordinarily, severe mucosal ulceration indicates a need for decreased chemotherapy until complete healing takes place, usually within a week. Analgesics, including opioids, may be needed when treatment cannot be altered, such as during BMT.

If rectal ulcers develop, meticulous toilet hygiene, warm sitz baths after each bowel movement, and an occlusive ointment applied to the ulcerated area promote healing; the use of stool softeners is necessary to prevent further discomfort. Parents should record bowel movements because the child may voluntarily avoid defecation to prevent discomfort. Rectal temperatures and suppositories are always avoided because they may traumatize the area.

Neurologic Problems

Vincristine, and to a lesser extent vinblastine, can cause various neurotoxic effects. One of the more common neurotoxic effects is severe constipation caused from decreased bowel innervation. Administration of opioids can further aggravate constipation. The nurse advises parents to record bowel movements and to notify the practitioner of a change in stool habits. Physical activity and stool softeners are helpful in preventing the problem, but laxatives, such as polyethylene glycol, are often necessary to stimulate evacuation. Dietary changes such as increased fiber may not be effective, because the increased bulk tends to increase fecal distention and discomfort without producing the necessary mechanical stimulation.

Footdrop and weakness and numbness of the extremities are another common neurotoxic effect and may cause difficulty in walking or fine hand movement. The nurse should look for these problems and warn parents of these side effects, which are reversible once the drug is stopped. Wearing high top tennis shoes or using a footboard in bed is used to preserve proper alignment. If weakness occurs while the child is attending school, temporary alteration of activity may be necessary. Parents should inform the teacher of the situation to avoid unrealistic expectations of the child's abilities.

Another neurotoxic effect is severe jaw pain. Analgesics may help relieve the discomfort. Children may avoid movement by not talking or chewing, although continuous chewing, such as with gum, may actually reduce the pain. A neurologic syndrome, post-irradiation somnolence, may develop 5 to 8 weeks after CNS irradiation and last for 4 to 15 days. It is characterized by somnolence with or without fever, anorexia, and nausea and vomiting. Parents should be warned of the possibility of such symptoms and encouraged to seek medical evaluation, because somnolence may be an early indicator of long-term neurologic sequelae after cranial irradiation.

Hemorrhagic Cystitis

Sterile hemorrhagic cystitis is a side effect of chemical irritation to the bladder from chemotherapy

or radiotherapy. It can be prevented by (1) a liberal oral or parenteral fluid intake (at least one and a half times the recommended daily fluid requirement [2 liter/m²/day]); (2) frequent voiding immediately after feeling the urge, including immediately before bed, one nighttime void, and upon arising; (3) administration of the drug early in the day to allow for sufficient fluids and frequent voiding; and (4) administration of mesna, a drug that inhibits the urotoxicity of cyclophosphamide and ifosfamide.

Nursing Alert

If signs of cystitis such as dysuria or hematuria occur, prompt medical evaluation is needed. Hemorrhagic cystitis warrants a full workup and prompt intervention.

In most cases, IV fluids are given before, during, and after the drug to ensure adequate hydration, thereby eliminating the need for the child's drinking large amounts of fluid. If oral home administration is prescribed, the family needs specific instructions on exactly how much fluid the child must have.

Alopecia

Hair loss is a side effect of several chemotherapeutic drugs and cranial irradiation. Not all children lose their hair during drug therapy, and some children may experience thinning of the hair rather than baldness. However, retaining hair is the exception rather than the rule. It is better to warn children and parents of this side effect to allow time to adapt to the side effect.

The family should know that the hair falls out in clumps, causing patchy baldness. To lessen the trauma of seeing large amounts of hair on bed linen or clothing, the child can wear a disposable surgical cap to collect the shed hair during the period of greatest hair loss, or the hair can be cut short or shaved. Families should also be aware that wigs are tax deductible and that hair typically regrows in 3 to 6 months. The hair is often a different color and texture than before cancer treatment.

Nursing Tip

Encouraging children to choose a wig similar to their own hairstyle and color before the hair falls out is helpful in fostering later adjustment to hair loss.

If the child chooses not to wear a wig, attention to some type of head covering is important, especially in cold or sunny climates. Scalp hygiene is also important. The scalp should be washed regularly as with any other body part.

Steroid Effects

Short-term steroid therapy produces physical changes and alterations in body image, which, although not clinically significant, can be extremely distressing to older children. One of these is cushingoid appearance. The child's face becomes rounded and puffy (see Fig. 28-2). Unlike hair loss, little can be done to camouflage this obvious change, although careful avoidance of salt and salt-containing foods can help reduce fluid accumulation. It is not unusual for other children to tease the child. It is helpful to reassure the child that, after cessation of the drug, the facial contours will return to normal. The use of loose-fitting clothes, such as warm-up outfits, can help camouflage the change in weight.

Children receiving steroid therapy look healthy. The moon face, red cheeks, supraclavicular fat pads, protuberant abdomen, and fluid retention indicate weight gain. However, the actual weight gain resulting from increased muscle mass and subcutaneous tissue may be small. Therefore, the nurse should evaluate weight gain by observing the extremities and measuring skinfold thickness and arm circumference during steroid therapy to determine whether the weight gain is a result of increased dietary intake.

Shortly after beginning steroid therapy, children may experience a number of mood changes, which range from feelings of well-being and euphoria to depression and irritability. If parents are unaware of these drug-induced changes, they may become unduly concerned. Therefore, the nurse should warn them of the reactions and encourage them to discuss the behavioral changes with each

other and the child.

Nursing Care during Blood or Marrow Transplantation

Because of the aggressive preconditioning therapy used to remove the marrow and the potential for complications while waiting for engraftment of transplanted stem cells, children undergoing BMT are usually hospitalized for several weeks. BMT patients must have numerous procedures performed, such as the insertion of a venous access device, administration of intensive chemotherapy and irradiation, and strict infectious precautions. During the period after transplantation and before the new marrow begins adequately replacing granulocytes, the child is extremely susceptible to infection, and any infection can be life-threatening. In addition, many of the side effects previously discussed occur in the child undergoing BMT.

The most common complication in allogeneic transplants is acute GVHD, which can affect the skin, gastrointestinal tract, and liver. The characteristics and severity of the manifestations vary according to the severity and area affected. Emphasis is now placed on the prevention of GVHD, using various agents such as a calcineurin inhibitor in conjunction with mycophenolate mofetil, methotrexate, or sirolimus (Gottschalk, Naik, Hegde, et al, 2016). Treatment involves the use of steroids or other immunosuppressive medications. However, this treatment further increases the risk of infection in the already susceptible patient. All blood products should be irradiated to minimize the introduction of additional antigens.

Skin breakdown and delayed wound healing frequently occur in the patient undergoing BMT. Preventive interventions to minimize pressure on dependent areas of the skin include the use of pressure-relieving or pressure-reducing beds or mattresses and frequent activity. Measures to promote healing when breakdown occurs include frequent sitz baths to the perianal area and protective skin barriers, such as hydrocolloid dressings or occlusive ointments.

Throughout this long ordeal the family is worried about successful engraftment and fatal complications. An unfortunate post-transplant possibility is recurrence of the disease after engraftment. Consequently, nurses need to provide sensitive care and maintain a supportive attitude during the many crises that may arise. If the procedure is not successful, the care needed by these families is consistent with that required by the family of any child with a life-threatening disorder (see [Chapter 17](#)).

Preparation for Procedures

Children in particular need psychological preparation for the various treatment modalities, which often involve surgery, IV injections, bone marrow aspiration, and LP. The diagnostic procedures initially employed to confirm the diagnosis and those that are repeated to monitor treatment can be a source of discomfort and stress to the child and family. Even noninvasive procedures such as imaging and radiologic tests are frightening to a young child. Many of these tests require the child to lie absolutely motionless for a prolonged time in a confined space with little or no communication with a supportive adult. Consequently, infants and young children are usually sedated, and older children need an explanation of what to expect and reminders during the test of how much longer they must remain still. The same principles for preparing children for procedures that are discussed in [Chapter 20](#) apply here, including the option of having parents stay with the child whenever possible. Children who undergo repeated tests need additional preparation and emotional support to decrease their stress.

Two procedures, bone marrow studies and LPs, are so commonly performed in many types of childhood cancer that they deserve special consideration in preparing children ([Fig. 25-2](#)). Professionals caring for children with cancer recommend the use of developmentally appropriate support using both pharmacologic and nonpharmacologic approaches and sedation if required (see [Chapter 5](#)).

FIG 25-2 Child with leukemia undergoing bone marrow aspiration.

Topical anesthetics such as eutectic mixture of local anesthetics (EMLA) and LMX4 creams are used as a local anesthetic before intrusive procedures, including venipunctures, implanted port access, LPs, and subcutaneous or intramuscular injections (Hockenberry, Kline, and Rodgers, 2016). Local intradermal anesthesia of lidocaine is frequently used for LP and bone marrow examination. To reduce the stinging sensation from lidocaine, sodium bicarbonate should be added (see [Pain Management, Chapter 5](#)). Deeper infiltration of the muscle and periosteum of the bone with buffered lidocaine further reduces the pain from the large-bore aspiration or biopsy needle entering the bone. For bone marrow studies, LPs, and other procedures, children of preschool age and beyond should be prepared beforehand. Physical care after the procedures is minimal. A small pressure bandage is applied to the bone marrow puncture site, and an adhesive bandage is applied to the LP site. No activity restriction is necessary after the bone marrow test, although the site is usually sore and the child may prefer to remain quiet. Recommendations after LP vary. If medication was instilled, the child may be placed in a slight Trendelenburg position to facilitate circulation of the medicated spinal fluid.

Pain Management

Nurses must be knowledgeable about the basic pathophysiology of cancer pain and treatment-related side effects. The World Health Organization's three-step analgesic pain ladder should be incorporated into the approach to pain management for every child with cancer (Wong, Lau, Palozzi, et al, 2012). Nurses must acquire extensive knowledge of nonopioid and opioid analgesics used in pediatric pain management (see [Chapter 5](#)). Interdisciplinary pain management teams are used in many pediatric cancer centers. These teams serve as consultants and provide expertise in the assessment and management of pain. The nurse often serves as the coordinator of care, playing a key role in cancer pain management.

[Chapter 5](#) discusses pharmacologic management of disease-related pain, which involves a variety of methods. It may take more than a trial of one type of medication to find the appropriate agent to manage a patient's pain. Nonsteroidal antiinflammatory drugs (NSAIDs), acetaminophen with codeine, oxycodone, and morphine are commonly used agents in the management of disease-related pain (Wong, Lau, Palozzi, et al, 2012). Appropriate dosing is imperative. Doses are titrated to increase the amount of analgesia and minimize side effects.

Health Promotion

Children with cancer require the same basic health supervision as any child. Sometimes the overwhelming needs and demands placed on the family, coupled with the singular concern focused on the cancer by both family and practitioners, result in a lack of attention to normal health care needs. Nurses should monitor the type of primary care the child receives, using as a guideline recommendations for health supervision. Areas of particular concern are growth, physical and cognitive development, and neurologic status. Two other areas are also important: (1) dental care, because of potential side effects from treatment, and (2) immunizations, because of concern with

live virus vaccines and immunosuppression.

Dental Care

Irradiation to the head and neck can cause a number of late complications (Landier, Armenian, Meadows, et al, 2016). Some are irreversible, such as facial asymmetry, but those affecting the teeth and gums (e.g., caries, periodontal disease) benefit from excellent oral hygiene, including regular use of systemic and topical fluoride and regular dental examinations and cleaning (see Dental Health, Chapter 14). There is evidence of delayed or absent development of the permanent teeth (Effinger, Migliorati, Hudson, et al, 2014). Children need to be aware of this possibility and need help to explain the delay to peers.

Immunizations

Viral replication after the administration of live vaccine for polio, measles, rubella, and mumps can cause serious disease in immunocompromised children. The child receiving chemotherapy for cancer should not receive live, attenuated vaccines. Inactivated vaccines can be given to immunosuppressed children. Siblings and other family members can receive the live measles, mumps, and rubella vaccine and the varicella vaccine without risk to the child who is immunosuppressed.

An important indication for isolation is an outbreak of childhood disease, especially chickenpox. If the child has been exposed to the varicella virus, varicella-zoster immune globulin given within 96 hours may favorably alter the course of the disease. Antiviral agents, such as acyclovir, should be given if the child develops varicella. Without treatment, death from disseminated varicella occurs in 7% to 20% of patients, due to disseminated disease in the liver, lung, and CNS (Ardura and Koh, 2016). (See also Immunizations, Chapter 6.)

Nursing Alert

Children vaccinated 2 weeks before or during chemotherapy should be considered unimmunized and should be revaccinated or receive live virus vaccines 6 months after chemotherapy has stopped (Ruggiero, Battista, Coccia, et al, 2011). Most institutions have individual guidelines regarding vaccinations in a child undergoing immunosuppressive therapy. The nurse should be aware of these guidelines and educate patients and families.

Family Education

Nurses working with children who have cancer have a significant supportive role in helping the family understand the various therapies, preventing or managing expected side effects or toxicities, and observing for late effects of treatment. Education is a constant feature of the nursing role, especially in terms of new treatments, clinical trials, and home care. Because of the anxiety generated by the diagnosis of cancer, some families may resort to unproven methods of treatment. Nurses are instrumental in helping families avoid seeking unproven and potentially unsafe “remedies” by encouraging the families to discuss concerns and questions openly with their health care provider. The American Cancer Society and local and state medical societies are reliable sources of information concerning research on investigational versus quack methods of cancer therapy. The Association of Pediatric Hematology/Oncology Nurses* has developed numerous educational materials for family and child teaching. The American Childhood Cancer Organization† is an international organization providing support, education, and advocacy programs for children with cancer and their families.

Instruction regarding home care frequently involves teaching about medication schedules, observing for side effects or toxicities that require further evaluation, taking measures to prevent or manage these problems, and caring for special devices such as central venous catheters.‡ Compliance is an important issue, because poor adherence to regimens can result in disease relapse or serious medical complications. Every effort must be made to ensure that the family understands the importance of adhering to the prescribed treatment schedule and measures to improve compliance (see Chapter 20).

Cessation of Therapy

Care does not end when the child completes therapy. With the increasing awareness of late effects, nurses play an important role in the assessment of the child for problems, such as delayed growth, secondary malignancies, and disturbances in any body system. The family needs to be aware of the importance of continued medical supervision. Other health care professionals caring for the child (such as school nurses, family physicians, and dentists) should be informed of the child's cancer diagnosis. As children reach adulthood, they may benefit from genetic counseling regarding cancers that are likely to be inherited. If the possibility of infertility exists, fertility options should be discussed for pubertal males and females prior to the start of treatment. The [Children's Oncology Group \(2013\)](#) has developed guidelines for long-term follow-up care for pediatric cancer survivors. Nurses involved with these children should be familiar with these guidelines and use all opportunities to teach patients and families regarding needed continued care.

Cancers of Blood and Lymph Systems

Leukemias

Acute Leukemias

Leukemia is a broad term given to a group of malignant diseases of the bone marrow and lymphatic system. It is a complex disease of varying heterogeneity. Consequently, classification has become increasingly complex, sophisticated, and essential because identification of the subtype of leukemia has therapeutic and prognostic implications. The following is an overview of the major classification systems currently used.

Morphology

In children, two forms are generally recognized: ALL and acute myelogenous leukemia (AML). Synonyms for ALL include lymphatic, lymphocytic, lymphoid, and lymphoblastic leukemia. ALL is the most common form of childhood cancer, with an annual incidence of two to five cases per 100,000 children (Rabin, Gramatges, Margolin, et al, 2016). It occurs more frequently in boys than in girls and in Caucasians than in African Americans (Rabin, Gramatges, Margolin, et al, 2016). The peak onset is between 2 and 5 years old. It is one of the forms of pediatric cancer that has demonstrated dramatic improvements in survival rates. Before the use of antileukemic agents in 1948, a child with ALL lived 2 to 3 months. Current long-term disease-free survival rates for children with ALL approach 80% in major research centers.

AML accounts for 20% of all cases of childhood leukemia and has an annual incidence of eight cases per million (Arceci and Meshinchi, 2016). The incidence is similar for males and females, and higher rates are seen during the first year of life. Overall survival rates vary dramatically according to sex, race, and constitutional characteristics of the disease (Arceci and Meshinchi, 2016).

Pathologic and Related Clinical Manifestations

Leukemia is an unrestricted proliferation of immature white blood cells in the blood-forming tissues of the body. Although not a “tumor” as such, the leukemic cells demonstrate the neoplastic properties of solid cancers. Thus the resultant pathologic and clinical manifestations of the disease are caused by infiltration and replacement of any tissue of the body with nonfunctional leukemic cells. Highly vascular organs, such as the spleen and liver, are most severely affected.

To understand the pathophysiology of the leukemic process, it is important to clarify two common misconceptions. First, although leukemia is an overproduction of white blood cells, most often the leukocyte count is low. Instead, the peripheral blood smear and, more definitively, the bone marrow examination reveal greatly elevated counts of immature cells, or blasts. Second, these immature cells do not deliberately attack and destroy the normal blood cells or vascular tissues. Cellular destruction occurs through the process of infiltration and subsequent competition for metabolic elements. The following discussion elaborates on the pathologic process and related clinical manifestations in the most susceptible organs of the body (Fig. 25-3).

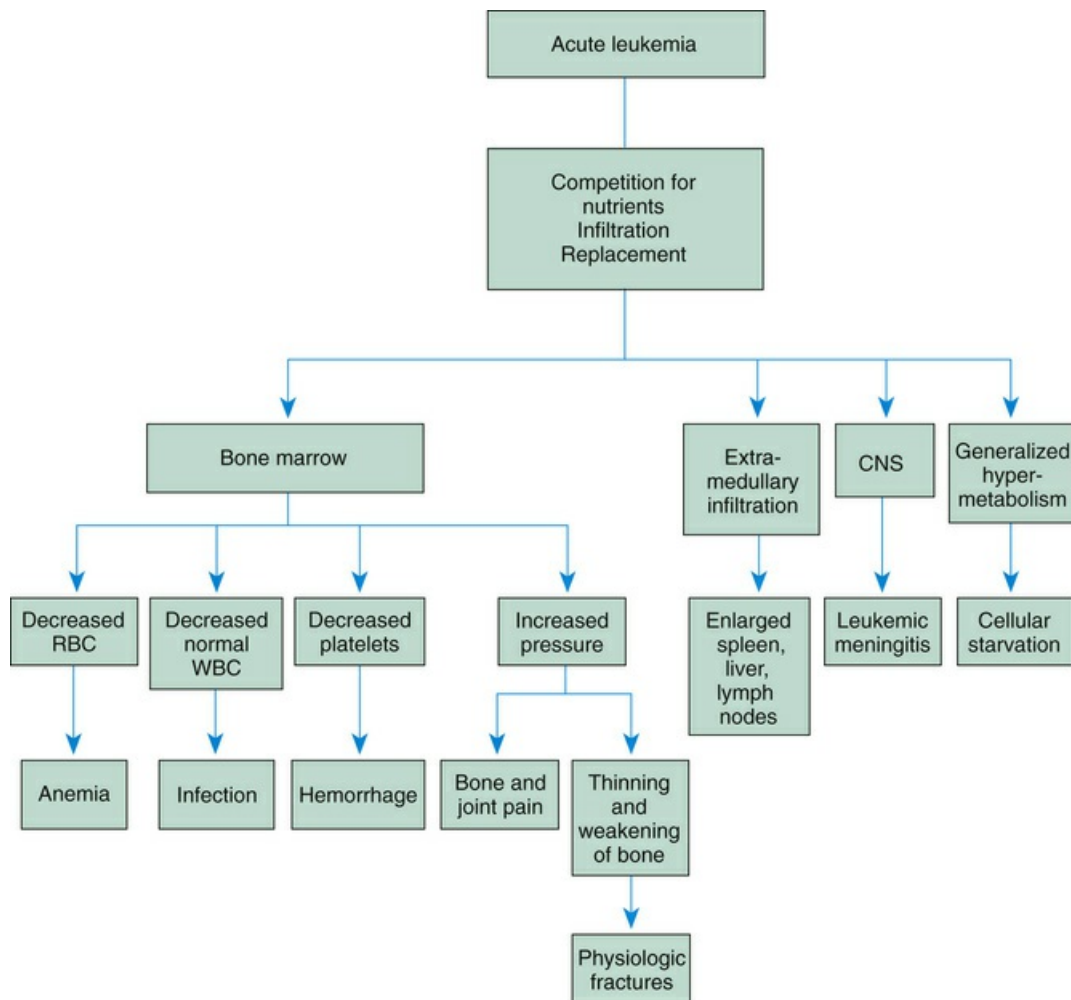

FIG 25-3 Principal sites of tissue involvement in leukemia. CNS, Central nervous system; RBC, red blood cell; WBC, white blood cell.

Bone Marrow Dysfunction

In all types of leukemia, the proliferating cells depress bone marrow production of the formed elements of the blood by competing for and depriving the normal cells of the essential nutrients for metabolism. The three main consequences are (1) anemia from decreased erythrocytes, (2) infection from neutropenia, and (3) bleeding from decreased platelet production.

The invasion of the bone marrow with leukemic cells gradually causes a weakening of the bone and a tendency toward fractures. As leukemic cells invade the periosteum, increasing pressure causes severe pain. The most frequent presenting signs and symptoms of leukemia are a result of infiltration of the bone marrow. These include fever, pallor, fatigue, anorexia, hemorrhage (usually petechiae), and bone and joint pain. In the presence of neutropenia, the body's normal bacterial flora can become aggressive pathogens. Any break in the skin is a potential site of infection. Frequently, vague abdominal pain is caused by areas of inflammation from normal flora within the intestinal tract.

Disturbance of Involved Organs

The spleen, liver, and lymph glands demonstrate marked infiltration, enlargement, and eventually fibrosis. Hepatosplenomegaly is typically more common than lymphadenopathy.

The next most important site of involvement is the CNS. Less than 5% of patients with B-cell ALL and 10% to 20% of patients with T-cell ALL have CNS involvement (Rabin, Gramatges, Margolin, et al, 2016). The use of prophylactic CNS intrathecal therapy has dramatically decreased the incidence of CNS relapse in these patients.

Additional sites of involvement may be the cranial nerves (most often cranial nerve VII, or the

facial nerve) and spinal nerves, particularly of the lumbosacral plexus, hypothalamus, and cerebellum. Clinical manifestations for these sites are directly related to the area involved. For example, with lumbosacral invasion, the patient has weakness in the lower extremities, pain radiating down the legs to the feet, and difficulty in voiding. Although such signs may suggest a brain tumor, the absence of localized signs often leads to the discovery of CNS involvement in leukemia. Other sites that may become invaded with leukemic cells include the kidneys, testes, prostate, ovaries, gastrointestinal tract, and lungs.

Onset

The onset of leukemia varies from acute to insidious. In most instances, the child displays remarkably few symptoms. For example, leukemia may be diagnosed when a minor infection, such as a cold, fails to completely disappear. The child is pale, listless, irritable, febrile, and anorexic. Parents often suspect some underlying problem when they observe the weight loss, petechiae, bruising without cause, and continued complaints of bone and joint pain.

At other times leukemia is diagnosed after an extended history of signs and symptoms mimicking such conditions as rheumatoid arthritis or mononucleosis. In some cases, the diagnosis of leukemia accompanies some totally unrelated event, such as a routine physical examination or injury.

The history not only yields valuable medical information regarding the subsequent course of the illness but also bears heavily on the parents' emotional reaction to the diagnosis. In most instances, the diagnosis is an unexpected revelation of catastrophic proportion.

Prognostic Factors

The most important prognostic factors in determining long-term survival for children with ALL are the initial white blood cell count, the patient's age at diagnosis, cytogenetics, the immunologic subtype, and the child's sex. Favorable indicators include a white blood cell count $<50,000/\text{mm}^3$, 2 to 10 years of age, hyperdiploid cytogenetics, early pre-B cell immunologic subtype, and female sex. For children with AML, prognostic factors associated with a poorer prognosis include certain chromosome abnormalities (monosomy 5 or 7), chromosomal rearrangements, and a poor initial response to therapy ([Arceci and Meshinchi, 2016](#)).

Diagnostic Evaluation

Leukemia is usually suspected from the history, physical manifestations, and a peripheral blood smear that contains immature forms of leukocytes, frequently in combination with low blood counts. Definitive diagnosis is based on bone marrow aspiration or biopsy. Typically the bone marrow shows a monotonous infiltrate of blast cells. Once the diagnosis is confirmed, an LP is performed to determine whether there is any CNS involvement. Although only a small number of children have CNS involvement, they are usually asymptomatic.

Therapeutic Management

Treatment of leukemia involves the use of IV and intrathecal chemotherapeutic agents. Radiation is sometimes used for resistant CNS disease or testicular relapse. Typically leukemia treatment is divided into phases: (1) induction, which achieves a complete remission or clinical disappearance of leukemic cells; (2) intensification, or consolidation, therapy, which further decreases the total tumor burden; and (3) maintenance, which consists of further chemotherapy to ensure the disease stays in remission. Although the combination of drugs and possibility of irradiation may vary according to the institution, the patient's prognostic or risk characteristics, and the type of leukemia being treated, the following general principles for each phase are consistently employed.

Remission Induction

Almost immediately after confirmation of the diagnosis, induction therapy is begun and lasts for 4 to 5 weeks. A complete remission is determined by the absence of clinical signs or symptoms of the disease and the presence of less than 5% blast cells in the bone marrow ([Rabin, Gramatges, Margolin, et al, 2016](#)).

Because many of the chemotherapy drugs also cause myelosuppression of normal blood elements, the period immediately after a remission can be critical. The body is defenseless against

invading organisms (especially normal bacterial flora) and susceptible to spontaneous hemorrhage. Consequently, supportive therapy during this time is essential.

Intensification, or Consolidation, Therapy

Intensification, or consolidation, therapy is used to further decrease the number of leukemic cells in the child's body. The intensification phase consists of pulses of chemotherapy medications given periodically during the first 6 months of treatment. The specific agents used for intensification therapy depend on the type of leukemia and the child's risk factors.

Maintenance

The goal of maintenance therapy is to preserve remission and further reduce the number of leukemic cells. Combined drug regimens have been more successful in maintaining remissions and preventing drug resistance.

During maintenance therapy, weekly or monthly complete blood counts are taken to evaluate the marrow's response to the drugs. If myelosuppression becomes severe (usually indicated by an ANC less than $1000/\text{mm}^3$) or if toxic side effects occur, therapy is temporarily stopped or the dose decreased. Duration of therapy has been based on clinical experience comparing survival rates for various time intervals and is concerned with preventing deleterious effects of excessive treatment. Although the optimum time for discontinuing therapy is not known, current practice is to continue treatment for 2 to 3 years. All children after cessation of therapy require regular medical evaluation for surveillance of relapse and long-term sequelae of treatment.

Central Nervous System Prophylactic Therapy

Children with leukemia are at risk for invasion of the CNS by the leukemic cells. For this reason, many children receive CNS prophylactic therapy. Because of the concern regarding late effects of cranial irradiation and secondary malignancies, this mode of therapy is generally reserved for high-risk patients or those with resistant CNS disease.

Reinduction After Relapse

For many children, additional therapy becomes necessary when a relapse occurs, as evidenced by the presence of leukemic cells within the bone marrow. Although remissions may be achieved after more than one relapse, each relapse indicates an increasingly poor prognosis. However, more long-term second and subsequent remissions are occurring, and these may have better outlooks than previously thought.

A site that is resistant to chemotherapy and is responsible for leukemic relapse is the testes. A minority of males experience relapses during maintenance therapy or have occult disease after cessation of therapy. Treatment for testicular disease includes bilateral testicular irradiation, and intensive systemic chemotherapy (Rabin, Gramatges, Margolin, et al, 2016).

Blood or Marrow Transplantation

BMT has been used successfully in treating some children with ALL and AML. In general, BMT is not recommended for children with ALL during the first remission because of the excellent results possible with chemotherapy. The indication for BMT are those with ALL who are stratified as high risk or have a poor early therapy response (Gottschalk, Naik, Hegde, et al, 2016). Because of the poorer prognosis in children with AML, transplantation may be considered during the first remission when a suitable donor is available (Gottschalk, Naik, Hegde, et al, 2016).

Nursing Care Management

Nursing care of the child with leukemia is directly related to the regimen of therapy. Myelosuppression, drug toxicity, and leukemic infiltration cause secondary complications that necessitate supportive physical care. This discussion focuses on supportive interventions for the child with leukemia and the family. General aspects of care appropriate for the child with leukemia are discussed earlier in the [Nursing Care Management](#) section.

Prepare the Family for Diagnostic and Therapeutic Procedures

From the time before diagnosis to cessation of therapy, children must undergo several tests, the

most traumatic of which are bone marrow aspiration or biopsy and LP. Multiple finger sticks and venipunctures for blood analysis and drug infusion are common occurrences for several years after the diagnosis. Therefore, the child needs an explanation of the rationale for each procedure and what can be expected (see [Preparation for Diagnostic and Therapeutic Procedures, Chapter 20](#)).

Provide Continued Emotional Support

Nursing care of the child with leukemia is based on typical problems the family confronts during the treatment phases. The nurse's role is one of continual support, guidance, clarification, and judgment. Parents need to know how to recognize symptoms that demand medical attention. Although some of the reactions discussed are expected, parents should still report them to their practitioner. Warning parents of their possible occurrence beforehand also allows parents to prepare. At the same time, it reassures them that these reactions are not caused by a return of leukemic cells.

Another aspect of continued emotional support involves prognosis. Leukemia is not invariably fatal, but present statistics must be correctly interpreted. Although almost 80% of children with ALL live 5 years or longer, these are average estimates that apply to those children treated with the most successful protocols since diagnosis. For the high-risk child with ALL, the prognosis may be significantly poorer. Of those who do survive after discontinuing therapy, a portion will relapse. The nurse must realize that a realistic understanding of the chances for survival requires an adjustment period. During the initial diagnosis or when a relapse occurs, parents may find it difficult to "hear" the facts. The nurse who is working with family members must individualize the numbers to relate to the people. An understanding of each member's emotional needs, as well as competent care of physical ones, is essential to the positive, growth-promoting support of the family. Comprehensive emotional support for the family of a child with a chronic illness and the child at end of life is discussed in [Chapter 17](#).

Lymphomas

The lymphomas, a group of neoplastic diseases that arise from the lymphoid and hematopoietic systems, are divided into Hodgkin disease and NHL. These diseases are further subdivided according to tissue type and extent of disease (staging). In children NHL is more common than Hodgkin disease. Although Hodgkin disease is extremely rare before 5 years of age, there is a striking increase in children 15 to 19 years old, when it occurs with almost the same frequency as leukemia.

Hodgkin Disease

Hodgkin disease affects about 29 in 1 million children, mostly adolescents ([National Cancer Institute, 2015a](#)). The malignancy originates in the lymphoid system and primarily involves the lymph nodes. It predictably metastasizes to non-nodal or extra lymphatic sites, especially the spleen, liver, bone marrow, lungs, and mediastinum (i.e., mass of tissues and organs separating the lungs, including the heart and its vessels, trachea, esophagus, thymus, and lymph nodes), although no tissue is exempt from involvement ([Fig. 25-4](#)). It is classified according to four histologic types: (1) lymphocytic predominance, (2) nodular sclerosis, (3) mixed cellularity, and (4) lymphocytic depletion. With present treatment protocols, the histologic stage of the disease has less prognostic significance.

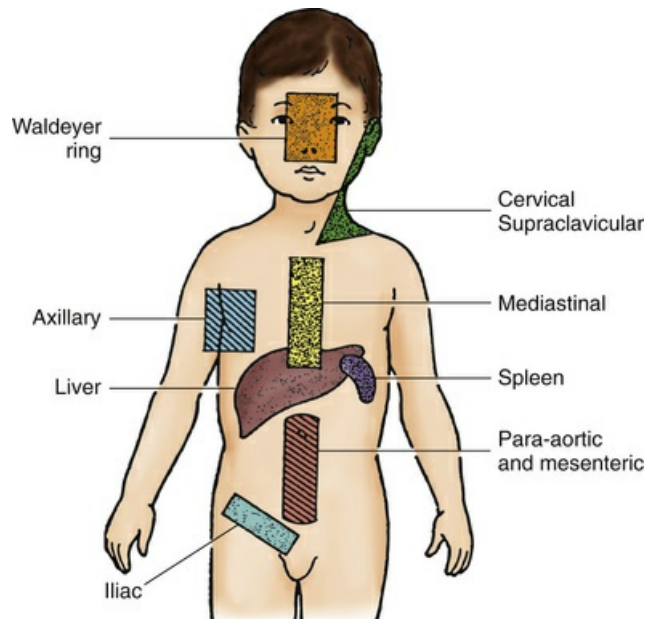

FIG 25-4 Main areas of lymphadenopathy and organ involvement in Hodgkin disease.

Staging and Prognosis

Accurate staging of the extent of disease is the basis for treatment protocols and expected prognosis. More than one staging system exists; [Box 25-2](#) shows the Ann Arbor Staging Classification.

Box 25-2

Staging of Hodgkin Disease

Stage I: Lesions are limited to one lymph node area or only one additional extralymphatic site (I-E), such as the liver, lungs, kidney, or intestines.

Stage II: Two or more lymph node regions on the same side of the diaphragm or one additional extralymphatic site or organ (II-E) on the same side of the diaphragm is involved.

Stage III: Lymph node regions on both sides of the diaphragm and has spread to one extralymphatic site (III-E), spleen (III-S), or both (III-SE).

Stage IV: Cancer has metastasized diffusely throughout the body to one or more extralymphatic sites with or without involvement of associated lymph nodes.

Each stage is further subdivided into A, B, E, or S. Stage A denotes absence of associated general symptoms. Stage B indicates presence of symptoms, such as night sweats, fever (100.4° F [38° C]), or weight loss of 10% or more during the preceding 6 months. Stage E represents extra lymphatic disease beyond the contiguous nodal disease. Stage S is used when the disease involves the spleen. Subtype B has a significantly poorer prognosis than others ([Metzger, Krasin, Choi, et al, 2016](#)).

The prognosis for patients with Hodgkin disease has improved dramatically, largely as a result of the systematic staging procedure and improved treatment protocols. The prognosis is excellent in children with localized disease. Overall the survival rate for patients with Hodgkin disease is as high as 95%; however, the survival rate is dependent on histology and staging ([Frew, Lewis, and Lucraft, 2013](#)). Even in those with disseminated disease, long-term remissions are possible in more than half the patients. For relapses, complete remission may occur in 30% to 60% of patients undergoing autologous BMT ([Metzger, Krasin, Choi, et al, 2016](#)).

Clinical Manifestations

Hodgkin disease is characterized by painless enlargement of lymph nodes. The most common

finding is enlarged, firm, nontender, movable nodes in the supraclavicular or cervical area. In children, the sentinel node located near the left clavicle may be the first enlarged node. Enlargement of axillary and inguinal lymph nodes is less frequent (see [Fig. 25-4](#)).

Other signs and symptoms depend on the extent and location of involvement. Mediastinal lymphadenopathy may cause a persistent, nonproductive cough. Enlarged retroperitoneal nodes may produce unexplained abdominal pain. Systemic symptoms include low-grade or intermittent fever (Pel-Ebstein disease), anorexia, nausea, weight loss, night sweats, and pruritus. Generally, such symptoms indicate advanced lymph node and extra lymphatic involvement.

Diagnostic Evaluation

The history and physical examination often yield important clues to the disease, such as fevers; night sweats; weight loss; and enlarged lymph nodes, spleen, or liver. Because of the multiple organs that can become involved, diagnosis consists of several tests to confirm the presence of Hodgkin disease and to assess the extent of involvement for accurate staging. Tests include complete blood count, uric acid levels, liver function tests, erythrocyte sedimentation rate or C-reactive protein, alkaline phosphatase, and urinalysis. Radiographic tests include CT scans of the neck, chest, abdomen, and pelvis; a gallium or PET scan (to identify metastatic or recurrent disease); a chest x-ray film; and, if clinically indicated, a bone scan to detect metastasis.

A lymph node biopsy is essential to establish histologic diagnosis and staging. The presence of Sternberg-Reed cell is considered diagnostic of Hodgkin disease because it is absent in the other lymphomas; however, it may occur in infectious mononucleosis. A bone marrow aspiration or biopsy is also usually performed.

Therapeutic Management

The primary modalities of therapy are chemotherapy and irradiation. Each may be used alone or in combination based on the clinical staging. The goal of treatment is obviously a cure; however, aggressive therapy increases the chances of complications in the disease-free state and can seriously compromise the quality of life. Consequently, numerous research studies are currently investigating treatment options to minimize long-term complications. One of the major concerns with combined radiation and antineoplastic drug therapy is the serious late effects in children with an excellent prognosis.

Radiation may entail involved field radiation, extended field radiation (involved areas plus adjacent nodes), or total nodal irradiation (the entire axial lymph node system), depending on the extent of involvement. In stage IV disease, chemotherapy is the primary form of treatment, although limited irradiation may be given to areas of bulky disease. Follow-up care of children no longer receiving therapy is essential to identify relapse and second malignancies. In children with splenectomy because of laparotomy, prophylactic antibiotics are administered for an indefinite period. Also, immunizations against pneumococci and meningococci are recommended before the splenectomy (see [Chapter 6](#)).

Nursing Care Management

Nursing care involves preparation for diagnostic and operative procedures, explanation of treatment side effects, and child and family support. Once the child is hospitalized for suspected Hodgkin disease, a battery of diagnostic tests is ordered. The family needs an explanation of why each test is performed, because many of them, such as bone marrow aspiration and lymph node biopsy, are invasive procedures (see [Chapter 20](#)).

Explanations of chemotherapeutic reactions vary with the specific drug regimen. The most common side effects, such as nausea and vomiting, body image changes, neuropathy, and mucosal ulceration, are discussed in the [Nursing Care Management](#) section. Radiation results in few side effects, sometimes consisting only of a mild skin reaction. With external field radiation to the chest and abdomen, nausea and vomiting, weight loss, and mucosal ulceration (esophagitis, gastric ulcers) are common. The usual measures for providing relief are discussed previously in this chapter and outlined in [Table 25-1](#).

The most common side effect of extensive irradiation is malaise, which may result from damage to the thyroid gland, causing hypothyroidism. Lack of energy is particularly difficult for adolescents because it prevents them from keeping up with their peers. Regular bedtimes and periodic rest times are important for these children, especially during chemotherapy, when

myelosuppression increases the risk of infection and debilitation. Before discharge, the nurse should discuss a feasible school schedule with the parents and child. If alterations are necessary (such as elimination of strenuous physical education), they are discussed with the teacher, school nurse, and principal. Follow-up care is essential to diagnose hypothyroidism early and institute thyroid replacement.

An area of concern for adolescents is the high risk of sterility from irradiation and chemotherapy. Both irradiation to the gonads and drugs, particularly alkylating agents, may lead to infertility. Younger patients with a greater complement of oocytes are more likely to retain ovarian function.

Although sexual function is not altered, the appearance of secondary sexual characteristics and menstruation may be delayed in the pubescent child. Adolescents should be informed of these side effects early in the course of the diagnosis and treatment. Delayed sexual maturation may be an extremely sensitive and painful area for children (see [Chapter 15](#)).

Non-Hodgkin Lymphoma

Approximately 800 new diagnoses of NHL occur each year in the United States, with an incidence of 10 children per 1 million younger than 20 years old ([National Cancer Institute, 2015b](#)). Histologic classification of childhood NHL is strikingly different from that of Hodgkin disease.

Staging and Prognosis

NHL is heterogeneous, exhibiting a variety of morphologic, cytochemical, and immunologic features, not unlike the diversity seen in leukemia. Classification is based on the pattern of histologic presentation: lymphoblastic, Burkitt or non-Burkitt, or large cell. Immunologically these cells are also classified as T cells; B cells (an example of which is Burkitt lymphoma); or non-T, non-B cells, which lack specific immunologic properties.

The clinical staging system used in Hodgkin disease is of little value in NHL, although that system has been modified for NHL and other systems have been developed. A favorable prognosis is defined by young age, low stage without mediastinal involvement, low tumor burden, and good response to initial therapy ([Allen, Kamdar, Bollard, et al, 2016](#)). [Box 25-3](#) presents the most commonly used staging system.

Box 25-3

Staging of Non-Hodgkin Lymphoma

Stage I: Disease limited to one lymph node area or only one additional extralymphatic site (I-E)

Stage II: Two or more lymph node regions on the same side of the diaphragm or one additional extralymphatic site or organ (II-E) on the same side of the diaphragm

Stage III: Tumor on both sides of abdomen and may have spread to an area or organ next to the lymph nodes (IIIE), spleen (IIIS), or both (IIISE)

Stage IV: Tumor has spread into any organ that is not right next to an involved node, and/or the tumor has spread to the central nervous system (CNS) or bone marrow

The use of aggressive combination chemotherapy has had a major impact on the survival rates of children with NHL. The most effective treatment regimens result in cure in 85% to 95% of children with limited disease involvement, and 70% to 90% of children with extensive disease are cured ([Allen, Kamdar, Bollard, et al, 2016](#)).

Clinical Manifestations

Clinical manifestations depend on the anatomic site and extent of involvement. Many of the manifestations seen in Hodgkin disease may be present in NHL, although rarely does a single symptom give rise to the diagnosis. Rather, metastasis to the bone marrow or CNS may produce signs and symptoms typical of leukemia. Lymphoid tumors compressing various organs may cause intestinal or airway obstruction, cranial nerve palsies, or spinal paralysis.

Diagnostic Evaluation

Because most children with NHL have widespread disease at diagnosis, thorough pathologic staging is unnecessary. Current recommendations for staging include a surgical biopsy for histopathologic confirmation of disease with immunophenotyping and cytogenetic evaluation; bone marrow aspiration; radiologic studies, especially CT scans of the lungs and gastrointestinal organs; and LP.

Therapeutic Management

The present treatment protocols for NHL include an aggressive approach using irradiation and chemotherapy. Similar to leukemic therapy, the protocols include induction, consolidation, and maintenance phases, some with intrathecal chemotherapy. Children with nonlymphoblastic lymphoma are treated with cyclic drug combinations and combination intrathecal chemotherapy. These multiagent regimens are administered for 6 to 24 months.

Nursing Care Management

Nursing care of the child with NHL is similar to the care discussed in the [Nursing Care Management](#) section. Because of the intensive chemotherapy protocol, nursing care is primarily directed toward managing the side effects of these agents.

Nervous System Tumors

Brain Tumors

Tumors of the CNS are the most common solid tumor in children and account for about 25% of all childhood cancers, with an annual incidence of 5 per 100,000 children younger than 20 years old (Crawford, 2013). About 60% of the tumors are infratentorial (below the tentorium cerebelli), which means they occur in the posterior part of the brain, primarily in the cerebellum or brainstem. This anatomic distribution accounts for the frequency of symptoms resulting from increased intracranial pressure (ICP). The other tumors are supratentorial or lie within the midbrain structures. Fig. 25-5 outlines major brain tumors of childhood.

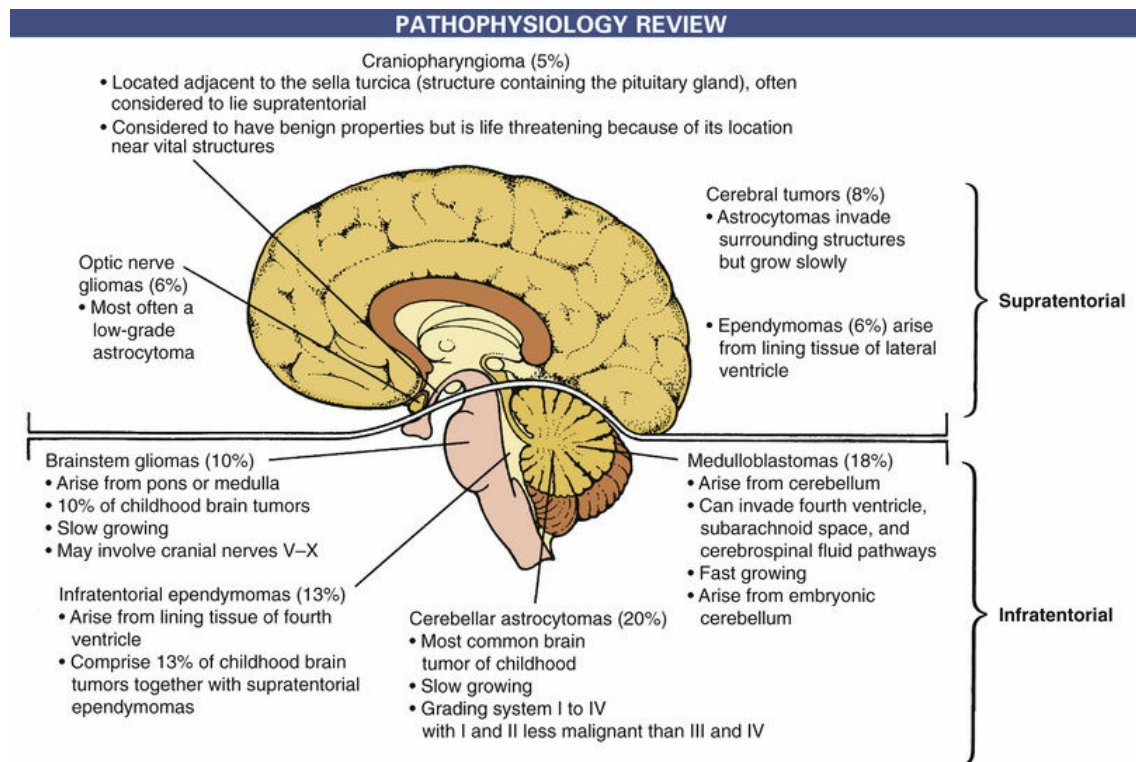

FIG 25-5 Location of brain tumors in children. (From McCance KL, Huether SE: *Pathophysiology: the biological basis for disease in adults and children*, ed 7, St Louis, 2014, Elsevier.)

Because the neoplasms can arise from any cell within the cranium, it is possible to have tumors originating from the glial cells, nerve cells, neuroepithelium, cranial nerves, blood vessels, pineal gland, and hypophysis. Within each of these structures, specific cells may be involved to provide a histologic classification of the major tumors found in children. Astrocytes, cells that form most of the supportive tissue for the neurons, may form astrocytomas, which is the most common glial tumor (Parsons, Pollack, Hass-Kogan et al, 2016). Brain tumors may be benign or malignant, although the designation of any tumor in the brain as “benign” should be done cautiously given the vital functions the brain controls.

Clinical Manifestations

The signs and symptoms of brain tumors are directly related to their anatomic location and size and to some extent the child's age. For instance, in infants whose sutures are still open, a bulging fontanel indicates hydrocephalus. Head circumference measurements allow for detection of increased head size. Even in older children, clinical manifestations may be nonspecific. However, the most common symptoms of infratentorial brain tumors are headache, especially on awakening, and vomiting that is not related to feeding. Tumors in this area of the brain often obstruct the flow

of cerebrospinal fluid, causing increased ICP and the symptoms mentioned earlier. In addition, patients may have symptoms related to the specific structure involved. Tumors of the cerebellum often cause nystagmus, ataxia, dysarthria, and dysmetria. Supratentorial symptoms more commonly include seizures, personality or behavioral changes, visual disturbances, and hemiparesis. Tumors involving the structures of the midbrain, including the hypothalamus and pituitary gland, may cause endocrinopathies, such as diabetes insipidus, delayed or precocious puberty, and growth failure. Table 25-2 presents the common presenting symptoms of brain tumors.

TABLE 25-2
Clinical Manifestations and Assessment of Brain Tumors

| Signs and Symptoms | Assessment |
|--|--|
| Headache | |
| Recurrent and progressive In frontal or occipital areas Usually dull and throbbing Worse on arising, less during day Intensified by lowering head and straining, such as during bowel movement, coughing, sneezing | Record description of pain, location, severity, and duration. Use pain rating scale to assess severity of pain (see Chapter 5). Note changes in relation to time of day and activity. Observe changes in behavior in infants (e.g., persistent irritability, crying, head rolling). |
| Vomiting | |
| With or without nausea or feeding Progressively more projectile More severe in morning upon arising Relieved by moving about and changing position | Record time, amount, and relationship to feeding, nausea, and activity. |
| Neuromuscular Changes | |
| Incoordination or clumsiness Loss of balance (e.g., use of wide-based stance, falling, tripping, banging into objects) Poor fine motor control Weakness Hyporeflexia or hyperreflexia Positive Babinski sign Spasticity Paralysis | Test muscle strength, gait, coordination, and reflexes (see Chapter 4). |
| Behavioral Changes | |
| Irritability Decreased appetite Failure to thrive Fatigue (frequent naps) Lethargy Coma Bizarre behavior (e.g., staring, automatic movements) | Observe behavior regularly. Compare observations with parental reports of normal behavioral patterns. Monitor growth and food intake. Monitor activity and sleep. |
| Cranial Nerve Neuropathy | |
| Cranial nerve involvement varied according to tumor location Most common signs: • Head tilt • Visual defects (e.g., nystagmus, diplopia, strabismus, episodic “graying out” of vision, visual field defect) | Assess cranial nerves, especially VII (facial), IX (glossopharyngeal), X (vagus), V (trigeminal, sensory roots), and VI (abducens) (see Chapter 4). Assess visual acuity, binocularity, and peripheral vision (see Chapter 4). |
| Vital Sign Disturbances | |
| Decreased pulse and respiration Increased blood pressure Decreased pulse pressure Hypothermia or hyperthermia | Measure vital signs frequently. Monitor pulse and respirations for 1 full min. Record pulse pressure (difference between systolic and diastolic blood pressure). |
| Other Signs | |
| Seizures Cranial enlargement* Tense, bulging fontanel at rest* Nuchal rigidity Papilledema (edema of optic nerve) | Record seizure activity (see Chapter 27). Measure head circumference daily (infant and young child). Perform funduscopic examination if skilled in procedure. |

*Present only in infants and young children.

Diagnostic Evaluation

Diagnosis of a brain tumor is based on presenting clinical signs and diagnostic imaging. Because the signs and symptoms may be vague and easily overlooked, early diagnosis necessitates a high index of suspicion during history taking. A number of tests may be employed in the neurologic evaluation (see Table 27-1), but the gold standard diagnostic procedure is MRI, which permits early diagnosis of brain tumors and assessment of tumor growth during or after treatment. Diffusion-weighted imaging, spectroscopy, and perfusion imaging are other MRI tools used to investigate and diagnose tumor types (Fleming and Chi, 2012). The CT scan permits direct visualization of the brain parenchyma, ventricles, and surrounding subarachnoid space, and it is commonly used in urgent cases of suspected tumors when MRI is not available. Other tests may include an MRI of the spine and electroencephalography. LP is dangerous in the presence of increased ICP because of possible brainstem herniation after sudden release of pressure.

Definitive diagnosis is based on tissue specimens obtained during surgery. Occasionally, special techniques are required for determining the cell type. This period of waiting is one of anxiety for family members who are aware of the link between cell type and prognosis. Because of the location of some brain tumors (such as brainstem tumors), a biopsy is not possible and the diagnosis is made by imaging findings alone.

Therapeutic Management

Treatment may involve the use of surgery, radiotherapy, and chemotherapy, depending on the type of tumor. The treatment of choice is total removal of the tumor without residual neurologic damage. Patients with the most complete tumor removal have the greatest chance of survival. Several surgical advances have allowed the biopsy and removal of tumors in areas previously considered too dangerous for traditional operative techniques.

Radiotherapy is used to treat most tumors and to shrink the size of the tumor before attempting surgical removal. The use of chemotherapy has emerged in the past decades with an increasingly important role, either in combination with surgery and/or radiation, or alone. The problems of treatment are compounded by the serious late effects of all three modes of therapy. Surgery can cause injury to important areas of the brain, especially when the surgeon is attempting to remove invasive tumors. Irradiation has serious long-term consequences, which may include tissue necrosis, secondary malignancies, endocrine dysfunction, and behavioral or intellectual deficits. For these reasons, the use of irradiation is deferred for as long as possible in young children. Proton radiation is now being used for treatment of brain tumors and provides a more focused beam of radiation that may reduce side effects (Fleming and Chi, 2012).

Nursing Care Management

Nursing care of the child with a brain tumor is similar regardless of the type of intracranial lesion. Because a brain tumor is potentially fatal, the reader is urged to incorporate the psychological interventions discussed in [Chapter 17](#) with those elaborated on in this section. Despite the grave nature of some brain tumors, it is important to realize the hope that new standard therapies and emerging therapies have brought to the families of many pediatric brain tumor patients.

Assess for Signs and Symptoms

A child admitted to the hospital with neurologic dysfunction is often suspected of having a brain tumor, even though the actual diagnosis is not yet confirmed. Establishing a baseline of data for comparing preoperative and postoperative changes is an essential step toward planning physical care and preventing complications. [Table 25-2](#) summarizes common presenting signs and assessment procedures to document significant changes in the child's condition.

Prepare the Family for Diagnostic and Operative Procedures

The suspected diagnosis of a brain tumor is always a crisis. Although some tumors are removed with excellent results, the physician can rarely give definitive answers regarding the prognosis until after surgery. Therefore, parents, the child, and other family members require much emotional support to face the diagnostic procedures and a craniotomy.

How the child is prepared for the diagnostic tests depends on the child's age and experience. Because most of the tests involve x-ray equipment, the child may be familiar with the procedure. [Chapter 20](#) discusses preparing children for an MRI or a CT scan. Once surgery is scheduled, the child needs an explanation of what to expect. Although it may be tempting to justify the surgery by stating that removing the tumor will take away various symptoms, the nurse should refrain from emphasizing this point too strenuously. Postsurgical headaches and cerebellar symptoms, such as ataxia, may be aggravated rather than improved. Surgery may not improve vision. With optic gliomas the child will be blind in one eye even if the tumor is fully resected. Finally, surgical removal of the mass may be impossible, and after surgery, functioning may temporarily deteriorate or result in permanent damage. Being honest before surgery most often makes honesty after the procedure easier because no false hopes were created.

It is best to deliver information in small amounts to let the child pursue additional answers. For example, some children ask about what happens when part of the tumor is left. An honest reply is that after surgery the physician will try to shrink the tumor with special x-rays and medicines. Delay a further explanation of irradiation or chemotherapy until a decision regarding these treatments is made.

The hair is usually shaved in the operating room just before surgery, or sometimes in the child's room, usually the night before surgery. When shaving is done with the child awake, the procedure is approached in a sensitive, positive way. Showing children how they look at different stages of the process helps them prepare for the final appearance. Once the hair is clipped short or shaved, offer

the child a cap or scarf. Take every precaution to provide privacy during the procedure. Depending on the child's immediate adjustment to the hair loss, the nurse may introduce the idea of wearing a wig until the hair grows in, particularly if additional irradiation or chemotherapy is anticipated.

Also tell children about the size of the dressing. Usually the entire scalp is covered to maintain tight wound closure, even if a small incision is made. Infratentorial head dressings may be attached to the upper back and extend forward to the neck to maintain slight extension and alignment as a precaution against wound rupture. Applying a similar dressing or “special hat” to a doll is often a less traumatic way of demonstrating the physical appearance.

Children also need a brief explanation of how they will feel after surgery and where they will be. Ordinarily they will return to a special intensive care unit, which they may visit beforehand, depending on hospital policy. They should be aware that they may be sleepy for some time after surgery and that a headache is likely, although it should last only a few days.

Parents need similar explanations before surgery, especially in terms of special equipment used in the intensive care unit, dressings, and their child's behavior. For example, they should know that it is not unusual for the child to be lethargic for a few days after surgery. The nurse may wish to encourage less frequent visiting during this period so that parents can rest and be able to support their child when the child is awake.

The nurse should participate in preoperative conferences with the physician and parents. The nurse needs to know what information the parents have been given in order to provide further explanations or emotional support when necessary.

Nursing Alert

Report sluggish, dilated, or unequal pupils immediately because they may indicate increased intracranial pressure (ICP) and potential brainstem herniation—a medical emergency.

Prevent Postoperative Complications

After surgery the surgeon prescribes specific orders for taking vital signs, positioning, regulating fluids, and administering medication. These vary somewhat, depending on the location of the craniotomy. The following are general principles of care for infratentorial or supratentorial surgery. [Chapter 27](#) discusses additional aspects of care, such as care of the child with seizures and care of the unconscious child in terms of respiratory status and neurologic assessment.

Assessment

Vital signs are taken as often as every 15 to 30 minutes until the patient is stable. Temperature measurement is particularly important because of hyperthermia resulting from surgical intervention in the hypothalamus or brainstem and from some types of general anesthesia.

Nursing Alert

To keep an accurate account of drainage, circle the soiled area with a pen and monitor for signs of continuous bleeding.

The presence of colorless drainage is reported immediately because it most likely is cerebrospinal fluid leaking from the incisional area. A foul odor from the dressing may indicate an infection. Such a finding is reported, and a culture is taken. The most likely types of infection are meningitis and respiratory tract infection. The probable cause of meningitis is wound contamination. The risk of respiratory tract infections is high because of the imposed immobility, danger of aspiration, and possible depression from the brainstem. The usual precautions of deep breathing and turning as allowed are instituted. Regular pulmonary assessments are performed to identify adventitious sounds or any areas of diminished or absent breath sounds.

As soon as possible, the nurse should begin testing reflexes, hand grip, and functioning of the cranial nerves. Muscle strength is usually less after surgery because of general weakness but should improve daily. Ataxia may be significantly worse with cerebellar intervention, but it slowly improves. Edema near the cranial nerves may depress important functions, such as the gag, blink, or swallowing reflex.

Neurologic checks are an essential aspect of care and include pupillary reaction to light, level of

consciousness, sleep patterns, and response to stimuli. Although children may be comatose for a few days, once they regain consciousness, there should be a steady increase in alertness. Regression to a lethargic, irritable state indicates increasing pressure, possibly caused by meningitis, hemorrhage, or edema.

Once the younger child is alert, the arms may need to be restrained to preserve the dressing. Even a child who has been cooperative before surgery must be closely supervised during the initial stages of regaining consciousness, which is when disorientation and restlessness are common. Elbow restraints are satisfactory to prevent the hands from reaching the head, although additional restraint may be necessary to preserve an infusion line and maintain a specific position.

Positioning

Correct positioning after surgery is critical to prevent pressure against the operative site, reduce ICP, and avoid the danger of aspiration. If a large tumor was removed, the child is not placed on the operative side, because the brain may suddenly shift to that cavity, causing trauma to the blood vessels, linings, and the brain itself. The nurse confers with the surgeon to be certain of the correct position, including the degree of neck flexion. The first 24 to 48 hours after brain surgery are critical. If positioning is restricted, notice of this is posted above the head of the bed. When the child is turned, every precaution is used to prevent jarring or misalignment to prevent undue strain on the sutures. Two nurses, one supporting the head and the other the body, are needed. The use of a turning sheet may facilitate turning a heavy child.

Nursing Alert

The Trendelenburg position is contraindicated in both infratentorial and supratentorial surgeries because it increases intracranial pressure (ICP) and the risk of hemorrhage. If shock is impending, the practitioner is notified immediately, before the head is lowered.

Fluid Regulation

With an infratentorial craniotomy, the child is allowed nothing by mouth for at least 24 hours or longer if the gag and swallowing reflexes are depressed or the child is comatose. With a supratentorial procedure, feeding may be resumed soon after the child is alert, sometimes within 24 hours. Clear water is always started first because of the danger of aspiration. If the child vomits, stop oral liquids. Vomiting not only predisposes the child to aspiration but also increases ICP and the risk for incisional rupture.

IV fluids are continued until fluids are well tolerated. Because of the cerebral edema postoperatively and the danger of increased ICP, fluids are carefully monitored and usually infused less than the maintenance rate. A hypertonic solution such as mannitol may be necessary to remove excess fluid. These drugs cause rapid diuresis. Urinary output is monitored after administration of these drugs to evaluate their effectiveness.

Comfort Measures

Headache may be severe and is largely the result of cerebral edema. Measures to relieve some of the discomfort include providing a quiet, dimly lit environment; restricting visitors; preventing any sudden jarring movement, such as banging into the bed; and preventing an increase in ICP. The last is most effectively achieved by proper positioning and prevention of straining, such as during coughing, vomiting, or defecating. The use of opioids, such as morphine, to relieve pain is controversial because it is thought that they may mask signs of altered consciousness or depress respirations. However, opioids are considered safe because naloxone can be used to reverse opioid effects, such as sedation or respiratory depression. Acetaminophen and codeine are also effective analgesics. Regardless of the drugs used, adequate dosage and regular administration are essential to provide optimum pain relief (see [Pain Assessment](#) and [Pain Management, Chapter 5](#)).

Brain edema may severely depress the gag reflex, necessitating suctioning of oral secretions. Facial edema may also be present, necessitating eye care if the lids remain partially open. Ice compresses applied to the eyes for short periods help relieve the edema. A depressed blink reflex also predisposes the corneas to ulceration. Irrigating the eyes with saline drops and covering them with eye dressings are important steps in preventing this complication.

Support the Family

The family's emotional needs are great when the diagnosis is a brain tumor, and the extent of surgery, any neurologic deficits, the prognosis, and additional therapy influence these feelings. Because few definitive answers can be given before surgery, the surgeon's report is a significant finding that can vary from a completely benign, resected neoplasm to a highly malignant, invasive, and only partially removed tumor. Although parents try to prepare themselves for a potentially fatal diagnosis, it is understandably a shock for them.

Ideally, a nurse who will be involved in the continuing care of this child should be with the family when the physician discusses the prognosis and plan of therapy. Regardless of the future prospects, direct the parents' thinking toward helping the child recover and resume a normal life to his or her fullest potential. Provide an opportunity for the family to share their concerns and questions and encourage parents to verbalize their feelings about the diagnosis.*

During this period the nurse should also discuss with parents what they plan to tell the child. If the child was prepared honestly, as described previously, the diagnosis can be expressed in a similar manner, such as "The surgeon removed most of the tumor, and the rest will be treated with special drugs and x-ray treatments." During recovery the child needs additional explanation about the treatment and the reason for residual neurologic effects, such as ataxia or blindness. Hair loss is a normal concern for the child, and its regrowth will be delayed, depending on the length of therapy. At this point it is advisable to reintroduce the idea of a wig.

Promote Return to Optimum Functioning

The ultimate goal is a cured child who has optimum functioning. As soon as possible, the child should resume usual activities within tolerable limits, especially returning to school.† Until the skull is completely healed, the child may need to wear a helmet when engaging in any active sport. This decision is made by the child's neurosurgeon. The school nurse and teacher should confer with the parents on activity restrictions, such as physical education, and the reactions of schoolmates to the child's appearance.

The vast realm of possible consequences after the diagnosis of a brain tumor is not discussed here. Rather, the reader is referred to other sections of the text that deal with possible outcomes, such as the paralyzed, visually impaired, or unconscious child or the child with a ventricular shunt, seizure disorder, or meningitis. Numerous physical problems can occur with progression of the tumor that may necessitate additional procedures. For example, frequent vomiting, anorexia, and nausea may require non-oral routes of feeding, such as gastrostomy or parenteral alimentation. Whenever these procedures are instituted, the nurse may be responsible for teaching the family appropriate home care to allow the child the highest quality of life (see the discussion of discharge planning and home care in [Chapter 19](#)).

Neuroblastoma

Neuroblastoma is the most common extracranial solid tumor of childhood and the most common cancer diagnosed in infancy. Approximately 650 new cases of neuroblastoma are diagnosed every year in the United States ([National Cancer Institute, 2015c](#)). The median age at diagnosis is 19 months ([National Cancer Institute, 2015c](#)). These tumors originate from embryonic neural crest cells that normally give rise to the adrenal medulla and the sympathetic nervous system. Consequently, the majority of the tumors arise from the adrenal gland or from the retroperitoneal sympathetic chain. The primary site is within the abdomen; other sites include the head and neck region, chest, and pelvis.

Clinical Manifestations

The signs and symptoms of neuroblastoma depend on the location and stage of the disease. With abdominal tumors, the most common presenting sign is a firm, nontender, irregular mass in the abdomen that crosses the midline (in contrast to Wilms tumor, which is usually confined to one side). Other primary tumor sites may cause significant clinical effects such as neurologic impairment, respiratory obstruction from a thoracic mass, or varying degrees of paralysis from compression of the spinal cord.

Distant metastasis frequently causes supraorbital ecchymosis, periorbital edema, and proptosis (exophthalmos) from invasion of retrobulbar soft tissue. Lymphadenopathy, hepatomegaly, and

skeletal pain are also present in patients with disseminated disease. Vague symptoms of widespread metastasis include pallor, weakness, irritability, anorexia, and weight loss.

Diagnostic Evaluation

Diagnostic evaluation is aimed at locating the primary site and areas of metastasis. A CT scan of the abdomen, pelvis, or chest is the preferred imaging modality to locate the primary tumor. A bone scan and MIBG (iodine-131 metaiodobenzylguanidine) scan should be performed to evaluate for the presence of skeletal metastases. Examination of the bone marrow with bilateral aspirates and biopsies should be performed in all patients. Neuroblastomas, particularly those arising on the adrenal glands or from a sympathetic chain, excrete the catecholamines epinephrine and norepinephrine. Urinary excretion of catecholamines is detected in approximately 95% of children with adrenal or sympathetic tumors.

Staging and Prognosis

Neuroblastoma is a “silent” tumor. In more than 70% of cases, diagnosis is made after metastasis occurs, with the first signs caused by involvement in the nonprimary site, usually the lymph nodes, bone marrow, skeletal system, or liver. Because of the frequency of invasiveness, the prognosis for neuroblastoma is generally poor.

The child's age and the stage of the disease (Box 25-4) at diagnosis are important prognostic factors. Survival is inversely correlated with age. If all stages are grouped together, the survival rates are approximately 80% for children younger than 1 year old and less than 50% for children older than 1 year old (Brodeur, Hogarty, Bagatell, et al, 2016). This marked difference in survival rates by age is partly accounted for by the larger proportion of very young children with stage I, II, or IV-S disease and the absence of the MYC-*N* gene amplification.

Box 25-4

Staging of Neuroblastoma

Stage I: Localized tumor that is confined to the area of origin capable of complete gross excision; representative ipsilateral lymph nodes negative for tumor microscopically (nodes that are attached to and removed with the primary tumor may be positive)

Stage II-A: Unilateral tumor with incomplete gross resection; representative ipsilateral nonadherent lymph nodes and contralateral lymph nodes negative for tumor microscopically

Stage II-B: Unilateral tumor with or without complete gross excision, with ipsilateral nonadherent lymph nodes positive for tumor; enlarged contralateral lymph nodes must be negative microscopically

Stage III: Tumor infiltrating across the midline, with or without regional lymph node involvement; or localized unilateral tumor with contralateral regional lymph node involvement; or midline tumor with bilateral lymph node involvement

Stage IV: Dissemination of tumor to distant lymph nodes, bone, bone marrow, liver, skin, and/or other organs

Stage IV-S: Localized primary tumor (as defined for stage I, II-A, or II-B) with dissemination limited to liver, skin, or bone marrow but not to bone

Infants who remain free of disease for 1 year after treatment are usually cured, but older children have experienced relapses several years after cessation of treatment. Surgical resection of the tumor in stage I appears to be greater than 90% curative (Brodeur, Hogarty, Bagatell, et al, 2016).

Neuroblastoma is one of the few tumors that demonstrate spontaneous regression (especially stage IV-S), possibly as a result of maturity of the embryonic cell or development of an active immune system.

Therapeutic Management

Accurate clinical staging is important for establishing initial treatment. Therefore, the purpose of surgery is both to remove as much of the tumor as possible and to obtain biopsies. In stages I and II, complete surgical removal of the tumor is the treatment of choice. If the tumors are large, partial resection is attempted, with a course of irradiation postoperatively to shrink the tumor in the hope of complete removal at a later date. Surgery is usually limited to biopsy in stages III and IV because of the extensive metastasis.

The precise role of radiotherapy is unclear. It does not appear to be of any benefit in children with stage I and II disease. It can be used with stage III disease, although it may not improve survival expectancy. Radiotherapy for paraspinal neuroblastoma is no longer recommended because the radiation therapy has long-term morbidity and chemotherapy is safe and effective initial treatment modality (Brodeur, Hogarty, Bagatell, et al, 2016).

Chemotherapy is the mainstay of therapy for extensive local or disseminated disease. The drugs are administered in a variety of combinations according to specific protocols. In addition, the use of consolidative myeloablative therapy using autologous marrow or peripheral stem cells followed by 13-*cis*-retinoic acid has improved the outcome of patients with high-risk disease.

Nursing Care Management

Nursing care management is similar to that discussed under [Nursing Care Management](#) section, including psychological and physical preparation for diagnostic and operative procedures; prevention of postoperative complications for abdominal, thoracic, or cranial surgery; and explanation of chemotherapy and radiotherapy and their side effects (see [Tables 25-1](#) and [25-3](#)).

TABLE 25-3
Late Effects of Cancer Treatment

| Systemic Effects and Clinical Manifestations | Associated Mode of Treatment |
|--|---|
| Central Nervous System | |
| Leukoencephalopathy (syndrome ranging from lethargy, dementia, and seizures to quadriplegia and death) | Methotrexate, intrathecal chemotherapy, or CNS irradiation |
| Mineralizing microangiopathy (headaches, focal seizures, incoordination, gait abnormalities) | Methotrexate or CNS irradiation |
| Peripheral neuropathy (footdrop, tingling sensation in hands and/or feet, incoordination) | Vincristine |
| Cognitive deficits (decline with intelligence, memory, attention, nonlanguage skills) | Intrathecal chemotherapy or cranial irradiation (especially before 3 years old) |
| Cardiovascular | |
| Cardiomyopathy (tachycardia, tachypnea, dyspnea, shortness of breath, edema, palpitations) | Anthracyclines (doxorubicin and daunorubicin) or irradiation to heart |
| Pericardial damage (pleural effusion, cardiomegaly) | High-dose cyclophosphamide Mediastinal irradiation |
| Respiratory | |
| Pneumonitis (dyspnea, nonproductive cough, fever) | Lung irradiation, alkylating agents, possibly bleomycin, vinblastine, cisplatin |
| Pulmonary fibrosis (dyspnea, restrictive ventilation, decreased exercise tolerance) | |
| Gastrointestinal | |
| Chronic enteritis (colic, abdominal pain, vomiting, diarrhea, obstipation, bleeding) | Abdominal irradiation, methotrexate, cytosine arabinoside |
| Hepatic fibrosis (jaundice, hepatomegaly) | Methotrexate, 6-mercaptopurine |
| Urinary | |
| Hemorrhagic cystitis (microscopic hematuria to gross hemorrhage) | Cyclophosphamide; ifosfamide; irradiation |
| Bladder fibrosis (decreased bladder capacity, ureteral reflux) | Cisplatin |
| Tubular necrosis (decreased creatinine clearance) | |
| Endocrine | |
| Thyroid dysfunction (see Chapter 28) | Irradiation to thyroid, pituitary gland, testes, ovaries |
| Reproductive | |
| Possible gonadal damage, both sexes (delayed puberty, amenorrhea, decreased sperm counts, increased follicle-stimulating and luteinizing hormones, decreased testosterone or estrogen) | Alkylating agents Irradiation to pituitary gland, testes, ovaries |
| Skeletal | |
| Growth retardation (short stature) | Irradiation, long-term steroids |
| Spinal deformities, scoliosis, kyphosis, asymmetric growth, pathologic fractures | Irradiation |
| Immune | |
| Asplenia (overwhelming infection, fever) | Splenectomy |
| Sensory Organs | |
| Cataracts (opacity over pupil) | Cranial irradiation, high-dose steroids |
| Hearing (decreased hearing, especially with high-frequency loss) | Cisplatin |
| Additional Effects | |
| Dental Problems | |
| Increased caries, periodontal disease, hypoplastic teeth, hypodontia (delayed or absent tooth development) | Irradiation to maxilla and mandible |
| Second Malignancies | |
| Bone and soft tissue tumors Leukemia (ALL or AML) | Irradiation, alkylating agents |

ALL, Acute lymphoblastic leukemia; AML, acute myelogenous leukemia; CNS, central nervous system.

Because this tumor carries a poor prognosis for many children, evaluate and address the needs of the family in terms of coping with a life-threatening illness (see [Chapter 17](#)). Because of the high degree of metastasis at the time of diagnosis, many parents suffer guilt for not having recognized signs earlier. Parents need much support in dealing with these feelings and expressing them to the appropriate people.

Bone Tumors

General Considerations

Bone tumors consist of osteosarcoma and Ewing sarcoma and account for about 6% of all malignant neoplasms in children in the United States (Scheurer, Lupo, and Bondy, 2016). Osteosarcoma is the most common bone tumor with approximately 4.4 cases per 1 million annually in the United States, whereas Ewing sarcoma occurs in 1 case per 1 million annually among children younger than 20 years old (National Cancer Institute, 2015d). The peak age for pediatric bone tumors is 15 years old, and they occur more often in males.

Clinical Manifestations

Most malignant bone tumors produce localized pain in the affected site, which may be severe or dull and may be attributed to trauma or the vague complaint of “growing pains.” The pain is often relieved by a flexed position, which relaxes the muscles overlying the stretched periosteum. Frequently it draws attention when the child limps, curtails physical activity, or is unable to hold heavy objects. A palpable mass is also a common manifestation of bone tumors, but systemic symptoms (such as fever) and other clinical symptoms (such as spinal cord compression and respiratory distress) are more frequent in patients with Ewing sarcoma.

Diagnostic Evaluation

Diagnosis begins with a thorough history and physical examination. A primary objective is to rule out causes, such as trauma or infection. Careful questioning regarding pain is essential in attempting to determine the duration and rate of tumor growth. Physical assessment focuses on functional status of the affected area; signs of inflammation; size of the mass; and any systemic indication of generalized malignancy, such as anemia, weight loss, and frequent infection.

Definitive diagnosis is based on radiologic studies, such as plain films and CT or MRI scan of the primary site, CT scan of the chest, and radioisotope bone scans to evaluate metastasis and bone marrow examination in patients with Ewing sarcoma. A needle or surgical biopsy is necessary to establish the diagnosis. Ewing sarcoma most commonly involves the pelvis, long bones of the lower extremities, and chest wall and radiographically involves the diaphysis with detachment of the periosteum from the bone (Codman triangle). In osteosarcoma, lesions are most commonly located in the metaphyseal region of the bone, often involving the long bones. Radial ossification in the soft tissue gives the tumor a “sunburst” appearance on plain radiograph.

Prognosis

A better understanding of the biology of neoplastic growth has resulted in more aggressive treatment and an improved prognosis. The natural history of osteogenic sarcoma and Ewing sarcoma suggests that multiple submicroscopic foci of metastatic disease are present at the time of diagnosis despite clinical evidence of localized involvement. The lungs, distant bones, and bone marrow are the most common sites for metastatic bone tumor disease. With current therapies that include surgery and chemotherapy for osteosarcoma and surgery, radiotherapy, and chemotherapy for Ewing sarcoma, the majority of patients with localized disease can be cured.

Osteosarcoma

Osteosarcoma (osteogenic sarcoma) presumably arises from bone-forming mesenchyme, which gives rise to malignant osteoid tissue. Most primary tumor sites are in the diaphyseal and metaphyseal region (wider part of the shaft, adjacent to the epiphyseal growth plate) of long bones, especially in the lower extremities. More than half occur in the femur, particularly the distal portion, with the rest involving the humerus, tibia, pelvis, jaw, and phalanges.

Therapeutic Management

Optimum treatment of osteosarcoma includes surgery and chemotherapy. The surgical approach consists of surgical biopsy followed by either limb salvage or amputation. To ensure local control,

all gross and microscopic tumors must be resected. A limb salvage procedure has become the standard approach to surgical intervention and involves resection of the primary tumor with prosthetic replacement of the involved bone (Gorlick, Janeway, Marina, 2016). Frequently children undergoing a limb salvage procedure receive preoperative chemotherapy in an attempt to decrease the tumor size and make surgery more manageable (Arndt, Rose, Folpe, et al, 2012).

Chemotherapy plays a vital role in treatment of osteosarcoma. Antineoplastic drugs may be administered singly or in combination and may be employed both before and after surgical resection of the tumor. When pulmonary metastases are found, thoracotomy and chemotherapy have resulted in prolonged survival and potential cure. These combined-modality approaches have significantly improved the prognosis in osteosarcoma to approximately 75% for nonmetastatic patients (Arndt, Rose, Folpe, et al, 2012).

Nursing Care Management

Nursing care depends on the type of surgical approach. The family may have more difficulty adjusting to an amputation than a limb salvage procedure. In either instance, preparation of the child and family is critical. Straightforward honesty is essential in gaining the child's cooperation and trust. The diagnosis of cancer should not be disguised with falsehoods such as "infection." To accept the need for surgery, the child should be told a few days before surgery to allow him or her time to think about the diagnosis and consequent treatment and to ask questions.

Sometimes children have many questions about the prosthesis, limitations on physical ability, and prognosis in terms of cure. At other times they react with silence or with a calm manner that belies their concern and fear. Either response must be accepted, since it is part of the grieving process of a loss. For those who desire information, it may be helpful to introduce them to another amputee before surgery or to show them pictures of the prosthesis.* However, the nurse must be careful not to overwhelm children with information. A sound approach is to answer questions without offering additional information. For those who do not pursue additional information, the nurse expresses a willingness to talk.

The child is also informed of the need for chemotherapy and its side effects before surgery. Exercise caution about offering too much information at one time. When discussing hair loss, emphasize coping strategies, such as wearing a wig. Because bone tumors affect adolescents and young adults, it is not unusual for them to become angry over all the radical body alterations.

The child requires stump care, which is the same as for any amputee. If an amputation is performed, the child is usually fitted with a temporary prosthesis immediately after surgery, which permits early functioning and fosters psychological adjustment. A permanent prosthesis is usually fitted within 6 to 8 weeks. During hospitalization the child begins physical therapy to become proficient in the use and care of the device.

Phantom limb pain may develop in 60% to 80% of patients after amputation and is caused from interruption of sensory nerve impulses (Wolff, Vanduyhoven, van Kleef, et al, 2011). This symptom is characterized by sensations such as tingling, itching, and, more frequently, pain felt in the amputated limb. The child and family need to know that the sensations are real—not imagined. A Cochrane Review reported that various medications such as morphine, gabapentin, and ketamine have been used for phantom limb pain, but complete pain relief has been unsuccessful (Alviar, Hale, and Dungca, 2011). Discharge planning must begin early in the postoperative period. Once the child has begun physical therapy, the nurse should consult with the therapist and practitioner to evaluate the child's physical and emotional readiness to reenter school. It is an opportune time to involve a community nurse in the child's home care. Every effort is made to promote normalcy and gradual resumption of realistic pre-amputation activities.* Role playing in anticipation of such experiences is beneficial in preparing the child for the inevitable confrontation by others. Environmental barriers, such as stairs, are assessed in terms of the accessibility in the school and home, especially because the child may need to use crutches or a wheelchair before complete healing and prosthetic competency are achieved. The nurse encourages the child to select clothing that best camouflages the prosthesis, such as pants or long-sleeved shirts. Well-fitted prostheses are so natural looking that girls can usually wear sheer stockings without revealing the device. Encouraging the child to wear jeans and a T-shirt may distract attention from the deformity and focus on familiar aspects of appearance.

The family and child need much support in adjusting not only to a life-threatening diagnosis but also to alteration in body form and function. Because loss of a limb entails a grieving process, those

caring for the child need to recognize that the reactions of anger and depression are normal and necessary. Often parents view the anger as a direct affront to them for allowing the amputation to occur, or they see the depression as rejection. These are not personal attacks but the child's attempts to cope with a loss.

Ewing Sarcoma (Primitive Neuroectodermal Tumor of the Bone)

Ewing sarcomas, which includes primitive neuroectodermal tumor of the bone, arise in the marrow spaces of the bone rather than from osseous tissue. The tumor originates in the shaft of long and trunk bones, most often affecting the pelvis, femur, tibia, fibula, humerus, ulna, vertebra, scapula, ribs, and skull. It occurs almost exclusively in individuals younger than 30 years old and affects Caucasians much more often than other races ([National Cancer Institute, 2015d](#)).

Therapeutic Management

Limb salvage procedures might be feasible in extremity lesions, and amputation may be considered if the results of radiotherapy render the extremity useless or deformed (e.g., from retarded growth in young children). The treatment of choice for the majority of lesions is involved field radiotherapy and chemotherapy.

Nursing Care Management

The psychological adjustment to Ewing sarcoma is typically less traumatic than it is to osteosarcoma because of the preservation of the affected limb. Many families accept the diagnosis with a sense of relief in knowing that this type of bone cancer does not necessitate amputation. Consequently, they need preparation for the various diagnostic tests, including bone marrow aspiration and surgical biopsy, and adequate explanation of the treatment regimen. Radiotherapy often causes a skin reaction of dry or moist desquamation followed by hyperpigmentation. The child should wear loose-fitting clothes over the irradiated area to minimize additional skin irritation. Because of increased sensitivity, protect the area from sunlight and sudden changes in temperature. Encourage the child to use the extremity as tolerated. Occasionally the physical therapist may plan an active exercise program to preserve maximum function.

The child needs the same considerations for adjusting to the effects of chemotherapy as any other patient with cancer. The drug regimen usually results in hair loss, severe nausea and vomiting, peripheral neuropathy, and possible cardiotoxicity. Make every effort to outline a treatment plan that allows the child maximum resumption of a normal lifestyle and activities.

Other Solid Tumors

In addition to the cancers already discussed, several other types of solid tumors may occur in children. Wilms tumor, rhabdomyosarcoma, and retinoblastoma are unique in that they tend to be diagnosed early, typically before 5 years old. Wilms tumor and retinoblastoma are also unusual in that they are among the few types of cancer that may occur in both hereditary and nonhereditary forms.

Wilms Tumor

Wilms tumor, or nephroblastoma, is the most common kidney tumor of childhood (Davidoff, 2012). Its frequency is estimated to be 8 cases per 1 million children younger than 15 years old, with approximately 650 new cases per year (Davidoff, 2012). Seventy-five percent of patients with Wilms tumor are diagnosed when they are younger than 5 years old, and it has a peak incidence between 2 and 3 years old (Davidoff, 2012). About 5% of Wilms tumors are familial (Davidoff, 2012).

Clinical Manifestations

The most common presenting sign is painless swelling or mass within the abdomen. The mass is characteristically firm, nontender, confined to one side, and deep within the flank. If it is on the right side, it may be difficult to distinguish from the liver, although, unlike that organ, it does not move with respiration. Parents usually discover the mass during routine bathing or dressing of the child.

Other clinical manifestations are the result of compression from the tumor mass, metabolic alterations secondary to the tumor, or metastasis. Hematuria occurs in less than one fourth of children with Wilms tumor. Anemia, usually secondary to hemorrhage within the tumor, results in pallor, anorexia, and lethargy. Hypertension, caused by secretion of excess amounts of renin by the tumor, occurs occasionally. Other effects of malignancy include weight loss and fever. If metastasis has occurred, symptoms of lung involvement (such as dyspnea, cough, shortness of breath, and pain in the chest) may be evident.

Diagnostic Evaluation

In a child suspected of having Wilms tumor, special emphasis is placed on the history and physical examination for the presence of congenital anomalies; a family history of cancer; and signs of malignancy, such as weight loss, enlarged liver and spleen, indications of anemia, and lymphadenopathy. Specific tests include radiographic studies, such as abdominal ultrasound, CT, and MRI of the abdomen; CT of the chest to look for metastases in the lung; and Doppler ultrasound of the inferior vena cava. Laboratory studies should include a complete blood count (polycythemia is sometimes present if the tumor secretes excess erythropoietin), biochemical studies, and urinalysis. Studies to demonstrate the relationship of the tumor to the ipsilateral kidney and the presence of a normally functioning kidney on the contralateral side are essential.

Staging and Prognosis

Wilms tumor arises from a malignant, undifferentiated metanephrogenic blastoma (a cluster of primordial cells capable of initiating the regeneration of an abnormal structure). Its occurrence slightly favors the left kidney, which is advantageous because surgically this kidney is easier to manipulate and remove. Although the tumor may become large, it remains encapsulated for an extended period.

The histology of the tumor cells is identified and classified according to two groups: favorable histology (FH) and unfavorable histology (UH). Only about 10% of Wilms tumors demonstrate UH, which is associated with a poorer prognosis and demands a more aggressive treatment protocol, regardless of the clinical stage (Davenport, Blanco, and Sandler, 2012).

Survival rates for Wilms tumor are one of the highest among all childhood cancers. Children with localized tumor have a 90% chance of cure with multimodal therapy (Davenport, Blanco, and Sandler, 2012). For those children who relapse, a better expectancy of disease-free survival is associated with FH of the tumor; time to recurrence and site of recurrence are no longer considered

prognostic indicators (Davidoff, 2012).

Therapeutic Management

Combined treatment with surgery and chemotherapy, with or without irradiation, is based on the clinical stage and histologic pattern. In unilateral disease, a large transabdominal incision is performed for optimum visualization of the abdominal cavity. The tumor, affected kidney, and adjacent adrenal gland are removed. Great care is taken to keep the encapsulated tumor intact because rupture can seed cancer cells throughout the abdomen, lymph channel, and bloodstream. The contralateral kidney is carefully inspected for evidence of disease or dysfunction. Regional lymph nodes are inspected, and a biopsy is performed when indicated. Any involved structures (such as part of the colon, diaphragm, or vena cava) are removed. Metal clips are placed around the tumor site for exact marking during radiotherapy.

If both kidneys are involved, the child may be treated with chemotherapy preoperatively to shrink the tumor, allowing more successful surgery (Davenport, Blanco, and Sandler, 2012). In some cases, a partial nephrectomy is performed, followed with additional administration of chemotherapy. When additional therapy is not effective, bilateral nephrectomy is performed with obligatory dialysis and a renal transplant is pursued (Davenport, Blanco, and Sandler, 2012).

Postoperative radiotherapy is indicated for children with metastatic disease (Davenport, Blanco, and Sandler, 2012). Chemotherapy is indicated for all children. The duration of therapy ranges from 6 to 15 months.

Nursing Care Management

The nursing care of the child with Wilms tumor is similar to that of other cancers treated with surgery, irradiation, and chemotherapy. However, some significant differences are discussed for each phase of nursing intervention.

Preoperative Care

As with many of the other cancers, the diagnosis of Wilms tumor is a shock. Frequently the child has no physical indication of the seriousness of the disorder other than a palpable abdominal mass. Because the parents usually discover the mass, the nurse needs to take into account their feelings regarding the diagnosis. Whereas some parents are grateful for their detection of the tumor, others feel guilty for not finding it sooner or anger toward the provider for missing it on earlier examinations.

The preoperative period is one of swift diagnosis. Typically, surgery is scheduled within 24 to 48 hours of admission. The nurse is faced with the challenge of preparing the child and parents for all laboratory and operative procedures. Because of the little time available, keep explanations simple and repeat them often, with attention to what the child will experience. In addition to usual preoperative observations, monitor blood pressure, because hypertension from excess renin production is a possibility.

There are several special preoperative concerns, the most important of which is not to palpate the tumor unless absolutely necessary because manipulation of the mass may cause dissemination of cancer cells to adjacent and distant sites.

Nursing Alert

To reinforce the need for caution, it may be necessary to post a sign on the bed that reads “Do not palpate abdomen.” Careful bathing and handling are also important in preventing trauma to the tumor site.

Because radiotherapy and chemotherapy are usually begun immediately after surgery, parents need an explanation of what to expect, such as major benefits and side effects, although the timing of the information should be considered to avoid overwhelming the family. Ideally the nurse should be present during physician-parent conferences to answer questions as they arise.

Postoperative Care

Despite the extensive surgical intervention necessary in many children with Wilms tumor, the

recovery period is usually rapid. The major nursing responsibilities are those following any abdominal surgery. Because these children are at risk for intestinal obstruction from postsurgical adhesion formation or side effects from the chemotherapy and radiation, the nurse monitors gastrointestinal activity, such as bowel movements, bowel sounds, distention, and vomiting. Other considerations are frequent evaluation of blood pressure and observation for signs of infection, especially during chemotherapy.

Support the Family

The postoperative period is frequently difficult for parents. The shock of seeing their child immediately after surgery may be the first realization of the seriousness of the diagnosis. From surgery, the stage and pathology of the tumor are determined. The physician discusses this information with the parents. The nurse's presence during this conversation is important to provide additional support and assess the parents' understanding of this information.

Older children need an opportunity to deal with their feelings concerning the many procedures to which they have been subjected in rapid succession. Therapeutic play can be beneficial in helping children of any age understand what they have undergone and express their feelings.

Rhabdomyosarcoma

Rhabdomyosarcoma (*rhabdo* means striated) is the most common soft tissue sarcoma in children. Striated (skeletal) muscle is found almost anywhere in the body, so these tumors occur in many sites—the most common of which are the head and neck, especially the orbit. The disease occurs in children in all age groups but is most common in children 9 years old or younger and is slightly more common in males (Wexler, Skapek, and Helman, 2016). Its incidence is approximately 4.5 cases per million children annually (National Cancer Institute, 2015e).

Rhabdomyosarcoma arises from embryonic mesenchyme with three recognized subtypes (Box 25-5). These malignant neoplasms originate from undifferentiated mesenchymal cells in muscles, tendons, bursae, and fascia, or in fibrous, connective, lymphatic, or vascular tissue. They derive their name from the specific tissue(s) of origin, such as myosarcoma (*myo* means muscle).

Box 25-5

Subtypes of Rhabdomyosarcoma

Embryonal: Most common type; most frequently found in the head, neck, abdomen, and genitourinary tract

Alveolar: Second most common type; most often seen in deep tissues of the extremities and trunk

Pleomorphic: Rare in children (adult form); most often occurs in soft parts of extremities and trunk

Clinical Manifestations

The initial signs and symptoms are related to the site of the tumor and compression of adjacent organs. Some tumor locations, such as the orbit, manifest early in the course of the illness. Other tumors, such as those of the retroperitoneal area, only produce symptoms when they are relatively big and compress adjacent organs. Unfortunately, many of the signs and symptoms attributable to rhabdomyosarcoma are vague and frequently suggest a common childhood illness, such as “earache” or “runny nose.” Often the site of the primary tumor site is never identified.

Diagnostic Evaluation

Diagnosis begins with a careful history and physical examination. Radiographic studies to delineate the primary tumor site should include PET/CT or MRI scans. Metastatic evaluation should include a CT of the chest, bone scan, and bilateral bone marrow aspirates and biopsies. For patients with tumors in the parameningeal area, an LP is performed to examine the spinal fluid. An excisional biopsy or surgical resection of the tumor, when possible, is done to confirm the diagnosis.

Staging and Prognosis

Careful staging is extremely important for planning treatment and determining the prognosis. The Intergroup Rhabdomyosarcoma Study has developed a surgicopathologic staging system, which includes four stage classifications depending on disease involvement.

With the use of contemporary multimodal therapy, more than 60% of patients with nonmetastatic disease are expected to survive, and if diagnosed in the early stage, the survival rate increases to 80% (Davenport, Blanco, and Sandler, 2012). If relapse occurs, the prognosis for long-term survival is poor.

Therapeutic Management

All rhabdomyosarcomas are high-grade tumors with the potential for metastases. Therefore, multimodal therapy is recommended for all patients. Complete removal of the primary tumor is advocated whenever possible. However, because the tumor is chemosensitive, radical procedures with high morbidity should be avoided. In the majority of cases, a biopsy is followed by chemotherapy, irradiation, or both.

Nursing Care Management

The nursing responsibilities are similar to those for other types of cancer, especially the solid tumors when surgery is employed. Specific objectives include careful assessment for signs of the tumor, especially during well-child examinations; preparation of the child and family for the multiple diagnostic tests; and supportive care during each stage of multimodal therapy. The reader is urged to review [Chapter 17](#) for emotional support of the family in the event of a poor prognosis.

Retinoblastoma

Retinoblastoma, which arises from the retina, is the most common intraocular malignancy of childhood (Dimaras, Kimani, and O Dimba, 2012). Approximately 4 cases per 1 million children occur annually in the United States (National Cancer Institute, 2015f). The average age of the child at the time of diagnosis is 2 years old, and bilateral and hereditary disease is diagnosed earlier than unilateral and nonhereditary disease (Hurwitz, Shields, Shields, et al, 2016). Of all cases of retinoblastoma, 60% are unilateral and nonhereditary, 25% are bilateral and hereditary, and 15% are unilateral and hereditary (National Cancer Institute, 2015f).

Retinoblastoma may be caused by various genetic alterations of the *Rb* gene, including a somatic mutation in nonhereditary cases, a germ-line mutation in hereditary cases, or a chromosomal deletion involving chromosome 13. A “two-hit hypothesis” was developed to explain genetic and sporadic cases and states that as few as two mutational events are required for tumor initiation. Children who have chromosome aberrations and retinoblastoma also often have an increased incidence of cognitive impairment and congenital malformations, although the vast majority of children with retinoblastomas apparently have normal chromosomes and intelligence.

Clinical Manifestations

Retinoblastoma has few grossly obvious signs. Typically the parents are the ones who first observe a whitish “glow” in the pupil, known as the cat’s eye reflex, or leukocoria ([Fig. 25-6](#)). The reflex represents visualization of the tumor as the light momentarily falls on the mass. When a tumor arises in the macular region (which is the area directly at the back of the retina when the eye is focused straight ahead), a white reflex may be visible when the tumor is small. It is best observed when a bright light is shining toward the child as the child looks forward. Sometimes parents accidentally discover it when taking a photograph of their child using a flash attachment.

FIG 25-6 Cat's eye reflex. Whitish appearance of lens is produced as light falls on tumor mass in left eye.

When the tumor arises in the periphery of the retina, it must grow to a considerable size before light can strike it sufficiently to produce the cat's eye reflex. In this situation it is visible only when the child looks in certain directions (sideways) or if the observer stands at an oblique angle to the child's face as the child looks straight ahead. The fleeting nature of the reflex often results in a delayed diagnosis because health care professionals fail to appreciate the ominous significance of the parents' findings.

The next most common sign is strabismus resulting from poor fixation of the visually impaired eye, particularly if the tumor develops in the macula, the area of sharpest visual acuity. Blindness is usually a late sign, but it frequently is not obvious unless the parent consciously observes for behaviors indicating loss of sight, such as bumping into objects, slowed motor development, or turning of the head to see objects lateral to the affected eye. Other signs and symptoms include heterochromia (different color of the iris), glaucoma, and pain.

Diagnostic Evaluation

A detailed family history and recording of eye symptoms are essential. Children suspected of having this disorder are referred to an ophthalmologist; the diagnosis is usually based on indirect ophthalmoscopy, ultrasound, CT, and MRI scans.

Metastatic disease at the time of retinoblastoma diagnosis is rare (Hurwitz, Shields, Shields, et al, 2016); therefore, staging procedures such as bone marrow aspiration, bone scan, and LP are not routinely performed.

Staging and Prognosis

Staging of retinoblastomas is done under indirect ophthalmoscopy before surgery to accurately determine the tumor size (measured in disc diameters [DDs]) and location (according to an imaginary line called the *equator* drawn on the midplane of the eye) (Hurwitz, Shields, Shields, et al, 2016).

Various classification systems have been used to stage retinoblastoma. The Reese-Ellsworth system classifies patients according to five groups and predicts survival when patients are treated with radiotherapy. A revised classification system, International Classification of Retinoblastoma, was developed in 2003 and is based on the extent and location of the intraocular tumor; it better predicts globe salvage using contemporary treatments. The overall 10-year survival rate is nearly 90% for unilateral and bilateral tumors (Hurwitz, Shields, Shields, et al, 2016). Retinoblastoma is one of the tumors that may spontaneously regress.

Of major concern in long-term survivors is the development of secondary tumors. Children with bilateral disease (hereditary form) are more likely to develop secondary cancers than are children with unilateral disease. Currently providers believe these individuals are predisposed to developing cancer and that radiation increases their risk.

Therapeutic Management

Treatment of retinoblastoma is complex. Enucleation may be used to treat advanced disease with

optic nerve invasion in which there is no hope for salvage of vision. Irradiation can be used when there is vitreous seeding. Chemotherapy has been used to decrease the tumor size to allow treatment with local therapies, such as plaque brachytherapy (surgical implantation of an iodine-125 applicator on the sclera until the maximum radiation dose has been delivered to the tumor), photocoagulation (use of a laser beam to destroy retinal blood vessels that supply nutrition to the tumor), and cryotherapy (freezing of the tumor, which destroys the microcirculation to the tumor and the cells themselves through microcrystal formation). The use of chemotherapy along with radiation or high-dose chemotherapy with autologous stem cell rescue is used to treat metastatic disease (Hurwitz, Shields, Shields, et al, 2016).

Nursing Care Management

Prepare the Family for Diagnostic and Therapeutic Procedures and Home Care

Because the tumor is usually diagnosed in infants or very young children, most of the preparation for diagnostic tests and treatment involves parents. Once the disease is staged, the physician confers with the parents regarding treatment. In most cases, enucleation can be avoided. In the event that an enucleation is performed, tell parents about the procedure and the benefits of a prosthesis. Showing parents pictures of another child with an artificial eye may help them adjust to the procedure. Although the loss of vision is distressing, most parents realize that there is no alternative. Emphasizing that the unaffected eye retains normal vision and that the affected eye is probably already blind is particularly helpful in promoting acceptance of the imposed impairment.

After surgery the parents need to be prepared for the child's facial appearance. An eye patch is in place, and the child's face may be edematous and ecchymotic. Parents often fear seeing the surgical site because they imagine a cavity in the skull. On the contrary, the lids are usually closed, and the area does not appear sunken because a surgically implanted sphere maintains the shape of the eyeball. The implant is covered with conjunctiva, and when the lids are open, the exposed area resembles the mucosal lining of the mouth. Once the child is fitted for a prosthesis, usually within 3 weeks, the facial appearance returns to normal.

After an uneventful recovery from enucleation, plans can be made for discharge from the hospital, usually within 3 to 4 days postoperatively. Parents need instruction regarding care of the surgical site and preparation for any additional therapy. They should be given the opportunity to see the socket as soon after surgery as possible. A good time to do this without unduly pressuring them is during dressing changes. They should then be encouraged to participate in the dressing changes.

Care of the socket is minimal and easily accomplished. The wound itself is clean and has little or no drainage. If an antibiotic ointment is prescribed, it is applied in a thin line on the surface of the tissues of the socket. The dressing consists of an eye pad changed daily. Once the socket has healed completely, a dressing is no longer necessary, although there are several reasons for having the child continue to wear an eye patch. Infants and toddlers explore their environment with their hands, and without an eye patch in place, the socket is available to exploring fingers. Although there is little danger of the child injuring the socket, parents may feel more secure with the socket covered. This also helps prevent infection.

The oculist, who fits and manufactures the prosthesis, gives initial instructions for care of the device. Once in place, the prosthesis need not be removed unless cleaning is necessary, in which case it is taken out by gently pulling down on the lower lid, which frees the lower edge of the prosthesis, and applying pressure to the upper lid. The prosthesis is cleaned by placing it in hot water and soaking it for several minutes. Reinsertion is easier if the prosthesis remains wet. To reinsert the prosthesis, the lids are separated; and with the prosthesis held in the correct position (it should be marked to indicate the nasal side), it is pushed up under the upper lid, allowing the lower lid to cover its lower edge.

Safety is a major concern to prevent damage to the unaffected eye. Safety measures should be practiced at all times, and children should avoid rough contact sports or wear protective eyewear.

Support the Family

The diagnosis of retinoblastoma presents some special concerns in addition to those raised by any type of cancer. Families with a history of the disorder may feel guilt for transmitting the defect to their offspring, especially if they knowingly "played the odds" and parented an affected child.

Conversely, when parents are aware of the probability and have an affected child, early treatment results in such favorable outcomes that parental adjustment may be rapid. In families with no history of retinoblastoma, the diagnosis is a shock, frequently complicated by guilt for not having discovered it sooner. Because parents frequently are the first to observe the cat's eye reflex, they may be angry at themselves or others, especially professionals, for delaying a more thorough examination. Consider each of these variables while offering supportive care to the family.

Other concerns also relate to the hereditary aspects of the disease. Of great importance to parents is the risk of retinoblastoma in their subsequent offspring and in the offspring of the surviving affected child. With improving prognoses for these children, genetic counseling to prevent transmission of the disease is assuming greater importance. Encourage these families to seek regular follow-up care for the affected child to detect secondary tumors, and all subsequent offspring of unaffected parents and survivors should undergo regular ophthalmoscopy to detect retinoblastoma at its earliest stage.

Germ Cell Tumors

Germ cell tumors account for about 2% of all tumors in children under the age of 15 years but account for 14% of all tumors in children 15 to 19 years of age (Frazier, Olson, Schneider, et al, 2016). Teratoma is the most common subtype of germ cell tumors in childhood (Frazier, Olson, Schneider, et al, 2016). The most common ovarian tumors are the mature cystic teratomas, followed by dysgerminomas and yolk sac tumors. The most common testicular tumors are yolk sac tumors, followed by teratomas. In general, most teratomas and localized gonadal tumors that are surgically resected can be observed without the need for further therapy. For patients with more advanced disease, the use of chemotherapy has produced excellent results.

Nursing Care Management

To supplement routine health assessment, every adolescent male should know how to perform frequent testicular self-examination to familiarize himself with his own anatomy and to ensure early detection of any abnormality. Ideally self-examination should be performed once a month beginning when physical development reaches Tanner stage 3, usually about 13 or 14 years old (see Fig. 15-3). Each testicle is examined individually, preferably after a warm bath or shower (when scrotal skin is more relaxed), using the thumbs and fingers of both hands and applying a small amount of firm, gentle pressure. The normal testicle is a firm organ with a smooth egg-shaped contour. The epididymis can be palpated as a raised swelling on the superior aspect of the testicle and should not be confused with an abnormality.

Liver Tumors

Liver tumors account for 1% of all childhood cancers; the most common histologic subtype is hepatoblastoma (Agarwala, 2012). Surgical resection is the treatment of choice for these tumors but is usually performed after the administration of chemotherapy to make the tumor resection more successful (Meyers, Trobaugh-Lotrario, Malogolowkin, et al, 2016). Liver transplantation is often used in unresectable tumors. Survival rates for patients with hepatoblastoma can be as high as 85% with current therapies (Agarwala, 2012).

The Childhood Cancer Survivor

Survival for children with cancer has greatly improved over the past 20 years. The overall 5-year survival rate is 80% (Scheurer, Lupo, and Bondy, 2016). Vigorous treatment of childhood cancers has resulted in dramatically improved survival rates. However, treatment programs combining surgery, irradiation, and chemotherapy are not without their complications. Some may occur immediately, such as loss of a limb from surgical amputation. However, current concern is with late effects—adverse changes related to treatment modalities, interactions between modes of treatment, individual characteristics of the child, and the disease process that may appear months to years after lifesaving treatment. Because more children are being cured and surviving into adulthood, increasing documentation of late effects is emerging (Table 25-3). Almost no organ is exempt, and almost every antineoplastic agent (especially irradiation) is responsible for some adverse effect. Many factors influence the development of late effects from irradiation; some of the more important ones include the total cumulative dose given, the child's age (the younger the child, the more radiosensitive the body organs are), and the tumor's location.

Radiotherapy to growing bones or reproductive glands responsible for growth-related hormones can delay or stunt growth. Nurses must document growth by assessing height and weight at each visit. Radiotherapy and some chemotherapy agents can cause hormonal dysfunction, decreased fertility, and sterility. The potential for gonadal dysfunction depends on the child's age and sex, the type of treatment, and the duration and total doses of treatment. Nursing assessment must begin with careful documentation of the child's sexual development using the Tanner staging scale (see [Pubertal Sexual Maturation, Chapter 15](#)).

Irradiation to developing bone and cartilage may cause numerous abnormalities. Assessment includes close observation of the irradiated bone for defects, such as spinal kyphoscoliosis, functional limitations, and osteoporosis. Children who have received irradiation to the mandibular area are at risk for dental caries, arrested tooth development, and incomplete dental calcification. A careful assessment in children who have received irradiation is performed at each clinic visit.

NCLEX Review Questions

1. At a visit to the pediatric clinic, a mother is concerned by her 4-year-old's symptoms over the last few weeks. Which of the following symptoms described by the mother would lead the nurse to be concerned about an oncologic disorder? Select all that apply.
 - a. Bruising in various stages, mainly on the legs
 - b. Frequent complaints of respiratory infections, while siblings remain healthy
 - c. Enlarged, firm lymph nodes
 - d. Asthma symptoms with increase in wheezing
 - e. Fever for more than 1 week
2. The nurse taking care of a 5-year-old cancer patient with ulcerative stomatitis is getting ready to perform mouth care. Which of the following principles should be followed? Select all that apply.
 - a. Due to pain of the stomatitis, viscous lidocaine should be used to swish the mouth three times per day.
 - b. A soft, bland diet, although not the favorite of the child, will help with the pain.
 - c. Lemon glycerin swabs are helpful because they remind children of lemon drops.
 - d. Using a soft sponge-type toothbrush will decrease the tendency for gums to bleed.
 - e. A solution of 1 tsp of baking soda and tsp of table salt in 1 quart of water is helpful for mouth rinse.
3. You are working with a new graduate and explaining prevention of infection for a child with acute lymphocytic leukemia. Which statement by this new nurse indicates understanding?
 - a. "Prophylaxis against *Pneumocystis* pneumonia is routinely given to most children during treatment for cancer."
 - b. "If blood is drawn, firm pressure should be applied to the area for a minimum of 10 minutes."
 - c. "Having a roommate with a routine surgery would be acceptable for this child."
 - d. "The child should be vaccinated completely to avoid childhood diseases."
4. The parents of a child with Hodgkin disease ask how the physician will know what type of cancer their child has. Which of the following definitive signs and symptoms should the nurse describe? Select all that apply.
 - a. The most common finding is enlarged, firm, nontender, movable nodes in the supraclavicular or cervical area.
 - b. Tests include complete blood count, prothrombin time and glucose-6-phosphate dehydrogenase (G6PD), erythropoietin, and sedimentation rate.
 - c. Generally a bone marrow biopsy is done to look for the presence of blast cells.
 - d. The presence of Sternberg-Reed cells is considered diagnostic of Hodgkin disease.
 - e. The presence of a white reflection as opposed to the normal red pupillary reflex in the pupil of a child's eye is a classic sign.
5. You are caring for a child on the pediatric unit with a suspected abdominal tumor. Which criteria would lead you to determine this tumor is a neuroblastoma rather than a Wilms tumor?
 - a. Most children present with neuroblastoma around age 4.
 - b. Neuroblastoma is a firm, nontender, irregular mass confined to one side, generally deep in the flank.
 - c. Hypertension is often noted due to secretion of excess amounts of rennin by the tumor.
 - d. Most tumors develop in the adrenal gland or the retroperitoneal sympathetic chain.

Correct Answers

1. b, c, e; 2. b, d, e; 3. a; 4. a, d; 5. d

UNIT 11

The Child with a Disturbance of Regulatory Mechanisms

OUTLINE

26 The Child with Genitourinary Dysfunction

27 The Child with Cerebral Dysfunction

28 The Child with Endocrine Dysfunction

The Child with Genitourinary Dysfunction

Patricia A. Ring, Cynthia J. Camille

Genitourinary Dysfunction

Assessment of kidney and urinary tract integrity and diagnosis of renal or urinary tract disease are based on several evaluative tools. Physical examination, history taking, and observation of symptoms are the initial procedures. In suspected urinary tract diseases or disorders, further assessment by laboratory, radiologic, and other evaluative methods is carried out. [Fig. 26-1](#) provides a review of the kidney and nephron structures.

FIG 26-1 A, Kidney structure. B, Components of the nephron. (From Patton KT, Thibodeau GA: *Anatomy and physiology*, ed 7, St Louis, 2010, Mosby.)

Clinical Manifestations

As in most disorders of childhood, the incidence and type of kidney or urinary tract dysfunction change with the age and maturation of the child. In addition, the presenting complaints and the significance of these complaints vary with age. For example, a complaint of enuresis has greater significance at 8 years old than at 4 years old. In newborns, renal abnormalities may be associated with a number of other malformations, for example, obvious neural tube defects to the subtle abnormal shape or position of the outer ear. Failure to thrive in children may be a sign of impaired renal function.

Many of the clinical manifestations of renal disease are common to a variety of childhood disorders, but their presence is an indication to obtain further information from the child's history, family history, and laboratory studies as part of a complete physical examination. Suspected renal disease can be further evaluated by means of radiographic studies and renal biopsy (Table 26-1).

TABLE 26-1
Radiologic and Other Tests of Urinary System Function

| Test | Procedure | Purpose | Comments and Nursing Responsibilities |
|-----------------------------------|--|---|--|
| Urine culture and sensitivity | Collection of sterile specimen | Determines presence of pathogens and the drugs to which they are sensitive | Send specimen to laboratory immediately after collection Catheterization, clean-catch, or suprapubic specimen |
| Renal and bladder ultrasonography | Transmission of ultrasonic waves through renal parenchyma, along ureteral course, and over bladder | Allows visualization of renal parenchyma and renal pelvis without exposure to external-beam radiation or radioactive isotopes Visualization of dilated ureters and bladder wall also possible Can show renal cysts and stones, though less sensitive than CT Doppler ultrasonography can be used to evaluate renal vascular flow | Noninvasive procedure |

| | | | |
|--|---|--|--|
| Testicular (scrotal) ultrasonography | Transmission of ultrasonic waves through scrotal contents and testis | Allows visualization of scrotal contents, including testis Testicular ultrasonography is used to identify masses, and Doppler-enhanced ultrasonography is used to differentiate hyperemia of epididymo-orchitis from ischemia or torsion | Noninvasive procedure |
| Plain film of the abdomen | Flat plate radiograph of abdomen and pelvis for KUB | Can identify certain types of stones that are calcium containing as well as calculi or opaque foreign bodies in bladder (diagnostic test of choice for nephrolithiasis is noncontrast helical CT) Assess stool burden | Prepare as for routine x-ray film |
| Voiding cystourethrography | Contrast medium injected into bladder through urethral catheter until bladder is full; films taken before, during, and after voiding | Visualizes bladder outline and urethra, reveals reflux of urine into ureters Provides information on bladder emptying and is also used to diagnosis PUV | Prepare child for catheterization Should not be done at time of active UTI |
| Radionuclide (nuclear) cystogram | Radionuclide-containing fluid injected through urethral catheter until bladder is full; images generated before, during, and after voiding | Alternative to voiding cystourethrography to evaluate reflux, although visualization of anatomic details is relatively poor Used in some institutions for follow up if initial VCUG due to less radiation | Prepare child for catheterization |
| Radioisotope imaging studies (renal scans) | Contrast medium injected intravenously; computer analysis to measure uptake or washout (excretion) for analysis of organ function | DMSA radioisotope used to visualize renal scars and differential renal function; does not visualize ureters and bladder MAG3 radioisotope assesses obstruction and differential function between the two kidneys DTPA is an alternative to MAG3 but imaging is limited because it is only filtered at the glomerulus | Insert or assist with insertion of IV infusion Monitor IV infusion Urethral catheterization may accompany MAG3 scan; prepare child for catheterization when indicated |
| MRI | Uses strong magnetic fields and radio waves to form images | MRI of kidneys used to evaluate renal mass Magnetic resonance angiography used to evaluate renovascular hypertension and has reduced need for renal angiography Magnetic resonance urogram used to detect specific urologic abnormalities, such as ectopic ureter | MRI often requires sedation in infants and children due to need to stay still, typically in an enclosed space; follow NPO guidelines depending on timing of study Assist with IV access if indicated Magnetic devices or implants may be unsafe for MRI, including cochlear implants and permanent pacemakers |
| CT | Narrow-beam x-rays and computer analysis provide precise reconstruction of area | Visualizes vertical or horizontal cross section of kidney Especially valuable to distinguish tumors, cysts, and stones Noncontrast helical CT is gold standard for radiologic diagnosis of renal stone disease Renal CT angiogram used to evaluate blood flow in hypertensive patients and is now used more commonly than renal arteriography | Noncontrast scan is noninvasive Contrast-enhanced CT scan preparation may require child be NPO for a few hours With speed of newer scans, the need for sedation is decreased but if required will also require NPO Assist with IV access if needed <i>Used selectively due to higher radiation exposure</i> |
| Cystoscopy | Direct visualization of bladder and lower urinary tract through small scope inserted via urethra | Investigation of bladder and lower tract lesions; visualizes ureteral openings, bladder wall, trigone, and urethra | NPO orders per protocol, typically no solid food after midnight, liquids until 4 to 6 hours before procedure Carry out preoperative preparations; cystoscopy is done under anesthesia in children |
| Renal biopsy | Removal of kidney tissue by open or percutaneous technique for study by light, electron, or immunofluorescent microscopy | Yields histologic and microscopic information about glomeruli and tubules; helps distinguish among types of nephritic syndromes Distinguishes other renal disorders | Nothing orally 4 to 6 hours before test Premedicate as ordered Prepare setup for procedure Assist with procedure Take vital signs Apply pressure to area with pressure dressing and, if feasible, a sandbag Bed rest for 24 hours Observe for abdominal pain, tenderness Monitor input and output Surgical incision may be required in infants |
| Urodynamics | Set of tests designed to measure bladder filling, storage, and evacuation functions: Uroflowmetry: Test to determine efficiency of urination Cystometry: Graphic comparison of bladder pressure as a function of volume Voiding pressure study: Comparison of detrusor contraction pressure, sphincter electromyogram, and urinary flow | Determine characteristic of voiding dysfunction Used to identify type (cause) of incontinence or urinary retention Especially valuable for voiding dysfunction complicated by urinary infection, urinary retention, or neurogenic bladder dysfunction | Prepare child for urinary catheterization The bladder will be filled with contrast, sterile water, or saline solution, and filling pressures will be recorded; the child may experience fullness, coolness from the fluid, and urine leakage during the study Insertion of needles may be required for sphincter EMG (institution specific, often use electrode patches) |

CT, Computed tomography; DMSA, dimercaptosuccinic acid; DTPA, diethylenetriamine pentaacetic acid; EMG, electromyography; IV, intravenous; KUB, kidney, ureters, and bladder; MAG3, mercaptoacetyltriglycine; MRI, magnetic resonance imaging; NPO, nothing by mouth; PUV, posterior urethral valve; UTI, urinary tract infection; VCUG, voiding cystourethrogram.

Laboratory Tests

Both urine and blood studies contribute vital information for detection of renal problems. The single most important test is probably routine urinalysis. Specific urine and blood tests provide additional information. Because nurses are usually the persons who collect the specimens for examination and who often perform many of the screening tests, they should be familiar with the test, its function, and factors that can alter or distort the results of the test. The major urine and blood tests are outlined in [Tables 26-2](#) and [26-3](#).

TABLE 26-2
Urine Tests of Renal Function

| Test | Normal Range | Deviations | Significance of Deviations |
|-----------------------|---|----------------------|---|
| Physical Tests | | | |
| Volume | Age related Newborn: 30 to 60 ml Children: Bladder capacity (oz) = Age (years) + 2 | Polyuria Oliguria | Osmotic factors (urinary glucose level in diabetes mellitus) Retention caused by obstructive disease Inadequate bladder emptying caused by neurogenic bladder or obstructive disorder |
| Specific gravity | With normal fluid intake: 1.016 to 1.022 Newborn: 1.001 to 1.020 Others: 1.001 to 1.030 | Anuria | Obstruction of urinary tract; AKI |
| | | High | Dehydration Presence of protein or glucose Presence of radiopaque contrast medium after radiologic examinations |
| | | Low | Excessive fluid intake Distal tubular dysfunction Insufficient ADH Diuresis |
| Osmolality | Newborn: 50 to 600 mOsm/L | Fixed at 1.010 | Chronic glomerular disease |

| | | | |
|--------------------------|---|--|---|
| | Thereafter: 50 to 1400 mOsm/L | High or low | Same as for specific gravity More sensitive index than specific gravity |
| Appearance | Clear pale yellow to deep gold | Cloudy Cloudy reddish pink to reddish brown Light Dark Red | Contains sediment Blood from trauma or disease Myoglobin after severe muscle destruction Dilute Concentrated Trauma |
| Chemical Tests | | | |
| pH | Newborn: 5 to 7 Thereafter: 4.8 to 7.8 Average: 6 | Weak acid or neutral Alkaline | If associated with metabolic acidosis, suggests tubular acidosis If associated with metabolic alkalosis, suggests potassium deficiency Urinary infection Metabolic alkalosis |
| Protein level | Absent | Present | Abnormal glomerular permeability (e.g., glomerular disease, changes in blood pressure) Most kidney disease Orthostatic in some individuals |
| Glucose level | Absent | Present | Diabetes mellitus Infusion of concentrated glucose-containing fluids Glomerulonephritis Impaired tubular reabsorption |
| Ketone levels | Absent | Present | Conditions of acute metabolic demand (stress) Diabetic ketoacidosis |
| Leukocyte esterase | Absent | Present | Can identify both lysed and intact WBCs via enzyme detection |
| Nitrites | Absent | Present | Most species of bacteria convert nitrates to nitrites in the urine |
| Microscopic Tests | | | |
| WBC count | <1 or 2 | >5 polymorphonuclear leukocytes/field Lymphocytes | Urinary tract inflammatory process Allograft rejection Malignancy |
| RBC count | <1 or 2 | 4 to 6/field in centrifuged specimen | Trauma Stones Glomerular injury Infection Neoplasms |
| Presence of bacteria | Absent to a few | >100,000 organisms/ml in centrifuged specimen | UTI |
| Presence of casts | Occasional | Granular casts Cellular casts WBC RBC Hyaline casts | Tubular or glomerular disorders Degenerative process in advanced renal disease Pyelonephritis Glomerulonephritis Proteinuria; usually transient |

ADH, Antidiuretic hormone; AKI, acute kidney injury; RBC, red blood cell; UTI, urinary tract infection; WBC, white blood cell.

TABLE 26-3

Blood Tests of Renal Function

| Test | Normal Range (mg/dl) | Deviations | Significance of Deviations |
|------------|---|------------|---|
| BUN | Newborn: 4 to 18 Infant, child: 5 to 18 | Elevated | Renal disease: Acute or chronic (the higher the BUN, the more severe the disease) Increased protein catabolism Dehydration Hemorrhage High protein intake Corticosteroid therapy |
| Uric acid | Child: 2.0 to 5.5 | Increased | Severe renal disease |
| Creatinine | Infant: 0.2 to 0.4 Child: 0.3 to 0.7 Adolescent: 0.5 to 1.0 | Increased | Renal impairment |

BUN, Blood urea nitrogen.

Nursing Care Management

Nursing responsibilities in the assessment of genitourinary disorders or diseases begin with observation of the child for any manifestations that might indicate dysfunction. Many conditions have specific characteristics that distinguish them from other disorders. These are discussed as appropriate throughout the chapter.

The nurse is generally the one who is responsible for preparing infants, children, and parents for tests and for collection of urine and (sometimes) blood specimens for observation and laboratory analysis (see [Preparation for Diagnostic and Therapeutic Procedures](#), and [Collection of Specimens, Chapter 20](#)). An important nursing responsibility is to maintain careful intake and output measurements and blood pressure for most children with genitourinary dysfunction and those who might be at risk for developing renal complications (e.g., children in shock, postoperative patients). For example, any significant degree of renal disease can diminish the glomerular filtration rate (GFR), a measure of the amount of plasma from which a given substance is totally cleared in 1 minute. A number of substances can be used, but the most useful clinical estimation of glomerular filtration is the clearance of **creatinine**, an end product of protein metabolism in muscle and a substance that is freely filtered by the glomerulus and secreted by renal tubular cells. The nurse's responsibility in this test is collection of urine, usually a 12- or 24-hour specimen.

Genitourinary Tract Disorders and Defects

Urinary Tract Infection

Urinary tract infection (UTI) is a common and potentially serious problem in children. The overall prevalence is approximately 7% in infants and young children, although there is some variability based on age, gender, race, and circumcision status (Shaikh, Morone, Bost, et al, 2008). Caucasians, females, and uncircumcised boys have the highest rates. Specifically, girls have a twofold to fourfold higher prevalence than do circumcised boys. Uncircumcised males younger than 3 months old and females younger than 12 months old have the highest baseline prevalence of UTI (Shaikh, Morone, Bost, et al, 2008). UTI may involve the urethra and bladder (lower urinary tract) or the ureters, renal pelvis, calyces, and renal parenchyma (upper urinary tract). Because of the difficulty in distinguishing upper from lower tract infection, particularly in young children, UTI is often broadly defined. Upper UTIs or kidney infections tend to present with fever and may lead to renal scarring that may be associated with decreased kidney function, hypertension, and renal disease over time. Diagnosis of UTI is made based on the presence of both pyuria and at least 50,000 colonies per ml of a single uropathic organism in an appropriately collected specimen (American Academy of Pediatrics Subcommittee on Urinary Tract Infection, Steering Committee on Quality Improvement and Management, and Roberts, 2011).

Classification

Infection of the urinary tract may be present with or without clinical symptoms. As a result, the site of infection is often difficult to pinpoint with any degree of accuracy. Various terms used to describe urinary tract disorders include:

Bacteriuria: Presence of bacteria in the urine

Pyuria: Presence of white blood cells in the urine

Asymptomatic bacteriuria: Significant bacteriuria (usually defined as >100,000 colony-forming units [CFUs]) with no evidence of clinical infection

Symptomatic bacteriuria: Bacteriuria accompanied by physical signs of UTI (dysuria, suprapubic discomfort, hematuria, fever)

Recurrent UTI: Repeated episode of bacteriuria or symptomatic UTI

Persistent UTI: Persistence of bacteriuria despite antibiotic treatment

Febrile UTI: Bacteriuria accompanied by fever and other physical signs of UTI; presence of a fever typically implies pyelonephritis

Cystitis: Inflammation of the bladder

Urethritis: Inflammation of the urethra

Pyelonephritis: Inflammation of the upper urinary tract and kidneys

Urosepsis: Febrile UTI coexisting with systemic signs of bacterial illness; blood culture reveals presence of urinary pathogen

Etiology

A variety of organisms can be responsible for UTI. *Escherichia coli* remains the most common uropathogen overall, but the prevalence is higher in females (83%) than males (50%) (Edlin, Shapiro, Hersh, et al, 2013). Other gram-negative organisms associated with UTI include *Proteus mirabilis*, *Pseudomonas aeruginosa*, *Klebsiella*, and *Enterobacter*. Gram-positive bacterial pathogens include *Enterococcus*, *Staphylococcus saprophyticus*, and, rarely, *Staphylococcus aureus*. Viruses and fungi are uncommon causes of UTI in children. Most uropathogens originate in the gastrointestinal tract, migrate to the periurethral area, and ascend to the bladder. A number of factors contribute to the development of UTI, including anatomic, physical, and chemical conditions or properties of the host's urinary tract.

Anatomic and Physical Factors

The structure of the lower urinary tract has traditionally been thought to account for the increased incidence of bacteriuria in females. The short urethra, which measures about 2 cm (0.75 inch) in young girls and 4 cm (1.6 inches) in mature women, provides a ready pathway for invasion of organisms. In addition, the closure of the urethra at the end of micturition may return contaminated bacteria to the bladder. The longer male urethra (as long as 20 cm [8 inches] in an adult) and the antibacterial properties of prostatic secretions inhibit the entry and growth of pathogens. The importance of the length of the urethra in the pathogenesis of UTI has been questioned because of the high incidence of UTI in male neonates. The presence or absence of the foreskin has been shown to be a significant factor, with prevalence of UTI in infant males younger than 3 months old being 2.4% in circumcised and 20.1% in uncircumcised males (Shaikh, Morone, Bost, et al, 2008). The presence of a foreskin is associated with a preputial colonization of uropathic bacteria that can ascend the urethra easily (Balat, Karakok, Guler, et al, 2008). Virulence factors are important in the pathogenesis; and these, coupled with the propensity of bacteria to adhere to the female periurethral mucosa may explain the increased incidence of UTI in females.

Nursing Tip

Considerable evidence shows significant reductions in the risk of urinary tract infection (UTI) in the first year of life in circumcised male infants. Current evidence indicates the health benefits of circumcision outweigh the risks and the benefits of the procedure justify access for families who choose it; but are not sufficient to recommend routine circumcision for all male newborns (American Academy of Pediatrics Task Force on Circumcision, 2012).

The single most important host factor influencing the occurrence of UTI is **urinary stasis**. Ordinarily, urine is sterile, but at 37° C (98.6° F), it provides an excellent culture medium. Under normal conditions, the act of completely and repeatedly emptying the bladder flushes away any organisms before they have an opportunity to multiply and invade surrounding tissue. However, urine that remains in the bladder allows bacteria from the urethra to rapidly become established in the rich medium. Incomplete bladder emptying (stasis) may result from **reflux** (see **Vesicoureteral Reflux** later in chapter), anatomic abnormalities, neurogenic bladder, voiding dysfunction, or extrinsic ureteral or bladder compression that may be caused by constipation. Overdistention of the bladder may increase risk of infection by decreasing host resistance, probably as a result of decreased blood flow to the mucosa. This occurs more often in a neurogenic bladder with increased bladder pressure, but it can be the result of voluntarily holding back urine (Vasudeva and Madersbacher, 2014).

Altered Urine and Bladder Chemistry

Several mechanical and chemical characteristics of the urine and bladder mucosa help maintain urinary sterility. Increased fluid intake promotes flushing of the normal bladder and lowers the concentration of organisms in the infected bladder. Diuresis also seems to enhance the antibacterial properties of the renal medulla.

Most pathogens favor an alkaline medium. Normally, urine is slightly acidic with a median pH of 6. A urine pH of 5 hampers but does not eliminate bacterial multiplication. Much has been reported about the use of cranberry products for prevention of UTI. Initially it was thought to alter the urine acidity, but studies have not shown that ingestion results in a lower pH; but instead it appeared to decrease the adherence of certain bacteria to the bladder wall. Recent review of the literature showed that cranberry products did not significantly reduce the occurrence of symptomatic UTI overall or in any of the subgroups, including children. Because the benefit is small, cranberry juice cannot currently be recommended for prevention of UTIs. Other cranberry preparations need to be quantified using standardized methods to ensure the potency before being evaluated in clinical studies or recommended for use (Jepson, Williams, and Craig, 2012).

Diagnostic Evaluation

The clinical manifestations of UTI depend on the child's age (Box 26-1). Diagnosis of UTI is confirmed by detection of bacteria in urine culture, but urine collection is often difficult, especially in infants and very small children. Several factors may alter a urine specimen, and contamination of a specimen by organisms from sources other than the urine, such as perineal and perianal flora in

bag specimens, is the most frequent cause of false-positive results. Unless the specimen is a first morning sample, a recent high fluid intake may indicate a falsely low organism count. Therefore, children should not be encouraged to drink large volumes of water in an attempt to obtain a specimen quickly.

Nursing Alert

A child who exhibits the following should be evaluated for UTI:

- Incontinence in a toilet-trained child
- Strong-smelling urine in association with other symptoms
- Frequency or urgency
- Pain with urination

Box 26-1

Clinical Manifestations of Urinary Tract Disorders or Disease

Neonatal Period (Birth to 1 Month Old)

Poor feeding

Vomiting

Failure to gain weight

Rapid respiration (acidosis)

Respiratory distress

Spontaneous pneumothorax or pneumomediastinum

Frequent urination

Screaming on urination

Poor urine stream

Jaundice

Seizures

Dehydration

Other anomalies or stigmata

Enlarged kidneys or bladder

Infancy (1 to 24 Months Old)

Poor feeding

Vomiting

Failure to gain weight

Excessive thirst

Frequent urination
Straining or screaming on urination
Foul-smelling urine
Pallor
Fever
Persistent diaper rash
Seizures (with or without fever)
Dehydration
Enlarged kidneys or bladder

Childhood (2 to 14 Years Old)

Poor appetite
Vomiting
Growth failure
Excessive thirst
Enuresis, incontinence, frequent urination
Painful urination
Swelling of face
Seizures
Pallor
Fatigue
Blood in urine
Abdominal or back pain
Edema
Hypertension
Tetany

The most accurate tests of bacterial content are **suprapubic aspiration** (for children younger than 2 years old) and properly performed **bladder catheterization** (as long as the first few milliliters are excluded from collection). The specimen must be fresh (<1 hour with storage at room temperature or <4 hours with refrigeration) to ensure sensitivity and specificity of the urinalysis and to prevent growth of organisms (American Academy of Pediatrics Subcommittee on Urinary Tract Infection, Steering Committee on Quality Improvement and Management, and [Roberts, 2011](#)). Clean catch and specimens collected by urine bags are prone to contamination, given the difficulty of obtaining a true mid-stream specimen with wiping of the meatus and retraction of the labia or foreskin or cleaning the perineum. In these instances, a negative specimen excludes infection and a positive culture is not necessarily diagnostic.

Predictive tests are utilized to direct therapy when UTI is suspected. Urine dipsticks indicate the

presence of leukocyte esterase and nitrites and are quick and inexpensive. Leukocyte esterase is a surrogate marker for pyuria, and nitrite is converted from dietary nitrates in the presence of most gram-negative enteric bacteria in the urine. Because the conversion takes 4 hours in the bladder, it is not a sensitive marker for infants or children who empty their bladder frequently. Also, not all urinary pathogens reduce nitrate to nitrite (American Academy of Pediatrics Subcommittee on Urinary Tract Infection, Steering Committee on Quality Improvement and Management, and Roberts, 2011).

Further radiographic evaluation, such as ultrasonography, voiding cystourethrogram (VCUG), and renal scans such as a dimercaptosuccinic acid (DMSA) scan, may be performed after the infection subsides to identify anatomic abnormalities contributing to the development of infection and existing kidney changes from recurrent infection.

Therapeutic Management

The objectives of treatment of children with UTI are to (1) eliminate current infection, (2) identify contributing factors to reduce the risk of recurrence, (3) prevent systemic spread of the infection, and (4) preserve renal function. Antibiotic therapy should be initiated on the basis of identification of the pathogen, the child's history of antibiotic use, and the location of the infection. Several antimicrobial drugs are available for treating UTI, but all of them can occasionally be ineffective because of resistance of organisms. Common anti-infective agents used for UTI include the penicillins, sulfonamide (including trimethoprim-sulfamethoxazole), the cephalosporins, and nitrofurantoin.

If anatomic defects such as primary reflux or bladder neck obstruction are present, surgical correction or urinary prophylaxis may be necessary to prevent recurrent infection. The aim of therapy and careful follow-up is to reduce the chance of renal scarring.

Vesicoureteral Reflux

Vesicoureteral reflux (VUR) refers to the retrograde flow of urine from the bladder into the upper urinary tract. **Primary reflux** results from congenitally abnormal insertion of ureters into the bladder; **secondary reflux** occurs as a result of an acquired condition.

Reflux increases the chance for febrile UTI but does not cause it. When bladder pressure is high enough, refluxing urine can fill the ureter and the renal pelvis. The International Reflux Study Group developed a classification system that describes the degree of reflux, ranging from Grade I to V, which is important because higher grades are associated with renal abnormalities and renal damage. Reflux with infection is the most common cause of pyelonephritis in children. These children are usually very symptomatic with high fevers, vomiting, and chills. In most cases, conservative therapy is sufficient with a high rate of spontaneous resolution of VUR over time; 51% at a mean duration of 2 years for all grades of VUR (Estrada, Passerotti, Graham, et al, 2009). Prevention of infection has been the goal with use of continuous antibiotic prophylaxis (CAP) common practice until resolution or correction of VUR. This practice was reviewed in a recent multisite trial and found to be associated with a substantially decreased risk of recurrence of UTI but not of renal scarring, leaving the use of CAP controversial (Hoberman A, Chesney RW, RIVUR Trial Investigators, 2014). Urine cultures are not recommended routinely but should be obtained if there are symptoms or unexplained fever, because breakthrough infections can occur despite CAP.

Surgical management of VUR corrects the anatomy at the insertion of the refluxing ureter into the bladder and consists of open or laparoscopic and robotic techniques or endoscopic correction. Surgical intervention is indicated in patients who are unlikely to resolve their VUR and are at risk for renal scarring; including those with Grade V reflux with scarring, Grade V reflux over 6 years of age, and children who fail medical therapy.

Prognosis

With prompt and adequate treatment at the time of diagnosis, the long-term prognosis for UTI is usually excellent. However, the risk of progressive renal injury due to scarring from a first UTI has been found to be highest in children with an abnormal renal bladder ultrasound or with a combination of high fever ($\geq 39^\circ$) and an etiologic organism other than *E. coli* (Shaikh, Craig, Rovers, et al, 2014). The presence of VUR, particularly high grade (IV to V) is an important risk factor for the development of renal scarring.

Quality Patient Outcomes: Urinary Tract Infections

- Treatment based on culture and sensitivity
- Renal function maintained
- Appropriate diagnosis of renal abnormalities

Nursing Care Management

Nurses should instruct parents to observe for signs and symptoms suggestive of UTI. These are not always obvious, particularly in an infant, young child, or developmentally delayed child. A high fever without obvious cause should be a signal to check the urine. Because infants and young children often are unable to express their feelings and sensations verbally, it is difficult to detect discomfort they may be experiencing from dysuria. A careful history regarding voiding habits, stooling pattern, feeding tolerance, and episodes of unexplained irritability may assist in detecting less obvious cases of UTI.

Nursing Tip

Another strategy for obtaining a daily urine protein is to place cotton balls in the diaper at night before bedtime and then squeeze them out in the morning

When infection is suspected, collecting an appropriate specimen is essential. It is the nurse's responsibility to take every precaution to obtain acceptable clean-voided specimens in a child who is able to void volitionally, taking care to cleanse the meatus and retract the foreskin in uncircumcised males or keep the labia separated in females. Having a young girl sit backwards on the toilet can facilitate this process, particularly the ability to obtain urine midstream, decreasing the risk of contamination. Because of the unreliability of a specimen obtained via a urine collection bag, suprapubic aspiration of urine or sterile catheterization should be done in infants and young children whose illness warrants immediate antibiotic therapy, such as high fever, vomiting, and lethargy.

Frequently, additional tests are performed to detect anatomic defects. Children are prepared for these tests as appropriate for their age. This includes an explanation of the procedure, its purpose, and what the children will experience (see [Preparation for Diagnostic and Therapeutic Procedures, Chapter 20](#)). Sometimes a simple description of the urinary system is helpful. For children younger than 3 to 4 years old, the procedure can be explained on a doll. For those who are older, a simple drawing of the bladder, urethra, ureters, and kidneys makes the procedure more understandable.

Handling actual equipment when feasible can be helpful in allaying anxiety in children of all ages. Anticipatory instruction on distraction techniques such as deep breathing, storytelling, and imagery may help the child relax and be more cooperative during the actual procedures.

Because antibacterial drugs are indicated in UTI, the nurse advises parents of proper dosage and administration. When used in low dose for prevention of UTI, parents need an explanation of the drug's continued necessity when no signs of infection are present. For all children, adequate fluid intake is encouraged.

Prevention

Prevention is the most important goal in both primary and recurrent infection, and many preventive measures are simple hygienic habits that should be a routine part of daily care (see [Nursing Care Guidelines](#) box). For example, parents are taught to cleanse their infant's genital areas from front to back to avoid contaminating the urethral area with fecal organisms. Girls are taught to wipe from front to back after voiding and defecating. Children should void as soon as they feel the urge.

Nursing Care Guidelines

Prevention of Urinary Tract Infection

Factors Predisposing to Development

Short female urethra close to vagina and anus

Incomplete emptying and overdistention of bladder

Concentrated urine

Constipation

Measures of Prevention

Practice perineal hygiene; wipe from front to back.

Avoid tight clothing or diapers; wear cotton panties rather than nylon.

Avoid “holding” urine; encourage child to void frequently.

Take time to empty bladder completely. This may be helped by relaxed toilet posture for girls, with feet supported on a stool and knees apart. Some children benefit from “double voiding” (void, wait a few minutes, and void again).

Avoid constipation.

Encourage adequate fluid intake.

Sexually active female adolescents are advised to urinate as soon as possible after they have intercourse to flush out any bacteria introduced. Children who have recurrent UTIs or neurogenic bladder are sometimes maintained on daily low-dose antibiotics. Giving the dose at bedtime in children who stay dry through the night allows the drug to remain in the bladder longer. The nurse should reinforce the importance of compliance to parents and older children.

Obstructive Uropathy

Structural or functional abnormalities of the urinary system that obstruct the normal flow of urine can result in renal dysfunction. The area above the obstruction may demonstrate increased pressure, dilation, and urinary stasis. If the blockage is low in the urinary tract, both ureters and kidneys may be affected; if one kidney or ureter is affected, the other may be normal. The renal pelvis and calyces typically show dilation termed **hydronephrosis** from obstruction, although a kidney may have hydronephrosis and not be obstructed.

Obstruction may be congenital or acquired, unilateral or bilateral, and complete or incomplete with acute or chronic manifestations. The obstruction can occur at any level of the upper or lower urinary tract (Fig. 26-2). Partial obstruction may not be symptomatic and changes caused may be partially or completely reversible if there is early intervention. Boys are affected more frequently than girls, and malformations should be suspected when patients have associated congenital defects (e.g., prune belly syndrome, chromosomal anomalies, anorectal malformations, neural tube defects). Prenatal diagnosis with ultrasonography has been a factor leading to early diagnosis and intervention with subsequent decrease in renal impairment.

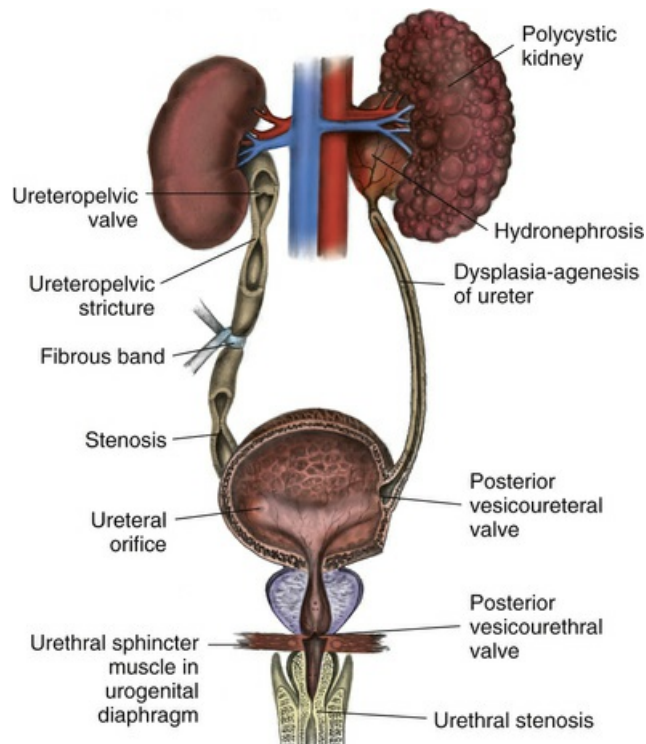

FIG 26-2 Major sites of urinary tract obstruction.

Causes of obstructive uropathy include congenital problems, such as posterior urethral valves (PUVs), ureteropelvic junction (UPJ) and ureterovesical junction (UVJ) obstruction, and ureterocele. Acquired causes include renal or bladder stones, tumor, and trauma. PUVs are obstructing membranous folds within the lumen of the posterior urethra and are the most common cause of obstruction of the urinary tract in newborn males, as well as the most common cause of chronic renal injury from obstructive uropathy (Khan, Fahim, Mansoor, 2012). Because the obstruction occurs in the urethra, the bladder and upper urinary tract are affected. Damage to distal nephrons in chronic uropathy may cause decreased glomerular filtration, which can lead to renal insufficiency. Damage to smooth muscle of the bladder and upper urinary tract also may occur with obstruction and can contribute to bladder dysfunction. Because stasis of urine serves as a medium for bacterial growth, infection can magnify destructive changes of obstruction and cause increased renal damage as well as increased morbidity.

Early diagnosis and surgical correction or procedures that divert the flow of urine to bypass the obstruction may prevent progressive renal damage. Medical complications of acute or chronic renal failure (CRF) or infection are managed as described for those disorders.

Nursing Care Management

Nursing goals in urinary tract obstruction include helping to identify cases, assisting with diagnostic procedures, and caring for children with complications (described elsewhere). Preparing parents and children for procedures is a major nursing responsibility (see [Preparation for Diagnostic and Therapeutic Procedures, Chapter 20](#)).

Parents and children need emotional support and counseling during the potentially lengthy management of these disorders. Children may be discharged with urinary drainage systems that require nursing education of the parents and older child to provide care and to recognize problems, such as obstruction of urine flow or infection. Drainage tubes should be observed for obstruction resulting from sediment, small blood clots, or kinking. If indicated, instructions on site care and drainage tube irrigation need to be provided, including observation for signs of infection or dislodgement.

Children with external diversion systems need psychological support and guidance, especially as they reach adolescence and body image concerns assume more prominence. Those with progressive renal deterioration may face the prospect of dialysis or transplantation and the physical and psychological challenges that accompany these procedures.

External Defects of the Genitourinary Tract

Defects of the external genitourinary tract have the potential to cause distortions of body image. Satisfactory surgical repair is successful for the more common disorders and is carried out or initiated as early as possible. The major anomalies of the lower genitourinary tract, their description, and their management are outlined in [Table 26-4](#).

TABLE 26-4
Defects of the Genitourinary Tract

| Defect | Therapeutic Management |
|--|---|
| Inguinal hernia: Protrusion of abdominal contents through inguinal canal into scrotum | Detected as painless inguinal swelling of variable size Surgical closure of inguinal defect |
| Hydrocele: Fluid in scrotum | Surgical repair indicated if persists past 1 year old |
| Phimosis: Narrowing or stenosis of preputial opening of foreskin | Mild cases: May not require therapy if urine flow not obstructed; steroid cream may be prescribed, typically twice a day for one month Severe cases: Circumcision or dorsal slit in severe, rare cases |
| Hypospadias: Urethral opening located behind glans penis or anywhere along ventral surface of penile shaft | Objectives of surgical correction: • Enable child to void in standing position and direct stream voluntarily in usual manner • Improve physical appearance of genitalia • Produce a sexually adequate organ |
| Chordee: Ventral curvature of penis, often associated with hypospadias | Surgical release of fibrous band causing the deformity |
| Epispadias: Meatal opening located on dorsal surface of penis | Surgical correction, usually including penile and urethral lengthening and bladder neck reconstruction (if necessary) |
| Cryptorchidism: Failure of one or both testes to descend normally through inguinal canal | Detected by inability to palpate testes within scrotum Medical: Administration of hormonal therapy has historically been used in some centers to induce testicular descent but is controversial and not currently recommended Surgical: Orchiopexy Objectives of therapy: Place and fix viable undescended testes in a normal scrotal position or remove nonviable testicular remnants Allows for easier examination of the testis because there is an increased risk of testicular cancer in undescended testes; early surgical correction may reduce the risk of cancer as well as infertility Decrease risk of trauma and torsion Decrease risk of inguinal hernia by closing the inguinal canal Potential improved body satisfaction |
| Exstrophy of bladder: Eversion of posterior bladder through anterior bladder wall and lower abdominal wall; associated with open pubic arch (a severe defect) | Potential objectives of surgical correction: • Preserve renal function • Attain urinary control • Provide adequate reconstructive repair • Improve sexual function |

Phimosis

Phimosis is a narrowing or stenosis of the preputial opening of the foreskin that prevents retraction of the foreskin over the glans penis. It is a normal finding in infants and young boys and usually resolves as the child grows and the distal prepuce dilates. Occasionally the narrowing obstructs the flow of urine, resulting in a dribbling stream or even ballooning of the foreskin with accumulated urine during voiding.

Balanitis is an inflammation or infection of the phimotic foreskin, which occurs occasionally and is managed as any other inflammation or infection. Phimosis is often treated effectively by application of steroid cream twice a day for 1 month, with the option for surgical treatment with circumcision in severe cases.

Nursing Care Management

Proper hygiene of the phimotic foreskin in infants and young boys consists of external cleansing during routine bathing. The foreskin should not be forcibly retracted, because it may create scarring that can prevent future retraction. Furthermore, retraction of the tight foreskin can result in paraphimosis, a condition in which the retracted foreskin cannot be replaced in its normal position over the glans. This causes edema and venous congestion created by constriction by the tight band of foreskin—a urologic emergency that requires immediate evaluation.

Hydrocele

A **hydrocele** is the presence of peritoneal fluid in the scrotum between the parietal and visceral layers of the tunica vaginalis and is the most common cause of painless scrotal swelling in children and adolescents, along with nonincarcerated inguinal hernia. Hydroceles may be communicating or noncommunicating. A communicating hydrocele usually develops when the processus vaginalis does not close during development, allowing for communication with the peritoneum. Noncommunicating hydroceles have no connection to the peritoneum with fluid coming from the mesothelial lining of the tunica vaginalis. Hydroceles are common in newborns and often resolve

spontaneously, usually by 12 months old. In older children, noncommunicating hydroceles may be idiopathic or a result of trauma, epididymitis, orchitis, testicular torsion, torsion of the appendix testis or appendix epididymis, or tumor.

Communicating hydroceles may change in size during the day or with straining; whereas noncommunicating hydroceles are not reducible and so not change size with crying or straining. Surgical repair is indicated for communicating hydroceles persisting past 1 year old, because there is a risk for development of incarcerated inguinal hernia. Idiopathic hydroceles are repaired if symptomatic and reactive hydroceles usually resolve with treatment of underlying cause, such as epididymitis.

Nursing Care Management

Surgical correction is an outpatient procedure. Advise parents that there may be temporary swelling and discoloration of the scrotum that resolves spontaneously. Straddle toys are avoided for 2 to 4 weeks and strenuous activities in older boys may be avoided for 1 month. If a dressing is used, it is removed in 2 to 3 days and typically the child can bathe in 3 days.

Cryptorchidism (Cryptorchism)

Cryptorchidism is failure of one or both testes to descend normally through the inguinal canal into the scrotum. Absence of testes within the scrotum can be a result of undescended (cryptorchid) testes, retractile testes, or anorchism (absence of testes). Undescended testes can be categorized further according to location:

Abdominal: Proximal to the internal inguinal ring

Canalicular: Between the internal and external inguinal rings

Ectopic: Outside the normal pathways of descent between the abdominal cavity and the scrotum

The incidence of cryptorchidism is reported to be as high as 45% in preterm boys and less than 5% in full-term boys; by 1 year old, the incidence decreases to less than 2% and does not change thereafter (Sijstermans, Hack, Meijer, et al, 2008).

Pathophysiology

Cryptorchidism occurs when one or both testes fail to descend through the inguinal canal and into the scrotum. Several processes may slow or arrest testicular descent, including endocrinologic abnormalities affecting the hypothalamic-pituitary-testicular axis, denervation of the genitofemoral nerve, traction of the gubernaculum, abnormal development of the epididymis, or preterm birth. Congenital hernias and abnormal testes often accompany cryptorchid testes, and they are at risk for subsequent torsion.

Anorchism is the complete absence of a testis. Anorchism is suspected whenever one or both testes cannot be palpated in the patient with apparent cryptorchidism. In some cases, bilateral anorchism is associated disorders of sex development with genotypic and phenotypic abnormalities, specifically congenital adrenal hyperplasia (CAH). Although it is commonly associated with a normal karyotype (46,XY) and normal genital development, it is critical to rule out the possibility of CAH in the newborn because of the potential for serious harm due to inability to regulate electrolyte levels (Kolon, Herndon, Baker, et al, 2014). An absent testis may be due to atrophy from prenatal testicular torsion, also known as *vanishing testes* or *testicular regression syndrome*.

The cryptorchid or ectopic testis must be differentiated from anorchism because of the risk for malignant degeneration and subfertility when the testis is left in an extrascrotal location. This differentiation requires laparoscopic or direct surgical exploration (Kolon, Herndon, Baker, et al, 2014).

Retractile testes can be found at any level within the path of testicular descent, but they are most commonly identified in the groin. Fortunately, they are not truly cryptorchid. Instead, they are introverted to an inguinal or abdominal position because of an overactive cremasteric reflex. The cremasteric reflex, observed as withdrawal of the testis above the scrotum and into the inguinal canal in response to various stimuli, including exposure to cool temperatures, is active during

infancy and peaks around 4 to 5 years old. Unlike the cryptorchid testis, the retractile testis can be gently moved into the scrotum without residual tension and does not require treatment. Retractable testes can become ascending testes and require annual monitoring.

Clinical Manifestations

A nonpalpable testis is typically observed by the parent or detected during routine physical examination by a nurse practitioner or physician. If one testis is not palpable, the affected hemiscrotum will appear smaller than the other. With bilateral nonpalpable testes, both hemiscrota appear small. In the case of retractile testes, the parents may report intermittently observing the testes in the scrotum, interspersed with periods when they cannot be visualized or palpated. Frequently, the retractile testis will be observed in the scrotum when the child is being bathed in warm water.

Diagnostic Evaluation

It is important to differentiate the true undescended testis from the more common retractile testis. Retractable testes can be “milked” or pushed back into the scrotum, but truly undescended ones cannot. For examination, the nurse can obviate the cremasteric reflex by placing the child in a squatting or cross-legged sitting position prior to checking the position of the testes.

Therapeutic Management

Although primary hormonal therapy with luteinizing hormone–releasing hormone (nasal spray) and human chorionic gonadotropin (injection) has been used more commonly in Europe, it is no longer recommended to induce testicular descent. Evidence shows low response rates and lack of long-term efficacy (Kolon, Herndon, Baker, et al, 2014). **Orchiopexy**, or surgical repositioning of the testis, is performed on palpable testes. Exploratory surgery may be required if the testis is not palpable. The goal of surgery is to place and fix viable undescended testes to a normal scrotal position or to remove nonviable testicular remnants. Scrotal positioning reduces the risk of torsion and trauma and permits easier examination of the testis, because there is an increased risk of testicular cancer despite treatment of undescended testes. In the routine surgical procedure for undescended testes, the testes are brought down into the scrotum and secured in that position without tension or torsion. A simple orchiopexy for a palpable testis can usually be performed as an outpatient. If exploratory surgery is needed to determine if a testis is present, an exam under anesthesia is the initial step. Depending on findings, a diagnostic laparoscopic procedure or an open inguinal approach may be performed. If an intraabdominal testis is identified, this permits planning for a definitive procedure, which may be open or laparoscopic. Approximately 10% of boys with nonpalpable testes are found to have an absent testicle at the time of surgery.

Nursing Care Management

Postoperative nursing care is directed toward preventing infection and instructing parents in home care of the child, including pain control. Observation of the wound for complications and activity restrictions are discussed. The child should avoid vigorous sports activities and use of toys that are straddled for 2 to 4 weeks postoperatively. General care is similar to that described for hydrocele repair.

Parents may be concerned about the child's future fertility, and recent studies show some decreased fertility in bilateral cryptorchism but in unilateral patients the fertility rate approximates that found in the general population. The risk of testicular cancer is a concern that is decreased if surgery is done before puberty, but all boys with cryptorchidism should be taught testicular self-examination at puberty to potentially facilitate early detection (Kolon, Herndon, Baker, et al, 2014). Surgical treatment is indicated as soon as possible after 6 months of age and definitely should be completed by 2 years old, because spontaneous descent rarely occurs after 6 months and treatment by 1 to 2 years old is associated with improved fertility and testicular growth.

Hypospadias

Hypospadias is a congenital anomaly of the male urethra that results in abnormal ventral placement of the urethral opening on the underside of the penis, ranging from the glans to the perineum (Fig. 26-3). It is one of the most common congenital anomalies with an incidence reported

to be 1 out of 250 to 300 live births, with 10% to 15% having a first degree male relative (sibling or father) with the same condition (Bukowski and Zeman, 2001; Gray and Moore, 2009). Both genetic and environmental factors have been associated with hypospadias. Severity of hypospadias is based on the position of the urethral opening and the degree of **chordee**, or ventral curvature of the penis. The more distant the opening from the normal position at the tip of the glans and the more marked curvature increases the severity and the need for more extensive surgical correction. In mild cases, the meatus is just below the tip of the penis. In the most severe malformation, the meatus is on the perineum between the halves of the bifid scrotum. In addition, the foreskin is usually absent ventrally and, when combined with chordee, gives the organ a hooded and crooked appearance. In severe cases the altered appearance may leave the infant's gender in doubt at birth because of the perineal position of the meatus and small penis. In any case of ambiguous genitalia, additional evaluation is essential. Cryptorchidism is present in about 10% of infants with hypospadias and increases with more proximal hypospadias with the meatus at the scrotum or perineum. There is an increased risk of disorders of sex development in patients with severe hypospadias, both with and without cryptorchidism.

FIG 26-3 Hypospadias. (Courtesy of H. Gil Rushton, MD, Children's National Medical Center, Washington, DC.)

Surgical Correction

The principal objectives of surgical correction are (1) to enhance the child's ability to void in the standing position with a straight stream, (2) to improve the physical appearance of the genitalia for psychological reasons, and (3) to preserve a sexually adequate organ. The choice of surgical procedure is affected primarily by the severity of the defect and the presence of associated anomalies. Numerous techniques are utilized in repair of hypospadias and are performed under general anesthesia and typically as an outpatient procedure.

Hypospadias repair may be done by primary tubularization for milder forms in which a new urethra is made by rolling a ventral strip of penile shaft skin that normally would have formed the urethra. For more severe hypospadias, an onlay island flap is used to create the urethra, transferring a strip of inner foreskin onto the ventral urethral plate. In severe forms of hypospadias, including those with significant chordee, a two-stage repair is used to straighten the penis and create a new urethra. These are typically performed at least 6 months apart. There is no consensus on the best surgical approach for correcting severe hypospadias and complication rates are high; specifically development of urethrocutaneous fistula, urethral stricture or meatal stenosis, and urethral diverticulum (Prat, Natasha, Polak, et al, 2012).

The preferred time for surgical repair is 6 to 12 months old, before the child has developed body image. Occasionally a short course of testosterone is administered preoperatively to achieve additional penile size to facilitate the surgery.

Nursing Care Management

Neonatal circumcision should be avoided in hypospadias where there is incomplete foreskin, because this is not conducive to a safe clamp or Plastibell circumcision. In severe cases, the foreskin

may be used in reconstruction. In mild hypospadias, the foreskin is not incomplete and the abnormality may not be noted until after circumcision. This does not affect future successful reconstruction if it is needed. In most cases, the appearance after reconstruction will be of a circumcised normal penis. Preparation of parents for the type of procedure to be done and the expected cosmetic result helps avert problems.

Frequently parents are informed of what is to be surgically corrected but are not advised of what to expect as a reasonable consequence. More refined surgical techniques performed by surgeons specializing in pediatric urologic conditions have improved cosmetic and functional outcomes in these boys. If children are old enough to understand what is occurring, the nurse also prepares them for the operation and the expected outcome.

Hypospadias repair may require some type of urinary diversion with a silicone stent or feeding tube to promote optimum healing and to maintain the position and patency of the newly formed urethra. This is left in the bladder to drain urine for 5 to 10 days. In most infants and children who are not toilet trained, the catheter drains directly into the diaper. In older children, the catheter is connected to a leg bag or a larger bedside bag at night. Drainage bags should always be positioned below the bladder level for proper drainage. Tub baths are avoided until the catheter is removed. Most children will have a caudal or penile nerve block in addition to general anesthesia, which lasts 6 to 8 hours. Appropriate administration of prescribed pain medication for 48 to 72 hours after surgery will help control discomfort. When a catheter is left in place, bladder spasms are common and are very uncomfortable. Anticholinergic medications, such as oxybutynin, are typically used to prevent spasms. Parents should be advised of the possibility of bladder spasms, which are usually brief and intense and child may arch his back and bring his knees up to his chest and may leak urine around the catheter with a spasm. Oxybutynin is given every 8 hours typically and may require dosing adjustment, such as increasing frequency to every 6 hours to control spasms. Once the catheter is removed, the medication is no longer needed. Often a prophylactic antibiotic is given until shortly after catheter removal. Anticholinergic medication is constipating, and this is a problem that is common in the postoperative period and may be avoided with preventative measures, such as giving adequate fluid and a stool softener or laxative if needed. Preparing parents for these potential problems is an important nursing responsibility. Patients usually go home with a dressing that often comes off in 1 to 2 days and typically is removed in the bath in 3 days if there is no stent in place. If the dressing is soiled, it can be cleaned gently and removed once the parent is prepared that the appearance of the penis is often swollen, discolored, and/or bruised; and this is expected and will resolve with time. While healing, applying petroleum jelly or KY jelly to the diaper to prevent the penis from sticking can help prevent bleeding and increase comfort.

Exstrophy-Epispadias Complex

Bladder exstrophy is a severe defect involving the musculoskeletal system and the urinary, reproductive, and intestinal tracts. It is one of three anomalies that define the exstrophy-epispadias complex (EEC). **Epispadias** is an exposed or open dorsal urethra. Bladder exstrophy is a more severe defect characterized by an open, inside out bladder with the inner surface exposed and the dorsal urethra on the lower abdominal wall (Figs. 26-4 and 26-5). The third disorder, **cloacal exstrophy**, is the most severe, and includes bladder exstrophy as well as exstrophy of the large intestine (hindgut) through an abdominal wall defect. In addition, there is anal atresia, omphalocele, hypoplasia of the colon, anomalous genitalia, and often spinal dysraphism. Fortunately, incidence of cloacal exstrophy is low—less than 1 per 100,000 live births (Feldkamp, Botto, Amar, et al, 2011). Classic bladder exstrophy typically includes findings of diastasis (separation) of the symphysis pubis (pelvic bone), low set umbilicus, anteriorly displaced anus, defects of the genitalia, and inguinal hernia. The incidence of bladder exstrophy ranges from 3.3 to 5 per 100,000 live births and is more common in males than females (Jayachandran, Bythell, Platt, et al, 2011).

FIG 26-4 Newborn with bladder exstrophy and epispadias. (Courtesy of Tim Yankee, St. Francis Hospital, Tulsa, OK.)

FIG 26-5 Exstrophy of bladder. (Courtesy of H. Gil Rushton, MD, Children's National Medical Center, Washington, DC.)

Pathophysiology

Exstrophy results from failure of the abdominal wall and underlying structures, including the ventral wall of the bladder, to fuse in utero. As a result, the lower urinary tract is exposed, and the everted bladder appears bright red through the abdominal opening. This is accompanied by a constant seepage of urine from the exposed ureteral orifices, making the area malodorous and susceptible to infection. The constant accumulation of urine on the surrounding skin produces tissue ulceration and further infection. Progressive renal damage from infection and obstruction may cause renal failure if left untreated.

In males with bladder exstrophy, the defect of the genitalia includes epispadias and upward curvature of a shortened penis and may include other problems, such as undescended testes and inguinal hernias. In females, there is epispadias, a bifid clitoris, and small labia minora. The vagina is shortened compared with normal and vaginal dilation may be needed to allow for sexual intercourse. In cloacal exstrophy patients, there are often more severe anomalies, such as bifid or duplicated uterus, split clitoris, completely separated labia, and a duplicate or absent vagina in females. Males may have a split penis and scrotum or a short, flat penis with hypospadias. In either sex, separation of the pubic bones is generally corrected by pelvic osteotomy, particularly if there is extreme diastasis to increase the likelihood of successful bladder closure. In bladder exstrophy patients, the upper urinary tract is usually normal. Fertility is possible in females but decreased in males, possibly because of semen abnormalities, abnormal ejaculation, or a combination of both. Assisted reproductive techniques remain a viable option for patients with infertility. Recent studies indicate good long-term outcomes on erectile and general sexual function in both men and women with epispadias and bladder exstrophy (Suominen, Santtila, Taskinen, 2015).

Therapeutic Management

The objectives of treatment are (1) preservation of renal function, (2) attainment of urinary control, (3) adequate reconstructive repair for acceptable appearance, (4) prevention of UTIs, and (5) preservation of optimum external genitalia with continence and sexual function. There are two surgical approaches currently utilized to correct bladder exstrophy. One is termed *modern staged repair of exstrophy (MSRE)*, typically involving three surgeries beginning with closure of the bladder and abdominal wall. Complete primary repair of bladder exstrophy (CPRE) is a single-stage surgical closure combining closure of the bladder, abdominal wall, partial tightening of the bladder neck, and bilateral ureteral reimplantation to correct reflux. Often, pelvic osteotomies are performed at the time of primary closure to deepen the flattened pelvis, close the pubic diastasis, and release tension on the abdominal wall to improve success of primary closure (Inouye, Turchi, and Di Carlo, 2014).

For the child with bladder exstrophy, CPRE may be performed within the first 72 hours of life or as a delayed procedure at about 2 months old. For the child with cloacal exstrophy, pelvic osteotomies are needed because of the wide pelvic diastasis and surgery is done within 48 to 72 hours of life to close the bladder and omphalocele and perform intestinal diversion (Inouye, Turchi, and Di Carlo, 2014).

In some children, reconstruction (tightening) of the bladder neck may not provide sufficient resistance to achieve urinary continence. In these cases, suburethral collagen injections or implantation of an artificial urinary sphincter may be performed. Occasionally, the bladder fails to achieve an adequate functional capacity, and augmentation enterocystoplasty is required. This procedure is typically combined with the creation of a Mitrofanoff appendiceal stoma, because catheterization is difficult after reconstruction of the proximal urethra. Abnormalities of the genitalia are addressed to ensure optimal sexual function. In boys, the testes are typically cryptorchid, and bilateral orchiopexy is combined with reconstruction of the bifid scrotum to preserve testicular function. In girls, surgical enlargement of the vaginal introitus may be needed to permit intercourse. In both genders, plastic surgery to reduce scarring of the genital area or to create an umbilicus may significantly improve the child's body image and emerging sexual identity.

Nursing Care Management

It is important to limit trauma to the exposed bladder mucosa, and the bladder is covered with a nonadherent film of plastic wrap or transparent dressing that will not stick to the bladder but can adhere to the surrounding skin. After bladder closure, the neonate is monitored for urinary output and for signs of urinary tract or wound infection. At the time of closure, the pelvic diastasis may be corrected with an osteotomy, but even if that is not performed, they typically require immobilization of the pelvis with traction for 2 to 4 weeks. A common form of traction for newborns is modified Bryant's traction, but spica casting and other alternatives are used. Monitoring of skin condition and circulation is critical as well as monitoring the incision for wound dehiscence. The focus of nursing care is pain management and maintenance of immobilization. Pain management may be achieved with continuous epidural therapy or patient/parent/nurse controlled intravenous analgesia (PCA) and may involve the acute pain service working with the bedside nurse to provide optimal pain control (Kozlowski, 2008). Postoperative nursing care also includes monitoring of hemodynamic stability, maintaining patency and stability of tubes and drains, provision of intravenous (IV) fluids and nutrition, and inclusion of the family in care.

Postoperative nursing care after bladder neck reconstruction and antireflux surgery (ureteral reimplantation) includes routine wound care and careful monitoring of urinary output from the bladder and ureteral drainage tubes. Care after a penile lengthening, chordee release, and urethral reconstruction is similar to care after hypospadias repair.

Children who fail to attain urinary continence after bladder neck reconstruction are offered a continent diversion. In addition to routine postoperative care, nursing after a continent diversion includes wound care, observation of nasogastric (NG) suction (surgery requires bowel resection), and measurement and observation of urinary output. Clean intermittent catheterization (CIC) is used to regularly empty the urinary reservoir. Most children are able to learn self-catheterization by 6 or 7 years old. Adult supervision is needed to ensure the child is compliant.

Family Support and Home Care

Bladder exstrophy and the other disorders of the EEC are significant congenital abnormalities that

require lifelong care by a team of specialists. Improvement in surgical techniques has helped achieve better outcomes, specifically that of the goal of continence. Parental stress is significant, and support services may be helpful for positive adaptation. Patients may also benefit from psychological support as adjustment problems are common, particularly in adolescents. Parents should receive teaching and practice on care of the infant or child at home and have access to resources to call if there are questions. Allowing time for the parent to voice concerns can facilitate evaluation of their understanding and help direct discharge needs. When the infant is discharged with an unrepaired defect, plastic wrap is placed over the defect, and diapers are changed frequently to prevent infection, ulceration, and odor. Parents are taught to recognize the signs of UTI and to report a suspected infection to the practitioner. General infant care remains unchanged—except for sponge baths rather than immersion in water.

Disorders of Sex Development

Infants born with a discrepancy between external genitalia, gonadal, and chromosomal sex, are now referred to as having a **disorder of sex development (DSD)** (Lee, Houk, Ahmed, et al, 2006). The presentation at birth may be a genital appearance that does not permit gender declaration and this is termed **ambiguous genitalia**. These may include bilateral cryptorchidism, perineal hypospadias with bifid scrotum, clitoromegaly, posterior labial fusion, phenotypic female appearance with a palpable gonad, and hypospadias and unilateral nonpalpable gonad. Also included in the DSD category are infants with discordant genitalia and sex chromosomes. Turner syndrome (45, XO) and Klinefelter syndrome (47, XXY) are also DSDs that do not present with ambiguous genitalia.

Pathophysiology

Normal sexual differentiation starts at 7 weeks gestation when fetuses with a Y chromosome begin developing testes. Early on both female (XX) and male (XY) fetuses have a similar reproductive structure. Multiple genes contribute to this process and mutations in these genes can lead to various DSDs. Congenital malformation of the genitalia are most frequently because of androgen deficiency in XY individuals and androgen excess in XX patient; though in many cases no endocrine etiology can be found (Grinspon and Rey, 2014).

Initial evaluation includes karyotype and assessment of adrenal and gonadal function, and this information can be used to categorize the infant into one of three categories:

- Virilized XX (XX DSD)
- Undervirilized XY (XY DSD)
- Mixed sex chromosome pattern

Therapeutic Management

The most common cause of ambiguous genitalia is **congenital adrenal hyperplasia (CAH)**, which can lead to life-threatening salt-wasting adrenal insufficiency in the first weeks of life. Though now a part of neonatal screening in the US, any infant with genital ambiguity should be evaluated urgently. Laboratory testing includes a measurement of 17-hydroxyprogesterone in addition to karyotype with immediate probe for SRY (sex-determining region on the Y chromosome). Serum electrolytes are monitored as signs and symptoms of adrenal insufficiency may include hypoglycemia, hypovolemia, hyponatremia, hyperkalemia, vomiting, and diarrhea. Fluids and electrolytes need to be replaced urgently, and the nurse plays a key role in assessing the infant and providing prescribed therapy. Additional laboratory testing may be indicated, as well as pelvic and abdominal ultrasonography to evaluate for gonads, uterus, and vagina.

Family Support

The birth of a child with ambiguous genitalia has been termed a *psychosocial emergency for the family*. They require support because the answers to a seemingly simple question as to what sex is their child requires evaluation and time. Involvement in a multidisciplinary team that may include endocrinology, urology, genetics, surgeons, in addition to nurses and social workers can make clear communication challenging and the nurse may be instrumental in coordinating family meetings with the team.

The infant and child with DSD pose very complex and controversial management questions,

including sex assignment and potential genital surgery. Traditional approaches are being questioned and continue to evolve. Referral to a specialized center for children with DSD is recommended.

Psychological Problems Related to Genital Surgery

Improved understanding of the psychological implications of genitourinary surgery in children, improvements in technical aspects of surgery, and advances in pediatric anesthesia have resulted in modifications of the surgical approach to children requiring genitourinary surgery. Some of the problems of hospitalization, separation, and anxiety can be eased by hospital practices that are sensitive to the child's needs (see [Chapter 19](#)).

A child's body image is largely derived as a result of feedback from primary caregivers and peers; and parental anxiety regarding an acceptable physical appearance is readily communicated to an affected child. This subtle communication increases the risk of development of a distorted body image and early repair may facilitate a positive body image. Sexual body image is another area that has been thought to be largely a function of socialization. In terms of disorders of sex development, this becomes a much more complex and multifaceted area.

The child's reaction to surgery is related to emotional and cognitive development. Separation of parent and child is important to minimize, particularly in the first 1 to 2 years of life. From about 3 to 6 years old, children are frightened of what they perceive to be threats to their body and bodily function. They are egocentric in their view of the world and may perceive surgery as punishment for real or imagined wrongdoing and require reassurance that they are not to blame. By age 7, they have more ability to understand but may still associate surgery with punishment. Surgical repair is ideally performed before these fears and anxieties develop. In terms of anesthesia risk, elective procedures are generally performed after 6 months of age. It is thought that children do not have memory of procedures performed by 18 to 24 months old. Age 24 to 36 months may be a time when trauma of surgery is relatively less, but in the case of an external defect this prolongs correction. The American Academy of Pediatrics Action Committee on Surgery first published recommendations in terms of timing of elective surgery on the genitalia of male children as a review in 1996.

Nursing Care Management

Preparing children and their families for diagnostic and surgical procedures (see [Preparation for Diagnostic and Therapeutic Procedures, Chapter 20](#)) and for home care is a major nursing function. Most postoperative care involves care of the surgical site. Tub baths may be discouraged for a few days or longer, depending on procedure, if a stent or catheter is left in place, and surgeon preference. It is common practice to leave a urethral stent or catheter in place to drain directly into the diaper after some reconstructive procedures, such as hypospadias repair. The surgical site is kept clean and is inspected for signs of infection or bleeding. More complex surgeries require additional care and observation, such as drainage tube care and irrigation, dressing changes, and monitoring of collection devices.

Postoperative activity restrictions vary with age and type of surgery. Activity of infants and toddlers are not typically limited with the exception of avoiding straddle toys following penile or scrotal surgery. Older children may need more restriction from strenuous activity for 1 month after these type procedures. In the case of more extensive abdominal surgery, there may be restrictions on lifting and strenuous activity for a longer period. Swimming may be restricted especially when any drains are still in place or until incisions are healed. Precise restrictions depend on the specific type of surgery and surgeon preference.

In most cases, the results of surgery are satisfactory. However, in some of the more severe defects, such as exstrophy and severe hypospadias, additional psychological support may be needed to help adjust to concerns about penis size, appearance of the genitalia, potential ability to procreate, and rejection by peers (especially the opposite sex). Ongoing open discussion and support groups for parents and children are useful in promoting optimum emotional adjustment, particularly during adolescence.

Glomerular Disease

Nephrotic Syndrome

Nephrotic syndrome is a clinical state that includes massive proteinuria, hypoalbuminemia, hyperlipidemia, and edema. The disorder can occur as (1) a primary disease known as **idiopathic nephrosis, childhood nephrosis, or minimal-change nephrotic syndrome (MCNS)**; (2) a secondary disorder that occurs as a clinical manifestation after or in association with glomerular damage that has a known or presumed cause; or (3) a congenital form inherited as an autosomal recessive disorder. The disorder is characterized by increased glomerular permeability to plasma protein, which results in massive urinary protein loss. This discussion is devoted to MCNS because it constitutes 80% of nephrotic syndrome cases.

Pathophysiology

The onset of MCNS can occur at any age but predominantly occurs in children between 2 and 7 years old. It is rare in children younger than 6 months old, uncommon in infants younger than 1 year old, and unusual after 8 years old. Patients with MCNS are twice as likely to be male.

The pathogenesis of MCNS is not fully understood. There may be a metabolic, biochemical, physiochemical, or immune-mediated disturbance that causes the basement membrane of the glomeruli to become increasingly permeable to protein, but the cause and mechanisms are only speculative.

The glomerular membrane, normally impermeable to albumin and other proteins, becomes permeable to proteins, especially albumin, that leak through the membrane and are lost in urine (**hyperalbuminuria**). This reduces the serum albumin level (**hypoalbuminemia**), decreasing the colloidal osmotic pressure in the capillaries. As a result, the vascular hydrostatic pressure exceeds the pull of the colloidal osmotic pressure, causing fluid to accumulate in the interstitial spaces (**edema**) and body cavities, particularly in the abdominal cavity (**ascites**). The shift of fluid from the plasma to the interstitial spaces reduces the vascular fluid volume (**hypovolemia**), which in turn stimulates the renin–angiotensin system and the secretion of antidiuretic hormone and aldosterone. Tubular reabsorption of sodium and water is increased in an attempt to increase intravascular volume. The elevation of serum lipids is not fully understood. The sequence of events in nephrotic syndrome is diagrammed in [Fig. 26-6](#).

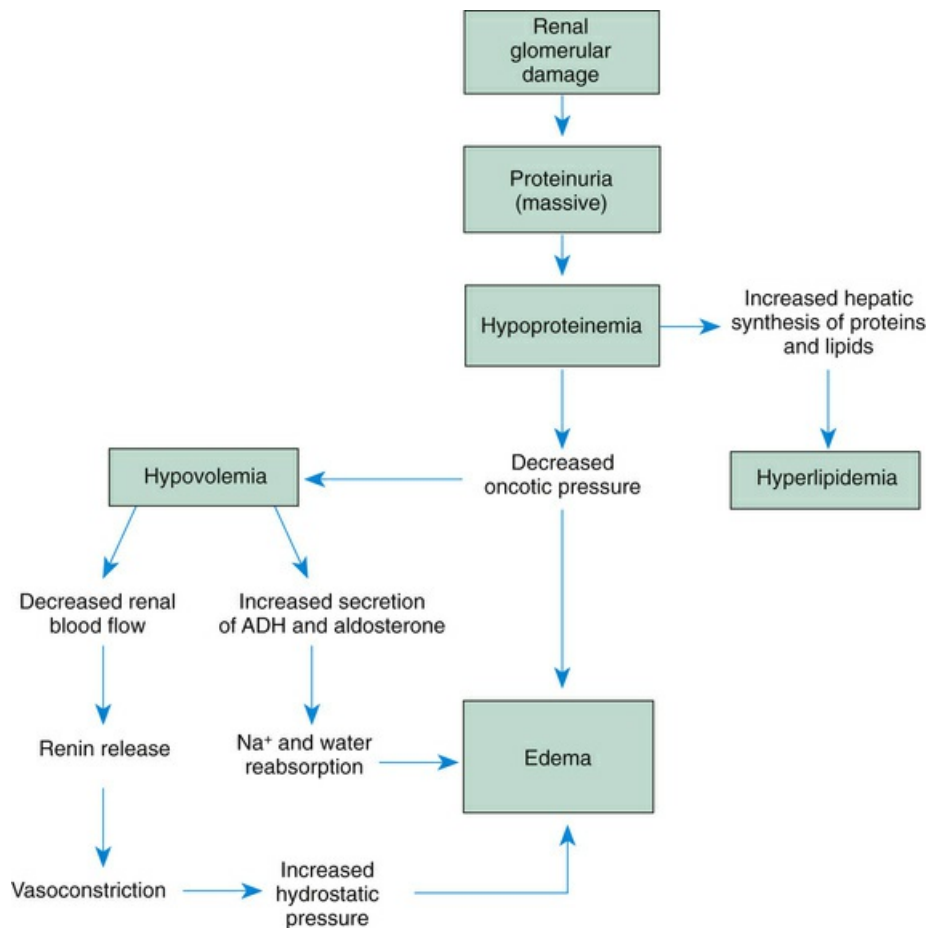

FIG 26-6 Sequence of events in nephrotic syndrome. *ADH*, Antidiuretic hormone.

Diagnostic Evaluation

The disease is suspected on the basis of clinical manifestations (Box 26-2). The generalized edema may develop rapidly or gradually but eventually prompts the family to seek medical attention. Parents usually give a history of the child being well but steadily gaining weight; appearing edematous; and then becoming anorexic, irritable, and less active.

Box 26-2

Clinical Manifestations of Nephrotic Syndrome

Weight gain

Puffiness of face (facial edema):

- Especially around the eyes
- Apparent on arising in the morning
- Subsides during the day

Abdominal swelling (ascites)

Pleural effusion

Labial or scrotal swelling

Edema of intestinal mucosal, possibly causing:

- Diarrhea
- Anorexia
- Poor intestinal absorption

Ankle or leg swelling

Irritability

Easily fatigued

Lethargic

Blood pressure normal or slightly decreased

Susceptibility to infection

Urine alterations:

- Decreased volume
- Frothy

The diagnosis of MCNS is suspected on the basis of the history and clinical manifestations (edema, proteinuria, hypoalbuminemia, and hypercholesterolemia in the absence of hematuria and hypertension) in children between 2 and 8 years old. The hallmark of MCNS is massive proteinuria (higher than 2+ on urine dipstick). Hyaline casts, oval fat bodies, and a few red blood cells (RBCs) can be found in the urine of some affected children, although there is seldom gross hematuria. The GFR is usually normal or high. Kidney function must be monitored, however, because acute kidney injury (AKI) may occur due to intravascular volume depletion, interstitial nephritis, acute tubular necrosis or other factors (Rheault, Wei, Hains, et al, 2014).

Total serum protein concentration is low, with the serum albumin significantly reduced and plasma lipids elevated. Hemoglobin and hematocrit are usually normal or elevated as a result of hemoconcentration. The platelet count may be elevated. Serum sodium concentration may be low. If the patient does not respond to an 8-week course of daily steroids, a renal biopsy may be needed to distinguish among other types of nephrotic syndrome. The biopsy results of children with MCNS are remarkable for effacement of the foot processes of the epithelial cells lining the basement membrane, but otherwise the kidney tissue is normal.

Therapeutic Management

Objectives of therapeutic management include (1) reducing excretion of urinary protein, (2) reducing fluid retention in the tissues, (3) preventing infection, and (4) minimizing complications related to therapies. Dietary restrictions include a low-salt diet and, in more severe cases, fluid restriction. If complications of edema develop, diuretic therapy may be initiated to provide temporary relief from edema. Sometimes infusions of 25% albumin are used. Acute infections are treated with appropriate antibiotics.

Corticosteroids are the first line of therapy for MCNS. The starting dosage for prednisone is usually 2 mg/kg body weight/day for 6 weeks followed by 1.5 mg/kg every other day for 6 weeks (Lombel, Gipson, and Hodson, 2013). About two thirds of children with MCNS have a relapse, heralded first by increased urine protein. Relapses can be diagnosed early if parents are taught

routine home monitoring of urine protein by dipstick. Relapses are treated with a repeated, but usually shorter, course of high-dose steroid therapy. Side effects of the steroids include increased appetite, weight gain, rounding of the face, and behavior changes. Long-term therapy may result in hirsutism, growth retardation, cataracts, hypertension, gastrointestinal bleeding, bone demineralization, infection, and hyperglycemia. Children who do not respond to steroid therapy, those who have frequent relapses, and those in whom the side effects threaten their growth and general health may be considered for a course of therapy using other immunosuppressant medications (cyclophosphamide, chlorambucil, or cyclosporine).

Episodes of MCNS, both the first episode and relapse, often happen in conjunction with a viral or bacterial infection. Relapses can also be triggered by allergies and immunizations. Relapses in children with MCNS may continue over many years.

Complications of nephrotic syndrome include infection, circulatory insufficiency secondary to hypovolemia, and thromboembolism. Infections that may be seen in children with nephrotic syndrome include peritonitis, cellulitis, and pneumonia and require prompt recognition and vigorous treatment with appropriate antibiotic therapy.

Prognosis

The prognosis for ultimate recovery in most cases is good. In children who respond to steroid therapy, the tendency to relapse decreases with time. With early detection and prompt implementation of therapy to eradicate proteinuria, progressive basement membrane damage is minimized so that when the tendency to relapse is past, renal function is usually normal or near normal. It is estimated that approximately 80% of affected children have this favorable prognosis.

Quality Patient Outcomes: Nephrotic Syndrome

- Protein-free urine
- Acute infections prevented
- Edema absent or minimal
- Nutrition maintained
- Metabolic abnormalities controlled

Nursing Care Management

Continuous monitoring of fluid retention or excretion is an important nursing function. Strict intake and output records are essential but may be difficult to obtain from very young children. Application of collection bags is irritating to edematous skin that is readily subject to breakdown. Applying diapers or weighing wet pads may be necessary.

Other methods of monitoring progress include urine examination for albumin, daily weight, and measurement of abdominal girth. Assessment of edema (e.g., increased or decreased swelling around the eyes and dependent areas), the degree of pitting, and the color and texture of skin are part of nursing care. Vital signs are monitored to detect any early signs of complications, such as shock or an infective process.

Infection is a constant source of danger to edematous children and those receiving corticosteroid therapy. These children are particularly vulnerable to upper respiratory tract infection; therefore, they must be kept warm and dry, active, and protected from contact with infected individuals (e.g., roommates, visitors, and personnel). The pneumococcal conjugate vaccine (13-valent) and pneumococcal polysaccharide vaccine (PPSV, 23-valent) are recommended for children with nephrotic syndrome ([Centers for Disease Control and Prevention, 2014](#)).

Loss of appetite accompanying relapse creates a perplexing problem for nurses. The combined efforts of nurse, dietitian, parents, and child are needed to formulate a nutritionally adequate and attractive diet. Salt is restricted (but not eliminated) during the edema phase and while the child is on steroid therapy. Fluid restriction (if prescribed) is limited to short-term use during massive edema. Every effort should be made to serve attractive meals with preferred foods and a minimum of fuss, but it usually requires considerable ingenuity to entice the child to eat (see [Feeding the Sick](#)

Child, Chapter 20). Once the child feels better, the appetite (enhanced by steroids) returns. At this point, care must be taken to prevent excessive caloric intake and weight gain.

Children usually adjust activities according to their tolerance level. However, they may require guidance in selecting play activities. Suitable recreational and diversional activities are an important part of their care. Irritability and mood swings that accompany steroid therapy are not unusual in these children and may create an additional challenge for the nurse and family.

Family Support and Home Care

Continuous support of the child and family is one of the major nursing considerations. Parents are taught to detect signs of relapse and to call for changes in treatment at the earliest indication. Unless the edema and proteinuria are severe or the parents, for some reason, are unable to care for the ill child, *home care is preferred*. Parents are instructed in testing urine for albumin, administering medications, and providing general care. Parents are also instructed regarding avoiding contact with infected playmates, but the child should attend school.

The prolonged course of the relapsing form of nephrotic syndrome is taxing to both the child and the family. The up-and-down course of remissions and exacerbations with periodic disruption of family life by hospitalization places a severe strain on the child and the family, both psychologically and financially. Reassurance regarding this characteristic of the course of the disease, with emphasis on the importance of long-term care, needs to be provided to parents and children. A satisfactory response is more likely when relapses are detected and therapy is instituted early, and remissions are prolonged when instructions are carried out faithfully. Continuous support of the child and family is one of the major nursing considerations (see Chapter 17).

Acute Glomerulonephritis

Acute glomerulonephritis (AGN) may be a primary event or a manifestation of a systemic disorder that can range from minimal to severe. Common features include oliguria, edema, hypertension and circulatory congestion, hematuria, and proteinuria. Most cases are postinfectious and have been associated with pneumococcal, streptococcal, and viral infections. **Acute poststreptococcal glomerulonephritis (APSGN)** is the most common of the postinfectious renal diseases in childhood and the one for which a cause can be established in the majority of cases. APSGN can occur at any age but affects primarily early school-age children, with a peak age of onset of 6 to 7 years old. It is uncommon in children younger than 2 years old, and boys outnumber girls two to one.

Etiology

APSGN is an immune-complex disease that occurs after an antecedent streptococcal infection with certain strains of the group A beta-hemolytic streptococci (GABHS). Most streptococcal infections *do not* cause APSGN. A latent period of 10 to 21 days occurs between the streptococcal infection and the onset of clinical manifestations. Disease secondary to streptococcal pharyngitis is more common in the winter or spring, but when APSGN is associated with pyoderma (principally **impetigo**), it may be more prevalent in late summer or early fall, especially in warmer climates. Second episodes of APSGN are rare.

Pathophysiology

The pathophysiology of APSGN is still uncertain. Immune complexes are deposited in the glomerular basement membrane. The glomeruli become edematous and infiltrated with polymorphonuclear leukocytes, which occlude the capillary lumen. The resulting decrease in plasma filtration results in an excessive accumulation of water and retention of sodium that expands plasma and interstitial fluid volumes, leading to circulatory congestion and edema. The cause of the hypertension associated with AGN cannot be completely explained by fluid retention. Excess renin may also be produced.

Diagnostic Evaluation

Typically, affected children are in good health until they experience a streptococcal infection. In some instances, they have a history of only a mild cold or no previous infection at all. The onset of nephritis appears after an average latency period of about 1 to 3 weeks (Box 26-3). Because the child appears to be well during the latency period, parents may not recognize the association. The edema

is usually relatively moderate and may not be appreciated by someone unfamiliar with the child's normal appearance.

Box 26-3

Clinical Manifestations of Acute Poststreptococcal Glomerulonephritis

Edema:

- Especially periorbital
- Facial edema more prominent in the morning
- Spreads during the day to involve extremities, genitalia and abdomen

Anorexia

Urine:

- Cloudy, smoky brown (resembles tea or cola)
- Severely reduced volume

Pallor

Irritability

Lethargy

Child appearing ill

Child seldom expresses specific complaints

Older children complaining of:

- Headaches
- Abdominal discomfort
- Dysuria

Vomiting possible

Mild to severely elevated blood pressure

Urinalysis during the acute phase characteristically shows hematuria and proteinuria. Proteinuria generally parallels the hematuria and may be 3+ or 4+ in the presence of gross hematuria. Gross discoloration of the urine reflects RBC and hemoglobin content. Microscopic examination of the sediment shows many RBCs, leukocytes, epithelial cells, and granular and RBC casts. Bacteria are not seen.

Azotemia that results from impaired glomerular filtration is reflected in elevated blood urea nitrogen (BUN) and creatinine levels in at least 50% of cases. Occasionally, proteinuria is excessive, and the patient may have nephrotic syndrome (i.e., hypoproteinemia and hyperlipidemia).

Cultures of the pharynx are rarely positive for streptococci because the renal disease occurs weeks after the infection.

Some serologic tests are necessary to make the diagnosis of APSGN. Circulating serum antibodies to streptococci indicate the presence of a previous infection. The antistreptolysin O (ASO) titer is the most familiar and readily available test for streptococcal infection. Other antibodies that may aid in diagnosis are elevated antihyaluronidase (AHase), anti-deoxyribonuclease B (ADNase-B), and streptozyme. All patients with APSGN have reduced serum complement 3 (C3) activity in the early stages of the disease. Rising C3 levels are used as a guide to indicate improvement of the disease and should be normal in almost all patients 8 weeks after the disease onset.

Studies that may be useful include chest x-ray examination, which generally shows cardiac enlargement, pulmonary congestion, or pleural effusion during the edematous phase of acute disease. Renal biopsy for diagnostic purposes is seldom required but may be useful in the diagnosis of atypical cases.

Therapeutic Management

Management consists of general supportive measures and early recognition and treatment of complications. Children who have normal blood pressure and a satisfactory urinary output can generally be treated at home. Those with substantial edema, hypertension, gross hematuria, or significant oliguria should be hospitalized because of the unpredictability of complications.

Dietary restrictions depend on the stage and severity of the disease, especially the extent of edema. Moderate sodium restriction and even fluid restriction may be instituted for children with hypertension and edema. Foods with substantial amounts of potassium are generally restricted during the period of oliguria.

Regular measurement of vital signs, body weight, and intake and output is essential to monitor the progress of the disease and to detect complications that may appear at any time during the course of the disease. A record of daily weight is the most useful means for assessing fluid balance. Rarely, children with APSGN will develop AKI with oliguria that significantly alters the fluid and electrolyte balance (resulting in hyperkalemia, acidosis, hypocalcemia, or hyperphosphatemia). These children require careful management. Peritoneal dialysis or hemodialysis is seldom needed.

Acute, sometimes severe, hypertension must be anticipated and identified early. Blood pressure measurements are taken every 4 to 6 hours. A variety of antihypertensive medications and diuretics are used to control hypertension. Antibiotic therapy is indicated only for children with evidence of persistent streptococcal infections. It is used to prevent transmission of nephritogenic streptococci to other family members.

Prognosis

Almost all children correctly diagnosed as having APSGN recover completely, and specific immunity is conferred, so subsequent recurrences are uncommon. Less than 1% of children will go on to develop **end-stage renal disease (ESRD)**, although abnormal urinalysis and renal function may persist for decades (Nast, 2012).

Nursing Care Management

Nursing care of the child with glomerulonephritis involves careful assessment of the disease status, with regular monitoring of vital signs (including frequent measurement of blood pressure), fluid balance, and behavior.

Vital signs provide clues to the severity of the disease and early signs of complications. They are carefully measured, and any deviations are reported and recorded. The volume and character of urine are noted, and the child is weighed daily. Children with restricted fluid intake, especially those who are not severely edematous or those who have lost weight, are observed for signs of dehydration.

Assessment of the child for signs of cerebral complications is an important nursing function, because the severity of the acute phase is variable and unpredictable. The child with edema, hypertension, and gross hematuria may be subject to complications, and anticipatory preparations such as seizure precautions and IV equipment are included in the nursing care plan (see the

[Nursing Care Plan](#) box later in this chapter).

For most children, a regular diet is allowed, but it should contain no added salt. Foods high in sodium and salted treats are eliminated, and parents and friends are advised not to bring snacks, such as potato chips or pretzels. Fluid restriction, if prescribed, is more difficult, and the amount permitted should be evenly divided throughout the waking hours. Meal preparation and service require special attention because the child is indifferent to meals during the acute phase. Again, collaboration with parents and the dietitian and special consideration for food preferences facilitate meal planning.

During the acute phase, children are generally content to lie in bed. As they begin to feel better and their symptoms subside, they will want to be up and about. Activities should be planned to allow for frequent rest periods and avoidance of fatigue. Children who have mild edema and no hypertension, as well as convalescent children who are being treated at home, need follow-up care. Parent education and support in preparation for discharge and home care include education in home management, dietary restrictions, infection prevention, and the need for follow-up care and health supervision. Health supervision is continued with weekly followed by monthly visits for evaluation and urinalysis.

Miscellaneous Renal Disorders

Hemolytic Uremic Syndrome

Hemolytic uremic syndrome (HUS) is an uncommon, acute renal disease that occurs primarily in infants and small children between 6 months and 5 years old. HUS is one of the most frequent causes of acquired AKI in children (Grisaru, 2014). The clinical features of the disease include acquired hemolytic anemia, thrombocytopenia, renal injury, and central nervous system (CNS) symptoms. The etiology of HUS is thought to be associated with bacterial toxins, chemicals, and viruses. The appearance of the disease has been associated with *Rickettsia* organisms, viruses (especially coxsackievirus, echovirus, and adenovirus), *E. coli*, pneumococci, shigellae, and salmonellae and may represent an unusual response to these infections. Multiple cases of HUS caused by enteric infection of the *E. coli* O157:H7 serotype have been traced to undercooked meat, especially ground beef. Other sources are unpasteurized milk or fruit juice, especially apple; alfalfa sprouts; lettuce; and salami. Drinking or swimming in sewage-contaminated water can also cause infection. The clinical presentation is usually a history of a prodromal illness (most often gastroenteritis or an upper respiratory tract infection) followed by the sudden onset of hemolysis and renal failure.

Pathophysiology

The primary site of injury appears to be the endothelial lining of the small glomerular arterioles, which become swollen and occluded with deposits of platelets and fibrin clots (intravascular coagulation). RBCs are damaged as they attempt to move through the partially occluded blood vessels. These damaged cells are removed by the spleen, causing acute hemolytic anemia. The platelet aggregation within the damaged blood vessels or the damage and removal of platelets produce the characteristic thrombocytopenia.

Diagnostic Evaluation

The triad of anemia, thrombocytopenia, and renal failure is sufficient for diagnosis (Box 26-4). Renal involvement is evidenced by proteinuria, hematuria, and urinary casts; BUN and serum creatinine levels are elevated. A low hemoglobin and hematocrit and a high reticulocyte count confirm the hemolytic nature of the anemia.

Box 26-4

Clinical Manifestations of Hemolytic Uremic Syndrome

Vomiting

Irritability

Lethargy

Marked pallor

Hemorrhagic manifestations:

- Bruising
- Petechiae
- Jaundice
- Bloody diarrhea

Oliguria or anuria

Central nervous system (CNS) involvement:

- Seizures
- Stupor or coma

Signs of acute heart failure (sometimes).

Therapeutic Management

The goals of therapy are early diagnosis and aggressive, supportive care of the AKI and hemolytic anemia. Hemodialysis or peritoneal dialysis is instituted in any child who has been anuric for 24 hours or who demonstrates oliguria with uremia or hypertension and seizures. Other treatments include use of pharmacologic agents, fresh-frozen plasma, and plasmapheresis. Blood transfusions with fresh, washed packed cells are administered for severe anemia but are used with caution to prevent circulatory overload from added volume.

Prognosis

With prompt treatment, the recovery rate is about 95%, but residual renal impairment ranges from 10% to 50%. Long-term complications include chronic kidney disease (CKD), hypertension, and CNS disorders. Death is usually caused by residual renal impairment or CNS injury.

Nursing Care Management

Nursing care is the same as that provided in AKI and, for children with continued impairment, includes management of chronic disease. Because of the sudden and life-threatening nature of the disorder in a previously well child, parents are often ill prepared for the impact of hospitalization and treatment. Therefore, support and understanding are especially important aspects of care.

Renal Failure

Renal failure is the inability of the kidneys to excrete waste material, concentrate urine, and conserve electrolytes. It can occur suddenly (e.g., AKI) in response to inadequate perfusion, kidney disease, or urinary tract obstruction, or it can develop slowly (e.g., CKD) as a result of longstanding kidney disease or an anomaly.

Azotemia and *uremia* are terms often used in relation to renal failure. **Azotemia** is the accumulation of nitrogenous waste within the blood. **Uremia** is a more advanced condition in which retention of nitrogenous products produces toxic symptoms. Whereas azotemia is not life threatening, uremia is a serious condition that often involves other body systems.

Acute Kidney Injury

AKI is said to exist when the kidneys suddenly are unable to regulate the volume and composition of urine appropriately in response to food and fluid intake and the needs of the organism. The principal feature of AKI is oliguria* associated with azotemia, metabolic acidosis, and diverse electrolyte disturbances. AKI is not common in childhood, and the outcome depends on the cause, associated findings, and prompt recognition and treatment.

The pathologic conditions that produce AKI caused by glomerulonephritis and HUS are discussed in relation to those disorders. AKI can also develop as a result of a large number of related or unrelated clinical conditions: poor renal perfusion; urinary tract obstruction; acute renal injury; cardiac surgery (Susantitaphong, Cruz, Cerda, et al, 2013); or the final expression of chronic, irreversible renal disease. The most common cause in children is transient renal failure resulting from severe dehydration or other causes of poor perfusion that may respond to restoration of fluid volume.

Pathophysiology

AKI is usually reversible, but the deviations of physiologic function can be extreme, and mortality in the pediatric age group remains high. There is severe reduction in the GFR, an elevated BUN level, and a significant reduction in renal blood flow.

The clinical course is variable and depends on the cause. In reversible AKI, there is a period of severe oliguria, or a low-output phase, followed by an abrupt onset of diuresis, or a high-output phase, and then a gradual return to (or toward) normal urine volumes.

In many instances of AKI, the infant or child is already critically ill with the precipitating disorder, and the explanation for development of oliguria may or may not be readily apparent (Box 26-5). When a previously well child develops AKI without an obvious cause, a careful history is taken to reveal symptoms that may be related to glomerulonephritis, obstructive uropathy, or exposure to nephrotoxic chemicals (e.g., ingestion of heavy metals, inhalation of organic solvents, or medications such as vancomycin, aminoglycosides, or nonsteroidal antiinflammatory drugs) known to be toxic to the kidneys (Blatt and Liebman, 2013). Significant laboratory measurements during renal failure that serve as a guide for therapy are BUN, serum creatinine, pH, sodium, potassium, and calcium.

Box 26-5

Clinical Manifestations of Acute Kidney Injury

Specific:

- Oliguria
- Anuria uncommon (except in obstructive disorders)

Nonspecific (may develop):

- Nausea
- Vomiting
- Drowsiness
- Edema
- Hypertension

Manifestations of underlying disorder or pathologic condition

Diminished urinary output and lethargy in a child who is dehydrated, is in shock, or has recently undergone surgery should be evaluated for possible AKI.

Nursing Alert

Any of the following signs of hyperkalemia constitute an emergency and are reported immediately:

- Serum potassium concentrations in excess of 7 mEq/L
- Presence of electrocardiographic abnormalities, such as prolonged QRS complex, depressed ST segment, high peaked T waves, bradycardia, or heart block

Therapeutic Management

Treatment of AKI is directed toward (1) treatment of the underlying cause, (2) management of the complications of renal failure, and (3) provision of supportive therapy within the constraints imposed by the renal failure.

Treatment of poor perfusion resulting from dehydration consists of volume restoration, as described in [Chapter 22](#), in treatment of dehydration. If oliguria persists after restoration of fluid volume or if the renal failure is caused by intrinsic renal damage, the physiologic and biochemical abnormalities that have resulted from kidney dysfunction must be corrected or controlled. Initially, a Foley catheter is inserted to rule out urine retention, to collect available urine for analysis, and to monitor results of diuretic administration. The catheter may or may not be removed during the oliguric phase.

The amount of exogenous water provided should not exceed the amount needed to maintain zero water balance. It is calculated on the basis of estimated endogenous water formation and losses from sensible (primarily gastrointestinal) and insensible sources. No allotment is calculated for urine as long as oliguria persists.

When the output begins to increase, either spontaneously or in response to diuretic therapy, the intake of fluid, potassium, and sodium must be monitored and adequate replacement provided to prevent depletion and its consequences. Some patients pass enormous amounts of electrolyte-rich urine.

Complications

The child with AKI has a tendency to develop water intoxication and hyponatremia, which makes it difficult to provide calories in sufficient amounts to meet the child's needs and reduce tissue catabolism, metabolic acidosis, hyperkalemia, and uremia. If the child is able to tolerate oral foods, food sources high in concentrated carbohydrate and fat but low in protein, potassium, and sodium may be provided. However, many children have functional disturbances of the gastrointestinal tract, such as nausea and vomiting; therefore, the IV route is generally preferred and usually consists of essential amino acids or a combination of essential and nonessential amino acids administered by the central venous route.

Control of water balance in these patients requires careful monitoring of feedback information, such as accurate intake and output, body weight, and electrolyte measurements. In general, during the oliguric phase, no sodium, chloride, or potassium is given unless there are other large, ongoing losses. Regular measurement of plasma electrolyte, pH, BUN, and creatinine levels is required to assess the adequacy of fluid therapy and to anticipate complications that require specific treatment.

Hyperkalemia is the most immediate threat to the life of the child with AKI. Hyperkalemia can be minimized and sometimes avoided by eliminating potassium from all food and fluid, reducing tissue catabolism, and correcting acidosis. Measures used for the reduction of serum potassium levels are oral or rectal administration of an ion-exchange resin, such as sodium polystyrene sulfonate (Kayexalate) and peritoneal dialysis or hemodialysis (see later in chapter). The resin produces its effect by exchange of its sodium for the potassium, thus binding potassium for removal from the body. This increased sodium concentration may contribute to fluid overload, hypertension, and cardiac failure. Dialysis removes potassium and other waste products from the serum by diffusion through a semipermeable membrane.

Hypertension is a frequent and serious complication of AKI, and to detect it early, blood pressure measurements are made every 4 to 6 hours. The most common cause of hypertension in AKI is overexpansion of extracellular fluid and plasma volume together with activation of the renin-angiotensin system. Hypertension is controlled with antihypertensive drugs. Other measures that may be used include limiting fluids and salt.

Anemia is frequently associated with AKI, but transfusion is not recommended unless the hemoglobin drops below 6 g/dl. Transfusions, if used, consist of fresh, packed RBCs given slowly to reduce the likelihood of increasing blood volume, hypertension, and hyperkalemia.

Seizures may occur when renal failure progresses to uremia and are also related to hypertension, hyponatremia, and hypocalcemia. Treatment is directed to the specific cause when known. More obscure causes are managed with antiepileptic drugs.

Cardiac failure with pulmonary edema is almost always associated with hypervolemia. Treatment is directed toward reduction of fluid volume, with water and sodium restriction and administration of diuretics.

Prognosis

The prognosis of AKI depends largely on the nature and severity of the causative factor or precipitating event and the promptness and competence of management. The outcome is least favorable in children with rapidly progressive nephritis and cortical necrosis. Children in whom AKI is a result of HUS or AGN may recover completely, but residual renal impairment or hypertension is more often seen. Complete recovery is usually expected in children whose renal failure is a result of dehydration, nephrotoxins, or ischemia. AKI after cardiac surgery is less favorable. It is often impossible to assess the extent of recovery for several months.

Quality Patient Outcomes: Acute Kidney Injury

- Underlying cause of acute kidney injury (AKI) identified and treated
- Water balance maintained
- Hypertension controlled
- Electrolyte balance maintained
- Diet maintains calories while minimizing tissue catabolism, metabolic acidosis, hyperkalemia, and uremia

Nursing Care Management

Meticulous attention to fluid intake and output is mandatory and includes all of the physical measurements discussed previously in relation to problems of fluid balance. Monitoring fluid balance and vital signs is a continuous process, and observers are constantly on the alert for signs of complications so that appropriate interventions can be implemented. Because these children require intensive observation and often specialized treatment (such as dialysis), they are usually admitted

to an intensive care unit in which needed equipment and trained personnel are available (see the [Nursing Care Plan](#) box later in this chapter).

Limiting fluid intake requires ingenuity on the part of caregivers to cope with the child who is thirsty. Rationing the daily intake in small amounts of fluid served in containers that give the impression of larger volumes is one strategy. Older children who understand the rationale of fluid limits can help determine how their daily ration should be distributed.

Meeting nutritional needs is sometimes a problem; the child may be nauseated, and encouraging concentrated foods without fluids may be difficult. When nourishment is provided by the IV route, careful monitoring is essential to prevent fluid overload. In addition, nursing measures such as maintaining an optimal thermal environment, reducing any elevation of body temperature, and reducing restlessness and anxiety are used to decrease the rate of tissue catabolism.

The nurse must be continually alert for changes in behavior that indicate the onset of complications. Infection from reduced resistance, anemia, and general morbidity is a constant threat. Fluid overload and electrolyte disturbances can precipitate cardiovascular complications, such as hypertension and cardiac failure. Fluid and electrolyte imbalances, acidosis, and accumulation of nitrogenous waste products can produce neurologic involvement manifested by coma, seizures, or alterations in sensorium.

Although children with AKI are usually quite ill and voluntarily diminish their activity, infants may become restless and irritable, and children are often anxious and frightened. Frequent, painful, and stress-producing treatments and tests must be performed. A supportive, empathetic nurse can provide comfort and stability in a threatening and unnatural environment.

Family Support

Providing support and reassurance to parents is among the major nursing responsibilities. The seriousness of AKI and its emergency nature are stressful to parents, and most feel some degree of guilt regarding the child's condition, especially when the illness is a result of ingestion of a toxic substance, dehydration, or a genetic disease. They also need to be kept informed of the child's progress and provided explanations regarding the therapeutic regimen. The equipment and the child's behavior are sometimes frightening and anxiety provoking. Nurses can do much to help parents comprehend and deal with the stresses of the situation.

Chronic Kidney Disease

The kidneys are able to maintain the chemical composition of fluids within normal limits until more than 50% of functional renal capacity is destroyed by disease or injury. Chronic renal insufficiency or failure begins when the diseased kidneys can no longer maintain the normal chemical structure of body fluids under normal conditions. Progressive deterioration over months or years produces a variety of clinical and biochemical disturbances that eventually culminate in the clinical syndrome known as **uremia**.

A variety of diseases and disorders can result in CKD. The most frequent causes are congenital renal and urinary tract malformations, VUR associated with recurrent UTI, chronic pyelonephritis, hereditary disorders, chronic glomerulonephritis, and glomerulonephropathy associated with systemic diseases, such as anaphylactoid purpura and lupus erythematosus (see the [Nursing Care Plan](#) box).

Nursing Care Plan

The Child with Chronic Kidney Disease

Case Study

Susie is a 9-year-old girl who has a history of chronic pyelonephritis. Over the past several months, she has experienced increased fatigue and lack of appetite, was unable to participate in physical activities, and appeared pale and listless. Her parents took her to her pediatrician who on examination, found signs and symptoms of weight loss, facial puffiness, bone and joint pain, and dryness of the skin. Susie told her pediatrician that she was having headaches and nausea. With Susie's history of chronic pyelonephritis, she was immediately referred to a pediatric nephrologist.

Assessment

Based on Susie's history, what are the most important signs and symptoms that you need to be aware of?

Chronic Kidney Disease Defining Characteristics

Elevated serum creatinine

Evidence of hyperkalemia, hyperphosphatemia, hypernatremia, and uremia

Anemia

Oliguria

Anuria uncommon (except in obstructive disorders)

Nonspecific (may develop):

Nausea

Vomiting

Headaches

Drowsiness

Edema

Dryness and itchiness of the skin

Hypertension

Inadequate growth

Poor nutritional intake

Nursing Diagnosis

Risk for electrolyte imbalance

Risk for ineffective renal perfusion

Risk for poor growth

Risk for anemia

Risk for cardiovascular complications

Risk for renal bone disease

Knowledge deficit regarding chronic kidney disease (CKD) and treatments

Nursing Interventions

What are the most appropriate nursing interventions for a child with CKD?

| Nursing Interventions | Rationale |
|--|--|
| Close monitoring of the patient's status. Follow clinical and laboratory findings. Blood studies included complete blood count (CBC), electrolyte and kidney status. | To identify changes in kidney status which require additional treatment |
| Observe for evidence of accumulated waste products. | To ensure prompt treatment |
| Provide dietary instructions for foods that reduce excretory demands on kidneys and provide sufficient calories and protein for growth. | To encourage appropriate diet, which can reduce kidney demands |
| Limit phosphorus, salt, and potassium as prescribed. | To prevent mineral excess |
| Monitor growth closely since short stature is a significant side effect. | To provide early detection of growth failure and, if appropriate, treatment with growth hormone |
| Monitor cardiovascular status including blood pressure measurement. | Early identification and treatment of hypertension decreases the risk of end organ damage such as left ventricular hypertrophy and further kidney damage |
| Minimize renal bone disease by maintaining optimal calcium, phosphorus, and intact parathyroid hormone levels, and acid-base balance. | Prevention and early treatment of renal bone disease optimizes growth |
| Monitor for anemia. Child may require school accommodations and rest periods due to fatigue. | Early identification of anemia allows for treatment with iron supplement and erythropoiesis stimulating medication maximizing energy level |
| Identify patient and family stressors that may accompany a diagnosis of CKD. | Providing financial and emotion support for family can help decrease some of the stressors associated with this condition. |
| Review disease, medication, dietary, and other information at every encounter. | Understanding the medical condition and therapies allows family to make informed decisions about care |

Expected Outcomes

The child will exhibit no evidence of waste product accumulation.

Sufficient calories and protein for growth maintained.

Excretory demands made on the kidney are limited.

Metabolic bone disease (osteodystrophy) is minimal.

Fluid and electrolyte disturbances are managed.

Hypertension is managed.

Patient/family indicate understanding of CKD and treatments.

Case Study (Continued)

Susie is now being followed by a nephrology specialty team and has returned to the clinic for her monthly evaluation. The nurse performing the assessment finds Susie's blood pressure to be elevated, and she notices that her skin appears pale and sallow in appearance. Susie tells her nurse that she has been really tired lately and her headaches have returned.

Assessment

What concerns you most based on the scenario?

Susie's kidney status may be deteriorating based on the history and examination. See the defining characteristics of CKD listed earlier.

What immediate steps should be taken to further evaluate Susie's kidney status?

Check CBC, electrolyte status, and kidney function tests.

Document weight, height, and blood pressure; compare to previous visit.

Evaluate patient adherence to medication and dietary recommendations.

The following laboratory results have returned from Susie's blood work:

CBC: Hemoglobin, 9.1; hematocrit (Hct), 27; white blood count (WBC), 8,500; platelets, normal

Urinalysis: Elevated protein

Electrolytes and kidney function: Potassium, 5.9; sodium, 138; phosphate, 6.0; calcium, 9.1; magnesium, 2.5; blood urea nitrogen (BUN), 25; serum creatinine, 1.8

Glomerular function rate (GFR), 30 ml/min/1.73 m² (The GFR shows how well the kidneys are working to pass liquid and waste from the bloodstream to the kidneys.)

Nursing Diagnosis

Risk for electrolyte imbalance (hyperkalemia)

Risk for ineffective renal perfusion

Nursing Interventions

What are the most appropriate nursing interventions for Susie at this time?

| Nursing Interventions | Rationale |
|--|---|
| Treat hyperkalemia with dietary restrictions and perhaps medication, such as Kayexalate. | To prevent cardiac arrhythmias and other symptoms associated with elevated potassium levels |
| Observe for evidence of accumulated waste products. | To ensure prompt treatment |
| Provide dietary instructions for foods that reduce excretory demands on kidneys and provide sufficient calories and protein for growth. This may include restriction of potassium, sodium, and/or phosphorus intake. | To encourage appropriate diet, which can reduce kidney demands |
| Treat anemia with adequate rest periods and possibly iron and erythropoiesis-stimulating medications. | To maximize energy level |

Expected Outcome

Susie will be managed to minimize further kidney function deterioration.

Case Study (Continued)

Susie's parents are anxious and upset with the new problems she is now having. They are concerned that she will need kidney transplantation in the near future. You are concerned that they are not adhering to the management plan that was designed for the parents to follow at home.

Assessment

What are the most important aspects of Susie's care to discuss with her parents at this time?

Family's Knowledge of Illness-Defining Characteristics

- Understands definition of CKD
- States four signs of kidney failure
- Describes medications the child is taking and rationale for use
- Describes dietary modifications and rationale for use
- Expresses fears and concerns
- Shows appropriate reactions to child's illness

Nursing Diagnosis

Readiness for enhanced knowledge related to parents' interest in Susie's health status.

Nursing Interventions

What are the most appropriate nursing interventions for this diagnosis?

| Nursing Interventions | Rationale |
|---|--|
| Review disease, medication, dietary, and other information at every encounter. | Understanding the medical condition and therapies allows families to make informed decisions about care. Optimal consistency with treatment will maximize renal function. |
| Arrange for renal dietitian to meet with family to review allowable foods and assist in dietary planning. | Improved understanding of the child's dietary needs increases ability to adhere to modifications. |
| Arrange for social worker to meet with family to assess emotional and financial needs. | This assistance is to identify and modify stressors associated with CKD. |
| As child nears end-stage kidney failure, arrange for discussions with a kidney transplant coordinator and/or dialysis nurse to discuss renal replacement therapies. | Family must be aware of positive and negative aspects of each therapy in order to make informed decisions. |

Expected Outcome

- Susie's parents will understand the signs and symptoms of CKD and will understand the actions being taken by the health care team.
- Susie and her parents will follow the plan designed for managing her chronic kidney failure at home.

Pathophysiology

Early in the course of progressive renal failure, the child remains asymptomatic with only minimal biochemical abnormalities. Unless the presence of CKD is detected in the process of routine assessment, signs and symptoms that indicate advanced renal damage frequently emerge only late in the course of the disease. Midway in the disease process, as increasing numbers of nephrons are totally destroyed and most others are damaged to varying degrees, the few that remain intact are hypertrophied but functional. These few normal nephrons are able to make sufficient adjustments to stresses to maintain reasonable degrees of fluid and electrolyte balance. Definitive biochemical examination at this time will reveal restricted tolerance to excesses or restrictions. As the disease progresses to the end stage, because of a severe reduction in the number of functioning nephrons, the kidneys are no longer able to maintain fluid and electrolyte balance, and the features of uremic syndrome appear.

The accumulation of various biochemical substances in the blood resulting from diminished renal function produces complications such as the following:

Retention of waste products, especially BUN and creatinine

Water and sodium retention, which contributes to edema and vascular congestion

Hyperkalemia of dangerous levels

Metabolic acidosis of a sustained nature because of continual hydrogen ion retention and bicarbonate loss

Calcium and phosphorus disturbances, resulting in altered bone metabolism, which in turn causes growth arrest or retardation, bone pain, and deformities known as **renal osteodystrophy**

Anemia caused by hematologic dysfunction, including a shortened life span of RBCs, impaired RBC production related to decreased production of erythropoietin, prolonged bleeding time, and nutritional anemia

Growth disturbance, probably caused by such factors as renal osteodystrophy, poor nutrition associated with dietary restrictions and loss of appetite, and biochemical abnormalities

Children with CKD seem to be more susceptible to infection, especially pneumonia, UTI, and septicemia, although the reason for this is unclear. These children become extraordinarily sensitive to changes in vascular volume that may cause pulmonary overload, CNS symptoms, hypertension, and cardiac failure.

Diagnostic Evaluation

The diagnosis of CKD is usually suspected on the basis of any number of clinical manifestations, a history of prior renal disease, or biochemical findings. The onset is usually gradual, and the initial signs and symptoms are vague and nonspecific (Box 26-6).

Box 26-6

Clinical Manifestations of Chronic Renal Failure

Early signs:

- Loss of normal energy
- Increased fatigue on exertion
- Pallor, subtle (may not be noticed)
- Elevated blood pressure (sometimes)

As the disease progresses:

- Decreased appetite (especially at breakfast)
- Less interest in normal activities
- Increased or decreased urinary output with compensatory intake of fluid
- Pallor more evident
- Sallow, muddy appearance of skin

Child may complain of:

- Headache
- Muscle cramps
- Nausea

Other signs and symptoms:

- Weight loss
- Facial edema
- Malaise
- Bone or joint pain
- Growth retardation
- Dryness or itching of the skin
- Bruised skin

- Sensory or motor loss (sometimes)
- Amenorrhea (common in adolescent girls)

Uremic syndrome (untreated):

- Gastrointestinal symptoms
- Anorexia
- Nausea and vomiting
- Bleeding tendencies
- Bruises
- Bloody diarrheal stools
- Stomatitis
- Bleeding from lips and mouth
- Intractable itching
- Uremic frost (deposits of urea crystals on skin)
- Unpleasant “uremic” breath odor
- Deep respirations
- Hypertension
- Congestive heart failure
- Pulmonary edema
- Neurologic involvement
- Progressive confusion
- Dulled sensorium
- Coma (ultimately)

- Tremors
- Muscular twitching
- Seizures

Laboratory and other diagnostic tools and tests are of value in assessing the extent of renal damage, biochemical disturbances, and related physical dysfunction (see [Tables 26-1 to 26-3](#)). Often they can help establish the nature of the underlying disease and differentiate among other disease processes and the pathologic consequences of renal dysfunction.

Therapeutic Management

In irreversible renal failure, the goals of medical management are to (1) promote maximum renal function, (2) maintain body fluid and electrolyte balance within safe biochemical limits, (3) treat systemic complications, and (4) promote as active and normal a life as possible for the child for as long as possible. The child is allowed unrestricted activity and is allowed to set his or her own limits regarding rest and extent of exertion. School attendance is encouraged as long as the child is able. When the effort is too great, home tutoring is arranged.

Diet regulation is the most effective means, short of dialysis, of reducing the quantity of materials that require renal excretion. The goal of diet management in renal failure is to provide sufficient calories and protein for growth while limiting the excretory demands made on the kidneys, to minimize metabolic bone disease (**osteodystrophy**), and to minimize fluid and electrolyte disturbances. Dietary protein intake is limited only to the reference daily intake (Recommended Dietary Allowance [RDA]) for the child's age. Restriction of protein intake below the RDA is believed to negatively affect growth and neurodevelopment. Malnutrition due to factors including anorexia, dietary restrictions, metabolic acidosis, and increased energy expenditure is common in these children ([Carrero, Stenvinkel, Cuppari, et al, 2013](#)).

Sodium and water are not usually limited unless there is evidence of edema or hypertension, and potassium is not usually restricted. However, restrictions of any or all three may be imposed in later stages or at any time that abnormal serum concentrations are evident.

Dietary phosphorus is controlled through reduction of protein and milk intake to prevent or correct the calcium–phosphorus imbalance. Phosphorus levels can be further reduced by oral administration of calcium carbonate preparations or other phosphate-binding agents that combine with the phosphorus to decrease gastrointestinal absorption and thus the serum levels of phosphate. Treatment with (inactive) 25-OH vitamin D and/or (active) 1, 25-dihydroxy vitamin D is begun to increase calcium absorption and suppress elevated parathyroid hormone levels ([Wesseling-Perry and Salusky, 2013](#)).

Metabolic acidosis is alleviated through administration of alkalizing agents, such as sodium bicarbonate or a combination of sodium and potassium citrate.

Growth failure is one major consequence of CKD, especially in preadolescents. These children grow poorly both before and after the initiation of hemodialysis. The use of recombinant human growth hormone to accelerate growth in children with growth retardation secondary to CKD has been successful ([Gupta and Lee, 2012](#)). **Osseous deformities** that result from renal osteodystrophy, especially those related to ambulation, are troublesome and require correction if they occur. Dental defects are common in children with CKD, and the earlier the onset of the disease, the more severe are the dental manifestations (including hypoplasia, hypomineralization, tooth discoloration, alteration in size and shape of teeth, malocclusion, and ulcerative stomatitis). Therefore, regular dental care is important in these children.

Anemia in children with CKD is related to decreased production of erythropoietin. Recombinant human erythropoietin (rHuEPO) is being offered to these children as thrice-weekly or weekly subcutaneous injections and is replacing the need for frequent blood transfusions. The drug corrects the anemia which in turn increases appetite, activity, and general well-being in the children who receive it.

Hypertension may be managed initially by cautious use of a low-sodium diet, fluid restriction, and perhaps diuretics, such as hydrochlorothiazide or furosemide. Severe hypertension requires the

use of other antihypertensive agents, singly or in combination.

Intercurrent infections are treated with appropriate antimicrobials at the first sign of infection; however, any drug eliminated through the kidneys is administered with caution. Other complications are treated symptomatically (e.g., central-acting antiemetics for nausea, antiepileptics for seizures, and diphenhydramine [Benadryl] for pruritus).

When the child reaches end-stage renal failure, death will eventually occur unless waste products and toxins are removed from body fluids by dialysis or kidney transplantation. These techniques have been adapted for infants and small children and are implemented in most cases of renal failure after conservative management is no longer effective (see [Technologic Management of Renal Failure](#), later in chapter).

Prognosis

Dialysis and transplantation are the only treatments currently available for children with ESRD. Although children may survive on dialysis, it is not an ideal long-term modality. Complications include infection of access sites, growth failure, and disruption of normal socialization. Many pediatric centers encourage families of children with ESRD to consider kidney transplantation. The [North American Pediatric Renal Trials and Collaborative Studies' \(2010\)](#) annual transplant report documents graft survival of 96% at 1 year and 84% at 5 years for living donor kidneys and 95% at 1 year and 78% at 5 years for deceased donor kidneys.

Post-transplant complications include infection, hypertension, steroid toxicity, hyperlipidemia, aseptic necrosis, malignancy, and growth retardation ([Sharma, Ramanathan, Posner, et al, 2013](#)). Long-term graft survival is not guaranteed, and many children require a second or third transplant. Successful kidney transplantation does improve rehabilitation of children with CKD, both educationally and psychologically. Increasing use of primary or preemptive kidney transplants is becoming the optimal form of renal replacement therapy, leading to substantial improvement in quality of life ([Goldstein, Rosburg, Warady, et al, 2009](#)).

Quality Patient Outcomes: Chronic Kidney Disease

- Sufficient calories and protein for growth maintained
- Excretory demands made on the kidney are limited
- Metabolic bone disease (osteodystrophy) minimal
- Fluid and electrolyte disturbances managed
- Hypertension managed
- Growth retardation treated

Nursing Care Management

The multiple complications of ESRD are managed according to medical protocols, such as the National Kidney Foundation Kidney Disease Outcomes Quality Initiative's evidence-based clinical practice guidelines (<http://www.kidney.org/professionals/KDOQI>). However, progressive disease places a number of stresses on the child and family, including those of a potentially fatal illness (see [Chapter 17](#)). There is a continuing need for repeated examinations that often entail painful procedures, side effects, and frequent hospitalizations. Diet therapy becomes progressively more restricted and intense, and the child is required to take a variety of medications. Ever present in all aspects of the treatment regimen is the realization that without treatment, death is inevitable.

Some specific stresses related to ESRD and its treatment are predictable. When it first becomes apparent that ESRD is inevitable, both parents and child experience depression and anxiety. Acceptance is particularly difficult if renal failure progresses rapidly after diagnosis. Denial and disbelief are usually pronounced. After renal failure is established and symptoms become progressively more distressing, the initiation of dialysis is usually perceived as a positive experience, and after experiencing initial concerns regarding the treatment, the child begins to feel better, and parental anxiety is relieved for a time.

For children, however, initiating a dialysis regimen is a traumatic and anxiety-provoking experience, because it involves surgery for implantation of a graft, fistula, or peritoneal catheter. The initial experience with the dialysis procedure is frightening to most children. They need reassurance about the nature of the preparations for dialysis and the conduct of the treatment.

Adolescents, with their increased need for independence and their urge for rebellion, usually adapt less well than younger children. They resent the control and enforced dependence imposed by the rigorous and unrelenting therapy program. They resent being dependent on hemodialysis technology, their parents, and the professional staff. Depression or hostility is common in adolescents undergoing hemodialysis.

Both the graft and the fistula require needle insertions at each dialysis. The goal is to perform pain-free venipuncture. Using buffered lidocaine with a small-gauge needle (30-gauge) to anesthetize the area before venipuncture of the graft or fistula is one method. Using an anesthetizing topical preparation, such as eutectic mixture of local anesthetics (EMLA; lidocaine and prilocaine) 1 hour before venipuncture is another approach (see [Pain Management, Chapter 5](#)). External dual-lumen venous access devices eliminate the need for needles but are more prone to infection and other central line complications.

The availability of home peritoneal dialysis has offered a greater degree of freedom for persons undergoing long-term dialysis. The nurse is responsible for teaching the family about (1) the disease, its implications, and the therapeutic plan; (2) the possible psychological effects of the disease and the treatment; and (3) the technical aspects of the procedure. The family learns to manage the various aspects of the dialysis procedure, how to maintain accurate records, and how to observe for signs of complications that need to be reported to the proper persons.

Body changes related to the disease process (such as pale or ashen skin color, growth retardation, and lack of sexual maturation) are stress provoking. Dietary restrictions are particularly burdensome for both children and parents. Children feel deprived when they are unable to eat foods previously enjoyed and that are unrestricted for other family members. Consequently, they may fail to cooperate. Diet restrictions may be interpreted as punishment. Some children, unable to understand fully the purpose of restrictions, will sneak forbidden food items at every opportunity. Allowing children, especially adolescents, maximum participation in and responsibility for their own treatment program is helpful.

After months or years of dialysis, the parents and child feel anxiety associated with the prognosis and continued pressures of the treatment. The continuous need for treatment interferes with family plans. The time spent in transportation to and from the dialysis unit and the time spent undergoing dialysis treatments cut into time for outside activities, including school. Graft and fistula problems, as well as peritoneal catheter exit site infections, may develop and present a common source of aggravation (see [Family-Centered Care](#) box).

Family-Centered Care

Family Priorities

Families that have children with long-term chronic illnesses, such as end-stage renal disease (ESRD), spend much time in hospitals, outpatient clinics, and primary health care facilities. When they miss appointments or respond less quickly than anticipated, sometimes they are quickly labeled “noncompliant.” It is important to remember that families have to develop priorities for the unit as a whole. Sometimes the family may decide that it is more important for the parent to go to work or to attend a sibling's school performance than to attend an appointment scheduled for them by health care personnel. The chronically ill child cannot and should not always be the number one priority for the family. The professional staff who works with the family can help the parents prioritize the needs of the ill child within the needs of the family constellation.

Sylmar, CA*

The possibility of kidney transplantation often provides hope for relief from the rigors of hemodialysis and peritoneal dialysis. Most children and families respond well to a kidney transplant, and most children can be successfully rehabilitated.

The National Kidney Foundation* and other agencies provide a number of services and information for families of children with renal disease.

Technologic Management of Renal Failure

Dialysis

Dialysis is the process of separating colloids and crystalline substances in solution by the difference in their rate of diffusion through a semipermeable membrane. Methods of dialysis currently available for clinical management of renal failure are **peritoneal dialysis**, wherein the abdominal cavity acts as a semipermeable membrane through which water and solutes of small molecular size move by osmosis and diffusion according to their respective concentrations on either side of the membrane, and **hemodialysis**, in which blood is circulated outside the body through artificial membranes that permit a similar passage of water and solutes. A third type of dialysis is **hemofiltration**, in which blood filtrate is circulated outside the body by hydrostatic pressure exerted across a semipermeable membrane with simultaneous infusion of a replacement solution. Types of hemofiltration include continuous venovenous hemofiltration, continuous venovenous hemodialysis, and continuous venovenous hemofiltration. These continuous renal replacement therapies are used in AKI, severe fluid overload, and inborn errors of metabolism or after bone marrow transplant.

Peritoneal dialysis is the preferred form of dialysis for infants, children, and parents who wish to remain independent, families who live a long distance from the medical center, and children who prefer fewer dietary restrictions and a gentler form of dialysis. Chronic peritoneal dialysis is most often performed at home. The two types of peritoneal dialysis are **continuous ambulatory peritoneal dialysis** and **continuous cycling peritoneal dialysis**. In both methods, commercially available sterile dialysis solution is instilled into the peritoneal cavity through a surgically implanted indwelling catheter tunneled subcutaneously and sutured into place. The warmed solution is allowed to enter the peritoneal cavity by gravity and remains a variable length of time according to the rate of solute removal and glucose absorption in individual patients. The care and management of the procedure are the responsibility of the parents of young children. Some centers have initiated use of home health nurses to give parents respite from care. Older children and adolescents can carry out the procedure themselves, which provides them with some control and less dependency. This is especially important for adolescents.

Nursing Alert

Observe for changes in the color of the dialysate draining from the child. The spent solution should be clear. If the color is cloudy, notify the practitioner immediately.

Hemodialysis requires the creation of a vascular access and the use of special dialysis equipment—the hemodialyzer, or so-called artificial kidney. Vascular access may be one of three types: fistulas, grafts, or external vascular access devices. An **arteriovenous fistula** is an access in which a vein and artery are connected surgically. The preferred site is the radial artery and a forearm vein that produces dilation and thickening of the superficial vessels of the forearm to provide easy access for repeated venipuncture. An alternative is the creation of a subcutaneous (internal) **arteriovenous graft** by anastomosing artery and vein, with a synthetic prosthetic graft for circulatory access. The most commonly used material is expanded polytetrafluoroethylene (ePTFE). Both the graft and the fistula require needle insertions with each dialysis treatment.

For external vascular access devices, percutaneous catheters are inserted in the femoral, subclavian, or internal jugular veins, even in very small children. A more permanent form of external access is available via a central catheter inserted surgically into the internal jugular vein. This catheter has a dual lumen, which allows a larger volume of blood flow with minimum recirculation. Catheters eliminate the need for skin punctures but require some home care.

Hemodialysis is best suited to children who do not have someone in the family who is able to perform home peritoneal dialysis and to those who live close to a dialysis center. The procedure is usually performed three times per week for 4 to 6 hours, depending on the child's size. Studies suggest that intensified hemodialysis (shorter sessions done 5 to 7 days weekly or longer sessions done overnight three to seven times weekly) may improve outcomes (Thumfart, Pommer, Querfeld, et al, 2014). Hemodialysis achieves rapid correction of fluid and electrolyte abnormalities but can

cause problems in association with this rapid change, such as muscle cramping and hypotension. Disadvantages include school absence during dialysis and strict fluid and dietary restrictions between dialysis sessions. Boredom for the child and family is often a problem during dialysis, and planned activities should be introduced (Fig. 26-7).

FIG 26-7 Diversional activities help lessen the boredom children can experience during hemodialysis.

Most children show rapid clinical improvement with the implementation of dialysis, although it is directly related to the duration of uremia before dialysis and good nutrition. Growth rate and skeletal maturation improve, but recovery of normal growth is infrequent. In many cases, sexual development, although delayed, progresses to completion.

Transplantation

Kidney transplantation is an acceptable and effective means of therapy in the pediatric age group. Although peritoneal dialysis and hemodialysis are life preserving, both require major alterations in lifestyle. Transplantation offers the opportunity for a relatively normal life and is the preferred form of treatment for children with ESRD.

Kidneys for transplant are available from two sources: a **living related donor**, usually a parent or a sibling, or a **cadaver donor**, wherein the family of a dead or brain-dead patient consents to donation of a healthy kidney. Retransplantation may be required if rejection occurs.

The primary goal in transplantation is the long-term survival of grafted tissue by securing tissue that is antigenically similar to that of the recipient and by suppressing the recipient's immune mechanism. The immunosuppressant therapy of choice has been corticosteroids (prednisone) in conjunction with cyclosporine or tacrolimus and mycophenolate mofetil. Other therapies include antilymphoblast globulin or monoclonal antibodies. New immunosuppressant medications and early withdrawal of steroids or steroid-free protocols are rapidly coming into clinical trials and use in large transplant centers (Kim, Webster, and Craig, 2013). It is important for the nurse to learn about the medications used in the antirejection protocol(s) and their side effects. Because the immunosuppressant medications are taken indefinitely, transplant patients experience many side effects of the drugs, including hypertension, growth retardation, cataracts, risk of infection, obesity, characteristics of Cushing syndrome, and hirsutism.

Nursing Alert

The child with a kidney transplant who exhibits any of the following should be evaluated immediately for possible rejection:

- Fever
- Swelling and tenderness over graft area
- Diminished urinary output
- Elevated blood pressure
- Elevated serum creatinine

Rejection of the transplanted kidney is the most common cause of transplant failure. Rejection is treated aggressively with immunosuppressant medications and can often be reversed. Some patients do not respond to treatment of acute rejection or develop chronic rejection and must eventually return to dialysis or undergo another kidney transplant.

NCLEX Review Questions

1. The nurse is caring for a 4-year-old girl with a history of frequent urinary tract infections (UTIs). What should the nurse be aware of before obtaining a urine sample? Select all that apply.
 - a. To obtain a clean-catch urine specimen, have the child sit on the toilet facing backward toward the tank.
 - b. Because children who have a UTI will have painful urination, have the child drink a large amount of fluid before obtaining the sample.
 - c. The specimen must be fresh—less than 1 hour after voiding with storage at room temperature or less than 4 hours after voiding with refrigeration.
 - d. If a urinalysis obtained by a bag specimen is negative, a specimen still needs to be obtained by catheterization or suprapubic aspiration.
 - e. The key to distinguishing a true UTI from asymptomatic bacteriuria is the presence of pyuria.
 - f. Because the child is febrile, the nurse should immediately start an antimicrobial and then obtain a urine culture.
2. A child with periorbital edema, decreased urine output, pallor, and fatigue is admitted to the pediatric unit. The child is being examined for acute glomerular nephritis. Which of the following nursing measures should be considered? Select all that apply.
 - a. On examination, there is usually a mild to moderate elevation in blood pressure compared with normal values for age, although severe hypertension may be present.
 - b. Urinalysis during the acute phase characteristically shows hematuria, proteinuria, and increased specific gravity,
 - c. The primary objective is to reduce the excretion of urinary protein and maintain protein-free urine.
 - d. Assessment of the child's appearance for signs of cerebral complications is an important nursing function because the severity of the acute phase is variable and unpredictable.
 - e. Because these children are particularly vulnerable to upper respiratory tract infection, protect them from contact with infected roommates, family, or visitors.
3. When caring for a child with acute renal failure, which nursing measure requires immediate attention?
 - a. Serum potassium concentrations in excess of 7 mEq/L
 - b. Sodium level of 135
 - c. Transfusion for hemoglobin of 8
 - d. Mannitol and furosemide for a urine output of 2 ml/kg/hr
4. When giving discharge instructions to a parent post hypospadias repair, the nurse recognizes a need for more teaching when the mother says which of the following? Select all that apply.
 - a. "I know that I should never clamp off the catheter."
 - b. "My child can take a tub bath when we arrive home because it will soothe the area."
 - c. "An antibacterial ointment may be applied to the penis daily for infection control."
 - d. "Fluids should be monitored and rationed to prevent fluid overload."
 - e. "My child should avoid straddle toys, sandboxes, swimming, and rough activities until allowed by the surgeon."
5. What is the 24-hour fluid requirement for a child weighing 32 kg?
 - a. 1920 ml/day
 - b. 1740 ml/day
 - c. 1840 ml/day
 - d. 1620 ml/day

Correct Answers

The Child with Cerebral Dysfunction

Cheryl C. Rodgers, Maureen Sheehan

Cerebral Dysfunction

Much of the information about the status of the brain is obtained by indirect measurements. Some of these measurements are discussed elsewhere in relation to numerous aspects of child care (e.g., as part of newborn status [Chapter 7], intellectual disability [Chapter 18], hypoxic injury [cerebral palsy, Chapter 30], and attainment of developmental milestones at each stage of development). Because increased intracranial pressure (ICP) and altered states of consciousness have such prominent places in neurologic dysfunction, they are described here followed by techniques for neurologic assessment and diagnostic tests.

Increased Intracranial Pressure

The brain, tightly enclosed in the solid bony cranium, is well protected but highly vulnerable to pressure that may accumulate within the enclosure (Fig. 27-1). Its total volume—brain (80%), cerebrospinal fluid (CSF) (10%), and blood (10%)—must remain approximately the same at all times. A change in the proportional volume of one of these components (e.g., increase or decrease in intracranial blood) must be accompanied by a compensatory change in another. In this way, the volume and pressure normally remain constant. Examples of compensatory changes are reduction in blood volume, decrease in CSF production, increase in CSF absorption, or shrinkage of brain mass by displacement of intracellular and extracellular fluid.

FIG 27-1 Coronal section of the top of the head showing meningeal layers. (From Patton KT, Thibodeau GA: *Anatomy and physiology*, ed 8, St. Louis, 2013, Mosby.)

Children with open fontanels compensate for increased volume by skull expansion and widened sutures. However, at any age, the capacity for spatial compensation is limited. An increase in ICP may be caused by tumors or other space-occupying lesions, accumulation of fluid within the ventricular system, bleeding, or edema of cerebral tissues. Once compensation is exhausted, any further increase in the cranium's volume will result in a rapid rise in ICP.

Early signs and symptoms of increased ICP are often subtle and assume many patterns (Box 27-1). As pressure increases, signs and symptoms become more pronounced, and the level of consciousness (LOC) deteriorates from drowsiness or eventual coma.

Box 27-1

Clinical Manifestations of Increased Intracranial Pressure in Infants and Children

Infants

Tense, bulging fontanel
Separated cranial sutures
Macewen (cracked-pot) sign
Irritability and restlessness
Drowsiness
Increased sleeping
High-pitched cry
Increased frontooccipital circumference
Distended scalp veins
Poor feeding
Crying when disturbed
Setting-sun sign

Children

Headache
Nausea
Forceful vomiting
Diplopia, blurred vision
Seizures
Indifference, drowsiness
Decline in school performance
Diminished physical activity and motor performance
Increased sleeping
Inability to follow simple commands
Lethargy

Late Signs in Infants and Children

Bradycardia
Decreased motor response to command
Decreased sensory response to painful stimuli

Alterations in pupil size and reactivity

Extension or flexion posturing

Cheyne-Stokes respirations

Papilledema

Decreased consciousness

Coma

Evaluation of Neurologic Status

General Aspects

Children younger than 2 years old require special evaluation because they are unable to respond to directions designed to elicit specific neurologic responses. Early neurologic responses in infants are primarily reflexive; these responses are gradually replaced by meaningful movement in the characteristic cephalocaudal direction of development. This evidence of progressive maturation reflects more extensive myelination and changes in neurochemical and electrophysiologic properties.

Most information about infants and small children is gained by observing their spontaneous and elicited reflex responses. As they develop increasingly complex gross and fine motor skills and communication skills, more sophisticated techniques are used to assess acquisition of developmental milestones. Delay or deviation from expected milestones helps identify high-risk children. Persistence or reappearance of primitive reflexes indicates a pathologic condition. In evaluating an infant or young child, it is also important to obtain the pregnancy and delivery history, respiratory status at birth, and neonatal health to determine the possible impact of intrauterine and extrauterine environmental influences known to affect the orderly maturation of the central nervous system (CNS). These influences include maternal infections, chemicals, medication, illicit drug use, trauma, and metabolic insults.

General aspects of assessment that provide clues to the etiology of dysfunction include:

Family history: Sometimes offers clues regarding possible genetic disorders with neurologic manifestations.

Health history: May provide valuable clues regarding the cause of neurologic dysfunction.

Information should include Apgar scores, age of developmental milestones, trauma or injuries, acute and chronic illnesses including diabetes mellitus or sickle cell disease, encounters with animals or insects, and ingestion or inhalation of neurotoxic substances or chemicals.

Physical evaluation of infants: Includes assessment of:

- Level of alertness
- Size and shape of the head, including presence of fontanelles
- Sensory responses
- Motor function, including posture, tone, and muscle strength
- Motility, including symmetry of movements and involuntary movements
- Respirations, including signs of prolonged apnea, ataxic breathing, paradoxical chest movement, or hyperventilation
- Dysmorphic facial features
- Behavioral cues, including consolability and habituation
- Primitive and deep tendon reflexes

- Cranial nerves

Altered States of Consciousness

Consciousness implies awareness—the ability to respond to sensory stimuli and have subjective experiences. There are two components of consciousness: **alertness**, an arousal-waking state, including the ability to respond to stimuli, and **cognitive power**, including the ability to process stimuli and produce verbal and motor responses.

An altered state of consciousness usually refers to varying states of unconsciousness that may be momentary or may extend for hours, for days, or indefinitely. **Unconsciousness** is depressed cerebral function—the inability to respond to sensory stimuli and have subjective experiences. **Coma** is defined as a state of unconsciousness from which the patient cannot be aroused even with powerful stimuli.

Nursing Alert

Lack of response to painful stimuli is abnormal and must be reported immediately.

Levels of Consciousness

Assessment of LOC remains the earliest indicator of improvement or deterioration in neurologic status. LOC is determined by observations of the child's responses to the environment. When LOC is being assessed in young children, it is often useful to have a parent present to help elicit a desired response. An infant or child may not respond in an unfamiliar environment or to unfamiliar voices. Children older than 3 years of age should be able to give their name, although they may not be cognizant of place or time. Other diagnostic tests, such as motor activity, reflexes, and vital signs, are more variable and do not necessarily directly parallel the depth of the comatose state. The most consistently used terms are described in [Box 27-2](#).

Box 27-2

Levels of Consciousness

Full consciousness: Awake and alert, orientated to time, place, and person; behavior appropriate for age

Confusion: Impaired decision making

Disorientation: Confusion regarding time, place; decreased level of consciousness (LOC)

Lethargy: Limited spontaneous movement, sluggish speech, drowsy, drowsiness

Obtundation: Arousable with stimulation

Stupor: Remaining in a deep sleep, responsive only to vigorous and repeated stimulation

Coma: No motor or verbal response or extension posturing to noxious (painful) stimuli

Persistent vegetative state (PVS): Permanently lost function of the cerebral cortex; eyes follow objects only by reflex or when attracted to the direction of loud sounds; all four limbs are spastic but can withdraw from painful stimuli; hands show reflexive grasping and groping; the face can grimace, some food may be swallowed, and the child may groan or cry but utter no words

Modified from Seidel HM, Ball JW, Dains JE, et al, editors: *Mosby's guide to physical examination*, ed 6, St Louis, 2006, Mosby.

Coma Assessment

Diminished alertness as a result of pathologic conditions occurs on a continuum, which extends from somnolence at one end to deep coma at the other. Several scales have been devised in an

attempt to standardize the description and interpretation of the degree of depressed consciousness. The most popular of these is the **Glasgow Coma Scale (GCS)**, which consists of a three-part assessment: eye opening, verbal response, and motor response (Fig. 27-2). Numeric values of 1 through 5 are assigned to the levels of response in each category. The sum of these numeric values provides an objective measure of the patient's LOC. The lower the score, the deeper the coma. A person with an unaltered LOC would score the highest, 15; a score of 8 or below is generally accepted as a definition of coma; and the lowest score, 3, indicates deep coma or death. A decrease in the GCS score indicates a deterioration of the patient's condition. Brain death is the total cessation of brainstem and cortical brain function that results from any condition that causes irreversible widespread brain injury. The pronouncement of brain death requires two conditions: (1) complete cessation of clinical evidence of brain function (as evidenced by lack of activity on flow study) and (2) irreversibility of the condition. The Task Force for the Determination of Brain Death in Clinic has established guidelines for the determination of brain death in children. At least two different attending physicians should participate in the diagnosing of brain death in children (Nakagawa, Ashwel, Mathur, et al, 2011).

| NEUROLOGIC ASSESSMENT | | | |
|--|------------------------|------------------------------|--------------------------------|
| Pupils | Right | Size | |
| | | Reaction | |
| | Left | Size | |
| | | Reaction | |
| Eyes open | Spontaneously | 4 | |
| | To speech | 3 | |
| | To pain | 2 | |
| | None | 1 | |
| Best motor response | Obeys commands | 6 | |
| | Localizes pain | 5 | |
| | Flexion withdrawal | 4 | |
| | Flexion abnormal | 3 | |
| | Extension | 2 | |
| | None | 1 | |
| Best response to auditory and/or visual stimulus | ≥ 2 years | | < 2 years |

Pupil scale (mm)

FIG 27-2 Pediatric coma scale. LOC, Level of consciousness.

Neurologic Examination

The purpose of the neurologic examination is to establish an accurate, objective baseline of neurologic function. It is essential that the neurologic examination be documented in a descriptive and detailed fashion, thereby enhancing the ability to detect subtle changes in neurologic status over time. Descriptions of behaviors should be simple, objective, and easily interpreted—for example: “Drowsy but awake and conversationally rational/oriented”; “Sleepy but arousable with vigorous physical stimuli; pressure to nail base of right hand results in upper extremity flexion/lower extremity extension.”

Vital Signs

Pulse, respiration, and blood pressure provide information regarding the adequacy of circulation and the possible underlying cause of altered consciousness. Autonomic activity is most intensively disturbed in cases of deep coma or brainstem lesions.

Body temperature is often elevated, and sometimes the elevation may be extreme. High temperature is most frequently a sign of an acute infectious process or heat stroke but may also be caused by ingestion of some drugs (especially salicylates, alcohol, and barbiturates) or by intracranial bleeding, especially subarachnoid hemorrhage. Hypothalamic involvement may cause elevated or decreased temperature. Serious infection may produce hypothermia.

The pulse is variable and may be rapid, slow and bounding, or feeble. Blood pressure may be normal, elevated, or very low. The Cushing reflex, or pressor response, causes a slowing of the pulse and an increase in blood pressure and is uncommon in children; when it occurs, it is a very late sign of increased ICP. Medications may also affect the vital signs. For assessment purposes, actual changes in pulse and blood pressure are more important than the direction of the change.

Respirations are often slow, deep, and irregular. Slow, deep breathing is often seen in heavy sleep caused by sedatives, after seizures, or in cerebral infections. Slow, shallow breathing may result from sedatives or opioids. Hyperventilation (deep and rapid respirations) is usually a result of metabolic acidosis or abnormal stimulation of the respiratory center in the medulla caused by salicylate poisoning, hepatic coma, or Reye syndrome (RS).

Breathing patterns have been described with a number of terms (e.g., apneustic, cluster, ataxic, Cheyne-Stokes). However, it is better to describe what is being observed rather than to place a label on it, because the terms are often used and interpreted incorrectly. Periodic or irregular breathing is an ominous sign of brainstem (especially medullary) dysfunction that often precedes complete apnea. The odor of the breath may provide additional clues (e.g., the fruity, acetone odor of ketosis; the foul odor of uremia; the fetid odor of hepatic failure; or the odor of alcohol).

Skin

The skin may offer clues to the cause of unconsciousness. The body surface should be examined for signs of injury, needle marks, petechiae, bites, and ticks. Evidence of toxic substances may be found on the hands, face, mouth, and clothing, especially in small children. In addition, the skin can provide clues of the child's condition. The skin should be evaluated for color (such as pallor, cyanosis, erythema, or jaundice), temperature, and turgor.

Eyes

Assess pupil size and reactivity (Fig. 27-3; see also Fig. 27-2). Pupils either do or do not react to light. Pinpoint pupils are commonly observed in poisoning, such as opiate or barbiturate poisoning, or in brainstem dysfunction. Widely dilated and reactive pupils are often seen after seizures and may involve only one side. Widely dilated and fixed pupils suggest paralysis of cranial nerve (CN) III (oculomotor nerve) secondary to pressure from herniation of the brain through the tentorium. Bilateral fixed pupils usually imply brainstem damage if present for more than 5 minutes. Dilated and nonreactive pupils are also seen in hypothermia, anoxia, ischemia, poisoning with atropine-like substances, or prior instillation of mydriatic drugs.

Nursing Alert

The sudden appearance of a fixed and dilated pupil(s) is a neurologic emergency.

FIG 27-3 Variations in pupil size with altered states of consciousness. **A**, Ipsilateral pupillary constriction with slight ptosis. **B**, Bilateral small pupils. **C**, Midposition, light fixed to all stimuli. **D**, Bilateral dilated and fixed pupils. **E**, Dilated pupils, left eye abducted with ptosis. **F**, Pinpoint pupils.

The description of eye movements should indicate whether one or both eyes are involved and how the reaction was elicited. The parents should be asked about preexisting strabismus, which will cause the eyes to appear normal under compromise. Posttraumatic strabismus indicates CN VI damage.

Special tests, usually performed by qualified persons, include:

Doll's head maneuver: Elicited by rotating the child's head quickly to one side and then to the other. Conjugate (paired or working together) movement of the eyes in the direction opposite to the head rotation is normal. Absence of this response suggests dysfunction of the brainstem or oculomotor nerve (CN III).

Nursing Alert

Any tests that require head movement are not attempted until after cervical spine injury has been ruled out.

Caloric test, or oculovestibular response: Elicited with the child's head up (head of bed is elevated 30 degrees) by irrigating the external auditory canal with 10 ml of ice water for approximately 20 seconds, which normally causes conjugate movement of the eyes toward the side of stimulation. This response is lost when the pontine centers are impaired, thus providing important information in assessment of the comatose patient.

Nursing Alert

The ice water caloric test is painful and is never performed on a child who is awake or on an individual with a ruptured tympanic membrane.

Funduscopy examination: Reveals additional clues. Papilledema will not be evident early in the course of unconsciousness because if it develops, it will not be evident for 24 to 48 hours. Papilledema is characterized by optic disc swelling, indistinct optic disc margins, hemorrhage, tortuosity of vessels, and absence of venous pulsations. The presence of preretinal (subhyaloid) hemorrhages in children is almost invariably a result of acute trauma with intracranial bleeding, usually subarachnoid or subdural hemorrhage.

Motor Function

Observation of spontaneous activity, gait, and response to painful stimuli provides clues to the location and extent of cerebral dysfunction. Asymmetric movements of the limbs or absence of movement suggests paralysis. In hemiplegia, the affected limb lies in external rotation and falls uncontrollably when lifted and allowed to drop. Observations should be described rather than labeled.

In the deeper comatose states, the child has little or no spontaneous movement, and the musculature tends to be flaccid. There is considerable variability in the motor behavior in lesser degrees of coma. For example, the child may be relatively immobile or restless and hyperkinetic; muscle tone may be increased or decreased. Tremors, twitching, and spasms of muscles are common observations. The patient may display purposeless movements. Combative or negativistic behavior is common. Hyperactivity is more common in acute febrile and toxic states than in cases of increased ICP. Seizures are common in children and may be present in coma as a result of any cause. Any repetitive or seizure movements are precisely described.

Posturing

Primitive postural reflexes emerge as cortical control over motor function is lost in brain dysfunction. These reflexes are evident in posturing and motor movements directly related to the area of the brain involved. Posturing reflects a balance between the lower exciting and the higher inhibiting influences and strong muscles overcoming weaker ones. **Decorticate** or flexion posturing (Fig. 27-4, A) occurs with severe dysfunction of the cerebral cortex or with lesions to corticospinal tracts above the brainstem. Typical posturing includes rigid flexion with the arms held tightly to the body; flexed elbows, wrists, and fingers; plantar flexed feet; legs extended and internally rotated; and possibly the presence of fine tremors or intense stiffness. **Decerebrate** posture or extension posturing (see Fig. 27-4, B) is a sign of dysfunction at the level of the midbrain or lesions to the brainstem. It is characterized by rigid extension and pronation of the arms and legs, flexed wrists and fingers, a clenched jaw, an extended neck, and possibly an arched back. Unilateral extension posture is often caused by tentorial herniation.

FIG 27-4 A, Decorticate. B, Decerebrate.

Posturing may not be evident when the child is quiet but can usually be elicited by applying painful stimuli, such as a blunt object pressed on the base of the nail. Nurses should avoid applying thumb pressure to the supraorbital region of the frontal bone (risk of orbital damage). Noxious stimuli (e.g., suctioning) will elicit a response, as may turning or touching. When the nurse is describing posturing, the stimulus needed to provoke the response is as important as the reaction.

Reflexes

Testing of some reflexes may be of limited value. In general, the corneal, pupillary, muscle-stretch,

superficial, and plantar reflexes tend to be absent in deep coma. The state of reflexes is variable in lighter grades of unconsciousness and depends on the underlying pathologic process and the location of the lesion. Absence of corneal reflexes and presence of a tonic neck reflex are associated with severe brain damage. The Babinski reflex, in which lateral portion of the foot is stroked, may be of value if it is found to be present consistently in children older than 1 year. A positive Babinski reflex is significant in assessment of pyramidal tract lesions when it is unilateral and associated with other pyramidal signs. A fluctuating Babinski reflex is often observed with seizures.

Nursing Alert

Three key reflexes that demonstrate neurologic health in young infants are the Moro, tonic neck, and withdrawal reflexes.

Special Diagnostic Procedures

Numerous diagnostic procedures are used for the assessment of cerebral function. Laboratory tests that may help determine the cause of unconsciousness include blood glucose, urea nitrogen, and electrolyte (pH, sodium, potassium, chloride, calcium, and bicarbonate) tests; clotting studies, a complete blood count; liver function tests; blood cultures if there is fever; and toxicology screen and blood lead levels if clinically indicated.

An electroencephalogram (EEG) may provide important information. For example, generalized random, slow activity suggests suppressed cortical function, and localized slow activity suggests a space-occupying issue. A flat tracing is one of the criteria used as evidence of brain death. Examination of spinal fluid is performed when toxic encephalopathy or infection is suspected. Lumbar puncture is ordinarily delayed if intracranial hemorrhage is suspected and is contraindicated in the presence of ICP because of the potential for brainstem herniation.

Auditory and visual evoked potentials are sometimes used in neurologic evaluation of very young children. Brainstem auditory evoked potentials are useful for evaluating the continuity of brainstem auditory tracts and are particularly useful for detecting demyelinating disease and neoplasms.

Highly sophisticated tests are carried out with specialized equipment. Two imaging techniques, computed tomography (CT) and magnetic resonance imaging (MRI), assist in diagnosis by scanning both soft tissues and solid matter. Most of these tests are outlined in [Table 27-1](#). Because such tests can be threatening to children, the nurse needs to prepare patients for the tests and provide support and reassurance during the tests (see [Preparation for Diagnostic and Therapeutic Procedures, Chapter 20](#)). Children who are old enough to understand require careful explanation of the procedure, reason for the procedure, what they will experience, and how they can help. School-age children usually appreciate a more detailed description of why contrast material is injected.

TABLE 27-1
Neurologic Diagnostic Procedures

| Test | Description | Purpose | Comments |
|----------------------------------|--|--|--|
| Lumbar puncture (LP) | Spinal needle is inserted between L3 and L4 or L4 and L5 vertebral spaces into subarachnoid space; CSF pressure is measured, and sample is collected for examination. | Measures spinal fluid pressure Obtains CSF for laboratory analysis Injection of medication | Contraindicated in patients with increased ICP or infected skin over puncture site. |
| Subdural tap | Needle is inserted into anterior fontanel or coronal suture (midline to pupil). | Helps rule out subdural effusions Removes CSF to relieve pressure | Place infant in semi-erect position after subdural tap to minimize leakage from site; prevent child from crying if possible. Check site frequently for evidence of leakage. |
| Ventricular puncture | Needle is inserted into lateral ventricle via coronal suture (midline to pupil). | Removes CSF to relieve pressure | Risk of intracerebral or ventricular hemorrhage. |
| Electroencephalogram (EEG) | EEG records changes in electrical potential of brain. Electrodes are placed at various points to assess electrical function in a particular area. Impulses are recorded by electromagnetic pen or digitally. | Detects spikes, or bursts of electrical activity that indicate the potential for seizures Used to determine brain death | Patient should remain quiet during procedure; may require sedation. Minimize external stimuli during procedure. |
| Nuclear brain scan | Radioisotope is injected intravenously then counted and recorded after fixed time intervals. Radioisotope accumulates in areas where blood-brain barrier is defective. | Identifies focal brain lesions (e.g., tumors, abscesses) Positive uptake of material with encephalitis and subdural hematoma Visualizes CSF pathways | Requires IV access; patient may require sedation. In normal children or noncommunicating hydrocephalus, no retrograde filling of ventricles occurs. Areas of concentrated uptake of material are termed <i>hot spots</i> . |
| Encephalography | Pulses of ultrasonic waves are beamed through head; echoes from reflecting surfaces are recorded graphically. | Identifies shifts in midline structures from their normal positions as a result of intracranial lesions May show ventricular dilation | Simple, safe, rapid procedure. |
| Real-time ultrasonography (RTUS) | Similar to CT but uses ultrasound instead of ionizing radiation. | Allows high-resolution anatomic visualization in variety of imaging planes | Produces images similar to CT scan. Especially useful in neonatal CNS problems. |

| | | | |
|--|--|--|--|
| Radiography | Skull films are taken from different views—lateral, posterolateral, axial (submento-vertical), half-axial. | Shows fractures, dislocations, spreading suture lines, craniosynostosis Shows degenerative changes, bone erosion, calcifications | Simple, noninvasive procedure. |
| Computed tomography (CT) scan | Pinpoint x-ray beam is directed on horizontal or vertical plane to provide series of images that are fed into computer and assembled in image displayed on video screen. CT uses ionizing radiation. | Visualizes horizontal and vertical cross section of brain in three planes (axial, coronal, sagittal) Distinguishes density of various intracranial tissues and structures—congenital abnormalities, hemorrhage, tumors, demyelinating and inflammatory processes, calcification | Requires IV access if contrast agent is used. Patient may require sedation. |
| Magnetic resonance imaging (MRI) | MRI produces radiofrequency emissions from elements (e.g., hydrogen, phosphorus), which are converted to visual images by computer. | Permits visualization of morphologic feature of target structures Permits tissue discrimination unavailable with many techniques | MRI is noninvasive procedure except when IV contrast agent is used. No exposure to radiation occurs. Patient may require sedation. Parent or attendant can remain in room with child. MRI does not visualize bone detail or calcifications. No metal can be present in scanner. |
| Positron emission tomography (PET) | PET involves IV injection of positron-emitting radionuclide; local concentrations are detected and transformed into visual display by computer. | Detects and measures blood volume and flow in brain, metabolic activity, and biochemical changes within tissue | Requires lengthy period of immobility. Minimum exposure to radiation occurs. Patient may require sedation. |
| Digital subtraction angiography (DSA) | Contrast dye is injected intravenously; computer “subtracts” all tissues without contrast medium, leaving clear image of contrast medium in vessels studied. | Visualizes vasculature of target tissue Visualizes finite vascular abnormalities | Safe alternative to angiography. Patient must remain still during procedure; may require sedation. |
| Single-photon emission computed tomography (SPECT) | Involves IV injection of photon-emitting radionuclide; radionuclides are absorbed by healthy tissue at different rate than by diseased or necrotic tissue; data are transferred to computer that converts image to film. | Provides information regarding blood flow to tissues; analyzing blood flow to organ may help determine how well it is functioning | Requires lengthy period of immobility. Minimum exposure to radiation occurs. Patient may require sedation. |

CNS, Central nervous system; CSF, cerebrospinal fluid; CT, computed tomography; ICP, intracranial pressure; IV, intravenous.

The importance of lying still for tests needs to be stressed. Children unfamiliar with the machines can be shown a picture beforehand. Although radiographic examinations are not painful, the machinery often appears so frightening that the child protests because of anxiety. This is especially true of CT and MRI, both of which require that the child's head be placed within a special immobilizing device. Chin and cheek pads are sometimes used to prevent the slightest head movement, and straps are applied to the body to prevent a slight change in body position. The nurse can explain these events to a frightened child by comparing them to an astronaut's preparation for a space flight. It is important to emphasize to the child that at no time is the procedure painful.

The nurse should not expect cooperation from a young child. Sedation may be required. If so, children should be helped through the preparation and administration and assured that someone will remain with them (if possible). Many different agents are currently used for sedation of children undergoing neurologic diagnostic procedures. Chloral hydrate or benzodiazepines have been used for decades as short-term sedative agents and remain safe methods of pediatric sedation (Arlachov and Ganatra, 2012). Other sedative agents have been used safely, alone and in combination, for children and include intravenous (IV) sodium pentobarbital (Nembutal), IV fentanyl (Sublimaze), IV midazolam (Versed), and intranasal midazolam (Arlachov and Ganatra, 2012). Propofol is a good sedating agent for diagnostic procedures because of its short induction and recovery time, but the medication can cause respiratory depression and apnea with little warning and should be administered only by trained personnel, such as anesthesiologists (Arlachov and Ganatra, 2012). (See *Pain Management, Chapter 5*.)

Children need continual support and reinforcement during procedures in which they remain conscious. Vital signs and physiologic responses to the procedure are monitored throughout. The nurse should review written instructions with parents if the child is discharged after a procedure. Children who have undergone a procedure with a general anesthetic require post anesthesia care, including positioning, to prevent aspiration of secretions and frequent assessment of the vital signs and LOC. In addition, other neurologic functions such as pupillary responses, motor strength, and movement are tested at regular intervals. Any surgical wound resulting from the test is checked for bleeding, CSF leakage, and other complications. Children who undergo repeated subdural taps should have their hematocrit monitored to detect excessive blood loss from the procedure.

The Child with Cerebral Compromise

Nursing Care of the Unconscious Child

The unconscious child requires nursing attention, with observation, recording, and evaluation of changes in objective signs. These observations provide valuable information regarding the patient's progress and often serve as a guide to diagnosis and treatment. Therefore, careful and detailed observations are essential for the child's welfare. In addition, vital functions must be maintained and complications prevented through conscientious and meticulous nursing care. The outcome of unconsciousness is variable and ranges from early and complete recovery, to death within a few hours or days, or persistent and permanent unconsciousness, or recovery with varying degrees of residual mental or physical disability. The outcome and recovery of the unconscious child may depend on the level of nursing care and observational skills.

Direct emergency measures toward ensuring a patent circulation, airway, and breathing (CAB); stabilizing the spine when indicated; treating shock; and reducing ICP (if present). Delayed treatment often leads to increased damage. As soon as emergency measures have been implemented—and in many cases concurrently—therapies for specific causes are begun. Because nursing care is closely related to medical management, both are considered here.

Continual observation of LOC, pupillary reaction, and vital signs is essential to manage CNS disorders. Regular assessment of neurologic status is an integral part of nursing care of unconscious children. The assessment frequency depends on the cause of unconsciousness, the LOC, and the progression of cerebral involvement. Intervals between observations may be as short as every 15 minutes or as long as every 2 hours. Significant alterations must be reported immediately.

Vital signs provide important information about the status of the unconscious child. The temperature is taken every 2 to 4 hours, depending on the patient's condition. Fevers can indicate an infective process, heat stroke, or hypothalamic regulatory abnormalities (Sharma, Kochar, Sankhyan, et al, 2010). Tachycardia is common with fevers, hypovolemic shock, or heart failure, whereas increased ICP or myocardial injury can cause bradycardia (Sharma, Kochar, Sankhyan, et al, 2010). Tachypnea is associated with lung pathology but quiet tachypnea indicates acidosis that can be associated with diabetic ketoacidosis or some poisonings (Sharma, Kochar, Sankhyan, et al, 2010). The LOC is assessed periodically and includes evaluating pupillary size, equality, and reaction to light. Signs of meningeal irritation such as nuchal rigidity are assessed. Assessment of LOC includes response to vocal commands, spontaneous behavior, resistance to care, and response to painful stimuli. Note any abnormal movement, changes in muscle tone or strength, and body position. Seizure activity is described according to the duration and body areas involved.

Pain management for the unconscious child requires astute nursing observation and management. Signs of pain include changes in behavior (e.g., increased agitation or rigidity); and alterations in vital signs (e.g., increased heart rate, respiratory rate, and blood pressure, and decreased oxygen saturation). Because these findings may not be specific for pain, the nurse should observe for their appearance during times of induced or suspected pain and their disappearance after the inciting procedure or the administration of analgesia. A pain assessment record is used to document indications of pain and the effectiveness of interventions (see [Pain Assessment, Chapter 5](#)).

The use of opioids, such as morphine, to relieve pain is controversial because they may mask signs of altered consciousness or depress respirations. However, unrelieved pain activates the stress response, which can elevate ICP. To block the stress response, some authorities advocate the use of analgesics, sedatives, and, in some cases such as head injury, paralyzing agents via continuous IV infusion. A commonly used combination is fentanyl, midazolam, and vecuronium (Norcuron). If there are concerns about assessing the LOC or respiratory depression, naloxone (Narcan) can be used to reverse the opioid effects. Regardless of which drugs are used, adequate dosage and regular administration are essential to provide optimal pain relief (see [Pain Management, Chapter 5](#)).

Other measures to relieve discomfort include providing a quiet, dimly lit environment; limiting visitors; preventing any sudden, jarring movement, such as banging into the bed; and preventing an increase in ICP. The latter is most effectively achieved by proper positioning and prevention of straining, such as during coughing, vomiting, and defecating. Antiepileptic drugs may be ordered for control of seizure activity.

Drug Alert

When opioids are used, bowel elimination must be closely monitored because of the potential constipating effect. A stool softener should be given regularly with laxatives as needed to prevent constipation.

Respiratory Management

Respiratory effectiveness is the primary concern in the care of the unconscious child, and establishment of an adequate airway is *always* the first priority. Carbon dioxide has a potent vasodilating effect and will increase cerebral blood flow (CBF) and ICP. Cerebral hypoxia at normal body temperature that lasts longer than 4 minutes nearly always causes irreversible brain damage.

Nursing Alert

Respiratory obstruction and subsequent compromise leads to cardiac arrest. Always maintain an adequate, patent airway.

Children in lighter states of coma may be able to cough and swallow, but those in deeper states of coma are unable to manage secretions, which tend to pool in the throat and pharynx. Dysfunction of CN IX and CN X (glossopharyngeal and vagus nerves) places the child at risk for aspiration and cardiac arrest. Therefore, position the child with the head and body to the side to prevent aspiration of secretions, and empty the stomach to reduce the likelihood of vomiting. In infants, blockage of air passages from secretions can happen in seconds. In addition, upper airway obstruction from laryngospasm is a frequent complication in comatose children.

An oral airway can be used for the child who is suffering a temporary loss of consciousness, such as after a contusion, seizure, or anesthesia. For children who remain unconscious for a longer time, a nasotracheal or orotracheal tube is inserted to maintain the open airway and facilitate removal of secretions. A tracheostomy is performed in cases in which laryngoscopy for introduction of an endotracheal tube would be difficult or dangerous or for a child who needs long-term ventilatory support. Suctioning is used only as needed to clear the airway, exerting care to prevent increasing ICP. Respiratory status is observed and evaluated regularly. Signs of respiratory distress may indicate a need for ventilatory assistance.

When the respiratory center is involved, mechanical ventilation is usually indicated (see [Chapter 20](#)). Blood gas analysis is performed regularly, and oxygen is administered when indicated. Moderately severe hypoxia and respiratory acidosis are often present but not always evident from clinical manifestations. Hypoventilation frequently accompanies unconsciousness and may lead to respiratory alkalosis, or it may represent the body's attempt to compensate for metabolic acidosis. Therefore, blood gas and pH determinations are essential guides for electrolyte therapy. Chest physiotherapy is carried out on a regular basis, and the child's position is changed at least every 2 hours to prevent pulmonary complications.

Intracranial Pressure Monitoring

Management of the child with increased ICP is a complex and important task. ICP monitoring is used to guide therapy to reduce ICP and provides information on intracranial compliance, cerebrovascular status, and cerebral perfusion ([Sankhyan, Vykunta Raju, Sharma, et al, 2010](#)). Indications for inserting an ICP monitor are as follows ([Singhi and Tiwari, 2009](#)):

- GCS evaluation of ≤ 8
- GCS evaluation >8 with respiratory assistance
- Deterioration of condition
- Subjective judgment regarding clinical appearance and response

Four major types of ICP monitors are:

1. Intraventricular catheter with fibroscopic sensors attached to a monitoring system
2. Subarachnoid bolt (Richmond screw)

3. Epidural sensor
4. Anterior fontanel pressure monitor

Direct ventricular pressure measurement remains the standard of ICP monitoring (Walker, Stone, Jacobson, et al, 2012). The catheter method involves introduction of a catheter into the lateral ventricle on the nondominant side, if known, or placement in the subdural space. The catheter has the advantage of providing a means of extraventricular (or continuous) drainage of CSF to reduce pressure. A drainage bag attached to the system is kept at the level of the ventricles and can be lowered to decrease ICP (see [Critical Thinking Case Study box](#)). This device requires full penetration of the brain, requires skill and experience with placement, and carries the risk of infection.

Critical Thinking Case Study

Hydrocephalus

Three-year-old Emma had a posterior fossa tumor removed 5 days ago. Although an EVD was placed to treat her hydrocephalus, she continues to demonstrate signs of increased ICP, including holding the back of her head, anorexia, crying when moved or when strangers enter the room, and intermittent lethargy. On examination, fluid drainage is noted on the mother's clothes, and Emma is experiencing repetitive, rapid eyelid blinking.

Questions

1. Evidence: Is there sufficient evidence to draw conclusions about Emma's behavior, physical assessment findings, and ICP?
2. Assumptions: Describe any underlying assumption about each of the following:
 - a. A preschool-age child who had a posterior fossa tumor removed 5 days ago
 - b. A preschool-age child who has an EVD placed to treat the hydrocephalus
 - c. A preschool-age child with an EVD who continues to demonstrate physical signs associated with increased ICP after recent surgery
3. What priorities for nursing care should be established?
4. Does the evidence support your nursing intervention?

EVD, External ventricular drain; *ICP*, intracranial pressure.

With the bolt method, the end of the bolt is placed into the subarachnoid space. The bolt cannot be adequately secured in a small child's pliant skull, although special modifications have been developed for children younger than 6 years old. The placement of the bolt is not adjusted by anyone except the neurosurgeon who placed the device.

Nursing Alert

If the external ventricular drain is unclamped for CSF drainage, carefully monitor the level of the collection container. If the container is too low, improper CSF decompression could lower ICP too rapidly, causing bleeding and pain.

Nursing Alert

With the bolt method, the bolt is stabilized with dressings, and these are not changed or disturbed, even to check the site.

An epidural sensor can be placed between the dura and the skull through a burr hole and connected to a stopcock assembly and transducer, which provides a readout of the pressure. Although less invasive, ICP measurements may be inconsistent. In infants, a fontanel transducer can be used to detect impulses from a pressure sensor and convert them to electrical energy. The electrical energy is then converted to visible waves or numeric readings on an oscilloscope. ICP measurement from the anterior fontanel is noninvasive but may prove to be inaccurate if the equipment is poorly placed or inconsistently recalibrated.

ICP can be increased by direct instillation of solutions; therefore, antibiotics are administered systemically if a positive CSF culture is obtained. However, ICP monitoring rarely causes infection. CSF is a body fluid; therefore, standard precautions are implemented according to hospital policy (see [Chapter 20](#)).

Nurses caring for patients with intracranial monitoring devices must be acquainted with the system, assist with insertion, interpret the monitor readings, and be able to distinguish between danger signals and mechanical dysfunction. Because systematic blood pressure, ICP, and therefore cerebral perfusion pressure (CPP) are normally lower in children, the child's age must be taken into account when deciding what constitutes abnormally high ICP or abnormally low CPP.

Several medical measures are available to treat increased ICP resulting from cerebral edema. These include sedation, CSF drainage, and osmotic diuretics. Osmotic diuretics may provide rapid relief of increased ICP in emergency situations. Although their effect is transient, lasting only about 6 hours, they can be lifesaving in emergencies. These substances are rapidly excreted by the kidneys and carry with them large quantities of sodium and water. Mannitol (or sometimes urea) administered intravenously is the drug most frequently used for rapid reduction of ICP. The infusion is generally given slowly but may be pushed rapidly in cases of herniation or impending herniation. Adrenocorticosteroids are not recommended for cerebral edema secondary to head trauma. Arterial carbon dioxide (PaCO_2) should be maintained at approximately 30 mm Hg to produce vasoconstriction, which reduces CBF, thereby decreasing ICP.

Nursing Activities

In cases of high levels of increased ICP, procedures tend to trigger reactive pressure waves in many patients. For example, increased intrathoracic or abdominal pressure is transmitted to the cranium. Particular care should be taken in positioning these patients to avoid neck vein compression, which may further increase ICP by interfering with venous return.

Nursing Alert

The head of the bed is elevated 15 to 30 degrees, and position the child so that the head is maintained in midline to facilitate venous drainage and avoid jugular compression. Turning side to side is contraindicated because of the risk of jugular compression.

It is important to avoid activities that may increase ICP by causing pain or emotional stress. Clustering nursing activities together and minimizing environmental stimuli by decreasing noxious procedures help to control ICP. Range-of-motion exercises can be carried out gently but should not be performed vigorously. Nontherapeutic touch can cause an increase in ICP. Any disturbing procedures to be performed should be scheduled to take advantage of therapies that reduce ICP, such as osmotherapy and sedation. Make efforts to minimize or eliminate environmental noise. Assessment and intervention to relieve pain are important nursing functions to decrease ICP.

Suctioning and percussion are poorly tolerated; therefore, these procedures are contraindicated unless concurrent respiratory problems exist. Hypoxia and the Valsalva maneuver associated with cough acutely elevate ICP. Vibration, which does not increase ICP, accomplishes excellent results and should be tried first if treatment is needed. If suctioning is necessary, it should be used judiciously and preceded by hyperventilation with 100% oxygen, which can be monitored during suctioning with a pulse oxygen sensor reading to determine oxygen saturation.

Nutrition and Hydration

In the unconscious child, fluids and calories are supplied initially by the IV route (see [Chapter 20](#)). An IV infusion is started early, and the type of fluid administered is determined by the patient's general condition. Fluid therapy requires careful monitoring and adjustment based on neurologic signs and electrolyte determinations. The goal of fluid therapy is euvolemia. Often, unconscious children cannot tolerate the same amounts of fluid as when they are healthy. Over-hydration must be avoided to prevent fatal cerebral edema. When cerebral edema is a threat, fluids may be restricted to reduce the chance of fluid overload. Examine skin and mucous membranes for signs of dehydration. Adjustments to fluid administration are based on urinary output, serum electrolytes and osmolarity, blood pressure, and arterial filling pressure. Observation for signs of altered fluid balance related to abnormal pituitary secretions is a part of nursing care.

Provide long-term nutrition with a balanced formula given by nasogastric or gastrostomy tube. Most children have continuous feedings, but if bolus feedings are used, the tube is rinsed with water after each feeding. Avoid overfeeding to prevent vomiting and the risk of aspiration. Stomach contents are aspirated with a syringe and measured before feeding to ascertain the amount remaining in the stomach. If the residual volume is excessive (depending on the child's size), consult the dietitian and the physician.

Altered Pituitary Secretion

An altered ability to handle fluid loads is attributed in part to the syndrome of inappropriate antidiuretic hormone secretion (SIADH) and diabetes insipidus (DI) resulting from hypothalamic dysfunction (see [Chapter 28](#)). SIADH frequently accompanies CNS diseases, such as head injury, meningitis, encephalitis, brain abscess, brain tumor, and subarachnoid hemorrhage. In patients with SIADH, scant quantities of urine are excreted, electrolyte analysis reveals hyponatremia and hyposmolality, and manifestations of overhydration are evident. It is important to evaluate all parameters because the reduced urinary output might be erroneously interpreted as a sign of dehydration. The treatment of SIADH consists of fluid restriction until serum electrolytes and osmolality return to normal levels.

DI may occur after intracranial trauma. In DI, there is increased urinary volume and the accompanying danger of dehydration. Adequate replacement of fluids is essential, and observation of electrolyte balance is necessary to detect signs of hypernatremia and hyperosmolality. Exogenous vasopressin may be administered.

Medications

The cause of unconsciousness determines specific drug therapies. Children with infectious processes are given antibiotics appropriate to the disease and the infecting organism. Corticosteroids are prescribed for inflammatory conditions and edema. Cerebral edema is an indication for osmotic diuretics. Sedatives or antiepileptics are prescribed for seizure activity. Sedation in the combative child provides amnesic and anxiolytic properties in conjunction with a paralytic agent. The combination decreases ICP and allows treatment of cerebral edema. Usual drugs include morphine and midazolam. Midazolam is attractive because of its short half-life.

Deep coma induced by administration of barbiturates is controversial in the management of ICP. Barbiturates are currently reserved for the reduction of increased ICP when all else has failed. Barbiturates decrease the cerebral metabolic rate for oxygen and protect the brain during times of reduced CPP. Barbiturate coma requires extensive monitoring, cardiovascular and respiratory support, and ICP monitoring to assess response to therapy. Paralyzing agents such as vecuronium may be needed to aid in performing diagnostic tests, improving effectiveness of therapy, and reducing risks of secondary complications. Elevation of ICP or heart rate of patients who are being given paralyzing agents or are under sedation may indicate the need for another dose of either or both medications.

Thermoregulation

Hyperthermia often accompanies cerebral dysfunction; if it is present, measures are implemented to reduce the temperature to prevent brain damage and to reduce metabolic demands generated by the increased body temperature. Antipyretic agents are the method of choice for fever reduction; cooling devices should be used for hyperthermia. Laboratory tests and other methods are used in

an attempt to determine the cause of the hyperthermia.

Elimination

A urinary catheter is usually inserted in the acute phase, but diapers may be used and weighed to record urinary output. The child who formerly had bowel and bladder control is generally incontinent. If the child remains unconscious for a long period, the indwelling catheter may be removed, and periodic bladder emptying can be accomplished by intermittent catheterization. Stool softeners are usually sufficient to maintain bowel function, but suppositories or enemas may be needed occasionally for adequate elimination and to prevent fecal impaction. The passage of liquid stool after a period of no bowel activity is usually a sign of an impaction. To avoid this preventable problem, daily recording of bowel activity is essential.

Hygienic Care

Routine measures for cleansing and maintaining skin integrity are an integral part of nursing care of the unconscious child. Unconscious children undergo numerous invasive procedures, and the skin sites used for these procedures require special assessment and intervention to promote healing and prevent infection. Skinfolds also require special attention to prevent excoriation.

Mouth care is performed at least twice daily because the mouth tends to become dry or coated with mucus. The teeth are carefully brushed with a soft toothbrush or cleaned with gauze saturated with saline. Commercially prepared cleansing devices, such as Toothettes, are convenient for cleansing the mouth and teeth. Lips are coated with ointment to protect them from drying, cracking, or blistering.

Unconscious children are prone to eye irritation. The corneal reflexes are absent; therefore, the eyes are easily irritated or damaged by linen, dust, or other substances that may come in contact with them. Excessive dryness results from incomplete closure of the lids or decreased secretions, especially if the child is undergoing osmotherapy to reduce or prevent cerebral edema.

Nursing Alert

The eyes are examined regularly and carefully for early signs of irritation or inflammation. Artificial tears are placed in the eyes every 1 to 2 hours. Eye patches may be necessary to protect the eyes from possible damage.

Positioning and Exercise

The unconscious child is positioned to minimize ICP and to prevent aspiration of saliva, nasogastric secretions, and vomitus. The head of the bed is elevated, and the child is placed in a side-lying or semiprone position. A small, firm pillow is placed under the head, and the uppermost limbs are flexed and supported with pillows. The weight of the body should not rest on the dependent arm. In the semiprone position, the child lies with the dependent arm at the side behind the body, the opposite side supported on pillows, and the uppermost arm and leg flexed and resting on the pillows. This position prevents undue pressure on the dependent extremities. The dependent position of the face encourages drainage of secretions and prevents the flaccid tongue from obstructing the airway.

Immobilization in the unconscious child causes effects on the muscular, skeletal, and integumentary system. See [Chapter 29](#) and [Table 29-1](#) for physical effects of immobilization. Normal range-of-motion exercises help maintain function, minimize contractures of joints, and prevent skin breakdown. Perform exercises gently to minimize increasing ICP. Place a small rolled pad in the palms to help maintain proper position of fingers. Footboards or high-top shoes can help prevent foot drop; and in some cases splinting is needed to prevent severe contractures of the wrist, knee, or ankle in children.

Stimulation

Sensory stimulation is important in the care of the unconscious child. For a temporarily unconscious or semiconscious child, sensory stimulation helps arouse the child to the conscious state and orient the child to time and place. Auditory and tactile stimulation are especially valuable. Tactile stimulation is not appropriate for a child in whom it may elicit an undesirable response.

However, for other children, tactile contact often has a relaxing and calming effect. When the child's condition permits, holding or rocking has a soothing effect and provides the body contact needed by young children.

The auditory sense is often intact in a state of coma. Hearing is the last sense to be lost and the first one to be regained; therefore, speak to the child as any other child. Conversation around the child should not include thoughtless or derogatory remarks. Soft music is often used to provide auditory stimulation. Singing the child's favorite songs or reading a favorite story is a strategy used to maintain the child's contact with a familiar world. Playing songs or favorite stories recorded in the parents' voices can provide a continuous source of familiar stimulation.

Regaining Consciousness

Awakening from a coma is a gradual process; however, sometimes children regain consciousness within a short time. Regaining orientation involves knowing person, place, and time in that order.

Certain behaviors have been observed when children awaken from the unconscious state. The stress and anxiety they appear to feel in a strange and unfamiliar environment can be expressed in silent, withdrawn behavior. Children respond to basic questioning but usually do not display their pre-hospitalization personality and social behavior until they are transferred from the critical care area.

Family Support

Helping the parents of an unconscious child cope with the situation is especially difficult. They may demonstrate all of the guilt, fear, hostility, and anxiety of any parent of a seriously ill child (see [Chapter 17](#)). In addition, these parents face the uncertain outcome of the cerebral dysfunction. The fear of death, cognitive impairment, or permanent physical disability is present. Nursing intervention with parents depends on the nature of the pathologic condition, the parents' personality, and the parent-child relationship before the injury or illness.

Probably the most difficult situations are those that involve children who never regain consciousness. Unlike losing a child through death, these situations lack finality, which often leaves the parents in a state of suspended grief. An awareness of these behaviors and coping mechanisms provides nurses with the understanding that helps them support the parents in their grief process.

Superimposed on the process of grieving for the "lost" child, parents may be faced with difficult decisions. When the child's brain is so severely damaged that vital functions must be maintained by artificial means, the parents must make the final decision of whether to remove life-support systems. Nurses continue to provide specialty care during this time that maintains the patient's physiological status while addressing informational and psychological needs of the family. This decision is difficult for parents, but having an open and honest dialog about the child's medical condition and prognosis can help make patient-centered conclusions ([de Vos, Box, Plötz, et al, 2015](#)). Parents' cultural, religious, and language needs along with their intellectual level, decision-making preferences, and emotional state are considered during the discussions ([Allen, 2014](#)). Sometimes parents may choose to refuse or not initiate treatment if they believe it to be best for the child and the family (informed dissent). At other times, parents request that "everything possible" be done for the child.

When the child has survived the cerebral insult but physical or mental capacity is limited (either minimally or severely), families must cope with and make decisions about the rehabilitation process and uncertain outcome. The family may need to make decisions whether to place their child in a chronic care facility or to care for their child at home. The drain on financial, emotional, and social resources can be enormous. For parents who choose to care for their child at home, planning begins early in the recovery process. The family should become involved with the child's care as soon as they indicate an interest and ability to do so. They need education and support in learning to care for the child, regular follow-up observation and assessment of the home management, and planning for respite care. Parents need to understand that it is important to plan for periodic relief from the continuous care of the child (see [Family-Centered Care, Chapter 19](#)).

Cerebral Trauma

Head Injury

Head injury is a pathologic process involving the scalp, skull, meninges, or brain as a result of mechanical force. According to the [Centers for Disease Control and Prevention \(2012\)](#) and [Safe Kids Worldwide](#),* unintentional injuries are the number one health risk for children and the leading cause of death in children 1 to 19 years old. Tragically, 12,175 children ages 0 to 19 years old are killed every year by unintentional injuries ([Centers for Disease Control and Prevention, 2012](#)). It has been estimated that each year, approximately 511,000 children ages 0 to 14 years sustain a traumatic brain injury, 35,000 children are hospitalized, and 2174 children die as a result of the brain injury ([Faul, Xu, Wald, et al, 2010](#)).

Etiology

The three major causes of brain damage in childhood, in order of importance, are (1) falls, (2) motor vehicle injuries, and (3) bicycle injuries. Neurologic injury accounts for the highest mortality rate, with boys affected twice as often as girls. Falls are the major source of all head injuries in children between 0 to 14 years old ([Faul, Xu, Wald, et al, 2010](#)). In motor vehicle accidents, children younger than 2 years old are almost exclusively injured as passengers, but older children may also be injured as pedestrians or cyclists. The majority of deaths from brain trauma caused by bicycle injuries occur between 5 and 19 years old. Bicycle helmet laws have been effective in reducing the risk of head injury by 85% and brain injury by 88% ([Rivara and Grossman, 2016](#)).

Many of the physical characteristics of children predispose them to craniocerebral trauma. For example, infants can be left unattended on beds, in high chairs, and in other places from which they can fall. Because the head of an infant or toddler is proportionately larger and heavier in relation to other body parts, it is the most likely to be injured. Incomplete motor development contributes to falls at young ages, and the natural curiosity and exuberance of children also increase their risk of injury.

Pathophysiology

The pathology of brain injury is directly related to the force of impact. Intracranial contents (brain, blood, CSF) are damaged because the force is too great to be absorbed by the skull and musculoligamentous support of the head. Although nervous tissue is delicate, it usually requires a severe blow to cause significant damage.

Primary head injuries are those that occur at the time of trauma and include skull fracture, contusions, intracranial hematoma, and diffuse injury. Subsequent complications include hypoxic brain damage, increased ICP, infection, and cerebral edema. The predominant feature of a child's brain injury is the amount of diffuse swelling that occurs. Hypoxia and hypercapnia threaten the energy requirements of the brain and increase CBF. The added volume across the blood-brain barrier, along with the loss of autoregulation, exacerbates cerebral edema. Pressure inside the skull that is greater than arterial pressure results in inadequate perfusion.

A child's response to head injury is different from that of an adult. The larger head size and insufficient musculoskeletal support render the very young child particularly vulnerable to head injuries. Physical forces act on the head through acceleration, deceleration, or deformation. Acceleration or deceleration is responsible for most head injuries. When the stationary head receives a blow, the sudden acceleration causes deformation of the skull and mass movement of the brain. Continued movement of the intracranial contents allows the brain to strike parts of the skull (e.g., the sharp edges of the sphenoid or the irregular surface of the anterior fossa) or the edges of the tentorium. Sudden deceleration, such as takes place in a fall, causes the greatest cerebral injury at the point of impact.

Although the brain volume remains unchanged, significant distortion takes place as the brain changes shape in response to the force of impact to the skull. This deformation can cause bruising at the point of impact (**coup**) or at a distance as the brain collides with the unyielding surfaces far removed from the point of impact (**contrecoup**) ([Fig. 27-5](#)). Thus, a blow to the occipital region can cause severe injury to the frontal and temporal areas of the brain. Children with an acceleration/deceleration injury demonstrate diffuse generalized cerebral swelling produced by

increased blood volume or a redistribution of cerebral blood volume (cerebral hyperemia) rather than by increased water content (edema).

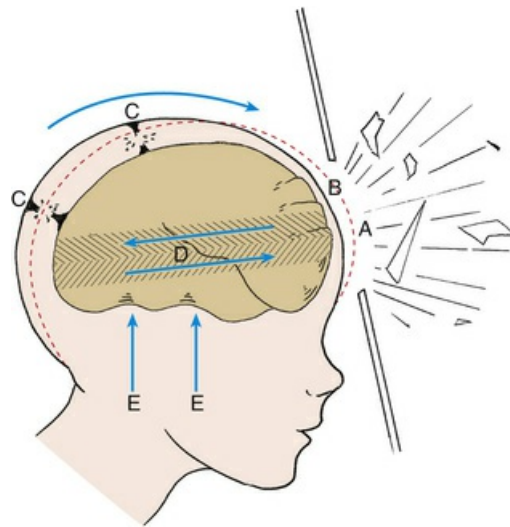

FIG 27-5 Mechanical distortion of the cranium during a closed head injury. *A*, Preinjury contour of the skull. *B*, Immediate post-injury contour of the skull. *C*, Torn subdural vessels. *D*, Shearing forces. *E*, Trauma from contact with the floor of the cranium. (Redrawn from Grubb RL, Coxe WS: Central nervous system trauma: cranial. In Eliasson SG, Presky AL, Hardin Jr WB, editors: *Neurological pathophysiology*, New York, 1974, Oxford University Press.)

Another effect of brain movement is shearing stresses, which are caused by unequal movement or different rates of acceleration at various levels of the brain. A shearing force may tear small arteries and cause subdural hemorrhages. Maximum stress from the shearing force occurs at the interface between the structures of different density so that the gray matter (cell body) rapidly accelerates, while the white matter (axons) tends to lag behind. Although shearing forces are maximum at the cerebral surface and extend toward the center of rotation within the brain, the most serious effects are often in the area of the brainstem. Damage can also occur when severe compression of the skull causes the brain to be forced through the tentorial opening. This can produce irreparable damage to the brainstem (Fig. 27-6).

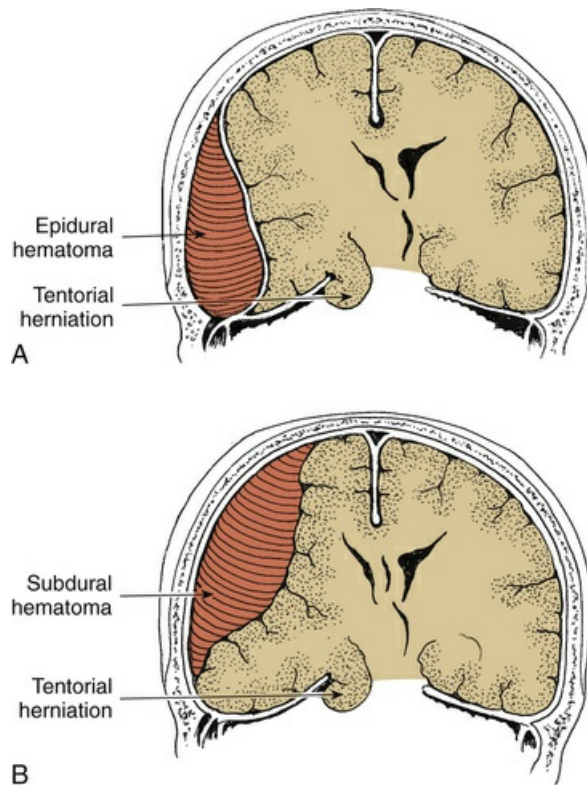

FIG 27-6 A, Epidural (extradural) hematoma and compression of temporal lobe through tentorial hiatus. B, Subdural hematoma.

Concussion

The most common head injury is **concussion**, a transient disturbance of brain function often traumatically induced that involves a complex pathophysiologic process (Liebig and Congeni, 2016). The hallmarks of a concussion are confusion and amnesia. The belief that loss of consciousness is the hallmark of concussion is a common misconception. A recent study among 182 adolescent athletes who sustain a concussion found that only 22% lost consciousness, while 34% experienced amnesia (Meehan, Mannix, Stracciolini, et al, 2013). Concussions usually resolve in 1 to 3 weeks without complications, but the child should rest until symptoms resolve, then resume activities gradually (Liebig and Congeni, 2016).

The pathogenesis of concussion is still unclear but may be a result of shearing forces that cause stretching, compression, and tearing of nerve fibers, particularly in the area of the central brainstem, which is the seat of the reticular activating system. It has also been suggested that the anatomic alterations of nerve fibers cause the release of large quantities of acetylcholine into the CSF and a reduction in oxygen consumption with increased lactate production.

Contusion and Laceration

The terms **contusion** and **laceration** are used to describe visible bruising and tearing of cerebral tissue. Contusions represent petechial hemorrhages or localized bruising along the superficial aspects of the brain at the site of impact (coup injury) or a lesion remote from the site of direct trauma (contrecoup injury). In serious accidents, there may be multiple sites of injury.

The major areas of the brain susceptible to contusion or laceration are the occipital, frontal, and temporal lobes. In addition, the irregular surfaces of the anterior and middle fossae at the base of the skull are capable of producing bruises or lacerations on forceful impact. Contusions may cause focal disturbances in strength, sensation, or visual awareness. The degree of brain damage in the contused areas varies according to the extent of vascular injury. Signs vary from mild, transient weakness of a limb to prolonged unconsciousness and paralysis. However, the signs and symptoms may be clinically indistinguishable from those of concussion.

Infants who are roughly shaken (referred to as *shaken baby syndrome* or *abusive head trauma*) can sustain profound neurologic impairment, seizures, retinal hemorrhages (usually bilateral), and

intracranial subarachnoid or subdural hemorrhages (Sieswerda-Hoogendoorn, Boos, Spivack, et al, 2012).

Cerebral lacerations are generally associated with penetrating or depressed skull fractures. However, they may occur without fracture in small children. When brain tissue is actually torn with bleeding into and around the tear, more severe and prolonged unconsciousness and paralysis usually occur, leaving permanent scarring and some degree of disability.

Fractures

Skull fractures result from a direct blow or injury to the skull and are often associated with intracranial injury. Falls are the most common cause of head injury. Many of the falls that resulted in a skull fracture in children younger than 2 years old involved short distances less than 3 feet, such as falls from a caregiver's arms (Ibrahim, Wood, Margulies, et al, 2012).

The types of skull fractures that occur are linear, depressed, comminuted, basilar, open, and growing fractures. As a rule, the faster the blow, the greater the likelihood of a depressed fracture; a low-velocity impact tends to produce a linear fracture.

Linear skull fractures are a single fracture line that starts at the point of maximum impact but does not cross suture lines. Linear skull fractures constitute the majority of childhood skull fractures and typically occur in the parietal bone. Most linear skull fractures are associated with an overlying scalp hematoma, particularly in infants younger than 1 year old and in the parietal or temporal region (Erlichman, Blumfield, Rajpathak, et al, 2010).

Depressed fractures are those in which the bone is locally broken, usually into several irregular fragments that are pushed inward. Depressed skull fractures may be associated with direct underlying parenchymal damage and should be suspected when a child's head appears misshapen. Surgery may be needed to elevate the depressed bone fragment if there is an associated intracranial hematoma and if the depression is greater than 1 cm (0.4 inch).

Comminuted fractures consist of multiple associated linear fractures. They usually result from intense impact. These types of fractures often result from repeated blows against an object or ejection from a car at a high rate of speed. They may suggest child abuse.

Basilar fractures involve the bones at the base of the skull in either the posterior or anterior region. The bones involved are the ethmoid, sphenoid, temporal, or occipital bones and usually result in a dural tear. Because of the proximity of the fracture line to structures surrounding the brainstem, a basal skull fracture is a serious head injury. Approximately 80% of the cases may include clinical features such as subcutaneous bleeding over the mastoid process (battle sign), bleeding around the orbit (raccoon eyes), bleeding behind the tympanic membrane (hemotympanum), or CSF leakage from the nose or ear (Perheentupa, Kinnunen, Grénman, et al, 2010).

Open fractures result in a communication between the skull and the scalp or the mucosa of the upper respiratory tract. The risk of CNS infection is increased with open fractures. Open fractures that involve the paranasal sinuses or middle ear may lead to CSF leakage. They may have a skin laceration overlying the bone fracture called a *compound fracture*. Antibiotics are recommended to prevent osteomyelitis.

Growing fractures result from a skull fracture with an underlying dura tear that fails to heal properly. The enlargement may be caused by a leptomeningeal cyst, dilated ventricles, or a herniated brain. The majority of growing skull fractures occur before the age of 3 years old (Liu, You, and Lu, 2012). Physical examination reveals a pulsatile mass or enlarging and sunken skull defect.

Complications

The major complications of trauma to the head are hemorrhage, infection, edema, and herniation through the brainstem. Infection is always a hazard in open injuries, and edema is related to tissue trauma. Vascular rupture may occur even in minor head injuries, causing hemorrhage between the skull and cerebral surfaces. Compression of the underlying brain produces effects that can be rapidly fatal or insidiously progressive.

Nursing Alert

Suspect posttraumatic meningitis in children with increasing drowsiness and fever who also have basilar skull fractures.

Epidural Hemorrhage

An epidural hemorrhage is a hemorrhage into the space between the dura and the skull. As the hematoma enlarges, the dura is stripped from the skull, forcing the underlying brain contents downward and inward as the brain expands (see [Fig. 27-6, A](#)). Because bleeding is generally arterial, brain compression occurs rapidly. Most often the expanding hematoma is located in the parietal and temporal regions ([Teichert, Rosales, Lopes, et al, 2012](#)). The lower incidence of epidural hematoma in childhood has been attributed to the fact that the middle meningeal artery is not embedded in the bone surface of the skull until approximately 2 years old. Therefore, a fracture of the temporal bone is less likely to lacerate the artery.

The classic clinical picture of epidural hemorrhage is a lucid interval (momentary unconsciousness followed by a normal period and then lethargy or coma) due to blood accumulation in the epidural space and compression of the brain (see [Box 27-3](#) for clinical manifestations). The period of impaired consciousness is frequently lacking, and common symptoms in a child with no neurologic deficit are irritability, headache, and vomiting. In infants younger than 1 year old the most common symptoms are irritability, pallor with anemia, and cephalhematoma. Infants may also have hypotonia, seizures, a bulging anterior fontanel, and lethargy. An epidural hematoma can be detected by a CT scan. If the severity of the child's signs and symptoms is not recognized, herniation and death will occur.

Box 27-3

Clinical Manifestations of Acute Head Injury

Minor Injury

May or may not lose consciousness

Transient period of confusion

Somnolence

Listlessness

Irritability

Pallor

Vomiting (one or more episodes)

Signs of Progression

Altered mental status (e.g., difficulty arousing child)

Mounting agitation

Development of focal lateral neurologic signs

Marked changes in vital signs

Severe Injury

Signs of increased ICP (see [Box 27-1](#))

Bulging fontanel (infant)

Retinal hemorrhages

Extraocular palsies (especially CN III)

Hemiparesis

Quadriplegia

Elevated temperature

Unsteady gait (older child)

Papilledema (older child)

Retinal hemorrhages

Associated Signs

Scalp trauma

Other injuries (e.g., to extremities)

CN, Cranial nerve; ICP, intracranial pressure.

Subdural Hemorrhage

A subdural hemorrhage is bleeding between the dura and the arachnoid membrane, usually as a result of rupture of cortical veins that bridge the subdural space and hemorrhage from the cortex of the brain (see [Fig. 27-6, B](#)). Subdural hematomas are more common than epidural hematomas, occurring most often in infancy, frequently as a result of birth trauma, falls, assaults, or violent shaking. Unlike epidural hemorrhage, which develops inwardly against the less resistant brain tissue, subdural hemorrhage tends to develop more slowly and spreads thinly and widely, crossing cranial sutures, until it is limited by the dural barriers—the falx and tentorium. The small subdural space and the dura, which is firmly attached to the skull in this area, are highly vulnerable to increased ICP.

Presenting signs include irritability, vomiting, increased head circumference, bulging anterior fontanels in infants, lethargy, coma, or seizures. In infants with open fontanels, large amounts of intracranial blood may accumulate, causing hemorrhagic shock or fever before there are any changes in the neurologic examination. Hemiparesis, hemiplegia, and unequal pupils are signs of brainstem compression and increased ICP. A child with a GCS of 12 or less requires emergency consultation with the neurosurgeon.

Nursing Alert

Children with a subdural hematoma and retinal hemorrhages should be evaluated for the possibility of child abuse, especially shaken baby syndrome.

The surgical management of subdural hematomas depends on the physical examination, size of the hematoma, and presence of other abnormalities on the CT scan. Various surgical options to treat subdural hematomas include transfontanel percutaneous aspiration, subdural drains, placement of burr hole, or craniotomy ([Klimo, Matthews, Lew, et al, 2011](#)).

Cerebral Edema

Some degree of brain edema is expected after craniocerebral trauma. Cerebral edema peaks at 24 to 72 hours after injury and may account for changes in a child's neurologic status. Cerebral edema associated with traumatic brain injury may be caused by cytotoxic edema or vasogenic edema. Either mechanism can result in increased ICP as a result of the increased intracranial volume and changes in CBF as a result of loss of autoregulation and/or hypercapnia or hypoxia.

Diagnostic Evaluation

A detailed health history, both past and present, is essential in evaluating the child with a craniocerebral trauma. Certain disorders (such as drug allergies, hemophilia, diabetes mellitus, or epilepsy) may produce similar symptoms. Even minor traumatic injury can aggravate a preexisting disease process, thereby producing neurologic signs out of proportion to the injury.

After a minor injury, initial unconsciousness (if present) is brief, and the child ordinarily exhibits a transient period of confusion, somnolence, and listlessness; this period is most often accompanied by irritability, pallor, and one episode of vomiting. Because head injuries are frequently accompanied by injuries in other areas, the examination is performed with care to avoid further damage.

Nursing Alert

Stabilize a child's spine after head injury until a spinal cord injury is ruled out.

Initial Assessment

Priorities in the initial stabilization phase of a child with a head injury include assessment of the CAB; neurologic examination focusing on mental status, pupillary responses, and motor responses; and assessment for spinal cord injury. The assessment is carried out quickly in relation to vital signs (see [Emergency Treatment box](#)).

Emergency Treatment

Head Injury

1. Assess child:

C: Circulation

A: Airway

B: Breathing

Neurologic and thermoregulatory status

2. Stabilize neck and spine immediately. Use jaw thrust, not chin lift, to open airway.

3. Clean any abrasions with soap and water.

- Apply clean dressing.
- If child is bleeding, apply pressure and then ice to relieve pain and swelling.

4. Keep child NPO until instructed otherwise.

5. Assess pain but do not give analgesics or sedatives.

6. Check pupil reaction every 4 hours (including twice during night) for 48 hours.

7. Awaken twice during the night to check LOC.

8. Seek medical attention for any of the following:

- Injury sustained at high speed (e.g., automobile)
- Fall from a significant distance (e.g., height greater than that of the child)
- Injury sustained from great force (e.g., baseball bat)
- Injury sustained under suspicious circumstances
- Loss of consciousness
- Amnesia
- Discomfort (crying) more than 10 minutes after injury
- Headache that is severe, worsening, interferes with sleep, or lasts more than 24 hours
- Fluid leak from ears or nose; blackened eyes
- Vomiting three or more times, beginning after injury, or continuing 4 to 6 hours after injury
- Swelling in front of or above earlobe or swelling that increases in size
- Confusion or abnormal behaving
- Difficulty arousing child from sleep
- Difficulty speaking
- Blurred vision or diplopia
- Unsteady gait
- Difficulty using extremities, weakness, or incoordination
- Neck pain or stiffness
- Pupils dilated, unequal, or fixed

- Infant with bulging fontanel
- Seizures

LOC, Level of consciousness; *NPO*, nothing by mouth.

Nursing Alert

Deep, rapid, periodic, or intermittent and gasping respirations; wide fluctuations or noticeable slowing of the pulse; and widening pulse pressure or extreme fluctuations in blood pressure are signs of brainstem involvement. Marked hypotension may represent internal injuries.

Ocular signs such as fixed, dilated, and unequal pupils; fixed and constricted pupils; and pupils that are poorly reactive or nonreactive to light and accommodation indicate increased ICP or brainstem involvement. It is important to remain with the patient who demonstrates fixed and dilated pupils because these are ominous signs with a high probability of respiratory arrest. Dilated, nonpulsating blood vessels indicate increased ICP before the appearance of papilledema. Retinal hemorrhages are seen in acute head injuries, specifically with shaken baby syndrome.

Nursing Alert

Observation of asymmetric pupils or one dilated, nonreactive pupil in a comatose child is a neurologic emergency.

Less urgent but important assessments include examination of the scalp for lacerations, widely separated sutures, and the size and tension of fontanels, which indicate intracranial hemorrhage or rapidly developing cerebral edema. A significant amount of blood loss can occur from scalp lacerations. An underlying skull fracture should be ruled out by CT scan.

Nursing Alert

Bleeding from the nose or ears needs further evaluation, and a watery discharge from the nose (rhinorrhea) that is positive for glucose (as tested with reagent strips [e.g., Dextrostix]) suggests leaking of CSF from a skull fracture.

An accurate assessment of clinical signs provides baseline information. Serial evaluations, preferably by a single observer, help detect changes in the neurologic status. Alterations in mental status, evidenced by increased difficulty in rousing the child, mounting agitation, development of focal neurologic signs, or marked changes in vital signs, usually indicate extension or progression of the basic pathologic process.

Special Tests

After a thorough clinical examination, a variety of diagnostic tests are helpful in providing a more definitive diagnosis of the type and extent of the trauma. The severity of a head injury may not be apparent on clinical examination of a child but is detectable on a CT scan. Whenever the child has a history consistent with a serious head injury (unrestrained occupant in a severe motor vehicle accident or a fall from a significant height), it is important to perform a diagnostic scan even if the child initially appears alert and oriented. All children with head injuries who have any alteration of consciousness, headache, vomiting, skull fracture, seizure, or a predisposing medical condition should undergo a diagnostic evaluation that includes CT scanning.

MRI may be done to further assess cerebral edema or structural brain abnormalities. A neurobehavioral assessment may be useful in documenting cognitive impairments. Skull radiographs are of little benefit in diagnosing skull fractures. Other radiographic tests may be indicated, depending on the severity or cause of the trauma. EEG is not helpful for diagnosis of head injury but is useful for defining seizures. Lumbar puncture is rarely used in craniocerebral trauma and is contraindicated in the presence of increased ICP because of the possibility of

herniation.

Posttraumatic Syndromes

Posttraumatic syndromes include postconcussion syndrome, posttraumatic seizures, and structural complications after a head injury.

Postconcussion syndrome is a sequela to brain injury with or without loss of consciousness. Symptoms can develop within hours to days after a mild head injury but can also occur after moderate to severe head injury. The manifestations vary with the child's age and include nausea, dizziness, headache, photophobia, fatigue, irritability, restlessness, difficulty concentrating, and memory impairment (Babcock, Byczkowski, Wade, et al, 2013). The duration of manifestations can vary from several days to several months.

Posttraumatic seizures occur in a number of children who survive a head injury, often within 24 hours after the injury but can occur up to 1 week after the trauma (Christensen, 2012). In comparison to children with no brain injury, seizures are two times more likely to occur in children with mild traumatic brain injury and seven times more likely to occur in children with severe head injury (Christensen, 2012).

Structural complications (e.g., hydrocephalus) may occur as a result of head injuries. Clinical sequelae include cognitive deterioration, gait changes, optic atrophy, cranial nerve palsies, or aphasia. The type of residual effect depends on the location and nature of the trauma.

Therapeutic Management

The majority of children with mild traumatic brain injury who have not lost consciousness can be cared for and observed at home after a careful examination reveals no serious intracranial injury. Nurses should provide parents with verbal and written instructions of signs and symptoms that warrant concern and the need for medical reevaluation (see [Family-Centered Care box](#)).

Family-Centered Care

Maintaining Contact

Maintaining contact with parents for continued observation and reevaluation of the child, when indicated, facilitates early diagnosis and treatment of possible complications from head injury, such as hematoma, cerebral edema, and posttraumatic seizures. Children are generally hospitalized for 24 to 48 hours of observation if their family lives far from medical facilities or lacks transportation or a telephone, which would provide access to immediate help. Other circumstances, such as language or other communication barriers, or even emotional trauma, may hinder learning and make it difficult for families to feel confident in caring for their child at home.

Parents are instructed to check the child every 2 hours to determine any changes in responsiveness. The sleeping child should be awakened to see if he or she can be roused normally. Parents are advised to maintain contact with the health professional, who typically examines the child again in 1 or 2 days. The manifestations of epidural hematoma in children do not generally appear until 24 hours or more after injury.

Children with severe injuries, those who have lost consciousness for more than a few minutes, and those with prolonged and continued seizures or other focal or diffuse neurologic signs must be hospitalized until their condition is stable and their neurologic signs have diminished. The child is maintained on NPO (nothing by mouth) status or restricted to clear liquids until it is determined that vomiting will not occur. IV fluids are indicated in the child who is comatose, displays dulled sensorium, or is persistently vomiting. The volume of IV fluid is carefully monitored to minimize the possibility of over hydration in cases of SIADH and cerebral edema. However, damage to the hypothalamus or pituitary gland may produce DI with its accompanying hypertonicity and dehydration. Fluid balance is closely monitored by daily weights; accurate intake and output measurements; and serum osmolality to detect early signs of water retention.

Sedating drugs are commonly withheld in the acute phase. Headaches are usually controlled with acetaminophen, although opioids may be needed. Antiepileptics are used for seizure control. Antibiotics may be administered if lacerations or penetrating injuries. Cerebral edema is managed

as described for the unconscious child. Hyperthermia is controlled with tepid sponges or a hypothermia blanket.

Surgical Therapy

Scalp lacerations are sutured after the underlying bone is carefully examined. Depressed fractures require surgical reduction and removal of bone fragments. Torn dura is sutured. Ping-pong ball skull fractures in very young infants can correct themselves within a few weeks; however, depressions larger than 5 mm may require surgical intervention (López-Elizalde, Leyva-Mastrapa, Muñoz-Serrano, et al, 2013).

Prognosis

The outcome of craniocerebral trauma depends on the extent of injury and complications. In general, the prognosis is more favorable for children than for adults. More than 90% of children with concussions or simple linear fractures recover without symptoms after the initial period. Outcomes in children with brain injuries are increasingly focused on cognitive, emotional, and mental problems. Children may experience a higher frequency of psychological disturbances after head injury than adults.

True coma (not obeying commands, eyes closed, and not speaking) usually does not last more than 2 weeks. A child's eventual outcome can range from brain death to a persistent vegetative state to complete recovery. However, even the best recovery may be associated with personality changes, including mood lability and loss of confidence, impaired short-term memory, headaches, and subtle cognitive impairments. Many children are left with significant disabilities after head injury that appear months later as learning difficulties, behavioral changes, or emotional disturbances (Anderson, Le Brocque, Iselin, et al, 2012).

Quality Patient Outcomes: Acute Head Injury

- Early recognition of signs and symptoms of increased intracranial pressure (ICP)
- Adequate ventilation, oxygenation, and circulation maintained
- Cerebral oxygen requirements minimized
- Sedation and analgesia provided while allowing for neurologic assessment

Nursing Care Management

The hospitalized child requires careful neurologic assessment and evaluation that are repeated at frequent intervals to establish a correct diagnosis, identify signs and symptoms of increased ICP, determine clinical management, and prevent many complications. The goals of nursing management of the child with a head injury are to maintain adequate ventilation, oxygenation, and circulation; to monitor and treat increased ICP; to minimize cerebral oxygen requirements; and to support the child and family during the recovery phases.

The child is placed on bed rest, usually with the head of the bed elevated slightly and the head in midline position. Appropriate safety measures (such as side rails kept up and seizure precautions) are implemented. Children may be restless and irritable, but often their reaction is to fall asleep when left undisturbed. A quiet environment helps reduce restlessness and irritability. For extremely restless children, hard surfaces may need to be padded and restraint used to prevent the possibility of further injury. Care is individualized according to the child's specific needs. Bright lights are irritating and make checking the ocular responses more difficult.

Frequent examinations of vital signs, neurologic signs, and LOC are extremely important nursing observations. When possible, they should be performed by a single observer to better detect subtle changes that may indicate worsening neurologic status. Pupils are checked for size, equality, reaction to light, and accommodation. After the initial changes seen after injury, the vital signs generally return to normal unless there is brainstem involvement.

The most important nursing observation is assessment of the child's LOC. Alterations in consciousness appear earlier in the progression of an injury than alterations of vital signs or focal

neurologic signs. Frequent examinations of alertness are fatiguing to the child; therefore, the child often desires to fall asleep, which may be confused with depressed consciousness. It is common to observe ocular divergence through the partially closed eyelids. A key nursing role is to provide sedation and analgesia for the child. The conflict between the need to promote the child's comfort and relieve anxiety versus the need to assess for neurologic changes presents a dilemma. Both goals can be achieved with close observation of the child's LOC and response to analgesics (using a pain assessment record), and effective communication with the practitioner. Decreasing restlessness after administration of an analgesic most likely reflects pain control rather than a decreasing LOC.

Observations of position and movement provide additional information. Note any abnormal posturing, as well as whether it occurs continuously or intermittently. Questions nurses might consider include:

- Are the child's hand grips strong and equal in strength?
- Are there any signs of flexion or extension posturing?
- What is the child's response to stimulation?
- Is movement purposeful, random, or absent?
- Are movement and sensation equal on both sides or restricted to one side only?

The child may complain of headache or other discomfort. A child who is too young to describe a headache may be fussy and resist being handled. A child who has vertigo will often vigorously resist being moved from a position of comfort. Forcible movement causes the child to vomit and display spontaneous nystagmus. Seizures are relatively common in children at the time of head trauma and may be of any type. Carefully observe, record, and report in detail any seizure activity. Children in postictal (postseizure) states are lethargic, with sluggish pupils.

Document drainage from any orifice. Bleeding from the ear suggests the possibility of a basal skull fracture. Clear nasal drainage is suggestive of an anterior basal skull fracture. Observe the amount and characteristics of the drainage.

Nursing Alert

Suctioning through the nares is contraindicated because of the risk of the catheter entering the brain parenchyma through a fracture in the skull.

Head trauma is often accompanied by other undetected injuries; therefore, any bruises, lacerations, or evidence of internal injuries or fractures of the extremities are noted and reported. Associated injuries are evaluated and treated appropriately.

The child with normal LOC is usually allowed clear liquids unless fluid is restricted. If the child has an IV infusion, it is maintained as prescribed. The diet is advanced to that appropriate for the child's age as soon as the condition permits. Intake and output are measured and recorded, and any incontinence of bowel or bladder is noted if the child has been toilet trained.

Observe the child for any unusual behavior, but behavior should be interpreted in relation to the child's normal behavior. For example, urinary incontinence during sleep would be of no consequence in a child who routinely wets the bed but would be highly significant for one who is always dry. Parents are valuable resources in evaluating objective behavior of their child. Information obtained from parents at or shortly after admission is essential in evaluating the child's behavior (e.g., the ease with which the child is roused normally, the usual sleeping position and patterns, motor activities [rolling over, sitting up, climbing], hearing and visual acuity, appetite, and manner of eating [spoon, bottle, cup]).

Family Support

The emotional and educational support of the family presents a challenging aspect to nursing care. Witnessing the parents' grief and helplessness on seeing their child in an altered state, connected to monitoring equipment, and in an intensive care unit evokes empathy. The nurse can encourage the family to be involved in the child's care, to bring in familiar belongings, or to make a tape recording of familiar voices and sounds. Parents may need a demonstration on how to touch or cuddle their child and may want to talk about their grief. The nurse can listen attentively, reinforce what is being done to assist the child, and direct parents toward signs and symptoms of recovery to instill hope without promises. Honesty and kindness, along with consistent and competent care, can help

families through this difficult time.

Rehabilitation

Rehabilitation and management of the child with permanent brain injury are essential aspects of care. Rehabilitation begins as soon as possible and usually involves the family and a rehabilitation team. Careful assessment of the child's capabilities, limitations, and probable potential is made as early as possible; and appropriate interventions are implemented to maximize the residual capacities. The Brain Injury Association of America* provides information and listings of rehabilitation services and support groups throughout the country.

Pediatric trauma rehabilitation is a national concern. Coordinating care and services for early rehabilitation involves identifying the child's and family's response to the traumatic injury and disability, securing available resources, and recognizing the parental role in the process.

Children with disabilities resulting from head trauma require assessment on a physical, cognitive, emotional, and social level. These children have experienced separation, pain, sensory deprivation and overload, changes in circadian cycle, and fear of the unknown. Recovery and transition require new coping strategies at the same time that regressive and acting-out behavior may start. Parents and children need honest communication for decision making. Rehabilitation is recommended when the child is making progress beyond what can be provided in a hospital setting. The Rancho Los Amigos Scale provides a systematic assessment of the possible progress that a child may achieve after a severe head injury.

Prevention

Tremendous strides have been taken in the prevention of cerebral damage after head injury in children. New developments are directed toward the prevention of cellular injury or the primary insult. The greatest benefit lies in the prevention of head injuries. Nurses can exert a valuable influence on prevention of children's head injuries through education. Preventable head injuries occur because unnecessary risks go unchecked. Inadequate supervision combined with children's natural sense of curiosity and exploration can lead to lethal results. Nurses are in the unique position of influencing caregivers in terms of growth and development. Banning the use of infant walkers is an example. This equipment does not help develop motor skills and places infants at risk for head and neck injuries from falls, especially down steps. Public education coupled with legislative support can aid in the prevention of childhood injuries. (For extensive discussions of childhood injuries and prevention, see [Chapters 9, 11, 12, 14, and 15](#). See also [Childhood Mortality, Chapter 1](#).)

Submersion Injury

Submersion injury is a major cause of unintentional injury related death in children 1 to 19 years old, with the highest rate occurring in the 0 to 4 year age group ([Weiss, 2010](#)). The term *submersion injury* has replaced *near-drowning* to include any person who experiences distress from submersion or immersion in liquid that either results in death (drowning) or survival at least 24 hours after submersion (near-drowning) ([Weiss, 2010](#)). Most cases of submersion are accidental, usually involving children who are helpless in water, such as inadequately attended children in or near swimming pools or infants in bathtubs; small children who fall into ponds, streams, and flooded excavations; occupants of pleasure boats who fail to wear life preservers; children who have diving accidents; and children who are able to swim but overestimate their endurance. Accidental submersion injury occurs more commonly in toddlers, males, and African Americans ([Nasrullah and Muazzam, 2011](#)).

Submersion injury can take place in any body of liquid, and sites of drowning are important to consider for preventive education. Children younger than 1 year old are most likely to have a submersion injury in a bathtub, whereas top-heavy toddlers fall head first into a pail of liquid and are unable to free themselves ([Caglar and Quan, 2016](#)). Preschoolers are at risk for injury in swimming pools, and school-age children and adolescents are most commonly at risk in natural bodies of water, such as lakes, ponds, and rivers ([Caglar and Quan, 2016](#)). The suction created at the outlet of pools, hot tubs, or whirlpool spas is strong enough to trap any child, even larger children, underwater. Submersion injury as a form of fatal child abuse has also been recognized as a problem.

Pathophysiology

Physiologically most organ systems are affected, especially pulmonary, cardiovascular, and neurologic systems. Cerebral hypoxia is a major component of morbidity and mortality with submersion events. Within minutes of a submersion, a lack of oxygen leads to loss of consciousness and progressive decreased cardiac output and ultimately apnea and cardiac arrest (Caglar and Quan, 2016). Recovery depends on the timeliness and effectiveness of initial resuscitation and subsequent supportive care measures.

Physiological features in submersion injuries are hypoxia, aspiration, and hypothermia.

Hypoxia is the primary problem because it results in global cell damage with different cells tolerating variable lengths of anoxia. Neurons, especially cerebral cells, sustain irreversible damage after 4 to 6 minutes of submersion; but the heart and lungs can survive up to 30 minutes. Regardless of the amount of liquid aspirated, if the victim suffers arterial hypoxemia (resulting from atelectasis and shunting of blood through the nonventilated alveoli), combined respiratory acidosis (resulting from retained carbon dioxide), and metabolic acidosis (caused by buildup of acid metabolites from anaerobic metabolism). Approximately 10% of submersion injury victims die without aspirating fluid but succumb from acute asphyxia as a result of prolonged reflex laryngospasm.

Aspiration of fluid occurs in the majority of submersion injuries. The aspirated fluid results in pulmonary edema, atelectasis, airway spasm, and pneumonitis, which aggravates the hypoxia.

Hypothermia is common after submersion, and children are at an increased risk of hypothermia because of their large surface area relative to body mass, decreased subcutaneous fat, and limited thermoregulation (Caglar and Quan, 2016). The temperature of the liquid plays an important role in developing hypoxemia. Cold water decreases metabolic demands and activates the diving reflex, which causes blood to be shunted away from the periphery to vital organs (i.e., the brain and heart). However, prolonged submersion in cold liquids can impair cognition, coordination, and muscle strength that ultimately results in loss of consciousness, decreased cardiac output, and cardiac arrest (Caglar and Quan, 2016).

Therapeutic Management

With rapid treatment, some children can be saved. Resuscitative measures should begin at the scene, and the victim should be transported to the hospital with maximum ventilatory and circulatory support. In the hospital, intensive care is implemented and continued according to the patient's needs.

In general, management of the victim with a submersion injury is based on the degree of cerebral insult. The first priority is to restore oxygen delivery to the cells and prevent further hypoxic damage. A spontaneously breathing child does well in an oxygen-enriched atmosphere; the more severely affected child requires endotracheal intubation and mechanical ventilation. Blood gases and pH are monitored frequently as a guide to oxygen, fluid, and electrolyte therapies. Seizures may occur due to hypoxia and cerebral edema.

All children who have a submersion injury should be observed for at least 6 to 8 hours for observation. Almost half of asymptomatic or minimally symptomatic alert children experience complications (e.g., respiratory compromise, cerebral edema) during the first 4 to 8 hours after the incident (Caglar and Quan, 2016). Aspiration pneumonia is a common complication that occurs approximately 48 to 72 hours after the episode. Bronchospasm, alveolocapillary membrane damage, atelectasis, abscess formation, and acute respiratory distress syndrome are other complications that occur after aspiration of fluid.

Prognosis

The best predictors of a good outcome are length of submersion less than 5 minutes and the presence of sinus rhythm, reactive pupils, and neurologic responsiveness at the scene. The worst prognoses—death or severe neurologic impairment—are for children submerged for more than 10 minutes and not responding to advanced life support within 25 minutes. Most children without spontaneous purposeful movement and normal brainstem function 24 hours after sustaining a submersion injury suffer severe neurologic deficits or death (Caglar and Quan, 2016). (See [Nursing Care Guidelines](#) box.)

Establishing Brain Death in Children

1. Coma and apnea must coexist. Child must exhibit complete loss of consciousness, vocalization, and volitional activity.
2. Brainstem function must be absent, as defined by:
 - a. Midposition or fully dilated pupils in both eyes that do not respond to light. Drugs may influence and invalidate pupillary assessment.
 - b. Absence of spontaneous eye movements and those induced by oculocephalic and caloric (oculovestibular) testing.
 - c. Absence of movement of bulbar musculature, including facial and oropharyngeal muscles.
 - d. Absence of the corneal, gag, cough, sucking, and rooting reflexes.
 - e. Absence of respiratory movements when child is removed from the respirator. Apnea testing using standardized methods can be performed but is done after other criteria are met.
3. Child must not be significantly hypothermic or hypotensive for age.
4. Flaccid tone and absence of spontaneous or induced movements, including spinal cord events such as reflex withdrawal or spinal myoclonus, should exist.
5. Examination should remain consistent with brain death throughout the observation and testing period.
6. Observation periods according to age:

37 weeks gestation to term infants 30 days old: Two separate examinations and two EEGs separated by at least 24 hours

Older than 30 days to 18 years old: Two separate examinations and two EEGs, separated by at least 12 hours

EEG, Electroencephalogram.

Modified from Nakagawa TA, Ashwal S, Mathur M, et al: Guidelines for the determination of brain death in infants and children: an update of the 1987 task force recommendations, *Pediatrics* 128:e720–e740, 2011.

Nursing Care Management

Nursing care depends on the child's condition. A child who survives may need intensive respiratory nursing care with attention to vital signs, mechanical ventilation or tracheostomy, blood gas determination, chest physiotherapy, and IV infusion. A child who has sustained a submersion injury requires the same care as an unconscious child. A difficult aspect in the care of the child victim of submersion injury is helping the parents cope with severe guilt reactions. Given the magnitude of the event, parents need repeated assurance that everything possible is being done to treat the child.

The parents of the child who is saved from death face the anxiety of not knowing the final outcome—to what extent will their child recover? This situation generates such intense feelings of loneliness and guilt that it is important for families to know that they are not alone. They should be reminded frequently that people are available to assist them through the crisis. Additional sources of support include psychiatric and social work consultants, community services, and religious support. Self-help groups may be beneficial if available in the community.

Nurses often have difficulty relating to the parents if obvious neglect has precipitated the accident and subsequent problems; therefore, it is important for those who care for these children and their families to assess their own feelings about the situation, in addition to assessing the family's coping abilities and resources. Caring for victims of a submersion injury and their families requires nurses to be sensitive to the needs of the child and family and to recognize his or her own reactions and emotions.

Prevention

Most submersion injuries are preventable. The most common cause of submersion injury of infants and young children is inadequate adult supervision, including a momentary lapse of supervision (Weiss, 2010). Close adult supervision of infants and children around any body of water is essential and should include the adult not engaging in any distracting activities. Other strategies include environmental prevention strategies, such as pool fencing, pool covers, water-entry alarms, and lifeguard and individual prevention, such as swimming and survival skills, cardiopulmonary resuscitation training, and the use of personal floatation devices (Weiss, 2010). (See also Injury Prevention, Chapters 9, 11, 12, 14, and 15.)

Intracranial Infections

The nervous system is subject to infection by the same organisms that affect other organs of the body. However, the nervous system is limited in the ways in which it responds to injury. Laboratory studies are needed to identify the causative agent. The inflammatory process can affect the meninges (meningitis) or brain (encephalitis).

Meningitis can be caused by a variety of organisms, but the three main types are (1) bacterial, or pyogenic, caused by pus-forming bacteria, especially meningococci and pneumococci organisms; (2) viral, or aseptic, caused by a wide variety of viral agents; and (3) tuberculous, caused by the tuberculin bacillus. The majority of children with acute febrile encephalopathy have either bacterial meningitis or viral meningitis as the underlying cause.

Bacterial Meningitis

Bacterial meningitis is an acute inflammation of the meninges and CSF. Suspected bacterial meningitis is a medical emergency, and immediate action must be taken to identify the causative organism and to initiate prompt treatment.

The advent of antimicrobial therapy has had a significant effect on the course and prognosis of children with bacterial meningitis. The introduction of conjugate vaccines against *Haemophilus influenzae* type b (Hib vaccine) in 1990 and *Streptococcus pneumoniae* (pneumococcus) in 2000 has led to dramatic changes in the epidemiology of bacterial meningitis (see [Translating Evidence into Practice](#) box later in this chapter).

Since the introduction of widespread vaccination for *S. pneumoniae*, the incidence of pneumococcal meningitis in children in the United States has decreased 62%, but it remains the most common cause of meningitis in children 3 months to 11 years old ([Thigpen, Whitney, Messonnier, et al, 2011](#)). The fatality rate for *S. pneumoniae* has not significantly changed, with a rate of 17.9% noted in 1999 and a rate of 14.7% noted in 2007 ([Thigpen, Whitney, Messonnier, et al, 2011](#)).

Currently *S. pneumoniae* is the leading cause of bacterial meningitis in children 3 months to 11 years old, whereas *Neisseria meningitidis* is the leading cause in children 11 to 17 years old ([Thigpen, Whitney, Messonnier, et al, 2011](#)). The leading causes of neonatal meningitis are group b streptococci ([Thigpen, Whitney, Messonnier, et al, 2011](#)). Meningococcal meningitis occurs in epidemic form and is the only type readily transmitted by droplet infection from nasopharyngeal secretions. Although this condition may develop at any age, the risk of meningococcal infection increases with the number of contacts; therefore, it occurs predominantly in school-age children and adolescents. College students, especially those living in dormitory residences, are at moderately increased risk for meningococcal disease compared with other persons their age. There appear to be some seasonal variations with the organisms. Pneumococcal and meningococcal infections can occur at any time but are more common in later winter and early spring.

Pathophysiology

The most common route of infection is vascular dissemination from a focus of infection elsewhere. For example, organisms from the nasopharynx invade the underlying blood vessels cross the blood brain barrier, and multiply in the CSF. Invasion by direct extension from infections in the paranasal and mastoid sinuses is less common. Organisms also gain entry by direct implantation after penetrating wounds, skull fractures that provide an opening into the skin or sinuses, lumbar puncture or surgical procedures, anatomic abnormalities such as spina bifida, or foreign bodies such as an internal ventricular shunt or an external ventricular device. Once implanted, the organisms spread into the CSF, by which the infection spreads throughout the subarachnoid space.

The infective process is similar to that seen in any bacterial infection and includes inflammation, exudation, white blood cell accumulation, and varying degrees of tissue damage. The brain becomes hyperemic and edematous, and the entire surface of the brain is covered by a layer of purulent exudate that varies with the type of organism. For example, meningococcal exudate is most marked over the parietal, occipital, and cerebellar regions; the thick, fibrinous exudate of pneumococcal infection is confined chiefly to the surface of the brain, particularly the anterior lobes; and the exudate of streptococcal infections is similar to that of pneumococcal infections but thinner.

As infection extends to the ventricles, thick pus, fibrin, or adhesions may occlude the narrow passages and obstruct the flow of CSF.

Clinical Manifestations

The onset of illness may be abrupt and rapid, or develop progressively over 1 day or several days, and may be preceded by a febrile illness. Most children with meningitis are seen with fever, chills, headache, and vomiting that are quickly followed by alterations in sensorium; however some may present only with lethargy and irritability (Bamberger, 2010). The child is extremely irritable and agitated and may develop seizures, photophobia, confusion, hallucinations, drowsiness, stupor, or coma. See Box 27-4 for clinical manifestations of bacterial meningitis. Nuchal rigidity is manifested by inability to flex neck and place chin on chest, as well as presence of Kernig and Brudzinski signs. The Kernig sign is present if the patient (in the supine position with the hip and knee flexed at 90 degrees), cannot extend the knee more than 135 degrees and pain is felt in the hamstrings. Flexion of the opposite knee may also occur. The Brudzinski sign is present if the patient, while in the supine position, flexes the lower extremities if passive flexion of the neck is attempted.

Nursing Alert

Any child who is ill and develops a purpuric or petechial rash may have meningococemia and must receive medical attention immediately.

Box 27-4

Clinical Manifestations of Bacterial Meningitis

Children and Adolescents

Usually abrupt onset

Fever

Chills

Headache

Vomiting

Alterations in sensorium

Seizures (often the initial sign)

Irritability

Agitation

May develop:

- Photophobia
- Delirium
- Hallucinations
- Aggressive behavior
- Drowsiness

- Stupor

- Coma

Nuchal rigidity; may progress to opisthotonos

Positive Kernig and Brudzinski signs

Hyperactivity but variable reflex responses

Signs and symptoms peculiar to individual organisms:

- Petechial or purpuric rashes (meningococcal infection), especially when associated with a shock-like state
- Joint involvement (meningococcal and *Haemophilus influenzae* infection)
- Chronically draining ear (pneumococcal meningitis)

Infants and Young Children

Classic picture (above) rarely seen in children between 3 months and 2 years old

Fever

Poor feeding

Vomiting

Marked irritability

Frequent seizures (often accompanied by a high-pitched cry)

Bulging fontanel

Nuchal rigidity possible

Brudzinski and Kernig signs not helpful in diagnosis

Difficult to elicit and evaluate in this age group

Subdural empyema (*H. influenzae* infection)

Neonates

Specific Signs

Child well at birth but within a few days begins to look and behave poorly

Refuses feedings

Poor sucking ability

Vomiting or diarrhea

Poor tone

Lack of movement

Weak cry

Full, tense, and bulging fontanel may appear late in course of illness

Neck usually supple

Nonspecific Signs That May Be Present

Hypothermia or fever (depending on the infant's maturity)

Jaundice

Irritability

Drowsiness

Seizures

Respiratory irregularities or apnea

Cyanosis

Weight loss

Diagnostic Evaluation

A lumbar puncture is the definitive diagnostic test for meningitis. The fluid pressure is measured, and samples are obtained for culture, Gram stain, blood cell count, and determination of glucose and protein content. These findings are usually diagnostic. Culture and sensitivity testing are needed to identify the causative organism. Spinal fluid pressure is usually elevated, but interpretation is often difficult when the child is crying. Sedation with fentanyl and midazolam can alleviate the child's pain and fear associated with this procedure. If there is evidence or suspicion of increased ICP (papilledema, focal neurologic deficits, bulging fontanel), a CT scan of the head may be warranted before the procedure (Bamberger, 2010). Lumbar puncture is contraindicated in any patient with imaging to suggest that the procedure is not safe (e.g., midline shift, mass effect, transependymal migration of CSF).

The patient with meningitis generally has an elevated white blood cell count, often predominantly polymorphonuclear leukocytes. Typically, in bacterial meningitis, the CSF glucose level is reduced, generally in proportion to the duration and severity of the infection. The protein concentration is usually increased.

A blood culture is advisable for all children suspected of having meningitis and occasionally will be positive when CSF culture is negative. Nose and throat cultures may provide helpful information in some cases.

Therapeutic Management

Acute bacterial meningitis is a medical emergency that requires early recognition and immediate therapy to prevent death and avoid residual disabilities. The initial therapeutic management includes:

- Isolation precautions
- Initiation of antimicrobial therapy
- Maintenance of hydration
- Maintenance of ventilation
- Reduction of increased ICP
- Management of systemic shock
- Control of seizures
- Control of temperature

- Treatment of complications

The child is isolated from other children, usually in an intensive care unit for close observation. An IV infusion is started to facilitate administration of antimicrobial agents, fluids, antiepileptic drugs, and blood, if needed. The child is placed in respiratory isolation.

Drugs

Until the causative organism is identified, empirical therapy is administered. After identification of the organism, antimicrobial agents are adjusted accordingly.

Drug Alert

Dexamethasone may play a role in the initial management of symptoms occurring from a cytokine-mediated inflammatory response after treatment has begun. Evidence indicates that dexamethasone therapy decreases the risk of neurologic sequelae in children with *H. influenzae* type b meningitis, but data regarding the benefits in other types of bacterial meningitis are inconclusive (Prober and Matthew, 2016).

Signs of gastrointestinal hemorrhage or secondary infection may complicate steroid administration. Antibiotic treatment with cephalosporins demonstrates superiority for promptly sterilizing the CSF and reducing the incidence of severe hearing impairment.

Nonspecific Measures

Maintaining hydration is a prime concern, and the patient's condition determines the type and amount of IV fluids. The optimum hydration involves correction of any fluid deficits and electrolyte abnormalities followed by fluid restriction until normal serum sodium levels and no signs of increased ICP are present. If needed, measures to decrease ICP are implemented (see earlier in this chapter). Long-term fluid restriction is not the standard of care, because a lack of adequate fluid volume can reduce blood pressure and CPP, causing CNS ischemia (Prober and Matthew, 2016).

Complications, such as aspiration of subdural effusion in infants and treatment for disseminated intravascular coagulation syndrome, are treated appropriately. Shock is managed by restoration of circulating blood volume and maintenance of electrolyte balance. Seizures can occur during the first few days of treatment. These are controlled with the appropriate antiepileptic drug. Hearing loss is common. The patient should undergo auditory evaluation 6 months after the illness has resolved.

Lumbar puncture is carried out as needed to determine the effectiveness of therapy. The patient is evaluated neurologically during the convalescent period.

Prognosis

Less than 10% of cases of bacterial meningitis are fatal (Thigpen, Whitney, Messonnier, et al, 2011). The child's age, duration of illness before antibiotic therapy, rapidity of diagnosis after onset, type of organism, and adequacy of therapy are important in the prognosis of bacterial meningitis. Survivors can experience significant physical and neurologic sequelae, including hearing loss, learning disability, and seizure disorder (Chandran, Herbert, Misurski, et al, 2011).

Clinical features that are associated with an increased risk of developing neurologic complications include young age, infection with *S. pneumoniae*, CSF with more than 10^7 colony forming units/ml or low CSF glucose content, delay in antimicrobial therapy for longer than 2 days, prolonged or complicated seizures, focal neurologic deficits, and adequacy of response to infection (Chandran, Herbert, Misurski, et al, 2011). The residual deficits in infants are primarily a result of communicating hydrocephalus and the greater effects of cerebritis on the immature brain. In older children, the residual effects are related to the inflammatory process itself or result from vasculitis associated with the disease.

Quality Patient Outcomes: Bacterial Meningitis

- Early recognition of signs and symptoms of meningitis
- Antibiotics administered as soon as diagnosis is established

- Cerebral edema prevented
- Exposure prevented by early isolation
- Side effects managed
- Neurologic sequelae prevented

Prevention

Vaccines are available for types A, C, Y, and W-135 meningococci and Hib. Meningococcal polysaccharide vaccination is routinely given to children 11 to 12 years old, with a booster at 16 years old; however, children 2 to 10 years old may be given the vaccine if they are at increased risk for meningococcal disease (Prober and Matthew, 2016). Routine vaccinations for Hib and pneumococcal conjugate vaccines are recommended for all children beginning at 2 months old (see Immunizations, Chapter 6) (see Translating Evidence into Practice box).

Translating Evidence into Practice

Children with Bacterial Meningitis and Preventive Vaccines

Ask the Question

PICOT Question

In children and adolescents with bacterial meningitis, has the administration of *Haemophilus influenzae* type B (Hib), pneumococcal, and meningococcal preventive vaccines reduced the incidence and mortality associated with bacterial meningitis?

Critically Analyze the Evidence

- Haddy, Perry, Chacko, and colleagues (2005) compared the incidence of *Streptococcus pneumoniae* disease before and after the introduction of conjugated pneumococcal vaccine from 1999 to 2002. The trend in the rates of invasive pneumococcal disease cases showed significant declines during the study period for all ages after the introduction of the heptavalent *S. pneumoniae* protein conjugate vaccine.
- Watt, Wolfson, O'Brien, and colleagues (2009) performed a literature review with studies evaluating Hib disease incidence, fatality ratios, and the effect of Hib vaccine. In 2000, there were 173,000 cases of Hib meningitis and 78,300 deaths among children younger than 5 years old worldwide. Expanded use of Hib vaccine can reduce the incidence and mortality of Hib-related disease.
- A Cochrane Review determined the effect, duration of protection, and age-specific effects of polysaccharide serogroup A vaccine (SgAV) to prevent meningococcal meningitis in children. The vaccine had a 95% protective effect during the first year in children older than 5 years old, but its efficacy after the first year could not be determined. Children 1 to 5 years old in low-income countries were also protected, but the exact efficacy could not be determined (Patel and Lee, 2005).
- A systematic review assessed the impact of the 7-valent pneumococcal vaccination on morbidity and mortality from invasive pneumococcal diseases. The six studies from North America consistently reported a decline in invasive pneumococcal disease mortality after the introduction

of the pneumococcal vaccine, with reductions ranging from 57% to 62% among children and 37% to 76% among all age groups (Myint, Madhava, Balmer, et al, 2013).

- Comparing invasive pneumococcal disease (IPD) in children from the pre-PCV 13 (2007–2009) to the post-PCV 13 (2010–2012) eras, Iroh Tam, Madoff, Coombes, and colleagues (2014) found a significant decline in incidence rates among the two groups (46/100,000 pre-PCV 13 and 23/100,000 post-PCV 13, $p < 0.00001$) but no difference in mortality (3.6% pre-PCV13 and 3.5% post-PCV 13).
- Using laboratory based and population based data, IPD was compared to actual incidence versus expected incidence if PCV 13 had not replaced PCV 7. Moore, Link-Gelles, Schaffner, and colleagues (2015) estimated that 10,000 IPD cases and 90 deaths among children were prevented in the first 3 years after the introduction of PCV 13.

Apply the Evidence: Nursing Implications

The evidence strongly suggests that all children should be immunized against the most common organisms responsible for bacterial meningitis (i.e., Hib, *S. pneumoniae*, and *Neisseria meningitidis*) as preventive vaccines to decrease the incidence of bacterial meningitis. Nurses should stress to the parents, children, adolescents, and young adults the importance of adhering to the immunization schedule to protect the child against serious childhood diseases.

Nursing Alert

A major priority of nursing care of a child suspected of having meningitis is to administer antibiotics as soon as they are ordered. The child is placed on respiratory isolation for at least 24 hours after initiation of antimicrobial therapy.

Nursing Care Management

Keep the room as quiet as possible, and keep environmental stimuli at a minimum because most children with meningitis are sensitive to noise, bright lights, and other external stimuli. Most children are more comfortable without a pillow and with the head of the bed slightly elevated. A side-lying position is more often assumed because of nuchal rigidity. The nurse should avoid actions that cause pain or increase discomfort, such as lifting the child's head. Evaluating the child for pain and implementing appropriate relief measures are important during the initial 24 to 72 hours. Acetaminophen with codeine is often used. The nurse should be cautious to evaluate if a patient is febrile before giving acetaminophen or ibuprofen because either of these medications may mask a fever, which is an important clinical indication of infection.

The nursing care of the child with meningitis is determined by the child's symptoms and treatment. Observation of vital signs, neurologic signs, LOC, urinary output, and other pertinent data is carried out at frequent intervals. The child who is unconscious is managed as described previously (see earlier in chapter), and all children are observed carefully for signs of the complications just described, especially increased ICP, shock, and respiratory distress. Frequent assessment of the open fontanels is needed in the infant because subdural effusions and obstructive hydrocephalus can develop as a complication of meningitis.

Administration of fluids and nourishment are determined by the child's status. The child with dulled sensorium is usually kept NPO. Other children are allowed clear liquids initially and, if tolerated, progress to a diet suitable for their age. Careful monitoring and recording of intake and output are needed to determine deviations that might indicate impending shock or increasing fluid accumulation, such as cerebral edema or subdural effusion.

One of the most difficult problems in the nursing care of children with meningitis is maintaining IV infusion for the length of time needed to provide adequate antimicrobial therapy (usually 10 days). Because continuous IV fluids are usually not necessary, an intermittent infusion device is used. In some cases, children who are recovering uneventfully are sent home with the device, and the parents are taught IV drug administration.

Family Support

The sudden nature of the illness makes emotional support of the child and parents extremely important. Parents are upset and concerned about their child's condition and often feel guilty for not having suspected the seriousness of the illness sooner. They need much reassurance that the natural onset of meningitis is sudden and that they acted responsibly in seeking medical assistance when they did. The nurse encourages the parents to openly discuss their feelings to minimize blame and guilt. They also are kept informed of the child's progress and of all procedures, results, and treatments. In the event that the child's condition worsens, they need the same psychological care as parents facing the possible death of their child (see [Chapter 17](#)).

Nonbacterial (Aseptic) Meningitis

The term *aseptic meningitis* refers to the onset of meningeal symptoms, fever, and pleocytosis without bacterial growth from CSF cultures. Aseptic meningitis is caused by many different viruses, including arbovirus, herpes simplex virus (HSV), cytomegalovirus, adenovirus, and human immunodeficiency virus (HIV). Enteroviruses are the most common cause of aseptic meningitis ([Prober and Matthew, 2016](#)). The onset may be abrupt or gradual, and many of the presenting signs and symptoms are the same as bacterial meningitis, including headache, fever, photophobia, and nuchal rigidity.

Diagnosis is based on clinical features and CSF findings. [Table 27-2](#) lists variations in CSF values in bacterial and viral meningitis. It is important to differentiate this self-limiting disorder from the more serious forms of meningitis.

TABLE 27-2

Variation of Cerebrospinal Fluid Analysis in Bacterial and Viral Meningitis

| Manifestations | Bacterial* | Viral |
|------------------------|---------------------------------|-------------------------------------|
| White blood cell count | Elevated; increased neutrophils | Slightly elevated; increased lymphs |
| Protein content | Elevated | Normal or slightly increased |

| | | |
|------------------------------|------------------|--------------------------|
| Glucose content | Decreased | Normal |
| Gram stain; bacteria culture | Positive | Negative |
| Color | Turbid or cloudy | Clear or slightly cloudy |
| Opening pressure | Elevated | Normal |

Results may vary in the neonate.

Treatment is primarily symptomatic, such as acetaminophen for headache and muscle pain, maintenance of hydration, and positioning for comfort. Until a definitive diagnosis is made, antimicrobial agents may be administered and isolation enforced as a precaution against the possibility that the disease might be of bacterial origin. Nursing care is similar to the care of the child with bacterial meningitis. The clinical course of viral meningitis is much shorter and typically without any significant complications.

Encephalitis

Encephalitis can occur as a result of (1) direct invasion of the CNS by a virus or (2) post infectious involvement of the CNS after a viral disease. Often the specific type of encephalitis may not be identified. The cause of more than half of the cases reported in the United States is unknown. The majority of cases of known etiology are associated with the childhood diseases of measles, mumps, varicella, and rubella and, less often, with the enteroviruses, herpesviruses, and West Nile virus.

Herpes simplex encephalitis is an uncommon disease, but 30% of cases involve children. The initial clinical findings are nonspecific (fever, altered mental status), but most cases evolve to demonstrate focal neurologic signs and symptoms. Children may experience focal seizures. The CSF is abnormal in most cases. Because of a rise in the number of children with herpes simplex encephalitis, suspected cases require prompt attention, especially because the diagnosis can be difficult. CSF polymerase chain reaction (PCR) testing can confirm the clinical diagnosis rapidly. The early use of IV acyclovir reduces mortality and morbidity. Empiric therapy with acyclovir is given before precise virologic diagnosis has been established. The multiplicity of causes of viral encephalitis makes diagnosis difficult. Most are those involved with arthropod vectors (togaviruses and bunyaviruses) and those associated with hemorrhagic fevers (arenaviruses, filoviruses, and hantaviruses). In the United States, the vector reservoir for most agents pathogenic for humans is the mosquito (St. Louis or West Nile encephalitis); therefore, most cases of encephalitis appear during the hot summer months and subside during the autumn.

The clinical features of encephalitis are similar regardless of the agent involved. Manifestations can range from a mild benign form that resembles aseptic meningitis, lasts a few days, and is followed by rapid and complete recovery, to rapidly progressing encephalitis with severe CNS involvement. The onset may be sudden or may be gradual with malaise, fever, headache, dizziness, apathy, nuchal rigidity, nausea and vomiting, ataxia, tremors, hyperactivity, and speech difficulties (Box 27-5). In severe cases, the patient has a high fever, stupor, seizures, disorientation, spasticity, and coma that may proceed to death. Ocular palsies and paralysis also may occur.

Box 27-5

Clinical Manifestations of Encephalitis

Onset: Sudden or Gradual

Malaise

Fever

Headache

Dizziness

Apathy

Lethargy

Nuchal rigidity

Ataxia

Tremors

Hyperactivity

Speech difficulties: Mutism

Altered mental status

Severe Cases

High fever

Stupor

Seizures

Disorientation

Spasticity

Coma (may proceed to death)

Ocular palsies

Paralysis

Diagnostic Evaluation

The diagnosis is made on the basis of clinical findings and, when possible, identification of the specific virus. Early in the course of encephalitis, CT scan results may be normal. Later, hemorrhagic areas in the frontotemporal region may be seen. Togaviruses (some of which were formerly labeled *arboviruses*) are rarely detected in the blood or spinal fluid, but viruses of herpes, mumps, measles, and enteroviruses may be found in the CSF. Serologic testing may be required. The first blood sample should be drawn as soon as possible after onset, with the second sample drawn 2 or 3 weeks later.

Therapeutic Management

Patients suspected of having encephalitis are hospitalized promptly for observation, including ICP monitoring. Only herpes simplex encephalitis has specific treatment available. In other cases, treatment is primarily supportive and includes conscientious nursing care, control of cerebral manifestations, and adequate nutrition and hydration, with observation and management as for other cerebral disorders. Viral encephalitis can cause devastating neurologic injury. Follow-up care with periodic reevaluation and rehabilitation is important for patients who develop residual effects of the disease.

The prognosis for the child with encephalitis depends on the child's age, the type of organism, and residual neurologic damage. Very young children (younger than 2 years old) may exhibit increased neurologic disabilities, including learning difficulties and epilepsy. Follow-up care with periodic reevaluation is important because symptoms are often subtle, and rehabilitation is essential for patients who develop residual effects of the disease.

Quality Patient Outcomes: Encephalitis

- Early recognition of signs and symptoms of meningitis
- Cerebral edema prevented
- Side effects managed

- Neurologic sequelae prevented

Nursing Care Management

Nursing care of the child with encephalitis is the same as for any unconscious child and for the child with meningitis. Additional nursing interventions include observation for deterioration in consciousness. Isolation of the child is not necessary; however, follow good hand-washing techniques. A main focus of nursing management is the control of rapidly rising ICP. Neurologic monitoring, administration of medications, and support of the child and parents are the major aspects of care.

Rabies

Rabies is an acute infection of the nervous system caused by a virus that is almost invariably fatal if left untreated. It is transmitted to humans by the saliva of an infected mammal and is introduced through a bite or skin abrasion. After entry into a new host, the virus multiplies in muscle cells and is spread through neural pathways without stimulating a protective host immune response.

Approximately 91% of rabies cases are transmitted by wild animals and 9% from domestic animals (Weant and Baker, 2013). Carnivorous wild animals such as skunks, raccoons, foxes, and bats are the animals most often infected with rabies and the cause of most indigenous cases of human rabies in the United States (Weant and Baker, 2013). The likelihood of human exposure to a rabid domestic animal has decreased greatly. The circumstances of a biting incident are important. An unprovoked attack is more likely than a provoked attack to indicate a rabid animal. Bites inflicted on a child attempting to feed or handle an apparently healthy animal can generally be regarded as provoked. Any child bitten by a wild animal is assumed to be exposed to rabies.

Nursing Alert

Unusual behavior in an animal is cause for suspicion; children should be warned to beware of wild animals that appear to be friendly.

Although rabies is common among wildlife species, human rabies is rarely acquired. The highest incidence occurs in children younger than 15 years old. The incubation period usually ranges from 1 to 3 months but may be as short as 5 days or longer than 6 months (Willoughby, 2016). Modern-day prophylaxis is nearly 100% successful. Only 10% to 15% of persons bitten develop the disease, but when symptoms are present, rabies progresses to a fatal outcome. In the United States, human fatalities associated with rabies occur in people who fail to seek medical attention, usually because they are unaware of their exposure.

The disease is characterized by a period of nonspecific symptoms, including general malaise, fever, headache, and weakness, followed by typical symptoms of severe encephalitis, including agitation, changes in LOC, and seizures. Attempts at swallowing may cause such severe spasm of the pharynx, neck, and diaphragm muscles that apnea, cyanosis, and anoxia are produced—the characteristics from which the term *hydrophobia* was derived.

Diagnosis is made on the basis of history and clinical features. Hydrophobia is a cardinal sign of a rabies diagnosis. The diagnosis is confirmed by skin biopsy, and antibodies may be detected 7 to 8 days after the onset of clinical symptoms (Crowcroft and Thampi, 2015).

Therapeutic Management

Treatment is of little avail after symptoms appear, but the long incubation period allows time for the induction of active and passive immunity before the onset of illness. The current therapy for a rabid animal bite consists of three steps: (1) thorough cleansing of the wound with soap and water, suturing of the wound should be avoided whenever possible; (2) administration of rabies vaccine; and (3) administration of rabies immunoglobulin. The rabies vaccine and immunoglobulin should be initiated as soon as possible after exposure. The rabies vaccine consists of four doses administered intramuscularly at days 0, 3, 7, and 14 but can be stopped if the animal remains healthy throughout the 10-day observation period or is proved to be negative for rabies by a reliable laboratory (Crowcroft and Thampi, 2015). Rabies immunoglobulin is administered locally at the wound and provides passive antibodies at the site of exposure. Rabies immunoglobulin is given

once within 7 days after the first vaccine dose before the child develops an active immune response (Crowcroft and Thampi, 2015).

Nursing Care Management

Parents and children are frightened by the urgency and seriousness of the situation. They need anticipatory guidance for the therapy and support and reassurance regarding the efficacy of the preventive measures for this dreaded disease. The vaccine is well tolerated by children, although they need preparation for the series of injections. Mass immunization is unnecessary and unlikely to be implemented. In areas where rabies is rare, the schedule given is sufficient. However, certain circumstances may warrant pre-exposure vaccination, such as when a child is being taken to an area of the world where rabies in stray dogs is still a problem.

Reye Syndrome

RS is a disorder defined as a metabolic encephalopathy associated with other characteristic organ involvement. It is characterized by fever, profoundly impaired consciousness, and disordered hepatic function.

The etiology of RS is not well understood, but most cases follow a common viral illness, typically influenza or varicella. RS is a condition characterized pathologically by cerebral edema and fatty changes of the liver. The onset of RS is notable for profuse effortless vomiting and lethargy that quickly progresses to neurologic impairment, including delirium, seizures, and coma, and can ultimately lead to increase ICP, herniation, and death (Ibrahim and Balistreri, 2016). The cause of RS is a mitochondrial insult induced by various viruses, drugs, exogenous toxins, and genetic factors. Elevated serum ammonia levels tend to correlate with the clinical manifestations and prognosis.

Definitive diagnosis is established by liver biopsy. The staging criteria for RS are based on liver dysfunction and on neurologic signs that range from lethargy to coma. As a result of improved diagnostic techniques, children who would have been diagnosed with RS in the past are now diagnosed with other illnesses, such as viral or inborn metabolic errors affecting organic acid, ammonia, and carbohydrate metabolism. Cases of unrecognized, drug-induced encephalopathy by antiemetics given to children during viral illnesses have symptoms similar to those of RS.

The potential association between aspirin therapy for the treatment of fever in children with varicella or influenza and the development of RS precludes its use in these patients. However, by the time the US Food and Drug Administration required aspirin product labeling in 1986, most of the decline in RS incidence had already occurred.

Nursing Care Management

The most important aspect of successful management of a child with RS is early diagnosis and aggressive supportive therapy. Rapid progression to coma and high peak ammonia concentrations are associated with a more serious prognosis. Cerebral edema with increased ICP represents the most immediate threat to life.

Care and observations are implemented as for any child with an altered state of consciousness (see earlier in this chapter) and increasing ICP. Accurate and frequent monitoring of intake and output is essential for adjusting fluid volumes to prevent both dehydration and cerebral edema. Because of related liver dysfunction, monitor laboratory studies to determine impaired coagulation, such as prolonged bleeding time.

Keep parents of children with RS informed of the child's progress and explain diagnostic procedures and therapeutic management. Families need to be aware that salicylate, the alleged offending ingredient in aspirin, is contained in other products (e.g., Pepto-Bismol). They should refrain from administering any product for influenza-like symptoms without first checking the label for "hidden" salicylates. Recovery from RS is rapid and usually without sequelae if the diagnosis is determined early and therapy is initiated promptly. Patients who survive have full liver function recovery (Ibrahim and Balistreri, 2016).

Seizure Disorders

A seizure is a “transient occurrence of signs and/or symptoms due to abnormal excessive and synchronous neuronal activity in the brain” (Fisher, Acevedo, Arzimanoglou, et al, 2014). Seizures are the most common pediatric neurologic disorder. About 4% to 10% of children will have at least one seizure in the first 16 years of life (Mikati and Hani, 2016). The manifestation of seizures depends on the region of the brain in which they originate and may include unconsciousness or altered consciousness, involuntary movements, and changes in perception, behaviors, sensations, and/or posture.

Seizures are a symptom of an underlying disease process. They are individual events. Potential causes include infections, intracranial lesions or hemorrhage, metabolic disorders, trauma, brain malformations, genetic disorders, or toxic ingestion. Epilepsy is defined as two or more unprovoked seizures more than 24 hours apart and can be caused by a variety of pathologic processes in the brain. A single seizure is not classified as epilepsy and is generally not treated with long-term antiepileptic drugs. Some seizures may result from an acute medical or neurologic illness and cease after the illness is treated. In other cases, children may have one or more seizures without the cause ever being found.

When a child has had a seizure, it is important to classify the seizure, according to the International Classification of Epileptic Seizures. Optimal treatment and prognosis require an accurate diagnosis and a determination of the cause whenever possible.

Etiology

Seizures in children have many different causes. Seizures are classified according to type and etiology. Acute symptomatic (reactive) seizures are associated with an acute insult, such as head trauma or meningitis. Remote symptomatic seizures are those without an immediate cause but with an identifiable prior brain injury such as major head trauma, meningitis or encephalitis, hypoxia, stroke, or a static encephalopathy, such as cognitive impairment or cerebral palsy. Cryptogenic seizures are those occurring with no clear cause. Idiopathic seizures are genetic in origin. A partial list of causative factors is presented in [Box 27-6](#).

Box 27-6

Etiology of Seizures in Children

Nonrecurrent (Acute)

Febrile episodes

Intracranial infection

Intracranial hemorrhage

Space-occupying lesions (cyst, tumor)

Acute cerebral edema

Anoxia

Toxins

Drugs

Tetanus

Lead encephalopathy

Shigella or *Salmonella* organisms

Metabolic alterations:

- Hypocalcemia
- Hypoglycemia
- Hyponatremia or hypernatremia
- Hypomagnesemia
- Alkalosis
- Disorders of amino acid metabolism
- Deficiency states
- Hyperbilirubinemia

Recurrent (Chronic)

Idiopathic epilepsy

Epilepsy secondary to:

- Trauma
- Hemorrhage
- Anoxia
- Infections
- Toxins
- Degenerative phenomena
- Congenital defects
- Parasitic brain disease
- Hypoglycemia injury

Epilepsy – sensory stimulus

Epilepsy-stimulating states

- Narcolepsy and catalepsy

- Psychogenic
- Tetany from hypocalcemia, alkalosis

Hypoglycemic states

- Hyperinsulinism
- Hypopituitarism
- Adrenocortical insufficiency
- Hepatic disorders

Uremia

Allergy

Cardiovascular dysfunction or syncopal episodes

Migraine

Pathophysiology

Regardless of the etiologic factor or type of seizure, the basic mechanism is the same. Abnormal electrical discharges (1) may arise from the simultaneous activation of neurons in both hemispheres of the brain (generalized seizures); (2) may be restricted to one area of the cerebral cortex, producing manifestations characteristic of that particular anatomic focus (partial seizure); or (3) may begin in a localized area of the cortex as a partial seizure and spread to other portions of the brain and, if sufficiently extensive, produce generalized seizure activity.

A seizure occurs when there is sudden excessive excitation and loss of inhibition within neuronal circuits, allowing the circuits to amplify their discharges simultaneously. These discharges occur in response to the activity of sodium, potassium, calcium, and chloride ion channels. Normally these discharges are restrained by inhibitory mechanisms. In response to physiologic stimuli, such as brain injury or infection, genetic abnormalities, cellular dehydration, severe hypoglycemia, electrolyte imbalance, sleep deprivation, emotional stress, and toxic exposures, these abnormal neuronal discharges can spread to nearby cortex and subcortical structures. Primary generalized seizures begin with abnormal discharges in both hemispheres, which can involve connections between the thalamus and neocortex. On the basis of these characteristic neuronal discharges (manifested as stereotypical symptoms observed and reported during seizures and/or as recorded by the EEG), seizures are designated as partial, generalized, and unclassified epileptic seizures.

Seizure Classification and Clinical Manifestations

There are many different types of seizures, and each has unique clinical manifestations. Seizures are classified into two major categories:

- Partial seizures, which have a local onset and involve a relatively small location in the brain
- Generalized seizures, which involve both hemispheres of the brain from onset or secondarily generalize from partial seizures ([Box 27-7](#) and [Table 27-3](#))

Box 27-7

Classification and Clinical Manifestations of Seizures

Partial Seizures

Simple Partial Seizures with Motor Signs

Characterized by:

- Localized motor symptoms
- Somatosensory, psychic, autonomic symptoms
- Combination of these
- Abnormal discharges remaining unilateral

Manifestations:

- Aversive seizure (most common motor seizure in children): Eye or eyes and head turn away from the side of the focus; awareness of movement or loss of consciousness
- Rolandic (Sylvan) seizure: Tonic-clonic movements involving the face, salivation, arrested speech; most common during sleep
- Jacksonian march (rare in children): Orderly, sequential progression of clonic movements beginning in a foot, hand, or face and moving, or “marching,” to adjacent body parts

Simple Partial Seizures with Sensory Signs

Uncommon in children younger than 8 years old

Characterized by various sensations, including:

- Numbness, tingling, prickling, paresthesia, or pain originating in one area (e.g., face or extremities) and spreading to other parts of the body
- Visual sensations or formed images
- Motor phenomena, such as posturing or hypertonia

Complex Partial Seizures (Psychomotor Seizures)

Observed more often in children from 3 years old through adolescence

Characterized by:

- Period of altered behavior

- Amnesia for event (no recollection of behavior)
- Inability to respond to environment
- Impaired consciousness during event
- Drowsiness or sleep usually following seizure
- Confusion and amnesia possibly prolonged
- Complex sensory phenomena (aura): Most frequent sensation is strange feeling in the pit of the stomach that rises toward the throat and is often accompanied by odd or unpleasant odors or tastes; complex auditory or visual hallucinations; ill-defined feelings of elation or strangeness (e.g., déjà vu, a feeling of familiarity in a strange environment); strong feelings of fear and anxiety; a distorted sense of time and self; and in small children, emission of a cry or attempt to run for help

Patterns of motor behavior:

- Stereotypic
- Similar with each subsequent seizure
- May suddenly cease activity, appear dazed, stare into space, become confused and apathetic, and become limp or stiff or display some form of posturing
- May be confused
- May perform purposeless, complicated activities in a repetitive manner (automatisms), such as walking, running, kicking, laughing, or speaking incoherently, most often followed by postictal confusion or sleep; may exhibit oropharyngeal activities, such as smacking, chewing, drooling, swallowing, and nausea or abdominal pain followed by stiffness, a fall, and postictal sleep; rarely manifests actions such as rage or temper tantrums; aggressive acts uncommon during seizure

Generalized Seizures

Tonic-Clonic Seizures (Formerly Known as Grand Mal)

Most common and most dramatic of all seizure manifestations

Occur without warning

Tonic phase lasts approximately 10 to 20 seconds

Manifestations:

- Eyes roll upward
- Immediate loss of consciousness
- If standing, falls to floor or ground
- Stiffens in generalized, symmetric tonic contraction of entire body musculature
- Arms usually flexed
- Legs, head, and neck extended
- May utter a peculiar piercing cry
- Apneic, may become cyanotic
- Increased salivation and loss of swallowing reflex

Clonic phase lasts about 30 seconds but can vary from only a few seconds to a half hour or longer

Manifestations:

- Violent jerking movements as the trunk and extremities undergo rhythmic contraction and relaxation
- May foam at the mouth
- May be incontinent of urine and feces

As event ends, movements less intense, occurring at longer intervals and then ceasing entirely

Status epilepticus: Series of seizures at intervals too brief to allow the child to regain consciousness between the time one event ends and the next begins

- Requires emergency intervention
- Can lead to exhaustion, respiratory failure, and death

Postictal state:

- Appears to relax

- May remain semiconscious and difficult to arouse
- May awaken in a few minutes
- Remains confused for several hours
- Poor coordination
- Mild impairment of fine motor movements
- May have visual and speech difficulties
- May vomit or complain of severe headache
- When left alone, usually sleeps for several hours
- On awakening, is fully conscious
- Usually feels tired and complains of sore muscles and headache
- No recollection of entire event

Absence Seizures (Formerly Called Petit Mal or Lapses)

Characterized by:

- Onset usually between 4 and 12 years old
- More common in girls than boys
- Usually cease at puberty
- Brief loss of consciousness
- Minimum or no alteration in muscle tone
- May go unrecognized because of little change in child's behavior
- Abrupt onset; suddenly develops 20 or more attacks daily
- Event often mistaken for inattentiveness or daydreaming
- Events possibly precipitated by hyperventilation, hypoglycemia, stresses (emotional and physiologic), fatigue, or sleeplessness

Manifestations:

- Brief loss of consciousness
- Appear without warning or aura
- Usually last about 5 to 10 seconds
- Slight loss of muscle tone may cause child to drop objects
- Ability to maintain postural control; seldom falls
- Minor movements such as lip smacking, twitching of eyelids or face, or slight hand movements
- Not accompanied by incontinence
- Amnesia for episode
- May need to reorient self to previous activity

Atonic and Akinetic Seizures (Also Known as Drop Attacks)

Characterized by:

- Onset usually between 2 and 5 years old
- Sudden, momentary loss of muscle tone and postural control
- Events recurring frequently during the day, particularly in the morning hours and shortly after awakening

Manifestations:

- Loss of tone causing child to fall to the floor violently
- Unable to break fall by putting out hand
- May incur a serious injury to the face, head, or shoulder
- Loss of consciousness only momentary

Myoclonic Seizures

A variety of seizure episodes

May be isolated as benign essential myoclonus

May occur in association with other seizure forms

Characterized by:

- Sudden, brief contractures of a muscle or group of muscles
- Occur singly or repetitively
- No postictal state
- May or may not be symmetric
- May or may not include loss of consciousness

Infantile Spasms

Also called *infantile myoclonus*, *massive spasms*, *hypsarrhythmia*, *salaam episodes*, or *infantile myoclonic spasms*

Most commonly occur during the first 6 to 8 months of life

Twice as common in boys as girls

Numerous seizures during the day without postictal drowsiness or sleep

Poor outlook for normal intelligence

Manifestations:

- Possible series of sudden, brief, symmetric, muscular contractions
- Head flexed, arms extended, and legs drawn up
- Eyes sometimes rolling upward or inward
- May be preceded or followed by a cry or giggling
- May or may not include loss of consciousness
- Sometimes flushing, pallor, or cyanosis

Infants who are able to sit but not stand:

- Sudden dropping forward of the head and neck with trunk flexed forward and knees drawn up—the *salaam* or *jackknife* seizure

Less often: Alternate clinical forms

- Extensor spasms rather than flexion of arms, legs, and trunk, and

head nodding

- Lightning events involving a single, momentary, shock-like contraction of the entire body

TABLE 27-3

Comparison of Simple Partial, Complex Partial, and Absence Seizures

| Clinical Manifestations | Simple Partial | Complex Partial | Absence |
|-------------------------|--------------------------------------|---|---|
| Age of onset | Any age | Uncommon before 3 years old | Uncommon before 3 years old |
| Frequency (per day) | Variable | Rarely over one or two times | Multiple |
| Duration | Usually <30 seconds | Usually >60 seconds, rarely <10 seconds | Usually <10 seconds, rarely >30 seconds |
| Aura | May be sole manifestation of seizure | Frequent | Never |
| Impaired consciousness | Never | Always | Always; brief loss of consciousness |
| Automatisms | No | Frequent | Frequent |
| Clonic movements | Frequent | Occasional | Occasional |
| Postictal impairment | Rare | Frequent | Never |
| Mental disorientation | Rare | Common | Unusual |

Diagnostic Evaluation

Establishing a diagnosis is critical for making a prognosis and planning appropriate treatment. The process of diagnosis in a child suspected of having had a seizure(s) or having epilepsy includes first determining whether the events thought to be seizures are epileptic seizures or non-epileptic events (NEEs) and then identifying the underlying cause, if possible. The assessment and diagnosis rely heavily on a thorough history, skilled observation, and several diagnostic tests.

It is important to differentiate epilepsy from other brief alterations in consciousness or behavior. Clinical entities that mimic seizures include staring, migraine headaches, toxic effects of drugs, syncope (fainting), breath-holding spells in infants and young children, movement disorders (tics, tremor, chorea), prolonged QT syndrome and other cardiac arrhythmias, sleep disturbances (night terrors), psychogenic seizures, rage attacks, and transient ischemic attacks (rare in children). The toxic effects of maternal drug use and withdrawal from these drugs should be considered in the differential diagnosis of new-onset seizure activity in a newborn.

A detailed description of the seizure should be obtained from the caregiver(s) who witnessed it. Ask questions about the child's behavior during the event, especially at the onset, and the time at which the seizure occurred (e.g., early morning, while awake, or during sleep). Any factors that may have precipitated the seizure are important, including fever, infection, head trauma, anxiety, fatigue, sleep deprivation, menstrual cycle, alcohol, and activity (e.g., hyperventilation or exposure to strong stimuli such as bright flashing light or loud noises). Record any sensory phenomena that the child can describe and if the child was able to hear during the seizure. The duration and progression of the seizure (if any) and the postictal feelings and behavior (e.g., confusion, inability to speak, amnesia, headache, and sleep) should also be noted. For children who have epilepsy, document how often they have seizures: daily, weekly, or monthly. Knowing the age of the child when they had their first seizure is important. It is important to determine whether more than one seizure type exists. It is often more informative to ask the parents to show you what the seizure looked like rather than relying on their verbal description. Demonstrating a seizure often reveals features, such as head turning, that would otherwise go unrecognized. Some seizures are overlooked by parents. For example, some parents may not identify brief head nods or brief single jerks as seizures unless specifically asked whether their child has these symptoms.

A thorough medical history must be obtained beginning with conception. Questions to consider include: Was the mother's pregnancy complicated by illness and drug use, either prescribed or recreational? How old was the baby when discharged from the hospital after birth? Has the child had any overnight hospitalizations or surgeries? A complete history is designed to uncover possible risk factors for the development of seizures or epilepsy.

The family history should include whether other family members have ever had a seizure of any kind, cognitive impairments, cerebral palsy, autism, or other neurologic disorders. Ask if there is a family history of sudden, unexpected deaths. A family history can offer clues to paroxysmal disorders, such as migraine headaches, breath-holding spells, febrile seizures, or neurologic diseases.

A complete physical and neurologic examination, including developmental assessment of

language, learning, behavior, and motor abilities, may provide clues to the cause of the seizures. A number of laboratory and neuroimaging tests may be ordered depending on the child's age, whether it is a new-onset seizure, characteristics of the seizure, and the history. Laboratory studies that may prove valuable include a white blood cell count (for signs of infection) and blood glucose measurements that may indicate hypoglycemic episodes. Serum electrolytes, blood urea nitrogen, calcium, serum amino acids, lactate, ammonia, and urine organic acids may indicate metabolic disturbances. Blood for chromosomal analysis may also be tested if a genetic etiology is suspected. A toxic screen should be performed if alcohol or drug ingestion or withdrawal is suspected. Lumbar puncture can confirm a suspected diagnosis of meningitis. CT may be done to detect a cerebral hemorrhage, infarctions, brain tumors, and gross malformations. MRI provides greater anatomic detail and is used to detect developmental malformations, tumors, and cortical dysplasias.

Most children with seizures will have an EEG. The EEG is the most useful tool for evaluating the child's risk of recurrent seizures, helping to determine the type of seizure the child had, and diagnosing the type of epilepsy. The EEG confirms the presence of abnormal electrical discharges and provides information on the seizure type and the focus. The EEG is carried out under varying conditions—with the child asleep, awake, awake with provocative stimulation (flashing lights, noise), and hyperventilation. Stimulation may elicit abnormal electrical activity, which is recorded on the EEG. Various seizure types produce characteristic EEG patterns: high-voltage spike discharges are seen in tonic-clonic seizures with abnormal patterns in the intervals between seizures; a three-per-second spike and wave pattern is observed in an absence seizure; and absence of electrical activity in an area suggests a large lesion, such as an abscess or subdural collection of fluid.

A normal EEG does not rule out seizures. The EEG is only a surface recording, lasts approximately 1 hour, and therefore may show normal interictal activity. If there is concern about whether a child has seizures or the seizure type cannot be determined, then a long-term video EEG may be done to record the child during wakefulness and sleep. The full-body image is recorded on video, with selected EEG channels displayed on the same screen for simultaneous recording and viewing. Amplitude-integrated electroencephalography (aEEG) monitoring is increasingly available in neonatal and pediatric intensive care units. This is a method of continuous monitoring of brain activity using recordings from a handful of leads as compared to the 24 leads of standard EEGs. aEEG is useful for diagnosing seizures when standard EEG or a neurophysiologist to interpret it is unavailable. Nurses in a variety of settings are now being taught how to place aEEG leads and obtain recordings. Although the EEG is valuable, it should not be used alone to determine the type of seizure. Rather, the EEG interpretation with a thorough clinical description of the child's behavior during the seizure will inform the correct classification of the seizure and the appropriate treatment choice.

Therapeutic Management

The goal of treatment of seizures and epilepsy is to control the seizures or to reduce their frequency and severity so that the child may live as normal a life as possible. Discovering and, when possible, correcting the underlying cause of the seizures can lead to complete control of all seizures. If the seizure activity is a manifestation of an infectious, traumatic, or metabolic process, the seizure therapy is instituted as part of the general therapeutic regimen. There are four treatment options for epilepsy: drug therapy, ketogenic diet therapy, vagus nerve stimulation (VNS), and epilepsy surgery.

Drug Therapy

It is known that persons predisposed to epilepsy have seizures when their basal level of neuronal excitability exceeds a critical point; no event occurs if the excitability is inhibited and remains below this seizure threshold. The administration of antiepileptic drugs serves to raise this threshold and prevent seizures. Consequently, the primary therapy for seizure disorders is the administration of the appropriate antiepileptic drug or combination of drugs in a dosage that provides the desired effect without causing adverse side effects or toxicity. Antiepileptic drugs are believed to exert their effect primarily by reducing the responsiveness of neurons to the sudden, high-frequency nerve impulses that arise in the epileptogenic focus. Thus, the seizure is effectively suppressed; however, the abnormal brain waves may or may not be altered. The chance of total control of seizures depends on the underlying cause of the seizures.

The initiation of anticonvulsant therapy is based on several factors, including the child's age, type of seizure, risk of recurrence, and other comorbid or predisposing medical issues. For children who develop recurrent seizures or epilepsy, treatment is begun with a single drug known to be effective for the child's seizure type and have the lowest risk of adverse side effects. The dosage is gradually increased until the seizures are controlled or the maximum recommended dose has been reached and seizures are still not controlled. If a child develops intolerable side effects, the medication is stopped and another one tried. If the drug reduces but does not stop all seizures, a second drug is added in gradually increasing doses. When seizures are controlled, the first drug may be tapered to reduce the potential adverse effects and drug interactions of polytherapy. Monotherapy remains the treatment method of choice for epilepsy, but a combination of medications may be a viable alternative for children who cannot attain seizure control with only one medication (Mikati and Hani, 2016).

A serious potential adverse side effect of antiepileptic medication is allergic drug rash. The rash can start with hives and is usually very itchy. Allergic drug rashes from antiepileptic drugs can spread quickly and become severe, life-threatening events. The drug should be stopped with any rash. A physician or nurse practitioner should evaluate the child within 24 hours or sooner if the child develops edema or respiratory problems. Treatment includes antihistamines, epinephrine, glucocorticoids, anabolic steroids, and/or airway management depending on the severity of the reaction (Blaszczyk, Lasorí, and Czuczwar, 2015).

Sleepiness, changes in mood or behavior, vision changes, and ataxia are some of the potential side effects of antiepileptic medications. These are very distressing to both children and families. They often disappear over time or when drug dosages are reduced. Blood cell counts, urinalysis, and liver function tests are obtained at regular intervals in children receiving particular antiepileptic medications that can affect organ function.

If complete seizure control is maintained on an antiepileptic drug for 2 years, it may be safe to slowly discontinue the drug for patients with no risk factors. Risk factors for recurrence of seizures include older age at onset, numerous seizures before control is achieved, presence of a neurologic dysfunction (e.g., motor or cognitive impairment), and the characteristics of epilepsy syndrome (Verrotti, D'Egidio, Agostinelli, et al, 2012). Recurrence occurs most often within the first year of discontinuation (Braun and Schmidt, 2014). When seizure medications are discontinued, the dosage is decreased gradually over weeks or months. Sudden withdrawal of a drug is not recommended because it can cause seizures, which may be longer and more intense than previously, to recur.

Drug Alert

Intravenous (IV) fosphenytoin is often used to treat seizures instead of IV phenytoin because of possible complications and drug interactions associated with IV phenytoin. If IV phenytoin is used, it should be administered via slow IV push at a rate that does not exceed 50 mg/min. Because phenytoin precipitates when mixed with glucose, only normal saline is used to flush the tubing or catheter. Fosphenytoin may be given in saline or glucose solutions at a rate of up to 150 mg phenytoin equivalent (PE)/min. It may be given intramuscularly if necessary.

Ketogenic Diet

The ketogenic diet is a high-fat, low-carbohydrate, and adequate protein diet (Kossoff, 2013). Consumption of the ketogenic diet forces the body to shift from using glucose as the primary energy source to using fat, and the individual develops a state of ketosis. Ketones can be measured in both the child's urine and blood. The mechanism(s) of action remain unclear. The diet is rigorous. All foods and liquids the child consumes must be carefully weighed and measured. There is a liquid formula available for children who cannot take solid foods. The diet is deficient in vitamins and minerals; therefore, vitamin and mineral supplementation is necessary. Potential adverse side effects include constipation, hypoglycemia while the diet is initiated, dehydration, acidosis, and lethargy. Less common but more serious side effects include urinary tract infections, kidney stones, and insufficient weight gain (Kossoff, 2013).

The ketogenic diet has been shown to be an effective and tolerable treatment for medically refractory seizures with seizure control comparable to antiepileptic drugs in some children. In a meta-analysis of the ketogenic diet, at least 38% of children had a 50% reduction in seizures for at least a year (Levy, Cooper, and Giri, 2012).

Vagus Nerve Stimulation

VNS was developed as palliative treatment for patients with seizures not controlled by drugs and who are not candidates for diet or surgical therapy (Moshé, Perucca, Ryvlin, et al, 2015). It is currently indicated as adjunct therapy in patients 12 years old and older with partial-onset seizures (with or without secondary generalization) who are refractory to antiepileptic drugs (Elliott, Rodgers, Bassani, et al, 2011). A programmable signal generator is implanted subcutaneously in the chest. Electrodes tunneled underneath the skin deliver electrical impulses to the left vagus nerve (CN X). The device is programmed noninvasively to deliver a precise pattern of stimulation to the left vagus nerve. The patient or caregiver can activate the device using a magnet at the onset of a seizure. No long-term adverse effects have been reported with VNS, but dysphonia, throat or neck pain, and cough can occur during stimulation. Studies show that about one third to one half of patients have a reduction in seizures after 1 year of therapy (Elliott, Rodgers, Bassani, et al, 2011).

Surgical Therapy

When seizures are determined to be caused by a hematoma, vascular malformation, or tumor, surgical removal is usually recommended. Epilepsy surgery is the most effective treatment for children with medically refractory epilepsy due to focal cortical dysplasia and mesial temporal sclerosis. About 80% of these patients will be seizure-free 4 years after surgery (Moosa and Gupta, 2014). Refractory seizures are usually defined as the persistence of seizures despite adequate trials of three antiepileptic medications, alone or in combination (Télez-Zenteno, Hernández-Ronquillo, Buckley, et al, 2014). Epilepsy surgery does not always eliminate the need for antiepileptic drug therapy. The goal is to improve seizure control without worsening or producing serious deficits. Some children will see improvements in their cognition, behavior, and quality of life (Ryvlin, Cross, and Rheims, 2014). Types of surgeries include focal resection of the epileptogenic focus, functional hemispherectomy, and corpus callosotomy which severs the connection between the hemispheres.

Status Epilepticus

Status epilepticus is a continuous seizure that lasts more than 30 minutes or a series of seizures from which the child does not regain a premorbid LOC (Huff and Fountain, 2011). It has been suggested that the term *impending status epilepticus* be used for a continuous seizure or series of seizures lasting between 5 and 30 minutes with the designation of *impending status* indicating that treatment should begin after 5 minutes of seizure activity (Freilich, Schreiber, Zelleke, et al, 2014). The initial treatment is directed toward support of vital functions, that is, the CAB of life support, measuring blood glucose, administering oxygen, and gaining IV access, immediately followed by IV administration of antiepileptic agents (Dulac and Takahashi, 2013). Simultaneously with life support measures and emergency medications, the underlying cause of the status epilepticus is identified and corrected (Abend and Loddenkemper, 2014). Buccal or intranasal midazolam, buccal lorazepam, and rectal diazepam are simple, effective, and safe treatments for home or prehospital treatment of status epilepticus (Shorvon, 2011). Cessation of seizure occurs in approximately 8 minutes with buccal midazolam and 15 minutes with rectal diazepam (Shorvon, 2011). Respiratory depression is a potential side effect of these medications when more than two doses are given (Abend and Loddenkemper, 2014); however, respiratory depression is not a side effect of rectal diazepam when it is administered as recommended (Shorvon, 2011). Intranasal midazolam is safe and effective for stopping seizures and also easier to administer than rectal diazepam or buccal lorazepam.

For in-hospital management of status epilepticus, IV lorazepam (Ativan) is the first-line drug of choice (Abend and Loddenkemper, 2014). Lorazepam is the preferred agent because of its rapid onset (2 to 5 minutes) and long half-life (12 to 24 hours). If IV access has not been established, rectal diazepam or intramuscular (IM), intranasal, or buccal midazolam should be given (Abend and Loddenkemper, 2014). The child must be closely monitored during administration to detect early alterations in vital signs that may indicate impending respiratory depression. When a benzodiazepine (diazepam or lorazepam) is ineffective, IV phenytoin or fosphenytoin or IV phenobarbital is given as the next line of treatment. This combination of therapy places the child at high risk for apnea; respiratory support is generally necessary. Children may also receive other antiepileptic medications including IV valproate or levetiracetam. Children who continue to have seizures despite this drug treatment may require general anesthesia with a continuous infusion of midazolam, propofol, or pentobarbital (Abend and Loddenkemper, 2014). In this situation, the child

will need to be intubated and continuous EEG monitoring begun to monitor for and treat electrographic seizures (Abend and Loddenkemper, 2014).

Nursing care of a child with status epilepticus includes, in addition to the CABs of life support, monitoring blood pressure and body temperature. During the first 30 to 45 minutes of the seizure, the blood pressure may be elevated. Thereafter, the blood pressure typically returns to normal but may be decreased depending on the medications being administered for seizure control. Hyperthermia requiring treatment may occur as a result of increased motor activity. Status epilepticus is a medical emergency that requires immediate intervention to prevent possible brain injury and death. Diagnosis and correction of the underlying cause of the status epilepticus is essential.

Prognosis

Only about half of children who experience a first seizure will experience additional seizures (El-Radhi, 2015). Therefore children who have had a single seizure are not diagnosed with epilepsy and rarely started on antiepileptic drugs. Children with cerebral palsy and/or cognitive impairments are at highest risk of developing epilepsy. Prognosis for eventual remission of childhood epilepsy depends on the etiology and epilepsy syndrome diagnosis. Some syndromes almost always remit, whereas others almost never do (Camfield and Camfield, 2014). Intractable seizures are failure to control seizures after two appropriately selected antiepileptic medications are trialed (Wassenaar, Leijten, Egberts, et al, 2013). Most mortality in children with epilepsy is due to factors associated with a child's coexisting neurological conditions and poorly controlled seizures (Berg and Rychlik, 2015). Deaths from epilepsy in children who have no other neurological conditions occur at the same rate as childhood deaths from other causes, such as accidents (Nickels, Grosshardt, and Wirrell, 2012).

Quality Patient Outcomes: Seizures

- Etiology of seizure determined
- Seizures controlled or reduced in frequency and severity
- Family and child receive education to manage seizures
- Child adhering to treatment
- Side effects of treatment minimized
- No physical injury as a result of seizure activity

Nursing Care Management

An important nursing responsibility is to observe the seizure episode and accurately document the events. Any alterations in behavior preceding the seizure and the characteristics of the episode, such as sensory-hallucinatory phenomena (e.g., an aura), motor effects (e.g., eye movements, muscular contractions), alterations in consciousness, and postictal state (e.g., behavior after the seizure), are noted and recorded (Box 27-8). The nurse should describe only what is observed rather than trying to label a seizure type. Note the duration of the seizure.

Box 27-8

General Observations

The Child During a Seizure

Observations During Seizure

Describe

Order of events (before, during, and after)

Duration of seizure

- Tonic-clonic: From first signs of event until jerking stops
- Absence: From loss of consciousness until consciousness is regained
- Complex partial: From first sign of unresponsiveness, motor activity, and automatisms until there are signs of responsiveness to environment

Onset

Time of onset

Significant precipitating events: Missed medication dosage, illness, stress, sleep deprivation, menses

Behavior

Change in facial expression

Cry or other sound

Stereotypic or automatous movements

Random activity (wandering)

Position of eyes, head, body, extremities

Unilateral or bilateral posturing of one or more extremities

Movement

Change of position, if any

Site of commencement: Hand, thumb, mouth, generalized

Tonic phase: Length, parts of body involved

Clonic phase: Twitching or jerking movements, parts of body involved, sequence of parts involved, generalized, change in character of movements

Lack of movement or muscle tone of body part or entire body

Face

Color change: Pallor, cyanosis, flushing

Perspiration

Mouth: Position, deviating to one side, teeth clenched, tongue bitten, frothing at mouth, flecks of blood or bleeding

Lack of expression

Asymmetric expression

Eyes

Position: Straight ahead, deviation upward or outward, conjugate or divergent gaze

Pupils: Change in size, equality, reaction to light

Respiratory Effort

Presence and length of apnea

Other

Incontinence

Postictal Observations

Duration of postictal period

State of consciousness

Orientation

Arousability

Motor ability

- Any change in motor function
- Ability to move all extremities
- Paresis or weakness

Speech

Sensations

- Complaint of discomfort or pain
- Any sensory impairment
- Recollection of pre-seizure sensations or aura

Based on a thorough assessment, several nursing diagnoses are identified. The more common diagnoses for the child with a seizure disorder are included in the [Nursing Care Plan box](#).

Nursing Care Plan

The Child with Seizures

Case Study

Jacob is a 7-year-old male who was playing during physical education class at school when he suddenly stopped his activity, stared into space, repetitively moved his left arm up and down, and smacked his lips. After approximately 1 minute, he stopped the behavior and was drowsy but responsive to his environment. Jacob had no memory of the event. Jacob was accompanied to the

school nurse by his teacher for further assessment.

Assessment

Based on these events, what are the most important subjective and objective data that should be assessed?

Seizure Defining Characteristics

From patient:

Aura

Sensory phenomena that the child can describe during the event (i.e., ability to hear)

Postictal feelings (i.e., confusion, inability to speak, amnesia, headache, sleepiness)

From person who observed the seizure:

Time of onset of seizure

Duration of seizure

Change in level of consciousness (LOC) before, during, and after the seizure

Movements (ask for demonstration of the seizure rather than relying on verbal description)

From parent or primary caregiver:

Previous seizures

Family history of seizures

Recent illness

Current medications

Nursing Diagnosis

Risk for injury

Risk for aspiration

Risk for ineffective coping

Nursing Interventions

What are the most appropriate nursing interventions for a child with seizures?

| Nursing Interventions | Rationale |
|---|--|
| Monitor time (onset and duration), movements, and LOC during seizure. | To provide an accurate description of the seizure, including the order of events before, during, and after the seizure |
| If child is at risk of falling, ease child to floor. Prevent child from hitting head on objects. Do not attempt to restrain child or use force. | To prevent physical harm |
| During seizure, place child in a side-lying position on a flat surface such as floor. Do not put anything in child's mouth. | To prevent possible aspiration |
| Stay with the child and reassure the child when awakening from seizure. | To decrease child's anxiety and fear |
| Evaluate postictal feelings. | To provide accurate description of the postictal state |
| Ensure antiepileptic drugs are being administered as directed. | To prevent further seizure activity |
| Involve child and parents in discussion of fears, anxieties, and resources and support options available to patient and family. | To promote coping by discussing fear and anxieties and encouraging participation in support resources |

Expected Outcomes

Child will not experience physical injury as a result of seizure activity.

Child's airway will remain patent.

Parent and child will cope with the condition and receive adequate support.

Case Study (Continued)

The following week, Jacob had another seizure while playing with his siblings in the backyard. His brother ran inside to get help and Jacob's mother ran outside to see Jacob staring into space with his head turned to the side and his left arm moving rhythmically up and down. This activity stopped for a few seconds then started back again. Jacob did not regain consciousness in between the episodes and was unable to speak. Jacob's mother called for emergency assistance (911), and Jacob was transported to a nearby hospital. Jacob had not regained consciousness during the transport.

Assessment

What are the most important signs and symptoms based in this child?

Status Epilepticus Defining Characteristics

Series of seizure activity

Lack of consciousness between seizures

Do the findings described in the case study concern you?

The fact that the child is not regaining a premorbid LOC between seizures is concerning and meets criteria for a diagnosis of status epilepticus. The child's circulation, airway, and breathing (CAB) should be monitored closely and supportive measures initiated (i.e., cardiopulmonary resuscitation) when indicated.

Nursing Diagnosis

Risk for impaired breathing pattern

Risk for aspiration

Risk for injury

Risk for imbalanced body temperature

Risk for impaired cardiovascular function

Nursing Interventions

What are the most appropriate nursing interventions for Jacob?

| Nursing Interventions | Rationale |
|--|---|
| Monitor circulation, airway, and breathing (CAB) closely. | To provide supportive measures as needed to maintain airway, breathing, and circulation |
| Monitor and record characteristics, onset, and duration of each episode including motor effects, | To accurately describe the seizure activity and postictal state |

| | |
|---|---|
| alterations in consciousness, postictal state. | |
| Do not attempt to stop the seizure; ease the child to the floor if upright. A child in a wheelchair usually has adequate support and padding and does not need to be removed. Side rails should be padded for a child on a stretcher. | To prevent injury during seizure |
| Place child in a side-lying position; suction the oral cavity and posterior oropharynx as needed. | During seizures, the swallowing reflex may be lost, salivation may increase, and the tongue is hypotonic, which causes the child to be at risk for aspiration and airway occlusion. |
| Administration of antiepileptic medications <ul style="list-style-type: none"> • During transport: buccal or intranasal midazolam, buccal lorazepam, rectal diazepam • Upon arrival to the hospital: Intravenous (IV) lorazepam, valproate, or levetiracetam | To decrease or stop the seizure activity |
| Closely monitor vital signs including temperature, respirations, heart rate, and blood pressure. | Hyperthermia and hypertension are a common result of increased motor activity. In addition, side effects from the medications may cause respiratory depression. |
| If possible, isolate the child from view of others by closing door or curtain. | To maintain privacy for the child and family and to minimize distress to the family, and other visitors |
| Perform diagnostic testing as indicated. | To determine the underlying cause of status epilepticus |

Expected Outcome

Child will have effective ventilation.

Child's airway will remain patent.

Child will not experience physical injury as a result of seizure activity.

Child's body temperature will remain in acceptable range

Child's blood pressure will remain normal for age

Case Study (Continued)

Jacob's parents are anxious and upset with the seizures. You are concerned that they do not understand what is happening to their son.

Assessment

What are the most important aspects of care to discuss with her parents at this time?

Family's Knowledge of Illness-Defining Characteristics

Understands definition of seizure and status epilepticus

Describes measures implemented to prevent harm during seizure

Describes treatment regimen including rationale for medications

Expresses fears and concerns

Shows appropriate reactions to child's condition

Nursing Diagnosis

Readiness for enhanced knowledge related to parents' interest in Jacob's health status.

Nursing Interventions

What are the most appropriate nursing interventions for this diagnosis?

| Nursing Interventions | Rationale |
|--|--|
| Educate family about characteristics of seizures including aura, seizure activity, and postictal state. | To promote understanding of seizures, including signs of impending seizure and characteristics to monitor during and after seizure |
| Educate family about safety precautions before and during a seizure including side-lying positioning, padding area if needed, and not placing items in mouth or attempting to stop the seizure. | To promote understanding of measures needed to protect child from harm |
| Educate family about Jacob's medication administration including scheduled and as needed (prn) medications and potential side effects of medications. | To promote understanding of medications including monitoring for side effects |
| Arrange for social worker to meet with family to assess emotional and financial needs. Consider consultation with child life specialist to assist with education of school personnel and classmates. | To identify and modify stressors associated with chronic illnesses and to assist with re-entry into school |
| Educate family about Jacob's daily care including the following: <ul style="list-style-type: none"> • Have child wear medical identification. • Always swim with a companion. • Shower preferred and bathe only with close supervision. • Use protective helmet and padding during bicycle riding, skateboarding, and in-line skating. | To promote understanding of safety measures for daily life |

Expected Outcomes

Parents verbalize understanding of seizure and status epilepticus and necessary monitoring.

Parents verbalize safety measures for daily living and during seizure activity.

Parents verbalize understanding of medications, including schedule, route, and potential side

effects.

Parents verbalize resources available for emotional, financial, and school support as indicated.

The child must be protected from injury during the seizure. Nursing observations made during the event provide valuable information for diagnosis and management of the disorder (see [Emergency Treatment box](#)).

Emergency Treatment

Seizures

Tonic-Clonic Seizure

During the Seizure

Remain calm.

Time seizure episode.

If child is standing or seated, ease child down to the floor.

Turn child to one side.

Place pillow or folded blanket under child's head.

Loosen restrictive clothing.

Remove eyeglasses.

Clear area of any hazards or hard objects.

Allow seizure to end without interference.

Do not:

- Attempt to restrain child or use force to control their movements.
- Put anything in child's mouth.
- Give any food or liquids.

After the Seizure

Time postictal period.

Check for breathing. Check position of head and tongue.

Reposition if head is hyperextended.

If child is not breathing, give rescue breathing and call EMS.

Keep child on side.

Remain with child.

Do not give food or liquids until child is fully alert and swallowing reflex has returned.

Look for medical identification and determine what factors occurred before onset of seizure that might have been triggers for seizure onset.

Check head and body for possible injuries.

Check inside of mouth to see if tongue or lips have been bitten.

Complex Partial Seizure

During the Seizure

Do not restrain the child's movements.

Remove harmful objects from area.

Redirect to safe area.

Talk in calm, reassuring manner.

Do not expect child to follow instructions.

Watch to see if seizure generalizes.

After the Seizure

Stay with child and reassure until fully conscious.

Call Emergency Medical Services

Call EMS if:

- Child stops breathing.
- There is evidence of injury or child is diabetic or pregnant.
- Seizure lasts for more than 5 minutes (unless duration of seizure is typically longer than 5 minutes) and written medical order is present.
- Seizures continue for more than 10 minutes after administration of rescue medication.
- Status epilepticus occurs.
- Pupils are not equal after seizure.
- Child vomits continuously 30 minutes after seizure has ended (sign of possible acute problem).
- Child cannot be awakened and is unresponsive to pain after seizure has ended.

- Seizure occurs in water.
- This is child's first seizure.

EMS, Emergency medical services.

Modified from *Seizure recognition and first aid*, 2013, Epilepsy Foundation, <http://www.epilepsy.com/learn/treating-seizures-and-epilepsy/seizure-first-aid>.

It is impossible to physically stop a seizure once it has begun, and no attempt should be made to do so. The nurse must remain calm, stay with the child, and prevent the child from harm during the seizure. If possible, isolate the child from the view of others by closing a door or curtain. A seizure can be upsetting to the child, other visitors, and their families. If other persons are present, they should be assured that everything is being done for the child. After the seizure, they can be given a simple explanation about the event as needed.

If the nurse is able to reach the child in time, a child who is standing or seated in a chair is eased to the floor immediately. Do not remove a child from a wheelchair as the wheelchair provides support and padding. During (and sometimes after) a tonic-clonic seizure, the swallowing reflex is lost, salivation increases, and the tongue is hypotonic. Therefore, the child is at risk for aspiration and airway occlusion. Placing the child on the side facilitates drainage and helps maintain a patent airway. Suctioning the oral cavity and posterior oropharynx may be necessary. Take vital signs, and allow the child to rest if at school or away from home. When feasible, the child is integrated into the environment as soon as possible. Sending a child with a chronic seizure disorder home from school is not necessary unless requested by the parents.

Seizure precautions are required for children who have a history of seizures (Box 27-9).

Nursing Alert

Do not move or forcefully restrain the child during a tonic-clonic seizure, and do not place anything in the mouth during a seizure.

Box 27-9

Seizure Precautions

The extent of precautions depends on type, severity, and frequency of seizures. They may include:

- Side rails raised when child is sleeping or resting
- Side rails and other hard objects padded
- Waterproof mattress or pad on bed or crib

Appropriate precautions during potentially hazardous activities may include:

- Swimming with a companion
- Showers preferred; bathing only with close supervision
- Use of protective helmet and padding during bicycle riding, skateboarding, in-line skating

- **Supervision during use of hazardous machinery or equipment**

Have child carry or wear medical identification.

Alert other caregivers to need for any special precautions.

Child may not drive or operate hazardous machinery or equipment unless seizure free for designated period (varies by state).

Long-Term Care

Care of the child with epilepsy involves physical care and instruction regarding the importance of adherence to the treatment plan. Probably more significant is education and support regarding the potential for the development of psychosocial, educational, and emotional problems in children with epilepsy and their families. Few diseases generate as much anxiety among families, friends, and school personnel as epilepsy. Fears and misconceptions about the disease and its treatment are common. For many, it represents the archetype of severe hereditary affliction. Nursing care is directed toward educating the child and family about epilepsy, helping them develop strategies for coping with the psychosocial problems related to epilepsy, and directing them to resources for children and families living with epilepsy.

Children with epilepsy are prescribed antiepileptic medications, which are administered at regular intervals to maintain adequate levels in the blood. The nurse can help the parents plan the administration of the medication at convenient times, usually breakfast and dinner or bedtime, to make taking the medication as easy as possible. It is important to talk with the family about the importance of giving the antiepileptic medication as scheduled to prevent recurrent seizures. Usually, antiepileptic medications are continued until the child has been seizure free for 2 years (Braun and Schmidt, 2014). The medication is then slowly tapered over a period of weeks to decrease the possibility of precipitating a seizure. It is sometimes easy to skip doses or omit them for a variety of reasons, especially when the child is free of seizures most of the time. This is particularly so when the child is older and assumes responsibility for his or her medication. The seizure threshold may be lowered during any illness but particularly with fever. Therefore, parents should be aware that if their child has an illness, he or she is at increased risk for seizures. Parents should contact their health professional if their child misses medications during an illness because of vomiting.

Rectal preparations of some antiepileptic medications are highly effective when a child is unable to take oral medications because of repeated vomiting, surgery, or status epilepticus. Parents can learn to administer rectal antiepileptic medication for home treatment. Buccal and intranasal midazolam or rectal diazepam are useful adjunctive home treatment for children at risk for prolonged seizures or clusters of seizures and can minimize the need for hospitalization while enhancing parental confidence.

Drug Alert

Children taking phenobarbital or phenytoin should receive adequate vitamin D and folic acid because deficiencies of both have been associated with these drugs. Phenytoin should not be taken with milk.

Nurses should educate the child and parents about the possible adverse reactions to the medications used to treat seizures. Parents must understand the rare but potentially serious side effect of allergic reaction to the medication. They must immediately report rashes to the child's health care provider. More common but less serious potential side effects include excessive sleepiness, changes in appetite, and worsening behavior and mood. Parents should be encouraged to share their observations with their child's health care provider. Parents should understand that the child needs periodic physical assessment. Depending on the medication prescribed, some children will need regular testing of their complete blood count and liver functions. Possible adverse effects on the hematopoietic system, liver, and kidneys may be reflected in symptoms, such as fever, sore throat, enlarged lymph nodes, jaundice, and bleeding (e.g., easy bruising, petechiae, ecchymosis, and epistaxis). The most common cause of status epilepticus in children taking

antiepileptic medications is missed medication.

Children with epilepsy are not at increased risk for injury with the exception of head injury (Baca, Vickrey, Vassar, et al, 2013). The degree to which activities are restricted is individualized for each child and depends on the type, frequency, and severity of the seizures; the child's response to therapy; and the length of time the seizures have been controlled. To prevent head injuries, children should always wear helmets and other safety devices when participating in sports, such as biking, skiing, skateboarding, horseback riding, and in-line skating. Only children with frequent seizures must avoid these activities. Children with epilepsy should avoid activities involving heights, such as climbing on play structures taller than they are. Submersion injuries are a serious risk for children with a history of seizures. Children should never be left alone in the bathtub, even for a few seconds. Older children and adolescents should be encouraged to use a shower and reminded not to lock the bathroom door when showering. They must have eyes-on supervision at all times when swimming.

Because the child is encouraged to attend school, camp, and other normal activities, the school nurse and teachers should be made aware of the child's condition and therapy. They can help ensure regularity of medication administration and provision of any special care the child might need. Teachers, child care providers, camp counselors, youth organization leaders, coaches, and other adults who assume responsibility for children should be instructed regarding care of the child during a seizure so that they can react calmly, provide for the child's safety, and influence the attitude of the child's peers.

Triggering Factors

Careful and detailed documentation of seizures over time may indicate a pattern of seizures. About half of the people 12 years old and older with epilepsy can recognize at least one trigger for their seizures (Wassenaar, Kasteleijn-Nolst Trenité, de Haan, et al, 2014). When this occurs, the child, nurse, or responsible adult can intervene to make changes in the lifestyle or environment that may prevent seizures or decrease their frequency. Often the necessary changes are simple but can make an enormous difference in the lives of the child and family.

The most common factors that may trigger seizures in children include physical psychological stress, sleep deprivation, fever, and illness (Novakova, Harris, Ponnusamy, et al, 2013). Other precipitating factors include flickering lights, menstrual cycle, and alcohol (Wassenaar, Kasteleijn-Nolst Trenité, de Haan, et al, 2014). Some individuals have pattern- or photo-sensitive epilepsy, that is, seizures precipitated by changes in dark/light patterns, such as those that occur with a flash on a camera, automobile headlights, reflections of light on snow or water, or rotating blades on a fan. Most of these individuals have absence, myoclonic, or generalized tonic-clonic seizures. A small minority of children have seizures while playing video games. Only these children need to be restricted from playing video games.

Febrile Seizures

A febrile seizure is a seizure associated with a febrile illness in a child who does not have a CNS infection. By definition, children who have a febrile seizure cannot have a history of neonatal or unprovoked seizures (Syndi Seinfeld and Pellock, 2013). Febrile seizures are the single most common seizure type, occurring in 2% to 5% of children between the ages of 1 month and 5 years (Syndi Seinfeld and Pellock, 2013).

There is evidence for both genetic and environmental causes for febrile seizures. Children with a family history of febrile seizures are at increased risk for both a single febrile seizure (10% to 46%) and for recurrent febrile seizures (Saghazadeh, Mastrangelo, and Rezaei, 2014). Environmental factors that have been implicated include viral illness and an age of younger than 18 months old (Mewasingh, 2014).

Most febrile seizures have stopped by the time the child is taken to a medical facility and require no treatment. Once the seizure continues for more than 5 minutes, it is likely that it will continue for some time (Seinfeld, Shinnar, Sun, et al, 2014). Initial treatment consists of administering a benzodiazepine: IV lorazepam; IV or rectal diazepam; or IV, buccal, or intranasal midazolam (Bassan, Barzilay, Shinnar, et al, 2013). The majority of children with febrile status epilepticus will require administration of multiple antiepileptic medications for seizure control (Seinfeld, Shinnar, Sun, et al, 2014). Antipyretic therapies will not prevent a seizure and are ineffective at lowering the

temperature of a fever that leads to a febrile seizure (Rosenbloom, Finkelstein, Adams-Webber, et al, 2013). Tepid sponge baths are not recommended for several reasons: they are ineffective in significantly lowering the temperature, the shivering effect further increases metabolic output, and cooling causes discomfort to the child. Parental education and emotional support are important interventions. Information may need to be repeated depending on the parents' anxiety and education level. Parents need reassurance that children who have had febrile seizures but do not have underlying developmental problems will perform as well as other children academically and behaviorally (Graves, Oehler, and Tingle, 2012).

There is no indication for the use of daily prophylactic antiepileptic medication for febrile seizures because the risk of adverse side effects outweighs any potential benefit (Offringa and Newton, 2013). Children who have had four or more febrile seizures, have a family history of epilepsy, and have complex febrile seizures have an increased risk but still a low rate of 2% to 7%, for developing epilepsy throughout the life span (Pavlidou and Panteliadis, 2013). The mechanism is unknown but is thought to be primarily genetic.

Nursing Alert

If a febrile seizure lasts more than 5 minutes, parents should seek medical attention right away. Parents should call for emergency assistance (911) and not place the child who is actively having a seizure in the car.

Cerebral Malformations

Hydrocephalus

Hydrocephalus is a condition caused by an imbalance in the production and absorption of CSF in the ventricular system. The causes of hydrocephalus are varied, but the result is either (1) impaired absorption of CSF fluid within the subarachnoid space, obliteration of the subarachnoid cisterns, or malfunction of the arachnoid villi (**nonobstructive** or **communicating hydrocephalus**) or (2) obstruction to the flow of CSF through the ventricular system (**obstructive** or **noncommunicating hydrocephalus**) (Kinsman and Johnston, 2016). Any imbalance of secretion and absorption causes an increased accumulation of CSF in the ventricles, which become dilated (ventriculomegaly) and compress the brain substance against the surrounding rigid bony cranium. When this occurs before fusion of the cranial sutures, it causes enlargement of the skull and dilation of the ventricles (Fig. 27-7). In children younger than 12 years old, previously closed suture lines, especially the sagittal suture, may become diastatic or opened. After 12 years old, the sutures are fused and will not open.

FIG 27-7 Hydrocephalus: A block in flow of cerebrospinal fluid (CSF). **A**, Patent CSF circulation. **B**, Normal-pressure hydrocephalus. (B, From Grossman RI, Yousem DM: *Neuroradiology: the requisites*, ed 3, St. Louis, 2010, Mosby/Elsevier.)

Most cases of hydrocephalus are a result of developmental malformations. Although the defect usually is apparent in early infancy, it may become evident at any time from the prenatal period to late childhood or early adulthood. Other causes include neoplasms, CNS infections, and trauma. An obstruction to the normal flow can occur at any point in the CSF pathway to produce increased pressure and dilation of the pathways proximal to the site of obstruction.

Developmental defects (e.g., Chiari malformations, aqueduct stenosis, aqueduct gliosis, and atresia of the foramina of Luschka and Magendie [Dandy-Walker syndrome]) account for most cases of hydrocephalus from birth to 2 years old. Hydrocephalus is so often associated with myelomeningocele that all such infants should be observed for its development. In the remainder of cases, there is a history of intrauterine infection, hemorrhage, and neonatal meningoencephalitis. In older children, hydrocephalus is most often a result of intracranial masses, intracranial infections, hemorrhage, preexisting developmental defects (e.g., aqueduct stenosis, Chiari malformation), or trauma.

Clinical Manifestations

The factors that influence the clinical picture in hydrocephalus are the time of onset, acuity of onset, and associated structural malformations. In infancy, before closure of the cranial sutures, head

enlargement (increasing occipitofrontal circumference) is the predominant sign, but in older infants and children, the lesions responsible for hydrocephalus produce other neurologic signs through pressure on adjacent structures.

In infants with hydrocephalus, the head grows at an abnormal rate, although the first signs may be bulging fontanels. The anterior fontanel is tense, often bulging and non-pulsatile. Scalp veins are dilated, especially when the infant cries. With the increase in intracranial volume, skull bones become thin and the sutures become palpably separated to produce a cracked-pot sound (Macewen sign) on percussion of the skull. In severe cases, infants display frontal protrusion (frontal bossing) with depressed eyes and the eyes may be rotated downward (setting-sun sign). Pupils are sluggish, with unequal responses to light.

The signs and symptoms in early to late childhood are caused by increased ICP, and specific manifestations are related to the focal lesion. Most commonly resulting from posterior fossa neoplasms and aqueduct stenosis, the clinical manifestations are primarily those associated with space-occupying lesions (e.g., headaches on awakening with improvement after emesis or being in an upright position, strabismus, ataxia).

Diagnostic Evaluation

Hydrocephalus in infants is based on head circumference that crosses one or more percentile line on the head measurement chart within 2 to 4 weeks and on associated neurologic signs that are progressive. In evaluation of a preterm infant, specially adapted head circumference charts are consulted to distinguish abnormal head growth from normal rapid head growth. The primary diagnostic tools to detect hydrocephalus in older infants and children are CT and MRI. Diagnostic evaluation of children who have symptoms of hydrocephalus after infancy is similar to that used in those with suspected intracranial tumor. In neonates, echoencephalography is useful in comparing the ratio of lateral ventricle to cortex.

Therapeutic Management

The treatment of hydrocephalus is directed toward relief of ventricular pressure, treatment of the cause of the ventriculomegaly, treatment of associated complications, and management of problems related to the effect of the disorder on psychomotor development. The treatment is, with few exceptions, surgical. This is accomplished by direct removal of an obstruction (e.g., a tumor or hematoma). Most children require placement of a shunt that provides primary drainage of the CSF from the ventricles to an extracranial compartment, usually the peritoneum (**ventriculoperitoneal [VP] shunt**) (Fig. 27-8).

FIG 27-8 Ventriculoperitoneal (VP) shunt. The catheter is threaded beneath the skin.

Most shunt systems consist of a ventricular catheter, a flush pump, a unidirectional flow valve, and a distal catheter. In all models, the valves are designed to open at a predetermined intraventricular pressure and close when the pressure falls below that level, thus preventing

backflow of secretions.

The major complications of VP shunts are malfunction and infection. All shunts are subject to mechanical difficulties, such as kinking, plugging, or separation or migration of the tubing. Malfunction is most often caused by mechanical obstruction either within the ventricles from particulate matter (tissue or exudate) or at the distal end from thrombosis or displacement as a result of growth. Functional obstruction of a shunt's anti-siphon device remains a common complication. Revisions are needed when signs of malfunction appear. The child with a shunt obstruction is often first seen in an emergency visit with clinical manifestations of increased ICP, which is frequently accompanied by worsening neurologic status.

The most serious complication, shunt infection, can occur at any time, but the period of greatest risk is within the first 6 months after placement (Sivaganesan, Krishnamurthy, Sahni, et al, 2012). The infection is generally a result of intercurrent infections at the time of shunt placement. Infections include sepsis, bacterial endocarditis, wound infection, shunt nephritis, meningitis, and ventriculitis. Meningitis and ventriculitis are of greatest concern because any complicating CNS infection is a significant predictor of subnormal intellectual outcome. Infection is treated with antibiotics administered intravenously or intrathecally for a minimum of 7 to 10 days. A persistent infection may require removal of the shunt until the infection is controlled. External ventricular drainage (EVD) is used until CSF is sterile. The EVD allows for removal of CSF through a tube that is placed in the child's ventricle and flows by gravity into a collection device.

The primary reasons for inserting an EVD include unstable status, increased ICP that is difficult to stabilize, or infection from an existing VP shunt. The EVD may drain CSF intermittently or continuously according to need. Accurate and frequent documentation of the incision site; amount, color, and consistency of drainage into the device; and the child's vital and neurologic signs are an important part of the nursing care.

Prognosis

The prognosis of children with treated hydrocephalus depends largely on the cause of the dilated ventricles before shunt placement and the amount of irreversible brain damage before shunting (Kinsman and Johnston, 2016). For example, malignant tumors have a high mortality rate regardless of other complicating factors.

Surgically treated hydrocephalus in patients with little or no evidence of irreversible brain damage has a survival rate of about 80%, with most deaths occurring within the first year of treatment (Paulsen, Lundar, and Lindegaard, 2010). Those with poor outcomes include children shunted for post hemorrhagic hydrocephalus or meningitis. Most children who require shunting must depend on the shunt for the remainder of their life.

Nursing Care Management

An infant with suspected or confirmed hydrocephalus is observed carefully for signs of increasing ventricular size and increasing ICP. In infants, the head is measured daily at the point of largest measurement, the frontooccipital circumference (see Chapter 4 for technique). To avoid the likelihood of wide discrepancies, the point at which the measurements are taken is indicated on the head with a marking pen. Fontanels and suture lines are palpated for size, signs of bulging, tenseness, and separation. Irritability, lethargy, seizure activity, and altered vital signs and feeding behavior, may indicate an advancing pathologic condition.

In older children, the most valuable indicators of increasing ICP are alterations in the child's LOC, complaint of headache, and changes in interaction with the environment. Changes are identified by observing and comparing present behavior with customary behavior, sleep patterns, developmental capabilities, and habits obtained through a detailed history and a baseline assessment. This baseline information serves as a guide for postoperative assessment and evaluation of shunt function.

The nurse is responsible for preparing the child for diagnostic tests such as MRI or CT scan and for assisting with procedures such as a ventricular tap, which is often performed to relieve excessive pressure and to obtain CSF for examination. Sedation is required because the child must remain absolutely still during diagnostic testing (see Chapter 5).

Nursing Alert

If surgery is anticipated, intravenous (IV) lines should not be placed in a scalp vein on a child with

hydrocephalus.

Postoperative Care

In addition to routine postoperative care and observation, the infant or child is positioned carefully on the unoperated side to prevent pressure on the shunt valve. The child remains flat to help avert complications resulting from too rapid reduction of intracranial fluid. The surgeon indicates the position to be maintained and the extent of activity allowed.

Observation is continued for signs of increased ICP, which indicates obstruction of the shunt. Neurologic assessment includes pupil dilation (pressure causes compression or stretching of the oculomotor nerve, producing dilation on the same side as the pressure) and blood pressure (hypoxia to the brainstem causes variability in these vital signs).

Nursing Alert

Arbitrary pumping of the shunt may cause obstruction or other problems and should not be performed unless indicated by a neurosurgeon.

Because infection is the greatest hazard of the postoperative period, nurses are continually on the alert for the usual manifestations of CSF infection, including elevated temperature, poor feeding, vomiting, decreased responsiveness, and seizure activity. There may be signs of local inflammation at the operative sites and along the shunt tract. The child is also observed for abdominal distention because CSF may cause peritonitis or a postoperative ileus as a complication of distal catheter placement. Antibiotics are administered by the IV route as ordered, and the nurse may also need to assist with intraventricular instillation. Inspect the incision site for leakage, and test any suspected drainage for glucose, an indication of CSF.

Family Support

Specific needs and concerns of parents during periods of hospitalization are related to the reason for the child's hospitalization (shunt revision, infection, diagnosis) and the diagnostic and surgical procedures to which the child is subjected. Parents may have little understanding of anatomy; therefore, they need further exploration and reinforcement of information that was given to them by the physician and neurosurgeon, including information about what to expect. They are especially frightened of any procedure that involves the brain, and the fear of disability or brain damage is real and pervasive. Nurses can calm their anxiety with explanations of the rationale underlying the various nursing and medical activities, such as positioning or testing, and by simply being available and willing to listen to their concerns.

To prepare for the child's discharge and home care, instruct the parents on how to recognize signs that indicate shunt malfunction or infection. Active children may have injuries, such as a fall, that can damage the shunt, and the tubing may pull out of the distal insertion site or become disconnected during normal growth. Contact sports should be avoided, and a helmet should be worn when outside play is vigorous. It is also important for the nurse to encourage families to enroll infants and toddlers with hydrocephalus into an early childhood development program.

The management of hydrocephalus in a child is a demanding task for both family and health professionals, and helping the family cope with the child's difficulties is an important nursing responsibility. Children with hydrocephalus have lifelong special health care needs and require evaluation on a regular basis. The overall aim is to establish realistic goals and an appropriate educational program that will help the child to achieve his or her optimal potential. Families can be referred to community agencies for support and guidance. The National Hydrocephalus Foundation* and the Hydrocephalus Association[†] provide information on the condition for families and assist interested groups in establishing local organizations.

NCLEX Review Questions

1. You are the nurse assigned to care for a child with a basilar skull fracture. Your most important nursing observation is change in level of consciousness (LOC). You will be highly alert for:
 - a. Alterations in vital signs that often appear before alterations in consciousness or focal neurologic signs
 - b. Bleeding from the ear, which is indicative of an anterior basal skull fracture
 - c. Seizures, which are relatively uncommon in children at the time of head injury
 - d. Changes in posturing, such as any signs of extension or flexion posturing, unusual response to stimuli, and random versus purposeful movement
2. As the nurse assigned to a child diagnosed with bacterial meningitis, you know that:
 - a. The child will not need to be placed in isolation because antibiotics have been started.
 - b. Enteric precautions will remain in place for up to 48 hours.
 - c. Respiratory isolation will remain in place for 24 hours after antibiotics are started.
 - d. Due to headache, the child will want the head of the bed elevated with two pillows.
3. You are working with a pediatric nurse who has just transferred to the pediatric clinic. You are role-playing phone triage related to a child with a head injury. You ascertain that the nurse needs more teaching based on what response?
 - a. "After initial physical exam, if there was no loss of consciousness with the head injury, the child can be observed at home."
 - b. "If there is a language barrier, written instructions can be given, followed by discharge."
 - c. "Another physical exam should take place in 1 or 2 days."
 - d. "Parents should call the doctor if their child has any of these signs: blurred vision, walking unsteadily, or is hard to awaken."
4. You are caring for a child with hydrocephalus who is postoperative from a shunt revision. Which assessment finding is your priority for increased intracranial pressure (ICP)?
 - a. Nausea and refusal to eat postoperatively
 - b. Complaint of a headache
 - c. Irritability and wanting to sleep
 - d. Decrease in heart rate over the last hour
5. You are working with a family that brought their child into the pediatric clinic. The mother describes what may be a type of seizure. What subjective data will help you determine the type? Select all that apply.
 - a. The presence or absence of an aura
 - b. If the child appeared disoriented after the seizure
 - c. Presence of vomiting after the seizure
 - d. The duration of the seizure
 - e. If the seizure was related to certain foods or occurred after a certain activity

Correct Answers

1. d; 2. c; 3. b; 4. d; 5. a, b, d

The Child with Endocrine Dysfunction

Amy Barry, Erin Connelly

The Endocrine System

The endocrine system controls and regulates metabolism; this includes energy production, growth, fluid and electrolyte balance, response to stress, and sexual development (Gardner and Shoback, 2011). This system has three components: (1) the cell that sends a chemical message using a hormone; (2) the target cells or organs, which receive the chemical message; and (3) the environment through which the chemical is transported from the site of synthesis to the site of cellular action (e.g., blood, lymph, extracellular fluids). The endocrine glands, which are distributed throughout the body, are listed in Table 28-1; also listed are several additional structures sometimes considered endocrine glands, although they are not usually included. The pathophysiology review in Fig. 28-1 provides a summary of the principle pituitary hormones and their target organs.

TABLE 28-1
Hormones and Their Function

| Hormone | Effect | Hypofunction | Hyperfunction |
|--|--|--|---|
| Adenohypophysis (Anterior Pituitary)* | | | |
| STH or GH (somatotropin) Target tissue: Bones | Promotes growth of bone and soft tissues Has main effect on linear growth Maintains a normal rate of protein synthesis Conserves carbohydrate utilization and promotes fat mobilization Is essential for proliferation of cartilage cells at epiphyseal plate Is ineffective for linear growth after epiphyseal closure Has hyperglycemic effect (anti-insulin action) | Epiphyseal fusion with cessation of growth Prepubertal dwarfism Pituitary cachexia (Simmonds disease) Generalized growth retardation Hypoglycemia | Prepubertal gigantism Acromegaly (after full growth is attained) DM Postpubertal hypoproteinemia |
| Thyrotropin (TSH) Target tissue: Thyroid gland | Promotes and maintains growth and development of thyroid gland Stimulates TH secretion | Hypothyroidism Marked delay of puberty Juvenile myxedema | Hyperthyroidism Thyrotoxicosis Graves disease |
| ACTH Target tissue: Adrenal cortex | Promotes and maintains growth and development of adrenal cortex Stimulates adrenal cortex to secrete glucocorticoids and androgens | Acute adrenocortical insufficiency (Addison disease) Hypoglycemia Increased skin pigmentation | Cushing syndrome |
| Gonadotropins Target tissue: Gonads | Stimulate gonads to mature and produce sex hormones and germ cells | Absent or incomplete spontaneous puberty | Precocious puberty Early epiphyseal closure |
| FSH Target tissue: Ovaries, testes | <i>Male:</i> Stimulates development of seminiferous tubules; initiates spermatogenesis <i>Female:</i> Stimulates graafian follicles to mature and secrete estrogen | Hypogonadism Sterility Absence or loss of secondary sex characteristics Amenorrhea | Precocious puberty Primary gonadal failure Hirsutism Polycystic ovary Early epiphyseal closure |
| LH [†] Target tissue: Ovaries, testes | <i>Male:</i> Stimulates differentiation of Leydig cells, which secrete androgens, principally testosterone <i>Female:</i> Produces rupture of follicle with discharge of mature ovum; stimulates secretion of progesterone by corpus luteum | Hypogonadism Sterility Impotence Absence or loss of secondary sex characteristics Ovarian failure Eunuchism | Precocious puberty Primary gonadal failure Hirsutism Polycystic ovary Early epiphyseal closure |
| Prolactin (luteotropic hormone) Target tissue: Ovaries, breasts | Stimulates milk secretion Maintains corpus luteum and progesterone secretion during pregnancy | Inability to lactate Amenorrhea | Galactorrhea Functional hypogonadism |
| MSH Target tissue: Skin | Promotes pigmentation of skin | Diminished or absent skin pigmentation | Increased skin pigmentation |
| Neurohypophysis (Posterior Pituitary) | | | |
| ADH (vasopressin) Target tissue: Renal tubules | Acts on distal and collecting tubules, making them more permeable to water, thus increasing reabsorption and decreasing excretion of urine | DI | SIADH Fluid retention Hyponatremia |
| Oxytocin Target tissue: Uterus, breasts | Stimulates powerful contractions of uterus Causes ejection of milk from alveoli into breast ducts (letdown reflex) | | |
| Thyroid | | | |
| THs: T ₄ and T ₃ | Regulate metabolic rate; control rate of growth of body cells Especially important for growth of bones, teeth, and brain Promote mobilization of fats and gluconeogenesis | Hypothyroidism Myxedema Hashimoto thyroiditis General growth greatly reduced; extent dependent on age at which deficiency occurs Intellectual disability in infant | Exophthalmic goiter (Graves disease) Accelerated linear growth Early epiphyseal closure |
| Thyrocalcitonin | Regulates calcium and phosphorus metabolism Influences ossification and development of bone | | |
| Parathyroid Glands | | | |
| PTH | Promotes calcium reabsorption from blood, bone, and intestines Promotes excretion of phosphorus in kidney tubules | Hypocalcemia (tetany) | Hypercalcemia (bone demineralization) Hypophosphatemia |
| Adrenal Cortex | | | |
| Mineralocorticoids Aldosterone | Stimulate renal tubules to reabsorb sodium, thus promoting water retention but potassium loss | Adrenocortical insufficiency | Electrolyte imbalance Hyperaldosteronism |
| Sex hormones: Androgens, estrogens, progesterone | Influence development of bone, reproductive organs, and secondary sex characteristics | Male feminization | Adrenogenital syndrome |
| Glucocorticoids Cortisol (hydrocortisone and compound F) Corticosterone (compound B) | Promote normal fat, protein, and carbohydrate metabolism Mobilize body defenses during periods of stress Suppress inflammatory reaction | Addison disease Acute adrenocortical insufficiency Impaired growth and sexual function | Cushing syndrome Severe impairment of growth with slowing in skeletal maturation In excess, tend to accelerate gluconeogenesis and protein and fat catabolism |
| Adrenal Medulla | | | |
| Epinephrine (adrenaline), norepinephrine (noradrenaline) | Produce vasoconstriction of heart and smooth muscles (raise blood pressure) Increase blood glucose via glycolysis Inhibit GI activity Activate sweat glands | | Hyperfunction caused by: • Pheochromocytoma • Neuroblastoma • Ganglioneuroma |
| Islets of Langerhans of Pancreas | | | |
| Insulin (β cells) | Promotes glucose transport into the cells Increases glucose utilization, glycogenesis, and glycolysis Promotes fatty acid transport into cells and lipogenesis Promotes amino acid transport into cells and protein synthesis | DM | Hyperinsulinism |
| Glucagon (α cells) | Acts as antagonist to insulin, thereby increasing blood glucose | | Hyperglycemia |

| | | | |
|--------------------------------|---|--|---|
| | concentration by accelerating glycogenolysis Able to inhibit secretion of both insulin and glycogen | | May be instrumental in genesis of DKA in DM |
| Somatostatin (δ cells) | Able to inhibit secretion of both insulin and glycogen | | |
| Ovaries | | | |
| Estrogen | Accelerates growth of epithelial cells, especially in uterus after menses Promotes protein anabolism Promotes epiphyseal closure of bones Promotes breast development during puberty and pregnancy Plays role in sexual function Stimulates water and sodium reabsorption in renal tubules Stimulates ripening of ova | Lack of or repression of sexual development | Precocious puberty, early epiphyseal closure |
| Progesterone | Prepares uterus for nidation of fertilized ovum and aids in maintenance of pregnancy Aids in development of alveolar system of breasts during pregnancy Inhibits myometrial contractions Has effect on protein catabolism Promotes salt and water retention, especially in endometrium | | |
| Testes | | | |
| Testosterone | Accelerates protein anabolism for growth Promotes epiphyseal closure Promotes development of secondary sex characteristics Plays role in sexual function Stimulates testes to produce spermatozoa | Delayed sexual development or eunuchoidism | Precocious puberty, early epiphyseal closure |

*For each anterior pituitary hormone there is a corresponding hypothalamic-releasing factor. A deficiency in these factors caused by inhibiting anterior pituitary hormone synthesis produces the same effects. (See text for more detailed information.)

†In males, LH is sometimes known as interstitial cell-stimulating hormone (ICSH).

ACTH, Adrenocorticotropic hormone; *ADH*, antidiuretic hormone; *DI*, diabetes insipidus; *DKA*, diabetic ketoacidosis; *DM*, diabetes mellitus; *FSH*, follicle-stimulating hormone; *GH*, growth hormone; *GI*, gastrointestinal; *LH*, luteinizing hormone; *MSH*, melanocyte-stimulating hormone; *PTH*, parathyroid hormone; *SIADH*, syndrome of inappropriate antidiuretic hormone secretion; *STH*, somatotropin hormone; *T₃*, triiodothyronine; *T₄*, thyroxine; *TH*, thyroid hormone; *TSH*, thyroid-stimulating hormone.

FIG 28-1 Principal anterior and posterior pituitary hormones and their target organs. *FSH*, Follicle-stimulating hormone; *LH*, luteinizing hormone. (From Patton KT, Thibodeau GA: *Anatomy and physiology*, ed 8, St Louis, 2013, Mosby/Elsevier.)

Hormones

A hormone is a complex chemical substance produced and secreted into body fluids by a cell or

group of cells that exerts a physiologic controlling effect on other cells. These effects may be local or distant and may affect either most cells of the body or specific “target” tissues. Most hormones are released by the endocrine glands into the bloodstream, and production is regulated by a feedback mechanism (see [Table 28-1](#)). The master gland of the endocrine system is the anterior pituitary. The pituitary is responsible for stimulation and inhibition of tropic hormones. Other hormones, such as insulin, are not regulated by the pituitary gland.

Disorders of Pituitary Function

The pituitary gland is divided into two lobes: the anterior pituitary (adenohypophysis) and the posterior pituitary (neurohypophysis). It is controlled by hormones secreted from the hypothalamus. Each lobe of the pituitary is responsible for secreting different hormones. The cause of pituitary dysfunction may be organic or idiopathic, and may involve one hormone or a combination of hormones. The clinical manifestations of pituitary dysfunction depend on the hormones involved and the age of the patient. *Panhypopituitarism* is defined clinically as the loss of all anterior pituitary hormones, leaving only posterior function intact (Toogood and Stewart, 2008).

Nursing Alert

Children with panhypopituitarism should wear medical identification, such as a bracelet.

Hypopituitarism

Hypopituitarism is the diminished secretion of one or more pituitary hormones. The consequences of the condition depend on the degree of dysfunction. It often leads to:

- Gonadotropin deficiency (decrease in luteinizing hormone [LH] or follicle-stimulating hormone [FSH]) where children show an absence or regression in secondary sex characteristics
- Growth hormone (GH) deficiency in which children display stunted somatic growth
- Thyroid-stimulating hormone (TSH) deficiency, which causes hypothyroidism
- Adrenocorticotropic hormone (ACTH) deficiency, which results in adrenal hypofunction

Hypopituitarism can result from any of the conditions listed in [Box 28-1](#). The most common organic cause of pituitary undersecretion is a tumor in the pituitary or hypothalamic region. Craniopharyngiomas are tumors well known to invade these regions of the brain and cause panhypopituitarism. Clinical manifestations of panhypopituitarism are listed in [Box 28-1](#). Children with panhypopituitarism should be advised to wear medical identification at all times.

Box 28-1

Clinical Manifestations of Panhypopituitarism

Growth Hormone

Short stature but proportional height and weight

Delayed epiphyseal closure

Retarded bone age proportional to height

Premature aging common in later life

Increased insulin sensitivity

Thyroid-Stimulating Hormone

Short stature with infantile proportions

Dry, coarse skin; yellow discoloration, pallor

Cold intolerance

Constipation

Somnolence

Bradycardia

Dyspnea on exertion

Delayed dentition, loss of teeth

Gonadotropins

Absence of sexual maturation or loss of secondary sexual characteristics

Atrophy of genitalia, prostate gland, breasts

Amenorrhea without menopausal symptoms

Decreased spermatogenesis

Adrenocorticotrophic Hormone

Severe anorexia, weight loss

Hypoglycemia

Hypotension

Hyponatremia, hyperkalemia

Adrenal apoplexy, especially in response to stress

Circulatory collapse

Antidiuretic Hormone

Polyuria

Polydipsia

Dehydration

Melanocyte-Stimulating Hormone

Decreased pigmentation

Congenital hypopituitarism can be seen in newborn infants and can run in families, suggesting a genetic cause ([Alatzoglou and Dattani, 2010](#)). Neonates may have symptoms of hypoglycemia and seizure activity ([Toogood and Stewart, 2008](#)). A child with combined GH deficiency and hypothyroidism should be screened for congenital pituitary defects and genetic mutations ([Pine-Twaddell, Romero, and Radovick, 2013](#)).

Idiopathic hypopituitarism, or idiopathic pituitary growth failure, is usually related to GH deficiency, which inhibits somatic growth in all cells of the body ([Amin, Mushtaq, and Alvi, 2015](#)). Isolated GH deficiency without other associated pituitary hormone deficiencies or a known organic cause is seen in children ([Stanley, 2012](#)). Growth failure is defined as an absolute height of less than -2 standard deviation (SD) for age or a linear growth velocity consistently less than -1 SD for age. When this occurs without the presence of hypothyroidism, systemic disease, or malnutrition, then an abnormality of the GH–insulin-like growth factor (IGF-I) axis should be considered ([Richmond and Rogol, 2008](#)).

However, not all children with short stature have GH deficiency. In most instances, the cause is considered idiopathic. Most children with idiopathic short stature (ISS) have either familial short stature or constitutional growth delay. **Familial short stature** refers to otherwise healthy children who have ancestors with adult height in the lower percentiles. **Constitutional growth delay** refers to individuals (usually boys) with delayed linear growth, generally beginning as a toddler, and

skeletal and sexual maturation that is behind that of age mates (Amin, Mushtaq, Alvi, 2015). GH therapy in children with ISS continues to be debated frequently by pediatric endocrinologists.

Clinical Manifestations

Children with GH deficiency generally grow normally during the first year and then follow a slowed growth curve that is below the third percentile. These children may appear overweight or obese due to stunted height in combination with good nutrition. A nourished appearance is an important diagnostic clue which may differentiate patients with GH deficiency from patients with failure to thrive. Sexual development is usually delayed but is otherwise normal unless the gonadotropin hormones are deficient. Growth may extend into the third or fourth decade of life, but permanent height is usually diminished if the disorder is left untreated. Because of an underdeveloped jaw, teeth may be crowded or malpositioned.

Diagnostic Evaluation

Only a small number of children with delayed growth or short stature have hypopituitary dysfunction. Diagnostic evaluation is aimed at isolating organic causes, which, in addition to GH deficiency, may include tumor growth, hypothyroidism, oversecretion of cortisol, gonadal aplasia, chronic illness, nutritional inadequacy, Russell-Silver dwarfism, or hypochondroplasia. A detailed family history, growth history and previous health status, physical examination, and psychosocial evaluation are important. Specific radiographic imaging, including magnetic resonance imaging (MRI), endocrine studies, and genetic testing may be warranted (Stanley, 2012). Accurate measurement of height and weight, and comparison with standard growth charts, are essential. Multiple height measures reflect a more accurate assessment of abnormal growth patterns (Box 28-2). Parental height and familial patterns of growth are important clues to diagnosis. A skeletal survey in children younger than 3 years old and radiographic examination of the hand/wrist for centers of ossification (bone age) (Box 28-3) in older children are important in evaluating growth.

Box 28-2

Evaluating the Growth Curve

Ensure reliability of measurements: Accurately obtain and plot height and weight measurements.

Determine absolute height: The child's absolute height bears some relationship to the likelihood of a pathologic condition. However, the majority of children who have a height below the lowest percentile (either the third or fifth percentile on the height curve) do not have a pathologic growth problem.

Assess height velocity: The most important aspect of a growth evaluation is the observation of a child's height over time, or height velocity. Accurate determination of height velocity requires at least 4 and preferably 6 months of observation. A substantial deceleration in height velocity (crossing several percentiles) between 3 and 12 or 13 years of age indicates a pathologic condition until proven otherwise.

Determine weight-to-height relationship: Determination of the weight-to-height ratio has some diagnostic value in ascertaining the cause of growth retardation in a short child.

Project target height: The height of a child can be judged inappropriately short only in the context of his or her genetic potential. Determine the target height of the child with the formula:

$[\text{Father's height (cm)} + \text{Mother's height (cm)} + 13]/2$ for boys
or

$[\text{Father's height (cm)} + \text{Mother's height (cm)} - 13]/2$ for girls

Most children achieve an adult stature within approximately 10 cm (4 inches) of the target height.

Modified from Vogiatzi MG, Copeland KC: The short child, *Pediatr Rev* 19(3):92–99, 1998.

Box 28-3

Bone Age for Evaluating Growth Disorders

Bone age refers to a method of assessing skeletal maturity by comparing the appearance of representative epiphyseal centers obtained on x-ray examination with age-appropriate published standards.

Most conditions that cause poor linear growth also cause a delay in skeletal maturation and a retarded bone age. Observation of even a profoundly delayed bone age is never diagnostic or even indicative of a specific diagnosis. A delayed bone age merely indicates that the associated short stature is to some extent “partially reversible,” because linear growth will continue until epiphyseal fusion is complete. In comparison, a bone age that is not delayed in a short child is of much greater concern and may, in fact, be of some diagnostic value under certain circumstances.

Modified from Vogiatzi MG, Copeland KC: The short child, *Pediatr Rev* 19(3):92–99, 1998.

A definitive diagnosis of GH deficiency is based on absent or subnormal reserves of pituitary GH. Because GH levels are variable in children, GH stimulation testing is usually required for diagnosis. It is recommended that GH stimulation tests be reserved for children with low serum IGF-I and insulin-like growth factor binding protein 3 (IGFBP3) levels and poor growth who do not have other causes for short stature (Hokken-Koelega, 2011). GH stimulation testing involves the use of pharmacologic agents such as levodopa, clonidine, arginine, insulin, propranolol, or glucagon, followed by the measurement of GH blood levels (Parks and Felner, 2016). Children with poor linear growth, delayed bone age, and abnormal GH stimulation tests are considered GH deficient.

Therapeutic Management

Treatment of GH deficiency caused by organic lesions is directed toward correction of the underlying disease process (e.g., surgical removal or irradiation of a tumor). The definitive treatment of GH deficiency is replacement of GH, which is successful in 80% of affected children. Biosynthetic GH is administered subcutaneously on a daily basis. Growth velocity increases in the first year of treatment and then declines in subsequent years. Final height is likely to remain less than normal (Deodati and Cianfarani, 2011; Bryant, Baxter, Cave, et al, 2007), and early diagnosis and intervention are essential.

The decision to stop GH therapy is made jointly by the child, family, and health care team. Growth rates of less than 1 inch per year and a bone age of more than 14 years in girls and more than 16 years in boys are often used as criteria to stop GH therapy (Parks and Felner, 2016). Children with other hormone deficiencies require replacement therapy to correct the specific disorders.

Nursing Care Management

The principal nursing consideration is identifying children with growth problems. Even though the majority of growth problems are not a result of organic causes, any delay in normal growth and sexual development may pose special emotional adjustments for these children.

The nurse may be a key person in helping establish a diagnosis. For example, if serial height and weight records are not available, the nurse can question parents about the child's growth compared with that of siblings, peers, or relatives. Preparation of the child and family for diagnostic testing is especially important if a number of tests are being performed, and the child requires particular attention during provocative testing. Blood samples are usually taken every 30 minutes for a 3-hour period. Children also have difficulty overcoming hypoglycemia generated by tests with insulin, so they must be observed carefully for signs of hypoglycemia. Those receiving glucagon are at risk of nausea and vomiting. Clonidine may cause hypotension, requiring administration of intravenous (IV) fluids.

Child and Family Support

Children undergoing hormone replacement require additional support. The nurse should provide education for patient self-management during the school-age years. Nursing functions include family education concerning medication preparation and storage, injection sites, injection technique, and syringe disposal (see [Chapter 20](#)). Administration of GH is facilitated by family routines that include a specific time of day for the injection.

Nursing Tip

Optimum dosing is often achieved when growth hormone (GH) is administered at bedtime. The pituitary release of GH is during the first 45 to 90 minutes after the onset of sleep.

Even when hormone replacement is successful, these children attain their eventual adult height at a slower rate than their peers; therefore, they need assistance in setting realistic expectations regarding improvement. Because these children appear younger than their chronologic age, others may relate to them in infantile or childish ways. Families should be counseled to set realistic expectations for the child based on age and abilities. For example, in the home, such children should have the same age-appropriate responsibilities as their siblings. As they approach adolescence, they should be encouraged to participate in group activities with peers. If abilities and strengths are emphasized rather than physical size, such children are more likely to develop a positive self-image.

Professionals and families can find resources for research, education, support, and advocacy from the Human Growth Foundation.* Treatment is expensive, but the cost is often partially covered by insurance if the child has a documented deficiency.

Pituitary Hyperfunction

Excess GH before closure of the epiphyseal shafts results in proportional overgrowth of the long bones until the individual reaches a height of 2.4 m (8 ft) or more. Vertical growth is accompanied by rapid and increased development of muscles and viscera. Weight is increased but is usually in proportion to height. Proportional enlargement of head circumference also occurs and may result in delayed closure of the fontanelles in young children. Children with a pituitary-secreting tumor may also demonstrate signs of increasing intracranial pressure, especially headache.

If oversecretion of GH continues after epiphyseal closure (growth plate), growth occurs in the transverse direction, producing a condition known as **acromegaly**. Typical facial features include overgrowth of the head, lips, nose, tongue, jaw, and paranasal and mastoid sinuses; separation and malocclusion of the teeth in the enlarged jaw; disproportion of the face to the cerebral division of the skull; increased facial hair; thickened, deeply creased skin; and an increased tendency toward hyperglycemia and diabetes mellitus (DM). Acromegaly can develop slowly, leading to delays in diagnosis and treatment.

Diagnostic Evaluation

Excessive secretion of GH by a pituitary adenoma causes most cases of acromegaly. Diagnosis is based on a history of excessive growth during childhood and evidence of increased levels of GH. MRI may reveal a tumor or an enlarged sella turcica, normal bone age, enlargement of bones (e.g., the paranasal sinuses), and evidence of joint changes. Endocrine studies to confirm excess of other hormones, specifically thyroid, cortisol, and sex hormones, should also be included in the differential diagnosis.

Therapeutic Management

If a lesion is present, surgery is performed to remove the tumor when feasible. Other therapies aimed at destroying pituitary tissue include external irradiation and radioactive implants. New pharmacologic agents have evolved and may be useful in combination with other therapies ([Nachtigall, Delgado, Swearingen, et al, 2008](#)). Depending on the extent of surgical extirpation and degree of pituitary insufficiency, hormone replacement with thyroid extract, cortisone, and sex hormones may be necessary.

Nursing Care Management

The primary nursing consideration is early identification of children with excessive growth rates. Although medical management is unable to reduce a patient's height, further growth can be retarded. If treatment for acromegaly is initiated early it improves a patient's chance of maintaining normal adult height. Nurses should also observe for signs of a tumor, especially headache, and evidence of concurrent hormonal excesses, particularly the gonadotropins, which cause sexual precocity. Children with excessive growth rates require as much emotional support as those with short stature.

Precocious Puberty

Concern that the onset of puberty may be occurring earlier has been debated for over 15 years (Carel and Léger, 2008). Traditionally, sexual development before 9 years old in boys and 8 years old in girls would warrant further evaluation (Carel and Léger, 2008). It is now accepted that puberty is occurring earlier than in previous generations (Biro, Huang, Crawford, et al, 2006; Slyper, 2006). The mean onset of puberty was 10.2 years old in white girls and 9.6 years old in African-American girls. Based on these findings, precocious puberty evaluation for a pathologic cause should be performed for white girls younger than 7 years old or for African-American girls younger than 6 years old. No change in the guidelines for evaluation of precocious puberty in boys is recommended. However, recent data suggest that boys may be beginning maturation earlier as well (Herman-Giddens, 2006; Slyper, 2006). Earlier puberty may be directly related to obesity, and data suggests that timing of puberty has not changed for children who are not overweight (Walvoord, 2010).

Normally, the hypothalamic-releasing factors stimulate secretion of the gonadotropic hormones from the anterior pituitary at the time of puberty. In boys, interstitial cell-stimulating hormone stimulates Leydig cells of the testes to secrete testosterone; in girls, FSH and LH stimulate the ovarian follicles to secrete estrogens (Nebesio and Eugster, 2007). This sequence of events is known as the **hypothalamic-pituitary-gonadal axis**. If for some reason the cycle undergoes premature activation, the child will display evidence of advanced or precocious puberty. Causes of precocious puberty are found in Box 28-4.

Box 28-4

Causes of Precocious Puberty

Central Precocious Puberty

Idiopathic, with or without hypothalamic hamartoma

Secondary

- Congenital anomalies
- Postinflammatory: Encephalitis, meningitis, abscess, granulomatous disease
- Radiotherapy
- Trauma
- Neoplasms

After effective treatment of long-standing pseudosexual precocity

Peripheral Precocious Puberty

Familial male-limited precocious puberty

Albright syndrome

Gonadal or extragonadal tumors

Adrenal

- Congenital adrenal hyperplasia (CAH)
- Adenoma, carcinoma
- Glucocorticoid resistance

Exogenous sex hormones

Primary hypothyroidism

Incomplete Precocious Puberty

Premature thelarche

Premature menarche

Premature pubarche or adrenarche

Modified from Root AW: Precocious puberty, *Pediatr Rev* 21(1):10–19, 2000.

Isosexual precocious puberty is more common among girls than boys. Approximately 80% of children with precocious puberty have **central precocious puberty (CPP)**, in which pubertal development is activated by the hypothalamic gonadotropin-releasing hormone (GnRH) (Greiner and Kerrigan, 2006). This produces early maturation and development of the gonads with secretion of sex hormones, development of secondary sex characteristics, and sometimes production of mature sperm and ova (Li, Li, and Yang, 2014; Lee, Houk, and Ahmed, 2006). CPP may be the result of congenital anomalies; infectious, neoplastic, or traumatic insults to the central nervous system (CNS); or treatment of long-standing sex hormone exposure (Trivin, Couto-Silva, Sainte-Rose, et al, 2006). CPP occurs more frequently in girls and is usually idiopathic, with 95% demonstrating no causative factor (Li, Li, and Yang, 2014; Greiner and Kerrigan, 2006; Nebesio and Eugster, 2007).

Peripheral precocious puberty (PPP) includes early puberty resulting from hormone stimulation other than the hypothalamic GnRH-stimulated pituitary gonadotropin release. Isolated manifestations that are usually associated with puberty may be seen as variations in normal sexual development (Greiner and Kerrigan, 2006). They appear without other signs of pubescence and are caused by excess secretion of sex hormones through the gonads or adrenal glands and may be isosexual or contrasexual. Included are premature thelarche (development of breasts in prepubertal girls), premature pubarche (premature adrenarche, early development of sexual hair), and premature menarche (isolated menses without other evidence of sexual development).

Therapeutic Management

Treatment of precocious puberty is directed toward the specific cause when known. In 50% of cases, precocious pubertal development regresses or stops advancing without any treatment (Carel and Léger, 2008). CPP is managed with monthly injections of a synthetic analog of **luteinizing hormone-releasing hormone (Greiner and Kerrigan, 2006)**. The available preparation, leuprolide acetate (Lupron Depot), is given once every 4 to 12 weeks depending on the preparation. With the initiation of treatment, breast development regresses or does not advance, and growth rates return to normal. Studies suggest that not all patients attain adult targeted heights, and the addition of GH

therapy may be warranted (Carel and Léger, 2008). Treatment is discontinued at a chronologically appropriate time, allowing pubertal changes to resume.

Nursing Care Management

Both parents and the affected child should be taught the injection procedure. Psychological support and guidance of the child and family are the most important aspects of management. Parents need anticipatory guidance, support, information resources, and reassurance of the benign nature of the condition (Greiner and Kerrigan, 2006). Dress and activities for the physically precocious child should be appropriate to the chronologic age. Sexual interest is not usually advanced beyond the child's chronologic age, and parents need to understand that the child's mental age is congruent with the chronologic age.

Diabetes Insipidus

The principal disorder of posterior pituitary hypofunction is diabetes insipidus (DI), also known as **neurogenic DI**, resulting from undersecretion of **antidiuretic hormone (ADH)**, or **vasopressin** (Pitressin), and producing a state of uncontrolled diuresis (Makaryus and McFarlane, 2006). This disorder is not to be confused with nephrogenic DI, a rare hereditary disorder affecting primarily males and caused by unresponsiveness of the renal tubules to the hormone.

Neurogenic DI may result from a number of different causes. Primary causes are familial or idiopathic; of the total cases, approximately 20% to 50% are idiopathic (Di Iorgi, Allegri, Napoli, et al, 2014). Secondary causes include trauma (accidental or surgical), tumors, granulomatous disease, infections (meningitis or encephalitis), and vascular anomalies (aneurysm). Certain drugs, such as alcohol and phenytoin (diphenylhydantoin), can cause a transient polyuria. DI may be an early sign of an evolving cerebral process (De Buyst, Massa, Christophe, et al, 2007).

The cardinal signs of DI are polyuria and polydipsia. In older children, signs such as excessive urination accompanied by a compensatory insatiable thirst may be so intense that the child does little more than go to the toilet and drink fluids. Frequently, the first sign is enuresis. In infants, the initial symptom is irritability that is relieved with feedings of water but not milk. These infants are also prone to dehydration, electrolyte imbalance, hyperthermia, azotemia, and potential circulatory collapse.

Dehydration is usually not a serious problem in older children, who are able to drink larger quantities of water. However, any period of unconsciousness (such as after trauma or anesthesia) may be life threatening because the voluntary demand for fluid is absent. During such instances, careful monitoring of urine volumes, blood concentration, and IV fluid replacement is essential to prevent dehydration.

Nursing Alert

Children with diabetes insipidus (DI) complicated by congenital absence of the thirst center must be encouraged to drink sufficient quantities of liquid to prevent electrolyte imbalance.

Diagnostic Evaluation

The simplest test used to diagnose this condition is restriction of oral fluids and observation of consequent changes in urine volume and concentration. Normally, reducing fluid intake results in concentrated urine and diminished volume. In DI, fluid restriction has little or no effect on urine formation but causes weight loss from dehydration. Accurate results from this procedure require strict monitoring of fluid intake and urinary output, measurement of urine concentration (specific gravity or osmolality), and frequent weight checks. A weight loss between 3% and 5% indicates significant dehydration and requires termination of the fluid restriction.

Nursing Alert

Small children require close observation during fluid deprivation to prevent them from drinking, even from toilet bowls, flower vases, and other unlikely sources of fluid.

If this test result is positive, the child should be given a test dose of injected **aqueous vasopressin**,

which should alleviate the polyuria and polydipsia. Unresponsiveness to exogenous vasopressin usually indicates nephrogenic DI. An important diagnostic consideration is to differentiate DI from other causes of polyuria and polydipsia, especially DM. DI may be the early sign of an evolving cerebral process (De Buyst, Massa, Christophe, et al, 2007).

Therapeutic Management

Treatment for DI requires hormone replacement using vasopressin. Vasopressin is administered by intramuscular or subcutaneous injection or using a nasal spray of aqueous lysine vasopressin (Makaryus and McFarlane, 2006). The injectable form has the advantage of lasting 48 to 72 hours; however, it has the disadvantage of requiring frequent injections and proper preparation of the drug.

Nursing Tip

To be effective, injectable vasopressin must be thoroughly resuspended before administration. If this is not done, the oil may be injected minus the antidiuretic hormone (ADH). Small brown particles, which indicate drug dispersion, must be seen in the suspension.

Nursing Care Management

An early sign of DI may be sudden enuresis in a child who is toilet trained. Excessive thirst with concurrent bedwetting indicates further investigation. Another clue is persistent irritability and crying in an infant that is relieved only by bottle feedings of water. After head trauma or certain neurosurgical procedures, the development of DI can be anticipated; therefore, these patients must be closely monitored.

Nursing assessment includes frequent measurements of a patient's weight, serum electrolytes, blood urea nitrogen (BUN), hematocrit, and urine specific gravity. Fluid intake and output should be frequently measured and recorded. Alert patients are able to adjust fluid intake but unconscious or very young patients require closer fluid observation. In children who are not toilet trained, collection of urine specimens may require application of a urine-collecting device.

After confirmation of DI, parents need comprehensive teaching. Specific clarification that DI is a different condition from DM should be reinforced. Parents and children must realize that treatment is lifelong. Caregivers should be taught the correct procedure for preparation and administration of vasopressin. When children are old enough, they should be encouraged to assume full responsibility for their care.

For emergency purposes, children with DI should wear medical alert identification. Older children should carry the nasal spray with them for temporary relief of symptoms. School personnel need to be aware of a child's diagnosis so that they can grant children unrestricted use of the lavatory.

Syndrome of Inappropriate Antidiuretic Hormone Secretion

The disorder that results from hypersecretion of ADH from the posterior pituitary hormone is known as syndrome of inappropriate antidiuretic hormone secretion (SIADH). It is observed with increased frequency in a variety of conditions, especially those involving infections, tumors, or other CNS disease or trauma, and it is the most common cause of hyponatremia in the pediatric population (Lin, Liu, and Lim, 2005; Rivkees, 2008).

The manifestations are directly related to fluid retention and hypotonicity. Excess ADH causes most of the filtered water to be reabsorbed from the kidneys back into central circulation. Serum osmolality is low, and urine osmolality is inappropriately elevated. When serum sodium levels are diminished to 120 mEq/L, affected children may display anorexia, nausea (and sometimes vomiting), stomach cramps, irritability, and personality changes. With progressive reduction in sodium, other neurologic signs including, stupor, and seizure may occur. The symptoms usually disappear when the underlying disorder is corrected.

Fluid restriction is the first management of SIADH. Subsequent management depends on the cause and severity. Fluids continue to be restricted to one-fourth to one-half maintenance. When there are no fluid abnormalities but SIADH can be anticipated, fluids are often restricted expectantly at two-thirds to three-fourths maintenance.

Nursing Care Management

The first goal of nursing management is recognizing the presence of SIADH from symptoms described in patients at risk.

Nursing Alert

Nausea, vomiting, and malaise may precede the onset of more severe stages, such as disorientation, confusion, coma, and seizures ([Gardner and Shoback, 2011](#)).

Accurately measuring intake and output, noting daily weight, and observing for signs of fluid overload are primary nursing functions, especially in children receiving IV fluids. Seizure precautions are implemented. Patients and families need education regarding the rationale for fluid restrictions. The rare child with chronic SIADH will be placed on long-term ADH-antagonizing medication, and the child and family will require instructions for its administration.

Disorders of Thyroid Function

The thyroid gland secretes two types of hormones: **thyroid hormone (TH)**, which consists of the hormones **thyroxine (T₄)** and **triiodothyronine (T₃)**, and **calcitonin**. The secretion of THs is controlled by TSH from the anterior pituitary, which in turn is regulated by thyrotropin-releasing factor (TRF) from the hypothalamus as a negative feedback response. Consequently, hypothyroidism or hyperthyroidism may result from a defect in the target gland or from a disturbance in the secretion of TSH or TRF. Because the functions of T₃ and T₄ are qualitatively the same, the term *thyroid hormone* is used throughout the discussion.

The synthesis of TH depends on available sources of dietary iodine and tyrosine. The thyroid is the only endocrine gland capable of storing excess amounts of hormones for release as needed. During circulation in the bloodstream, T₄ and T₃ are bound to carrier proteins (T₄-binding globulin). They must be unbound before they are able to exert their metabolic effect.

The main physiologic action of TH is to regulate the basal metabolic rate and thereby control the processes of growth and tissue differentiation. Unlike GH, TH is involved in many more diverse activities that influence the growth and development of body tissues. Therefore, a deficiency of TH exerts a more profound effect on growth than that seen in GH deficiency.

Calcitonin helps maintain blood calcium levels by decreasing the calcium concentration. Its effect is the opposite of parathyroid hormone (PTH) in that it inhibits skeletal demineralization and promotes calcium deposition in the bone.

Juvenile Hypothyroidism

Hypothyroidism is one of the most common endocrine problems of childhood. It may be either congenital (see [Chapter 8](#)) or acquired and represents a deficiency in secretion of TH ([Parks and Felner, 2016](#)).

Beyond infancy, primary hypothyroidism may be caused by a number of defects. For example, a congenital hypoplastic thyroid gland may provide sufficient amounts of TH during the first year or two but be inadequate when rapid body growth increases demands on the gland. A partial or complete thyroidectomy for cancer or thyrotoxicosis can leave insufficient thyroid tissue to furnish hormones for body requirements. Radiotherapy for Hodgkin disease or other malignancies may lead to hypothyroidism ([Pizzo and Poplack, 2016](#)). Infectious processes may cause hypothyroidism. It can also occur when dietary iodine is deficient, although it is now rare in the United States because iodized salt is a readily available source of the nutrient.

Clinical manifestations depend on the extent of dysfunction and the child's age at onset. Primary congenital hypothyroidism is characterized by low levels of circulating THs and raised levels of TSH at birth ([Rastogi and LaFranchi, 2010](#)). If left untreated, congenital hypothyroidism causes decreased mental capacity. Improvements in newborn screening have led to earlier detection and prevention of complications ([American Academy of Pediatrics, Rose, Section on Endocrinology and Committee on Genetics of the American Thyroid Association, et al, 2006](#)). The GnRH test and baseline measurement of gonadotropin and sex hormone serum concentrations at 3 months old are promising options for assessment of hypothalamic–pituitary–gonadal function in infants with congenital hypothyroidism ([van Tijn, Schroor, Delemarre-van de Waal, et al, 2007](#)). The presenting symptoms are decelerated growth from chronic deprivation of TH or thyromegaly. Impaired growth and development are less severe when hypothyroidism is acquired at a later age, and because brain growth is nearly complete by 2 to 3 years old, intellectual disability and neurologic sequelae are not associated with juvenile hypothyroidism. Other manifestations are myxedematous skin changes (dry skin, puffiness around the eyes, sparse hair), constipation, lethargy, and mental decline ([Box 28-5](#)).

Box 28-5

Clinical Manifestations of Juvenile Hypothyroidism

Decelerated growth

- Less when acquired at later age

Myxedematous skin changes

- Dry skin
- Puffiness around eyes
- Sparse hair
- Constipation
- Sleepiness
- Mental decline

Therapy is TH replacement, the same as for hypothyroidism in infants, although the prompt treatment needed in infants is not required in children. Levothyroxine is administered over a period of 4 to 8 weeks to avoid symptoms of hyperthyroidism. Children treated early continue to have mild delays in reading, comprehension, and arithmetic but catch up. However, adolescents may demonstrate problems with memory, attention, and visuospatial processing.

Nursing Care Management

The importance of early recognition in the infant is discussed in [Chapter 8](#). Growth cessation or retardation in a child whose growth has previously been normal should alert the observer to the possibility of hypothyroidism. Treatment is daily oral TH replacement. The importance of daily compliance and the need for periodic monitoring of serum thyroid levels should be stressed to patients and their families.

Goiter

A goiter is an enlargement or hypertrophy of the thyroid gland. It may occur with deficient (hypothyroid), excessive (hyperthyroid), or normal (euthyroid) TH secretion. It can be congenital or acquired. Congenital disease occurs as a result of maternal administration of antithyroid drugs or iodides during pregnancy or as an inborn error of TH production. Acquired disease can result from increased secretion of pituitary TSH in response to decreased circulating levels of TH or from infiltrative neoplastic or inflammatory processes. In areas where dietary iodine (essential for TH production) is deficient, goiter can be endemic.

Enlargement of the thyroid gland may be mild and noticeable only when there is an increased demand for TH (e.g., during periods of rapid growth). Enlargement of the thyroid at birth can be sufficient to cause severe respiratory distress. Sporadic goiter is usually caused by lymphocytic thyroiditis. TH replacement is necessary to treat resulting hypothyroidism and reverse the TSH effect on the gland.

Nursing Care Management

Large goiters are identified by their obvious appearance. Smaller nodules may be evident only on palpation. Benign enlargement of the thyroid gland may occur during adolescence and should not be confused with pathologic states. Nodules rarely are caused by a cancerous tumor but always require evaluation. Nurses should be aware of the possibility of goiters and report findings. Questions regarding radiation exposure should be included in patient assessments.

Nursing Alert

If an infant is born with a goiter, immediate precautions are instituted for emergency ventilation, such as supplemental oxygen and a tracheostomy set nearby. Hyperextension of the neck often facilitates breathing.

Immediate surgery to remove part of the gland may be lifesaving in infants born with a goiter. When thyroid replacement is necessary, parents have the same needs regarding its administration as discussed for the parents of children who have hypothyroidism.

Lymphocytic Thyroiditis

Lymphocytic thyroiditis (**Hashimoto disease, chronic autoimmune thyroiditis**) is the most common cause of thyroid disease in children and adolescents and accounts for the largest percentage of juvenile hypothyroidism. It accounts for many of the enlarged thyroid glands formerly designated *thyroid hyperplasia of adolescence* or *adolescent goiter*. Although lymphocytic thyroiditis can occur during the first 3 years of life, it occurs more frequently after 6 years old, with peak incidence occurring during adolescence. The presence of a goiter and elevated thyroglobulin antibody with progressive increase in both thyroid peroxidase antibody and TSH may be predictive factors for future development of hypothyroidism (Radetti, Gottardi, Bona, et al, 2006).

An enlarged thyroid gland is often detected during routine examination. Parents may notice it when a child swallows. In most children, the entire gland is enlarged symmetrically (although it may be asymmetric) and is firm, freely movable, and nontender. There may be manifestations of moderate tracheal compression (sense of fullness, hoarseness, and dysphagia). However, it is extremely rare for a nontoxic diffuse goiter to cause airway obstruction. Most children are euthyroid, but some display symptoms of hypothyroidism. Other signs suggestive of thyroiditis are found in [Box 28-6](#).

Box 28-6

Clinical Manifestations of Lymphocytic Thyroiditis

Enlarged Thyroid Gland

Usually symmetric

Firm

Freely movable

Nontender

Tracheal Compression

Sense of fullness

Hoarseness

Dysphagia

Hyperthyroidism (Possible)

Nervousness

Irritability

Increased sweating

Hyperactivity

Diagnostic Evaluation

Thyroid function test results are usually normal, although TSH levels may be slightly or moderately elevated. With progressive disease, the T_4 decreases, followed by a decrease in T_3 levels and an increase in TSH. The majority of children have antithyroid antibody titers. However, levels in children are lower than in adults; therefore, repeated measurements may be needed in doubtful cases because titers may increase later in the disease.

Therapeutic Management

In many cases, the goiter is transient, asymptomatic and regresses spontaneously within a year or two. Therapy of a nontoxic diffuse goiter is usually simple, uncomplicated, and effective. Oral administration of TH provides the feedback needed to suppress TSH stimulation and decrease the size of the thyroid gland. TSH levels should be monitored, with the goal of restoring normal growth and development. Surgery is contraindicated in this disorder. Untreated patients should be evaluated periodically.

Nursing Care Management

Nurses help identify children with thyroid enlargement and provide reassurance and education regarding therapy and positive outcome.

Hyperthyroidism

Graves disease is the most common cause of hyperthyroidism in children. This disease often runs in families. **Graves disease** associated hyperthyroidism is caused by autoantibodies to the TSH receptor causing excess secretion of TH. Most cases of Graves disease in children occur in adolescence, with a peak incidence between 12 and 14 years old. Transient **Graves disease** may be present at birth in children of thyrotoxic mothers. The incidence is higher in girls than boys (Léger and Carel, 2013). There is no cure for **Graves disease**, and treatment options continue to be debated among pediatric endocrinologists (Léger and Carel, 2013).

Signs and symptoms of **Graves disease** develop gradually, with an interval between onset and diagnosis of approximately 6 to 12 months. Clinical features include irritability, hyperactivity, short attention span, tremors, insomnia, and emotional lability. Clinical manifestations are presented in [Box 28-7](#).

Box 28-7

Clinical Manifestations of Hyperthyroidism (Graves Disease)

Cardinal Signs

- Emotional lability
- Physical restlessness, characteristically at rest
- Decelerated school performance
- Voracious appetite with weight loss in 50% of cases
- Fatigue

Physical Signs

- Tachycardia
- Widened pulse pressure
- Dyspnea on exertion
- Exophthalmos (protruding eyeballs)

Wide-eyed, staring expression with eyelid lag

Tremor

Goiter (hypertrophy and hyperplasia)

Warm, moist skin

Accelerated linear growth

Heat intolerance (may be severe)

Hair fine and unable to hold a curl

Systolic murmurs

Thyroid Storm

Acute onset:

- Severe irritability and restlessness
- Vomiting
- Diarrhea
- Hyperthermia
- Hypertension
- Severe tachycardia
- Prostration

May progress rapidly to:

- Delirium
- Coma
- Death

Exophthalmos (protruding eyeballs), which is observed in many children, is accompanied by a wide-eyed staring expression, increased blinking, eyelid lag, lack of convergence, and absence of wrinkling of the forehead when looking upward. As exophthalmos progresses, the eyelid may not fully cover the cornea. Visual disturbances may include blurred vision and loss of visual acuity. Eye disease associated with hyperthyroidism can develop before or after the clinical diagnosis.

Diagnostic Evaluation

Graves disease is established on the basis of increased levels of T_4 and T_3 . TSH is suppressed to unmeasurable levels (Ma, Kuang, Xie, et al, 2008). Other tests are rarely indicated.

Therapeutic Management

Therapy for hyperthyroidism is controversial, but the end goal is the same—decrease the circulating TH. The three acceptable modes available are antithyroid drugs, subtotal thyroidectomy, and ablation with radioiodine (¹³¹I iodide) (Lee and Hwang, 2014; Léger and Carel, 2013). Each therapy has advantages and disadvantages.

When affected children exhibit signs and symptoms of hyperthyroidism (e.g., increased weight loss, pulse, pulse pressure, and blood pressure), their activity should be limited to classwork only. Vigorous exercise is restricted until thyroid levels are decreased to normal or near-normal values.

Thyrotoxicosis (thyroid “crisis” or thyroid “storm”) may occur from sudden release of TH. Although thyrotoxicosis is unusual in children, it can be life threatening. Clinical signs of thyroid storm are acute onset of severe irritability and restlessness, vomiting, diarrhea, hyperthermia, hypertension, severe tachycardia, and prostration. There may be rapid progression to delirium, coma, and even death. A crisis may be precipitated by acute infection, surgical emergencies, or discontinuation of antithyroid therapy. In addition to antithyroid drugs, beta blockers are used to control symptoms until normal thyroid function is achieved (Léger and Carel, 2013). Therapy is usually required for 2 to 3 weeks.

The American Thyroid Association* has an extensive website with information related to prevention, treatment, and cure of thyroid disease.

Nursing Care Management

Because the clinical manifestations often appear gradually, the goiter and ophthalmic changes may not be noticed, and the excessive activity may be attributed to behavioral problems. Nurses in ambulatory settings, particularly schools, need to be alert to signs that suggest this disorder. Weight loss despite an excellent appetite, academic difficulties resulting from a short attention span, inability to sit still, unexplained fatigue and sleeplessness, and difficulty with fine motor skills such as writing, can all be signs of this disease. Exophthalmos may develop long before the onset of the signs and symptoms and may be the only presenting sign.

Nursing care focuses on treating physical symptoms before a response to drug therapy is achieved. Children with hyperthyroidism need a quiet, unstimulating environment that is conducive to rest. Increased metabolic rate may cause heat intolerance and increased food intake in these patients. Mood swings and irritability can disrupt relationships, creating difficulties within and outside the home. Nurses can help parents understand the medical reason for behavior changes and offer ways to minimize them. A school consultation is important to provide education and suggest ways to assist a child after diagnosis.

Nurses should know the side effects of antithyroid drug therapy, including urticarial rash, fever, arthralgias, vasculitis, liver dysfunction, and agranulocytosis. Lymphadenopathy, edema, and diminished taste can also occur. Parents must understand the signs of hypothyroidism, which can occur from overdose.

Nursing Alert

Children being treated with propylthiouracil or methimazole must be carefully monitored for side effects of the drug. Because sore throat and fever accompany the grave complication of leukopenia, these children should be seen by a practitioner if such symptoms occur. Parents and children should be taught to recognize and report symptoms immediately.

Nursing Alert

The earliest indication of hypoparathyroidism may be anxiety and mental depression followed by paresthesia and evidence of heightened neuromuscular excitability, such as:

Chvostek sign: Facial muscle spasm elicited by tapping the facial nerve in the region of the parotid gland

Trousseau sign: Carpal spasm elicited by pressure applied to nerves of the upper arm

Tetany: Carpopedal spasm (sharp flexion of wrist and ankle joints), muscle twitching, cramps, seizures, and stridor

Disorders of Parathyroid Function

The parathyroid glands secrete **parathyroid hormone (PTH)**. Along with vitamin D and calcitonin, PTH regulates the homeostasis of serum calcium concentrations ([Gardner and Shoback, 2011](#)). The effect of PTH on calcium is opposite that of calcitonin. PTH and vitamin D work together to maintain serum calcium levels within a narrow normal range. They are required for bone mineralization. Secretion of PTH is controlled by a negative feedback system involving the serum calcium ion concentration. Low ionized calcium levels stimulate PTH secretion, causing absorption of calcium by the target tissues; high ionized calcium concentrations suppress PTH.

Hypoparathyroidism

Hypoparathyroidism is a spectrum of disorders that result in deficient PTH. **Congenital hypoparathyroidism** may be caused by a specific defect in the synthesis or cellular processing of PTH, or by aplasia or hypoplasia of the gland ([Gardner and Shoback, 2011](#)).

Hypoparathyroidism may occur secondary to other causes, including infection and autoimmune syndromes. Postoperative hypoparathyroidism may follow thyroidectomy. Two forms of transient hypoparathyroidism may be present in newborns, both of which are the result of PTH deficiency. One type is caused by maternal hyperparathyroidism. A more common form appears almost exclusively in infants fed a milk formula with a high phosphate-to-calcium ratio.

Pseudohypoparathyroidism occurs when there is a genetic defect in the cellular receptors to PTH. The result is normal parathyroid gland and PTH levels. Abnormal calcium and phosphorus levels are not affected by administration of PTH. These children typically have a short, stocky build; a round face; and abnormally shaped hands and fingers. Other endocrine dysfunction may be found concurrently ([Shoback, 2008](#)).

Clinical signs of hypoparathyroidism are found in [Box 28-8](#). Muscle cramps are an early symptom, progressing to numbness, stiffness, and tingling in the hands and feet. A positive Chvostek or Trousseau sign or laryngeal spasms may be present. Convulsions with loss of consciousness may occur. These episodes may be preceded by abdominal discomfort, tonic rigidity, head retraction, and cyanosis. Headaches and vomiting with increased intracranial pressure and papilledema may occur and may suggest a brain tumor ([Doyle, 2016](#)). Hypoparathyroidism is associated with poor growth in children ([Waller, 2011](#)).

Box 28-8

Clinical Manifestations of Hypoparathyroidism

Pseudohypoparathyroidism

Short stature

Round face

Short, thick neck

Short, stubby fingers and toes

Dimpling of skin over knuckles

Subcutaneous soft tissue calcifications

Intellectual disability a prominent feature

Idiopathic Hypoparathyroidism

None of the above physical characteristics observed

May include papilledema

May have intellectual disability

Both Types

Dry, scaly, coarse skin with eruptions

Hair often brittle

Nails thin and brittle with characteristic transverse grooves

Dental and enamel hypoplasia

Muscle contractions:

- Tetany
- Carpopedal spasm
- Laryngospasm (laryngeal stridor)
- Muscle cramps and twitching
- Positive Chvostek sign or Trousseau sign
- Paresthesias, tingling

Neurologic:

- Headache
- Seizures (generalized, absence, or focal)
- Swings of emotion
- Loss of memory
- Depression
- Confusion possible

Gastrointestinal:

- Muscle cramps
- Diarrhea
- Vomiting
- Retarded skeletal growth

Diagnostic Evaluation

The diagnosis of hypoparathyroidism is made on the basis of clinical manifestations associated with **decreased serum calcium** and **increased serum phosphorus**. Levels of plasma PTH are low in idiopathic hypoparathyroidism but high in pseudohypoparathyroidism. End-organ responsiveness is tested by the administration of PTH with measurement of urinary cyclic adenosine monophosphate (cAMP). Kidney function tests are included in the differential diagnosis to rule out renal insufficiency. Magnesium levels should also be tested. Although bone radiograph findings are

usually normal, they may demonstrate increased bone density and suppressed growth.

Therapeutic Management

The objective of treatment is to maintain normal serum calcium and phosphate levels with minimum complications. Acute or severe tetany is corrected immediately by IV and oral administration of calcium gluconate and follow-up daily doses to achieve normal levels. Twice-daily serum calcium measurements are taken to monitor the efficacy of therapy and prevent hypercalcemia. When diagnosis is confirmed, **vitamin D therapy** is begun. Vitamin D therapy is somewhat difficult to regulate because the drug has a prolonged onset and a long half-life. Some advocate beginning with a lower dose with stepwise increases and careful monitoring of serum calcium until stable levels are achieved. Others prefer rapid induction with higher doses and rapid reduction to lower maintenance levels (Cooper and Gittoes, 2008; Doyle, 2016).

Long-term management usually consists of vitamin D and oral calcium supplementation. Blood calcium and phosphorus are monitored frequently until the levels have stabilized. Renal function, blood pressure, and serum vitamin D levels are measured every 6 months. Serum magnesium levels are measured to permit detection of hypomagnesemia, which may raise the requirement for vitamin D.

Nursing Care Management

Unexplained convulsions, irritability (especially to external stimuli), gastrointestinal symptoms (diarrhea, vomiting, cramping), and positive signs of tetany are signs of hypocalcemia related to hypoparathyroidism. Nursing care includes institution of seizure and safety precautions; reduction of environmental stimuli; and observation for signs of laryngospasm, such as stridor, hoarseness, and a feeling of tightness in the throat. A tracheostomy set and injectable calcium gluconate should be available for emergency use. The administration of calcium gluconate requires precautions against extravasation of the drug and tissue destruction.

The nurse educates the family about continuous daily calcium and vitamin D. Because vitamin D toxicity can be a serious consequence of therapy, parents are advised to watch for signs that include weakness, fatigue, lassitude, headache, nausea, vomiting, and diarrhea. Polyuria, polydipsia, and nocturia are signs of early renal impairment.

Hyperparathyroidism

Hyperparathyroidism is rare in childhood but can be primary or secondary. The most common cause of primary hyperparathyroidism is adenoma of the gland (Doyle 2016). The most common causes of secondary hyperparathyroidism are chronic renal disease, renal osteodystrophy, and congenital anomalies of the urinary tract. The common factor is hypercalcemia. The clinical signs of hyperparathyroidism are listed in Box 28-9.

Box 28-9

Clinical Manifestations of Hyperparathyroidism

Gastrointestinal

Nausea

Vomiting

Abdominal discomfort

Constipation

Central Nervous System

Delusions

Confusion

Hallucinations

Impaired memory

Lack of interest and initiative

Depression

Varying levels of consciousness

Neuromuscular

Weakness

Easy fatigability

Muscle atrophy (especially proximal muscles of lower limbs)

Tongue twitching

Paresthesias in extremities

Skeletal

Vague bone pain

Subperiosteal resorption of phalanges

Spontaneous fractures

Absence of lamina dura around teeth

Renal

Polyuria

Polydipsia

Renal colic

Hypertension

Diagnostic Evaluation

Blood studies to identify elevated calcium and decreased phosphorus levels are routinely performed. Measurement of PTH and tests to isolate the cause of the hypercalcemia, such as renal function studies, should be included. If parathyroid adenoma is suspected, imaging using ultrasound and a sestamibi nuclear subtraction study are recommended (Igbal and Wahoff, 2009). Other procedures used to substantiate the physiologic consequences of the disorder include electrocardiography and radiographic bone surveys.

Therapeutic Management

Treatment depends on the cause of hyperparathyroidism. The treatment of primary hyperparathyroidism is surgical removal of the tumor (Lietman, Germain-Lee, and Levine, 2010). Treatment of secondary hyperparathyroidism is directed at the underlying contributing cause, which subsequently restores the serum calcium balance. However, in some instances (such as in chronic renal failure), the underlying disorder is irreversible. In this case, treatment is aimed at raising serum calcium levels to inhibit the stimulatory effect of low levels on the parathyroids. This includes oral administration of calcium salts, high doses of vitamin D to enhance calcium absorption, a low-phosphorus diet, and administration of a phosphorus-mobilizing aluminum

hydroxide to reduce phosphate absorption.

Nursing Care Management

The initial nursing objective is recognition of the disorder. Because secondary hyperparathyroidism is a consequence of chronic renal failure, the nurse is always alert to signs that suggest this complication, especially bone pain and fractures. Because urinary symptoms are the earliest indication, assessment of other body systems for evidence of high calcium levels is indicated when polyuria and polydipsia coexist. Clues to the possibility of hyperparathyroidism include change in behavior, especially inactivity; unexplained gastrointestinal symptoms; and cardiac irregularities.

Disorders of Adrenal Function

The **adrenal cortex** secretes three main groups of hormones collectively called **steroids** and classified according to their biologic activity: (1) **glucocorticoids** (cortisol, corticosterone), (2) **mineralocorticoids** (aldosterone), and (3) **sex steroids** (androgens, estrogens, and progestins). The glucocorticoids and mineralocorticoids affect metabolism and stress. The sex steroids influence sexual development but are not essential because the gonads secrete the major supply of these hormones.

The **adrenal medulla** secretes the **catecholamines epinephrine** and **norepinephrine**. Both hormones have the same effects on various organs as those caused by direct sympathetic stimulation except the hormonal effects last several times longer. Catecholamine-secreting tumors are the primary cause of adrenal medullary hyperfunction.

Acute Adrenocortical Insufficiency

The acute form of adrenocortical insufficiency (**adrenal crisis**) may have a number of causes during childhood. Although rare, causes of adrenal insufficiency in children include hemorrhage into the gland from trauma, which may be caused by a difficult labor; fulminating infections, such as meningococemia; abrupt withdrawal of exogenous sources of cortisone or failure to increase exogenous supplies during stress; or congenital adrenogenital hyperplasia of the salt-losing type.

Early symptoms of adrenocortical insufficiency include increased irritability, headache, diffuse abdominal pain, weakness, nausea and vomiting, and diarrhea. Other clinical signs are found in [Box 28-10](#). In newborns, adrenal crisis is accompanied by high fever, tachypnea, cyanosis, and seizures. Usually there is no evidence of infection or clinical signs of bleeding. However, hemorrhage into the adrenal gland may be evident as a palpable retroperitoneal mass.

Box 28-10

Clinical Manifestations of Acute Adrenocortical Insufficiency

Early Symptoms

Increased irritability

Headache

Diffuse abdominal pain

Weakness

Nausea and vomiting

Diarrhea

Generalized Hemorrhagic Manifestations (Waterhouse-Friderichsen Syndrome)

Fever (increases as condition worsens)

Central nervous system (CNS) signs:

- Nuchal rigidity
- Seizures

- Stupor
- Coma

Shocklike State

Weak, rapid pulse

Decreased blood pressure

Shallow respirations

Cold, clammy skin

Cyanosis

Circulatory collapse (terminal event)

Newborn

Hyperpyrexia

Tachypnea

Cyanosis

Seizures

Gland evident as palpable retroperitoneal mass (hemorrhagic)

Diagnostic Evaluation

There is no rapid, definitive test to confirm acute adrenocortical insufficiency. Diagnosis is often made based on clinical presentation, especially when a fulminating sepsis is accompanied by hemorrhagic manifestations and signs of circulatory collapse despite adequate antibiotic therapy. Because there is no real danger in administering a cortisol preparation for a short period, treatment is instituted immediately. Improvement with cortisol therapy confirms the diagnosis.

Therapeutic Management

Treatment involves replacement of cortisol, replacement of body fluids to combat dehydration and hypovolemia, administration of glucose solutions to correct hypoglycemia, and specific antibiotic therapy in the presence of infection. Initially, IV hydrocortisone (Solu-Cortef) is administered. Normal saline containing 5% glucose is given parenterally to replace lost fluid, electrolytes, and glucose. If hemorrhage has been severe, whole blood may be replaced. In the event that these measures do not reverse the circulatory collapse, vasopressors are used for immediate vasoconstriction and elevation of blood pressure.

After the child's condition has been stabilized, oral doses of cortisone, fluids, and salt are given, similar to the regimen used for chronic adrenal insufficiency. To maintain sodium retention, aldosterone is replaced by synthetic salt-retaining steroids.

Nursing Care Management

Because of the abrupt onset and potentially fatal outcome of this condition, prompt recognition is essential. Vital signs and blood pressure are taken every 15 minutes. Seizure precautions are instituted. The nurse should monitor the child's response to fluid and cortisol replacement. Rapid administration of fluids can precipitate cardiac failure and overdosage with cortisol may cause hypotension and a sudden fall in temperature.

When the acute phase is over and the hypovolemia has been corrected, the child is given oral fluids in small quantities. Rapid ingestion of oral fluids may induce vomiting, which increases

dehydration. Therefore, the nurse should plan a gradual schedule for reintroducing liquids.

Nursing Alert

Monitor serum electrolyte levels and observe for signs of hypokalemia or hyperkalemia (e.g., weakness, poor muscle control, paralysis, cardiac dysrhythmias, and apnea). The condition is rapidly corrected with IV or oral potassium replacement.

Nursing Tip

When an oral potassium preparation is given, it should be mixed with a small amount of strongly flavored fruit juice to disguise its bitter taste.

The sudden, severe nature of this disorder necessitates a great deal of emotional support for the child and family. The child may be placed in an intensive care unit where the surroundings are strange and frightening. Despite the need for emergency intervention, the nurse must be sensitive to the family's psychological needs and prepare them for each procedure even if this is a brief statement, such as "The IV infusion is necessary to replace fluid that the child is losing." Because recovery within 24 hours is often dramatic, the nurse should keep the parents apprised of the child's condition, emphasizing signs of improvement, such as a lowered temperature and elevated blood pressure.

Chronic Adrenocortical Insufficiency (Addison Disease)

Chronic adrenocortical insufficiency is rare in children. Causes include infection, a destructive lesion of the adrenal gland, and autoimmune processes, but they may also be idiopathic. Because 90% of adrenal tissue must be nonfunctional before signs of insufficiency are manifested, onset of symptoms is often gradual. However, during periods of stress, when demands for additional cortisol are increased, symptoms of acute insufficiency may appear in a previously well child (Box 28-11).

Box 28-11

Clinical Manifestations of Chronic Adrenocortical Insufficiency

Neurologic Symptoms

Muscular weakness

Mental fatigue

Irritability, apathy, and negativism

Increased sleeping, listlessness

Pigmentary Changes

Previous scars

Palmar creases

Mucous membranes

Hair

Hyperpigmentation over pressure points (elbows, knees, or waist)

Less frequently, vitiligo (loss of pigmentation)

Gastrointestinal Symptoms

Dehydration

Anorexia

Weight loss

Circulatory Symptoms

Hypotension

Small heart size

Dizziness

Syncopal (fainting) attacks

Hypoglycemia

Headache

Hunger

Weakness

Trembling

Sweating

Other Signs (Seen in Some Children)

Recurrent, unexplained seizures

Intense craving for salt

Acute abdominal pain

Electrolyte imbalances

Definitive diagnosis is based on measurements of functional cortisol reserve. The fasting serum cortisol and urinary 17-hydroxycorticosteroid levels are low and fail to rise, and plasma **adrenocorticotropic hormone (ACTH)** levels are elevated with corticotropin (ACTH) stimulation, the definitive test for the disease.

Therapeutic Management

Treatment involves replacement of **glucocorticoids (cortisol)** and **mineralocorticoids (aldosterone)**. Some children are able to be maintained solely on oral supplements of cortisol (cortisone or hydrocortisone preparations) with a liberal intake of salt. During stressful situations (such as fever, infection, emotional upset, or surgery), the dosage must be tripled to accommodate the body's increased need for glucocorticoids. Failure to meet this requirement will precipitate an acute crisis. Overdosage produces appearance of cushingoid signs.

Children with more severe states of chronic adrenal insufficiency require mineralocorticoid replacement to maintain fluid and electrolyte balance. Other forms of therapy include monthly injections of desoxycorticosterone acetate or implantation of desoxycorticosterone acetate pellets subcutaneously every 9 to 12 months.

Nursing Care Management

After the disorder is diagnosed, parents need guidance concerning drug therapy. They must be

aware of the continuous need for cortisol replacement. Sudden termination of the drug because of inadequate supplies or inability to ingest the oral form because of vomiting, places the child in danger of an acute adrenal crisis. Parents should always have a spare supply of medication. Ideally, families will have a prefilled syringe of hydrocortisone and have training to administer this drug during a crisis. Unnecessary administration of cortisone will not harm the child, but if it is needed, it may be lifesaving. Any evidence of acute insufficiency should be reported to the practitioner immediately.

Undesirable side effects of cortisone include gastric irritation, which is minimized by ingestion with food or the use of an antacid; increased excitability and sleeplessness; weight gain, which may require dietary management to prevent obesity; and occasionally, behavioral changes, including depression or euphoria. Parents should be aware of signs of overdose and report these to the practitioner. In addition, the drug has a bitter taste, which creates a challenge.

Because the body cannot supply endogenous sources of cortical hormones during times of stress, the home environment should be stable and relatively unstressful. Parents need to be aware that during periods of emotional or physical crisis, the child requires additional hormone replacement. The child should wear a medical identification bracelet, to notify medical personnel during emergency care.

Cushing Syndrome

Cushing syndrome is a characteristic group of manifestations caused by excessive circulating free cortisol. It can result from a variety of causes, which generally fall into one of five categories (Box 28-12).

Box 28-12

Etiology of Cushing Syndrome

Pituitary: Cushing syndrome with adrenal hyperplasia, usually attributed to an excess of ACTH

Adrenal: Cushing syndrome with hypersecretion of glucocorticoids, generally a result of adrenocortical neoplasms

Ectopic: Cushing syndrome with autonomous secretion of ACTH, most often caused by extrapituitary neoplasms

Iatrogenic: Cushing syndrome, frequently a result of administration of large amounts of exogenous corticosteroids

Food dependent: Inappropriate sensitivity of adrenal glands to normal postprandial increases in secretion of gastric inhibitory polypeptide

ACTH, Adrenocorticotrophic hormone.

Adapted from Magiakou MA, Mastorakos G, Oldfield EH, et al: Cushing's syndrome in children and adolescents: presentation, diagnosis, and therapy, *N Engl J Med* 331(10):629–636, 1994.

Cushing syndrome is uncommon in children. When seen, it is often caused by excessive or prolonged steroid therapy that produces a cushingoid appearance (Fig. 28-2). This condition is reversible after the steroids are gradually discontinued. Abrupt withdrawal will precipitate acute adrenal insufficiency. Gradual withdrawal of exogenous supplies is necessary to allow the anterior pituitary an opportunity to secrete increasing amounts of ACTH to stimulate the adrenals to produce cortisol.

FIG 28-2 Characteristics of Cushing syndrome.

Clinical Manifestations

Because the actions of cortisol are widespread, clinical manifestations are equally profound and diverse. The symptoms that produce changes in physical appearance occur early in the disorder and are of considerable concern to school-age and older children. The physiologic disturbances, such as hyperglycemia, susceptibility to infection, hypertension, and hypokalemia, may have life-threatening consequences unless recognized early and treated successfully. Children with short stature may be responding to increased cortisol levels, resulting in Cushing syndrome. Cortisol inhibits the action of GH.

Diagnostic Evaluation

Several tests are helpful in confirming excess Cushing syndrome. Serum cortisol levels should be measured at midnight and in the morning along with corticotropin hormone, urinary free cortisol, fasting blood glucose levels for hyperglycemia, serum electrolyte levels for hypokalemia and alkalosis, and 24-hour urinary levels of elevated 17-hydroxycorticoids and 17-ketosteroids (Lowitz and Keil, 2015). Imaging of the pituitary and adrenal glands to assess for tumors, bone density studies for evidence of osteoporosis, and skull radiographs to determine enlargement of the sella turcica may also aid in the diagnosis. Another procedure used to establish a more definitive diagnosis is the dexamethasone (cortisone) suppression test (Batista, Riar, and Keil, 2007). Administration of an exogenous supply of cortisone normally suppresses ACTH production. However, in individuals with Cushing syndrome, cortisol levels remain elevated. This test is helpful in differentiating between children who are obese and those who appear to have cushingoid features.

Therapeutic Management

Treatment depends on the cause. In most cases, surgical intervention involves bilateral adrenalectomy and postoperative replacement of the cortical hormones (the therapy for this is the same as that outlined for chronic adrenocortical insufficiency). If a pituitary tumor is found, surgical

extirpation or irradiation may be chosen. In either of these instances, treatment of panhypopituitarism with replacement of GH, TH, ADH, gonadotropins, and steroids may be necessary for an indefinite period (Lau, Rutledge, and Aghi, 2015).

Nursing Care Management

Nursing care also depends on the cause. When cushingoid features are caused by steroid therapy, the effects may be lessened with administration of the drug early in the morning and on an alternate-day basis. Giving the drug early in the day maintains the normal diurnal pattern of cortisol secretion. If given during the evening, it is more likely to produce symptoms because endogenous cortisol levels are already low, and the additional supply exerts more pronounced effects. An alternate-day schedule allows the anterior pituitary an opportunity to maintain more normal hypothalamic–pituitary–adrenal control mechanisms.

If an organic cause is found, nursing care is related to the treatment regimen. Although a bilateral adrenalectomy permanently solves one condition, it reciprocally produces another syndrome. Before surgery, parents need to be adequately informed of the operative benefits and disadvantages. Postoperative teaching regarding drug replacement is the same as discussed in the previous section.

Nursing Alert

Postoperative complications of adrenalectomy are related to the sudden withdrawal of cortisol. Observe for shocklike symptoms (e.g., hypotension, hyperpyrexia).

Anorexia and nausea and vomiting are common and may be improved with the use of nasogastric decompression. Muscle and joint pain may be severe, requiring use of analgesics. The psychological depression can be profound and may not improve for months. Parents should be aware of the physiologic reasons behind these symptoms in order to be supportive of the child.

Congenital Adrenal Hyperplasia

Congenital adrenal hyperplasia (CAH) is a family of disorders caused by decreased enzyme activity required for cortisol production in the adrenal cortex. The adrenal gland produces excessive amounts of cortisol precursors and androgens to compensate. The most common defect is **21-hydroxylase deficiency**, which constitutes more than 90% of all cases of CAH (Kaye, Committee on Genetics, Accurso F, et al, 2006). This deficiency is an autosomal recessive disorder that results in improper steroid hormone synthesis (Mendes, Vaz Matos, Ribeiro, et al, 2015).

Excessive androgens cause masculinization of the urogenital system at approximately the tenth week of fetal development. The most pronounced abnormalities occur in girls, who are born with varying degrees of ambiguous genitalia. Masculinization of external genitalia causes the clitoris to enlarge so that it appears as a small phallus. Fusion of the labia produces a saclike structure resembling the scrotum without testes. However, no abnormal changes occur in the internal sexual organs, although the vaginal orifice is usually closed by the fused labia. The label *ambiguous genitalia* should be applied to any infant with hypospadias or micropenis and no palpable gonads, and a diagnostic evaluation for CAH should be contemplated (Gardner and Shoback, 2011).

Increased pigmentation of skin creases and genitalia caused by increased ACTH may be a subtle sign of adrenal insufficiency. A salt-wasting crisis frequently occurs, usually within the first few weeks of life (White, 2016a). Infants fail to gain weight, and hyponatremia and hyperkalemia may be significant. Cardiac arrest can occur.

Untreated CAH results in early sexual maturation, with enlargement of the external sexual organs; development of axillary, pubic, and facial hair; deepening of the voice; acne; and a marked increase in musculature with changes toward an adult male physique. However, in contrast to precocious puberty, breasts do not develop in girls, and they remain amenorrheic and infertile. In boys, the testes remain small, and spermatogenesis does not occur. In both sexes, linear growth is accelerated, and epiphyseal closure is premature, resulting in short stature by the end of puberty.

Diagnostic Evaluation

Clinical diagnosis is initially based on congenital abnormalities that lead to difficulty in assigning

sex to the newborn and on signs and symptoms of adrenal insufficiency. Newborn screening is currently done in all 50 states by measurement of the cortisol precursor 17-hydroxyprogesterone. Definitive diagnosis is confirmed by evidence of increased 17-ketosteroid levels in most types of CAH (Kaye, Committee on Genetics, Accurso, et al, 2006). In complete 21-hydroxylase deficiency, blood electrolytes demonstrate loss of sodium and chloride and elevation of potassium. In older children, bone age is advanced, and linear growth is increased. Deoxyribonucleic acid (DNA) analysis for positive sex determination and to rule out any other genetic abnormality (e.g., Turner syndrome) is always done in any case of ambiguous genitalia.

Another test that can be used to visualize the presence of pelvic structures is ultrasonography, a noninvasive, painless imaging technique that does not require anesthesia or sedation. It is especially useful in CAH because it readily identifies the absence or presence of female reproductive organs or male testes in a newborn or child with ambiguous genitalia. Because ultrasonography yields immediate results, it has the advantage of determining the child's gender long before the more complex laboratory results for chromosome analysis or steroid levels are available.

Therapeutic Management

After diagnosis is confirmed, medical management includes administration of glucocorticoids to suppress the abnormally high secretions of ACTH and adrenal androgens. If cortisone is begun early enough, it is very effective. Cortisone depresses the secretion of ACTH by the anterior pituitary, which in turn inhibits the secretion of adrenocorticosteroids, which stems the progressive virilization. The signs and symptoms of masculinization in girls gradually disappear, and excessive early linear growth is slowed. Puberty occurs normally at the appropriate age.

The recommended oral dosage is divided to simulate the normal diurnal pattern of ACTH secretion. Because these children are unable to produce cortisol in response to stress, it is necessary to increase the dosage during episodes of infection, fever, surgery, or other stresses. Acute emergencies require immediate IV or intramuscular administration. Children with the salt-losing type of CAH require aldosterone replacement, as outlined under chronic adrenal insufficiency, and supplementary dietary salt. Frequent laboratory tests are conducted to assess the effects on electrolytes, hormonal profiles, and renin levels. The frequency of testing is individualized to the child.

Gender assignment and surgical intervention in the newborn with ambiguous genitalia is complex and controversial. It is a significant stress for families, who need support from a multidisciplinary team of experienced specialists. Factors that influence gender assignment include genetic diagnosis, genital appearance, surgical options, fertility, and family and cultural preferences. Generally, genetically female (46XX) infants should be raised as girls. Early reconstructive surgery should be considered only in the case of severe virilization (Lee, Houk, Ahmed, et al, 2006). Emphasis is on functional rather than cosmetic outcomes, and surgery can often be delayed. Reports concerning sexual satisfaction after partial clitoridectomy indicate that the capacity for orgasm and sexual gratification is not necessarily impaired. Male infants may require phallic reconstruction by an experienced surgeon.

Unfortunately, not all children with CAH are diagnosed at birth and raised in accordance with their genetic sex. Particularly in the case of affected females, masculinization of the external genitalia may have led to sex assignment as a male. In males, diagnosis is usually delayed until early childhood, when signs of virilism appear. In these situations, it is advisable to continue rearing the child as a male in accordance with assigned sex and phenotype. Hormone replacement may be required to permit linear growth and to initiate male pubertal changes. Surgery is usually indicated to remove the female organs and reconstruct the phallus for satisfactory sexual relations. These individuals are not fertile.

Nursing Care Management

Of major importance is recognition of ambiguous genitalia and diagnostic confirmation in newborns. Parents need assistance in understanding and accepting the condition and time to grieve for the loss of perfection in their newborn child. As soon as the sex is determined, parents should be informed of the findings and encouraged to choose an appropriate name, and the child should be identified as a male or female with no reference to ambiguous sex.

In general, rearing a genetically female child as a girl is preferred because of the success of surgical intervention and the satisfactory results with hormones in reversing virilism and providing

a prospect of normal puberty and the ability to conceive. This is in contrast to the choice of rearing the child as a boy, in which case the child is sterile and may never be able to function satisfactorily in heterosexual relationships. If the parents persist in their decision to assign a male sex to a genetically female child, a psychological consultation should be requested to explore their motivations and ensure their understanding of the future consequences for the child.

Nursing care management regarding cortisol and aldosterone replacement are the same as those discussed for chronic adrenocortical insufficiency. Because infants are especially prone to dehydration and salt-losing crises, parents need to be aware of signs of dehydration and the urgency of immediate medical intervention to stabilize the child's condition. Parents should have injectable hydrocortisone available and know how to prepare and administer the intramuscular injection (see [Chapter 20](#)).

In the unfortunate situation in which the sex is erroneously assigned and the correct sex determined later, parents need a great deal of help in understanding the reason for the incorrect sex identification and the options for sex reassignment or medical-surgical intervention.

Parents should be referred for genetic counseling before they conceive another child because CAH is an autosomal recessive disorder. Prenatal diagnosis and treatment are available.

Nursing Alert

The parents should be advised that there is no physical harm in treating for suspected adrenal insufficiency that is not present, but the consequence of not treating acute adrenal insufficiency can be fatal.

Pheochromocytoma

Pheochromocytoma is a rare tumor characterized by secretion of catecholamines. The tumor most commonly arises from the chromaffin cells of the adrenal medulla but may occur wherever these cells are found, such as along the paraganglia of the aorta or thoracolumbar sympathetic chain. In children, they are frequently bilateral or multiple and are generally benign. Often there is a familial transmission of the condition as an autosomal dominant trait (White, 2016b).

The clinical manifestations of pheochromocytoma are caused by an increased production of catecholamines, producing hypertension, tachycardia, headache, decreased gastrointestinal activity and resulting constipation, increased metabolism with anorexia, weight loss, hyperglycemia, polyuria, polydipsia, hyperventilation, nervousness, heat intolerance, and diaphoresis. In severe cases, signs of congestive heart failure are evident.

Diagnostic Evaluation

The clinical manifestations mimic those of other disorders, such as hyperthyroidism or DM. Usually the tumor is identified by computed tomography (CT) scan or MRI. Definitive tests include 24-hour measurement of urinary levels of the catecholamine metabolites, histamine stimulation, and α -adrenergic blocking agents.

Therapeutic Management

Definitive treatment consists of surgical removal of the tumor. In children, the tumors may be bilateral, requiring a bilateral adrenalectomy and lifelong glucocorticoid and mineralocorticoid therapy. The major complications that can occur during surgery are severe hypertension, tachyarrhythmias, and hypotension. The first two are caused by excessive release of catecholamines during manipulation of the tumor, and the latter results from catecholamine withdrawal and hypovolemic shock.

Preoperative medication to inhibit the effects of catecholamines is begun 1 to 3 weeks before surgery to prevent these complications. The major group of drugs used is the α -adrenergic blocking agents. To control catecholamine release when α -adrenergic blocking agents are inadequate, the child is given β -adrenergic blocking agents.

Success of therapy is judged by lowering of blood pressure to normal, absence of hypertensive attacks (flushing or blanching, fainting, headache, palpitations, tachycardia, nausea and vomiting, profuse sweating), heat tolerance, a decrease in perspiration, and disappearance of hyperglycemia. The disadvantage of these drugs is their inability to block the effects of catecholamines on beta receptors.

Nursing Care Management

Children with hypertension and hypertensive attacks should be assessed for pheochromocytoma. Because of behavioral changes (nervousness, excitability, overactivity, and even psychosis), increased cardiac and respiratory activity may appear to be related to an acute anxiety attack. Therefore, a careful history of the onset of symptoms and association with stressful events is helpful in distinguishing between an organic and a psychological cause for the symptoms.

Preoperative nursing care involves frequent monitoring of vital signs and observation for evidence of hypertensive attacks and congestive heart failure. Therapeutic effects are evidenced by normal vital signs and absence of glycosuria. Daily blood glucose levels, urine acetone, and any signs of hyperglycemia are noted and reported immediately.

Nursing Alert

Do not palpate the mass. Preoperative palpation of the mass releases catecholamines, which can

stimulate severe hypertension and tachyarrhythmias.

The environment is made conducive to rest and free of emotional stress. This requires adequate preparation during hospital admission and before surgery. Parents are encouraged to room-in with their child and to participate in care. Play activities need to be tailored to the child's energy level without being overly strenuous or challenging, because these can increase metabolic rate and promote frustration and anxiety.

After surgery, the child is observed for signs of shock from removal of excess catecholamines. If a bilateral adrenalectomy was performed, the nursing interventions are those discussed for chronic adrenocortical insufficiency.

Disorders of Pancreatic Hormone Secretion

Diabetes Mellitus

DM is a chronic disorder of metabolism characterized by hyperglycemia and insulin resistance. It is the most common metabolic disease, resulting in metabolic adjustment or physiologic change in almost all areas of the body. The most recent statistics (2010) indicate that in the United States, approximately 215,000 children younger than 20 years old have either type 1 or type 2 diabetes (Centers for Disease Control and Prevention, 2010). The odds are higher for African-American and Hispanic children—nearly 50% of them will develop diabetes (Urrutia-Rojas and Menchaca, 2006). DM in children can occur at any age, but 40% of children diagnosed are between 10 to 14 years old and 60% are between 15 to 19 years old. Girls are 1.3 to 1.7 times more likely to develop type 2 diabetes than boys (Laffel and Svoren, 2015).

Traditionally, DM had been classified according to the type of treatment needed. The old categories were insulin-dependent diabetes mellitus (IDDM), or type I, and non-insulin-dependent diabetes mellitus (NIDDM), or type II. In 1997, these terms were eliminated because treatment can vary (some people with NIDDM require insulin) and because the terms do not indicate the underlying problem. The new terms are *type 1* and *type 2*, using Arabic symbols to avoid confusion (e.g., type II could be read as type eleven) (American Diabetes Association, 2001). The characteristics of type 1 DM and type 2 DM are outlined in Table 28-2.

TABLE 28-2

Characteristics of Type 1 and Type 2 Diabetes Mellitus

| Characteristic | Type 1 | Type 2 |
|-----------------------------------|--|---|
| Age at onset | <20 years | Increasingly occurring in younger children |
| Type of onset | Abrupt | Gradual |
| Sex ratio | Affects males slightly more than females | Females outnumber males |
| Percentage of diabetic population | 5% to 8% | 85% to 90% |
| Heredity: | | |
| Family history | Sometimes | Frequently |
| Human leukocyte antigen | Associations | No association |
| Twin concordance | 25% to 50% | 90% to 100% |
| Ethnic distribution | Primarily whites | Increased incidence in American Indians, Hispanics, African Americans |
| Presenting symptoms | Three Ps common—polyuria, polydipsia, polyphagia | May be related to long-term complications |
| Nutritional status | Underweight | Overweight |
| Insulin (natural): | | |
| Pancreatic content | Usually none | >50% normal |
| Serum insulin | Low to absent | High or low |
| Primary resistance | Minimum | Marked |
| Islet cell antibodies | 80% to 85% | <5% |
| Therapy: | | |
| Insulin | Always | 20% to 30% of patients |
| Oral agents | Ineffective | Often effective |
| Diet only | Ineffective | Often effective |
| Chronic complications | >80% | Variable |
| Ketoacidosis | Common | Infrequent |

In the age group younger than 10 years old, most diabetes cases are type 1 and occur most frequently in non-Hispanic whites. In the age group 10 to 19 years old, type 1 diabetes is more prominent in non-Hispanic whites followed by African Americans and then Hispanics; the lowest prevalence is among American Indians.

Type 1 diabetes is characterized by destruction of the pancreatic beta cells, which produce insulin; this usually leads to absolute insulin deficiency. Type 1 diabetes has two forms. Immune-mediated DM results from an autoimmune destruction of the beta cells; it typically starts in children or young adults who are slim, but it can arise in adults of any age. **Idiopathic type 1** refers to rare forms of the disease that have no known cause.

Type 2 diabetes usually arises because of insulin resistance in which the body fails to use insulin properly combined with relative (rather than absolute) insulin deficiency. People with type 2 can range from predominantly insulin resistant with relative insulin deficiency to predominantly deficient in insulin secretion with some insulin resistance. It typically occurs in those who are older than 45 years of age, are overweight and sedentary, and have a family history of diabetes.

The symptomatology of diabetes is more readily recognizable in children than in adults, so it is surprising that the diagnosis may sometimes be missed or delayed. Diabetes is a great imitator; influenza, gastroenteritis, and appendicitis are the conditions most often diagnosed when it turns out that the disease is really diabetes (Box 28-13).

Box 28-13

Clinical Manifestations of Type 1 Diabetes Mellitus

Polyphagia

Polyuria

Polydipsia

Weight loss

Enuresis or nocturia

Irritability; “not himself” or “not herself”

Shortened attention span

Lowered frustration tolerance

Dry skin

Blurred vision

Poor wound healing

Fatigue

Flushed skin

Headache

Frequent infections

Hyperglycemia

- Elevated blood glucose levels
- Glucosuria

Diabetic ketosis

- Ketones and glucose in urine
- Dehydration in some cases

Diabetic ketoacidosis (DKA)

- Dehydration
- Electrolyte imbalance
- Acidosis
- Deep, rapid breathing (Kussmaul respirations)

Pathophysiology

Insulin is needed to support the metabolism of carbohydrates, fats, and proteins, primarily by facilitating the entry of these substances into the cells. Insulin is needed for the entry of glucose into the muscle and fat cells, prevention of mobilization of fats from fat cells, and storage of glucose as glycogen in the cells of liver and muscle. Insulin is not needed for the entry of glucose into nerve cells or vascular tissue. The chemical composition and molecular structure of insulin are such that it fits into receptor sites on the cell membrane. Here it initiates a sequence of poorly defined chemical reactions that alter the cell membrane to facilitate the entry of glucose into the cell and stimulate enzymatic systems outside the cell that metabolize the glucose for energy production.

With a deficiency of insulin, glucose is unable to enter the cells, and its concentration in the bloodstream increases. The increased concentration of glucose (**hyperglycemia**) produces an osmotic gradient that causes the movement of body fluid from the intracellular space to the interstitial space and then to the extracellular space and into the glomerular filtrate to “dilute” the hyperosmolar filtrate. Normally, the renal tubular capacity to transport glucose is adequate to reabsorb all the glucose in the glomerular filtrate. When the glucose concentration in the glomerular filtrate exceeds the renal threshold (180 mg/dl), glucose spills into the urine (**glycosuria**) along with an osmotic diversion of water (**polyuria**), a cardinal sign of diabetes. The urinary fluid losses cause the excessive thirst (**polydipsia**) observed in diabetes. This water “washout” results in a depletion of other essential chemicals, especially potassium.

Protein is also wasted during insulin deficiency. Because glucose is unable to enter the cells, protein is broken down and converted to glucose by the liver (**glucogenesis**); this glucose then contributes to the hyperglycemia. These mechanisms are similar to those seen in starvation when substrate (glucose) is absent. The body is actually in a state of starvation during insulin deficiency. Without the use of carbohydrates for energy, fat and protein stores are depleted as the body attempts to meet its energy needs. The hunger mechanism is triggered, but increased food intake (polyphagia) enhances the problem by further elevating blood glucose.

Ketoacidosis

When insulin is absent or insulin sensitivity is altered, glucose is unavailable for cellular metabolism, and the body chooses alternate sources of energy, principally fat. Consequently, fats break down into fatty acids, and glycerol in the fat cells is converted by the liver to ketone bodies (β -hydroxybutyric acid, acetoacetic acid, acetone). Any excess is eliminated in the urine (**ketonuria**) or the lungs (**acetone breath**). The ketone bodies in the blood (ketonemia) are strong acids that lower serum pH, producing **ketoacidosis**.

Ketones are organic acids that readily produce excessive quantities of free hydrogen ions, causing a fall in plasma pH. Then chemical buffers in the plasma, principally bicarbonate, combine with the hydrogen ions to form carbonic acid, which readily dissociates into water and carbon dioxide. The respiratory system attempts to eliminate the excess carbon dioxide by increased depth and rate (Kussmaul respirations, or the hyperventilation characteristic of metabolic acidosis). The ketones are buffered by sodium and potassium in the plasma. The kidneys attempt to compensate for the increased pH by increasing tubular secretion of hydrogen and ammonium ions in exchange for fixed base, thus depleting the base buffer concentration.

With cellular death, potassium is released from the cells (intracellular fluid) into the bloodstream (extracellular fluid) and excreted by the kidneys, where the loss is accelerated by osmotic diuresis. The total body potassium is then decreased even though the serum potassium level may be elevated as a result of the decreased fluid volume in which it circulates. Alteration in serum and tissue potassium can lead to cardiac arrest.

If these conditions are not reversed by insulin therapy in combination with correction of the fluid deficiency and electrolyte imbalance, progressive deterioration occurs, with dehydration, electrolyte imbalance, acidosis, coma, and death. **Diabetic ketoacidosis (DKA)** should be diagnosed promptly in a seriously ill patient and therapy instituted in an intensive care unit.

Long-Term Complications

Long-term complications of diabetes involve both the microvasculature and the macrovasculature. The principal microvascular complications are **nephropathy**, **retinopathy**, and **neuropathy**. Microvascular disease develops during the first 30 years of diabetes, beginning in the first 10 to 15 years after puberty, with renal involvement evidenced by proteinuria and clinically apparent

retinopathy. Macrovascular disease develops after 25 years of diabetes and creates the predominant problems in patients with type 2 DM. The process appears to be one of glycosylation, wherein proteins from the blood become deposited in the walls of small vessels (e.g., glomeruli), where they become trapped by “sticky” glucose compounds (glycosyl radicals). The buildup of these substances over time causes narrowing of the vessels, with subsequent interference with microcirculation to the affected areas (Rosenson and Herman, 2008).

With poor diabetic control, vascular changes can appear as early as $2\frac{1}{2}$ to 3 years after diagnosis; however, with good to excellent control, changes can be postponed for 20 or more years. Intensive insulin therapy appears to delay the onset and slow the progression of retinopathy, nephropathy, and neuropathy. Hypertension and atherosclerotic cardiovascular disease are also major causes of morbidity and mortality in patients with DM (Karnik, Fields, and Shannon, 2007).

Other complications have been observed in children with type 1 DM. Hyperglycemia appears to influence thyroid function, and altered function is frequently observed at the time of diagnosis and in poorly controlled diabetes. Limited mobility of small joints of the hand occurs in 30% of 7- to 18-year-old children with type 1 DM and appears to be related to changes in the skin and soft tissues surrounding the joint as a result of glycosylation.

Nursing Alert

Recurrent vaginal and urinary tract infections, especially with *Candida albicans*, are often an early sign of type 2 DM, especially in adolescents.

Diagnostic Evaluation

Three groups of children who should be considered as candidates for diabetes are (1) children who have glycosuria, polyuria, and a history of weight loss or failure to gain despite a voracious appetite; (2) those with transient or persistent glycosuria; and (3) those who display manifestations of metabolic acidosis, with or without stupor or coma. In every case, diabetes must be considered if there is glycosuria, with or without ketonuria, and unexplained hyperglycemia.

Glycosuria by itself is not diagnostic of diabetes. Other sugars, such as galactose, can produce a positive result with certain test strips, and a mild degree of glycosuria can be caused by other conditions, such as infection, trauma, emotional or physical stress, hyperalimentation, and some renal or endocrine diseases.

DM is diagnosed based upon any of the following four abnormal glucose metabolites: (1) 8-hour fasting blood glucose level of 126 mg/dl or more, (2) a random blood glucose value of 200 mg/dl or more accompanied by classic signs of diabetes, (3) an oral glucose tolerance test (OGTT) finding of 200 mg/dl or more in the 2-hour sample, and (4) hemoglobin A1C of 6.5% or more is almost certain to indicate diabetes (Laffel and Svoren, 2015). Postprandial blood glucose determinations and the traditional OGTTs have yielded low detection rates in children and are not usually necessary for establishing a diagnosis. Serum insulin levels may be normal or moderately elevated at the onset of diabetes; delayed insulin response to glucose indicates impaired glucose tolerance.

Ketoacidosis must be differentiated from other causes of acidosis or coma, including hypoglycemia, uremia, gastroenteritis with metabolic acidosis, salicylate intoxication encephalitis, and other intracranial lesions. DKA is a state of relative insulin insufficiency and may include the presence of hyperglycemia (blood glucose level ≥ 200 mg/dl), ketonemia (strongly positive), acidosis (pH < 7.30 and bicarbonate < 15 mmol/L), glycosuria, and ketonuria (Wolsdorf, Craig, Daneman, et al, 2009). Tests used to determine glycosuria and ketonuria are the glucose oxidase tapes (Keto-Diastix).

Therapeutic Management

The management of the child with type 1 DM consists of a multidisciplinary approach involving the family; the child (when appropriate); and professionals, including a pediatric endocrinologist, diabetes nurse educator, nutritionist, and exercise physiologist. Often psychological support from a mental health professional is also needed. Communication among the team members is essential and extends to other individuals in the child's life, such as teachers, school nurse, school guidance counselor, and coach.

The definitive treatment is replacement of insulin that the child is unable to produce. However, insulin needs are also affected by emotions, nutritional intake, activity, and other life events, such as

illnesses and puberty. The complexity of the disease and its management requires that the child and family incorporate diabetes needs into their lifestyle. Medical and nutritional guidance are primary, but management also includes continuing diabetes education, family guidance, and emotional support.

Insulin Therapy

Insulin replacement is the cornerstone of management of type 1 DM. Insulin dosage is tailored to each child based on home blood glucose monitoring. The goal of insulin therapy is maintaining near-normal blood glucose values while avoiding too frequent episodes of hypoglycemia. Insulin is administered as two or more injections per day or as continuous subcutaneous infusion using a portable insulin pump.

Healthy pancreatic cells secrete insulin at a low but steady basal rate with superimposed bursts of increased secretion that coincide with intake of nutrients. Consequently, insulin levels in the blood increase and decrease coincidentally, with the rise and fall in blood glucose levels. In addition, insulin is secreted directly into the portal circulation; therefore, the liver, which is the major site of glucose disposal, receives the largest concentration of insulin. No matter which method of insulin replacement is used, this normal pattern cannot be duplicated. Subcutaneous injection results in absorption of the drug into the general circulation, thus reducing the concentrations of insulin to which the liver is exposed.

Insulin Preparations

Insulin is available in highly purified pork preparations and in human insulin biosynthesized by and extracted from bacterial or yeast cultures. Most clinicians suggest human insulin as the treatment of choice. Insulin is available in rapid-, intermediate-, and long-acting preparations; and all are packaged in the strength of 100 units/ml. Some insulins are available as premixed insulins, such as 70/30 and 50/50 ratios, the first number indicating the percentage of intermediate-acting insulin and the second number the percentage of rapid-acting insulin. The different types of insulin are found in [Box 28-14](#).

Nursing Alert

The human insulins from various manufacturers may be interchangeable, but human insulin and pork insulin or pure pork insulin should never be substituted for one another.

Box 28-14

Types of Insulin

There are four types of insulin, based on the following criteria:

- How soon the insulin starts working (onset)
- When the insulin works the hardest (peak time)
- How long the insulin lasts in the body (duration)

However, each person responds to insulin in his or her own way. That is why onset, peak time, and duration are given as ranges.

Rapid-acting insulin (e.g., NovoLog) reaches the blood within 15 minutes after injection. The insulin peaks 30 to 90 minutes later and may last as long as 5 hours.

Short-acting (regular) insulin (e.g., Novolin R) usually reaches the blood within 30 minutes after injection. The insulin peaks 2 to 4 hours later and stays in the blood for about 4 to 8 hours.

Intermediate-acting insulins (e.g., Novolin N) reach the blood 2 to 6 hours after injection. The insulins peak 4 to 14 hours later and stay in the blood for about 14 to 20 hours.

Long-acting insulin (e.g., Lantus) takes 6 to 14 hours to start working. It has no peak or a very

small peak 10 to 16 hours after injection. The insulin stays in the blood between 20 and 24 hours.

Some insulins come mixed together (e.g., Novolin 70/30). For example, you can buy regular insulin and NPH insulins already mixed in one bottle, which makes it easier to inject two kinds of insulin at the same time. However, you cannot adjust the amount of one insulin without also changing how much you get of the other insulin.

NPH, Neutral protamine Hagedorn.

Dosage.

Conventional management is a twice-daily insulin regimen of a combination of **rapid-acting** and **intermediate-acting** insulin drawn up into the same syringe and injected before breakfast and before the evening meal. The amount of morning regular insulin is determined by patterns in the late morning and lunchtime blood glucose values. The morning intermediate-acting dosage is determined by patterns in the late afternoon and supper blood glucose values. Fasting blood glucose patterns at breakfast help determine the evening dose of intermediate insulin, and the blood glucose patterns at bedtime help determine the evening dose of rapid-acting (regular) insulin. For some children, better morning glucose control is achieved by a later (bedtime) injection of intermediate-acting insulin.

Regular insulin is best administered at least 30 minutes before meals. This allows sufficient time for absorption and results in a significantly greater reduction in the postprandial rise in blood glucose than if the meal were eaten immediately after the insulin injection. Intensive therapy consists of multiple injections throughout the day with a once- or twice-daily dose of long-acting (Ultralente) insulin to simulate the basal insulin secretion and injections of rapid-acting insulin before each meal. A multiple daily injection program reduces microvascular complications of diabetes in young, healthy patients who have type 1 DM.

The precise dose of insulin needed cannot be predicted. Therefore, the total dosage and percentage of regular- to intermediate-acting insulin should be determined empirically for each child. Usually 60% to 75% of the total daily dose is given before breakfast, and the remainder is given before the evening meal. Furthermore, insulin requirements do not remain constant but change continuously during growth and development; the need varies according to the child's activity level and pubertal status. For example, less insulin is required during spring and summer months when children are more active. Illness also alters insulin requirements. Some children require more frequent insulin administration. This includes children with difficult-to-control diabetes and children during the adolescent growth spurt.

Methods of administration.

Daily insulin is administered subcutaneously by twice-daily injections, by multiple-dose injections, or by means of an insulin infusion pump. The insulin pump is an electromechanical device designed to deliver fixed amounts of regular or lispro insulin continuously (basal rate), thereby more closely imitating the release of the hormone by the islet cells ([Phillip, Battelino, Rodriguez, et al, 2007](#)). Although the pump delivers a programmed amount of basal insulin, the child or parent must program a dose for the pump to deliver before each meal.

The system consists of a syringe to hold the insulin, a plunger, and a computerized mechanism to drive the plunger. The insulin flows from the syringe through a catheter to a needle inserted into subcutaneous tissue (the abdomen or thigh), and the lightweight device is worn on a belt or a shoulder holster. The needle and catheter are changed every 48 to 72 hours by the child or parent using aseptic technique and then taped in place.

Although the pump provides more consistent insulin delivery, it has certain disadvantages. Pump therapy is expensive and requires commitment from the parent and child. A certain level of math skills is required to calculate infusion rates. It should also not be removed for more than 1 hour at a time, which may limit some activities. Skin infections are common, and as with any other mechanical device, it is subject to malfunction. However, the pumps are equipped with alarms that signal problems, such as a depleted battery, an occluded needle or tubing, or a microprocessor malfunction.

Monitoring

Daily monitoring of blood glucose levels is an essential aspect of appropriate DM management.

Plasma blood glucose and hemoglobin A1C goal ranges are found in [Table 28-3](#).

TABLE 28-3

Plasma Blood Glucose and Hemoglobin A1C Goals for Type 1 Diabetes Mellitus by Age Group

| Age | Value* before Meals (mg/dl) | Value* at Bedtime/ Overnight (mg/dl) | Hemoglobin A1C (%) | Implications |
|--|-----------------------------|--------------------------------------|--------------------|---|
| Toddlers and preschoolers (<6 years) | 100 to 180 | 110 to 200 | ≤8.5% (but ≥7.5%) | High risk and vulnerability to hypoglycemia |
| School age (6 to 12 years) | 90 to 180 | 100 to 180 | <8% | Risks of hypoglycemia and relatively low risk of complications before puberty |
| Adolescents (>12 years) and young adults | 90 to 130 | 90 to 150 | <7.5% | Risk of hypoglycemia Developmental and psychological issues |

*Plasma blood glucose goal range.

Modified from American Diabetes Association: Standards of medical care in diabetes, *Diabetes Care* 28(Suppl):S4–36, 2005.

Blood glucose.

Self-monitoring of blood glucose (SMBG) has improved diabetes management and is used successfully by children from the onset of their diabetes. By testing their own blood, children are able to change their insulin regimen to maintain their glucose level in the euglycemic (normal) range of 80 to 120 mg/dl. Diabetes management depends to a great extent on SMBG. In general, children tolerate the testing well.

Glycosylated hemoglobin.

The measurement of glycosylated hemoglobin (hemoglobin A1C) levels is a satisfactory method for assessing control of the diabetes. As red blood cells circulate in the bloodstream, glucose molecules gradually attach to the hemoglobin A molecules and remain there for the lifetime of the red blood cell, approximately 120 days. The attachment is not reversible; therefore, this glycosylated hemoglobin reflects the average blood glucose levels over the previous 2 to 3 months. The test is a satisfactory method for assessing control, detecting incorrect testing, monitoring the effectiveness of changes in treatment, defining patients' goals, and detecting nonadherence. Nondiabetic hemoglobin A1C values are generally between 4% and 6% but can vary by laboratory. Diabetes control for children depends on age, with hemoglobin A1C levels of 6.5% to 8% indicating a slightly elevated but acceptable range ([Silverstein, Klingensmith, Copeland, et al, 2005](#)).

Urine.

Urine testing for glucose is no longer used for diabetes management; there is poor correlation between simultaneous glycosuria and blood glucose concentrations. However, urine testing can be carried out to detect evidence of ketonuria.

Nursing Alert

It is recommended that urine be tested for ketones every 3 hours during an illness or whenever the blood glucose level is over 240 mg/dl when illness is not present.

Nutrition

Essentially, the nutritional needs of children with diabetes are no different from those of healthy children. Children with diabetes need no special foods or supplements. They need sufficient calories to balance daily expenditure for energy and to satisfy the requirement for growth and development. Unlike children without diabetes, whose insulin is secreted in response to food intake, insulin injected subcutaneously has a relatively predictable time of onset, peak effect, duration of action, and absorption rate depending on the type of insulin used. Consequently, the timing of food consumption must be regulated to correspond to the timing and action of the insulin prescribed.

Meals and snacks must be eaten according to peak insulin action, and the total number of calories and proportions of basic nutrients must be consistent from day to day. The constant release of insulin into the circulation makes the child prone to hypoglycemia between the three daily meals unless a snack is provided between meals and at bedtime. The distribution of calories should be

calculated to fit the activity pattern of each child. For example, a child who is more active in the afternoon will need a larger snack at that time. This larger snack might also be split to allow some food at school and some food after school. Food intake should be altered to balance food, insulin, and exercise. Extra food is needed for increased activity.

Concentrated sweets are discouraged; and because of the increased risk of atherosclerosis in persons with DM, fat is reduced to 30% or less of the total caloric requirement. Dietary fiber has become increasingly important in dietary planning because of its influence on digestion, absorption, and metabolism of many nutrients. It has been found to diminish the rise in blood glucose after meals.

For growing children, food restriction should never be used for diabetes control, although caloric restrictions may be imposed for weight control if the child is overweight. In general, the child's appetite should be the guide for the amount of calories needed, with the total caloric intake adjusted to appetite and activity.

Exercise

Exercise is encouraged and never restricted unless indicated by other health conditions. Exercise lowers blood glucose levels, depending on the intensity and duration of the activity. Consequently, exercise should be included as part of diabetes management, and the type and amount of exercise should be planned around the child's interests and capabilities. However, in most instances, children's activities are unplanned, and the resulting decrease in blood glucose can be compensated for by providing extra snacks before (and if the exercise is prolonged, during) the activity. In addition to a feeling of well-being, regular exercise aids in utilization of food and often results in a reduction of insulin requirements.

Hypoglycemia

Occasional episodes of hypoglycemia are an integral part of insulin therapy, and an objective of diabetes management is to achieve the best possible glycemic control while minimizing the frequency and severity of hypoglycemia. Even with good control, a child may frequently experience mild symptoms of hypoglycemia. If the signs and symptoms are recognized early and promptly relieved by appropriate therapy, the child's activity should be interrupted for no more than a few minutes.

Nursing Alert

Hypoglycemic episodes most commonly occur before meals or when the insulin effect is peaking.

The signs and symptoms of hypoglycemia are caused by both increased adrenergic activity and impaired brain function. The increased adrenergic nervous system activity plus increased secretion of catecholamines produces nervousness, pallor, tremulousness, palpitations, sweating, and hunger (Cryer, 2008). Weakness, dizziness, headache, drowsiness, irritability, loss of coordination, seizures, and coma are more severe responses and reflect CNS glucose deprivation and the body's attempts to elevate the serum glucose levels.

It is often difficult to distinguish between hyperglycemia and a hypoglycemic reaction (Table 28-4). Because the symptoms are similar and usually begin with changes in behavior, the simplest way to differentiate between the two is to test the blood glucose level. The blood glucose level is low in hypoglycemia, but in hyperglycemia, the glucose level is significantly elevated. Urinary ketones may be present after hypoglycemia as a result of starvation ketone production. In doubtful situations, it is safer to give the child some simple carbohydrate. This will help alleviate the symptoms in the case of hypoglycemia but will do little harm if the child is hyperglycemic.

TABLE 28-4

Comparison of Manifestations of Hypoglycemia and Hyperglycemia

| Variable | Hypoglycemia | Hyperglycemia |
|----------------|--|-------------------------------|
| Onset | Rapid (minutes) | Gradual (days) |
| Mood | Labile, irritable, nervous, weepy | Lethargic |
| Mental status | Difficulty concentrating, speaking, focusing, coordinating Nightmares | Dulled sensorium Confusion |
| Inward feeling | Shaky feeling Hunger | Thirst Weakness |

| | | |
|------------------|---|-------------------------------------|
| | Headache | Nausea and vomiting |
| | Dizziness | Abdominal pain |
| Skin | Pallor | Flushed |
| | Sweating | Signs of dehydration |
| Mucous membranes | Normal | Dry, crusty |
| Respirations | Shallow, normal | Deep, rapid (Kussmaul) |
| Pulse | Tachycardia, palpitations | Less rapid, weak |
| Breath odor | Normal | Fruity, acetone |
| Neurologic | Tremors | Diminished reflexes Paresthesia |
| Ominous signs | Late: Hyperreflexia, dilated pupils, seizure Shock, coma | Acidosis, coma |
| Blood: | | |
| Glucose | Low: <60 mg/dl | High: ≥250 mg/dl |
| Ketones | Negative | High, large |
| Osmolarity | Normal | High |
| pH | Normal | Low (<7.25) |
| Hematocrit | Normal | High |
| Bicarbonate | Normal | <20 mEq/L |
| Urine: | | |
| Output | Normal | Polyuria (early) to oliguria (late) |
| Glucose | Negative | Enuresis, nocturia |
| Ketones | Negative or trace | High |
| Visual | Diplopia | Blurred vision |

Children are usually able to detect the onset of hypoglycemia, but some are too young to implement treatment. Parents should become adept at recognizing the onset of symptoms—for example, a change in a child's behavior, such as tearfulness or euphoria. In the majority of cases, 10 to 15 g of simple carbohydrate, such as 1 Tbsp of table sugar, will elevate the blood glucose level and alleviate the symptoms. The simpler the carbohydrate, the more rapidly it will be absorbed (8 oz of milk equals 15 g of carbohydrate). The rapidly releasing sugar is followed by a complex carbohydrate (such as a slice of bread or a cracker) and by a protein (such as peanut butter or milk).

For a mild reaction, milk or fruit juice is a good food to use in children. Milk supplies them with lactose or milk sugar, as well as a more prolonged action from the protein and fat (aids in decreased absorption). Other glucose sources include Insta-Glucose (cherry-flavored glucose), carbonated drinks (not sugarless), sherbet, gelatin, or cake icing. All children with diabetes should carry with them glucose tabs, Insta-Glucose, sugar cubes, or sugar-containing candy, such as LifeSavers or Charms. A difficulty with candies or icing is that the child may learn to fake a reaction to get the sweets; therefore, commercial treatment products such as Insta-Glucose or glucose tabs may be preferred.

Glucagon is sometimes prescribed for home treatment of hypoglycemia. It is available as an emergency kit that must be mixed at the time of use and is administered intramuscularly or subcutaneously. Glucagon functions by releasing stored glycogen from the liver and requires about 15 to 20 minutes to elevate the blood glucose level.

Nursing Alert

Vomiting may occur after administration of glucagon; therefore, precautions against aspiration must be taken (e.g., placing the child on the side) because the child often becomes unconscious.

Morning hyperglycemia.

The management of elevated morning blood glucose levels depends on whether the increase is a true dawn phenomenon, **insulin waning**, or a rebound hyperglycemia (the **Somogyi effect**). Insulin waning is a progressive rise in blood glucose levels from bedtime to morning. It is treated by increasing the nocturnal insulin dose. The true dawn phenomenon shows relatively normal blood glucose level until about 3 AM, when the level begins to rise. The Somogyi effect may occur at any time but often entails an elevated blood glucose level at bedtime and a drop at 2 AM, with a rebound rise following. The treatment for this phenomenon is decreasing the nocturnal insulin dose to prevent the 2 AM hypoglycemia. The rebound rise in the blood glucose level is a result of counterregulatory hormones (epinephrine, GH, and corticosteroids), which are stimulated by hypoglycemia. More frequent blood monitoring (especially at times of anticipated peak insulin action) will usually identify these conditions. Trace amounts of urinary ketones aid in identifying undetected hypoglycemia.

Illness Management

Illness alters diabetes management, and maintaining control is usually related to the seriousness of the illness. In a well-controlled child, an illness will run its course as it does in unaffected children. The goals during an illness are to restore euglycemia, treat urinary ketones, and maintain

hydration. Blood glucose levels and urinary ketones should be monitored every 3 hours. Some hyperglycemia and ketonuria are expected in most illnesses, even with diminished food intake, and are an indication for increased insulin. Insulin should never be omitted during an illness, although dosage requirements may increase, decrease, or remain unchanged, depending on the severity of the illness and the child's appetite. Often the child will need supplemental insulin between usual dose times. If the child vomits more than once, if blood glucose levels remain above 240 mg/dl, or if urinary ketones remain high, the health care practitioner should be notified. Simple carbohydrates may be substituted for carbohydrate-containing exchanges in the meal plan. Although insulin and diet are important tools in sick-day care, fluids are the most important intervention. Fluids must be encouraged to prevent dehydration and to flush out ketones.

Therapeutic Management of Diabetic Ketoacidosis

DKA, the most complete state of insulin deficiency, is a life-threatening situation. Management consists of rapid assessment, adequate insulin to reduce the elevated blood glucose level, fluids to overcome dehydration, and electrolyte replacement (especially potassium).

DKA constitutes an emergency situation, thus a child should be admitted to an intensive care facility for management. The priority is to obtain a venous access for administration of fluids, electrolytes, and insulin. The child should be weighed, measured, and placed on a cardiac monitor. Blood glucose and ketone levels are determined at the bedside, and samples are obtained for laboratory measurement of glucose, electrolytes, BUN, arterial pH, PO₂, PCO₂, hemoglobin, hematocrit, white blood cell count and differential, calcium, and phosphorus.

Oxygen may be administered to patients who are cyanotic and in whom arterial oxygen is less than 80%. Gastric suction is applied to unconscious children to avoid the possibility of pulmonary aspiration. Antibiotics may be administered to febrile children after appropriate specimens are obtained for culture. A Foley catheter may or may not be inserted for urine samples and measurement. Unless the child is unconscious, a collection bag is usually sufficient for accurate assessments.

Fluid and Electrolyte Therapy

All patients with DKA experience dehydration (10% of total body weight in severe ketoacidosis) because of the osmotic diuresis, accompanied by depletion of electrolytes, sodium, potassium, chloride, phosphate, and magnesium. Serum pH and bicarbonate reflect the degree of acidosis. Prompt and adequate fluid therapy restores tissue perfusion and suppresses the elevated levels of stress hormones.

The initial hydrating solution is 0.9% saline solution. Traditionally, deficits have been replaced at a rate of 50% over the first 8 to 12 hours and the remaining 50% over the next 16 to 24 hours. Current trends suggest more cautious fluid management to reduce the risk of cerebral edema. Therefore the fluid deficit should be replaced evenly over a period of 36 to 48 hours (Cooke and Plotnick, 2008).

Nursing Alert

Potassium must never be given until the serum potassium level is known to be normal or low and urinary voiding is observed. All maintenance IV fluids should include 30 to 40 mEq/L of potassium. Never give potassium as a rapid IV bolus, or cardiac arrest may result.

Serum potassium levels may be normal on admission, but after fluid and insulin administration, the rapid return of potassium to the cells can seriously deplete serum levels, with the attendant risk of cardiac arrhythmias. As soon as the child has established renal function (is voiding at least 25 ml/hr) and insulin has been given, vigorous potassium replacement is implemented. The cardiac monitor is used as a guide to therapy, and configuration of T waves should be observed every 30 to 60 minutes to determine changes that might indicate alterations in potassium concentration (widening of the QT interval and the appearance of a U wave following a flattened T wave indicate hypokalemia; an elevated and spreading T wave and shortening of the QT interval indicate hyperkalemia).

Insulin should not be given until urinary ketones and a blood glucose level have been obtained. Continuous IV regular insulin is given at a dosage of 0.1 units/kg/hr. Insulin therapy should be

started after the initial rehydration bolus because serum glucose levels fall rapidly after volume expansion. Blood glucose levels should decrease by 50 to 100 mg/dl/hr. When blood glucose levels fall to 250 to 300 mg/dl, dextrose is added to the IV solution. The goal is to maintain blood glucose levels between 120 and 240 mg/dl by adding 5% to 10% dextrose. Sodium bicarbonate is used conservatively; it is used for pH less than 7.0, severe hyperkalemia, or cardiac instability. Because sodium bicarbonate has been associated with an increased risk for cerebral edema, children receiving this substance must be carefully monitored for changes in level of consciousness.

When the critical period is over, the task of regulating the insulin dosage in relation to diet and activity is started. Children should be actively involved in their own care and are given responsibility according to their ability and the guidance of the nurse.

Nursing Alert

Because insulin can chemically bind to plastic tubing and in-line filters, thereby reducing the amount of medication reaching the systemic circulation, an insulin mixture is run through the tubing to saturate the insulin-binding sites before the infusion is started.

Nursing Care Management

Children with DM may be admitted to the hospital at the time of their initial diagnosis; during illness or surgery; or for episodes of ketoacidosis, which may be precipitated by any of a variety of factors (see the [Translating Evidence into Practice](#) box evaluating hospitalization compared with outpatient care for children newly diagnosed with type 1 DM). Many children are able to keep the disease under control with periodic assessment and adjustment of insulin, diet, and activity as needed under the supervision of a practitioner. Under most circumstances, these children can be managed well at home and require hospitalization only for serious illnesses or upsets.

Translating Evidence into Practice

Outpatient Treatment of Type I Diabetes

A *Cochrane Systematic Review* of seven studies evaluating whether children newly diagnosed with type 1 diabetes should be admitted to a hospital or treated in the outpatient setting found no disadvantages to allowing the child to remain as an outpatient. Studies evaluated metabolic control, acute diabetic complications and hospitalizations, psychosocial variables and behavior, and total care costs ([Clar, Waugh, and Thomas, 2007](#)).

However, a small number of children with diabetes exhibit a degree of metabolic lability and have repeated episodes of DKA that require hospitalization, which interferes with their education and social development. These children appear to display a characteristic personality structure. They tend to be unusually passive and nonassertive and to come from families that are inclined to smooth over conflicts without resolution. Children in this type of setting experience emotional arousal with little, if any, opportunity or ability to resolve it. Other children from psychosocially dysfunctional families display behavioral and personality problems. This emotional stress causes an increased production of endogenous catecholamines, which stimulate fat breakdown, leading to ketonemia and ketonuria.

Hospital Management

Children with DKA require intensive nursing care. Vital signs should be observed and recorded frequently. Hypotension caused by the contracted blood volume of the dehydrated state may cause decreased peripheral blood flow, which can be particularly hazardous to the heart, lungs, and kidneys. An elevated temperature may indicate infection and should be reported so that treatment can be implemented immediately.

Careful and accurate records should be maintained, including vital signs (pulse, respiration, temperature, and blood pressure), weight, IV fluids, electrolytes, insulin, blood glucose level, and intake and output. A urine collection device or retention catheter is used to obtain the urine measurements, which include volume, specific gravity, and glucose and ketone values. The volume

relative to the glucose content is important because 5% glucose in a 300-ml sample is a significantly greater amount than a similar reading from a 75-ml sample. A diabetic flow sheet maintained at the bedside provides an ongoing record of the vital signs, urine and blood tests, amount of insulin given, and intake and output. The level of consciousness is assessed and recorded at frequent intervals. The comatose child generally regains consciousness fairly soon after initiation of therapy but is managed like any unconscious child until then.

When the critical period is over, the task of regulating insulin dosage to diet and activity is begun. The same meticulous records of intake and output, urine glucose and acetone levels, and insulin administration are maintained. Capable children should be actively involved in their own care and are given responsibility for keeping the intake and output record; testing the blood and urine; and, when appropriate, administering their own insulin—all under the supervision and guidance of the nurse (see [Nursing Care Plan](#) box).

Nursing Care Plan

The Child with Diabetes Mellitus

Case Study

Tommy is an 8-year-old who has been healthy all his life. Recently his mother has noticed that he has lost weight and that he is getting up several times during the night to go to the bathroom. He was drinking a great deal more the past week, and she thought that was the reason for being awakened at night to use the bathroom. However, today Tommy says he is too tired to go to school and when she goes into his bedroom she notices that he has wet the bed during the night. She becomes alarmed and calls the pediatrician for an appointment the next day. Tommy's mom has a brother with diabetes and thinks that Tommy's symptoms are similar to her brother's problems when he was first diagnosed as a child.

Assessment

What are the most important signs of type 1 diabetes mellitus (DM) that you need to look for in a child?

Type 1 Diabetes Mellitus Defining Characteristics

Polyphagia

Polyuria

Polydipsia

Weight loss

Enuresis or nocturia

Irritability; “not himself” or “not herself”

Shortened attention span

Lowered frustration tolerance

Fatigue

Dry skin

Blurred vision

Poor wound healing

Flushed skin

Headache

Frequent infections

Nursing Diagnosis

Risk for injury related to insulin deficiency

Case Study (Continued)

At the pediatrician's office several tests are completed to evaluate Tommy. His blood glucose level is 220 mg/dl, and his hemoglobin (Hgb) A1C level is 10.5%. Tommy provides a urine specimen. And the urine dip test is positive for glucose and ketones in his urine. Tommy is admitted to the hospital for further evaluation to establish a diagnosis.

Tommy has met the criteria for new onset diabetes that will require insulin injections to help manage. Initially Tommy will start with twice daily insulin regimen combining a rapid acting (regular) insulin with an intermediate acting (neutral protamine Hagedorn [NPH]/Lente) insulin drawn up in the same syringe. One injection will be given at least 30 minutes before breakfast. The second one will be given 30 minutes before dinner. Tommy will learn how to self-monitor his blood glucoses. Even though he will start off only administering insulin twice daily, he'll still need to check his blood glucose before meals and at bedtime. Based on Tommy's age, his glucose goal range before meals should be 90 to 180 mg/dl and 100 to 180 mg/dl at bedtime.

Nursing Interventions and Rationales

What are the most appropriate nursing interventions for administering insulin in a child newly diagnosed with type 1 DM?

| Nursing Interventions | Rationales |
|---|---|
| Obtain blood glucose level before administering insulin. | To determine most appropriate dose of insulin |
| Administer insulin as prescribed. | To maintain normal blood glucose level |
| Understand the action of insulin: differences in composition, time of onset, and duration of action for the various preparations. | To ensure accurate insulin administration |
| Employ aseptic techniques when preparing and administering insulin. | To prevent infection |
| Rotate insulin injection sites. | To enhance absorption of insulin |

Expected Outcomes

Tommy's glucose levels will be maintained within the targeted range.

Diabetic ketoacidosis (DKA) will be prevented.

Hgb A1C levels will range from 6.5% to 8%.

Case Study (Continued)

Tommy's parents are in shock and are asking lots of questions related to diabetes and the care Tommy will require. Tommy is quiet and listens as his mom and dad talk with you and express their fear and concern.

Nursing Interventions and Rationales

What are the most important interventions to focus on with Tommy and his family regarding his diagnosis? Where would you start to teach him and his family regarding diabetes management?

Treatment consists of glucose monitoring, insulin therapy, observing for common problems, and encouraging healthy eating and physical activity. Focus on these four major categories for beginning your education with Tommy and his family.

| Nursing Interventions | Rationales |
|---|---|
| Discuss glucose monitoring. | To determine most appropriate dose of insulin |
| Teach how to administer insulin. | To maintain normal blood glucose level |
| Discuss signs and symptoms to look for. | To prevent complications |
| Promote healthy eating patterns. | To ensure accurate insulin administration |
| Encourage physical activity. | To enhance absorption of insulin |

Expected Outcomes

Parents and Tommy demonstrate an understanding of:

- What diabetes is
- The need to administer insulin
- How to administer insulin

- How to monitor glucose
- Signs and symptoms to observe when glucose is low or high
- How to promote healthy eating
- How to remain physically active

Case Study (Continued)

Tommy is expecting to be discharged today. After the morning dose of insulin when the nurse is preparing the family for discharge, Tommy tells her that he feels funny and his head hurts. He is dizzy when he stands and his hands are shaking. In questioning Tommy's mother about the morning, you are told that he did not eat breakfast because he wanted to eat on the way home.

Assessment

What are the most important signs and symptoms of hypoglycemia?

Hypoglycemia

Shaky feeling

Hunger

Headache

Dizziness

Difficulty concentrating, speaking, and focusing

Tremors

Tachycardia

Shallow respirations

Can lead to convulsion, shock, and coma

Nursing Diagnosis

Risk for injury related to hypoglycaemia

Nursing Interventions and Rationales

What are the most appropriate nursing interventions for a child newly diagnosed with diabetes who is experiencing hypoglycemia?

| Nursing Interventions | Rationales |
|---|---|
| Immediately administer $\frac{1}{2}$ cup of fruit juice or a glass of nonfat or 1% milk. | To increase blood sugar |
| Check blood glucose after 15 minutes. | To check blood sugar |
| Give a starch-protein snack. | To stabilize blood sugar |
| Give parents instructions regarding signs and symptoms of hypoglycemia versus hyperglycemia. | To promote maintaining blood sugar within an acceptable range |
| Teach parents how to administer intramuscular (IM) glucagon if unresponsive, unconscious, or seizing. | To increase blood sugar |

Expected Outcome

Tommy's blood sugar will return to the targeted range.

Case Study (Continued)

After 15 minutes, Tommy is feeling better and his blood sugar is within an acceptable range. Tommy's mother is quite concerned and is worried that she will not be able to identify whether his blood sugar level is too high or too low. She is quite worried about Tommy being discharge today.

Assessment

What are some key points that you can review with Tommy's mom about the signs and symptoms of low and high blood sugar?

Family's Knowledge of Illness, Defining Characteristics

Hypoglycemia (see earlier)

Hyperglycemia

Thirst

Weakness

Fatigue

Nausea and vomiting

Abdominal pain

Frequent urination

Confusion

Flushed

Rapid respirations

Breath odor (fruity)

Nursing Diagnosis

Knowledge deficit related to signs and symptoms of hypoglycemia and hyperglycemia.

Nursing Interventions and Rationales

What should you focus on regarding the family's education needs at this time to assure Tommy's blood glucose is kept within the targeted range?

| Nursing Interventions | Rationales |
|---|--|
| Review how to recognize high and low blood sugar levels to prevent glucose levels that lead to medical emergencies. | To ensure prompt and appropriate treatment |
| Reinforce the importance of keeping the blood sugar within a target range. | To keep blood glucose levels stable |
| Discuss when to contact the doctor, including fever for 2 days, vomiting and diarrhea, unable to keep fluids down, and glucose levels above target range. | To ensure prompt and appropriate treatment |
| Discuss that exercise and increased activity will affect blood glucose levels, so increased monitoring will be necessary. | To keep blood glucose levels stable |

Expected Outcome

Tommy and his parents will understand the signs and symptoms of high or low blood sugar levels and will understand the actions needed when this occurs. His parents will be prepared to manage help Tommy manage his disease at home.

Child and Family Education

Several organizations are prepared to assist with education and dissemination of knowledge about diabetes. The American Diabetes Association,^{*} Canadian Diabetes Association,[†] Juvenile Diabetes Research Foundation International,[‡] and American Association of Diabetes Educators[§] are valuable resources for a wide variety of educational materials. The National Institute of Diabetes and Digestive and Kidney Diseases[¶] publishes a number of comprehensive annotated bibliographies, including "Educational Materials for and About Young People with Diabetes," a compilation of resource materials for children, siblings, parents, teachers, and health professionals, and "Sports and Exercise for People with Diabetes."

Medical Identification

One of the first things the nurse should call to the parents' attention is the need for the child to wear some means of medical identification. Usually recommended is the Medic-Alert identification, a stainless steel or silver- or gold-plated identification bracelet that is visible and immediately recognizable. It contains a collect telephone number that medical personnel can call around the clock for medical records and personal information.

Nature of Diabetes

The better the parents understand the pathophysiology of diabetes and the function and action of insulin and glucagon in relation to caloric intake and exercise, the better they will understand the disease and its effects on the child. Parents need answers to a number of questions (voiced or unvoiced) to increase their confidence in coping with the disease. For example, they may want to know about the various procedures performed on their child and treatment rationale, such as what is being put in the IV bottle and the expected effect.

Meal Planning

Normal nutrition is a major aspect of the family education program. Diet instruction is usually conducted by the nutritionist, with reinforcement and guidance from the nurse. The emphasis is on adequate intake for age, consistent menus, complex carbohydrates, and consistent eating times. The family is taught how the meal plan relates to the requirements of growth and development, the disease process, and the insulin regimen. Meals and snacks are modified based on the child's preferences and current menu, preserving cultural patterns and preferences as much as possible. Extensive exchange lists are available that include foods compatible with most lifestyles.

Learning about foods within specific food groups helps in making choices. Weights and measures of foods are used as eye-training devices for defining serving sizes and should be practiced for about 3 months, with gradual progression to estimation of food portions. Even when the child and family become competent in estimating portion sizes, reassessment should take place weekly or monthly and when there is any change of brands.

Family members should also be guided in reading labels for the nutritional value of foods and food content. They need to become familiar with the carbohydrate content of food groups. Substitution with foods of equal carbohydrate content is the skill needed for successful carbohydrate counting. Substitution might be necessary if a food is not available in sufficient quantity or for the teenager who wishes to eat fast food with peers. The use of a multiple daily injection program lends flexibility to the timing of meals.

Lists of popular fast-food items and items served at the major fast-food chains can be obtained from the restaurants to help guide food selections. It is important that the child know the nutritional value of these items (the major chains are remarkably uniform), but the child should be cautioned to avoid high-fat and high-sugar/high-carbohydrate items; for example, the child could choose a plain hamburger instead of a double cheeseburger.

Children should use sugar substitutes in moderation in items such as soft drinks. Artificial sweeteners have been shown to be safe, but if there is any question about amounts, the physician, dietitian, or nurse specialist can provide guidelines based on body weight. Sugar-free chewing gum and candies made with sorbitol may be used in moderation by children with DM. Although sorbitol is less cariogenic than other varieties of sugar substitutes, it is an alcohol sugar that is metabolized to fructose and then to glucose. Furthermore, large amounts can cause osmotic diarrhea. Most dietetic foods contain sorbitol. They are more expensive than regular foods. Also, although a product may be sugar free, it is not necessarily carbohydrate free.

Traveling

Traveling requires planning, especially when a trip involves crossing time zones. A number of tips are included in pamphlets available free of charge. Suggestions for traveling encompass what will be needed from the practitioner before leaving, what and how much to take along, needs in transit, what to consider at the destination, and planning for when the child returns home. Planning is needed no matter what type of travel is considered—automobile, plane, bus, or train.

Insulin

Families need to understand the treatment method and the insulin prescribed, including the

effective duration, onset, and peak action. They also need to know the characteristics of the various types of insulins, the proper mixing and dilution of insulins, and how to substitute another type when their usual brand is not available (insulin is a nonprescription drug). Insulin need not be refrigerated but should be maintained at a temperature between 15° and 29.4° C (59° and 85° F). Freezing renders insulin inactive.

Insulin bottles that have been “opened” (i.e., the stopper has been punctured) should be stored at room temperature or refrigerated for up to 28 to 30 days. After 1 month, these vials should be discarded. Unopened vials should be refrigerated and are good until the expiration date on the label. Diabetic supplies should not be left in a hot environment.

Injection Procedure

Learning to give insulin injections is a source of anxiety for both parents and children. It is helpful for the learner to know that this important aspect of care will become as routine as brushing the teeth. First, the basic injection technique is taught using an orange or similar item and sterile normal saline for practice. To gain children's confidence, the nurse can demonstrate the technique by giving a skillful injection to the parent and then having the parent return the demonstration by giving the nurse an injection. With practice and confidence, the parents will soon be able to give the insulin injection to their children, and their children will trust them. Another effective strategy is to instruct the children and then have them teach the technique to the parents while the nurse observes. Both parents should participate, and as little time as possible should elapse between instruction and the actual injection, especially with parents and teenage learners.

Insulin can be injected into any area in which there is adipose (fat) tissue over muscle; the drug is injected at a 90-degree angle. Newly diagnosed children may have lost adipose tissue, and care should be exerted not to inject intramuscularly. The pinch technique is the most effective method for tenting the skin to allow easy entrance of the needle to subcutaneous tissues in children. The site selected will sometimes depend on whether children or parents administer the insulin. The arms, thighs, hips, and abdomen are usual injection sites for insulin. The children can reach the thighs, abdomen, and part of the hip and arm easily but may require help to inject other sites. For example, a parent can pinch a loose fold of skin of the arm while the child injects the insulin.

The parents and child are helped to work out a rotation pattern to various areas of the body to enhance absorption because insulin absorption is slowed by fat pads that develop in overused injection areas. The most efficient rotation plan involves giving about four to six injections in one area (each injection about 2.5 cm [1 inch] apart, or the diameter of the insulin vial from the previous injection) and then moving to another area.

Remember that the absorption rate varies in different parts of the body (Table 28-5). The methodical use of one anatomic area and then movement to another (as described in the previous paragraph) minimizes variations in absorption rates. However, absorption is also altered by vigorous exercise, which enhances absorption from exercised muscles; therefore, it is recommended that a site be chosen other than the exercising extremity (e.g., avoiding legs and arms when playing in a tennis tournament).

TABLE 28-5
Onset and Duration of Action Related to Injection Site

| | SITE OF INJECTION | | | |
|----------|-------------------|-------|------|-----------|
| | Abdomen | Arm | Leg | Buttock |
| Rate | Very fast | Fast | Slow | Very slow |
| Duration | Very short | Short | Long | Very long |

From Albisser AM, Sperlich M: Adjusting insulins, *Diabetes Educ* 18(3):211–218, 1992.

Injection sites for an entire month can be determined in advance on a simple chart. For example, a “paper doll” (body outline) can be constructed and insulin sites marked by the child. After injection, the child places the date on the appropriate site. To keep in practice, it is a good idea for the parent to give two or three injections a week in areas that are difficult for the child to reach. The same basic methodology is used when teaching children to give their own insulin injections (Fig. 28-3). They should practice first on an orange or a doll, building courage gradually. Other devices are available for insulin injection and may offer advantages to some children. Children who do not wish to give themselves injections can be taught to use a syringe-loaded injector (Inject-Ease). With

the device, puncture is always automatic. Adolescents respond well to a self-contained and compact device resembling a fountain pen (NovoPen), which eliminates conventional vials and syringes. Preloaded pens may also cause less pain because the needle is not blunted by piercing the rubber top of the insulin vial (Rex, Jensen, and Lawton, 2006).

FIG 28-3 School-age children are able to administer their own insulin.

Continuous subcutaneous insulin infusion.

Some children are considered candidates for use of a portable insulin pump, and even some young children with unsatisfactory metabolic control can benefit from its use. The child and the parents are taught to operate the device, including the mechanics of the pump, battery changes, and alarm systems. A number of devices are on the market that vary in the basal rates they are able to deliver and in the cost of the equipment. Families can investigate the various devices and select the model that best suits their needs. Product information is available from pump manufacturers and distributors.*

Parents and children learn (1) the technical aspects of the pump and SMBG; (2) prevention and treatment for hyperglycemia, sick-day management, and meal planning; (3) the effects of exercise, stress, and diet on blood glucose levels; and (4) decision-making strategies to evaluate blood glucose patterns and make adjustments in all aspects of the regimen.

Numerous blood glucose measurements (at least four times per day) are an essential part of infusion pump use. Intensive education and supervision are critical to obtaining maximum efficiency and control. This is particularly important if the family has been accustomed to a conventional insulin regimen. They must realize that simply wearing the pump will not normalize blood glucose. The pump is merely an insulin delivery device, and frequent, routine blood glucose determinations are necessary to adjust the insulin delivery rate.

The major problems with use of the insulin pump are inflammation from irritation and infection at the insertion site. The site should be cleaned thoroughly before the needle is inserted and then covered with a transparent dressing. The site is changed and rotated every 48 to 72 hours (this may vary) or at the first sign of inflammation. Nurses working where pumps are part of the therapeutic regimen should become familiar with the operation of the specific device being used and the protocol of disease management. Others should be aware of this management technique and be prepared to assist patients using the pump.

Monitoring

Nurses should also be prepared to teach and supervise blood glucose monitoring. SMBG is associated with few complications, and although it does not necessarily lead to improved metabolic control, it provides a more accurate assessment of blood glucose levels than can be obtained with the historical urine testing. Blood glucose monitoring has the added advantage that it can be performed anywhere (see [Atraumatic Care](#) box).

Atraumatic Care

Minimizing Pain of Blood Glucose Monitoring

- To enhance blood flow to the finger, hold it under warm water for a few seconds before the puncture.
- When obtaining blood samples, use the ring finger or thumb (blood flows more easily to these areas) and puncture the finger just to the side of the finger pad (more blood vessels and fewer nerve endings).
- To prevent a deep puncture, press the platform of the lancet device lightly against the skin and avoid steadying the finger against a hard surface.
- Use lancet devices with adjustable-depth tips. Begin with the shallowest setting.
- Use glucose monitors that require small blood samples (e.g., Ascensia Elite) to avoid repeated punctures.

Blood for testing can be obtained by two different methods: manually or with a mechanical bloodletting device. A mechanical device is recommended for children, although the child and family should learn to use both methods in the event of mechanical failure. Several lancet devices are available, and each provides a means for obtaining a large drop of blood for testing (Fig. 28-4).

Nursing Alert

Caution children not to allow anyone else to use their lancet because of the risk of contracting hepatitis B virus or human immunodeficiency virus infection.

FIG 28-4 Child using a finger-stick device to obtain a blood sample.

The blood sample may be obtained from fingertips or alternate sites, such as the forearm. Alternate site testing requires a meter that can test a small volume of blood. Not all meters are capable of this.

Signs of redness and soreness at the site of finger puncture should be examined by the practitioner. It may be evidence of poor technique, poor hygiene, or poor skin healing relative to poor control. Many types of blood-testing meters are available for home use. Newer technology has brought about improvements in meter size and ease of use. The family should be shown features of several meters, including advantages and disadvantages, and allowed to choose equipment that best meets their needs.

The least expensive testing method uses a reagent strip to which blood is applied (Fig. 28-5). After blotting, the color change is compared against a color scale for an estimation of the blood glucose level. The strips can be cut in half (although not all professionals recommend this) to obtain two

readings per strip. This method is not accepted practice but may be necessary for some families or situations.

FIG 28-5 Child using a blood glucose monitor and reagent strips to test his blood for glucose.

Urine testing.

Testing for urinary ketones is recommended during times of illness and when blood glucose values are elevated. Information on a specific ketone-testing product should include correct procedure, storage, and product expiration. Families need a clear understanding of home management of ketones (fluids and additional insulin as directed by the health care team).

Signs of Hyperglycemia

Severe hyperglycemia is most often caused by illness, growth, emotional upset, or missed insulin doses. Emotional stress from school finals or examinations or physical response to immunizations are examples of causes of hyperglycemia. With careful glucose monitoring, any elevation can be managed by adjustment of insulin or food intake. Parents should understand how to adjust food, activity, and insulin at the time of illness or when the child is treated for an illness with a medication known to raise the blood glucose level (e.g., steroids). The hyperglycemia is managed by increasing insulin soon after the increased glucose level is noted. Health care professionals should be aware that adolescent girls often become hyperglycemic around the time of their menses and should be advised to increase insulin dosages if necessary.

Signs of Hypoglycemia

Hypoglycemia is caused by imbalances of food intake, insulin, and activity. Ideally, hypoglycemia should be prevented, and parents need to be prepared to prevent, recognize, and treat the problem. They should be familiar with the signs of hypoglycemia and instructed in treatment, including care of the child with seizures. Early signs are adrenergic, including sweating and trembling, which help raise the blood glucose level, similar to the reaction when an individual is startled or anxious. The second set of symptoms that follow an untreated adrenergic reaction is neuroglycopenic (also called *brain hypoglycemia*). These symptoms typically include difficulty with balance, memory, attention, or concentration; dizziness or lightheadedness; and slurred speech. Severe and prolonged hypoglycemia leads to seizures, coma, and possible death (Cryer, 2008). Hypoglycemia can be managed effectively as outlined in the [Emergency Treatment](#) box.

Emergency Treatment

Hypoglycemia

Mild Reaction: Adrenergic Symptoms

Give child 10 to 15 g of a simple, high-carbohydrate substance (preferably liquid; e.g., 3 to 6 oz of orange juice).

Follow with starch-protein snack.

Moderate Reaction: Neuroglycopenic Symptoms

Give child 10 to 15 g of a simple carbohydrate as above.

Repeat in 10 to 15 minutes if symptoms persist.

Follow with larger snack.

Watch child closely.

Severe Reaction: Unresponsive, Unconscious, or Seizures

Administer glucagon as prescribed.

Follow with planned meal or snack when child is able to eat or add a snack of 10% of daily calories.

Nocturnal Reaction

Give child 10 to 15 g of a simple carbohydrate.

Follow with snack of 10% of daily calories.

It is advisable for parents to plan for anticipated excitement or exercise. In addition, gastroenteritis may decrease insulin needs slightly as a result of poor appetite, vomiting, or diarrhea. If the blood glucose level is low but urinary ketones are present, the family should be aware of the increased need for simple carbohydrates and liquids.

Hygiene

All aspects of personal hygiene should be emphasized for children with diabetes. Children should be cautioned against wearing shoes without socks, wearing sandals, and walking barefoot. Correct nail and extremity care tailored to the individual child (with the guidance of a podiatrist) can begin health practices that last a lifetime. These children's eyes should be checked once a year unless the child wears glasses and then as directed by the ophthalmologist. Regular dental care is emphasized, and cuts and scratches should be treated with plain soap and water unless otherwise indicated. Diaper rash in infants and candidal infections in teens may indicate poor diabetes control.

Exercise

Exercise is an important component of the treatment plan. If the child is more active at one time of the day than at another time, food or insulin can be altered to meet that activity pattern. Food should be increased in the summer, when children tend to be more active. Decreased activity on return to school may require a decrease in food intake or increase in insulin dosage. Children who are active in team sports will need a snack about a half hour before the anticipated activity. Races or other competition may call for a slightly higher food intake than at practice times.

Food intake will usually need to be repeated for prolonged activity periods, often as frequently as every 45 minutes to 1 hour. Families should be informed that if increased food is not tolerated, decreased insulin is the next course of action. If the timing of the exercise is changed so that the supper meal is delayed, the insulin in the second or third dose of the day may be moved back to precede the mealtime. Sugar may sometimes be needed during exercise periods for quick response. Elevated blood glucose levels after extreme activity may represent the body's adrenergic response to exercise. If the blood glucose level is elevated (>240 mg/dl) before planned exercise, urinary ketones should be checked, and the activity may need to be postponed until the blood glucose is

controlled.

Nursing Alert

Ketonuria in the presence of hyperglycemia is an early sign of ketoacidosis and a contraindication to exercise.

Record Keeping

Home records are an invaluable aid to diabetes self-management. The nurse and family devise a method to chart insulin administered, blood glucose values, urine ketone results, and other factors and events that affect diabetes control. The child and family are encouraged to observe for patterns of blood glucose responses to events such as exercise. If lapses in management occur (e.g., eating a candy bar), the child should be encouraged to note this and not be criticized for the transgression.

Self-Management

Self-management is the key to close control. Being able to make changes when they are needed rather than waiting until the next contact with health care professionals is important for self-management and gives the individual and family the feeling that they have control over the disease. Psychologically, this helps family members believe they are useful and participating members of the team. Allowing the child to learn to look at records objectively promotes independence in self-management support. As children grow and assume more responsibility for self-management, they develop confidence in their ability to manage their disease and confidence in themselves as persons. They learn to respond to the disease and to make more accurate interpretations and changes in treatment when they become adults.

Puberty is associated with decreased sensitivity to insulin that normally would be compensated for by an increased insulin secretion. Health care professionals should anticipate that pubertal patients will have more difficulty maintaining glycemic control. Insulin doses commonly need to be increased, often dramatically (Tfayli and Arisianian, 2007). Patients should be taught to give themselves additional doses of rapid-acting insulin (5% to 10% of their daily dose) when their blood glucose levels are increased. The use of supplemental rapid-acting insulin is preferred to withholding food in adolescents.

Child or Adolescent and Family Support

Just as the physiologic responses affect the child, the parents and other family members of the child with newly diagnosed DM experience various emotional responses to the crisis. Care in the acute setting is short but may create fears and frustrations. The prospect of a chronic illness in their child engenders all the feelings and concerns that are faced by parents of children with other chronic illnesses (see Chapter 17). The threat of complications and death is always present, as well as the continuing drain on emotional and financial resources.

Certain fears may develop as a result of past experiences with the disease. A severe insulin reaction with seizures can contribute to fear of repetition. If parents observe a seizure or the adolescent has one in a public place, the desire to maintain better control is reinforced. They must understand how to prevent problems and how to handle problems calmly and coolly if they occur, and they must understand the complexities of the body, the disease, and its complications. Young children usually adjust well to problems related to the disease. With toddlers and preschoolers, insulin injections and glucose testing may be difficult at first. However, they usually accept the procedures when the parents use a matter-of-fact approach, without calling attention to a “hurt,” and treat the procedure like any other routine part of the child's life. After the injection, time with some special and positive attention, such as reading or talking, or another pleasant activity, is one way to convert children who initially refuse injections to those who accept them.

In the years before adolescence, children probably accept their condition most easily. They are able to understand the basic concepts related to their disease and its treatment. They are able to test blood glucose and urine, recognize food groups, give injections, keep records, and distinguish fear or excitement from hypoglycemia. They understand how to recognize, prevent, and treat hypoglycemia. However, they still need considerable parental involvement.

Nursing Tip

Ongoing motivation to adhere to a regimen is difficult. An older child and parent (or another caregiver) may enjoy negotiating a day off when the responsibility for testing and recording blood glucose is delegated from the child to the caregiver (or vice versa).

Adolescents appear to have the most difficulty adjusting. Adolescence is a time of stress in trying to be perfect and similar to one's peers, and no matter what others say, having diabetes is being different. Some adolescents are more upset about not being able to have a candy bar than about injections, diet, and other aspects of management. If children can accept the difference as a part of life—in other words, that each person is different in some way—then, with adequate parental support, they should be able to adjust well (see [Critical Thinking Case Study](#) box).

Critical Thinking Case Study

Type 1 Diabetes Mellitus

Shelly, a 14-year-old adolescent with a 3-year history of type 1 DM, has been admitted to the pediatric intensive care unit for treatment of DKA. This is her fifth hospital admission for DKA in the past year. Shelly's parents are divorced, and she has four younger siblings, none of whom has diabetes. Shelly's mother has maintained two jobs for the past 5 years and frequently leaves Shelly in charge of the household. In anticipation of her discharge, you are planning a patient education program for Shelly and her mother. What important issues regarding Shelly's unstable diabetes management must you consider to plan the education program?

Questions

1. Evidence: Is there sufficient evidence to draw conclusions about Shelly's recurrent episodes of DKA?
2. Assumptions: Describe an underlying assumption about each of the following:
 - a. Type 1 DM in adolescence
 - b. Type 1 DM and menses
 - c. Emotional stress and elevated blood glucose levels
 - d. Blood glucose monitoring for insulin management
3. What priorities for nursing care should be established for Shelly?
4. Does the evidence support your nursing intervention?

DKA, Diabetic ketoacidosis; *DM*, diabetes mellitus.

Camping and other special group activities are useful. At diabetes camp, children learn that they are not alone. As a result, they become more independent and resourceful in other settings. Useful information about such camps and organizations can be obtained from the American Diabetes Association. A list of accredited camps specifically for children and teenagers with diabetes is also available from the American Camping Association.*

NCLEX Review Questions

1. Discharge teaching for parents of a school-age patient with diabetes insipidus (DI) should include which of the following? Select all that apply.
 - a. Education and support regarding the rationale for fluid restrictions
 - b. Information for school personnel regarding the diagnosis so that they can grant children unrestricted use of the lavatory
 - c. A thorough explanation regarding the condition with specific clarification that DI is a different condition from diabetes mellitus (DM)
 - d. Understanding that treatment will only be needed until the child reaches puberty
 - e. Knowing that school-age children may assume full responsibility for their care
2. You are working with a nurse who is new to your endocrine unit and has never worked with an infant born with congenital adrenal hyperplasia (CAH). You want to make sure he has a full understanding of this diagnosis. Which statement by the nurse indicates a need for further teaching?
 - a. "Definitive diagnosis is confirmed by evidence of increased 17-ketosteroid levels in most types of CAH."
 - b. "Blood studies to identify elevated calcium and decreased phosphorus levels are routinely performed."
 - c. "Another test that can be used to visualize the presence of pelvic structures, such as female reproductive organs is ultrasonography."
 - d. "This deficiency is an autosomal recessive disorder that results in improper steroid hormone synthesis."
3. A father calls the pediatrician's office concerned about his 5-year-old type 1 diabetic child who has been ill. He reports that upon checking the child's urine, it was positive for ketones. What is the nurse's best response to this father?
 - a. "Come to the office immediately."
 - b. "Encourage the child to drink calorie-free liquids."
 - c. "Hold the next dose of insulin."
 - d. "Administer an extra dose of insulin now."
4. A nurse working on a pediatric unit is assigned to an infant with hypothyroidism. She knows that the assessment may include:
 - a. Thyroid function tests that are usually normal, although thyroid-stimulating hormone (TSH) levels may be slightly or moderately elevated
 - b. Increased secretion of pituitary TSH in response to decreased circulating levels of **thyroid hormone** (TH) or from infiltrative neoplastic or inflammatory processes
 - c. Dry skin, puffiness around the eyes, sparse hair, constipation, sleepiness, lethargy, and mental decline
 - d. Clinical features, including irritability, hyperactivity, short attention span, tremors, insomnia, and emotional lability
5. You are working in the emergency department, and a 10-year-old child with type 1 diabetes mellitus (DM) has just been admitted. He has been diagnosed with diabetic ketoacidosis (DKA). Which assessment data will you expect to note in this child?
 - a. Shallow or normal respirations, hypertension, and tachycardia
 - b. Fruity breath odor and decreasing level of consciousness
 - c. Headache, hunger, and excessive irritability
 - d. Normal urine output with specific gravity less than 1.020 and a trace of ketones

Correct Answers

1. b, c, e; 2. b; 3. b; 4. c; 5. b

UNIT 12

The Child with a Problem that Interferes with Physical Mobility

OUTLINE

29 The Child with Musculoskeletal or Articular Dysfunction

30 The Child with Neuromuscular or Muscular Dysfunction

The Child with Musculoskeletal or Articular Dysfunction

Angela Drummond, Martha R. Curry

The Immobilized Child

Immobilization

One of the most difficult aspects of illness in children is the immobility it often imposes on a child. Children's natural tendency to be active influences all aspects of their growth and development. Impaired mobility presents a challenge to children, their families, and their caregivers.

Physiologic Effects of Immobilization

Many clinical studies, including space program research, have documented predictable consequences that occur after immobilization and the absence of gravitational force. Functional and metabolic responses to restricted movement can be noted in most of the body systems. Each has a direct influence on the child's growth and development because of homeostatic mechanisms that thrive on normal use and feedback to maintain dynamic equilibrium. Inactivity leads to a decrease in the functional capabilities of the whole body as dramatically as the lack of physical exercise leads to muscle weakness.

Disuse from illness, injury, or a sedentary lifestyle can limit function and potentially delay age-appropriate milestones. Most of the pathologic changes that occur during immobilization arise from decreased muscle strength and mass, decreased metabolism, and bone demineralization, which are closely interrelated, with one change leading to or affecting the others.

The major effects of immobilization are outlined briefly in [Table 29-1](#) and are related directly or indirectly to decreased muscle activity, which produces numerous primary changes in the musculoskeletal system with secondary alterations in the cardiovascular, respiratory, skeletal, metabolic, and renal systems. The musculoskeletal changes that occur during disuse are a result of alterations in the effect of gravity and stress on the muscles, joints, and bones. Muscle disuse leads to tissue breakdown and loss of muscle mass (**atrophy**). Muscle atrophy causes decreased strength and endurance, which may take weeks or months to restore.

TABLE 29-1

Summary of Physical Effects of Immobilization with Nursing Interventions*

| Primary Effects | Secondary Effects | Nursing Considerations |
|--|--|---|
| Muscular System | | |
| Decreased muscle strength, tone, and endurance | Decreased venous return and decreased cardiac output | Use antiembolism stockings or intermittent compression devices to promote venous return (monitor circulatory and neurovascular status of extremities when such devices are used). |
| | Decreased metabolism and need for oxygen | |
| | Decreased exercise tolerance | Plan play activities to use uninvolved extremities. |
| | Bone demineralization | Place in upright posture when possible. |
| Disuse atrophy and loss of muscle mass | Catabolism | Have patient perform range-of-motion, active, passive, and stretching exercises. |
| | Loss of strength | |
| Loss of joint mobility | Contractures, ankylosis of joints | Maintain correct body alignment. |
| | | Use joint splints as indicated to prevent further deformity. |
| Weak back muscles | Secondary spinal deformities | Maintain range of motion. |
| Weak abdominal muscles | Impaired respiration | Maintain body alignment. |
| | | See nursing considerations for respiratory system. |
| Skeletal System | | |
| Bone demineralization—osteoporosis, hypercalcemia | Negative bone calcium uptake | With paralysis, use upright posture on tilt table. |
| | Pathologic fractures | |
| | Calcium deposits | Handle extremities carefully when turning and positioning. |
| | Extraosseous bone formation, especially at hip, knee, elbow, and shoulder | Administer calcium-mobilizing drugs (diphosphonates) and normal saline infusions if ordered. |
| | Renal calculi | Ensure adequate intake of fluid; monitor output. |
| | | Acidify urine. |
| | | Promptly treat urinary tract infections. |
| Negative bone calcium uptake | Life-threatening electrolyte imbalance | Monitor serum calcium levels. |
| | | Provide electrolyte replacement as indicated. |
| Metabolism | | |
| Decreased metabolic rate | Slowing of all systems | Mobilize as soon as possible. |
| | Decreased food intake | |
| | | Have patient perform active and passive resistance exercises and deep-breathing exercises. |
| | | Ensure adequate food intake. |
| | | Provide a high-protein, high-fiber diet. |
| Negative nitrogen balance | Decline in nutritional state | Encourage small, frequent feedings with protein and preferred foods. |
| | Impaired healing | Prevent pressure areas. |
| Hypercalcemia | Electrolyte imbalance | See nursing consideration for skeletal system. |
| Decreased production of stress hormones | Decreased physical and emotional coping capacity | Identify causes of stress. |
| | | Implement appropriate interventions to lower physical and psychosocial stresses. |
| Cardiovascular System | | |
| Decreased efficiency of orthostatic neurovascular reflexes | Inability to adapt readily to upright position (orthostatic intolerance) | Monitor peripheral pulses and skin temperature changes. |
| | Pooling of blood in extremities in upright posture | |
| Diminished vasopressor mechanism | Orthostatic intolerance with syncope, hypertension, decreased cerebral blood flow, tachycardia | Use antiembolism stockings or intermittent compression devices to decrease pooling when upright. |
| | | Provide abdominal support. |
| | | In severe cases, use anti-gravitational pants. |
| | | Position horizontally. |
| Altered distribution of blood volume | Increased cardiac workload | Monitor hydration, blood pressure, and urinary output. |
| | Decreased exercise tolerance | |
| Venous stasis | Pulmonary emboli or thrombi | Encourage and assist with frequent position changes. |
| | | Elevate extremities without knee flexion. |
| | | Ensure adequate fluid intake. |
| | | Have patient perform active or passive exercises or movement as needed. |
| | | Prescribe routine wearing of antiembolism stockings or intermittent compression devices. |

| | | |
|---|--|--|
| | | Monitor for signs of pulmonary embolism—sudden dyspnea, chest pain, respiratory arrest. Promptly intervene to maintain adequate oxygenation if signs and symptoms of pulmonary emboli are noted. Measure circumference of extremities periodically. Give anticoagulant drugs as prescribed. |
| Dependent edema | Tissue breakdown and susceptibility to infection | Administer skin care. Turn every 2 to 4 hours. Monitor skin color, temperature, and integrity. Use pressure-reduction surface as necessary to prevent skin breakdown (see Chapter 20). |
| Respiratory System | | |
| Decreased need for oxygen | Altered oxygen/carbon dioxide exchange and metabolism | Promote exercise as tolerated. Encourage deep-breathing exercises. |
| Decreased chest expansion and diminished vital capacity | Diminished oxygen intake Dyspnea and inadequate arterial oxygen saturation; acidosis | Position for optimum chest expansion. Semi-Fowler position may assist in lung expansion if patient can tolerate. Use prone positioning without pressure on abdomen to allow gravity to aid in diaphragmatic excursion. Ensure that patient maintains proper alignment when sitting to prevent pressure on respiratory mechanism. |
| Poor abdominal tone and distention | Interference with diaphragmatic excursion | Avoid restriction of chest and abdominal musculature. Supply torso support to promote chest expansion. |
| Mechanical or biochemical secretion retention | Hypostatic pneumonia Bacterial and viral pneumonia Atelectasis | Change position frequently. Carry out chest percussion, vibration, and drainage (or suctioning) as necessary. Use incentive spirometer. Monitor breath sounds. |
| Loss of respiratory muscle strength | Poor cough | Encourage coughing and deep breathing. Support chest wall by splinting with pillow when patient coughs. Use incentive spirometer. Observe for signs of respiratory distress with pulse oximetry or blood gas measurement as necessary. |
| | Upper respiratory tract infection | Prevent contact with infected persons. Provide adequate hydration. Administer immunizations as necessary (pneumococcal, meningococcal). |
| Gastrointestinal System | | |
| Distention caused by poor abdominal muscle tone | Interference with respiratory movements Difficulty in feeding in prone position | Monitor bowel sounds. Encourage small, frequent feedings. |
| No specific primary effect | Possible constipation caused by gravitational effect on feces through ascending colon or weakened smooth muscle tone | Have patient sit in upright position in bedside chair if possible. Carry out bowel training program with hydration, stool softeners, increased fiber intake, and mild laxatives if necessary. |
| | Anorexia | Stimulate appetite with favored foods. |
| Urinary System | | |
| Alteration of gravitational force | Difficulty in voiding in prone position | Position as upright as possible to void. |
| Impaired ureteral peristalsis | Urinary retention in calyces and bladder Infection Renal calculi | Hydrate to ensure adequate urinary output for age. Stimulate bladder emptying with warm running water, as necessary. Catheterize only for severe urinary retention. Administer antibiotics as indicated. |
| Integumentary System | | |
| Altered tissue integrity | Decreased circulation and pressure leading to tissue injury | Turn and reposition at least every 2 to 4 hours. Frequently inspect total skin surface. Eliminate mechanical factors causing pressure, friction, moisture, or irritation. Place on pressure-reduction mattress. |
| | Difficulty with personal hygiene | Assess ability to perform self-care and assist with bathing, grooming, and toileting as needed. Encourage self-care to potential ability. Ensure adequate intake of protein, vitamins, and minerals. |

*Individualize care according to child's needs; interventions may vary in different institutions.

The daily stresses on bone created by motion and weight bearing maintain the balance between bone formation (osteoblastic activity) and bone resorption (osteoclastic activity). During immobilization, increased calcium leaves the bone, causing osteopenia (demineralization of the bones), which may predispose bone to pathologic fractures. A **joint contracture** begins when the arrangement of collagen, the main structural protein of connective tissues, is altered, resulting in a denser tissue that does not glide as easily. Eventually, muscles, tendons, and ligaments can shorten and reduce joint movement, ultimately producing contractures that restrict function. The major musculoskeletal consequences of immobilization are:

- Significant decrease in muscle size, strength, and endurance
- Bone demineralization leading to osteoporosis
- Contractures and decreased joint mobility

Circulatory stasis combined with hypercoagulability of the blood, which results from factors such as damage to the endothelium of blood vessels (Virchow triad), can lead to thrombus and embolus formation. **Deep vein thrombosis (DVT)** involves the formation of a thrombus in a deep vein, such as the iliac and femoral veins, and can cause significant morbidity if it remains undetected and untreated. The larger the portion of the body immobilized and the longer the immobilization, the greater the risks of immobility.

Psychological Effects of Immobilization

For children, one of the most difficult aspects of illness is immobilization. Throughout childhood, physical activity is an integral part of daily life and is essential for physical growth and development. It also serves children as an instrument for communication and expression and as a means for learning about and understanding their world. Activity helps them deal with a variety of feelings and impulses and provides a mechanism by which they can exert control over inner tensions. Children respond to anxiety with increased activity. Removal of this power deprives them of necessary input and a natural outlet for their feelings and fantasies. Through movement, children also gain sensory input, which provides an essential element for developing and maintaining body

image.

When children are immobilized by disease or as part of a treatment regimen, they experience diminished environmental stimuli with a loss of tactile input and an altered perception of themselves and their environment. Sudden or gradual immobilization narrows the amount and variety of environmental stimuli children receive by means of all their senses: touch, sight, hearing, taste, smell, and proprioception (a feeling of where they are in their environment). This sensory deprivation frequently leads to feelings of isolation and boredom and of being forgotten, especially by peers.

The quest for mastery at every stage of development is related to mobility. Even speech and language skills require sensorimotor activity and experience. For toddlers, exploration and imitative behaviors are essential to developing a sense of autonomy. Preschoolers' expression of initiative is evidenced by the need for vigorous physical activity. School-age children's development is strongly influenced by physical achievement and competition. Adolescents rely on mobility to achieve independence.

The monotony of immobilization may lead to sluggish intellectual and psychomotor responses; decreased communication skills; increased fantasizing; and rarely, hallucinations and disorientation. Children are likely to become depressed over loss of ability to function or the marked changes in body image. Physical interference with the activity of infants and young children gives them a feeling of helplessness. They may regress to earlier developmental behaviors, such as wanting to be fed, bedwetting, and baby talk.

Children may react to immobility by active protest, anger, and aggressive behavior, or they may become quiet, passive, and submissive. They may believe the immobilization is a justified punishment for misbehavior. Children should be allowed to display their anger, but it should be within the limits of safety to their self-esteem and not damaging to the integrity of others (see *Providing Opportunities for Play and Expressive Activities*, [Chapter 19](#)). When children are unable to express anger, aggression is often displayed inappropriately through regressive behavior and outbursts of crying or temper tantrums.

Effect on Families

Even brief periods of immobilization may disrupt family function, and catastrophic illness or disability may severely tax a family's resources and coping abilities. The family's needs often must be met by the services of a multidisciplinary team, and nurses play a key role in anticipating the services that they will need and in coordinating conferences to plan care. Home management is frequently planned prior to discharge, including special considerations for addressing cultural, economic, physical, and psychological needs. A child with a severe disability is very dependent, and caregivers need respite to revitalize themselves. Individual and group counseling is beneficial for solving problems in advance and provides an emotional support system. Parent groups are also helpful and often allow nonthreatening social contact. The families of children with permanent disabilities need long-term resources because some of the most difficult problems arise as they try to sustain high-quality care for many years (see [Chapter 17](#)).

Nursing Care Management

Physical assessment of the child who is immobilized for any number of reasons (e.g., injury or illness) includes a focus not only on the injured part (e.g., fracture) but also on the functioning of other systems that may be affected secondarily—the circulatory, renal, respiratory, muscular, and gastrointestinal systems. With long-term immobilization, there may also be neurologic impairment and changes in electrolytes (especially calcium), nitrogen balance, and the general metabolic rate. The psychological impact of immobilization should also be assessed.

Children who require prolonged total immobility and are unable to move themselves in bed should be placed on a pressure-reduction mattress to prevent skin breakdown. Frequent position changes also help prevent dependent edema and stimulate circulation, respiratory function, gastrointestinal motility, and neurologic sensation. Children at greater risk for skin breakdown include those with prolonged immobilization, mechanical ventilation, casts, and assistive devices including orthotics, prosthetics, and wheelchairs. Additional risk factors include poor nutrition, friction (from bed linen with traction), and moist skin (from urine or perspiration). Nursing care of children at risk includes strategies for preventing skin breakdown when such conditions are present. The Braden Q Scale is a reliable, objective tool that may be used in the assessment for

pressure ulcer development in children who are acutely ill or who are at risk for skin breakdown from neurologic conditions and immobilization (Noonan, Quigley, and Curley, 2011).

The use of antiembolism stockings or intermittent compression devices prevents circulatory stasis and dependent edema in the lower extremities and the development of DVT. Anticoagulant therapy may also be implemented with low-molecular-weight heparin, unfractionated heparin, or vitamin K antagonists. The child should be allowed as much activity as possible within the limitations of the illness or treatment. Any functional mobility, however minimal, is preferred to total immobility.

High-protein, high-calorie foods are encouraged to prevent negative nitrogen balance, which may be difficult to correct by diet, especially if there is anorexia as a result of immobility and decreased gastrointestinal function (decreased motility and possibly constipation). Stimulating the appetite with small servings of attractively arranged, preferred foods may be sufficient. At times, supplementary nasogastric or gastrostomy feedings or intravenous (IV) nutrition or fluids may be needed, but these are reserved for serious disability in which oral intake is impossible. Adequate hydration and, when possible, an upright position and remobilization promote bowel and kidney function and help prevent complications in these systems.

Children are encouraged to be as active as their condition and restrictive devices allow. This poses few problems for children, whose innate ingenuity and natural inclination toward mobility provide them with the impetus for physical activity. They need the opportunity, the materials and objects to stimulate activity, and the encouragement and participation of others. Those who are unable to move may benefit from passive exercise and movement in consultation with a physical therapist.

Using dolls, stuffed animals, or puppets to illustrate and explain the immobilization method (e.g., traction, cast) is a valuable tool for small children. Placing a cast, tubing, or other restraining equipment on the doll offers the child a nonthreatening opportunity to express, through the doll, feelings concerning the restrictions and feelings toward the nurse and other health care providers. The doll or puppet may also be used for teaching the child and family procedures, such as IV therapy, procedural sedation, and general anesthesia.

Whenever possible, transporting the child outside the confines of the room increases environmental stimuli and allows social contact with others. Specially designed wheelchairs or carts for increased mobility and independence are available. While hospitalized, children benefit from visitors, computers, books, interactive video games, and other items brought from their own room at home. An activity center or slanting tray can be helpful for the child with limited mobility to use for drawing, coloring, writing, and playing with small toys, such as trucks and cars. Accessibility to clocks, calendars, and a program of diversional therapy are also beneficial. All these interventions help children to function in a more typical way while hospitalized. Children are able to express frustration, displeasure, and anger through play activities (see [Chapter 19](#)), which is helpful in their recovery. A child life specialist should be consulted for recreational planning.

All efforts should be made to minimize family disruption resulting from the hospitalization. Children should be allowed to wear their own clothes (street clothes, especially for preadolescent and adolescent girls) and resume school and preinjury activities if able. A parent or siblings should be allowed to stay overnight and room in with the hospitalized child to prevent the effects of family disruption. Visits from significant persons, such as family members and friends, offer occasions for emotional support and also provide opportunities for learning how to care for the child. Privacy is necessary, especially for adolescents.

One of the most useful interventions to help children cope with immobility is participation in their own care. Self-care to the maximum extent is usually well received by children. They can help plan their daily routine; select their diet; and choose "street clothes," including innovative adornment, such as a baseball cap or brightly colored stockings to express their autonomy and individuality. They are encouraged to do as much for themselves as they are able to keep their muscles active and their interest alive.

Although most of the suggestions discussed relate to hospital care, the same consultations (physical therapist, occupational therapist, child life specialist, speech therapist) and environment may be considered in the home as well to help the child and family achieve independence and normalization (see [Chapter 18](#)). For a child with greatly restricted movement (e.g., child with a bilateral hip spica cast or confined to bed rest), care is often a challenge. These situations require long-term management either in the hospital or at home. Wherever the care occurs, consistent planning and coordination of activities with other health care workers and caregivers are vital nursing functions.

Family Support and Home Care

The needs of a child with severe disabilities can be complex, and family members require time to assimilate the teachings and demonstrations needed to understand the child's situation and care. Even a child who is confined on a short-term basis can be a challenge for the family, which is usually unprepared for the problems imposed by the child's special needs. Home modification is usually needed for facilitating care, especially when it involves traction, a large cast, or extended confinement. Suitable child care may be needed for times when all family members work.

Just as in the hospital, the child at home is encouraged to be as independent as possible and to follow a schedule that approximates his or her normal lifestyle as nearly as possible, such as continuing school lessons, regular bedtime, and suitable recreational activities.

Traumatic Injury

Soft-Tissue Injury

Injuries to the muscles, ligaments, and tendons are common in children (Fig. 29-1). In young children, soft-tissue injury usually results from mishaps during play. In older children and adolescents, participation in sports is a common cause of such injuries.

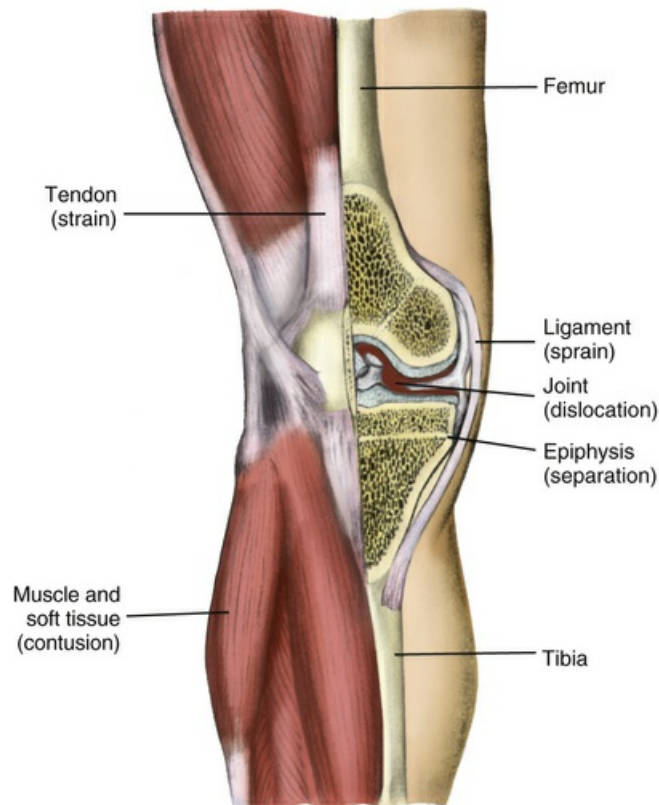

FIG 29-1 Sites of injuries to bones, joints, and soft tissues.

Contusions

A contusion (bruise) is damage to the soft tissue, subcutaneous structures, and muscle. The tearing of these tissues and small blood vessels and the inflammatory response lead to hemorrhage, edema, and associated pain when the child attempts to move the injured part. The escape of blood into the tissues is observed as **ecchymosis**, a black-and-blue discoloration.

Large contusions cause gross swelling, pain, and disability and usually receive immediate attention from health personnel. Smaller injuries may go unnoticed, allowing continued participation. However, they can become disabling after rest because of pain and muscle spasm. Immediate treatment consists of cold application, as in the treatment of sprains described later. Return to participation is allowed when the strength and range of motion of the affected extremity are equal to those of the opposite extremity or are demonstrated under conditions, such as sport-specific tests. **Myositis ossificans** may occur from deep contusions to the biceps or quadriceps muscles; this condition may result in a restriction of flexibility of the affected limb.

Crush injuries occur when children's extremities or digits are crushed (e.g., fingers slammed in doors, folding chairs, or equipment) or hit (as when hammering a nail). A severe crush injury involves the bone, with swelling and bleeding beneath the nail (subungual) and sometimes laceration of the pulp of the nail. The **subungual hematoma** can be released by creating a hole at the proximal end of the nail with a special cautery device or a heated sterile 18-gauge needle.

Dislocations

Long bones are held in approximation to one another at the joint by ligaments. A dislocation occurs when the force of stress on the ligament is so great as to displace the normal position of the opposing bone ends or the bone end to its socket. The predominant symptom is pain that increases with attempted passive or active movement of the extremity. In dislocations, there may be an obvious deformity and inability to move the joint. Children with naturally lax joints are more prone to dislocation of joints. Dislocation of the phalanges is the most common type seen in children, followed by elbow dislocation. In the adolescent population, shoulder dislocations are more common and dislocation unaccompanied by fracture is rare.

A common injury in young children is subluxation, or partial dislocation, of the radial head, also called *pulled elbow* or **nursemaid's elbow**. In the majority of cases, the injury occurs in a child younger than 5 years old who receives a sudden longitudinal pull or traction at the wrist while the arm is fully extended and the forearm pronated. It usually occurs when an individual who is holding the child by the hand or wrist gives a sudden pull or jerk to prevent a fall or attempts to lift the child by pulling the wrist or when the child pulls away by dropping to the floor or ground. The child often cries, appears anxious, complains of pain in the elbow or wrist, and refuses to use the affected limb. The practitioner manipulates the arm by applying firm finger pressure to the head of the radius and then supinates and flexes the forearm to return the bone structure to normal alignment. A click may be heard or felt, and functional use of the arm returns within minutes. Immobilization is not required. However, the longer the subluxation is present, the longer it takes for the child to recover mobility after treatment. No anesthetic is usually required, but a mild pain reliever such as acetaminophen or ibuprofen may be administered. In an older child, severe elbow injury or dislocation should be immediately evaluated by a practitioner. If a traumatic elbow injury in a younger child is not a subluxation or if attempts at reduction are unsuccessful, the child should be carefully evaluated, with the consideration of radiographs.

In children younger than 5 years old, the hip can be dislocated by a fall. The greatest risk after this injury is the potential loss of blood supply to the head of the femur. Relocation of the hip within 60 minutes after the injury provides the best chance for prevention of damage to the femoral head.

Shoulder dislocations and separations occur most often in older adolescents and are often sports related. Temporary restriction of the joint, with a sling or bandage that secures the arm to the chest in a shoulder dislocation, can provide sufficient comfort and immobilization until medical attention is received.

Simple dislocations should be reduced as soon as possible with the child under procedural sedation combined with local anesthesia. An unreduced dislocation may be complicated by increased swelling, making reduction difficult and increasing the risk of neurovascular problems. Treatment is determined by the severity of the injury.

Sprains

A sprain occurs when trauma to a joint is so severe that a ligament is partially or completely torn or stretched by the force created as a joint is twisted or wrenched, often accompanied by damage to associated blood vessels, muscles, tendons, and nerves. Common sprain sites include ankles and knees.

The presence of joint laxity is the most valid indicator of the severity of a sprain. In a severe injury, the child complains of the joint "feeling loose" or as if "something is coming apart" and may describe hearing a "snap," "pop," or "tearing." Pain may or may not be the principal subjective symptom, and in some children, it may prevent optimal examination of ligamentous instability. There is a rapid onset of swelling, often diffuse, accompanied by immediate disability and appreciable reluctance to use the injured joint.

Strains

A strain is a microscopic tear to the musculotendinous unit and has features in common with sprains. The area is painful to touch and swollen. Most strains are incurred over time rather than suddenly, and the rapidity of the appearance provides clues regarding severity. In general, the more rapidly the strain occurs, the more severe the injury. When the strain involves the muscular portion, there is more bleeding, often palpable soon after injury and before edema obscures the hematoma.

Therapeutic Management

The first 12 to 24 hours are the most critical period for virtually all soft-tissue injuries. Basic principles of managing sprains and other soft-tissue injuries are summarized in the acronyms **RICE** and **ICES**.

| | |
|-------------|-------------|
| Rest | Ice |
| Ice | Compression |
| Compression | Elevation |
| Elevation | Support |

Soft-tissue injuries should be iced immediately. This is best accomplished with crushed ice wrapped in a towel, a screw-top ice bag, or a resealable plastic storage bag. Chemical-activated ice packs are also effective for immediate treatment but are not reusable and must be closely monitored for leakage. A wet elastic wrap, which transfers cold better than dry wrap, is applied to provide compression and to keep the ice pack in place. A cloth barrier should be used between the ice container and the skin to prevent trauma to the tissues. Ice has a rapid cooling effect on tissues that reduces edema and pain. Ice should never be applied for more than 30 minutes at a time.

Nursing Tip

A plastic bag of frozen vegetables, such as peas, serves as a convenient ice pack for soft-tissue injuries. It is clean, watertight, and easily molded to the injured part. When available, snow placed in a plastic bag may serve as an ice bag.

Elevating the extremity uses gravity to facilitate venous return and reduce edema formation in the damaged area. The point of injury should be kept several inches above the level of the heart for therapy to be effective. Several pillows can be used for elevation. Allowing the extremity to be dependent causes excessive fluid accumulation in the area of injury, delaying healing and causing painful swelling.

Torn ligaments, especially those in the knee, are usually treated by immobilization with a knee immobilizer or a knee brace that allows flexion and extension until the child is able to walk without a limp. Crutches are used for mobility to rest the affected extremity. Passive leg exercises, gradually increased to active ones, are begun as soon as sufficient healing has taken place. Parents and children are cautioned against using any form of liniment or other heat-producing preparation before examination. If the injury requires casting or splinting, the heat generated in the enclosed space can cause extreme discomfort and even tissue damage. In some cases, torn knee ligaments are managed with arthroscopy and ligament repair or reconstruction as necessary depending on the extent of the tear, ligaments involved, and child's age. Surgical reconstruction of the anterior cruciate ligament may be performed in young athletes who wish to continue in active sports.

Fractures

Bone fractures occur when the resistance of bone against the stress being exerted yields to the stress force. Fractures are a common injury at any age but are more likely to occur in children and older adults. Because childhood is a time of rapid bone growth, the pattern of fractures, problems of diagnosis, and methods of treatment differ in children compared with adults. In children, fractures heal much faster than in adults. Consequently, children may not require as long a period of immobilization of the affected extremity as an adult with a fracture.

Fracture injuries in children are most often a result of traumatic incidents at home, at school, in a motor vehicle, or in association with recreational activities. Children's everyday activities include vigorous play that predisposes them to injury, including climbing, falling down, running into immovable objects, skateboarding, trampolines, skiing, playground activities, and receiving blows to any part of their bodies by a solid, immovable object.

Aside from automobile accidents or falls from heights, true injuries that cause fractures rarely occur in infancy. Bone injury in children of this age group warrants further investigation. In any small child, radiographic evidence of fractures at various stages of healing is, with few exceptions, a result of **nonaccidental trauma** (child abuse). Any investigation of fractures in infants, particularly multiple fractures, should include consideration of **osteogenesis imperfecta (OI)** after nonaccidental trauma has been ruled out.

Fractures in school-age children are often a result of playground falls or bicycle/automobile or

skateboard injuries. Adolescents are vulnerable to multiple and severe trauma because they are mobile on bicycles, all-terrain vehicles, skateboards, skis, snowboards, trampolines, and motorcycles and are active in sports.

A distal forearm (radius, ulna, or both) fracture is the most common fracture in children. The clavicle is also a common fracture sustained in childhood, with approximately half of clavicle fractures occurring in children younger than 10 years old. Common mechanisms of injury include a fall with an outstretched hand or direct trauma to the bone. In neonates, a fractured clavicle may occur with a large newborn and a small maternal pelvis. This may be noted in the first few days after birth by a unilateral Moro reflex or at the 2-week well-child check, when a fracture callus is palpated on the infant's healing clavicle.

Types of Fractures

A fractured bone consists of fragments—the fragment closer to the midline, or the **proximal** fragment, and the fragment farther from the midline, or the **distal** fragment. When fracture fragments are separated, the fracture is **complete**; when fragments remain attached, the fracture is **incomplete**. The fracture line can be any of the following:

Transverse: Crosswise at right angles to the long axis of the bone

Oblique: Slanting but straight between a horizontal and a perpendicular direction

Spiral: Slanting and circular, twisting around the bone shaft

The twisting of an extremity while the bone is breaking results in a spiral break. If the fracture does not produce a break in the skin, it is a **simple**, or **closed, fracture**. **Open**, or **compound, fractures** are those with an open wound through which the bone protrudes. If the bone fragments cause damage to other organs or tissues (e.g., lung, liver), the injury is said to be a **complicated fracture**. When small fragments of bone are broken from the fractured shaft and lie in the surrounding tissue, the injury is a **comminuted fracture**. This type of fracture is rare in children. The types of fractures that are seen most often in children are described in [Box 29-1](#) and [Fig. 29-2](#).

Box 29-1

Types of Fractures in Children

Plastic deformation: Occurs when the bone is bent but not broken. A child's flexible bone can be bent 45 degrees or more before breaking. However, if bent, the bone will straighten slowly but not completely, producing some deformity but without the angulation seen when the bone breaks. Bends occur most commonly in the ulna and fibula, often in association with fractures of the radius and tibia.

Buckle, or torus, fracture: Produced by compression of the porous bone; appears as a raised or bulging projection at the fracture site. These fractures occur in the most porous portion of the bone near the metaphysis (the portion of the bone shaft adjacent to the epiphysis) and are more common in young children.

Greenstick fracture: Occurs when a bone is angulated beyond the limits of bending. The compressed side bends, and the tension side fails, causing an incomplete fracture similar to the break observed when a green stick is broken.

Complete fracture: Divides the bone fragments. These fragments often remain attached by a **periosteal hinge**, which can aid or hinder reduction.

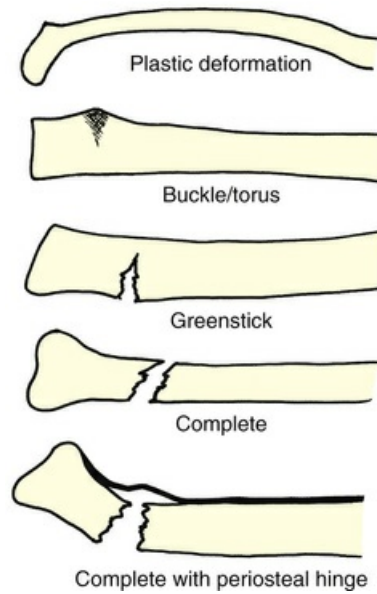

FIG 29-2 Types of fractures in children.

Growth Plate (Physeal) Injuries

The weakest point of long bones is the cartilage growth plate, or the physis. Consequently, this is a frequent site of damage of childhood trauma. Growth plate fractures are classified with the Salter-Harris classification system (Fig. 29-3). Detection of physeal injuries is sometimes difficult but critical. Close monitoring and early treatment, if indicated, is essential to prevent longitudinal or angular growth deformities (or both). Treatment of these fractures may include surgical open reduction and internal fixation to prevent or reduce growth disturbances.

FIG 29-3 Salter-Harris fracture classification. Types of epiphyseal injury in order of increasing risk. The injuries are classified as follows: *Type I*, separation or slip of growth plate without fracture of the bone; *type II*, separation of growth plate and breaking off of section of metaphysis; *type III*, fracture of epiphysis extending through joint surface; *type IV*, fracture of growth plate, epiphysis, and metaphysis; and *type V*, crushing injury of epiphysis (can be diagnosed only in retrospect). This classification of epiphyseal injuries was developed by orthopedists RB Salter and WR Harris. (First published in Salter RB, Harris WR: Injuries involving the physeal plate, *J Bone Joint Surg Am* 45[3]:587-622, 1963.)

Immediately after a fracture occurs, the muscles contract and physiologically splint the injured area. This phenomenon accounts for the muscle tightness observed over a fracture site and the deformity that is produced as the muscles pull the bone ends out of alignment. This muscle response must be overcome by traction or complete muscle relaxation (e.g., anesthesia) to realign the distal bone fragment to the proximal bone fragment.

Bone Healing and Remodeling

Bone healing is rapid in growing children because of the thickened periosteum and generous blood supply. When there is a break in the continuity of bone, the osteoblasts are stimulated to maximal activity. New bone cells are formed in immense numbers almost immediately after the injury and,

in time, are evidenced by a bulging growth of new bone tissue between the fractured bone fragments. This is followed by deposition of calcium salts to form a **callus**. Remodeling is a process that occurs in the healing of long bone fractures in growing children. The irregularities produced by the fracture become indistinct as the angles and bone overgrowth are smoothed out, giving the bone a straighter appearance.

Fractures heal in less time in children than in adults. The approximate healing times for a femoral shaft are as follows:

Neonatal period: 2 to 3 weeks

Early childhood: 4 weeks

Later childhood: 6 to 8 weeks

Adolescence: 8 to 12 weeks

Diagnostic Evaluation

A history of the injury may be lacking in childhood injuries. Infants and toddlers are unable to communicate, and older children may not volunteer information (even under direct questioning) when the injury occurred during questionable activities. Whenever possible, it is helpful to obtain information from someone who witnessed the injury. In cases of nonaccidental trauma, providers may give false information to protect themselves or family members.

The child may exhibit the same manifestations seen in adults that may include swelling bruising, pain or tenderness, deformity, and diminished function ([Box 29-2](#)). However, often a fracture is remarkably stable because of intact periosteum. The child may even be able to use an affected arm or walk on a fractured leg. Because bones are highly vascular, a soft, pliable hematoma may be felt around the fracture site.

Nursing Alert

A fracture should be strongly suspected in a small child who refuses to walk or crawl.

Box 29-2

Clinical Manifestations of a Fracture

Signs of injury:

- Generalized swelling
- Pain or tenderness
- Deformity
- Diminished functional use of affected limb or digit

May also demonstrate:

- Bruising
- Severe muscular rigidity
- Crepitus (grating sensation at fracture site)

Radiographic examination is the most useful diagnostic tool for assessing skeletal trauma. The calcium deposits in bone make the entire structure radiopaque. Radiographic films are taken after fracture reduction and, in some cases, may be taken during the healing process to determine satisfactory progress.

Therapeutic Management

The goals of fracture management are:

- To regain alignment and length of the bony fragments (reduction)
- To retain alignment and length (immobilization)
- To restore function to the injured parts
- To prevent further injury and deformity

The majority of children's fractures heal well, and nonunion is rare. Fractures are splinted or casted to immobilize and protect the injured extremity. Children with displaced fractures may have immediate surgical reduction and fixation (internal or external) rather than being immobilized by traction (Fig. 29-4). This practice is more common and holds true for all types of fractures, including femur fractures, although there is variation based on provider preference and institutional practice. Some conditions require immediate medical attention, including open fractures, compartment syndrome, fractures associated with vascular or nerve injury, and joint dislocations that are unresponsive to reduction maneuvers.

FIG 29-4 Fractured femur. Most fractured femurs in childhood are of the spiral type shown here. (From Mark JA, Hockberger RS, Walls RM: *Rosen's emergency medicine: Concepts and clinical practice*, ed 8, St. Louis, 2014, Elsevier.)

In children, immobilization is used until adequate callus is formed. The position of the bone fragments in relation to one another influences the rapidity of healing and residual deformity. Weight bearing and active movement for the purpose of regaining function may begin after the fracture site is determined to be stable by the medical provider. The child's natural tendency to be active is usually sufficient to restore normal mobility, and physical or occupational therapy is rarely indicated.

Children are most frequently hospitalized for fractures of the femur and supracondylar area of the distal humerus. If simple reduction cannot be achieved or a neurovascular problem is detected after the injury, observation in a hospital setting may be indicated. The trend is to avoid hospitalization. The major methods for immobilizing a fracture, casting and traction, are described later.

Nursing Care Management

Nurses are frequently the persons who make the initial assessment of a child with a suspected fracture (see [Emergency Treatment](#) box). The child and parents may be frightened and upset, and the child is often in pain. Therefore, if the child is alert and there is no evidence of hemorrhage, the initial nursing interventions are directed toward calming and reassuring the child and parents so that a more extensive assessment can be more easily accomplished.

Emergency Treatment

Fracture

Determine the mechanism of injury.

Assess the 6 Ps.

Move the injured part as little as possible.

Cover open wounds with a sterile or clean dressing.

Immobilize the limb, including joints above and below the fracture site; do not attempt to reduce the fracture or push protruding bone under the skin.

Use a soft splint (pillow or folded towel) or rigid splint (rolled newspaper or magazine).

Uninjured leg can serve as a splint for a leg fracture if no splint is available.

Reassess neurovascular status.

Apply traction if circulatory compromise is present.

Elevate the injured limb if possible.

Apply cold to the injured area.

Call emergency medical services or transport to medical facility.

While remaining calm and speaking in a quiet voice, the nurse can ask the parents and older child to describe what happened. The child may arrive with the limb supported in some manner; if not, careful support or immobilization may be provided to the affected site. In the event that the limb is supported or immobilized, it may be best not to touch the child but to ask him or her to point to the painful area and to wiggle the fingers or toes. By this time the child may feel relatively safe and will allow someone to gently touch the area just enough to feel the pulses and test for sensation. A child's anxiety is greatly influenced by previous experiences with injury and with health personnel. However, he or she needs to be told what will happen and what to do to help. The affected limb need not be palpated, and it should not be moved unless properly splinted. If the child is at home or if the practitioner is not present to examine the child, some type of splint is applied carefully for transport to the medical facility. Parental anxiety may be heightened by the child's pain reaction and fear and possibly by other events surrounding the accident. It is important to communicate to the parent that the child will receive the necessary care, including pain management.

Nursing Alert

Compartment syndrome is a serious complication that results from compression of nerves, blood vessels, and muscle inside a closed space. This injury may be devastating, resulting in tissue death, and thus requires emergency treatment (fasciotomy). The six Ps of ischemia from a vascular, soft-tissue, nerve, or bone injury should be included in an assessment of any injury:

1. Pain
2. Pulselessness
3. Pallor
4. Paresthesia
5. Paralysis
6. Pressure (Box 29-3)

Box 29-3

Compartment Syndrome Evaluation

Assess the extent of injury — “the 6 Ps”:

1. **Pain:** Severe pain that is not relieved by analgesics or elevation of the limb, movement that increases pain
2. **Pulselessness:** Inability to palpate a pulse distal to the fracture or compartment
3. **Pallor:** Pale appearing skin, poor perfusion, capillary refill greater than 3 seconds
4. **Paresthesia:** Tingling or burning sensations
5. **Paralysis:** Inability to move extremity or digits
6. **Pressure:** Involved limb or digits may feel tense and warm; skin is tight, shiny; pressure within the compartment is elevated

The Child in a Cast

The completeness of the fracture, the type of bone involved, and the amount of weight bearing influence how much of the extremity must be included in the cast to immobilize the fracture site completely. In most cases, the joints above and below the fracture are immobilized to eliminate the possibility of movement that might cause displacement at the fracture site. Four major categories of casts are used for fractures: **upper extremity** to immobilize the wrist or elbow, **lower extremity** to immobilize the ankle or knee, spinal and cervical to immobilize the spine, and spica casts to immobilize the hip and knee (Fig. 29-5).

FIG 29-5 Spica cast with hip abductor. Note casts on doll as well.

The Cast

Casts are constructed from gauze strips and bandages impregnated with plaster of Paris or, more commonly, from synthetic lighter weight and water-resistant materials (e.g., waterproof liners, fiberglass and polyurethane resin).

Both types of casting produce heat from chemical reaction activated by water immediately after application. Plaster casts mold closely to the body part, take 10 to 72 hours to dry, have a smooth exterior, and are inexpensive. The newer synthetic casting material is lightweight, dries in 5 to 20 minutes, permits earlier weight bearing, and is water resistant when applied with a waterproof liner. It is always desirable to give children choices, and synthetic casting materials come in a variety of colors. The disadvantages of synthetic casting are its inability to mold closely to body parts and its rough exterior, which may scratch surfaces. Synthetic casts are also difficult to write on; a waterproof marker or color markers may be used.

Cast Application

The child's developmental age should be considered before the cast is applied. For preschoolers who fear bodily harm and fantasize about the loss of an extremity, it may be helpful to use a plastic doll or stuffed animal to explain the procedure beforehand. Toddlers and preschoolers do not have easily defined body boundaries; if an extremity is wrapped in a bandage, cast, or splint, to the young child the extremity ceases to function or exist. It is also helpful to explain that some synthetic cast material will become warm during application but will not burn. During the application of the cast, various distraction methods can be used, including discussing favorite pets or activities at school, blowing bubbles, and so forth. In this age group, explanations, such as "This will help your arm get better," are futile because the child has no concept of causality.

Before the cast is applied, the extremities are checked for any abrasions, cuts, or other alterations in the skin surface and for the presence of rings or other items that might cause constriction from swelling; such objects are removed. A tube of cloth stockinette or Gore-Tex liner is stretched over the area to be casted, and bony prominences are padded with soft cotton sheeting. Dry rolls of casting material are immersed in a pail of water. The wet rolls are put on in a bandage fashion and molded to the extremity. During application of the cast, the underlying stockinette is pulled over the rough edges of the cast and secured with casting material to form a padded edge to protect the skin.

Nursing Care Management

The complete evaporation of the water from a hip spica cast can take 24 to 48 hours when older types of plaster materials are used. Drying occurs within minutes with fiberglass cast material. The cast must remain uncovered to allow it to dry from the inside out. Turning the child in a plaster cast at least every 2 hours will help to dry a body cast evenly and prevent complications related to

immobility. A regular fan or cool-air hair dryer to circulate air may be helpful when the humidity is high.

Nursing Alert

Heated fans or dryers are not used because they cause the cast to dry on the outside and remain wet beneath or cause burns from heat conduction by way of the cast to the underlying tissue.

A wet plaster cast should be supported by a pillow that is covered with plastic and handled by the palms of the hands to prevent indenting the cast, which can create pressure areas. A dry plaster-of-Paris cast produces a hollow sound when it is tapped with the finger. After it has dried, “hot spots” felt on the cast surface or a foul-smelling odor may indicate an infection. This should be reported for further evaluation, and if concern continues, an opening, or a “window,” may be exposed over the area of concern to evaluate the site.

During the first few hours after a cast is applied, the chief concern is that the extremity may continue to swell to the extent that the cast becomes a tourniquet, shutting off circulation and producing neurovascular complications (**compartment syndrome**) (see [Box 29-3](#)). To reduce the likelihood of this potential problem, the body part can be elevated, thereby increasing venous return. If edema is excessive, casts are bivalved (i.e., cut to make anterior and posterior halves that are held together with an elastic bandage). The cast and the involved extremity are observed frequently for neurovascular integrity and any signs of compromise. Permanent muscle and tissue damage can occur within a few hours.

Nursing Alert

Observations such as pain (unrelieved by pain medication 1 hour after administration, especially with passive range of motion), swelling, discoloration (pallor or cyanosis) of the exposed portions, decreased pulses, decreased temperature, paresthesia, or the inability to move the distal exposed part(s) should be reported immediately. Pallor, paralysis, and pulselessness are late signs (see [Box 29-3](#)).

When an extremity that has sustained an open fracture is casted, a window is often left over the wound area to allow for observation and dressing of the wound. For the first few hours after surgery, substantial bleeding may soak through the cast. Periodically, the circumscribed bloodstained area should be outlined with a waterproof marker and the time indicated to provide a guide for assessing the amount of bleeding.

Appropriate cast care guidelines for the child's caregiver are necessary before discharge. Instructions are also given for checking for signs and symptoms that indicate that the cast is too tight (see [Family-Centered Care](#) box). Parents should also be told to take the child to the health professional for attention if the cast becomes too loose because a loose cast no longer serves its purpose.

Family-Centered Care

Cast Care

Keep the casted extremity elevated on pillows or similar support for the first day or as directed by the health professional.

Avoid denting the plaster cast with fingertips (use palms of hand to handle) while it is still wet to avoid creating pressure points.

Expose the plaster cast to air until dry.

Observe the extremities (fingers or toes) for any evidence of swelling or discoloration (darker or lighter than a comparable extremity) and contact the health professional if noted.

Check movement and sensation of the visible extremities frequently.

Follow health professional's orders regarding any restriction of activities.

Restrict strenuous activities for the first few days:

- Engage in quiet activities but encourage use of muscles.
- Move the joints above and below the cast on the affected extremity.

Encourage frequent rest for a few days, keeping the injured extremity elevated while resting.

Avoid allowing the affected limb to hang in a dependent position for any length of time:

- Keep an injured upper extremity elevated (e.g., in a sling) while upright.
- Elevate a lower limb when sitting and avoid standing for too long.

Do not allow the child to put anything inside the cast. Keep small items that might be placed inside the cast away from small children.

Keep a clear path for ambulation. Remove toys, hazardous floor rugs, pets, and other items over which the child might stumble.

Use crutches appropriately if lower limb fracture requires non-weight bearing on affected extremity.

The crutches should fit properly, have a soft rubber tip to prevent slipping, and be well padded at the axilla.

With crutch walking, the child's body weight is supported on the hand grips, not the axilla.

Nurses can help families adapt the child's home environment to meet the temporary encumbrance of a large cast or one that restricts the child's mobility (e.g., a long-leg or spica cast [Fig. 29-6]). Commonplace situations become problematic (e.g., transporting a child safely and comfortably in a car). Standard seat belts and car seats may not be readily adapted for use by children in some casts. Specially designed car seats and restraints are available that meet safety requirements.* Alterations to standard car seats to accommodate the cast are not recommended because the structure may be adversely altered and fail to properly restrain the child. A bedside commode or rental wheelchair maybe be necessary equipment for a child who is nonambulatory.

FIG 29-6 Types of casts.

Parents are taught the proper care of the cast or brace and are helped to devise means for maintaining cleanliness. A superabsorbent disposable diaper is tucked beneath the entire perineal opening of the cast. A larger diaper can be applied and fastened over the small diaper and cast to hold the smaller diaper in place. In the event that the larger diaper becomes wet or soiled, it is likely the cast is as well.

For tightly fitting casts, transparent film dressings can be cut into strips as for petaling with one edge applied to the cast edge and the other directly to the perineum; this forms a continuous, waterproof bridge between the perineum and the cast to prevent leakage. An additional advantage to the use of this transparent dressing is that it keeps both the skin and the cast dry while allowing for observation of skin beneath the dressing.

Older infants and small children may stuff bits of food, small toys, or other items under the cast; parents should be alerted to this possibility so they can initiate suitable preventive measures.

Feeding an infant in a hip spica cast offers problems in positioning. Very young infants can be fed in the supine position with the head elevated. With the infant's hips and legs supported on a pillow at the side, the parent can cuddle the infant in his or her arms during feeding. A somewhat similar position can be used for breastfeeding (i.e., with the infant supported on pillows or held in a "football" hold facing the mother with the legs behind her). An alternate position is to hold the infant upright on the caregiver's lap with the legs of the infant astride the adult's leg.

Children in spica casts usually find the prone position easier for self-feeding from a small table placed next to the dining table; alternatively, they may manage a semi-sitting position in bed or in a wheelchair (Fig. 29-7). The use of a conventional toilet is almost impossible. A bedside toilet can be adapted for use. Small bedpans or other containers offer alternatives for elimination. The nurse may suggest waterproofing methods by devising plastic wraps for elimination and showers. Baths are possible only if the plaster cast is kept out of the water and covered to prevent it from becoming wet.

FIG 29-7 Single spica cast. Note diaper to maintain dryness. (Courtesy of Texas Children's Hospital, Houston, TX.)

Cast Removal

Cutting the cast to remove it or to relieve tightness is frequently a frightening experience for children. They fear the sound of the cast cutter and are terrified that their flesh, as well as the cast, will be cut. The oscillating blade vibrates rapidly back and forth and will not cut when placed *lightly* on the skin. Children have described it as producing a “tickly” sensation. The vibration also generates heat that may be felt by the child. Both of these feelings should be explained.

Preparation for the procedure will help reduce anxiety, especially if a trusting relationship has been established between the child and the nurse. Many young children come to regard the cast as part of themselves, which intensifies their fear of removal (Fig. 29-8). They need continual reassurance that all is going well and that their behavior is accepted. After the cast is removed, the parents and child should be given the option of keeping the cast. If the cast has been in place for a lengthy period, decreased muscle mass will be noted. The child should be reassured that resuming exercise and routine activities will return function and appearance (provided there was no significant trauma beforehand).

FIG 29-8 Young children come to regard a cast as part of their body.

After the cast is removed, the skin surface will be caked with desquamated skin and sebaceous secretions. Application of mineral oil (e.g., baby oil) or lotion may remove the particles as well as

provide comfort. Soaking the extremity in a bathtub is usually sufficient for their removal, but it may take several days to eliminate the accumulation completely. The parents and child should be instructed not to pull or forcibly remove this material with vigorous scrubbing because it may cause excoriation and bleeding.

The Child in Traction

The ever-changing health care arena has witnessed the demise of many long-term treatments involving lengthy hospitalization; one such change is in the area of traction. Most balanced skeletal traction is applied in children after a severe or complex injury to allow physiologic stability, align bone fragments, and permit closer evaluation of the injured site. Newer technology has produced orthopedic fixation devices that allow partial or full mobility, thus preventing long-term immobilization and its consequences. In many situations, surgical intervention may be carried out within a matter of days; therefore, skeletal traction devices described herein may be used infrequently in pediatrics.

Purposes of Traction

The six primary purposes of traction are:

1. To fatigue the involved muscles and reduce muscle spasm so that bones can be realigned
2. To position the distal and proximal bone ends in desired realignment to promote satisfactory bone healing
3. To immobilize the fracture site until realignment has been achieved and sufficient healing has taken place to permit casting or splinting
4. To help prevent or improve contracture deformity
5. To provide immobilization of specific areas of the body
6. To reduce muscle spasms (rare in children)

The three essential components of traction management are traction, counter traction, and friction (Fig. 29-9). To reduce or realign a fracture site, **traction** (forward force) is produced by attaching weight to the distal bone fragment. Body weight provides **counter traction** (backward force), and the patient's contact with the bed constitutes the **frictional** force. These forces are used to align the distal and proximal bone fragments by adjusting the line of pull upward or downward and adducting or abducting the extremity.

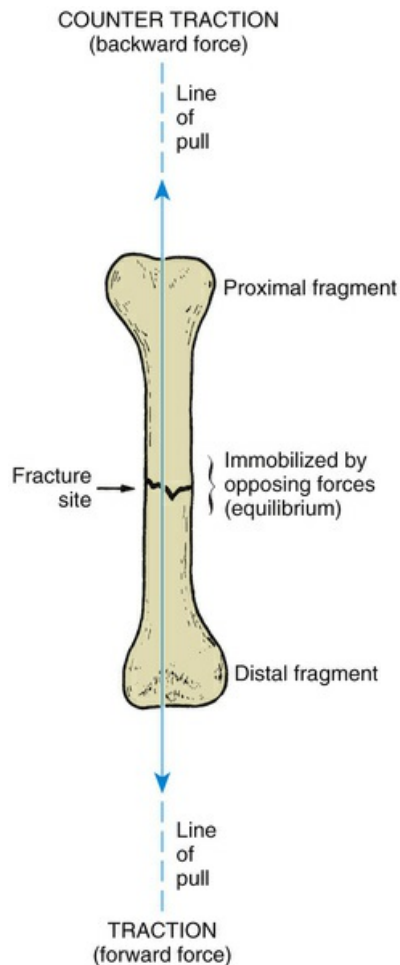

FIG 29-9 Application of traction for maintaining equilibrium.

To attain equilibrium, the amount of forward force is adjusted by adding weight to or subtracting weight from the traction, or counter traction can be increased by elevating the foot of the bed to create a greater gravitational pull to the backward force.

The **all-or-none law**, characteristic of muscle contractibility, influences the complete relaxation. When muscles are stretched, muscle spasm ceases, which permits the realignment of the bone ends. The continuous maintenance of traction is important during this phase because releasing the traction allows the muscle's normal contracting ability to again cause a malpositioning of the bone ends.

The realignment of the fragments is a gradual process that is achieved more rapidly in infants, who have limited muscle tone, than in muscular teenagers. The desired vector force and callus formation are checked periodically by radiographic examination. The traction pull to some degree immobilizes the fracture site; however, adjunctive immobilizing devices such as splints or casts are sometimes used with skeletal traction. Immobilization with traction is maintained until the bone ends are in satisfactory realignment after which a less confining type of immobilization—a cast, pins, or external stabilization device—is applied.

Types of Traction

The pull needed for traction can be applied to the distal bone fragment in several ways (Box 29-4). The type of traction applied is determined primarily by the child's age, the condition of the soft tissues, and the type and degree of displacement of the fracture. Fractures most commonly treated by application of traction are those involving the femur and vertebrae. The major types of traction for specific fractures are briefly discussed in the following paragraphs.

Box 29-4

Types of Traction

Manual traction: Applied to the body part by the hand placed distal to the fracture site. Manual traction may be provided during application of a cast but more commonly when a closed reduction is performed.

Skin traction: Applied directly to the skin surface and indirectly to the skeletal structures. The pulling mechanism is attached to the skin with adhesive material or an elastic bandage. Both types are applied over soft, foam-backed traction straps to distribute the traction pull.

Skeletal traction: Applied directly to the skeletal structure by a pin, wire, or tongs inserted into or through the diameter of the bone distal to the fracture.

The use of upper extremity traction in children is uncommon. Newer surgical techniques allow for early mobilization and optimal results without traction. Nursing care of the child with upper extremity traction is the same as that for lower extremity traction, which is discussed later.

The frequent site for a femoral fracture is in the middle third of the shaft. With this fracture, there may be significant overriding but minimal displacement. In a fracture in the lower third of the shaft, the pull of the gastrocnemius muscle causes the distal fragment to become downwardly displaced.

Fractures of the femur can often be reduced with immediate application of a hip spica cast in young children. When traction is required, several types may be used based on the initial assessment.

Bryant traction is a type of running traction in which the pull is in only one direction. Skin traction is applied to the legs, which are flexed at a 90-degree angle at the hips. The child's trunk (with the buttocks raised slightly off the bed) provides counter traction.

Buck extension traction (Fig. 29-10) is a type of traction with the legs in an extended position. Except for fracture cases, turning from side to side with care is permitted to maintain the involved leg in alignment. Buck extension traction is used primarily for short-term immobilization, such as preoperative management of a child with a dislocated hip, or for correction of contractures or bone deformities, such as in Legg-Calvé-Perthes disease. Buck traction may be accomplished with either skin straps or a special foam boot designed for traction.

FIG 29-10 Buck extension traction.

Russell traction uses skin traction on the lower leg and a padded sling under the knee. Two lines of pull, one along the longitudinal line of the lower leg and one perpendicular to the leg, are produced. This combination of pulls allows realignment of the lower extremity and immobilizes the hip and knee in a flexed position. The hip flexion must be kept at the prescribed angle to prevent fracture malalignment because there is no direct support under the fracture and the skin traction may slip. Special nursing measures include carefully checking the position of the traction so that the amount of desired hip flexion is maintained and damage to the common peroneal nerve under the knee does not produce footdrop.

A common skeletal traction is **90-degree–90-degree traction** (90-90 traction). The lower leg is supported by a boot cast or a calf sling, and a skeletal Steinmann pin or Kirschner wire is placed in the distal fragment of the femur, resulting in a 90-degree angle at both the hip and the knee. From a nursing standpoint, this traction facilitates position changes, toileting, and prevention of complications related to traction.

Balanced suspension traction may be used with or without skin or skeletal traction. Unless used

with another traction, the balanced suspension merely suspends the leg in a desired flexed position to relax the hip and hamstring muscles and does not exert any traction directly on a body part. A **Thomas splint** extends from the groin to midair above the foot, and a **Pearson attachment** supports the lower leg. Towels or pieces of felt covered with stockinette are clipped or pinned to the splints for leg support. When the child is lifted off the bed, the traction lifts with the child without loss of alignment. This traction requires careful checking of splints and ropes to make certain that no slippage or fraying has occurred. The traction is of great value in an older and heavier child when it is essential to lift the patient for care.

The cervical area is a vulnerable site for flexion or extension injuries to muscle, vertebrae, or the spinal cord. Cervical muscle trauma without other complications is treated with a cervical hard collar to relieve the weight of the head from the fracture site. When a child displaces or fractures a cervical vertebra, it may be necessary to reduce and immobilize the site with cervical skeletal traction. The spinal cord runs through the intravertebral canal, and dislocation or fracture of the vertebrae can also cause spinal cord injury. Nursing assessment of neurologic function is essential to prevent further injury during the application and use of cervical skeletal traction.

Most cervical traction is accomplished with the use of a **halo brace** or **halo vest** (Fig. 29-11, A). This device consists of a steel halo attached to the head by four screws inserted into the outer skull; several rigid bars connect the halo to a vest that is worn around the chest, thus providing greater mobility of the rest of the body while avoiding cervical spinal motion altogether. If the injury has been limited to a vertebral fracture without neurologic deficit, a halo brace can be applied to permit earlier ambulation. Gardner-Wells tongs may be used with cervical traction to immobilize the cervical spine (see Fig. 29-11, B). Gardner-Wells tongs are spring loaded, so making burr holes and shaving hair are not required; a local anesthetic may be used during application. As the neck muscles fatigue with constant traction pull, the vertebral bodies gradually separate so that the cord is no longer pinched between the vertebrae. Immobilization until fracture healing or surgical fixation can occur is an essential goal of cervical traction. If immobilization is required in an infant or young child, a special cervical spine cast (Minerva cast) is applied.

FIG 29-11 A, Halo vest. B, Cervical traction with Gardner-Wells tong.

Nursing Care Management

To assess the child in traction, it is essential to know the purpose for which the traction is applied and to understand the basic principles of traction. Regular assessment of both the child and the traction apparatus is required (see [Nursing Care Guidelines](#) box). Many of the nursing problems associated with a child in traction are related to immobility. Modifying the child's diet, encouraging fluids, increasing fiber, and offering a mild stool softener may be necessary to prevent constipation.

Nursing Care Guidelines

Traction Care

Understand Therapy

Understand purpose of traction.

Understand function of traction in each specific situation.

Maintain Traction

Check desired line of pull and relationship of distal fragment to proximal fragment. Check whether fragment is being directed upward, adducted, or abducted.

Check function of each component:

- Position of bandages, frames, splints, specialized boot
- Ropes: In center track of pulley, taut, no fraying, knots tied securely
- Pulleys: In original position on attachment bar; have not slid from original site; wheels freely movable
- Weights: Correct amount of weight, hanging freely, in safe location

Check bed position: Head or foot elevated as directed for desired amount of pull and counter traction.

Do not remove skeletal traction or adhesive traction straps on skin traction.

Maintain Alignment

Observe for correct body alignment with emphasis on alignment of shoulder, hip, and leg.

Check after child has moved.

Maintain correct angles at joints.

Skin Traction

Replace nonadhesive straps or elastic bandage on skin traction *when permitted* or absolutely necessary, but make certain that traction on limb is maintained by someone during procedure.

Assess straps or bandages to ascertain if they are correctly applied (diagonal or spiral) and not too loose or too tight, which could cause slippage and malalignment of traction.

Assess traction boot to ensure it has not slipped and is not causing compression of the foot, thus impairing the circulation.

Skeletal Traction

Check pin sites frequently for signs of bleeding, inflammation, or infection.

Cleanse and dress pin sites per institution protocol or as ordered.

Apply topical antiseptic or antibiotic to pin sites daily as ordered.

Cover ends of pins with protective rubber or padding to prevent child being scratched by pin.

Note pull of traction on pin; pull should be even.

Check pin screws to be certain that screws are tight in metal clamp that attaches traction apparatus to pin.

Prevent Skin Breakdown

Provide alternating-pressure mattress underneath hips and back.

Make total-body skin checks for redness or breakdown, especially over areas that receive greatest pressure.

Wash and dry skin at least daily.

Inspect pressure points daily or more often if risk for breakdown is observed.

Use a skin breakdown assessment scale, such as Braden Q.

Stimulate circulation with gentle massage over pressure areas.

Change position at least every 2 hours to relieve pressure.

Encourage increase in intake of oral fluids.

Provide and encourage patient to eat a balanced diet, including vegetables and fruits.

Prevent Complications

Check pulses in affected area and compare with pulses in contralateral site.

Assess circular dressings for excessive tightness.

Assess restrictive bandages or devices used to maintain traction on affected limb:

1. Make certain that they are not too loose or too tight.
2. Remove periodically and check for skin breakdown or pressure areas.

Encourage deep breathing or use of incentive spirometry:

- Monitor the 6 Ps (see [Box 29-3](#)).

Take immediate action to correct problem or report to practitioner if neurovascular changes are present.

Record findings of neurovascular changes.

Carry out passive, active, or active-with-resistance exercises of uninvolved joints.

Note if any tightness, weakness, edema, or contractures are developing in uninvolved joints and muscles.

Take measures to correct or prevent further development of weakness, such as applying footboard or foot orthoses to prevent footdrop.

When indicated by the attending practitioner, the nurse may remove nonadhesive skin traction. In these cases, intermittent traction is periodically released and reapplied as ordered. A child may have several types of traction at one time, and each one must be assessed separately to avoid problems.

Nursing Alert

Skeletal traction is never released by the nurse (except under direct supervision by the practitioner). This precaution includes not lifting the weights that are applying traction (e.g., for moving the child in bed, for repositioning).

In addition to routine skin observation and care, the child in skeletal traction will need special skin care at the pin sites according to hospital policy or practitioner preference. Pin sites should be frequently assessed and cleaned to prevent infection; after the first 48 to 72 hours, pin site care may be performed once daily or weekly for mechanically stable pins ([Holmes, Brown, and Pin Site Care Expert Panel, 2005](#)). Use of a 2-mg/ml chlorhexidine solution has been proposed as best practice care for skeletal pin sites by the National Association of Orthopaedic Nurses ([Holmes, Brown, and Pin Site Care Expert Panel, 2005](#)). A pressure-reduction device, such as a pressure-reduction mattress, decreases the chance of skin breakdown.

Nursing Tip

A small hand mirror facilitates visualization of inaccessible skin areas.

When the child is first placed in traction, increased discomfort is common as a result of the traction pull fatiguing the muscle. It has been determined that orthopedic conditions are associated with a higher-than-average number of painful events and a higher percentage of bodily symptoms than other common conditions. Analgesics, including IV opioids, and muscle relaxants, help during this phase of care and should be administered liberally.

Nursing Alert

For skeletal traction to be effective, ensure that the weights are hanging freely at all times.

The specific nursing responsibilities for the patient in traction are outlined in the [Nursing Care Guidelines](#) box earlier.

Distraction

Unlike traction, which helps bones realign and fuse properly, **distraction** is the process of separating opposing bone to encourage regeneration of new bone in the created space. Distraction can also be used when limbs are of unequal lengths and new bone is needed to elongate the shorter limb.

External Fixation

Monolateral, Taylor Spatial Frame, and **Ilizarov external fixators (IEFs)** are common external fixation devices. The IEF uses a system of wires, rings, and telescoping rods that permits limb lengthening to occur by manual distraction ([Fig. 29-12](#)). In addition to lengthening bones, the device can be used to correct angular or rotational defects or to immobilize fractures. The device is attached surgically by securing a series of external full or half rings to the bone with wires. External telescoping rods connect the rings to each other. Manual distraction is accomplished by manipulating the rods to increase the distance between the rings. A percutaneous osteotomy is performed when the device is applied to create a “false” growth plate. A special osteotomy or corticotomy involves cutting only the cortex of the bone while preserving its blood supply, bone marrow, endosteum, and periosteum. Capillary blood flow to the transected area is essential for proper bone growth. Cut bone ends typically grow at a rate of 1 cm (0.4 inches) per month. The IEF can result in up to a 15-cm (6-inch) gain in length.

FIG 29-12 Child with Ilizarov external fixator (IEF; on right leg) during physical therapy on parallel bars.

Nursing Care Management

Success of the fixation devices depends on the child's and family's cooperation; therefore, before surgery, they must be fully informed of the appearance of the device, how it accomplishes bone growth and limits bone mobility, alterations in activities, and home and follow-up care. Children are involved in learning to adjust the device to accomplish distraction. Children and parents should be instructed in pin care, including observation for infection and loosening of the pins. Cleaning routines for the pin sites vary among practitioners but should not traumatize the skin.

Children who participate actively in their care report less discomfort. Because the device is external, the child and family need to be prepared for the reactions of others and assisted in camouflaging the device with appropriate apparel, such as wide-legged pants that close with self-adhering fasteners around the device. A loose sock or stockinette may also be used over the device

to decrease public awareness. Partial weight bearing is allowed, and the child learns to walk with crutches. Alterations in activity include modifications at school and in physical education (PE). Full weight bearing is not allowed until the distraction is completed and bone consolidation has occurred. Follow-up care is essential to maintain appropriate distraction until the desired limb length is achieved. The device is removed surgically after the bone has consolidated, and the child may need to use crutches or have a cast for 4 to 6 weeks after removal to reduce the risk of fracture.

Amputation

A child may be born with the congenital absence of an extremity, have a traumatic loss of an extremity, or need a surgical amputation for a pathologic condition such as **osteosarcoma** (see later in chapter). With today's surgical technology and the quick thinking of bystanders who save a traumatically amputated body part, some children have had fingers and arms sewn back on with variable degrees of functional use regained.

Nursing Alert

For an amputated limb or body part that may be reattached, do the following:

1. Rinse limb gently with normal saline.
2. Loosely wrap limb in sterile gauze.
3. Place wrapped limb in a watertight bag.
4. Cool (without freezing) bag in ice water (do not pack in ice because this may harm tissue).
5. Label with child's name, date, and time, and transport with the child to the hospital.

Surgical amputation or the surgical repair of a permanently severed limb focuses on constructing an adequately nourished residual limb. A smooth, healthy, padded stump, free of nerve endings, is important in prosthesis fitting and subsequent ambulation. In some situations in which there is no vascular or neurologic deficit, a cast is applied to the stump immediately after the procedure, and a pylon, metal extension, and artificial foot are attached so the patient can walk on the temporary prosthesis within a few hours.

Nursing Care Management

Stump shaping is done postoperatively with special elastic bandaging using a figure-eight bandage, which applies pressure in a cone-shaped fashion. This technique decreases stump edema, controls hemorrhage, and aids in developing desired contours so the child will bear weight on the posterior aspect of the skin flap rather than on the end of the stump. Stump elevation may be used during the first 24 hours, but after this time, the extremity should not be left in this position because contractures in the proximal joint will develop and seriously hamper ambulation. Monitoring proper body alignment will further decrease the risk of flexion contractures.

For older children and adolescents, arm exercises, bed pushups, and prosthesis-training programs using parallel bars help build up the arm muscles necessary for walking with crutches. Full range-of-motion exercises of joints above the amputation must be performed several times daily using active and isotonic exercises. Young children are often spontaneously active and require little encouragement.

Depending on the child's age, children or their parents will need to learn hygiene, including carefully washing with soap and water every day and checking for skin irritation, breakdown, and infection. A tube of stockinette or powder is used to slide the prosthesis on more easily. Skin must be checked carefully every time the prosthesis is removed, and prosthesis tolerance time must be adjusted to prevent skin breakdown.

For children who have had an amputation, **phantom limb sensation** is an expected experience because the nerve-brain connections are still present. Gradually, these sensations fade, although in many people who have had amputations, they persist for years. Preoperative discussion of this phenomenon will aid a child in understanding these "unusual feelings" and not hiding the

experiences from others. Limb pain, especially pain that increases with ambulation, should be evaluated for the possibility of a **neuroma** at the free nerve endings in the stump or other problems such as a poorly fitting prosthesis or joint instability.

Sports Participation and Injury

Every sport has the potential for injury to participants—whether an adolescent engages in serious competition or participates for enjoyment. Serious injury occurs most often during rough contact sports or to persons who are not physically prepared for the activity. Injuries also occur when the children's or adolescents' bodies are not suited to the sport, when their muscles and body systems (respiratory and cardiovascular) are not conditioned to endure physical stress, or when they lack the insight and judgment to recognize that an activity exceeds their physical abilities. Rapidly growing bones, muscles, joints, and tendons are especially vulnerable to unusual strain. In general, more injuries occur during recreational sports participation than during organized athletic competition.

The environment and the sports or recreational equipment can also present risks (Fig. 29-13). Children and adolescents who participate in physical activity or sports do so in many different environments, including indoors and outdoors, on floors, on the ground and snow, on or beneath water surfaces, and sometimes in free air space. Most of these activities also involve equipment, which children and adolescents may not be physically mature enough to manage safely. A common example is skateboarding when the child or adolescent does not take safety precautions and perceives increased risk taking as a part of the sport.

FIG 29-13 A number of injuries may occur with sports participation.

Acute overload injuries are those that occur suddenly during an activity and produce immediate symptoms. A blow or overstretching, twisting, or sudden stress to tissues can cause these injuries. For descriptions and management of traumatic injuries, see earlier in chapter.

Overuse Syndromes

To excel in sports, young athletes are forced to train longer, harder, and earlier in life than previously. The rewards are an increased level of fitness, better performance, faster times, and the satisfaction of attaining a personal goal. However, risks are associated when young people overtrain; these risks include recurrent upper respiratory infections, sleep and mood disturbances, loss of appetite, decreased interest in training and competition, and inability to concentrate (Winsley and Matos, 2011). Growing numbers of young people participate in organized sports, resulting in an increase in overuse injuries. Nearly half of all injuries evaluated in pediatric sports medicine are overuse injuries (Biber and Gregory, 2010).

The risk of overuse injury is always present and can be related to several factors, including training errors, muscle/tendon imbalance, anatomic malalignment (e.g., femoral anteversion, excessive lumbar lordosis, tibial torsion), incorrect footwear or playing surface, an associated disease state, and growth (growth cartilage is less resistant to microtrauma). Chronic pain in athletes is often associated with overuse injury, which can occur at any level of athletic

participation. The common feature in overuse injuries is the **repetitive microtrauma** that occurs to a particular anatomic structure. Performing the same movements repeatedly can cause several types of injury:

1. **Frictional**, or rubbing of one structure against another
2. **Tractional**, or repeated pull on a ligament or tendon
3. **Cyclic**, or repetitive loading of impact forces (stress fractures)

The end result is inflammation of the involved structure with complaints of pain, tenderness, swelling, and disability.

Stress Fractures

Stress fractures are a consequence of repetitive, excessive stress on the bone that causes microfractures within the bone. Continued stress to the bone can lead to spread of the microfracture and eventual macrofracture. The pathogenesis of stress injury to the bone is multifactorial and includes everything from the footwear to the fitness level of the athlete. Stress fractures occur most commonly in the lower extremities, particularly the tibia. Track and field athletes have the highest incidence of stress fractures (Patel, Roth, and Kapil, 2011).

The most common symptom of stress fracture is a sharp, persistent, progressive pain or a deep, persistent dull ache located over the bone. Sometimes there is pain on impact (heel strike), but the most important clinical sign is pain over the involved bony surface. Diagnosis is based on clinical observation and history. Plain radiographs are rarely diagnostic of stress fractures during the initial few weeks because callus formation is not yet evident. Magnetic resonance imaging (MRI) is used when other causes of pain must be ruled out.

Therapeutic Management

Development of inflammation is common to all overuse syndromes; therefore, management involves rest or alteration of activities, physical therapy, and medication. Rest is the primary therapy, usually interpreted as reduced activity and the use of alternative exercise—not bed rest or immobilization with an orthosis. The main purpose is to alleviate the repetitive stress that initiated the symptoms. It is important to keep the adolescent mobile, and training can be continued.

Alternative exercise is selected that maintains conditioning without aggravating the injury. For example, pool running (treading water in the deep end of a pool) can use the same movements as running but without the weight bearing; bicycling, swimming, and rowing are viable alternatives.

Other modalities include cryotherapy and cold whirlpool baths. Sometimes taping, bracing, splinting, and other orthoses are used, depending on the injury. **Nonsteroidal antiinflammatory drugs (NSAIDs)** are often prescribed to reduce inflammation and pain. Topical medications are of questionable value.

Nurse's Role in Sports for Children and Adolescents

Nurses are often involved in sports activities in the areas of preparation and evaluation for activities, prevention of injury, treatment of injuries, and rehabilitation after injury. Selecting an appropriate sport for both recreation and competition is a joint effort of the adolescent, parents, and health professionals. The best approach to counseling children, adolescents, and parents regarding sports participation is to encourage activities that are most likely to provide pleasure and physical benefits throughout childhood and into adulthood. Exposure to a variety of activities is better for young children than limiting them to one sport. Parents should be cautioned against overcommitting children to sports activities so they have time for other activities.

When children sustain athletic injuries, nurses are often responsible for instructions regarding care. Instructions (e.g., schedule for appointments, application of ice, any restrictions in activity) should be clear and accompanied by written directions. The importance of taking medications as prescribed is emphasized, especially if medications are needed for an extended period and if adherence is an issue. Antiinflammatory medications given an hour before practice or competition may help children continue their activities.

Prevention of sports injuries is the most important aspect of athletic programs. Children should

be suited to the activity, and the environment and the equipment must be safe. Children should be prepared for the sport, especially if it requires strenuous or continuous physical exertion. Nurses, coaches, and athletic trainers must collaborate to ensure that safety measures are implemented. Stretching exercises, warm-up and cool-down activities, and appropriate training are requirements for safe participation. Protective measures such as pads, taping, and wrapping are also important to prevent injury. Finally, nurses must be aware of environmental safety risks (see Head Injury, [Chapter 27](#)).

Birth and Developmental Defects

Some skeletal defects may be diagnosed at birth or within days, weeks, or months after birth. In other cases, the deviation may be difficult to detect without careful inspection. Therefore, it is imperative that nurses become acquainted with signs of these defects and understand the principles of therapy in order to direct families in the care and management of these children.

Developmental Dysplasia of the Hip

The broad term **developmental dysplasia of the hip (DDH)** describes a spectrum of disorders related to abnormal development of the hip that may occur at any time during fetal life, infancy, or childhood. A change in terminology from *congenital hip dysplasia* and *congenital dislocation of the hip* to DDH more properly reflects a variety of hip abnormalities in which there is a shallow acetabulum, subluxation, or dislocation.

The incidence of hip dysplasia varies depending on ethnicity/race but is approximately 1 to 2 infants per 1000 live births in the United States. Girls are affected more commonly than boys and a positive family history increases a child's risk of having DDH. Approximately 7% to 40% of infants with DDH have a breech intrauterine position (Loder and Skopelja, 2011a).

Pathophysiology

The cause of DDH is unclear but is likely multifactorial. Certain factors such as gender, birth order, family history, intrauterine position, joint laxity, and postnatal positioning are believed to affect the risk of DDH. Predisposing factors associated with DDH may be divided into three broad categories: (1) physiologic factors, which include maternal hormone secretion and intrauterine positioning; (2) mechanical factors, which involve breech presentation, multiple fetus, oligohydramnios, and large infant size as well as swaddling where the hips are maintained in adduction and extension which in time may cause a dislocation; and (3) genetic factors, which entail a higher incidence of DDH in siblings of affected infants and an even greater incidence of recurrence if a sibling and one parent were affected.

Some experts categorize DDH into two major groups: (1) **idiopathic**, in which the infant is neurologically intact, and (2) **teratologic**, which involves a neuromuscular defect, such as arthrogryposis or myelodysplasia. The teratologic forms usually occur in utero and are much less common.

Three degrees of DDH are illustrated in Fig. 29-14.

1. **Acetabular dysplasia:** This is the mildest form of DDH, in which there is a delay in acetabular development evidenced by osseous hypoplasia of the acetabular roof that is oblique and shallow, although the cartilaginous roof is comparatively intact. The femoral head remains in the acetabulum.
2. **Subluxation:** The largest percentage of DDH, subluxation, implies incomplete dislocation of the hip. The femoral head remains in contact with the acetabulum, but a stretched capsule and ligamentum teres cause the head of the femur to be partially displaced. Pressure on the cartilaginous roof inhibits ossification and produces a flattening of the socket.
3. **Dislocation:** The femoral head loses contact with the acetabulum and is displaced posteriorly and superiorly over the fibrocartilaginous rim. The ligamentum teres is elongated and taut.

Normal
FIG 29-14 Configuration and relationship of structures in developmental dysplasia of the hip (DDH).
 Dysplasia
 Subluxation
 Dislocation

Factors related to infant handling are indicated in the [Cultural Considerations](#) box.

Cultural Considerations

Developmental Dysplasia of the Hip

A striking relationship exists between the development of hip dislocation and methods of swaddling the hips. Among the cultures with the highest incidence of dislocation (Navajo Indians and Canadian Natives), newly born infants are tightly wrapped with the hips adducted and extended in blankets or other swaddling material or are strapped to cradle boards. In cultures such as those in Central and South America, Asia, and Africa, where mothers traditionally carry infants on their backs with the infants' hips in the abducted and flexed hip position, hip dysplasia is much less common.

Recently, several prominent orthopedic specialty organizations recommended that infants' hips be placed in slight flexion and abduction during swaddling. It was further recommended that infants' knees be maintained in slight flexion and that forced or sustained passive hip extension in the first few months should be avoided ([Price and Schwend, 2011](#)). These recommendations were supported by evidence that demonstrated a significant relationship between tight swaddling and hip dysplasia and are aimed at decreasing the incidence of hip dysplasia in infants.

Diagnostic Evaluation

DDH is often not detected at the initial examination after birth; thus, all infants should be carefully monitored for hip dysplasia at follow-up visits throughout the first year of life at routine well-child checks. In the newborn period, hip dysplasia usually appears as hip joint laxity rather than as outright dislocation. Subluxation and the tendency to dislocate can be demonstrated by the Ortolani or Barlow maneuvers ([Fig. 29-15, D](#)). The Ortolani and Barlow tests are most reliable from birth to 4 weeks of age. With the Barlow test, the thigh is adducted and light pressure is applied to see if the femoral head can be felt to slip posteriorly out of the acetabulum. The Ortolani test involves abducting the thighs and placing anterior pressure at the hip to see if the femoral head slips forward into the acetabulum. Other signs of DDH are shortening of the limb on the affected side (see [Fig. 29-15, C](#)), asymmetric thigh and gluteal folds (see [Fig. 29-15, A](#)), and decreased hip abduction on the affected side (see [Fig. 29-15, B](#)). See [Box 29-5](#).

Nursing Alert

These tests must be performed by an experienced clinician to prevent an injury to the infant's hip.

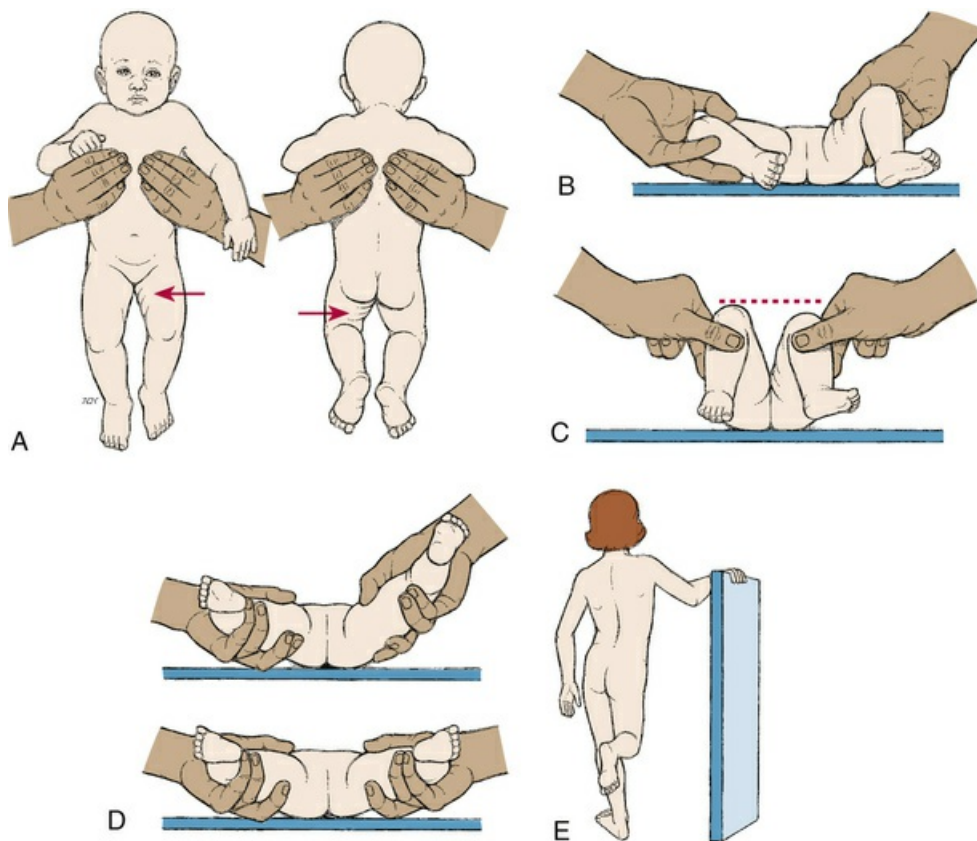

FIG 29-15 Signs of developmental dysplasia of the hip (DDH). **A**, Asymmetry of gluteal and thigh folds. **B**, Limited hip abduction, as seen in flexion. **C**, Apparent shortening of the femur, as indicated by the level of the knees in flexion (Galeazzi sign). **D**, Ortolani maneuver with clunk elicited. **E**, Positive Trendelenburg sign (if child is weight bearing).

Box 29-5

Clinical Manifestations of Developmental Dysplasia of the Hip

Infants

- Shortening of limb on affected side (Galeazzi sign)
- Restricted abduction of hip on affected side
- Unequal gluteal folds (best visualized with infant prone)
- Positive Ortolani test (hip is reduced by abduction)
- Positive Barlow test (hip is dislocated by adduction)

Older Infants and Children

- Affected leg appears shorter than the other
- Telescoping or piston mobility of joint: Head of femur felt to move up and down in buttock when extended thigh is pushed first toward child's head and then pulled distally
- Trendelenburg sign: When child stands first on one foot and then on the other (holding onto a chair, rail, or someone's hands) bearing weight on affected hip, pelvis tilts downward on normal side instead of upward, as it would with normal stability

Greater trochanter prominent and appearing above a line from anterosuperior iliac spine to tuberosity of ischium

Marked lordosis and waddling gait (bilateral hip dislocation)

Radiographic examination in early infancy is not reliable because ossification of the femoral head does not normally take place until the 4th to 6th month of life. However, the cartilaginous head can be visualized directly by ultrasonography. Universal newborn screening with ultrasonography has been proposed; however, numerous studies reveal that this approach has a high rate of false-positive results and subsequent overtreatment. Therefore, ultrasonography is recommended as an adjunct to the physical examination ([American Academy of Pediatrics, 2000](#)). In infants older than 6 months old and in children, radiographic examination is useful in confirming the diagnosis. An upward slope in the roof of the acetabulum (acetabular angle) greater than 30 degrees with upward and outward displacement of the femoral head is seen in a child with hip dysplasia. The [American Academy of Pediatrics \(2000\)](#) has published extensive clinical guidelines for screening and early detection of DDH.

Therapeutic Management

Treatment is begun as soon as the condition is recognized because early intervention is more favorable to the restoration of normal bony architecture and function. The longer treatment is delayed, the more severe the deformity, the more difficult the treatment, and the less favorable the prognosis. The treatment varies with the child's age and the extent of the dysplasia. The goal of treatment is to obtain and maintain a safe, congruent position of the hip joint to promote normal hip joint development.

Newborns to Age 6 Months

The hip joint is maintained, by dynamic splinting, in a safe position with the proximal femur centered in the acetabulum in a degree of flexion. Of the numerous devices available, the **Pavlik harness** is the most widely used, and with time, motion, and gravity, the hip works into a more abducted, reduced position ([Fig. 29-16](#)). The harness is worn continuously until the hip is proved stable on both clinical and ultrasound examination, usually within 6 to 12 weeks.

FIG 29-16 Child in Pavlik harness. (Courtesy of Amanda Politte, St Louis, MO.)

When there is difficulty in maintaining stable reduction of the femoral head, a surgical closed reduction of the hip and application of a hip spica cast is performed. The cast is changed periodically to accommodate the child's growth. Once sufficient stability is acquired, after approximately 3 months, the child is transitioned to a removable hip abduction orthosis. The duration of treatment in the orthosis depends on development of the acetabulum.

Ages 6 to 24 Months

In this age group, the dislocation is often not recognized until the child begins to stand and walk, when shortening of the limb and contractures of hip adductor and flexor muscles become apparent. In less severe DDH or acetabular dysplasia, use of a hip abduction orthosis may be initiated. Duration of treatment depends on development of the acetabulum. When adduction contracture is present, devices such as traction may be used to slowly and gently stretch the hip to full abduction, after which wide abduction is maintained until stability is attained. A surgical closed reduction of the hip is performed in cases of hip subluxation or dislocation, and in the event that the hip remains unstable, an open reduction may be necessary. The child is placed in a spica cast for approximately 12 weeks, and a hip abduction orthosis may be used following casting.

Older Children

Correction of the hip deformity in older children is inherently more difficult than in the preceding age groups because secondary adaptive changes and other etiologic factors (such as juvenile arthritis and cerebral palsy) complicate the condition. Operative reduction, which may involve preoperative traction, lengthening of contracted muscles, and pelvic osteotomy procedures designed to construct an acetabular roof, often combined with proximal femoral osteotomy, are usually required. After cast removal, range-of-motion exercises help restore movement. Other rehabilitation measures may include muscle strengthening, a period of crutch or walker use, and gait training.

Nursing Care Management

Nurses are in a unique position to detect DDH in early infancy. During the infant assessment process and routine nurturing activities, the hips and extremities are inspected for any deviations from normal. Any observations or concerns are reported to the attending provider. An ambulatory child who displays a limp or an unusual gait should be referred for evaluation. This may indicate an orthopedic or neurologic problem. Nonambulatory children with cerebral palsy should also be assessed for evidence of hip problems throughout their growing years.

The major nursing problems in the care of an infant or child in a cast or other device are related to maintenance of the device and adaptation of nurturing activities to meet the patient's needs. Generally, treatment and follow-up care of these children are carried out in an outpatient setting.

Nursing Alert

The former practice of double or triple diapering for DDH is not recommended because there is no evidence to support its efficacy.

The primary nursing goal is teaching parents to apply and maintain the reduction device. The Pavlik harness allows for easy handling of the infant and usually produces less apprehension in the parent than heavy braces and casts. It is important that parents understand the correct use of the harness, which may or may not allow for its removal during bathing. Removing the harness is determined individually on the basis of the provider's recommendation, the degree of hip instability, and the family's level of understanding. Parents are instructed to not adjust the harness. The child should be examined by the provider before any adjustment is attempted to make certain the hips are in correct placement.

Skin care is an important aspect of the care of an infant in a harness. The following instructions for preventing skin breakdown are stressed:

- Check frequently (at least two or three times a day) for red areas or skin irritation in skin folds or under the straps.
- Gently massage healthy skin under the straps once a day to stimulate circulation. In general, avoid lotions and powders because they can cake and irritate the skin.
- Always place the diaper under the straps.

Parents are encouraged to hold the infant with a harness and continue care and nurturing activities. The nurse can assist by being available for parents' questions about the necessary adaptations to daily care to decrease the parents' anxiety and possible feelings about the child being hurt by routine caring.

Casts and orthotic devices (braces) offer more challenging nursing and caregiver problems because they cannot be removed for routine care, although sometimes a brace may be removed for bathing. Care of an infant or small child with a cast requires nursing innovation to reduce irritation and to maintain cleanliness of both the child and the cast, particularly in the diaper area. (See earlier in this chapter for care of the child in a cast.)

It is important for nurses, parents, and other caregivers to understand that children in corrective devices need to be involved in all typical age appropriate activities. Confinement in a cast or appliance should not exclude children from family (or unit) activities. They can be held astride the lap for comfort and transported to areas of activity. An adapted wheelchair, stroller, or wagon can offer mobility to an older infant or child.

Clubfoot

Clubfoot or talipes equinovarus (TEV) is a complex deformity of the ankle and foot that includes forefoot adduction, midfoot supination, hindfoot varus, and ankle equinus. The foot is pointed downward (plantarflexed) and inward in varying degrees of severity (Fig. 29-17). Clubfoot may occur as an isolated deformity or in association with other disorders or syndromes, such as chromosomal abnormalities, arthrogryposis, or spina bifida.

FIG 29-17 Bilateral congenital talipes equinovarus (TEV; clubfoot) in a 2-month-old infant. (From Zitelli BJ, McIntire SC, Nowalk AJ: *Zitelli and Davis' atlas of pediatric physical diagnosis*, ed 6, St Louis, 2012, Saunders/Elsevier.)

The incidence of clubfoot in the general population is approximately 1 per 1000 live births, with boys affected twice as often as girls. Bilateral clubfeet occur in 50% of the cases (Winell and Davidson, 2016). The precise cause of clubfoot is unknown. However, there is a strong familial tendency, with a 1 in 10 chance that a parent with clubfoot will have an affected offspring. Other possible theories as to the cause of clubfoot include arrested or abnormal fetal development or abnormal positioning and restricted movement in utero, although the evidence is not conclusive. Whereas arrested development during this early stage tends to result in a rigid deformity, mechanical pressures from intrauterine positioning are likely causes of more flexible deformities (Shyy, Wang, Sheffield, et al, 2010).

Clubfoot may be further divided into three categories: (1) positional clubfoot (also called *transitional, mild, or postural clubfoot*), which is believed to occur primarily from intrauterine crowding and responds to simple stretching and casting; (2) congenital clubfoot, also referred to as *idiopathic*, which may occur in an otherwise normal child and has a wide range of rigidity and prognosis; and (3) syndromic (or teratologic) clubfoot, which is associated with other congenital anomalies (such as myelomeningocele or arthrogryposis) and is a more severe form of clubfoot that is often resistant to typical treatment.

Classification

The mild, or postural, clubfoot may correct spontaneously or may require passive exercise or serial casting. There is no bony abnormality, but there may be tightness and shortening of the soft tissues medially and posteriorly. The teratologic clubfoot usually requires surgical correction and has a high incidence of recurrence. The congenital idiopathic clubfoot, or "true clubfoot," almost always

requires surgical intervention because there is bony abnormality.

Diagnostic Evaluation

The deformity is readily apparent at birth if it has not been detected prenatally through ultrasonography. However, it must be differentiated from some positional deformities that can be passively corrected. Once it is detected, a careful yet comprehensive physical assessment of the affected foot (or feet) should be completed to allow for appropriate decision making regarding treatment plans and prognosis. The affected foot (or feet) is usually smaller and shorter with an empty heel pad midfoot medial crease. When the deformity is unilateral, the affected limb may be shorter and calf atrophy is present. Radiographs of the feet are generally not necessary. A thorough hip examination should be performed for all infants with clubfoot; an increased risk of hip dysplasia is associated with clubfoot deformities.

Therapeutic Management

The goal of treatment for clubfoot is to achieve a painless, plantigrade, and functional foot. Treatment of clubfoot involves three stages: (1) correction of the deformity, (2) maintenance of the correction until normal muscle balance is regained, and (3) follow-up observation to avert possible recurrence of the deformity. Some feet respond to treatment readily; some respond only to prolonged, vigorous, and sustained efforts; and the improvement in others remains disappointing even with maximal effort.

Recommended treatment of clubfoot is with the use of the Ponseti method. Serial casting is begun shortly after birth. Weekly gentle manipulation and stretching of the foot along with placement of serial long-leg casts allow for gradual improvement in the alignment of the foot (Fig. 29-18). The extremity or extremities are casted until maximum correction is achieved, usually within 6 to 10 weeks. The majority of the time, a percutaneous heel-cord tenotomy is performed at the end of casting to correct the equinus deformity. After the tenotomy, a long-leg cast is applied and left in place for 3 weeks. After casting is completed, children are transitioned to utilizing Ponseti sandals with a bar set in abduction to help maintain the correction and prevent a recurrence of the foot deformity. Inability to achieve normal foot alignment after casting and tenotomy indicates the need for surgical intervention (Ponseti, 1996).

FIG 29-18 Feet casted for correction of bilateral talipes equinovarus (TEV).

Nursing Care Management

Nursing care of the child with clubfoot is the same as for any child who has a cast (see earlier in this chapter). Because the child will spend considerable time in a corrective device, nursing care plans include both long- and short-term goals. Careful observation of the skin and circulation is particularly important in young infants because of their rapid growth rate.

Because treatment and follow-up care are handled in the orthopedic clinic or outpatient department, parent education and support are important in nursing care of these children. It is

important for parents to understand the diagnosis, overall treatment program, the importance of regular cast changes, and the role they play in the long-term effectiveness of the therapy. Reinforcing and clarifying the orthopedic provider's explanations and instructions, teaching parents about care of the cast or bracing (including vigilant observation for potential problems), and encouraging parents to facilitate normal development within the limitations imposed by the treatment are all part of nursing responsibilities.

Metatarsus Adductus (Varus)

Metatarsus adductus, or metatarsus varus, is probably the most common congenital foot deformity. In most instances, it is a result of abnormal intrauterine positioning, particularly in a firstborn child, and is usually detected at birth. The deformity is characterized by medial adduction of the toes and forefoot, frequently in association with inversion and convexity of the lateral border of the foot (kidney shaped). Metatarsus adductus may be divided into three categories:

- Type I: The forefoot is flexible and corrects easily with manipulation
- Type II: The forefoot is only partial flexible and corrects passively past neutral position but only to neutral position with active manipulation
- Type III: The forefoot is rigid and will not stretch to neutral position with manipulation

Unlike a clubfoot, with which it is often confused, the angulation occurs at the tarsometatarsal joint while the heel and ankle remain in a neutral position. Ankle range of motion is normal. This deformity may cause a pigeon-toed or intoeing gait in the child. A thorough hip examination should be performed for all infants with metatarsus adductus as an increased risk of hip dysplasia is associated with foot deformities.

Management depends on the rigidity and type of the deformity. With types I and II, correction can usually be accomplished by gentle manipulation and passive stretching of the foot, which the parent is taught to perform. Repeated and consistent stretching is continued for the first 6 weeks, after which the treatment is based on the flexibility of the foot. With type III, the child usually requires serial manipulation and casting to correct the deformity, after which a corrective shoe or orthosis may be used. Surgical correction is rarely required for the condition but may be performed in children older than 4 to 6 years old who have considerable pain on ambulation or functional difficulties as a result of the deformity (Winell and Davidson, 2016).

Nursing Care Management

The nursing role primarily involves identifying the defect so that early therapy and instruction of the parents can be initiated. The nurse teaches the parents how to hold the heel firmly and to stretch only the forefoot; otherwise, undue force on the heel may produce a valgus deformity. If casting or an orthosis is required, the nurse instructs the parents in cast care and use of the brace.

Skeletal Limb Deficiency

Congenital limb deficiencies, or reduction malformations, are manifested by a variety of degrees of loss of functional capacity. They are characterized by underdevelopment of skeletal elements of the extremities. The range of malformation can extend from minor defects of the digits to serious abnormalities, such as **amelia**, absence of an entire extremity, or **meromelia**, partial absence of an extremity, which includes **phocomelia** (seal limbs), an interposed deficiency of long bones with relatively good development of hands and feet attached at or near the shoulder or the hips. Most reduction defects are primary defects of development of the limb, but prenatal destruction of the limb can occur, such as full or partial amputation of a limb in utero from constriction of an amniotic band (**amniotic band syndrome**). Neonates with congenital limb deficiencies often have associated malformations and should be thoroughly assessed for cardiovascular, central nervous system, renal, and digestive abnormalities (Stoll, Alembik, Dott, et al, 2010).

Pathophysiology

Limb deficiencies can be attributed to both heredity and environment and can originate at any stage of limb development. Formation of limbs may be suppressed at the time of limb bud formation, or there may be interference in later stages of differentiation and growth. Heredity appears to play a

prominent role, and prenatal environmental insults have been implicated in a number of cases, such as the well-publicized **thalidomide** tragedy of the 1950s and early 1960s, which demonstrated a clear relationship between the time of exposure of the pregnant woman to the antiemetic drug and the presence and type of limb deformity in the newborn. There are still drugs that may have similar **teratogenic** effects in the first trimester of pregnancy. Therefore, medication administration during this period should be carefully evaluated by the provider.

Therapeutic Management

The child with a limb deficiency should be fitted with prosthetic devices, and the devices should be applied at the earliest possible stage of development in an attempt to match the infant's motor readiness. This favors natural progression of prosthetic use. For example, an infant with an upper extremity deficiency is fitted with a simple passive device between 3 to 6 months old to encourage limb exploration, sitting (with the extremities needed for support), and bilateral hand activities. Lower limb prostheses are applied when the infant is ready to pull to a standing position.

In preparation for prosthetic devices, surgical modification of the residual limb may be necessary to ensure the most effective use of the device or prosthetic. Phocomelic digits are preserved for controlling switches of externally powered appliances in the upper extremities. Digits (in both the upper and lower extremities) provide the child with surfaces for tactile exploration and stimulation. Prostheses are replaced to accommodate the child's growth and increasing capabilities.

Nursing Care Management

Prosthetic application, training and use are most successfully carried out in a center that specializes in meeting the special needs of these children, especially very young children and those with multiple amputations or missing limbs. Management involves a **prosthetist**, who specializes in the development, fitting, and maintenance of prosthetic limbs, and other health care providers, such as physical and occupational therapists. Parents need support and are encouraged to assist the child in making age-appropriate adjustments to the environment. Although these children need assistance, overprotection may produce overdependence, with later maladjustment to school and other situations.

Osteogenesis Imperfecta

OI is a rare genetic disorder characterized by bones that fracture easily. Although inheritance follows an autosomal dominant pattern in most cases, rare autosomal recessive inheritance exists. Most types of OI have defects in the *COL1A1* or *COL1A2* genes, which code for polypeptide chains in type 1 procollagen, a precursor of type 1 collagen, which is a major structural component of bone. The error results in faulty bone mineralization, abnormal bone architecture, and increased susceptibility to fracture. There are at least 12 described types of OI, which accounts for significant disease variability. Clinical features may include varying degrees of bone fragility and deformity, short stature, blue sclerae, hearing loss, and dentinogenesis imperfecta (hypoplastic discolored teeth) (Marini and Blissett, 2013).

Classification is based on clinical features and patterns of inheritance (Box 29-6). Clinically, type I is the most common and mildest form with most fractures occurring before puberty. Stature is near normal and bone deformity is minimal or absent. Type II is the most severe and considered lethal in infancy. Type III OI is characterized by multiple fractures often present at birth, short stature, severe bone deformity and disability with a shortened life expectancy. Type IV is similar to type I although slightly more severe with short stature and mild to moderate bone deformities. Types V and VI do not have a type 1 collagen defect and are clinically similar to type IV. Both types demonstrate a unique pattern to their bone. Individuals affected have hypertrophic callus formation at fracture sites, a radiodense metaphyseal band, and calcification of the interosseous membrane of the forearm. In type VI, bone has a characteristic mineralization defect or microscopic "fish scale" appearance with elevated alkaline phosphatase activity. Types VII through XII are rare, recessive forms of OI with different genetic defects being found. Clinical severity is variable and overlaps types II and III in relation to clinical features. Those who survive have white sclerae, short stature, and rhizomelia (Marini and Blissett, 2013).

Box 29-6

Classification of Osteogenesis Imperfecta*

Type I[†]

A: Mild bone fragility; blue sclerae; normal teeth; hearing loss (occurs between 20 and 30 years old); autosomal dominant inheritance

B: Same as A except dentinogenesis imperfecta instead of normal teeth

C: Same as B but no bone fragility

Type II: Lethal; stillborn or die in early infancy; severe bone fragility, multiple fractures at birth; 10% of cases of OI; autosomal recessive inheritance

Type III: Severe bone fragility leading to severe progressive deformities; normal sclerae; marked growth failure; most autosomal recessive inheritance; few autosomal dominant inheritance

Type IV

A: Mild to moderate bone fragility; normal sclerae; normal teeth; short stature; variable deformity; autosomal dominant inheritance

B: Same as A except dentinogenesis imperfecta instead of normal teeth; approximately 6% of cases of OI

Type V: Clinically similar to type IV; hyperplastic callus; collagen mutation negative

Type VI: Sclerae and dentition normal; moderate to severe bone fragility; diagnosis by bone biopsy because of similarities to other types

Types VII and VIII (recessive form): Clinically overlap types II and III but have white sclerae, rhizomelia, and small to normal head circumference; severe osteochondroplastica and short stature in survivors. Type VII is associated with *CRTAP* gene, and type VIII is associated with the *LEPRE1* genetic mutation.

OI, Osteogenesis imperfecta.

*Two thirds of cases are type I.

†This classification is based on that proposed by Silience DO, Senn A, Danks DM: Genetic heterogeneity in osteogenesis imperfecta, *J Med Genet* 16(2):101–116, 1979, which originally included OI types I to IV. Additional types have been described but are not included herein.

Therapeutic Management

The treatment for OI has historically been primarily supportive; although patients and families are optimistic about new research advances. The use of bisphosphonate therapy with IV pamidronate to promote increased bone density and prevent fractures has become standard therapy for many children with OI. However, bisphosphonate therapy is reportedly more beneficial for increasing vertebral bone density and less effective for long bones (Marini, 2016).

The goals of a rehabilitative approach to management are directed toward preventing (1) positional contractures and deformities, (2) muscle weakness and osteoporosis, and (3)

malalignment of lower extremity joints prohibiting weight bearing. Lightweight braces and splints help support limbs, prevent fractures, and aid in ambulation. Physical therapy helps prevent disease osteoporosis and strengthens muscles, which in turn improves bone density. Surgery is sometimes used to help treat the manifestations of the disease. Surgical techniques are used to prevent or correct deformities that interfere with bracing, standing, or walking. The placement of intramedullary rods into the long bones can provide stability to bone, as well as prevent or correct deformities.

Nursing Care Management

Infants and children with this disorder require careful handling to prevent fractures. They must be supported when they are being turned, positioned, moved, and held. Even changing a diaper may cause a fracture in severely affected infants. These children should never be held by the ankles when being diapered but should be gently lifted by the buttocks or supported with pillows. However, nurses should not be afraid to touch or handle the infant or child with OI. Such children need compassionate handling and care as much as any other patient.

Both parents and the affected child need education regarding the child's limitations and guidelines in planning suitable activities that promote optimal development and protect the child from harm. Realistic occupational planning and genetic counseling are part of the long-term goals of care. Educational materials and information can be obtained from the Osteogenesis Imperfecta Foundation,* which also has a network that places families in contact with other families with a similar condition.

Children with current fractures or healing fractures should be screened for OI; the assumption that abuse or neglect is the cause of fractures in children must be carefully evaluated by a multidisciplinary team. A detailed history, no evidence of associated soft-tissue injury, and the presence of other symptoms related to OI help to determine the diagnosis.

Acquired Defects

Legg-Calvé-Perthes Disease

Legg-Calvé-Perthes disease is a self-limiting disorder in which there is avascular necrosis of the femoral head. The disease affects children 2 to 12 years old, but most cases occur as an isolated event in boys between 4 and 8 years old with a male-to-female ratio of 4 : 1. In approximately 10% of cases, the involvement is bilateral; most of the affected children have a skeletal age significantly below their chronologic age. Caucasian children are affected 10 times more frequently than African-American children (Loder and Skopelja, 2011b).

Pathophysiology

The cause of the disease is unknown, but a temporary disturbance of circulation or vascular supply to the femoral capital epiphysis produces an ischemic avascular necrosis of the femoral head. During middle childhood, circulation to the femoral epiphysis is more tenuous than at other ages and can become obstructed by trauma, inflammation, coagulation defects, and a variety of other causes. The pathologic events seem to take place in four stages (Box 29-7). The entire disease process may encompass as little as 18 months or continue for several years. The reformed femoral head may be severely altered or minimally impacted.

Box 29-7

Radiographic Stages of Legg-Calvé-Perthes Disease

Stage I: Initial, or avascular, stage: Avascular necrosis or infarction of the proximal femoral epiphysis with degenerative changes producing flattening of the upper surface of the femoral head or a decrease in femoral head height

Stage II: Fragmentation, or resorptive, stage: Femoral head resorption and revascularization produces collapse of the femoral head and fragmentation that gives a mottled appearance on radiographs

Stage III: Reossification stage: New bone formation, which is represented on radiographs as calcification and ossification or increased density in the areas of radiolucency; this filling-in process appears to begin in the periphery of the femoral head and progress centrally

Stage IV: Healing, or remodeling, stage: Gradual reformation of the head of the femur without radiolucency; this occurs until skeletal maturity

Clinical Manifestations and Diagnostic Evaluation

The onset of Legg-Calvé-Perthes disease is usually insidious, and the history may reveal only intermittent appearance of a limp on the affected side or a symptom complex, including hip soreness, ache, or stiffness, which can be constant or intermittent. The parents may report seeing the child limping, and the limp becomes more pronounced with increased activity. The pain may be experienced in the hip, along the entire thigh, or in the vicinity of the knee joint. The pain and limp are usually most evident on arising and at the end of a long day of activities. The pain is usually accompanied by joint dysfunction and limited range of motion at the hip. There may be a vague history of trauma but not necessarily. The diagnosis is established by characteristic radiographic findings including medial joint space widening, flattening of the femoral head with irregular ossification and possible subchondral fracture. A perfusion MRI of the hip may be obtained to assess the blood flow to the femoral head.

Therapeutic Management

Because deformity occurs early in the disease process, the aims of treatment are to restore and maintain adequate hip range of hip motion; prevent femoral head collapse, extrusion, or subluxation; and preserve as well-rounded femoral head as possible at the time of healing.

Treatment varies according to the child's age at the time of diagnosis and the appearance of the femoral head and position within the acetabulum. Activity causes microfractures of the soft ischemic epiphysis, which tend to induce synovitis, stiffness, and adductor contracture.

The initial therapy is rest or activity restrictions and limited weight bearing, which helps reduce inflammation and irritability of the hip. The use of NSAIDs can provide relief of pain or discomfort; physical therapy or range of motion exercises help restore hip motion. In some cases, traction is applied to stretch tight adductor muscles and improve containment of the femoral head. Abduction braces or casting may also be utilized for containment of the femoral head. If nonsurgical or conservative management is unsuccessful, surgical reconstruction or containment procedures such as a pelvic or proximal femoral osteotomy may be necessary.

The disease is self-limiting, but the ultimate outcome of therapy depends on early and efficient treatment. Children 5 years old and younger, whose epiphyses are more cartilaginous, tend to have the best prognosis or outcome. Children older than 8 years old have a significant risk for degenerative arthritis, especially if they have femoral head deformity at the time of diagnosis. The later the diagnosis is made, the more femoral damage will have occurred before treatment is implemented (Herring, 2011).

Nursing Care Management

Because these children are largely cared for on an outpatient basis, the major emphasis of nursing care is teaching the family the required care and management. The family needs to comprehend the diagnosis and understand the purpose and function of activity restrictions and limitations in achieving the desired outcome. The child and family may rely on the nurse to help them understand and adjust to therapeutic measures (see [Family-Centered Care](#) box).

Family-Centered Care

Legg-Calvé-Perthes Disease

A family with five healthy children was startled one day to learn that their 2-year-old son could no longer walk. He was diagnosed with Legg-Calvé-Perthes disease. Through several years of prosthetic devices and numerous physician visits, hospitalizations, and surgeries, this family turned a potentially devastating experience into one with cherished memories.

Today, the parents reflect on how their family coped with the reality of a debilitating disease. It was difficult for the parents to observe an eager, energetic child watch other children riding bicycles, running, or playing outdoor games. They are warmed by memories of watching their other children make the difference for their sibling. They all developed a strong bond through caring and sharing with one another. Coping as a family was an easy adjustment and, most of all, therapeutic. Today, more than 20 years later, the parents believe that each family member has grown with feelings of faith and trust. The experience proved to them that life will go on and that life is what you make it!

Shona Swenson Lens, MS, RN, FNP
Cheyenne, WY

One of the most difficult aspects associated with the disorder is the need to cope with a normally active child who feels well but must remain relatively inactive. It is important to emphasize that children should continue to attend school and engage in activities that can be adapted to the prescribed regimen. Suitable activities must be devised to meet the needs of a child in the process of developing a sense of initiative or industry. Activities that fulfill creative urges are well received.

Slipped Capital Femoral Epiphysis

Slipped capital femoral epiphysis (SCFE) refers to the spontaneous displacement of the proximal femoral epiphysis in a posterior and inferior direction. It develops most frequently shortly before or during accelerated growth and the onset of puberty (children between 8 and 15 years old; median age of 12 years old for boys and 11 years old for girls) and is seen more often in boys and obese children. The incidence is 0.3 to 24 cases per 100,000 children. Bilateral involvement occurs in up to 50% of cases (Loder and Skopelja, 2011c).

Pathophysiology

In a hip with SCFE, the capital femoral epiphysis remains in the acetabulum, but the femoral neck slips, deforming the femoral head and stretching blood vessels to the epiphysis. Most cases of SCFE are idiopathic, although it can be associated with endocrine disorders, such as hypothyroidism, low growth hormone levels, pituitary tumors, and renal osteodystrophy. The cause of idiopathic SCFE is multifactorial and includes obesity, physeal architecture and orientation, and pubertal hormone changes that affect physeal strength. Although obesity stresses the physeal plate, SCFE can also occur in children who are not obese.

Diagnostic Evaluation

SCFE is suspected when an adolescent or preadolescent displays clinical signs of a limp or complains of hip, groin, thigh, or knee pain. See [Box 29-8](#) for additional clinical manifestations. The diagnosis is confirmed by anteroposterior and frog-leg hip radiographs that reflect a change in position of the proximal femoral epiphysis. Radiographs show medial displacement of the epiphysis and uncovered upper portion of the femoral neck adjacent to the physis. There is a widened growth plate and irregular metaphysis.

Box 29-8

Clinical Manifestations of Slipped Capital Femoral Epiphysis

Very often obese (body mass index >95%)

Limp on affected side

Possible inability to bear weight because of severe pain

Pain in groin, thigh, or knee

- May be acute, chronic, or acute-on-chronic
- Continuous or intermittent

Affected leg is externally rotated

Loss of hip flexion, abduction, and internal rotation as severity increases

Affected leg may appear shorter

Therapeutic Management

The treatment goals of SCFE are to prevent further slipping of the femoral epiphysis until physeal closure, avoid further complication such as avascular necrosis, and maintain adequate hip function ([Peck and Herrera-Soto, 2014](#)). If the diagnosis is suspected or has been established, the child should be non-weight bearing to prevent further slippage. Surgical intervention is necessary and most often occurs within 24 hours to avoid further slippage and potential complications such as avascular necrosis.

Currently, in situ pinning using a single screw or alternatively multiple screws through the femoral neck into the proximal femoral epiphysis is the treatment of choice. For moderate to severe SCFE, an experience surgeon may choose to perform a surgical hip dislocation to improve the anatomy at the site of the deformity ([Tibor and Sink, 2013](#)). Postsurgical care includes non-weight bearing or limited weight bearing with use of crutches for ambulation for weeks to months. Children may be restricted from certain sports or activities until fusion or closure of the proximal femoral physis has occurred in order to prevent further slippage.

Nursing Care Management

Nursing care involves preparing the child and family for the surgical procedure and recovery. Postoperative care involves hemodynamic stabilization, pain management, and assessment for complications. The adolescent is taught the proper use of crutches and the importance of avoiding weight bearing on the affected hip. Self-care and performance of activities of daily living to capability are encouraged to promote confidence and decrease a sense of helplessness.

Nursing Alert

Children with hip issues, such as Legg-Calvé-Perthes or slipped capital femoral epiphysis (SCFE), often present with groin, thigh, or knee pain. This is often because of referred pain and is anatomically related to the obturator nerve. Any time a child presents with groin, thigh, or knee pain, a complete hip examination is paramount to rule out underlying hip pathology.

Kyphosis and Lordosis

The spine, which consists of numerous segments, can acquire deformity curves of three types: kyphosis, lordosis, and scoliosis (Fig. 29-19). **Kyphosis** is the lateral convex angulation in the curvature of the thoracic spine (see Fig. 29-19, B). If it is increased (greater than 45 degrees), it may occur secondary to disease processes, such as tuberculosis (TB), chronic arthritis, osteodystrophy, or compression fractures of the thoracic spine. The most common form of hyperkyphosis is posture-related. Children, especially during the time when skeletal growth outpaces growth of muscle, are prone to exaggeration of a normal kyphosis. This is particularly common in self-conscious adolescent girls who assume a round-shouldered slouching posture in an attempt to hide their developing breasts and increasing height. **Scheuermann kyphosis** is a thoracic curve greater than 45 degrees with wedging of more than 5 degrees of at least three adjacent vertebral bodies and vertebral irregularity.

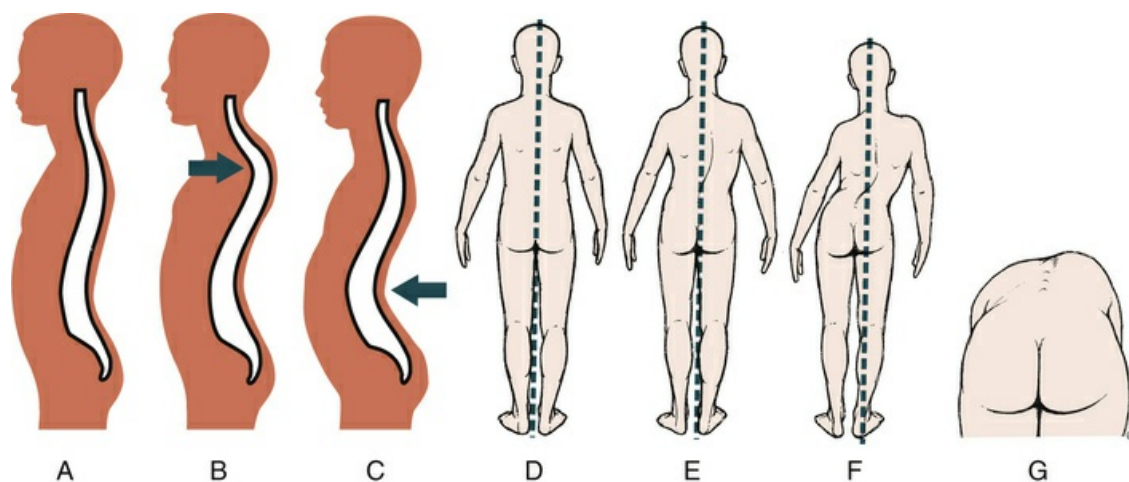

FIG 29-19 Defects of spinal column. **A**, Normal spine. **B**, Kyphosis. **C**, Lordosis. **D**, Normal spine in balance. **E**, Mild scoliosis in balance. **F**, Severe scoliosis not in balance. **G**, Rib hump and flank asymmetry seen in flexion caused by rotary component. (Redrawn from Hill NE, Schmitt EW: *Pediatric orthopedic nursing*, St Louis, 1975, Mosby.)

Postural (flexible) hyperkyphosis is almost always accompanied by a compensatory postural lordosis, an abnormally exaggerated concave lumbar curvature. Treatment of kyphosis consists of exercises to strengthen shoulder and abdominal muscles and bracing for more marked deformity. With adolescents who are significantly self-conscious about their appearance, the best approach is to emphasize the cosmetic value of corrective therapy and to place the responsibility on the adolescent for carrying out an exercise program at home with regular visits to and assessments by a physical therapist. Treatment with a brace may be indicated until skeletal maturity, and surgical fusion may be considered for severe, painful, or progressive thoracic curves, such as Scheuermann kyphosis.

Lordosis is the lateral inward curve of the cervical or lumbar curvature (see Fig. 29-19, C). Hyperlordosis may be a secondary complication of a disease process, a result of trauma, or idiopathic. Hyperlordosis is a normal observation in toddlers and, in older children, is often seen in association with flexion contractures of the hip, obesity, DDH, and SCFE. During the pubertal growth spurt, lordosis of varying degrees is observed in teenagers, especially girls. In obese children, the weight of the abdominal fat alters the center of gravity, causing a compensatory lordosis. Unlike kyphosis, severe lordosis is usually accompanied by pain.

Treatment involves management of the predisposing cause when possible, such as weight loss and correction of deformities. Postural exercises or support garments are helpful in relieving symptoms in some cases; however, these do not usually provide a permanent cure.

Idiopathic Scoliosis

Scoliosis is a complex spinal deformity in three planes, usually involving lateral curvature, spinal rotation causing rib asymmetry, and when in the thoracic spine, often thoracic hypokyphosis (see Fig. 29-19, E to G). It is the most common spinal deformity and is classified according to age of onset: *congenital* occurs in fetal development; *infantile* occurs at birth up to 3 years old; *juvenile* occurs in children ages 3 to 10 years old; and *adolescent* occurs at 10 years old or older.

Scoliosis can be caused by a number of conditions and may occur alone or in association with other diseases, particularly neuromuscular conditions (neuromuscular scoliosis). In most cases, however, there is no apparent cause, hence the name *idiopathic scoliosis*. There appears to be a genetic component to the etiology of idiopathic scoliosis; however, the exact relationship has yet to be established. The following section is limited to a discussion of adolescent idiopathic scoliosis.

Clinical Manifestations

Idiopathic scoliosis is most commonly identified during the preadolescent growth spurt. Parents frequently bring a child for follow-up on an abnormal school scoliosis screening or because of ill-fitting clothes, such as poorly fitting jeans. School screening is controversial because there are no controlled studies to demonstrate improved outcomes and a reported number of false-positive results lead to referrals. The American Academy of Orthopaedic Surgeons and the American Academy of Pediatrics published a joint statement favoring scoliosis screening for preadolescents and adolescents in the school, provider's office, or nurses' clinic (Richards and Vitale, 2008). According to the American Academy of Orthopaedic Surgeons (Richards and Vitale, 2008), girls should be screened at 10 and 12 years old, whereas boys should be screened once either at 13 or 14 years old. The benefits of early detection, referral, and medical treatment are considered to be significant, but the persons performing the screenings must be educated in the detection of spinal deformity.

Diagnostic Evaluation

Observation is performed behind a standing child wearing only shorts or undergarments. The child with scoliosis may exhibit asymmetry of shoulder height, scapular or flank shape, and hip height or pelvic obliquity. When the child bends forward at the waist so that the trunk is parallel with the floor and the arms hang free (the Adams forward bend test), asymmetry of the ribs and flanks may be appreciated (see Fig. 29-19, G). A scoliometer is used in the initial screening to measure truncal rotation. Often a primary curve and a compensatory curve will place the head in alignment with the gluteal cleft. However, with an uncompensated curve, the head and hips are not aligned (see Fig. 29-19, E and F).

Definitive diagnosis is made by radiographs of the child in the standing position and use of the Cobb technique, a standard measurement of angle curvature. The Risser scale is used to evaluate skeletal maturity on the radiograph. This scale assists in making a determination of the likely progression of the spinal curvature based on growth potential. The sexual maturity rating is also used to evaluate the risk of curve progression in adolescents. Not all spinal curvatures are scoliosis. A curve of less than 10 degrees is considered a postural variation. Curves measured between 10 to 25 degrees are mild and, if nonprogressive, do not require treatment (Hresko, 2013).

Intraspinous conditions or other disease processes that can cause scoliosis must be ruled out. The presence of pain, sacral dimpling or hairy patches, cutaneous vascular changes, absent or abnormal reflexes, bowel or bladder incontinence, or a left thoracic curve may indicate an intraspinal

abnormality, such as syringomyelia, diastematomyelia, or tethered cord syndrome. An MRI scan of the spine is usually obtained for evaluation.

Therapeutic Management

Current management options include observation with regular clinical and radiographic evaluation, orthotic intervention (bracing), and surgical spinal fusion. Treatment decisions are based on the magnitude, location, and type of curve; the age and skeletal maturity of the child or adolescent; and any underlying or contributing disease process.

Bracing and Exercise

For moderate curves (25 to 45 degrees) in the growing child and adolescent, bracing may be the treatment of choice. Historically bracing has not been shown to be curative; the goal is to slow the progression of the curvature to allow skeletal growth and maturity. The two most common types of bracing are the Boston and Wilmington braces, which are underarm orthoses customized from prefabricated plastic shells, with corrective forces using lateral pads and decreasing lumbar lordosis, and a thoracolumbosacral orthosis (TLSO), which is an underarm orthosis made of plastic that is custom molded to the body and then shaped to correct or hold the deformity (Fig. 29-20). The Milwaukee brace, which is an individually adapted brace that includes a neck ring, is rarely used in scoliosis but is sometimes used in the treatment of kyphosis. The Charleston nighttime bending brace is worn only when the child is in bed, because it prevents walking because of the severity of the trunk bend. Wearing the brace is challenging due to the child's age and preoccupation with body image and appearance. Bracing, although used as the gold standard treatment for moderate curves in a growing child, has not proved to be entirely effective in the treatment of idiopathic scoliosis.

FIG 29-20 A, Standard thoracolumbosacral orthotic (TLSO) brace for idiopathic scoliosis. The brace may be decorated to make it more acceptable to adolescents. B, Posterior view of the same brace.

There is very limited evidence regarding the effect of exercises and chiropractic treatment in the prevention of curve progression in scoliosis. Transcutaneous electrical nerve stimulation has proved to be an ineffective treatment. Exercises are of benefit when used in conjunction with bracing to maintain and increase the strength and range of motion of the spine.

Operative Management

Surgical intervention may be required for treatment of severe curves, which are typically greater than 45 degrees (Mistovich and Spiegel, 2016). The child's age, location of the curvature, and curve magnitude influence the decision for surgery. Any progressive or severe curve that does not respond to conservative orthotic measures (such as bracing) requires surgical correction. Bracing and exercise have been found to be ineffective in managing curves greater than 45 degrees. Neuromuscular, dysplastic and congenital curves, which eventually progress, are best treated with surgical stabilization. Difficulties with balance or seating, respiratory compromise, or pain are also considered.

There are a number of surgical techniques for severe scoliosis. A spinal fusion consists of realignment and straightening of the spine with internal fixation and instrumentation combined with bony fusion (arthrodesis). Posterior and/or anterior surgical approaches may be implemented. The goals of surgical intervention are to improve the curvatures on the sagittal and coronal planes and to provide a solid, pain-free fusion in a well-balanced torso, with maximum mobility of the remaining spinal segments.

Advances in surgical technology currently being evaluated include thoracoscopic spinal fusion and placement of implants; metallic staples may also be placed into the vertebral bodies to achieve spinal fusion and to correct the deformity (Mistovich and Spiegel, 2016). The use of minimally invasive surgery techniques has gained acceptance for its small incisions, decreased blood loss, decreased recovery time, earlier mobilization, and decreased pain and need for pain medications (Sarwahi, Wollowick, Sugarman, et al, 2011).

Nursing Care Management

Treatment for scoliosis extends over a significant portion of the affected child's period of growth. In adolescents, this period is the one in which their identity, both physical and psychological, is formed. The identification of scoliosis as a "deformity," in combination with unattractive braces and a significant surgical procedure, can have a negative effect on the already fragile adolescent body image. The adolescent and family require excellent nursing care to meet not only physical needs but also psychological needs associated with the diagnosis, surgery, postoperative recovery, and eventual rehabilitation.

Although adolescents with scoliosis are encouraged to participate in most peer activities, necessary therapeutic modifications are likely to make them feel different and isolated. Nursing care of the adolescent who is facing scoliosis surgery, potential social isolation, pain, and uncertainty, not to mention misunderstood emotions and body image issues, must be evaluated from the adolescent's perspective to be successful in meeting the individual's needs.

When a child or adolescent first faces the prospect of a prolonged period in a brace or other device, the therapy program and the nature of the device must be explained thoroughly to both the child and the parents so they will understand the anticipated results, how the appliance corrects the defect, the freedoms and constraints imposed by the device, and what they can do to help achieve the desired goal. Management involves the skills and services of a team of specialists, including the orthopedist, physical therapist, orthotist (a specialist in fitting orthopedic braces), nurse, social worker, and sometimes a thoracic or pulmonary specialist.

It is difficult for a child to be restricted at any phase of development, but adolescents need continual positive reinforcement, encouragement, and as much independence as can be safely assumed during this time. Guidance and assistance regarding anticipated problems, such as selection of clothing and participation in social activities, are appreciated by adolescents. Socialization with peers is strongly encouraged, and every effort is expended to help the adolescent feel attractive and worthwhile.

Preoperative Care

The preoperative workup usually involves a radiographic series, including bending or traction spine films, pulmonary function studies, and serologic laboratory studies (including prothrombin, partial thromboplastin, and platelet function test; blood count; electrolyte levels; urinalysis and urine culture; and blood levels of any medications). Spinal surgery typically results in considerable blood loss, so several options are considered preoperatively to maintain or replace blood volume. These options include autologous blood donations obtained from the patient before the surgery; intraoperative blood salvage; intraoperative hemodilution; erythropoietin administration; and controlled induced hypotension, which must be carefully monitored at all times to prevent physiologic instability.

Surgery for spinal fusion is complex, and often adolescents who require the procedure due to idiopathic scoliosis are not familiar with medical terms or procedures. Preoperative teaching is critical for the adolescent to be able to cooperate and participate in his or her treatment and recovery. Because the surgery is extensive, the patient is taught how to manage his or her own patient-controlled analgesia (PCA) pump; how to log roll; and the use and function of other equipment, such as a chest tube (for anterior repair) and Foley urinary catheter. It is recommended that the child or adolescent bring a favorite toy (age dependent) or personal items such as a favorite stuffed animal, laptop computer, cell phone, MP3 player, or movie player for postoperative use. Meeting with a peer who has undergone a similar surgery may also be valuable.

Postoperative Care

Following surgery, patients are monitored in an acute care setting and log rolled when changing position to prevent damage to the fusion and instrumentation. In some cases, an immobilization brace or cast is used postoperatively depending on the type of surgical intervention. Skin care is important, and pressure-relieving mattresses or beds may be needed to prevent pressure wounds (see *Maintaining Healthy Skin*, [Chapter 20](#)).

In addition to the usual postoperative assessments of wound, circulation, and vital signs, the neurologic status of the patient's extremities requires special attention. Prompt recognition of any neurologic impairment is imperative because delayed paralysis may develop that requires surgical intervention. Common postoperative problems after spinal fusion include neurologic injury or

spinal cord injury, hypotension from acute blood loss, wound infection, syndrome of inappropriate antidiuretic hormone, atelectasis, pneumothorax, ileus, delayed neurologic injury, and implanted hardware complications (Freeman, 2013). Superior mesenteric artery syndrome may occur several days after spinal surgery; this involves duodenal compression by the aorta and superior mesenteric artery and may result in acute partial or complete duodenal obstruction. Clinical manifestations include epigastric pain, nausea, copious vomiting, and eructation; symptoms are aggravated in the supine position and often relieved with the patient in a left lateral decubitus or prone position.

The adolescent usually has considerable pain for the first few days after surgery and requires frequent administration of pain medication, preferably opioids administered intravenously on a regular schedule. For children able to understand the concept, PCA is recommended (see Pain Assessment; Pain Management, Chapter 5). In addition to pain management, the patient is evaluated for skin integrity, adequate urinary output, fluid and electrolyte balance, and ileus. Discharge planning should include a timetable for follow-up with the provider and resumption of regular activities.

In most cases, the patient begins ambulation as soon as possible. Depending on the instrumentation used and the surgical approach, most patients are walking by the second or third postoperative day and discharged within 5 to 7 days. The patient may start physical therapy as soon as he or she is able, beginning with range-of-motion exercises on the first postoperative day and many of the activities of daily living in the following days. Self-care, such as washing and eating, is always encouraged. Throughout the hospitalization, age-appropriate activities and contact with family and friends are important parts of nursing care and planning (see Immobilization, earlier in this chapter). The family is encouraged to become involved in the patient's care to facilitate the transition from hospital to home management. An organization that provides education and services to both families and professionals is the National Scoliosis Foundation.*

Infections of Bones and Joints

Osteomyelitis

Osteomyelitis, an infectious process in the bone, can occur at any age but most frequently is seen in children 10 years old or younger. Boys are more commonly affected than girls, and the median age of diagnosis is 5 to 6 years old. The limbs most commonly affected include the foot, femur, tibia, and pelvis. *Staphylococcus aureus* is the most common causative organism. Neonates are also likely to have osteomyelitis caused by group B streptococci. Children with sickle cell disease may develop osteomyelitis from *Salmonella* organisms as well as *S. aureus*. *Neisseria gonorrhoeae* is a potential causative organism in sexually active adolescents. *Kingella kingae* has been reported as one of the most causative organisms in children younger than 5 years old (Kaplan, 2016a).

Acute hematogenous osteomyelitis results when a bloodborne bacterium causes an infection in the bone. Common foci include infected lesions, upper respiratory tract infections, otitis media, tonsillitis, abscessed teeth, pyelonephritis, and infected burns. **Exogenous osteomyelitis** is acquired from direct inoculation of the bone from a puncture wound, open fracture, surgical contamination, or adjacent tissue infection. **Subacute osteomyelitis** has a longer course and may be caused by less virulent microbes with a walled-off abscess or **Brodie abscess**, typically in the proximal or distal tibia. **Chronic osteomyelitis** is a progression of acute osteomyelitis and is characterized by dead bone, bone loss, and drainage and sinus tracts.

Generally, healthy bone is not likely to become infected. Factors that contribute to infection include inoculation with a large number of organisms, presence of a foreign body, bone injury, high virulence of an organism, immunosuppression, and malnutrition; certain types and locations of bone are also more vulnerable to infection.

Typically, children with acute hematogenous osteomyelitis are seen with a 2- to 7-day history of pain, warmth, tenderness, and decreased range of motion in the affected limb along with systemic symptoms of fever, irritability, and lethargy (Box 29-9). Infants may have an adjacent joint effusion as well. Symptoms often resemble those observed in other conditions involving bones, such as arthritis, leukemia, or sarcoma.

Box 29-9

Causative Microorganisms of Osteomyelitis According to Age

Newborns

Staphylococcus aureus

Group B streptococcus

Gram-negative enteric rods

Infants

S. aureus (methicillin-sensitive *S. aureus*, methicillin-resistant *S. aureus* [MRSA])

Haemophilus influenzae

Older Children

S. aureus

Pseudomonas organisms

Salmonella organisms

Neisseria gonorrhoeae

Adolescents and Adults

Pseudomonas organisms

Mycobacterium tuberculosis

From McCance KL, Huether SE: *Pathophysiology: the biological basis for disease in adults and children*, ed 6, St Louis, 2010, Mosby/Elsevier.

Pathophysiology

In acute osteomyelitis, bacteria adhere to bone, causing a suppurative infection with inflammatory cells, edema, vascular congestion, and small-vessel thrombosis; the result is bone destruction, abscess formation, and dead bone (sequestra). Infection within the bone can rupture through the cortex into the subperiosteal space, stripping loose periosteum and forming an abscess. As dead bone is resorbed, new bone is formed along the live bone and infection borders. This surrounding sheath of live bone is called an **involucrum**. Sinus tracts from perforations in the involucrum may drain pus through soft tissue to the skin.

The pathology of osteomyelitis is different in infants, children older than 1 year old, and adults. In infants, blood vessels cross the growth plate into the epiphysis and joint space, which allows infection to spread into the joint. In children, the infection is contained by the growth plate, and joint infection is less likely (unless the infection is intracapsular). In older adolescents (with a closed growth plate), the infection is poorly contained and the joint is compromised. Adult periosteum is attached to bone; consequently, rupture through the periosteum and sinus drainage is more common in adults.

Diagnostic Evaluation

Organism identification and antibiotic susceptibility testing are essential for effective therapy. Cultures of aspirated purulent drainage along with cultures of blood, joint fluid, and infected skin samples should be obtained. Bone biopsy is indicated if blood culture results and radiographic findings are not consistent with osteomyelitis. Supporting evidence for osteomyelitis includes leukocytosis and elevated erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP). Radiographic signs, except for soft-tissue swelling, are evident only after 2 to 3 weeks. A three-phase technetium bone scan can show areas of increased blood flow, such as occurs in early stages in infected bone, and is useful in locating multiple sites; however, it is not a diagnostic test. CT can detect bone destruction, and MRI provides anatomic details useful in delineating the area of involvement, especially if surgical intervention is planned. MRI is reported to be the most sensitive diagnostic radiologic tool for diagnosing osteomyelitis (Kaplan, 2016a). Sometimes the osteomyelitis may be unrecognized if it occurs as a complication of a severe toxic and debilitating disease. Neonates may not present with clinical manifestations other than limited mobility of the affected extremity; fever may or may not be present, and the neonate may not appear to be sick (Kaplan, 2016a).

Therapeutic Management

After culture specimens are obtained, empiric therapy is started with IV antibiotics covering the mostly likely organisms. For *S. aureus*, nafcillin or clindamycin is generally used. Consideration should be given to the increased rates of community-acquired methicillin-resistant *S. aureus* (MRSA) in the selection of first-line antibiotic therapy; MRSA may require vancomycin, or in some cases, clindamycin may be appropriate. When the infectious agent is identified, administration of the appropriate antibiotic is initiated and continued for at least 3 to 4 weeks, but the length of therapy is determined by the duration of the symptoms, the response to treatment, and the sensitivity of the organism; 6 weeks to 4 months may be required in some cases (Kaplan, 2016a). In selected cases, oral antibiotic therapy may follow the IV treatment. Because of the prolonged duration of high-dose antibiotic therapy, it is important to monitor for hematologic, renal, hepatic, ototoxic, and other potential side effects. To prevent antibiotic-associated diarrhea in some children, administration of a probiotic may be considered.

Surgery may be indicated if there is no response to specific antibiotic therapy, a penetrating injury, persistent soft-tissue abscess is seen, or the infection spreads to the joint. Opinions differ

regarding surgical intervention, but many advocate sequestrectomy and surgical drainage to decompress the metaphyseal space before purulent fluid erupts and spreads to the subperiosteal space, forming abscesses that strip the periosteum from bone or form draining sinuses. When these complications occur, a chronic infection usually persists, which may require antibiotic therapy for several months.

Nursing Care Management

During the acute phase of illness, movement of the affected limb will cause discomfort; therefore, the child is positioned comfortably with the affected limb supported. A temporary splint or cast may be applied. Weight bearing is avoided in the acute phase, and moving and turning are carried out carefully to minimize pain. The child may require long-term pain medication to deal with the bone pain. Postoperatively, pain medication should be considered as with any other surgical procedure.

Antibiotic therapy requires careful observation and monitoring of the IV equipment and site. A peripherally inserted central catheter (PICC) may be inserted for long-term antibiotic therapy. Antibiotic therapy is often continued at home or through an outpatient infusion clinic.

Standard precautions are implemented for all children with osteomyelitis. If there is an open wound, it is managed according to standard wound care precautions. If a PICC line or central venous catheter (CVC) is inserted, meticulous care should be taken to prevent catheter-related infection.

Provision of diversional and constructive activities becomes an important nursing intervention. Children are usually confined to bed for some time during the acute phase but may be allowed to move about on a stretcher or in a wheelchair if isolation is not necessary.

As the infection subsides, physical therapy is instituted to ensure restoration of optimum function. The child may eventually be transitioned to a regimen of oral antibiotics, and progress is followed closely for some time.

Septic Arthritis

Septic arthritis is a bacterial infection in the joint. It usually results from hematogenous spread or from direct extension of an adjacent cellulitis or osteomyelitis. Direct inoculation from trauma accounts for 15% to 20% of septic arthritis cases. The most common causative organism is *S. aureus*. Community-acquired MRSA is commonly a cause of septic arthritis. In addition to *S. aureus*, pathogens seen in neonates include group B streptococci, *Escherichia coli*, and *Candida albicans*. In children 2 months to 5 years old, *S. aureus*, *Streptococcus pyogenes*, *Streptococcus pneumoniae*, and *K. kingae* are the primary organisms causing infection. Children older than 5 years old are more likely to be infected by *S. aureus* and *S. pyogenes*, and sexually active adolescents may be infected by *N. gonorrhoeae* (Gutierrez, 2005; Kaplan, 2016b).

The knees, hips, ankles, and elbows are the most common joints affected. Clinical manifestations include severe joint pain, swelling, warmth of overlying tissue, and occasionally erythema. An infection involving the hip, however, is considered a surgical emergency to prevent compromised blood supply to the head of the femur (Kaplan, 2016b).

The child is resistant to any joint movement. Features of systemic illness such as fever, malaise, headache, nausea, vomiting, and irritability may also be present.

Therapeutic Management and Nursing Care Management

The affected joint is aspirated and the specimen evaluated by Gram stain, cultures (including separate cultures for *H. influenzae* and *N. gonorrhoeae*), and determination of leukocyte count. In addition, perform blood cultures and obtain complete blood count with differential and ESR or CRP level. Early radiographic findings are limited to soft-tissue swelling but may reveal a foreign body, and such films always provide a baseline for comparison. Technetium scans reveal areas of increased blood flow but will not differentiate between sites. MRI and CT scans provide more detailed images of cartilage loss, joint narrowing, erosions, and ankylosis of progressive disease. Ultrasonography is helpful in the detection of joint effusions and fluid in the soft tissue and subperiosteum (Kaplan, 2016b).

Treatment is IV antibiotic therapy based on Gram stain results and the clinical presentation. The benefits of serial aspirations to demonstrate sterility of synovium fluid and reduce pressure or pain

are controversial. Pain management is an important aspect of nursing care, particularly with involvement of a large joint such as the hip. Surgical intervention may also be required if there was a penetrating wound or a foreign object was possibly involved. Physical therapy may be initiated for the child who is immobilized to prevent flexion contractures. Additional nursing care is the same as for osteomyelitis.

Skeletal Tuberculosis

In children, tubercular infection of the bones and joints is acquired by lymphohematogenous spread at the time of primary infection. Occasionally, it is from chronic pulmonary TB. Skeletal tubercular infection is not common in the United States but should be considered in communities with high TB case rates. The condition is a late manifestation of TB and is most likely to involve the vertebrae, causing tubercular spondylitis. If the infection is progressive, it causes **Pott disease** with destruction of the vertebral bodies and results in kyphosis and spinal malalignment. Symptoms are insidious. The child may report persistent or intermittent pain. Other findings include joint swelling and stiffness; fever and weight loss are not common. Tubercular arthritis can also affect single joints (such as a knee or hip) and tends to cause severe destruction of adjacent bone. Infection in the fingers causes spina ventosa, a tuberculous dactylitis.

As with pulmonary TB, the index case should be located. A family and environmental history needs to be obtained and tuberculin skin tests (TSTs) performed. Results of TSTs are positive for the majority of children with tuberculous arthritis; however, the results are not diagnostic, and the clinical and laboratory features do not differentiate tubercular arthritis from a nontubercular septic arthritis. Diagnosis requires isolation of *Mycobacterium tuberculosis* from the site. Patients with the susceptible organism start treatment with combined antituberculosis chemotherapy (isoniazid, rifampin, and pyrazinamide); directly observed therapy (DOT) is preferred.

Nursing Care Management

Nursing care depends on the site and extent of infection. Tuberculous spondylitis and hip infection may require immobilization, casting, and surgical fusion. Nursing care is individualized but is generally the same as for osteomyelitis and septic arthritis.

Disorders of Joints

Juvenile Idiopathic Arthritis

Juvenile idiopathic arthritis (JIA) refers to chronic childhood arthritis. A group of heterogeneous autoimmune diseases, JIA causes inflammation in the joint synovium and surrounding tissue. The cause of JIA is unknown. JIA starts before 16 years old with a peak onset between 1 and 3 years old. Twice as many girls as boys are affected. The reported incidence of chronic childhood arthritis varies from 1 to 20 cases per 100,000 children with a prevalence of 10 to 400 per 100,000 (Cassidy and Petty, 2011). Genetic factors and environmental triggers (e.g., rubella, Epstein-Barr virus, parvovirus B19) have been associated with the onset of JIA, but the etiology remains unclear.

Pathophysiology

The disease process is characterized by chronic inflammation of the synovium with joint effusion and eventual erosion, destruction, and fibrosis of the articular cartilage. Adhesions between joint surfaces and ankylosis of joints may occur if the inflammatory process persists.

Clinical Manifestations

Whether single or multiple joints are involved, swelling and loss of motion develop in the affected joint. The swollen joint may be slightly warm and mildly tender to touch, but it is not uncommon for pain not to be reported despite a large joint effusion. Loss of motion in the joint from joint inflammation and muscle spasm may be exacerbated by inactivity. Morning stiffness of the joints(s) is characteristic of JIA and may be present on arising or inactivity. Functional change may be an obvious limp or subtle limitations in joint motion, such as fisting to avoid wrist extension with pressure. Growth disturbances (either overgrowth or undergrowth) may occur, such as bony enlargement of the adjacent femoral or tibial condyles with a knee effusion or a receding chin from temporomandibular arthritis.

Classification of Juvenile Idiopathic Arthritis

JIA is not a single disease but a heterogeneous group of diseases. The universal Durban classification of JIA, developed in 1997 and revised in 1998 and 2001, lists several disease categories, each with its own set of criteria and exclusions, which continue to be revised (Petty, Southwood, Manners, et al, 2004).

- Systemic arthritis is arthritis in one or more joints associated with at least 2 weeks of quotidian fever and daily for at least 3 days and one or more of the following: rash, lymphadenopathy, hepatosplenomegaly, and serositis. **Exclusions: a, b, c, d*
- Oligoarthritis is arthritis in one to four joints for the first 6 months of disease. It is subdivided to persistent oligoarthritis if it remains in four joints or fewer or becomes extended oligoarthritis if it involves more than four joints after 6 months. **Exclusions: a, b, c, d, e*
- Polyarthritis rheumatoid factor (RF) negative affects five or more joints in the first 6 months with a negative RF. **Exclusions: a, b, c, e*
- Polyarthritis RF positive also affects five or more joints in first 6 months, but these children have a positive RF. **Exclusions: a, b, c, e*
- Psoriatic arthritis is arthritis with psoriasis or an associated dactylitis, nail pitting, or onycholysis or psoriasis in a first-degree relative. **Exclusions: b, c, d, e*
- Enthesitis-related arthritis is arthritis or enthesitis associated with at least two of the following: sacroiliac or lumbosacral pain, HLA-B27 antigen, arthritis in a boy older than 6 years old, acute anterior uveitis, inflammatory bowel disease, Reiter syndrome, or acute anterior uveitis in a first-degree relative. **Exclusions: a, d, e*
- Undifferentiated arthritis fits no other category above or fits more than one category.

Diagnostic Evaluation

JIA is a diagnosis of exclusion; there are no definitive tests. Classifications are based on the clinical criteria of age of onset before 16 years old, arthritis in one or more joints for 6 weeks or longer, and

exclusion of other causes. Laboratory tests may provide supporting evidence of disease. The ESR/CRP may or may not be elevated. Leukocytosis is frequently present during exacerbations of systemic JIA. Antinuclear antibodies are common in JIA but are not specific for arthritis; however, they help identify children who are at greater risk for uveitis. Plain radiographs are the best initial imaging studies and may show soft-tissue swelling and joint space widening from increased synovial fluid in the joint. Later films can reveal osteoporosis, narrow joint space, erosions, subluxation, and ankylosis. A slit-lamp eye examination is necessary to diagnosis uveitis, inflammation in the anterior chamber of the eye, which is most common in antinuclear antibody-positive young girls with oligoarthritis. Routine examinations are necessary for early diagnosis and treatment to avoid or minimize sight-threatening disease (Qian and Acharya, 2010).

Therapeutic Management

There is no cure for JIA. The major goals of therapy are to control pain, preserve joint range of motion and function, minimize effects of inflammation such as joint deformity, and promote normal growth and development. Outpatient care is the mainstay of therapy; lengthy hospitalizations are infrequent in this era of managed care. The treatment plan can be exhaustive and intrusive for the child and family, including medications, physical and occupational therapy, ophthalmologic slit lamp examinations, splints, comfort measures, dietary management, school modifications, and psychosocial support.

Medications

In 2011, the American College of Rheumatology published recommendations for the treatment of JIA intended to lend guidance to the provider. The guidelines are divided into four groups: children with (1) four or fewer affected joints, (2) five or more affected joints, (3) systemic arthritis and active systemic features, and (4) systemic arthritis with active arthritis. Each path provides recommendations for a step-wise escalation of the medication and therapy (Beukelman, Patkar, Saag, et al, 2011). All tracks consider poor prognostic indicators, such as erosions on radiograph; arthritis of the hip, cervical spine, ankle or wrist; and a positive RF. Additionally, each track takes into account disease activity levels that include elevated acute phase reactants and global assessments of both the provider and the patient/parent.

Medications included in the guidelines include those described in the following sections.

Nonsteroidal antiinflammatory drugs.

NSAIDs (e.g., naproxen and ibuprofen) are used alone or in combination with other drugs depending on the amount of disease activity and poor prognostic features. NSAIDs offer an analgesic effect but may require higher dosing for an antiinflammatory effect. Patient/parent education is important and should include potential side effects of gastrointestinal, renal, hepatic, and prolonged coagulation.

Disease-modifying antirheumatic drugs.

Disease-modifying antirheumatic drugs (DMARDs) include non-biologic drugs, methotrexate and sulfasalazine. The decision to use a DMARD at initiation of therapy or later in the escalation of therapy is guided by the amount of disease activity and poor prognostic features. Effective against arthritis and uveitis, antirheumatic low-dose methotrexate has a time proven safety profile, but parents may be overwhelmed with the potential adverse effects of liver disease, infections, bone marrow suppression, gastrointestinal disturbance, teratogenic effects, and alarming but unconfirmed risk of cancer. Patient/parent education includes frank discussion about sexual activity and birth defects. Sexually active teenagers need effective birth control. As a precaution, pregnant caregivers or those trying to conceive need to avoid contact with methotrexate. Instructions about avoiding live immunizations and alcohol are essential during patient education. Sulfasalazine may be used in children with axial arthritis, a positive test result for HLA-B27, or symptoms of inflammatory bowel disease, given this drug's success in these select groups of patients.

Biologic disease-modifying antirheumatic drugs.

Biologic DMARDs are initiated when there is significant disease activity and/or poor prognostic indicators after unsuccessful treatment with methotrexate. Tumor necrosis factor-alpha (TNF- α) inhibitors are the most frequently used biologic DMARDs and include etanercept, infliximab, and

adalimumab. All three reduce the proinflammatory response that promotes arthritis. Anakinra (interleukin-1 receptor antagonist), tocilizumab (interleukin-6 receptor antagonist), and abatacept (selective T-cell costimulation blocker) are also biologics that may be selected for use in systemic JIA (tocilizumab and off-label anakinra) or in children with JIA and limited response to other biologics (tocilizumab and abatacept). Patient education focuses on the increased risk for infection, holding the scheduled dose if the child has fever or symptoms of infection, and seeking medical attention at early onset of illness. All patients starting biologic DMARDs need a negative TST prior to starting. Although biologic DMARDs have been found safe and effective, the potential for malignancy needs to be addressed and patients need routine safety monitoring (Tarkiainen, Tynjälä, Vähäsalo, et al, 2015; Ruperto and Martini, 2011).

Glucocorticoids.

Glucocorticoids are potent antiinflammatory agents; however the significant adverse effects of long-term systemic steroids are undesirable, consequently they are used in conjunction with other medications to provide prompt antiinflammatory response with acute arthritis then tapered and discontinued. High-dose IV steroids may be used with acutely active arthritis or systemic features (fevers, rash, and pericarditis). Intra-articular long-acting steroid injections are effective in treating individual joint effusions with minimal adverse effects and frequently provide sustained control. Glucocorticoid education is extensive and includes discussion of potential risks of infection, adrenal insufficiency, cushingoid features, weight gain, mood/sleep changes, hypertension, diabetes, and osteoporosis and avascular necrosis. Simultaneous dietary changes (low calorie and low salt) and, if possible, an active exercise program should be considered when steroids are initiated.

Physical and Occupational Therapy

Physical therapy programs are individualized for each child and designed to reach the ultimate goal—preserving function or preventing deformity. Physical therapy is directed toward specific joints, focusing on strengthening muscles, mobilizing restricted joint motion, and preventing or correcting deformities. Occupational therapists are responsible for evaluating and improving performance of activities of daily living.

Treatment or maintenance programs vary; a child may be seen a couple times a week, or monthly, but the mainstay of any program is the child doing their daily home exercise program, which is demonstrated and revised at each therapy session.

Exercising in a pool is excellent therapy, because it allows an almost weightless freedom of movement against gentle resistance of water. If there is pain on motion, a hot pack or warm bath before therapy may help.

Providers may recommend nighttime splinting to help minimize pain and reduce flexion deformity. Joints most frequently splinted are the knees, wrists, and hands. Loss of extension in the knee, hip, and wrist causes special problems and requires vigilance to detect the earliest signs of involvement and vigorous attention to prevent deformity with specialized passive stretching, positioning, and resting splints.

Nursing Care Management

Nursing the child with JIA involves assessment of the child's general health, the status of involved joints, and the child's emotional response to all ramifications of the disease—discomfort, physical restrictions, therapies, and self-concept.

The effects of JIA are manifest in every aspect of the child's life, including physical activities, social experiences, and personality development. Nursing interventions to support the parents may foster successful adaptation for the entire family. Parental concerns about the disease prognosis, financial and insurance issues, spouse and sibling relationships, and job and schedule conflicts must all be addressed. Referral to social workers, counselors, or support groups may be needed.

Relieve Pain

The pain of JIA is related to several aspects of the disease, including disease severity, functional status, individual pain threshold, family variables, and psychological adjustment. The aim is to provide as much relief as possible with medication and other therapies to help children tolerate the pain and cope as effectively as possible. Nonpharmacologic modalities, such as behavioral therapy and relaxation techniques, have proved effective in modifying pain perception (see Pain

Management, [Chapter 5](#)) and activities that aggravate pain. Opioid analgesics are typically avoided in juvenile arthritis; however, for children immobilized with refractory pain, short-term opioid analgesics can be part of a comprehensive plan that uses multiple pain relief techniques ([Connelly and Schanberg, 2006](#)).

Promote General Health

The child's general health must be considered. A well-balanced diet with sufficient calories to maintain growth is essential. If the child is relatively inactive, caloric intake needs to match energy needs to avoid excessive weight gain, which places additional stress on affected joints. Sleep and rest are essential for children with JIA. Some children require rest during the day; however, daytime napping that interferes with nighttime sleepiness should be avoided. A bedtime routine that involves comfort measures can help induce sleep. A firm mattress, electric blanket, or sleeping bag helps provide warmth, comfort, and rest. Nighttime splints needed to maintain range of motion might initially be a source of bedtime conflict. The family needs to be instructed on how to use the splint appropriately; the splint should not be painful or impede sleep. Behavior modification programs that reward splint and exercise compliance may be helpful in reducing adherence barriers. Well-child care to assess growth, development, and immunization requirements needs to be coordinated between the primary care provider and the rheumatologist. Common childhood illnesses, such as upper respiratory tract infections, may cause arthritis to worsen; consequently, medical attention must be sought quickly for relatively minor illness to prevent arthritis flares. Effective communication among the family, the primary care provider, and the rheumatology team is essential for care coordination.

Children are encouraged to attend school even on days when they have some pain or discomfort. The school nurse's assistance is enlisted so that a child is permitted to take the prescribed medication at school and to arrange for rest in the nurse's office during the day. Split days or half days may help a child remain involved in school. Permitting the child to come to school late allows time to gain joint movement and reduces the time at school to avoid exhaustion. It is important that the child attend school to learn skills and engage in social interaction, especially if the JIA continues to limit physical skills. Arranging for two sets of textbooks—one for home and one for school—eliminates heavy backpacks, or rolling backpacks may be used. Additionally, extra time to take tests, allowing to stand and stretch, participating in PE as tolerated or in a modified PE program, an elevator pass, and extra time changing class can all reduce barriers and maximize the students attendance and participation in school. A formal school hearing may be necessary to obtain an individualized education program (IEP), ensured by public law, which includes intensive school modifications.

Facilitate Adherence

The child and family need to be actively involved in the treatment plan to commit to it. They need to know the purpose and correct use of any splints, exercise programs, and medications prescribed. Pill boxes can help foster adherence, although parents should continue to monitor adherence of the older child who is able to safely take medications independently. Nurses can facilitate adherence by demonstrating and providing written instructions on proper techniques for pill crushing or pill swallowing skills. Teaching parents and patients how to give subcutaneous injections lays the groundwork for future adherence by identifying and addressing potential barriers. Shots are never a pleasant activity; but if available, enlist a child life specialist as a resource in providing the child skills to cope and better understand and accept unpleasant but necessary medical treatments.

Comfort Measures and Exercise

Heat has been shown to be beneficial to children with arthritis. Moist heat is best for relieving pain and stiffness, and the most efficient and practical method is in the bathtub with warm water. In some cases, a daily whirlpool bath, paraffin bath, or hot packs may be used as needed for temporary relief of acute swelling and pain. Hot packs are easily applied using a damp hand towel wrung out after being immersed in hot water or heated in a microwave oven; after testing for heat, hot packs are applied to the area, and covered with plastic to retain heat. Commercial pads that warm in only a few seconds in the microwave are also available. Painful hands or feet can be immersed in a pan of warm water or a paraffin unit.

Pool therapy is the easiest method for exercising a large number of joints. Swimming activities

strengthen muscles and maintain mobility in larger joints. Very small children who are frightened of the water can carry out their exercises in the bathtub. Small children love to splash, kick, and throw things in the water. Remember, adult supervision is necessary for all water activities.

Activities of daily living provide satisfactory exercise for older children to maintain maximal mobility with minimal pain. These children are encouraged in their efforts to be independent and patiently allowed to dress and groom themselves, to assume daily tasks, and to care for their belongings. It is often difficult for children to manipulate buttons, comb or brush their hair, and turn faucets, but unless there is an acute flare with significant loss of motion and pain, parents and other caregivers should not offer assistance but extra time and encouragement to proceed independently. In turn, children should learn and understand why others do not help them. Many helpful devices, such as self-adhering fasteners, tongs for manipulating difficult items, and grab bars installed in bathrooms for safety, can be used to facilitate tasks. A raised (higher) toilet seat often makes the difference between dependent and independent toileting because weak quadriceps muscles and sore knees inhibit the ability to raise the body from a low sitting position.

A child's natural affinity for play offers many opportunities for incorporating therapeutic exercises. Throwing or kicking a ball and riding a tricycle (with the seat raised to achieve maximum leg extension) are excellent moving and stretching exercises for a young child whose daily living activities are physically limited.

An effective approach to beginning the day's activities is to awaken children early to give them their medication and then to allow them to sleep for an hour. On arising, children take a hot bath (or shower) and perform a simple ritual of limbering-up exercises, after which they commence the activities of the day, such as going to school. Exercise, heat, and rest are spaced throughout the remainder of the day according to the child's individual needs and schedules. Parents are instructed in exercises that meet the child's needs.

The Arthritis Foundation and the American Juvenile Arthritis Alliance (an organization within the Arthritis Foundation) provide information and services for both parents and professionals, and nurses can refer families to these agencies as an added resource.

Support Child and Family

JIA affects every aspect of life for the child and family. Physical limitations may interfere with self-care, school participation, and recreational activities. The intensive treatment plan, including multiple medications, physical therapy, comfort measures, and medical appointments, is intrusive and disruptive to the parents' work schedule and the family routine. To prevent isolation and foster independence, the family is encouraged to pursue their normal activities. Unfortunately, the adaptations necessary to make that occur take resourcefulness and commitment from all family members. At diagnosis and throughout the span of JIA, it is essential to recognize signs of stress and counterproductive coping and provide the necessary support to maximize adaptation. The problems and needs of these families are discussed in [Chapter 17](#) and readers are directed to that chapter for guidance in planning care.

Systemic Lupus Erythematosus

Systemic lupus erythematosus (SLE) is a severe chronic autoimmune disease that results in inflammation and multi-organ system damage. Other forms of lupus include discoid lupus, which is limited to the skin, and neonatal lupus, which occurs when maternal autoantibodies cause a transient lupus-like syndrome in a newborn with the potential serious complication of heart block. The remaining discussion focuses on SLE.

The [Lupus Foundation of America \(2015\)](#) and [National Kidney Foundation \(2015\)](#) estimates that 1.5 million individuals have lupus, and 10% to 15% of these adults were diagnosed with SLE as children or adolescents. SLE in children tends to be more severe at onset and has more aggressive clinical course than adult-onset type ([Mina and Brunner, 2013](#)).

SLE is more common in girls, with an approximate 4 : 3 female-to-male predominance before 10 years old and 4 : 1 in the second decade, indicating a potential hormonal trigger with maturation. There is a familial tendency, although many newly diagnosed patients are unaware of other affected family members. SLE has been reported in all cultures, but within the United States, there has been a disproportionately higher incidence in African-American, Asian, and Hispanic children.

The cause of SLE is not known. It appears to result from a complex interaction of genetics with an

unidentified trigger that activates the disease. Suspected triggers include exposure to ultraviolet (UV) light, estrogen, pregnancy, infections, and drugs. Genetic predisposition to SLE is evidenced in an increased concordance rate in twins (tenfold), increased incidence within family members (10% to 16%), and increased frequency of certain gene alleles in population-based studies.

Clinical Manifestations and Diagnostic Evaluation

The child with SLE may have any clinical manifestation with mild to life-threatening severity (Box 29-10). The diagnosis is established when four of the 11 diagnostic criteria are met (Box 29-11). Kidney involvement heralds progressive disease and the need for rigorous therapeutic management.

Box 29-10

Manifestations of Systemic Lupus Erythematosus

Constitutional: Fever, fatigue, weight loss, anorexia

Cutaneous: Erythematosus butterfly rash over bridge of nose and across cheeks, discoid rash, photosensitivity, mucocutaneous ulceration, alopecia, periungual telangiectasias

Musculoskeletal: Arthritis, arthralgia, myositis, myalgia, tenosynovitis

Neurologic: Headache, seizure, forgetfulness, behavior change, change in school performance, psychosis, chorea, stroke, cranial and peripheral neuropathy, pseudotumor cerebri

Pulmonary and cardiac: Pleuritis, basilar pneumonitis, atelectasis, pericarditis, myocarditis, and endocarditis

Renal: Glomerulonephritis, nephrotic syndrome, hypertension

Gastrointestinal: Abdominal pain, nausea, vomiting, blood in stool, abdominal crisis, esophageal dysfunction, colitis

Hepatic, splenic, and nodal: Hepatomegaly, splenomegaly, lymphadenopathy

Hematologic: Anemia, cytopenia

Ophthalmologic: Cotton wool spots, papilledema, retinopathy

Vascular: Raynaud phenomenon, thrombophlebitis, livedo reticularis

Box 29-11

Classification Criteria for Systemic Lupus Erythematosus*

Malar rash: Fixed malar erythema

Discoid rash: Patchy erythematous lesions

Photosensitivity: Rash with sunlight exposure

Oronasal ulcers: Painless ulcers in mouth and nose

Arthritis: Swelling, tenderness, or effusion in two or more peripheral joints (nonerosive)

Serositis: Pleuritis, pericarditis

Renal disorder: Proteinuria, casts in urine

Neurologic disorder: Psychosis, seizures

Hematologic disorder: Hemolytic anemia, thrombocytopenia, leukopenia, lymphopenia

Immunologic disorder: Anti-double-stranded deoxyribonucleic acid, anti-Sm, antiphospholipid antibodies; lupus anticoagulant; false-positive result on syphilis test (rapid plasma reagin)

Antinuclear antibodies: Presence of antinuclear antibody by immunofluorescence or an equivalent assay

*The presence of four criteria is required for classification as systemic lupus erythematosus (SLE).

Therapeutic Management

The goal of treatment is to ensure the child's health by balancing the medications necessary to avoid exacerbation and complications while preventing or minimizing treatment-associated morbidity. Therapy involves the use of specific medications and general supportive care. The drugs used to control inflammation are corticosteroids administered in doses sufficient to control inflammation and then tapered to the lowest suppressive dose or given intravenously during acute flares. Hydroxychloroquine, an antimalarial, is a useful medication for inflammatory control, rash, and arthritis; NSAIDs, which relieve muscle and joint inflammation; and immunosuppressive agents, such as cyclophosphamide, for renal and CNS disease. Mycophenolate, azathioprine, and methotrexate are effective immunosuppressive drugs that may be used to control SLE and allow steroids to be reduced. Rituximab is a monoclonal antibody that results in decreased antibody formation and has been used off-label in pediatric lupus patients who have not responded to standard therapy (Nwobi, Abitbol, Chandar, et al, 2008). Antihypertensives, low-dose aspirin (as a blood thinner), and calcium and vitamin D supplements are just a few of the additional remedies that may be necessary to treat or avoid complications.

General supportive care includes sufficient nutrition, sleep and rest, and exercise. Exposure to the sun and ultraviolet B (UVB) light is limited because of its association with SLE exacerbation.

Nursing Care Management

The principal nursing goal is to help the child and family positively adjust to the disease and therapy. The child and family must learn to recognize subtle signs of disease exacerbation and potential complications of medication therapy and to communicate these concerns to their care provider. Consequently, patient and family education is an ongoing process initiated at diagnosis and tailored to the patient's individual needs. Referral to a social worker, psychologist, or support group may help the child and family make a successful adjustment. Support groups are associated with the Lupus Foundation of America and the Arthritis Foundation.

Key issues include therapy compliance; body-image problems associated with rash, hair loss, and steroid therapy; school attendance; vocational activities; social relationships; sexual activity; and pregnancy. (See [Chapter 17](#) for a discussion on adjusting to a chronic illness.) Specific instructions for avoiding exposure to the sun and UVB light, such as using sunscreens, wearing sun-resistant clothing, and altering outdoor activities, must be provided with great sensitivity to ensure compliance while minimizing the associated feeling of being different from peers. Patients need to be instructed to maintain regular medical supervision and seek attention quickly during illness or before elective surgical procedures, such as dental extraction, because of potential needs for increased steroids or prophylactic antibiotics. People with SLE should carry medical identification for their disease and steroid dependence.

NCLEX Review Questions

1. The potential physiologic and psychological effects of prolonged immobilization on a 9-year-old child who has experienced significant trauma in a motor vehicle crash include which of the following? Select all that apply.
 - a. Orthostatic intolerance
 - b. Deep vein thrombosis (DVT)
 - c. Pressure ulcer formation
 - d. Pneumonia
 - e. Diarrhea
 - f. Kidney stones
 - g. Sense of euphoria and elation
 - h. Constipation
2. A 12-year-old who was in an all-terrain vehicle (ATV) accident has a long-leg fiberglass cast on his left leg for a tibia-fibula fracture. He requests pain medication at 2:00 AM for pain he rates at a 10/10 on the Numeric Scale. The nurse brings the pain medication and notes that he has removed the pillows that kept his leg elevated. He complains of pain in the left foot, and she notes that there is 3+ edema in the exposed leg and foot, and she is unable to slip a finger under the cast. The nurse's priority interventions in this situation should include:
 - a. Administer the pain medication and elevate the child's leg on the pillows.
 - b. Elevate the leg on the pillows and follow up within 2 to 3 hours to see if the edema has decreased.
 - c. Let the child know that he cannot have any additional pain medication until 6:00 AM.
 - d. Notify the surgeon of the findings immediately.
3. Disordered eating patterns, which may be observed in the female athlete triad, may include which of the following? Select all that apply.
 - a. Use of diet pills and laxatives
 - b. Fasting
 - c. Binge eating
 - d. Restriction of certain foods
 - e. Inadequate caloric intake
 - f. Excessive vitamin consumption
4. Following the sudden death of a 14-year-old seemingly healthy basketball player, his parents ask the school administration to install an automatic external defibrillator (AED) in a central area of the athletic center. The school nurse is asked to participate in a meeting with the parents in which the administrators insist such a device is not necessary. The school nurse advocates by providing which information about AEDs and children?
 - a. An AED should be used only by health care persons trained in its use.
 - b. An AED provides too much of an energy shock dose for children younger than 12 years old.
 - c. An AED can be effective in the resuscitation of a child or adolescent with a shockable rhythm.
 - d. An AED is more commonly used in adults who have heart attacks than in children with undiagnosed heart conditions.
5. A 2-day-old infant in the newborn nursery is diagnosed with developmental dysplasia of the hip (DDH), and treatment is started by the orthopedist. The nurse assists the parents by providing home care instructions that include:
 - a. Return to the orthopedist's office in 2 weeks to remove the hip spica cast.
 - b. The infant's bilateral foot casts should be elevated on pillows as much as possible.
 - c. Remove the Pavlik harness once a day for no more than 2 hours and inspect skin.
 - d. Remove the Pavlik harness while the infant is awake to allow "tummy time."

Correct Answers

1. a, b, c, d, f, h; 2. d; 3. a, b, d, e; 4. c; 5. c

^{††}Exclusion: (a) Psoriasis/history of psoriasis in the patient or first-degree relative; (b) arthritis in an HLA-B27-positive male beginning after the sixth birthday; (c) ankylosing spondylitis, enthesitis-related arthritis, sacroiliitis with inflammatory bowel disease, Reiter syndrome, or symptomatic anterior uveitis, or a history of one of these disorders in a first-degree relative; (d) the presence of immunoglobulin M rheumatoid factor (RF) on at least two occasions at least 3 months apart; (e) the presence of systemic JIA in the patient.

The Child with Neuromuscular or Muscular Dysfunction

Anne Feierabend Stanton, Teri Lavenbarg

Congenital Neuromuscular or Muscular Disorders

Cerebral Palsy

A new definition proposed in 2006 describes cerebral palsy (CP) as a “group of permanent disorders of the development of movement and posture, causing activity limitation, that are attributed to nonprogressive disturbances that occurred in the developing fetal or infant brain” (Rosenbaum, Paneth, Leviton, et al, 2007). In addition to motor disorders, the condition often involves disturbances of sensation, perception, communication, cognition, and behavior; secondary musculoskeletal problems; and epilepsy (Rosenbaum, Paneth, Leviton, et al, 2007). The etiology, clinical features, and course vary and are characterized by abnormal muscle tone and coordination as the primary disturbances. CP is the most common permanent physical disability of childhood, and the incidence is reported to be between 2.4 to 3.6 per every 1000 live births in the United States (Hirtz, Thurman, Gwinn-Hardy, et al, 2007; Yeargin-Allsopp, Van Naarden Braun, Doernberg, et al, 2008).

One systematic review and meta-analysis indicated a prevalence of 2.11 per 1000 live births, with the highest prevalence among infants born weighing 1000 grams to 1499 grams at birth; the prevalence of CP was higher among infants born prior to completion of 28 weeks' gestation (Oskoui, Coutinho, Dykeman, et al, 2013). Since the 1960s, the prevalence of CP has risen approximately 20%, which most likely reflects the improved survival of extremely low birth weight (ELBW) and very low birth weight (VLBW) infants.

However, in the past two decades, there has been a decrease in the incidence of CP among ELBW and VLBW infants (Hack and Costello, 2008). The incidence is higher in males than females and more likely to occur in African Americans than in Caucasian or Hispanic children (Centers for Disease Control and Prevention, 2013).

Although the prevalent traditional hypothesis has been that CP results from perinatal problems, especially birth asphyxia, it is now believed that CP results more often from existing prenatal brain abnormalities; the exact cause of these abnormalities remains elusive but may include genetic factors, including clotting disorders as well as brain malformations. It has been estimated that as many as 70% to 80% of the cases of CP are caused by unknown prenatal factors (Johnston, 2016; Krigger, 2006). Intrauterine exposure to maternal chorioamnionitis is associated with an increased risk of CP in infants of normal birth weight and preterm infants (Hermansen and Hermansen, 2006; Shatrov, Birch, Lam, et al, 2010); however, not all term infants exposed to chorioamnionitis develop CP.

In general, infants exposed to maternal and perinatal infections are at increased risk for the development of CP as a result of the effects on the developing brain. Although CP occurs in term births, preterm birth of ELBW and VLBW infants continues to be the single most important risk factor for CP. Still, in some cases no identifiable cause is determined. Periventricular leukomalacia and intracerebral hemorrhage in low birth weight (LBW) infants are significant risk factors in the development of CP. Perinatal ischemic stroke is also associated with a later diagnosis of CP (Golomb, Saha, Garg, et al, 2007).

Additional factors that may contribute to the development of CP postnatally include bacterial meningitis, multiple births, viral encephalitis, motor vehicle crashes, and child abuse (shaken baby syndrome [traumatic brain injury]) (Krigger, 2006). One study found a higher risk of CP occurring among infants born at 42 weeks' gestation or later than among those born at 37 or 38 weeks' gestation (Moster, Wilcox, Vollset, et al, 2010). One study found that 10% to 15% of children with CP acquired the condition after birth from causes such as falls, motor vehicle crashes, and infections, such as meningitis (Centers for Disease Control and Prevention, 2013). A significant percentage (15% to 60%) of children with CP also have epilepsy. In summary, as many as 80% of the total cases of CP may be linked to a perinatal or neonatal brain lesion or brain maldevelopment, regardless of the cause (Krageloh-Mann and Cans, 2009). A number of biochemical disorders may cause motor abnormalities often seen in CP and may be initially misdiagnosed as CP (Nehring, 2010).

Pathophysiology

It is difficult to establish a precise location of neurologic lesions on the basis of etiology or clinical

signs, because there is no characteristic pathologic picture. In some cases, there are gross malformations of the brain. In others, there may be evidence of vascular occlusion, atrophy, loss of neurons, and laminar degeneration that produce narrower gyri, wider sulci, and low brain weight. Anoxia appears to play the most significant role in the pathologic state of brain damage, which is often secondary to other causative mechanisms.

There are a few exceptions. In some cases, the manifestation or etiology is related to anatomic areas. For example, CP associated with preterm birth is usually spastic diplegia caused by hypoxic infarction or hemorrhage with periventricular leukomalacia in the area adjacent to the lateral ventricles. The athetoid (extrapyramidal) type of CP is most likely to be associated with birth asphyxia but can also be caused by kernicterus and metabolic genetic disorders, such as mitochondrial disorders and glutaric aciduria (Johnston, 2016). Hemiplegic (hemiparetic) CP is often associated with a focal cerebral infarction (stroke) secondary to an intrauterine or perinatal thromboembolism, usually a result of maternal thrombosis or hereditary clotting disorder (Johnston, 2016). Cerebral hypoplasia and sometimes severe neonatal hypoglycemia are related to ataxic CP. Generalized cortical and cerebral atrophy often cause severe quadriplegia with cognitive impairment and microcephaly.

Clinical Classification

A revision of the Winter classification was proposed in 2005 to reflect the child's actual clinical problems and their severity, an assessment of the child's physical and quality-of-life status across time, and long-term support needs (Bax, Goldstein, Rosenbaum, et al, 2005; Nehring, 2010). The proposed new definition has four major dimensions of classification (Bax, Goldstein, Rosenbaum, et al, 2005):

Motor abnormalities: Nature and typology of the motor disorder; functional motor abilities

Associated impairments: Seizures; hearing or vision impairment; attentional, behavioral, communicative, or cognitive deficits; oral motor and speech function

Anatomic and radiologic findings: Anatomic distribution or parts of the body affected by motor impairments or limitations; radiologic findings sometimes including white matter lesions or brain anomaly noted on computed tomography (CT) or magnetic resonance imaging (MRI)

Causation and timing: Identification of a clearly identified cause such as a postnatal event (e.g., meningitis, traumatic brain injury).

CP has four primary types of movement disorders: spastic, dyskinetic, ataxic, and mixed (Nehring, 2010). The most common clinical type, spastic CP (77.4% reported by the Centers for Disease Control and Prevention [2013]), represents an upper motor neuron muscular weakness (Box 30-1). The reflex arc is intact, and the characteristic physical signs are increased stretch reflexes, increased muscle tone, and (often) weakness. Early neurologic manifestations are usually generalized hypotonia or decreased tone that lasts for a few weeks or may extend for months or even as long as a year.

Box 30-1

Clinical Classification of Cerebral Palsy

Spastic (Pyramidal)

Characterized by persistent primitive reflexes, positive Babinski reflex, ankle clonus, exaggerated stretch reflexes, eventual development of contractures

- 70% to 80% of all cases of cerebral palsy (CP)
- Diplegia: All extremities affected; lower more than upper (30% to 40% of spastic CP)

- Tetraplegia: All four extremities involved—legs and trunk, mouth, pharynx, and tongue (10% to 15% of spastic CP)
- Triplegia: Three limbs involved
- Monoplegia: Only one limb involved
- Hemiplegia: Motor dysfunction on one side of the body; upper extremity more affected than lower (20% to 30% of spastic CP)

Other features:

- Hypertonicity with poor control of posture, balance, and coordinated motion
- Impairment of fine and gross motor skills

Dyskinetic (Nonspastic, Extrapyramidal)

Athetoid: Chorea (involuntary, irregular, jerking movements); characterized by slow, wormlike, writhing movements that usually involve the extremities, trunk, neck, facial muscles, and tongue

Dystonic: Slow, twisting movements of the trunk or extremities; abnormal posture

Involvement of the pharyngeal, laryngeal, and oral muscles causing drooling and dysarthria (imperfect speech articulation)

Ataxic (Nonspastic, Extrapyramidal)

Wide-based gait

Rapid, repetitive movements performed poorly

Disintegration of movements of the upper extremities when the child reaches for objects

Mixed Type

Combination of spastic CP and dyskinetic CP

May be labeled *mixed* when no specific motor pattern is dominant; however, this term is losing favor to more precise descriptions of motor function and affected area of brain involved (Rosenbaum, Paneth, Leviton, et al, 2007)

Data from Nehring W: Cerebral palsy. In Allen PJ, Vessey JA, Schapiro NA, editors: *Primary care of the child with a chronic condition*, ed 5, St Louis, 2010, Mosby/Elsevier; Jones MW, Morgan E, Shelton JE, et al: Cerebral palsy: introduction and diagnosis, part 1, *J Pediatr Health Care* 21(3):146–152, 2007; and National Institute of Neurologic Disorders and Stroke: *Cerebral palsy: hope through research*, 2015, http://www.ninds.nih.gov/disorders/cerebral_palsy/detail_cerebral_palsy.htm.

Diagnostic Evaluation

Infants at risk according to known etiologic factors associated with CP warrant careful assessment during early infancy to identify the signs of neuromotor dysfunction as early as possible. The neurologic examination and history are the primary modalities for diagnosis. Neuroimaging of the child with suspected brain abnormality and CP is now recommended for diagnostic assessment, with MRI being a strong predictor of CP when performed at term (corrected age); general

movements assessment (GMA) also had a strong predictive value in children older than 2 years old and younger than 5 years old (Bosanquet, Copeland, Ware, et al, 2013). Metabolic and genetic testing is recommended if no structural abnormality is identified by neuroimaging; routine laboratory tests are no longer recommended in the diagnostic process for CP.

Early recognition is made more difficult by the lack of reliable neonatal neurologic signs. However, nurses should monitor infants with known etiologic risk factors and evaluate them closely in the first 2 years of life. Because cortical control of movement does not occur until later in infancy, motor impairment associated with voluntary control is usually not apparent until after 2 to 4 months of age at the earliest. More often the diagnosis cannot be confirmed until 2 years old, because motor tone abnormalities may be indicative of another neuromuscular condition. In addition, some children who show signs consistent with CP before 2 years old do not demonstrate such signs after 2 years old (Nehring, 2010). However, there is no consensus regarding an age cut-off for the onset of symptoms. Clinical manifestations of CP at the time of diagnosis are listed in Box 30-2; early warning signs are listed in Box 30-3, but these are not considered diagnostic.

Box 30-2

Clinical Manifestations of Cerebral Palsy (at Time of Diagnosis)

Delayed Gross Motor Development

- A universal manifestation
- Delay in all motor accomplishments
- Increases as growth advances
- Delays more obvious as growth advances

Abnormal Motor Performance

- Very early preferential unilateral hand preference
- Abnormal and asymmetric crawl
- Standing or walking on toes
- Uncoordinated or involuntary movements
- Poor sucking
- Feeding difficulties
- Persistent tongue thrust

Alterations of Muscle Tone

- Increased or decreased resistance to passive movements
- Opisthotonic posturing (arching of back)
- Feels stiff on handling or dressing
- Difficulty in diapering
- Rigid and unbending at the hip and knee joints when pulled to sitting position (early sign)

Abnormal Postures

- Maintains hips higher than trunk in prone position with legs and arms flexed or drawn under the body
- Scissoring and extension of legs with feet plantar flexed in supine position
- Persistent infantile resting and sleeping position
- Arms abducted at shoulders
- Elbows flexed
- Hands fisted

Reflex Abnormalities

- Persistence of primitive infantile reflexes
- Obligatory tonic neck reflex at any age
- Nonpersistence beyond 6 months old
- Persistence or hyperactivity of the Moro, plantar, and palmar grasp reflexes
- Hyperreflexia, ankle clonus, and stretch reflexes elicited in many muscle groups on fast, passive movements

Associated Disabilities*

- Altered learning and reasoning
- Seizures
- Impaired behavioral and interpersonal relationships
- Sensory impairment (vision, hearing)

*May or may not be present.

From Nehring WM: Cerebral palsy. In Allen PJ, Vessey JA, Schapiro NA, editors, *Primary care of the child with a chronic condition*, ed 5, St Louis, 2010, Mosby/Elsevier. Adapted from Jones MW, Morgan E, Shelton JE: Primary care of the child with cerebral palsy: a review of systems (part II), *J Pediatr Health Care* 21:226–237, 2007.

Box 30-3

Early Signs of Cerebral Palsy

- Failure to meet any developmental milestones, such as rolling over, raising head, sitting up, crawling
- Persistent primitive reflexes, such as Moro, atonic neck
- Poor head control (head lag) and clenched fists after 3 months old
- Stiff or rigid arms or legs; scissoring legs
- Pushing away or arching back; stiff posture
- Floppy or limp body posture, especially while sleeping
- Inability to sit up without support by 8 months old

- Using only one side of the body or only the arms to crawl
- Feeding difficulties
- Persistent gagging or choking when fed
- After 6 months old, tongue pushing soft food out of the mouth
- Extreme irritability or crying
- Failure to smile by 3 months old
- Lack of interest in surroundings

Data from Pathways Awareness Foundation: *Parents if you see any of these warning signs don't delay*, Chicago, 1991, Author; Nehring W: Cerebral palsy. In Allen PJ, Vessey JA, editors: *Primary care of the child with a chronic condition*, St Louis, 2004, Mosby/Elsevier; and Jones MW, Morgan E, Shelton JE, et al: Cerebral palsy: introduction and diagnosis, part 1, *J Pediatr Health Care* 21(3):146-152, 2007.

Establishing a diagnosis may be facilitated by the persistence of primitive reflexes: (1) either the asymmetric tonic neck reflex or the persistent Moro reflex (beyond 4 months old) and (2) the crossed extensor reflex. The tonic neck reflex normally disappears between 4 and 6 months old. An obligatory response is considered abnormal. This is elicited by turning the infant's head to one side and holding it there for 20 seconds. When a crying infant is unable to move from the asymmetric posturing of the tonic neck reflex, it is considered obligatory and an abnormal response. The crossed extensor reflex, which normally disappears by 4 months old, is elicited by applying a noxious stimulus to the sole of one foot with the knee extended. Normally, the contralateral foot responds with extensor, abduction, and then adduction movements. The possibility of CP is suggested if these reflexes persist after 4 months old.

A number of assessment instruments are now available to evaluate muscle spasticity; functional independence in self-care, mobility, and cognition; self-initiated movements over time; and capability and performance of functional activities in self-care, mobility, and social function (Kriger, 2006).

Therapeutic Management

The goals of therapy for children with CP are early recognition and promotion of optimal development to enable affected children to attain normalization and realize their potential within the limits of the existing health problems. The disorder is permanent, and therapy is primarily preventive and symptomatic.

Therapy has five broad goals:

1. To establish locomotion, communication, and self-help skills
2. To gain optimal appearance and integration of motor functions
3. To correct associated defects as early and effectively as possible
4. To provide educational opportunities adapted to the child's needs and capabilities
5. To promote socialization experiences with other affected and unaffected children

Each child is evaluated and managed on an individual basis. The plan of therapy may involve a variety of settings, facilities, and specially trained persons. The scope of the child's needs requires multidisciplinary planning and care coordination among professionals and the child's family. The outcome for the child and family with CP is normalization and promotion of self-care activities that empower the child and family to achieve maximum potential.

Ankle-foot orthoses (AFOs, braces) are worn by many of these children and are used to help prevent or reduce deformity, increase the energy efficiency of gait, and control alignment. Wheeled scooter boards allow children to propel themselves while on the abdomen, or total body is supported while the legs are positioned with wedges to prevent scissoring. Wheeled go-carts

provide sitting balance which may serve as early “wheelchair” experience for young children. Manual or powered wheelchairs allow for more independent mobility (Figs. 30-1 and 30-2). Strollers can be equipped with custom seats for dependent mobilization. A number of wheelchairs can be customized to meet the needs and preferences of older children.

FIG 30-1 Mobilization device for a child.

FIG 30-2 Bike walker used to provide mobility and to enhance leg muscle strength. (Courtesy of Texas Children's Hospital, Houston, TX.)

Orthopedic surgery may be required to correct contracture or spastic deformities, to provide stability for an unstable joint, and to provide balanced muscle power. This includes tendon-lengthening procedures, release of spastic muscles, and correction of hip and adductor muscle spasticity or contracture to improve locomotion. Hip dislocation often occurs in children with CP, so hip surveillance may be a routine care for a child with CP. Spinal fusion may be required for scoliosis. Computerized motion analysis, radiographs, and clinical findings are used to make decisions about orthopedic surgery. Selective dorsal rhizotomy may provide marked improvement in some children with CP (Nordmark, Josenby, Lagergren, et al, 2008). The procedure involves selectively cutting dorsal column sensory rootlets that have an abnormal response to electrical stimulation. Achieving the benefits from the surgery requires intensive physical therapy and family commitment. Because the procedure results in flaccid muscles, the child must be retaught to sit,

stand, and walk.

Surgical intervention is usually reserved for children who do not respond to more conservative measures, but it is also indicated for children whose spasticity causes progressive deformities. Orthopedic surgery is generally not performed until after the child is 6 years old (Nehring, 2010). Surgery is primarily used to improve function rather than for cosmetic purposes and is followed by physical therapy. Surgery may also be performed to improve caloric intake, correct gastroesophageal reflux disease, prevent aspiration, and correct associated dental problems (Nehring, 2010).

Intense pain may occur with muscle spasms in patients with CP. Pharmacologic agents given orally (dantrolene sodium, baclofen [Lioresal], and diazepam [Valium]) have had limited effectiveness in improving muscle coordination in children with CP; however, they are effective in decreasing overall spasticity. The most common side effects of these agents include hepatotoxicity (dantrolene), drowsiness, fatigue, and muscle weakness; less commonly, central nervous system (CNS) depression, hypotension, diaphoresis, and constipation may be seen with baclofen. Diazepam is used frequently but should be restricted to older children and adolescents.

Botulinum toxin A (Botox) is also used to reduce spasticity in targeted muscles. Botulinum toxin A is injected into a selected muscle (commonly the quadriceps, gastrocnemius, or medial hamstrings) after a topical anesthetic is applied. The drug inhibits the release of acetylcholine into a specific muscle group, thereby reducing spasticity. When administered early in the course of the condition, affected muscle contractures may be minimized, particularly in the lower extremities, thus avoiding surgical procedures with possible adverse effects. The goal is to allow stretching of the muscle as it relaxes and permit ambulation with an AFO. The major reported adverse effects of botulinum toxin A injection are pain at the injection site and temporary weakness (Lukban, Rosales, and Dressler, 2009). Prime candidates for botulinum toxin A injections are children with spasticity confined to the lower extremities; the drug reduces spasticity so that the muscles can be stretched and the child may walk with or without orthoses. The onset of action occurs within 24 to 72 hours, with a peak effect observed at 2 weeks and duration of action of 3 to 6 months.

Children with CP may also experience pain as a result of surgical procedures intended to reduce contracture deformities, body position, gastroesophageal reflux, and physical therapy (McKernan, Kieckhefer, Engel, et al, 2004). Therefore, pain management is an important aspect of the care of children with CP. Decreasing spasticity with botulinum toxin A may also result in less pain from spasms (Lundy, Lumsden, and Fairhurst, 2009).

The neurosurgical and pharmacologic approach to managing the spasticity associated with CP involves the implantation of a pump to infuse baclofen directly into the intrathecal space surrounding the spinal cord to provide relief of spasticity. Intrathecal baclofen therapy is best suited for children with severe spasticity that interferes with activities of daily living (ADLs) and ambulation. High doses of oral baclofen are associated with significant side effects, including drowsiness and confusion, yet are often unable to provide adequate relief of spasticity. Direct infusion of baclofen into the intrathecal space provides relief without as many side effects (Motta, Antonello, and Stignani, 2011). Intrathecal baclofen is especially helpful in improving comfort (Morton, Gray, and Vloeberghs, 2011). Oral tizanidine given in conjunction with botulinum type A has been reported to be more effective than oral baclofen and botulinum type A in one study of children with CP (Dai, Wasay, and Awan, 2008).

Patients may be screened before pump placement by the infusion of a "test dose" of intrathecal baclofen delivered via a lumbar puncture. Close monitoring for side effects (hypotonia, somnolence, seizures, nausea, vomiting, headache) is necessary. Relief of spasticity occurs for several hours after the infusion. If a favorable response is noted, the patient is considered a candidate for pump placement. The implantation procedure is done in the operating room by a neurosurgeon. The pump, which is approximately the size of a hockey puck, is placed in the subcutaneous space of the midabdomen. An intrathecal catheter is tunneled from the lumbar area to the abdomen and connected to the pump. The pump is filled with baclofen and programmed to provide a set dose using a telemetry wand and a computer. Benefits of intrathecal baclofen include fewer systemic side effects than oral baclofen, dosage titration for maximizing effects, and reversibility of therapy with removal of the pump if so desired. The patient may remain hospitalized for 3 to 7 days to adjust the dosage and ensure proper healing. Outpatient visits to refill the pump and make dosage adjustments are scheduled about every 3 to 6 months depending on the patient's response to the treatment. This procedure is most suited for a multidisciplinary setting where rehabilitation specialists are readily available and consistently involved in the patient's ongoing care. Abrupt

withdrawal of intrathecal baclofen may result in adverse effects, such as rebound spasticity, pruritus, hyperthermia, rhabdomyolysis, disseminated intravascular coagulation, multiorgan failure, and death; in some cases, intrathecal baclofen withdrawal may mimic sepsis. Treatment of withdrawal centers on reestablishing the medication dosage, with improvements observed within 1 to 2 hours. Hospitalization and surgery may be required for withdrawal as a result of pump or catheter failure.

Antiepileptic drugs (AEDs) such as carbamazepine (Tegretol); divalproex (valproate sodium and valproic acid; Depakote), lacosamide (Vimpat), levetiracetam (Keppra), oxcarbazepine (Trileptal), and lamotrigine (Lamictal) are prescribed routinely for children who have seizures. Other medications include levodopa to treat dystonia; trihexyphenidyl (Artane) for treating dystonia, and for increasing the use of upper extremities and vocalizations; and reserpine for hyperkinetic movement disorders, such as chorea or athetosis (Johnston, 2016). Gabapentin (Neurontin) has been used for decreasing spasticity pain in children with CP successfully (National Institute of Neurologic Disorders and Stroke, 2015). All medications should be weighed for risk/benefit ratio; monitored for maintenance of therapeutic levels and avoidance of subtherapeutic or toxic levels.

Dental hygiene is essential in the care of children with CP. Regular visits to the dentist and prophylaxis, including brushing, fluoride, and flossing, should be started as soon as the teeth erupt. Dental care is especially important for children given phenytoin because they often develop gum hyperplasia. Decreased oral intake can lead to more tartar buildup. Additional problems common among children with CP include constipation caused by neurologic deficits and lack of exercise, poor bladder control and urinary retention, osteopenia (related to decrease bone density from immobility), chronic respiratory tract infections, problems with airway clearance, and aspiration pneumonia; which may be a consequence of gastroesophageal reflux, abnormal muscle tone, immobility, and altered positioning. Skin problems may result from pressure areas, malalignment; poor bracing, nutrition, and immobility. Latex allergy has also been reported in children with CP (Nehring, 2010).

A wide variety of technical aids are available to improve the function of children with CP. Airway clearance devices help mobilize secretions (e.g., therapy vest which essentially performs what was done formerly by clap pulmonary therapy, or physiotherapy). Eye/hand coordination can be enhanced by computerized toys and games. Toys may be operated by a head or hand switch. Microcomputers combined with voice synthesizers aid children with speech difficulties to “speak.” Smart phones with speech applications are appropriate for some children.

Many other electronic devices allow independent functioning. Sensors can be activated and deactivated by using a head stick or tongue or other voluntary muscle movement over which the child has control. Voice-activated computer technology may also allow increased mobility and ambulation with specially designed devices, such as wheelchairs. The application of this technology makes it possible for persons with CP to function in their own residences and can be extended into the workplace.

There is some evidence that **neuromuscular electrical stimulation (NMES)** in addition to dynamic splinting may result in increased muscle strength, range of motion, and function of upper limbs in children with CP. Further studies are needed in children with CP to support the use of botulinum toxin A in conjunction with NMES to decrease muscle spasticity and improve function (Wright, Durham, Ewins, et al, 2012).

Behavior problems are common and often interfere with the child's development. Attention-deficit/hyperactivity disorder and other learning problems require professional attention. In addition, children with CP may have vision difficulties, such as strabismus, nystagmus, and optic atrophy (Johnston, 2016). Speech-language therapy involves the services of a speech-language pathologist who may also assist with feeding problems.

Physical therapy is one of the most frequently used conservative treatment modalities. This requires the specialized skills of a qualified therapist with an extensive repertoire of exercise methods who can design a program to stimulate and guide each child to achieve his or her functional goals.

An active therapy program involves the family; the physical therapist; and often other members of the health team, including the nurse. The most common approach uses traditional types of therapeutic exercises that consist of stretching, passive, active, and resistive movements applied to specific muscle groups or joints to maintain or increase range of motion, strength, or endurance.

Prognosis

The prognosis for the child with CP depends largely on the type and severity of the condition. Children with mild to moderate involvement (85%) have the capability of achieving ambulation between 2 and 7 years old (Berker and Yalçin, 2008). If the child does not achieve independent ambulation by this time, chances are poor for later ambulation and independence. Approximately 30% to 50% of individuals with CP have significant cognitive impairments, and an even higher percentage have mild cognitive and learning deficits. However, many children with severe spastic tetraplegic CP have normal intelligence. Growth is affected in children with spastic tetraplegia, and many children remain below the fifth percentile for age and sex.

As children with CP become adults, about 30% remain in the home and are cared for by a parent or caregiver; 50% of individuals with spastic tetraplegia live in independent settings and function at appropriate social levels considering their disability (Green, Greenberg, and Hurwitz, 2003). Vocational rehabilitation and higher education are possible for adults with CP. Children with severe CP mobility impairment and feeding problems often succumb to respiratory tract infection in childhood. The few survival rate studies on children or adults with CP show that survival is influenced by existing comorbidities (Nehring, 2010).

Prevention of some cases of CP may become a reality in the near future. Studies indicate that early neuroprotection in term infants with moderate encephalopathy due to hypoxic-ischemic injury with the use of **therapeutic hypothermia** (head cooling or whole-body cooling to 33° to 35° C) within 6 hours of birth improved survival without CP by approximately 40% (Johnston, Fatemi, Wilson, et al, 2011). A *Cochrane Database Systematic Review* of 11 randomized controlled trials of therapeutic hypothermia in 1,505 term and late preterm infants with intrapartum asphyxia showed significant reduction in mortality and neurodevelopmental disability at 18 months old (Jacobs, Berg, Hunt, et al, 2013). Erythropoietin, a hormone that increases red blood cells (RBCs) and oxygen in the blood is being studied alone and in combination with therapeutic hypothermia treatment in preterm infants with the hope of improving outcomes when exposed to hypoxic ischemic encephalopathy (HIE).

Nursing Alert

The use of mobile infant walkers and door frame jumping seats should not be used; they pose a risk of injury to normal children and are especially hazardous for children with CP. Safer alternatives are available (e.g., stationary musical activity jumper).

Nursing Care Management

Because children with CP expend so much energy in their efforts to accomplish ADLs, more frequent rest periods should be arranged to avoid fatigue. Meeting the child's nutritional needs may be a challenge because of gastroesophageal reflux, feeding and swallowing difficulties, chronic constipation and subsequent anorexia, and absence or diminished ability to independently feed himself or herself. The diet should be tailored to the child's activity and metabolic needs. Gastrostomy feedings may be necessary to supplement regular feedings and ensure adequate weight gain, particularly in children at risk for growth failure and chronic malnutrition, those with severe CP and subsequent oral feeding difficulties, and children whose well-being is affected by illness and decreased fluid or medication intake (Rogers, 2004). Oral feedings may be continued to maintain oral motor skills as tolerated. Weight gain is perceived as an important measure of adequate oral feeding efficiency.

Parents may need assistance and advice with medication administration through a gastrostomy tube to prevent clogging. A skin-level gastrostomy is particularly suited for children with CP. Because jaw control is often compromised, more normal control can be achieved if the feeder provides stability of the oral mechanism from the side or front of the face. When directed from the front, the middle finger of the non-feeding hand is placed posterior to the body portion of the chin, the thumb is placed below the bottom lip, and the index finger is placed parallel to the child's mandible (Fig. 30-3). Manual jaw control from the side assists with head control, correction of neck and trunk hyperextension, and jaw stabilization. The middle finger of the non-feeding hand is placed posterior to the bony portion of the chin, the index finger is placed on the chin below the lower lip, and the thumb is placed obliquely across the cheek to provide lateral jaw stability (Fig. 30-4).

FIG 30-3 Manual jaw control provided anteriorly.

FIG 30-4 Manual jaw control provided from the side.

Safety precautions are implemented, such as having children wear protective helmets if they are subject to falls or capable of injuring their heads on hard objects. Because children with CP are at risk for altered proprioception and subsequent falls, the home and play environments should be adapted to their needs to prevent bodily harm. Appropriate immunizations should be administered to prevent childhood illnesses and protect against respiratory tract infections, such as influenza or pneumonia. Dental problems may be more common in children with CP, which creates a need for meticulous attention to all aspects of dental care. Transportation of the child with motor problems and restricted mobility may be especially challenging for the family and child. Attention must be given to the child's safety when riding in a motor vehicle; a federally-approved safety restraint should be used at all times. It is recommended that children with CP ride in a rear-facing position as long as possible because of their poor head, neck, and trunk control (Lovette, 2008). Car restraints especially designated for children with poor head and neck control are available and should be used.*

The involvement of physical therapy, speech therapy, and occupational therapy is particularly important in establishment and maintenance of muscle function, development of adequate speech and phonation, and identification of modifications necessary for the child's environment so that ADLs can be performed to the child's satisfaction.

As in all aspects of care, educational requirements are determined by the child's needs and potential. Children with mild to moderate cognitive involvement are generally able to participate in regular classes. Resource rooms are available in most schools to provide more individualized attention. Integration of children with CP into regular classrooms should be the initial goal. For those who are unable to benefit from formal education, a vocational training program may be appropriate. At adolescence, prevocational and vocational counseling and guidance are arranged.

At any phase or in any setting, education is geared toward the child's assets.

Recreation and after-school activities should be considered for children who are unable to participate in the regular athletic programs and other peer activities. Some children can compete in athletic and artistic endeavors, and many games and pastimes are suited to their capabilities. Competitive sports are also becoming increasingly available to children with disabilities and offer an added dimension to physical activities. Recreational activities serve to stimulate children's interest and curiosity, help them adjust to their disability, improve their functional abilities, and build self-esteem. Any accomplishment that helps children approach a normal way of life enhances their self-concept.

Support the Family

Probably the nursing interventions most valuable to the family are support and help in coping with the emotional aspects of the disorder, many of which are discussed in relation to the child with a disability (see [Chapter 18](#)). Initially, the parents need supportive counseling directed toward understanding the meaning of the diagnosis and all of the feelings that it engenders. Later they need clarification regarding what they can expect from the child and from health professionals. Educating families in the principles of family-centered care and parent/professional collaboration is essential. The family may require help in modifying the home environment for care of the child (see also [Chapter 18](#)). Transportation to the practitioner's office and other health care agencies often requires special arrangements.

Care coordination for the child and family with CP is an important nursing role. In many cases, the family assumes complete care of the child and becomes quite adept at caring for her or his individual needs. The home health nurse or case manager has an important role in the support and encouragement for families/caregivers who assume the primary care of a child with CP. Having a child with CP implies numerous problems of daily management and changes in family life. The nurse can help with education, assessment, and mobilization of resources, and can stress principles of normalization.

The nurse can support the parents by acknowledging and addressing their concerns and frustrations; by noting and appreciating their problem-solving skills and their approaches to helping the child. Parents and other family members may need support and counseling. Siblings of a child with a disability are affected and may respond to the child's presence with overt or less evident behavioral problems. The family needs a relationship with nurses who can provide continued contact, support, and encouragement through the long process of habilitation.

Parents may find help and support from parent groups, where they can share experiences, accomplishments, problems, and concerns while deriving comfort and practical information. Parent support groups are most helpful through sharing experiences and accomplishments. For example, parents can learn from others what it is like to have a child with CP, which is generally not possible from professionals (see [Family-Centered Care](#) box).

Family-Centered Care

The Reality of Acceptance of Cerebral Palsy

Acceptance is rarely achieved in the length of time implied in the literature.

In the first place, what is acceptance? To me, it is the end of comparing my son with every other child I see. I focus on *his* gains, not society's expectations.

It is also being able to laugh periodically *at* his "clumsiness." It is "gallows humor" as he achieves adulthood; jokes about CP can be funny now.

The bitterness is gone; I am now happy for people who have children without CP.

I no longer feel sorry for my son but rather for the people who cannot see him for the great person he is; the CP does *not* come first.

He is now a young man of 25 years, and I am learning to accept his independence.

It is a "never-ending story."

Elaine A. Dunham, RN

*Shriners Hospitals for Children
Springfield, MA*

United Cerebral Palsy has branches in most communities and provides a variety of services for children and families.

A number of excellent books also are available to guide parents and nurses who work with children with CP. Many of the books are written by people with CP who have triumphed.

Support Hospitalized Child

CP is not a disorder that requires hospitalization; therefore, when children with CP are hospitalized, they are usually admitted for illness or corrective surgery. To facilitate the care and management of hospitalized children with CP, the therapy program should be continued (as their condition allows) while they are hospitalized. This should be incorporated into the multidisciplinary care plan, with every effort expended to make certain the ground that has been so laboriously gained is not lost. Nursing care of the child with CP is similar to that of any child with a disability, and children with CP should be approached as would any child in the hospital. Speech impairment is common in children with CP, but this may not correlate with their ability to understand. Therapy programs should be continued, when appropriate, during the time they are hospitalized. Encouraging the parent to room-in and actively participate in the child's care helps promote family-centered care. However, it is also important to remember that hospitalization may be the first time a parent can defer care to a nurse and not be the primary caregiver. This respite may be crucial to the parent's well-being. Respect the parent's preference in this regard.

Neural Tube Defects (Myelomeningocele)

Abnormalities that derive from the embryonic neural tube (**neural tube defects [NTDs]**) constitute the largest group of congenital anomalies that are consistent with multifactorial inheritance. Normally, the spinal cord and cauda equina are encased in a protective sheath of bone and meninges (Fig. 30-5, A). Failure of neural tube closure produces defects of varying degrees (Box 30-4). They may involve the entire length of the neural tube or may be restricted to a small area.

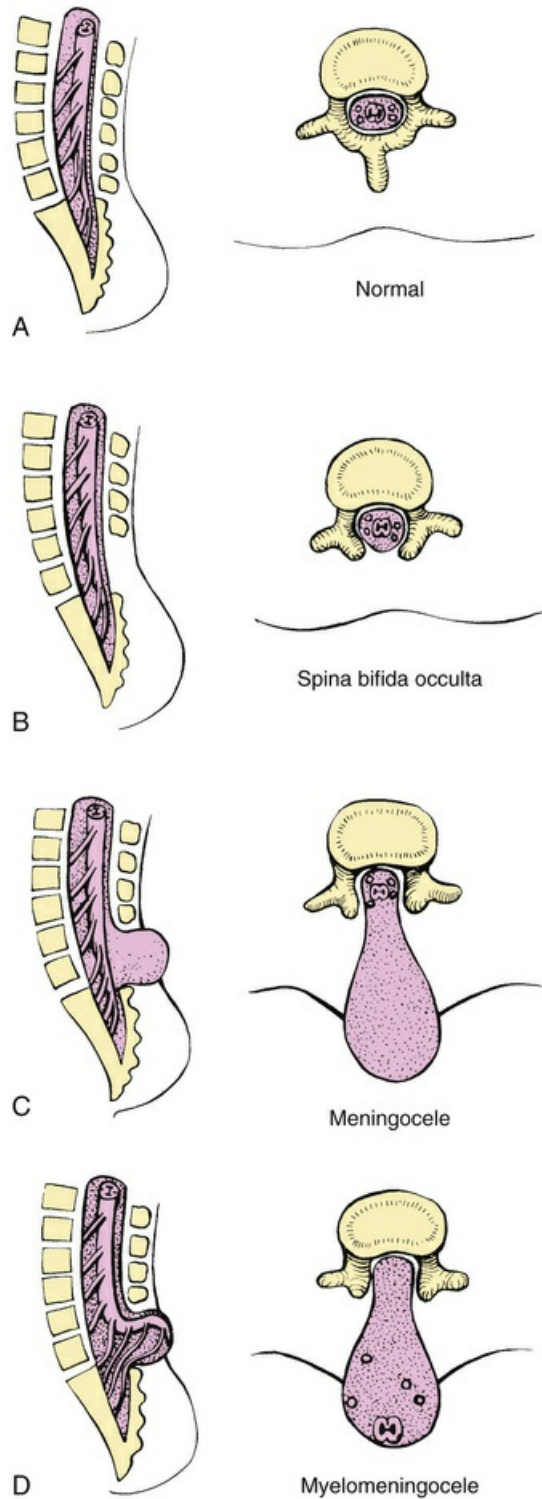

FIG 30-5 Midline defects of the osseous spine with varying degrees of neural herniations. **A.** Normal. **B.** Spina Bifida Occulta. **C.** Meningocele. **D.** Myelomeningocele.

Box 30-4

Significant Neural Tube Defects

Cranioschisis: A congenital skull defect through which various tissues protrude

Exencephaly: Brain totally exposed or extruded through an associated skull defect; fetus usually

aborted

Anencephaly: If fetus with exencephaly survives, degeneration of the brain to a spongiform mass with no bony covering; incompatible with life usually beyond a few days to weeks

Encephalocele: Herniation of brain and meninges through a defect in the skull, producing a fluid-filled sac; can be frontal or posterior

Rachischisis or spina bifida (SB): Fissure in the spinal column that leaves the meninges and spinal cord exposed

Meningocele: Hernial protrusion of a saclike cyst of meninges filled with spinal fluid (see Fig. 30-5, C)

Myelomeningocele (meningomyelocele): Hernial protrusion of a saclike cyst containing meninges, spinal fluid, and a portion of the spinal cord with its nerves (see Fig. 30-5, D)

In the United States, rates of NTDs have declined from 1.3 per 1000 births in 1970 to 0.3 per 1000 births after the introduction of mandatory food fortification with folic acid in 1998. One concern is that NTD rates have not decreased among Hispanic and non-Hispanic white mothers since 1999 (Centers for Disease Control and Prevention, 2009). In 2005, the rates for spina bifida (SB) were estimated by the Centers for Disease Control and Prevention to be 17.96 per 100,000 live births, thus making this one of the most common birth defects in the United States (Matthews, 2009; Wolff, Witkop, Miller, et al, 2009). Increased use of prenatal diagnostic techniques and termination of pregnancies have also affected the overall incidence of NTDs (see also Prevention, later in chapter).

Anencephaly, the most serious NTD, is a congenital malformation in which both cerebral hemispheres are absent. The condition is usually incompatible with life, and many affected infants are stillborn. For those who survive, no specific treatment is available. The infants have a functional portion of the brainstem and are able to maintain vital functions (e.g., temperature regulation and cardiac and respiratory function) for a few hours to several weeks but eventually die of respiratory failure.

Myelodysplasia refers broadly to any malformation of the spinal canal and cord. Midline defects involving failure of the osseous (bony) spine to close are called **spina bifida (SB)**, the most common defect of the CNS. SB is categorized into two types—SB occulta and SB cystica.

Spina bifida occulta refers to a defect that is not visible externally. It occurs most frequently in the lumbosacral area (L5 and S1) (see Fig. 30-5, B). SB occulta may not be apparent unless there are associated cutaneous manifestations or neuromuscular disturbances.

Spina bifida cystica refers to a visible defect with an external saclike protrusion. The two major forms of SB cystica are **meningocele**, which encases meninges and spinal fluid but no neural elements (see Fig. 30-5, C), and **myelomeningocele** (or **meningomyelocele**), which contains meninges, spinal fluid, and nerves (see Fig. 30-5, D). Meningocele is not associated with neurologic deficit, which occurs in varying, often serious, degrees in myelomeningocele. Clinically, the term *spina bifida* is used to refer to myelomeningocele.

Pathophysiology

The pathophysiology of SB is best understood when related to the normal formative stages of the nervous system. At approximately 20 days of gestation, a decided depression, the neural groove, appears in the dorsal ectoderm of the embryo. During the fourth week of gestation, the groove deepens rapidly, and its elevated margins develop laterally and fuse dorsally to form the neural tube. Neural tube formation begins in the cervical region near the center of the embryo and advances in both directions—caudally and cephalically—until by the end of the fourth week of gestation, the ends of the neural tube, the anterior and posterior neuropores, close.

Most authorities believe the primary defect in neural tube malformations is a failure of neural tube closure. However, some evidence indicates that the defects are a result of splitting of the already closed neural tube as a result of an abnormal increase in cerebrospinal fluid (CSF) pressure during the first trimester.

Etiology

There is evidence of a multifactorial etiology, including drugs, radiation, maternal malnutrition, chemicals, and possibly a genetic mutation in folate pathways in some cases, which may result in abnormal development. There is also evidence of a genetic component in the development of SB; myelomeningocele may occur in association with syndromes, such as trisomy 18, PHAVER (limb pterygia, congenital heart anomalies, vertebral defects, ear anomalies, and radial defects) syndrome, and Meckel-Gruber syndrome (Shaer, Chescheir, and Schulkin, 2007). Additional factors predisposing children to an increased risk of NTDs include prepregnancy maternal obesity, maternal diabetes mellitus, low maternal vitamin B₁₂ status, maternal hyperthermia, and the use of AEDs in pregnancy. The genetic predisposition is supported by evidence of the risk of recurrence after one affected child (3% to 4%) and a 10% risk of recurrence with two previously affected children (Kinsman and Johnston, 2016).

The degree of neurologic dysfunction depends on where the sac protrudes through the vertebrae, the anatomic level of the defect, and the amount of nerve tissue involved. The majority of myelomeningoceles (75%) involve the lumbar or lumbosacral area (Fig. 30-6). Hydrocephalus is a frequently associated anomaly in 80% to 90% of the children. About 80% of patients with myelomeningocele have an associated type II Chiari malformation (Kinsman and Johnston, 2016). There is some evidence that prolonged exposure of the myelomeningocele sac to amniotic fluid predisposes to the development of hindbrain herniation and Chiari II malformation (Adzick, 2013).

Diagnostic Evaluation

The diagnosis of SB is made on the basis of clinical manifestations (Box 30-5) and examination of the meningeal sac. Diagnostic measures used to evaluate the brain and spinal cord include MRI, ultrasonography, and CT. A neurologic evaluation will determine the extent of involvement of bowel and bladder function as well as lower extremity neuromuscular involvement. Flaccid paralysis of the lower extremities is a common finding with absent deep tendon reflexes.

Box 30-5

Clinical Manifestations of Spina Bifida

Spina Bifida Cystica

Sensory disturbances usually parallel to motor dysfunction

- Below second lumbar vertebra:
- Flaccid, partial paralysis of lower extremities
- Varying degrees of sensory deficit
- Overflow incontinence with constant dribbling of urine
- Lack of bowel control
- Rectal prolapse (sometimes)
- Below third sacral vertebra:
- No motor impairment
- May have saddle anesthesia with bladder and anal sphincter paralysis

Joint deformities (sometimes produced in utero):

- Talipes valgus or varus contractures
- Kyphosis
- Lumbosacral scoliosis
- Hip dislocation or subluxation

Spina Bifida Occulta

Frequently no observable manifestations

May be associated with one or more cutaneous manifestations:

- Skin depression or dimple
- Port-wine angiomatous nevi
- Dark tufts of hair
- Soft, subcutaneous lipomas

May have neuromuscular disturbances:

- Progressive disturbance of gait with foot weakness
- Bowel and bladder sphincter disturbances

Prenatal Detection

It is possible to determine the presence of some major open NTDs prenatally. Ultrasonographic scanning of the uterus and elevated maternal concentrations of alpha-fetoprotein (AFP, or MS-AFP), a fetal-specific gamma-1-globulin, in amniotic fluid may indicate anencephaly or myelomeningocele. The optimum time for performing these diagnostic tests is between 16 and 18 weeks of gestation before AFP concentrations normally diminish and in sufficient time to permit a therapeutic abortion. It is recommended that such diagnostic procedures and genetic counseling be considered for all mothers who have borne an affected child, and testing is offered to all pregnant women ([American College of Obstetrics and Gynecology Committee on Practice Bulletins, 2007](#)). Chorionic villus sampling is also a method for prenatal diagnosis of NTDs; however, it carries certain risks (skeletal limb depletion) and is not recommended before 10 weeks of gestation ([Simpson, Richards, and Otano, 2012](#)).

Therapeutic Management

Management of the child who has a myelomeningocele requires a multidisciplinary team approach involving the specialties of neurology, neurosurgery, pediatrics, urology, orthopedics, rehabilitation, physical therapy, occupational therapy, and social services, as well as intensive nursing care in a variety of specialty areas. The collaborative efforts of these specialists focus on (1) the myelomeningocele and the problems associated with the defect—hydrocephalus, paralysis, orthopedic deformities (e.g., developmental dysplasia of the hip, clubfoot; scoliosis), and genitourinary abnormalities; (2) possible acquired problems that may or may not be associated, such as Chiari II malformation, meningitis, seizures, hypoxia, tethered cord, and hemorrhage; and (3) other abnormalities, such as cardiac or gastrointestinal (GI) malformations. Many hospitals have routine outpatient care by multidisciplinary teams to provide the complex follow-up care needed for children with myelodysplasia.

Many authorities believe that early closure, within the first 24 to 72 hours, offers the most favorable outcome. Surgical closure within the first 24 hours is recommended if the sac is leaking CSF ([Kinsman and Johnston, 2016](#)).

A variety of neurosurgical and plastic surgical procedures are used for skin closure without disturbing the neural elements or removing any portion of the sac. The objective is satisfactory skin coverage of the lesion and meticulous closure. Wide excision of the large membranous covering may damage functioning neural tissue.

Associated problems are assessed and managed by appropriate surgical and supportive measures. Shunt procedures provide relief from imminent or progressive hydrocephalus (see [Chapter 27](#)). When diagnosed, ventriculitis, meningitis, urinary tract infection, and pneumonia are treated with vigorous antibiotic therapy and supportive measures. Surgical intervention for Chiari II malformation is indicated only when the child is symptomatic (i.e., high-pitched crowing cry, stridor, respiratory difficulties, apnea, oral-motor difficulties, upper extremity spasticity).

Early surgical closure of the myelomeningocele sac through fetal surgery has been evaluated in relation to prevention of injury to the exposed spinal cord tissue and the improvement of neurologic and urologic outcomes in the affected child. The Management of Myelomeningocele Study, a clinical trial supported by the National Institute of Health, found that prenatal surgery for myelomeningocele reduced the need for shunting (for hydrocephalus), evaluated at 12 months, and there was an improvement in mental and motor function scores at 30 months in the children who had prenatal surgery (compared with children who had postnatal surgery) ([Adzick, Thom, Spong, et al, 2011](#)). Outcome data for urologic and bowel function are not available at this time.

Infancy

Initial care of the newborn involves preventing infection; performing a neurologic assessment, including observing for associated anomalies; and dealing with the impact of the anomaly on the family. Although meningoceles are repaired early, especially if there is danger of rupture of the sac,

the philosophy regarding skin closure of myelomeningocele varies. Most authorities believe that early closure, within the first 24 to 72 hours, offers the most favorable outcome. Early closure, preferably in the first 12 to 18 hours, not only prevents local infection and trauma to the exposed tissues but also avoids stretching of other nerve roots (which may occur as the meningeal sac expands during the first hours after birth), thus preventing further motor impairment. Broad-spectrum antibiotics are initiated, and neurotoxic substances, such as povidone/iodine are avoided at the malformation.

Improved surgical techniques do not alter the major physical disability and deformity or chronic urinary tract infections that affect the quality of life for these children. Superimposed on these physical problems are the disorder's effects on family life and finances and on school and hospital services.

Orthopedic Considerations

According to most orthopedists, musculoskeletal problems that will affect later locomotion should be evaluated early, and treatment, when indicated, should be instituted without delay. Neurologic assessment will determine the neurosegmental level of the lesion and enable recognition of spasticity and progressive paralysis, potential for deformity, and functional expectations. Orthopedic management includes prevention of joint contractures, correction of any existing deformities, prevention or minimization of the effects of motor and sensory deficits, prevention of skin breakdown, and obtaining the best possible function of affected lower extremities. Common orthopedic problems requiring attention in SB include deformities of the hips, knees, feet, and spine; fractures and insensate skin further complicate orthopedic care. Other problems that may occur later include kyphosis and scoliosis (Lazzaretti and Pearson, 2010; Liptak and Dosa, 2010). Because children with this condition often have decreased sensitivity in their lower extremities, preventive skin care is important. A high percentage (60%) of children seen in a wound clinic for skin breakdown had myelomeningocele (Samaniego, 2003). The status of the neurologic deficit remains the most important factor in determining the child's ultimate functional abilities.

With technologic advances, a variety of lightweight orthoses, including braces, special "walking" devices, and custom-built wheelchairs, are available to provide mobility to children with spinal cord lesions (see also Chapter 29). Early in infancy, intervention with passive range-of-motion exercises, positioning, and stretching exercises may help decrease the incidence of muscle contractures. Corrective surgical procedures, when indicated, are best initiated at an early age so the child will not lag significantly behind age mates in developmental progress. The degree of lower extremity function guides decisions about whether orthopedic surgery will be needed.

Management of Genitourinary Function

Myelomeningocele is one of the most common causes of **neuropathic (neurogenic) bladder dysfunction** among children. In infants, the goal of treatment is to preserve renal function. In older children, the goal is to preserve renal function and achieve optimal urinary continence. Urinary incontinence is a chronic, often debilitating problem for the child. In addition, the neuropathic bladder may produce **urinary system distress**, characterized by symptomatic urinary tract infections, ureterohydronephrosis, and vesicoureteral reflux or renal insufficiency. The characteristics of bladder dysfunction in children vary according to the level of the neurologic lesion and the influence of bony growth and development on the spine. Therefore, ongoing urologic monitoring is essential. Evidence is growing that early intervention, based on evaluation during the neonatal period and before complications occur, improves bladder function, reduces the risk of subsequent urinary system distress, and decreases the need for reconstructive surgery of the lower urinary tract (Snodgrass and Gargollo, 2010; Tarcan, Onol, Ilker, et al, 2006).

Treatment of renal problems includes (1) regular urologic care with prompt and vigorous treatment of infections; (2) a method of regular emptying of the bladder, such as **clean intermittent catheterization (CIC)** taught to and performed by parents and self-catheterization taught to children; (3) medications to improve bladder storage and continence, such as oxybutynin chloride (Ditropan) and tolterodine (Detrol); and (4) surgical procedures such as **vesicostomy** (bladder surgically brought out to the abdominal wall, allowing continuous urinary drainage) and **augmentation enterocystoplasty** (using a segment of bowel or stomach to increase bladder capacity, thereby reducing high bladder pressures).

However, despite the combined efforts of CIC, medication, and surgical intervention, some

children with myelodysplasia may continue to experience debilitating urinary incontinence. Many of these children are able to attain social continence with a continent **urinary diversion** commonly referred to as a *Mitrofanoff procedure*. In this procedure, a catheterizable channel is surgically created from appendix, ureter, or tapered bowel. The proximal end of the channel is connected to the bladder with the distal end brought out as a small stoma on the abdominal wall, usually near the umbilicus. The bladder neck may be sutured to prevent urinary leakage from the urethra. CIC through the easily accessible abdominal route fosters greater independence in children, especially in those unable to transfer from wheelchair to toilet to perform CIC.

Bowel Control

Some degree of fecal continence can be achieved in most children with myelomeningocele with diet modification, regular toilet habits, and prevention of constipation and impaction. It is frequently a lengthy process. Dietary fiber supplements (recommended 10 g/day), laxatives, suppositories, or enemas aid in producing regular evacuation. Older children and adolescents seeking more independence may attain bowel continence and higher quality of life after undergoing an **antegrade continence enema (ACE)** procedure (Doolin, 2006). In a procedure similar to the Mitrofanoff, the appendix or ileum is used to create a catheterizable channel with attachment of the proximal end to the colon. The distal end of the channel exits through a small abdominal stoma. Every 1 or 2 days, a catheter is passed through the stoma, allowing enema solution to be instilled directly into the colon. After administration of the enema solution, the child sits on the toilet for 30 to 60 minutes as stool is flushed out through the rectum. The frequency of enemas and volume of solution used to completely evacuate the bowel vary among individuals.

Prognosis

The early prognosis for the child with myelomeningocele depends on the neurologic deficit present at birth, including motor ability, bladder innervation, and associated neurologic anomalies. Early surgical repair of the spinal defect, antibiotic therapy to reduce the incidence of meningitis and ventriculitis, prevention of urinary system dysfunction, and early detection and correction of hydrocephalus have significantly increased the survival rate and quality of life in such children. *Children with SB have normal intelligence.* Many children with SB achieve partial independent living and gainful employment. Reports of survival rates vary, and many include adults who were born before medical advances and surgical techniques seen in the past 25 years. Coordinated care for adults with SB is essential; however, multidisciplinary adult care is often inadequate (Lazzaretti and Pearson, 2010). In children and adolescents with SB, the achievement of urinary continence is associated with improved self-concept and esteem, especially among girls (Moore, Kogan, and Parekh, 2004). This chronic condition has an array of associated complications, including hydrocephalus and shunt malfunctions, scoliosis, bowel and bladder management issues, latex allergy, and epilepsy. However, based on current medical knowledge and ethical considerations, aggressive, early management is favored for the child with myelomeningocele.

Prevention

The Centers for Disease Control and Prevention (2009) continues to affirm that 50% to 70% of NTDs can be prevented by daily consumption of 0.4 mg of folic acid among women of childbearing age. The data indicate that serum folate concentrations among women of childbearing age decreased 16% from 2003 to 2004 in all ethnic groups studied. Lowest serum folate levels were seen in non-Hispanic whites in 2003 to 2004; however, overall serum folate levels remained below recommended levels in non-Hispanic African Americans during all three periods studied (Centers for Disease Control and Prevention, 2007). These results indicate that nurses and other health care workers have an important task in disseminating information that may decrease the incidence of birth defects in children by promoting maternal consumption of folic acid.*

To ensure adequate daily intake of the recommended amount of folic acid, women must take a folic acid supplement, eat a fortified breakfast cereal containing 100% of the Recommended Dietary Allowance (RDA) of folic acid (e.g., Kellogg's Product 19, General Mills Total, Multigrain Cheerios Plus), or increase their consumption of fortified foods (cereal, bread, rice, grits, pasta) and foods naturally rich in folate (green, leafy vegetables and citrus fruits). For women who have had a previous pregnancy affected by NTDs, folic acid intake is increased to 4 mg under the supervision of a practitioner beginning 1 month before a planned pregnancy and continuing through the first

trimester. Supplementation of 4 mg of folate should not be given solely in multivitamin preparations because of the risk of overdose of other vitamins. Drugs that affect folic acid metabolism and increase the risk of myelomeningocele should be avoided before pregnancy (if plans are to become pregnant in the near future) and during pregnancy; these include trimethoprim and the AEDs—carbamazepine, phenytoin, phenobarbital, valproic acid, and primidone (Kinsman and Johnston, 2016).

Nursing Care Management

At birth, an examination is performed to assess the integrity of the membranous cyst. During transport to the nursery, every effort is made to prevent trauma to this protective covering. In addition to the routine assessment of the newborn (see [Chapter 7](#)), assess the infant for the level of neurologic involvement. Note movement of extremities or skin response, especially an anal reflex that might provide clues to the degree of motor or sensory impairment. It is important to observe the infant's behavior in conjunction with the stimulus, because limb movements can be induced in response to spinal cord reflex activity that has no connection with the higher centers. Observation of urinary output, especially if a diaper remains dry, may indicate urinary retention. Abdominal assessment revealing bladder distention, even with a wet diaper, may indicate urinary overflow in a retentive bladder. The head circumference is measured daily (see [Chapter 7](#)), and the fontanelles are examined for signs of tension or bulging.

Care of the Myelomeningocele Sac

The infant is usually placed in an incubator or warmer so temperature can be maintained without clothing or covers that might irritate the spinal lesion. When an overhead warmer is used, the dressings over the defect require more frequent moistening because of the dehydrating effect of the radiant heat.

Before surgical closure, the myelomeningocele is prevented from drying by the application of a sterile, moist, nonadherent dressing. The moistening solution is usually sterile normal saline. Dressings are changed frequently (every 2 to 4 hours), and the sac is closely inspected for leaks, abrasions, irritation, and any signs of infection. The sac must be carefully cleansed if it becomes soiled or contaminated. Sometimes the sac ruptures during delivery or transport, and any opening in the sac greatly increases the risk of infection to the CNS.

Nursing Alert

Observe for early signs of infection, such as temperature instability (axillary), irritability, and lethargy, and for signs of increased intracranial pressure, which might indicate developing hydrocephalus.

Nursing Alert

Avoid measuring rectal temperatures in infants with spina bifida (SB). Because bowel sphincter function is frequently affected, the thermometer can cause irritation and rectal prolapse.

One of the most important and challenging aspects in the early care of the infant with myelomeningocele is positioning. Before surgery, the infant is kept in the prone position to minimize tension on the sac and the risk of trauma. The prone position allows for optimal positioning of the legs, especially in cases of associated hip dysplasia. The infant is placed prone with the hips slightly flexed and supported to reduce tension on the defect. The legs are maintained in abduction with a pad between the knees to counteract hip subluxation, and a small roll is placed under the ankles to maintain a neutral foot position. A variety of aids, including diaper rolls, foam pads, or specially designed frames and appliances, can be used to maintain the desired position.

Prevent Complications

The prone position affects other aspects of the infant's care. For example, in this position, the infant is more difficult to keep clean, pressure areas are a constant threat, and feeding becomes a problem. The infant's head is turned to one side for feeding. Fortunately, most defects are repaired early, and the infant can be held for feeding soon after surgery. Special care must be taken to avoid pressure

on the operative site.

Diapering the infant may be contraindicated until the defect has been repaired and healing is well advanced or epithelialization has taken place. The padding beneath the diaper area is changed as needed to keep the skin dry and free of irritation. When urinary retention is detected, CIC is used. Because the bowel sphincter is frequently affected, there is continual passage of stool, often misinterpreted as diarrhea, which is a constant irritant to the skin and a source of infection to the spinal lesion.

Nursing Tip

To prevent stool contamination of the spina bifida (SB) defect preoperatively, obtain a surgical drape (e.g., Steri-Drape). Cut a portion of the drape to fit the infant's sacrum and secure the drape using nonlatex tape. Place the rest of the drape loosely over the dressing, covering the defect and thus preventing exposure to stool.

Areas of sensory and motor impairment are subject to skin breakdown and therefore require meticulous care. Placing the infant on a special mattress or mattress overlay reduces pressure on the knees and ankles. Periodic cleansing, application of lotion, and gentle massage aid circulation.

Gentle range-of-motion exercises are carried out to prevent contractures, and stretching of contractures is performed when indicated. However, these exercises may be restricted to the foot, ankle, and knee joint. When the hip joints are unstable, stretching against tight hip flexors or adductor muscles, which act much like bowstrings, may aggravate a tendency toward subluxation. Consultation with a physical therapist is an important aspect of the short- and long-term management of infants with myelomeningocele.

Cuddling infants with unrepaired myelomeningocele is contraindicated. Their need for tactile stimulation is met by caressing, stroking, and other comfort measures. Individualized developmental care with age-appropriate stimulation is provided (see Developmental Outcome, Chapter 7).

Provide Postoperative Care

Postoperative care of the infant with myelomeningocele involves the same basic care as that of any postsurgical infant and includes monitoring vital signs, monitoring intake and output, providing nourishment, observing for signs of infection, and managing pain. Care of the operative site is carried out under the direction of the surgeon and includes close observation for signs of leakage of CSF. General care is done as preoperatively.

The prone position is maintained after surgical closure, although many neurosurgeons allow a side-lying or partial side-lying position unless it aggravates a coexisting hip dysplasia or permits undesirable hip flexion. This offers an opportunity for position changes, which reduces the risk of pressure sores and facilitates feeding. If permitted, the infant can be held upright against the body, with care taken to avoid pressure on the operative site. After the effects of anesthesia have subsided and the infant is alert, feedings may be resumed unless there are other anomalies or associated complications.

Support Family and Educate About Home Care

As soon as the parents are able to cope with the infant's condition, they are encouraged to become involved in care. They need to learn how to continue at home the care that has been initiated in the hospital, including positioning, feeding, skin care, and range-of-motion exercises when appropriate. They are taught CIC technique when it is prescribed. Parents also need to know the signs of complications (urinary, neurologic, orthopedic) and how to obtain assistance when needed.

The mother who wishes to breastfeed the infant is encouraged to do so, because this will be beneficial. Shortly after delivery, the mother is started on a program of pumping to initiate and maintain milk supply until the infant is stable enough to begin breastfeeding (Hurtekant and Spatz, 2007). This process may require considerable support from nurses, physicians, and family members because of separation from the infant for surgical care and recovery.

The long-range planning with and support of the parents and newborn begin in the hospital continuing throughout childhood and even into young adulthood. The life expectancy of children with SB extends well into adulthood; therefore, planning should involve long-term goals and plans

for optimum function as an adult. Discussion about aspects of adulthood such as receiving educational or vocational training and education, living independently, having a mate, having sexual relationships, and bearing and rearing children is important and should not be overlooked (Rowe and Jadhav, 2008). The unique service needs of adolescents with SB as they attempt to gain independence from family and establish lives of their own have not been adequately addressed in the literature (Sawyer and Macnee, 2010). Betz, Linroth, Butler, and colleagues (2010) interviewed young people with SB making the transition to adulthood. Some common themes that emerged among these young people were as follows: (1) challenges in preparation for self-management; (2) limited social relationships; (3) awareness of their cognitive challenges; and (4) the cost of independence. Nurses assume an important role as central members of the health team. As care managers and coordinators, nurses review information with the family, take responsibility for family teaching, and act as a liaison between inpatient and outpatient services. The child may require numerous hospitalizations over the years, and each one will be a source of stress to which the younger child is especially vulnerable (see Chapter 18 for a discussion of care of the child with a disability).

Habilitation involves not only solving problems of self-help and locomotion but also solving the most distressing problem of urinary or bowel incontinence, which threatens the child's social acceptability. Assistance in preparing the child and the school regarding the special needs of children with disabilities helps provide a better initial adjustment to this broader social experience.

A Life Course Model has been developed for patients, families, caregivers, teachers, and clinicians to facilitate, through a developmental approach, the care of the child and young person with SB; this program has been made into a web-based tool that can be used to assist in the transition to adulthood (Dicianno, Fairman, Juengst, et al, 2010). Additional information regarding this program is available through the Spina Bifida Association's website at <http://www.spinabifidaassociation.org>. The Spina Bifida Association of America* is organized to provide services and support for families of children with spinal lesions.

Latex Allergy

Latex allergy, or latex hypersensitivity, was identified as being a serious health hazard when a report linked intraoperative anaphylaxis with latex in children with SB. Latex, a natural product derived from the rubber tree, is used in combination with other chemicals to give elasticity, strength, and durability to many products. Children with SB are at high risk for developing latex allergy because of repeated exposure to latex products during surgery and procedures. Therefore, such children should not be exposed to latex products from birth onward to minimize the occurrence of latex hypersensitivity. Allergic reactions range from urticaria, wheezing, watery eyes, and rashes to anaphylactic shock. More severe reactions tend to occur when latex comes in contact with mucous membranes, wet skin, the bloodstream, or an airway. There also can be cross-reactions to a number of foods (e.g., banana, avocado, kiwi, chestnut).

Allergic reactions to latex protein can also occur when the substance is transferred to food by food handlers wearing latex gloves, prompting several states to pass legislation that prohibits the use of latex gloves in food service. In addition to patients with SB, high-risk populations include patients with urogenital anomalies or multiple surgeries, as well as health care workers. Box 30-6 lists medical conditions associated with the risk of latex allergy.

Box 30-6

Medical Conditions Associated with Risk of Latex Allergy

- Spina bifida (SB)
- Urogenital anomalies
- Imperforate anus
- Tracheoesophageal fistula

- VATER* association
- Preterm infants
- Ventriculoperitoneal shunt
- Cognitive impairment
- Cerebral palsy (CP)
- Spinal cord injuries (SCIs)
- Multiple surgeries
- Atopy

*Vertebral defects, Anal atresia, Tracheoesophageal fistula, Esophageal atresia, and Renal/radial defects.

The most important goals are prevention of latex sensitivity and identification of children with known hypersensitivity (see [Nursing Care Guidelines](#) box). High-risk and latex-allergic individuals must be managed in a **latex-free environment**. Take care that they do not come in direct or secondary contact with products or equipment containing latex at *any time* during medical treatment. Allergy testing can identify latex sensitivity with varying success. Skin prick testing and provocation testing carry the risk of allergic reaction or anaphylaxis. Several commercially available assays can be useful in confirming latex sensitivity. To date, none of these tests demonstrates complete diagnostic reliability, and they should not be the sole determinant of the presence or absence of an allergic response to latex.

Nursing Care Guidelines

Identifying Latex Allergy

- Does your child have any symptoms, such as sneezing, coughing, rashes, or wheezing, when handling rubber products (e.g., balloons, tennis or Koosh balls, adhesive bandage strips) or when in contact with rubber hospital products (e.g., gloves, catheters)?
- Has your child ever had an allergic reaction during surgery?
- Does your child have a history of rashes; asthma; or allergic reactions to medication or foods, especially milk, kiwi, bananas, or chestnuts?
- How would you identify or recognize an allergic reaction in your child?
- What would you do if an allergic reaction occurred?
- Has anyone ever discussed latex or rubber allergy or sensitivity with you?
- Has your child had any allergy testing?
- When did your child last come in contact with any type of rubber product? Were you present?

Modified from Romanczuk A: Latex use with infants and children: it can cause problems, *MCN Am J Matern Child Nurs* 18(4):208–212, 1993.

Because children who have SB are prone to develop sensitivity to latex, reducing exposure from birth onward may decrease the chance of allergy development. Nonlatex products lists are available to parents and health care workers; these products may be substituted for those containing latex. In the health care arena, it is important to use products with the lowest potential risk of sensitizing

patients and staff members.*

The identification of those sensitive to latex is best accomplished through careful screening of all patients. During the health interview with the parent or child, ask *all* patients, not only those at risk, about sensitivity to latex. Be certain this is a routine part of all preoperative and preprocedural histories. Stress the importance of the allergy history to all personnel (e.g., phlebotomists). (See the [Nursing Care Guidelines](#) box for questions related to latex allergy.) Children with latex hypersensitivity should carry some form of allergy identification, such as a Medic-Alert bracelet. Education programs regarding latex hypersensitivity are aimed at those who care for high-risk groups, such as children with SB, and may include relatives, school nurses, teachers, child care workers, and babysitters. In addition to educating caregivers about the child's exposure to medical products that contain latex, nurses need to inform them of common nonmedical latex objects, such as water toys, pacifiers, and plastic storage bags.* Items brought to the hospital, such as floral bouquets, should also be screened for latex toys and balloons. Parents should also receive literature explaining signs and symptoms of latex hypersensitivity and appropriate emergency treatment (see Anaphylaxis, [Chapter 23](#)).

Spinal Muscular Atrophy, Type 1 (Werdnig-Hoffmann Disease)

Spinal muscular atrophy (SMA) type 1 (Werdnig-Hoffmann disease) is a disorder characterized by progressive weakness and wasting of skeletal muscles caused by degeneration of anterior horn cells. It is inherited as an autosomal recessive trait and is the most common paralytic form of the **floppy infant syndrome (congenital hypotonia)**. The sites of the pathologic condition are the anterior horn cells of the spinal cord and the motor nuclei of the brainstem, but the primary effect is atrophy of skeletal muscles. The age of onset is variable, but the earlier the onset, the more disseminated and severe the motor weakness. The disorder may be manifested early—often at birth—and almost always before 2 years old; death may occur as a result of respiratory failure by 2 years old ([Iannaccone and Burghes, 2002](#); [Lunn and Wang, 2008](#)). The manifestations ([Box 30-7](#)) and prognosis are categorized according to the age of onset, severity of weakness, and clinical course; some children may fluctuate between exhibiting symptoms of types 1 and 2 or types 2 and 3 in regard to clinical function ([Sarnat, 2016a](#)). Some experts also categorize SMA according to the highest level of motor function ([Lunn and Wang, 2008](#)); type 1 includes “nonsitters,” type 2 includes “sitters,” and type 3 includes “walkers” ([Iannaccone, 2007](#)). A severe rare fetal form of SMA, classified as type 0, is reported to be quite lethal in the perinatal period; motor neuron degeneration may be noted as early as midgestation in type 0 ([Sarnat, 2016a](#)). Type 4 may present between 20 and 30 years of age and may be referred to as *proximal adult type SMA* ([Sarnat, 2016a](#)).

Box 30-7

Clinical Manifestations of Spinal Muscular Atrophy*

Type 1 (Werdnig-Hoffmann Disease)

Clinical manifestations within first few weeks or months of life

Onset within 6 months of life

Inactivity the most prominent feature

Infant lying in a frog-leg position with legs externally rotated, abducted, and flexed at knees

Generalized weakness

Absent deep tendon reflexes

Limited movements of shoulder and arm muscles

Active movement usually limited to fingers and toes

Diaphragmatic breathing with sternal retractions (diaphragmatic paralysis may occur)

Abnormal tongue movements (at rest)

Weak cry and cough

Poor suck reflex

Tiring quickly during feedings (if breastfed, may lose weight before noticeable)

Growth failure (nutritional)

Alert facies

Normal sensation and intellect

Affected infants not able to sit alone, roll over, or walk

Early death possible from respiratory failure or infection

Type 2 (Intermediate Spinal Muscular Atrophy)

Onset before 18 months old

Early: Weakness confined to arms and legs

Later: Becomes generalized

Legs usually involved to greater extent than arms

Prominent pectus excavatum

Movements absent during complete relaxation or sleep

Some infants able to sit if placed in position, but few can ambulate

Life span from 7 months to 7 years, although many have normal life expectancy

Type 3 (Kugelberg-Welander Disease; Mild Spinal Muscular Atrophy)

Onset of symptoms after 18 months old

Normal head control and ability to sit unassisted by 6 to 8 months old

Thigh and hip muscles weak

Scoliosis common

Failure to walk a common presentation

In those who manage to walk:

- Waddling gait
- Genu recurvatum
- Protuberant abdomen
- Ambulation becoming increasingly difficult

- Confinement to a wheelchair by second decade
- Deep tendon reflexes possibly present early but disappear

*These classifications are general, but some research suggests there may be variations in life span and other characteristics (Iannaccone and Burghes, 2002; Russman, Buncher, White, et al, 1996; Russman, Iannaccone, Buncher, et al, 1992).

Diagnostic Evaluation and Therapeutic Management

The diagnosis is based on the molecular genetic marker for the *SMN* (survival motor neuron) gene, which is located on chromosome 5q13. Prenatal diagnosis may be made by genetic analysis of circulating fetal cells in maternal blood (Bérout, Karliova, Bonnefont, et al, 2003) or circulating fetal cells in amniotic fluid. The risk of subsequent affected offspring in carriers of the mutant gene or in families with known cases of SMA may also be evaluated genetically. Further diagnostic studies include muscle electromyography (EMG), which demonstrates a denervation pattern, and muscle biopsy; however, the genetic analysis has become the gold standard for diagnosis of the condition (Sarnat, 2016a).

There is no cure for the disease, and treatment is symptomatic and preventive, primarily preventing joint contractures and treating orthopedic problems, the most serious of which is scoliosis. Hip subluxation and dislocation may also occur. Many children benefit from powered wheelchairs, lifts, special pressure-adjustable mattresses, and accessible environmental controls. Muscle and joint contractures require careful attention and care to prevent further complications. Nutritional growth failure may occur in infants and toddlers as a result of poor feeding; supplemental gastrostomy feedings may be required to maintain adequate nutritional status and maintain weight gain. The use of lower extremity orthoses may assist with ambulation, but eventually, the child may be confined to a wheelchair as muscle atrophy progresses. Restrictive lung disease is the most serious complication of SMA (Iannaccone, 2007). Upper respiratory tract infections often occur and are treated with antibiotic therapy; they are the cause of death in many children. Rapid eye movement (REM)-related sleep-disordered breathing is common in children with SMA type 1; this progresses to sleep-disordered breathing during REM and non-REM sleep followed by respiratory failure, which often requires nocturnal noninvasive mechanical ventilation (Schroth, 2009). Noninvasive ventilation methods such as bilevel positive airway pressure (BiPAP) have decreased the morbidity and increased the survival rate of children with SMA types 1 and 2. A decreased ability to cough and clear secretions may be managed with airway clearance therapies such as the cough-assist machine and manual cough assistance. Guidelines for the standardization of respiratory care for patients with SMA have been published elsewhere (Schroth, 2009).

Prognosis

Prognosis varies according to the age of onset or group as described in Box 30-7. Individuals with SMA type 1 may succumb to respiratory infections or failure between 1 and 24 months of age (Iannaccone and Burghes, 2002; Sarnat, 2016a); however, some may live into their third or fourth decade of life. A significant number of infants with SMA require a tracheotomy, and associated medical conditions in survivors include gastroesophageal reflux, scoliosis, early onset puberty, hip dysplasia, and recurrent oral candidiasis (Bach, 2007). Drug therapy with riluzole, valproic acid, gabapentin, and oral phenylbutyrate has been shown to slow the progression of the condition, but none has demonstrated significant overall benefits (Wadman, Bosboom, van der Pol, et al, 2012; Sarnat, 2016a).

Nursing Care Management

An infant or small child with progressive muscle weakness requires nursing care similar to that of an immobilized patient (see Chapter 29). However, the underlying goal of treatment should be to assist the child and family in dealing with the illness while progressing toward a life of normalization within the child's capabilities. Special attention should be directed to preventing muscle and joint contractures, promoting independence in performance of ADLs, and becoming incorporated into the mainstream of school when possible. In addition, parents need support and

resources to be able to provide for the child and remain an intact family. Because children with neuromuscular disease have abnormal breathing patterns that often contribute to early death, it is important to assess adequate oxygenation, especially during the sleep phase when shallow breathing occurs and hypoxemia may develop. Home pulse oximetry may be used to assess the child during sleep and provide noninvasive mechanical ventilation as necessary (Bush, Fraser, Jardine, et al, 2005; Young, Lowe, Fitzgerald, et al, 2007) (see Duchenne [Pseudohypertrophic] Muscular Dystrophy later in this chapter for respiratory management). Supportive care also includes management of orthoses and other orthopedic equipment as required. Because children with SMA are intellectually normal, verbal, tactile, and auditory stimulation are important aspects of developmental care. Supporting them so that they can see the activities around them and transporting them in appropriate conveyances (e.g., wagon, power wheelchair) for a change of environment provide stimulation and a broader scope of contacts.

Children who are able to sit require proper support and attention to alignment to prevent deformities and other complications. Children who survive beyond infancy need attention to educational needs and opportunities for social interaction with other children. The parents of a child who is chronically ill require much support and encouragement* (see Chapter 17). Parents who have not sought genetic counseling should be encouraged to do so to evaluate further risk potential.

Congenital muscular dystrophies have an onset at birth and clinical manifestations in the first 2 years of life. Although rare disorders, these are divided into three major groups: (1) collagenopathies, (2) merosinopathies, and (3) dystroglycanopathies. In addition to progressive skeletal muscle weakness and hypotonia, some are associated with joint hyperlaxity and eye or brain abnormalities. Genetic studies may help to correlate with specific phenotypes. Evidence-based guidelines for evaluation, diagnosis, and management of congenital muscular dystrophies have been published recently by the American Academy of Neurology (Kang, Morrison, Iannaccone, et al, 2015).

Spinal Muscular Atrophy, Type 3 (Kugelberg-Welander Disease)

SMA type 3 (Kugelberg-Welander disease) is a result of anterior horn cell and motor nerve degeneration. The disease is characterized by a pattern of muscular weakness similar to that of type 1 SMA (see Box 30-7). Several modes of inheritance have been reported for the disease: autosomal recessive, autosomal dominant, and X-linked recessive.

The onset occurs from younger than 1 year old into adulthood, with symptoms resembling type 3 SMA. Proximal muscle weakness (especially of the lower limbs) and muscular atrophy are the predominant features. The disease runs a slowly progressive course. Some children lose the ability to walk 8 to 9 years after the onset of symptoms, but many can still walk after 30 years or more. Many affected persons have a normal life expectancy (Lunn and Wang, 2008).

Therapeutic Management and Nursing Care Management

The management is primarily symptomatic and supportive and is related to maintaining mobility as long as possible, preventing complications such as skin breakdown, optimizing and maintaining respiratory function, and providing support to the child and family. The discussion of family support in the section for Duchenne muscular dystrophy (DMD) is also applicable to families of children with SMA.

Muscular Dystrophies

Muscular dystrophies (MDs) constitute the largest and most important single group of muscle diseases of childhood. The MDs have a genetic origin in which there is gradual degeneration of muscle fibers, and they are characterized by progressive weakness and wasting of symmetric groups of skeletal muscles, with increasing disability and deformity. In all forms of MD, there is an insidious loss of strength, but each type differs in regard to the muscle groups affected (Fig. 30-7), age of onset, rate of progression, and inheritance pattern. The most common form, **Duchenne muscular dystrophy (DMD)**, is discussed separately in the next section.

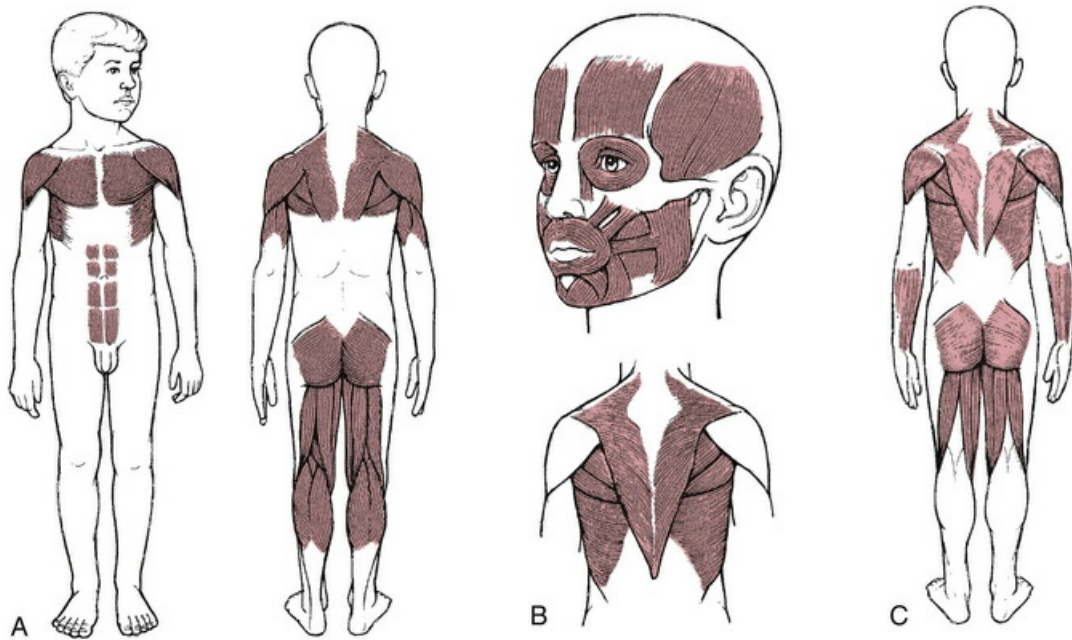

FIG 30-7 Initial muscle groups involved in muscular dystrophies (MDs). **A**, Pseudohypertrophic. **B**, Fascioscapulohumeral. **C**, Limb girdle.

Facioscapulohumeral (Landouzy-Dejerine) muscular dystrophy is inherited as an autosomal dominant disorder with onset in early adolescence. It is characterized by difficulty in raising the arms over the head, lack of facial mobility, and a forward slope of the shoulders. The progression is slow, and the life span is usually unaffected.

Limb-girdle muscular dystrophy (LGMD) is a heterogenous group of disorders with autosomal dominant and recessive inheritance whose clinical manifestations often appear in later childhood, adolescence, or early adulthood with variable but usually slow progression (Quan, 2011). All types of LGMD are characterized by weakness of proximal muscles of the pelvic and shoulder girdles. Other forms of MD include myotonic dystrophy, scapulohumeral MD (Emery-Dreifuss MD), facioscapulohumeral MD (Landouzy-Dejerine disease), and congenital MD; these forms consist of subtypes of MD and are discussed at length elsewhere (see Sarnat, 2016b).

Treatment of the MDs consists mainly of supportive measures, including physical therapy, orthopedic procedures to minimize deformity, ventilation support, and assistance for the affected child in meeting the demands of daily living.

Duchenne (Pseudohypertrophic) Muscular Dystrophy

DMD is the most severe and the most common MD of childhood. It is inherited as an X-linked recessive trait, and the single-gene defect is located on the short arm of the X chromosome. DMD has a high mutation rate, with a positive family history in about 65% of cases. Genetic counseling is an important aspect of the care of the family. In about 30% of cases, it is a new mutation, and the mother is *not* the carrier (Sarnat, 2016b).

As in all X-linked disorders, males are affected almost exclusively. The female carrier may have an elevated serum creatine kinase, but muscle weakness is usually not a problem; however, about 10% of female carriers develop cardiomyopathy (Manzur, Kinali, and Muntoni, 2008). In rare instances, a female may be identified with DMD disease yet with muscular weakness that is milder than in boys (Sarnat, 2016b). At the genetic level, both DMD and Becker MD (a milder variant) result from mutations of the gene that encodes dystrophin, a protein product in skeletal muscle. Dystrophin is absent from the muscles of children with DMD and is reduced or abnormal in children with Becker MD. Children with Becker MD have a later onset of symptoms, which are usually not as severe as those seen in DMD. The incidence is approximately 1 in 3600 male births for the Duchenne form and approximately 1 in 30,000 live births for the Becker type (Sarnat, 2016b). [Box 30-8](#) describes the characteristics of DMD.

Box 30-8

Characteristics of Duchenne Muscular Dystrophy

- Early onset, usually between 3 and 7 years old
- Progressive muscular weakness, wasting, and contractures
- Calf muscle pseudohypertrophy in most patients
- Loss of independent ambulation by 9 to 12 years old
- Slowly progressive, generalized weakness during teenage years

Most children with DMD reach the appropriate developmental milestones early in life, although they may have mild, subtle delays. Evidence of muscle weakness usually appears during the third to seventh year, although there may have been a history of delay in motor development, particularly walking. Difficulties in running, riding a bicycle, and climbing stairs are usually the first symptoms noted. Typically, affected boys have a waddling gait and lordosis, fall frequently, and develop a characteristic manner of rising from a squatting or sitting position on the floor (**Gower sign**) (Fig. 30-8). Lordosis occurs as a result of weakened pelvic muscles, and the waddling gait is a result of weakness in the gluteus medius and maximus muscles (Battista, 2010). In the early years, rapid developmental gains may mask the progression of the disease.

FIG 30-8 A child with Duchenne muscular dystrophy (DMD) attains standing posture by kneeling and then gradually pushing his torso upright (with knees straight) by “walking” his hands up his legs (Gower sign). Note the marked lordosis in an upright position.

Muscles, especially in the calves, thighs, and upper arms, become enlarged from fatty infiltration and feel unusually firm or woody on palpation (Box 30-9). The term **pseudohypertrophy** is derived from this muscular enlargement. Profound muscular atrophy occurs in the later stages; contractures and deformities involving large and small joints are common complications as the disease progresses. Ambulation usually becomes impossible by 12 years old. The loss of mobilization further increases the spectrum of complications, which may include osteoporosis, fractures, constipation, skin breakdown, and psychosocial and behavioral problems. Atrophy of facial, oropharyngeal, and respiratory muscles does not occur until the advanced stage of the disease. Ultimately, the disease process involves the diaphragm and auxiliary muscles of respiration, and cardiomyopathy is seen in approximately 50% to 80% of patients with DMD (Sarnat, 2016b).

Box 30-9

Clinical Manifestations of Duchenne Muscular Dystrophy

Relentless progression of muscle weakness; possible death from respiratory or cardiac failure

Waddling gait

Lordosis

Frequent falls

Gower sign (child turns onto side or abdomen; flexes knees to assume a kneeling position; and then with knees extended, gradually pushes torso to an upright position by “walking” the hands up the legs)

Enlarged (hypertrophied) muscles (especially calves, thighs, and upper arms); feel unusually firm or woody on palpation

Later stages—profound muscular atrophy

Mental deficiency (common)

- Mild (\approx 20 IQ points below normal)
- Mental deficit present in 25% to 30% of patients

Complications:

- Contracture deformities of hips, knees, and ankles
- Disuse atrophy
- Cardiomyopathy
- Obesity and at times undernutrition
- Respiratory compromise and cardiac failure

IQ, Intelligence quotient.

Obesity is a common complication that contributes to premature loss of ambulation. Children who have restricted opportunities for physical activity and who are bored easily consume calories in excess of their needs. This may be compounded by overfeeding by well-meaning family and friends. Proper dietary intake and a diversified recreational program help reduce the likelihood of obesity and enable children to maintain ambulation and functional independence for a longer time.

Mild to moderate cognitive impairment is commonly associated with MD. A deficiency of dystrophin isoforms in brain tissue causes cognitive and intellectual impairment ([Manzur, Kinali, and Muntoni, 2008](#)). The mean intelligence quotient (IQ) is approximately 20 points below normal, and frank mental deficit is present in 20% to 30% of these children. Verbal IQ is markedly low in boys with DMD, and emotional disturbance is more common than in other children with disabilities; however, children with DMD should be involved in early learning programs and eventually moved into regular classrooms as much as possible. Patients with Becker MD present later in life than those with DMD, but they often do not survive past the middle of the second decade, with few patients living into their 40s ([Sarnat, 2016b](#)).

Diagnostic Evaluation

The diagnosis of DMD is primarily established by blood polymerase chain reaction (PCR) for the dystrophin gene mutation ([Sarnat, 2016b](#)). Prenatal diagnosis is also possible as early as 12 weeks of gestation. Serum enzyme measurement, muscle biopsy, and EMG may also be used in establishing the diagnosis. Serum creatine kinase levels are extremely high in the first 2 years of life before the

onset of clinical weakness. If the child demonstrates the usual characteristics, has a positive family history for DMD, and the PCR result is positive, the muscle biopsy may be deferred.

Therapeutic Management

No curative treatment exists for childhood MD. The use of the corticosteroids prednisone and deflazacort has been evaluated as a treatment for DMD. Several clinical trials demonstrated increased muscle strength and improved performance and pulmonary function, with significant decrease in the progression of weakness, when prednisone was administered for 6 months to 2 years (Manzur, Kuntzer, Pike, et al, 2008). The American Academy of Neurology has published a practice parameter for the administration of corticosteroids in the treatment of DMD (Moxley, Ashwal, Pandya, et al, 2005). Major side effects in these studies included weight gain and a cushingoid facial appearance.

Maintaining optimal function in all muscles for as long as possible is the primary goal; secondary is the prevention of contractures. Children with DMD who remain as active as possible are able to avoid wheelchair confinement for a longer time. Maintenance of function often involves stretching exercises, strength and muscle training, breathing exercises to increase and maintain vital lung capacity, range-of-motion exercises, surgery to release contracture deformities, bracing, and performance of ADLs.

Parents should always be involved in making decisions about the child's care, and teaching regarding home safety and prevention of falls is important as well. Parents should also be encouraged to have the child keep follow-up appointments for medical care and physical and occupational therapy. Because respiratory tract infections are most troublesome in these children, influenza and pneumococcal vaccines are encouraged, and contact with persons with respiratory tract infections should be avoided. Action plans for prompt treatment of respiratory illness are important.

Eventually, respiratory and cardiac problems become the central focus of the debilitating illness. Children with neuromuscular disease develop abnormal breathing patterns, and hypoxia may occur as a result of inadequate oxygenation. Polysomnography should be performed once daytime symptoms of sleep-disordered breathing occur. The child and parents should be involved in a discussion of long-term ventilation options. Cardiac and respiratory assessment during wake/sleep cycles is imperative. Respiratory care for children with neuromuscular conditions such as SMA and DMD may involve the use of noninvasive ventilation with BiPAP on a temporary or full-time basis, mechanically assisted coughing (MAC), or tracheotomy and relief of airway obstruction with coughing and suctioning devices; the tracheotomy, however, is associated with more complications (Simonds, 2006; Young, Lowe, Fitzgerald, et al, 2007). Home pulse oximetry may be used to monitor oxygenation during sleep or to aid in decision making regarding the use of MAC to clear the airways.

Several devices are available for children with neuromuscular disease to assist in clearing the airway when the cough reflex is ineffective or diminished. The mechanical in-exsufflator (MIE; also referred to as *cough assist*) has been found to be safe and effective in the daily management of respiratory function (Kravitz, 2009; Miske, Hickey, Kolb, et al, 2004). The MIE delivers positive inspiratory pressures at a set rate followed by negative pressure exsufflation coordinated with the patient's own breathing rhythm. The exsufflation is designed to mimic a cough reflex so that mucus can be effectively cleared. Airway suctioning after exsufflation is accomplished as necessary to clear the airways. In children, the MIE device may be connected directly to a tracheostomy or used with a mouthpiece or face mask. Boitano's (2009) article provides a variety of equipment options, including various masks that can be used to deliver noninvasive positive pressure.

Manual cough-assisting techniques include glossopharyngeal breathing or air stacking (frog breathing); the abdominal thrust, which is similar to the Heimlich maneuver (Kravitz, 2009); and manual hyperinflation with a self-inflating resuscitation bag (without oxygen) and a mouthpiece. Hyperinflation may be used in conjunction with abdominal thrusts to improve peak cough flows (Boitano, 2009).

The use of routine chest physiotherapy (postural drainage) for DMD has not been adequately evaluated for its effectiveness in clearing the airway of mucus except when there is focal atelectasis and mucus plugging the airways (Kravitz, 2009).

Survival in individuals with DMD may be prolonged several years with the use of noninvasive ventilation and MAC as alternatives to tracheotomy and airway suctioning (Bach and Martinez,

2011; Simonds, 2006). The American Thoracic Society has published extensive guidelines for respiratory monitoring and care of children and adults with DMD (Finder, Birnkrant, Carl, et al, 2004).

The American Academy of Pediatrics Section on Cardiology and Cardiac Surgery (2005) recommends an extensive cardiac evaluation of the child diagnosed with either DMD or Becker MD. Patients with neuromuscular conditions may not have the typical signs and symptoms of cardiac dysfunction. Therefore, symptoms such as weight loss, nausea and vomiting, cough, increased fatigue on performance of ADLs, and orthopnea should be carefully evaluated to detect early signs of cardiomyopathy.

Genetic counseling is recommended for parents, sisters, and maternal aunts and their daughters. Long-term care, end-of-life care, and palliative care options are issues that the health care team must discuss with the child and family affected by MD (Finder, 2009). Professional counseling is necessary in some cases to allow frank discussion of these issues, and referrals should be made as appropriate.

Nursing Care Management

The care and management of a child with MD involve the combined efforts of a multidisciplinary health care team. Nurses can help clarify the roles of these health care professionals to family and colleagues. The major emphasis of nursing care is to help the child and family cope with a chronic, progressive, incapacitating disease; to help design a program that will afford maximal independence and reduce the predictable and preventable disabilities associated with the disorder; and to help the child and family deal constructively with the limitations the disease imposes on their daily lives. Because of advances in technology, children with MD may live into early adulthood; therefore, the goals of care should also involve decisions regarding quality of life, achievement of independence, and transition to adulthood.

Working closely with other team members, nurses assist the family in developing the child's self-help skills to give the child the satisfaction of being as independent as possible for as long as possible. This requires continual evaluation of the child's capabilities, which are often difficult to assess. Fortunately, most children with MD instinctively recognize the need to become as independent as possible and strive to do so.

Practical difficulties faced by families are physical limitations of housing, transportation, and mobility. Some families live in houses or apartments that are unsuited to wheelchairs. Transportation may also be a barrier for families of children with MD. Assisting with these challenges requires team problem solving. Diet, nutritional needs, and nutrition modification are discussed according to the needs of the individual child and family.

Children with MD tend to become socially isolated as their physical condition deteriorates to the point that they can no longer keep up with their friends and classmates. Their physical capabilities diminish, and their dependency increases at the age at which most children are expanding their range of interests and relationships. To gain peer associations, they often learn and use behaviors that bring them the rewards of other children's company. These friends are often children who have been rejected by more able-bodied classmates.

The parents' social activities are also restricted, and the family's activities must be continually modified to accommodate the needs of the affected child. When the child becomes increasingly incapacitated, the family may consider home-based care, an assisted living facility, or respite care. Unless the child is severely incapacitated, he should also be involved in the decisions regarding such care. Nurses can assist with decision making by exploring all available options and resources and support the child and family in the decision. Older boys with MD may also need psychiatric or psychological counseling to deal with issues such as depression, anger, and quality of life. Parents need encouragement to become involved in support groups because there is evidence that adequate social support from family, community, and other parents is crucial to appropriate coping in families with children with chronic illness.

Regardless of how successful the program or how well the family adapts to the disorder, superimposed on the physical and emotional problems associated with a child with a long-term disability is the constant knowledge of the ultimate outcome of the disease. These families encounter all of the manifestations of the child with a chronic fatal illness (see Chapter 17).

Nurses are especially valuable health professionals as they come to know the family and the family's challenges. Nurses can be alert to the problems and needs and make necessary referrals

when supplementary services are indicated. The Muscular Dystrophy Association—USA* has branches in most communities to assist families that have a member with MD.

Acquired Neuromuscular Disorders

Guillain-Barré Syndrome (Infectious Polyneuritis)

Guillain-Barré syndrome (GBS), also known as *infectious polyneuritis*, is an uncommon acute demyelinating polyneuropathy with a progressive, usually ascending flaccid paralysis. The hallmark of GBS is acute peripheral motor weakness. The paralysis usually occurs approximately 10 days after a nonspecific viral infection; GBS has also been reported after administration of certain vaccines (rabies, influenza, polio, and meningococcal) (Sarnat, 2016c). Several subtypes of GBS include acute inflammatory demyelinating neuropathy, acute motor axonal neuropathy, acute motor sensory axonal neuropathy, and Miller Fisher syndrome. Children are less often affected than adults; among children, those between 4 and 10 years old have higher susceptibility. The male-to-female ratio is reported to be 1.5 : 1. Two peak periods with an increased incidence of GBS have been identified: late adolescence and young adulthood.

Chronic inflammatory demyelinating polyradiculoneuropathies (CIDPs) are chronic types of GBS that recur intermittently or do not improve over a period of months to years (Sarnat, 2016c). The following discussion focuses on GBS.

Congenital GBS is rare yet may occur in the neonatal period and consists of hypotonia, weakness, and decreased or absent reflexes. Maternal neuromuscular disease may or may not be present. Diagnosis is established by the same criteria as in older children, but the symptoms gradually subside over the first few months of life and disappear by 12 months old (Sarnat, 2016c).

Pathophysiology

GBS is an immune-mediated disease often associated with a number of viral or bacterial infections or the administration of certain vaccines. It has been associated with infectious mononucleosis, measles, mumps, *Campylobacter jejuni* (gastroenteritis), cytomegalovirus, *Borrelia burgdorferi* (Lyme disease), Epstein-Barr virus, *Helicobacter pylori*, and *Mycoplasma* and *Pneumocystis* infections. Onset of GBS symptoms usually occurs within 10 days of the primary infection. Pathologic changes in spinal and cranial nerves consist of inflammation and edema with rapid, segmented demyelination and compression of nerve roots within the dural sheath. Nerve conduction is impaired, producing ascending partial or complete paralysis of muscles innervated by the involved nerves. GBS has three phases:

1. **Acute:** Phase starts when symptoms begin and continues until new symptoms stop appearing or deterioration ceases; it may last as long as 4 weeks.
2. **Plateau:** Symptoms remain constant without further deterioration; it may last from days to weeks.
3. **Recovery:** Patient begins to improve and progress to optimal recovery; it usually lasts a few weeks to months depending on the deficits incurred by the illness.

Diagnostic Evaluation

The diagnosis of GBS is based on clinical manifestations (Box 30-10), CSF analysis, and EMG findings. CSF analysis reveals an abnormally elevated protein concentration, normal glucose, and fewer than 10 white blood cells (WBCs)/mm³ (Sarnat, 2016c). EMG shows evidence of acute muscle denervation, but other laboratory studies are usually noncontributory. The symmetric nature of the paralysis helps differentiate this disorder from spinal paralytic poliomyelitis, which usually affects sporadic muscles.

Box 30-10

Clinical Manifestations of Guillain-Barré Syndrome

Initial Symptoms

Muscle tenderness

Paresthesia and cramps (sometimes)

Proximal symmetric muscle weakness

Ascending paralysis from lower extremities

Frequently involves muscles of trunk and upper extremities and those supplied by cranial nerves (especially facial)

Flaccid paralysis with loss of reflexes

May involve facial, extraocular, labial, lingual, pharyngeal, and laryngeal muscles

Intercostal and phrenic nerve involvement:

- Breathlessness in vocalizations
- Shallow, irregular respirations

Other Manifestations

Tendon reflexes depressed or absent

Variable degrees of sensory impairment

Muscle tenderness or sensitivity to slight pressure

Urinary incontinence or retention and constipation

Therapeutic Management

Treatment of GBS is primarily supportive. In the acute phase, patients are hospitalized because respiratory and pharyngeal involvement may require assisted ventilation, sometimes with a temporary tracheostomy. Treatment modalities include aggressive ventilatory support in the event of respiratory compromise, intravenous immunoglobulin (IVIG), and sometimes steroids; plasmapheresis and immunosuppressive drugs may also be used. Plasmapheresis has been shown to decrease the length of recovery in patients with severe GBS yet is expensive, and the side effects include hypotension, fever, bleeding disorders, chills, urticaria, and bradycardia. Some evidence reports equal benefits to treatment of GBS with IVIG administration or plasmapheresis; both sped up recovery time in studies reviewed (Hughes and Cornblath, 2005). There is evidence, however, of significant improvement in children with high-dose IVIG therapy (vs. supportive treatment alone) (Hughes, Swan, and van Doorn, 2012).

IVIG is now recommended as the primary treatment of GBS when administered within 2 weeks of disease onset (Hughes, 2008). Corticosteroids alone do not decrease the symptoms or shorten the duration of the disease.

Medications that may be administered during the acute phase include a low-molecular-weight heparin to prevent deep vein thrombosis (DVT), a mild laxative or stool softener to prevent constipation, pain medication such as acetaminophen, and a histamine-antagonist to prevent stress ulcer formation. Chronic neuropathic pain after GBS may be treated with gabapentin, which is reported to be more effective than carbamazepine (Sarnat, 2016c).

Rehabilitation after the acute phase may involve physical therapy, occupational therapy, and speech therapy. Additional consideration should be given to problems of general weakness and retraining for toileting and feeding (Lyons, 2008).

Course and Prognosis

Better outcomes are associated with younger age, no requirement for mechanical respiratory assistance, slower progression of disease, normal peripheral nerve function on EMG, and treatment with either IVIG or plasmapheresis. Recovery usually begins within 2 to 3 weeks, and most patients

regain full muscle strength. The recovery of muscle strength progresses in the reverse order of onset of paralysis, with lower extremity strength being the last to recover. Poor prognosis with subsequent residual effects in children is reportedly associated with cranial nerve involvement, extensive disability at time of presentation, and intubation.

Most deaths associated with GBS are caused by respiratory failure; therefore, early diagnosis and access to respiratory support are especially important. The rate of recovery is usually related to the degree of involvement and may extend from a few weeks to months. The greater the degree of paralysis, the longer the recovery phase.

Nursing Care Management

Nursing care is primarily supportive and is the same as that required for children with immobilization and respiratory compromise. The emphasis of care is on close observation to assess the extent of paralysis and on prevention of complications, including aspiration, ventilator-associated pneumonia (VAP), atelectasis, DVT, pressure ulcer, fear and anxiety, autonomic dysfunction, and pain.

During the acute phase of the disease, the nurse should carefully observe the child's condition for possible difficulty in swallowing and respiratory involvement. The child's respiratory function is closely monitored, and oxygen source, appropriate-sized insufflation bag and mask, endotracheal intubation and suctioning equipment, tracheotomy tray, and vasoconstrictor drugs are kept available. Vital signs are monitored frequently, as well as neurologic signs and level of consciousness. For children who develop respiratory impairment, the care is the same as that for any child with respiratory distress requiring mechanical ventilation.

Respiratory care, if intubation is required, requires close monitoring of oxygenation status (usually by pulse oximetry and sometimes arterial blood gases), maintenance of an open airway with suctioning, and postural changes to prevent pneumonia. Consideration should be given to preventing opportunistic infections such as VAP; meticulous oral care and hypopharynx suctioning, elevation of the head of bed 30 degrees, and strict asepsis with suctioning equipment (including catheters, a Yankauer device, or both) should be implemented to prevent VAP. Children with oral and pharyngeal involvement may be fed via a nasogastric or gastrostomy tube to ensure adequate feeding. It is also important to consider the possibility of stress ulcers in such patients and administer a proton pump inhibitor. Immobilization, which occurs with GBS, decreases GI function; therefore, attention to problems such as decreased gastric emptying, constipation, and feeding residuals requires nursing assessment and appropriate collaborative interventions. Temporary urinary catheterization may be required; urinary retention is common, and appropriate assessment of urinary output is vital. Sensory impairment and paralysis in the lower extremities make the child susceptible to skin breakdown; therefore, attention should be given to meticulous skin care. Passive range-of-motion exercises and application of orthoses to prevent muscle contracture are important when paralysis is present. Prevention of DVT is accomplished with pneumatic compression (antiembolism) devices, administration of a low-molecular-weight heparin, and early mobilization and ambulation. Autonomic dysfunction may be life threatening; thus, close monitoring of vital signs in the acute phase is essential.

A key to recovery in the child with GBS is the prevention of muscle and joint contractures, so passive range-of-motion exercises must be carried out routinely to maintain vital function. Although the child may have a generalized paralysis, cognitive function remains intact; therefore, it is important for nursing care to involve communication with the child or adolescent regarding procedures and treatments that may be frightening, especially if mechanical ventilation is required. Encourage parents to talk to the child and make eye and physical contact and to reassure the child during this phase of the illness.

Pain management is crucial in the care of children with GBS. Although neuromuscular impairment may make pain perception more difficult to accurately evaluate, objective pain scales should be used. Gabapentin and carbamazepine may be used to manage neuropathic pain in patients with GBS.

Physical therapy may be limited to passive range-of-motion exercises during the evolving phase of the disease. Later, as the disease stabilizes and recovery begins, an active physical therapy program is implemented to prevent contracture deformities and facilitate muscle recovery. This may include active exercise, gait training, and bracing.

Throughout the course of the illness, child and parent support is paramount. The usual rapidity

of the paralysis and the long recovery period greatly tax the emotional reserves of all family members. The parents and child benefit from repeated reassurance that recovery is occurring and from realistic information regarding the possibility of permanent disability. In the event of a residual disability, the family needs assistance in accepting and adjusting to the loss of function (see [Chapter 17](#)). The GBS/CIDP Foundation International* is a nonprofit organization devoted to support, education, and research. It provides families with support from recovered persons, publishes informational literature and a newsletter, and maintains a list of practitioners experienced with the disease.

Tetanus

Tetanus, or lockjaw, is an acute, preventable, but often fatal disease caused by an exotoxin produced by the anaerobic spore-forming, gram-positive bacillus *Clostridium tetani*. It is characterized by painful muscular rigidity primarily involving the masseter and neck muscles. There are four requirements for the development of tetanus: (1) presence of tetanus spores or vegetative forms of the bacillus, (2) injury to the tissues, (3) wound conditions that encourage multiplication of the organism, and (4) a susceptible host.

Tetanus spores are found in soil; dust; and the intestinal tracts of humans and animals, especially herbivorous animals. The organisms are more prevalent in rural areas but are readily carried to urban areas by the wind. The organisms are not invasive but enter the body by way of wounds, particularly a puncture wound, burn, or crushed area. They may enter through a minor, unnoticed break in the skin, such as a thorn or needle prick, bee sting, or scratch. In newborns, infection may occur through the umbilical cord, usually in situations in which infants are delivered in contaminated surroundings, severing the umbilical cord with non-sterile instruments, or the mother is not adequately immunized. The disease has the greatest incidence in months when persons are more involved in outdoor activities.

Pathophysiology

When prevention efforts are not effective and conditions are favorable, the organisms proliferate and form potent exotoxins, one of which is tetanospasmin. Tetanospasmin affects the CNS to produce the clinical manifestations of the disease. The ideal conditions for the organisms' growth are devitalized tissues without access to air, such as wounds that have not been washed or kept clean and those that have crusted over, trapping pus beneath. The exotoxin appears to reach the CNS by way of either the neuron axons or the vascular system. The toxin becomes fixed on nerve cells of the anterior horn of the spinal cord and the brainstem. The toxin acts at the myoneural junction to produce muscular stiffness and lower the threshold for reflex excitability.

The incubation period for tetanus varies from 3 days to 3 weeks and averages 8 days; most cases occur within 14 days. In neonates, it is usually 5 to 14 days. Shorter incubation periods have been associated with more heavily contaminated wounds, more severe disease, and a worse prognosis (American Academy of Pediatrics, Committee on Infectious Diseases, and [Pickering, 2012](#)).

The manner of onset varies, but the initial symptoms are usually a progressive stiffness and tenderness of the muscles in the neck and jaw. Eventually, all voluntary muscles are affected ([Box 30-11](#)). As the child recovers from the disease, the paroxysms become less frequent and gradually subside. Survival beyond 4 days usually indicates recovery, but complete recovery may require weeks.

Box 30-11

Clinical Manifestations of Tetanus

Initial Symptoms

Progressive stiffness and tenderness of muscles in neck and jaw

Characteristic difficulty in opening the mouth (trismus)

Risus sardonicus (sardonic smile) caused by facial muscle spasm

Progressive Involvement

Opisthotonic positioning

Boardlike rigidity of abdominal and limb muscles

Difficulty swallowing

Extreme sensitivity to external stimuli (slight noise, gentle touch, or bright light):

- Trigger paroxysmal muscle contractions that last seconds to minutes
- Contractions recur with increased frequency until almost continuous (sustained, tetanic)

Laryngospasm and tetany of respiratory muscles:

- Accumulated secretions
- Respiratory arrest
- Atelectasis
- Pneumonia

Other Aspects

Mentation unaffected; patient alert

Pain, anxiety, and distress reflected in:

- Rapid pulse
- Sweating
- Anxious facial expression
- Fever usually absent or only mild

Therapeutic Management

Primary prevention is key and occurs through immunization and boosters (American Academy of Pediatrics, Committee on Infectious Diseases, and Pickering, 2012). Once an injury has occurred, further preventive measures are based on the child's immune status and the nature of the injury. Specific prophylactic therapy after trauma is administration of **tetanus toxoid** or **tetanus antitoxin**. A dose of tetanus toxoid is not necessary for clean, minor wounds in children who have completed the immunization series (see Immunizations, Chapter 9, for age-specific recommendations).

An unprotected or inadequately immunized child who sustains a "tetanus-prone" wound (including wounds contaminated with dirt, feces, soil, and saliva; puncture wounds; avulsions; and wounds resulting from missiles, crushing, burns, and frostbite) should receive **tetanus immunoglobulin (TIG)**. Concurrent administration of both TIG and tetanus toxoid at separate sites is recommended both to provide protection and to initiate the active immune process (American

Academy of Pediatrics, Committee on Infectious Diseases, and [Pickering, 2012](#)).

After the individual has received primary tetanus immunization, antitoxin is believed to provide protection for at least 10 years and for a longer period after booster immunization (American Academy of Pediatrics, Committee on Infectious Diseases, and [Pickering, 2012](#)). Recently, the Advisory Committee on Immunization Practices recommended no specific time intervals between the administration of a tetanus- or diphtheria-toxoid containing vaccine and Tdap (tetanus, diphtheria, and pertussis) to provide protection against pertussis; other than a localized pain reaction, no other side effects were noted in persons who received the Td and Tdap at intervals as short as 18 months ([Centers for Disease Control and Prevention, 2011](#)). Completion of active immunization is carried out according to the usual pattern. Antibiotic treatment with penicillin G (or erythromycin or tetracycline in older children with allergy to penicillin) is important in the management of tetanus as an adjunct against clostridia; metronidazole is a viable alternative ([Arnon, 2016a](#)).

Safety Alert

Tetanus immunoglobulin (TIG) and tetanus toxoid are always administered via the intramuscular route in separate syringes and at separate sites; they are never administered by the intravenous (IV) route.

Aggressive supportive care is necessary to treat tetanus in the acute phase. The acutely ill child is best treated in an intensive care facility where close and constant observation and equipment for monitoring and respiratory support are readily available.

General supportive care is indicated, including maintaining an adequate airway and fluid and electrolyte balance, managing pain, and ensuring adequate caloric intake. Indwelling oral or nasogastric feedings may be required to maintain adequate fluid and caloric intake; continued laryngospasm may necessitate total parenteral nutrition or gastrostomy feeding. Severe or recurrent laryngospasm or excessive secretions may require advanced airway management, such as endotracheal intubation or tracheotomy.

TIG therapy to neutralize toxins is the most specific therapy for tetanus. Local care of the wound by surgical debridement and cleansing helps reduce the numbers of proliferating organisms at the site of injury. The cleansing should be repeated several times during the first 48 hours, and deep, infected lacerations are usually exposed and debrided. Infiltration of the wound with TIG is no longer considered necessary (American Academy of Pediatrics, Committee on Infectious Diseases, and [Pickering, 2012](#)).

Diazepam is the drug of choice for seizure control and muscle relaxation ([Arnon, 2016a](#)), but lorazepam (Ativan) may be used in some cases. Intrathecal baclofen, IV magnesium sulfate, dantrolene sodium, and midazolam may also be used in the management of muscle spasticity associated with tetanus. Patients with severe tetanus and those who do not respond to other muscle relaxants may require the administration of a neuromuscular blocking agent, such as rocuronium or vecuronium; intrathecal baclofen may be used as a muscle relaxant but only in the intensive care unit, because it often induces apnea. Because of their paralytic effect on respiratory muscles, use of these drugs requires mechanical ventilation with endotracheal intubation or tracheotomy and constant cardiopulmonary monitoring. Endotracheal tube insertion or tracheotomy is often indicated and should be performed before severe respiratory distress develops. Despite the absence of pain manifestation with these drugs, it is important to administer adequate analgesia. The administration of corticosteroids has met with success in some cases.

Nursing Care Management

The care of the child with tetanus requires supportive management with particular attention to airway and breathing. Respiratory status is carefully evaluated for any signs of distress, and appropriate emergency equipment is kept available at all times. The location, extent, and severity of muscle spasms are important nursing observations. Muscle relaxants, opioids, and sedatives that may be prescribed can also cause respiratory depression; therefore, the child should be assessed for excessive CNS depression. Attention to hydration and nutrition involves monitoring an IV infusion, monitoring nasogastric or gastrostomy feedings, and suctioning oropharyngeal secretions when indicated.

In caring for a child with tetanus during the acute phase, every effort should be made to control or eliminate stimulation from sound, light, and touch. Although a darkened room is ideal, sufficient light is essential so that the child can be carefully observed; light appears to be less irritating than vibratory or auditory stimuli. The infant or child is handled as little as possible, and extra effort is expended to avoid any sudden or loud noise to prevent seizures.

If a potent muscle relaxant such as vecuronium is used, the total paralysis makes oral communication impossible. The drug is not a sedative, however, and anxiety should be considered in children who are intubated. Therefore, all the child's needs must be anticipated and procedures carefully explained beforehand. Additional care is focused on preventing the complications associated with prolonged immobility, including decreased bowel and bladder tone and subsequent constipation, anorexia, DVT, pneumonia, and skin breakdown.

Because their mental status is clear, children are aware of what is happening to them and are often extremely anxious. They should not be left alone, and all efforts should be made to reduce anxiety, which can contribute to muscle spasms. Parents are encouraged to stay with the child to offer security and support. They also need support, information, and reassurance from the nurse.

Botulism

Botulism is an acute flaccid paralysis caused by the preformed toxin produced by the anaerobic bacillus *Clostridium botulinum*. In classic, or foodborne botulism, the most common source of the toxin is a contaminated food source. The disease has a wide variation in severity, from constipation to progressive sequential loss of neurologic function and respiratory failure. The most common source of the toxin is improperly sterilized home-canned foods. CNS symptoms appear abruptly approximately 12 to 36 hours after ingestion of contaminated food and may or may not be preceded by acute digestive disturbance (Box 30-12).

Box 30-12

Clinical Manifestations of Botulism

General Signs

- Weakness
- Dizziness
- Headache
- Difficulty talking and speaking
- Diplopia
- Vomiting
- Progressive, life-threatening respiratory paralysis

Infant Botulism*

- Constipation (a common symptom)
- Generalized weakness
- Decrease in spontaneous movements
- Diminished or absent deep tendon reflexes
- Loss of head control
- Poor feeding

Weak cry

Reduced gag reflex

Progressive respiratory paralysis

*Most commonly diagnosed as “rule out sepsis” in the acute phase because of clinical presentation. Sometimes may be misdiagnosed as spinal muscular atrophy or metabolic disease.

Human botulism is caused by neurotoxins A, B, E, and rarely F (American Academy of Pediatrics, Committee on Infectious Diseases, and Pickering, 2012). Types A and B are the most common causes of infant botulism. In addition to foodborne botulism, other forms include wound botulism; infant botulism; and artificial botulism, usually a result of bioterrorism.

Treatment consists of IV administration of botulism antitoxin and general supportive measures, primarily respiratory and nutritional. Toxins vary in protein-binding capacity. Some have a relatively short half-life and do not bind to tissues firmly; therefore, therapy is continued until paralysis subsides. Other toxins appear to bind irreversibly to nerve endings and are therefore not amenable to neutralization.

Infant Botulism

Infant botulism, unlike foodborne botulism in older persons, is caused by ingestion of spores or vegetative cells of *C. botulinum* and the subsequent release of the toxin from organisms colonizing the GI tract. *C. botulinum* types A and B are the most common causative strains of infant botulism. This form of botulism has become more prevalent than any other form. Many cases of infant botulism occur in breastfed infants who are being introduced to nonhuman milk substances (American Academy of Pediatrics, Committee on Infectious Diseases, and Pickering, 2012). There appears to be no common food or drug source of the organisms; however, the *C. botulinum* organisms have been found in honey. Botulism may occur in infants as young as 1 week old up to 12 months old with peak incidence between 2 and 4 months old.

The severity of the disease varies widely, from mild constipation to progressive sequential loss of neurologic function and respiratory failure (see Box 30-12). The affected infant is usually well before the onset of symptoms. Constipation is a common presenting symptom, and almost all infants exhibit generalized weakness and a decrease in spontaneous movements. Deep tendon reflexes are usually diminished or absent. Cranial nerve deficits are common, as evidenced by loss of head control, difficulty in feeding, weak cry, and reduced gag reflex. SMA type 1 and metabolic disorders are often mistaken for infant botulism in the initial diagnostic phase because of the similarities in clinical manifestations of hypotonia, lethargy, and poor feeding (Arnon, 2016b). Presenting clinical signs also often mimic those of sepsis in young infants. Botulism toxin exerts its effect by inhibiting the release of acetylcholine at the myoneural junction, thereby impairing motor activity of muscles innervated by affected nerves.

Diagnosis is made on the basis of the clinical history, physical examination, and laboratory detection of the organism in the patient's stool and, less commonly, blood. However, isolation of the organism may take several days; therefore, suspicion of botulism by clinical presentation should require emergent treatment (Arnon, 2016b). EMG may be helpful in establishing the diagnosis; however, results may be normal early in the course of the illness.

Treatment consists of immediate administration of botulism immune globulin intravenously (BIG-IV) (Arnon, 2016b) without delaying for laboratory diagnosis. Early administration of BIG-IV neutralizes the toxin and stops the progression of the disease. The human-derived botulism antitoxin (BIG-IV) has been evaluated and is now available nationwide for use only in infant botulism. Infants treated with BIG-IV usually have a shortened hospital stay from approximately 6 weeks to 2 weeks, reportedly as a result of decreased requirements for mechanical ventilation and intensive care (Arnon, 2016b). Approximately 50% of affected infants require intubation and mechanical ventilation; therefore, respiratory support is crucial, as is nutritional support because these infants are unable to feed. Trivalent equine botulinum antitoxin and bivalent antitoxin, used in adults and older children, are *not* administered to infants. Antibiotic therapy is not part of the management because the botulinum toxin is an intracellular molecule, and antibiotics would not be

effective; aminoglycosides in particular should not be administered because they may potentiate the blocking effects of the neurotoxin (Arnon, 2016b).

The prognosis is generally good if the patient is adequately treated, although recovery may be slow, requiring a few weeks after severe illness. Untreated patients may require a longer hospitalization.

Nursing Alert

Although the precise source of *C. botulinum* spores has not been identified as originating from honey in many cases of infant botulism, it is still recommended that honey not be given to infants younger than 12 months old because the spores have been found in honey (Centers for Disease Control and Prevention, 2010).

Nursing Care Management

Nursing responsibilities include observing, recognizing, and reporting signs of poor feeding, constipation, and muscle impairment in the infant with botulism and providing intensive nursing care when an infant is hospitalized (see Nursing Care Management for the infant with SMA, earlier in chapter, and Nursing Care of the High-Risk Newborn and Family, Chapter 8). Parental support and reassurance are important. Most infants recover when the disorder is recognized and BIG-IV therapy is implemented. Nursing care of the infant on mechanical ventilation requires observation of oxygenation status and vigilance for any complications. Parents should be aware that during recovery, infants fatigue easily when muscular action is sustained. This has important implications for timing the resumption of feedings because of the risk of aspiration. Parents should also be advised that normal bowel activity may not return for several weeks. Therefore, a stool softener can be beneficial.

Spinal Cord Injuries

Spinal cord injuries (SCIs) with major neurologic involvement traditionally have not been a common cause of physical disability in children. However, many children with these injuries are admitted to major medical centers, and because of the increased survival rate as a result of improved management, nurses have an important role in the care and rehabilitation of children with SCI.

Mechanisms of Injury

The most common cause of serious spinal cord damage in children is trauma involving motor vehicle accidents (MVAs) (including automobile-bicycle, all-terrain vehicles, and snowmobiles), sports injuries (especially from diving, trampoline activities, gymnastics, and football), birth trauma, and nonaccidental trauma. MVAs accounted for 56% of SCI in children, and adolescents and falls and firearm injury caused 14% and 9% of SCIs, respectively. The children injured (SCI) in MVAs were not properly restrained in 67.7% of the cases (Vitale, Goss, Matsumoto, et al, 2006). The increased use of recreational activities involving motorized vehicles such as jet water skis, all-terrain vehicles, and motorcycles has also increased the incidence of SCIs in children. Congenital defects of the spine (such as myelomeningocele) also may in some cases produce the effects of SCI.

Transverse myelitis (inflammation of the spinal cord) may be caused by illness and has also been reported to develop from inadvertent intraarterial administration of long-acting penicillin injected into the buttocks. Damage can be extensive enough to result in paraplegia or even lower limb amputation.

In MVAs, most SCIs in children are a result of indirect trauma caused by sudden hyperflexion or hyperextension of the neck, often combined with a rotational force. Trauma to the spinal cord without evidence of vertebral fracture or dislocation (**spinal cord injury without radiographic abnormality [SCIWORA]**) is particularly likely to occur in an MVA when proper safety restraints are not used. An unrestrained child becomes a projectile during sudden deceleration and is subject to injury from contact with a variety of objects inside and outside the vehicle. Individuals who use only a lap seat belt restraint are at greater risk of SCI than those who use a combination lap and shoulder restraint. High cervical spine injuries have been reported in children younger than 2 years old who are improperly restrained in forward-facing car seats. Infants who are improperly

restrained in an infant car seat may experience cervical trauma in a car crash. Small children may also be severely injured by deploying front seat air bags.

Falling from heights occurs less often in children than in adults, but vertebral compression from blows to the head or buttocks can occur in water sports (diving and surfing), falls from horses, or other athletic activities. Birth injuries may occur in breech deliveries from traction force on the spinal cord during delivery of the head and shoulders. When shaken, infants commonly sustain cervical cord damage, as well as subdural hematoma and retinal hemorrhages; cognitive impairment and death may occur subsequent to the traumatic event. Infants have weak neck muscles, and during vigorous shaking, their large and heavy heads rapidly wobble back and forth. A significant number of adolescents receive SCIs secondary to gunshot wounds, stabbings, and other violent inflicted injury.

Because of the marked mobility of the neck, fracture or subluxation (partial dislocation) is the most common immediate cause of SCI, particularly in the lower cervical region. Although unusual in adults, SCI without fracture is common in children, whose spines are suppler, weaker, and more mobile than those of adults. Therefore, the force is more easily dissipated over a larger number of segments. In infants and small children younger than 5 years old, upper cervical spine fractures and spinal compression are more common, but adolescents tend to have lower cervical and thoracolumbar fracture dislocations (Pruitt and McMahon, 2016).

The severity of the force, the mechanisms of the injury, and the degree of the individual's muscular relaxation at the time of the injury greatly influence the extent of the trauma. SCIs are classified as either complete or incomplete. In a complete injury, there is no motor or sensory function more than three segments below the neurologic level of the injury (Mathison, Kadom, and Krug, 2008). Incomplete lesions have several typical characteristics (Mathison, Kadom, and Krug, 2008):

Central cord syndrome: Central gray matter destruction and preservation of peripheral tracts; tetraplegia with sacral sparing common; some motor recovery gained

Anterior cord syndrome: Complete motor and sensory loss with trunk and lower extremity proprioception and sensation of pressure

Posterior cord syndrome: Loss of sensation, pain, and proprioception with normal cord function, including motor function; able to move extremities but have difficulty controlling such movements

Brown-Séquard syndrome: Unilateral cord lesion with a motor deficit on the opposite side of the body from the primary insult; absence of pain and temperature sensation on the opposite side from the injury

Spinal cord concussion: Transient loss of neural function below the level of the acute spinal cord lesion, resulting in flaccid paralysis and loss of tendon, autonomic, and cutaneous reflex activity; may last hours to weeks

The ASIA Impairment Scale (Box 30-13) combines motor and sensory function and is used to determine the severity of impairment from the injury (complete or incomplete). It may also be used to measure neurologic changes and functional goals for rehabilitation (Mathison, Kadom, and Krug, 2008).

Box 30-13

American Spinal Injury Association Impairment Scale

A—complete: No motor or sensory function is preserved in the sacral segments S4 to S5.

B—incomplete: Sensory but not motor function is preserved below the neurologic level and includes the sacral segments S4 to S5.

C—incomplete: Motor function is preserved below the neurologic level, and more than half of key muscles below the neurologic level have a muscle grade less than 3.

D—incomplete: Motor function is preserved below the neurologic level, and at least half of key muscles below the neurologic level have a muscle grade of 3 or more.

E—normal: Motor and sensory function are normal.

Clinical Syndromes (Optional)

Central cord

Brown-Séquard

Anterior cord

Conus medullaris

Cauda equina

Used with permission, [American Spinal Injury Association, 2009](#).

The injury sustained can affect any of the spinal nerves, and the higher the injury, the more extensive the damage. The child can be left with complete or partial paralysis of the lower extremities (**paraplegia**) or with damage at a higher level and without functional use of any of the four extremities (**tetraplegia**). A high cervical cord injury that affects the phrenic nerve paralyzes the diaphragm and leaves the child dependent on mechanical ventilation.

A mild but equally frightening form of cord trauma is **spinal cord compression**, a temporary neural dysfunction without visible damage to the cord. Complete tetraplegia can result but initially may not be differentiated from serious cord injury.

Clinical Manifestations

It is often difficult to determine the extent and severity of damage at first. Immediate loss of function is caused by both anatomic and impaired physiologic function, and improved function may not be evident for weeks or even months. Manifestation of the initial response to acute SCI is flaccid paralysis below the level of the damage. This stage is often referred to as **spinal shock syndrome** and is caused by the sudden disruption of central and autonomic pathways. Local effects of cord edema and ischemia produce a physiologic transection with or without an anatomic severance. Most children with an SCI experience some spinal shock. Manifestations include the absence of reflexes at or below the cord lesion, with flaccidity or limpness of the involved muscles, loss of sensation and motor function, and autonomic dysfunction (symptoms of hypotension, low or high body temperature, loss of bladder and bowel control, and autonomic dysreflexia).

Autonomic paralysis also affects thermoregulatory functions. Afferent impulses from temperature receptors in the skin are not integrated; therefore, the patient is subject to temperature increases or decreases in response to alterations in environmental temperature. Hyperthermia can result from excessive ambient temperature, such as too many covers.

Except in the situations previously mentioned, flaccid paralysis is replaced by spinal reflex activity and increasing spasticity or, in incomplete lesions, greater or lesser degree of neurologic recovery.

The paralytic nature of autonomic function is replaced by **autonomic dysreflexia**, especially when the lesions are above the mid-thoracic level. This autonomic phenomenon is caused by visceral distention or irritation, particularly of the bowel or bladder. Sensory impulses are triggered and travel to the cord lesion, where they are blocked, which causes activation of sympathetic reflex action with disturbed central inhibitory control. Excessive sympathetic activity is manifested by a flushing face, sweating forehead, pupillary constriction, marked hypertension, headache, and bradycardia. The precipitating stimulus may be merely a full bladder or rectum or other internal or external sensory input. It can be a catastrophic event unless the irritation is relieved.

Additional clinical findings of SCI may include numbness, tingling, or burning; priapism; weakness; and loss of bowel and bladder control ([Hayes and Arriola, 2005](#)).

Neurogenic shock occurs as a result of a disruption in the descending sympathetic pathways with loss of vasomotor tone and sympathetic innervations to the cardiovascular system ([Hayes and](#)

Arriola, 2005). Hypotension, bradycardia, and peripheral vasodilation occur as a result of neurogenic shock.

Children with suspected SCI may have suffered multiple injuries (e.g., head injury); therefore, multiple clinical manifestations may occur that may mask those of an SCI.

Therapeutic Management

Initial care begins at the scene of the accident with proper immobilization of the cervical, thoracic, and lumbar spine. Because of the complexity of these injuries, it is usually recommended that these persons be transported to a spinal injury center for care by specially trained health care personnel as soon as possible after the injury for appropriate diagnostic evaluation and intervention.

The initial management of the child with a suspected SCI should begin with an assessment of the ABCs—airway, breathing, and circulation. Guidelines for the child who is found unconscious with an unknown cause are discussed in [Chapter 23](#) (Cardiopulmonary Resuscitation). The airway should be opened using the jaw-thrust technique to minimize damage to the cervical spine. The child is monitored for cardiovascular instability, and measures are taken to support systemic blood pressure and maintain optimal cardiac output. Because MVA and other trauma in children may involve internal organ damage and potential bleeding, abdominal distention and other signs are acted on immediately to prevent further systemic shock. After the child is stabilized and transported to a regional trauma center, a thorough evaluation of neurologic status and any other associated trauma is carried out by the multidisciplinary team. In the emergency department, spinal immobilization should be maintained until a thorough neurologic assessment is completed; in children, this typically involves a CT scan and possibly an MRI. Additional interventions are discussed in the Nursing Care Management section.

SCI management guidelines and standards of care have been published for adult and pediatric patients with SCIs by the American Association of Neurological Surgeons and the Congress of Neurological Surgeons. Recently, evidence-based guidelines for the management of SCI in children were published (Rozelle, Aarabi, Dhall, et al, 2013).

IV methylprednisone may be started within the first 12 hours after the injury to decrease inflammation and minimize further injury; however, its use in small children is controversial.

A number of progressive rehabilitation modalities have been developed in recent years that have the potential for increasing the quality of life for children with SCI. One treatment is functional electrical stimulation (FES), also referred to as *functional neuromuscular stimulation*, or *neuromuscular electrical stimulation* (NMES). With this treatment, an electrical stimulator is surgically implanted under the skin in the abdomen, and electrode leads are tunneled to paralyzed leg muscles, enabling the child to sit, stand, and walk with the aid of crutches, a walker, or other orthoses. The stimulator can also be used to elicit a voluntary grasp and release with the hand. Before the latter can be accomplished, a number of surgical tendon transfers may be required for elbow extension, wrist extension, and finger and thumb flexion. In addition, FES has therapeutic benefits, which include increased muscle strength, improved gait function, and increased cardiovascular fitness (Thrasher and Popovic, 2008). Tendon transfers have been shown to be successful in enhancing hand and arm function, increasing pinch force, and facilitating independence in ADLs (Hosalkar, Pandya, Hsu, et al, 2009). Restoration of hand and arm function enables children with SCI to perform self-catheterization and achieve greater independence in personal hygiene.

Exercise is considered an integral part of SCI rehabilitation; exercise may enhance neuroplasticity and decrease further muscle atrophy. Examples of exercise modalities in SCI patients include upper body strength training and hand cycling (Hosalkar, Pandya, Hsu, et al, 2009).

Administration of pharmacologic agents such as clonidine hydrochloride may improve ambulation in patients with partial SCIs, and exercise therapy through interactive locomotor training has helped some individuals with SCI regain ambulatory function.

A number of orthoses or ambulation aids such as crutches may still be necessary to achieve upright mobility, yet as robotic technology advances, so do the chances for improved mobilization in children with SCI. Mechanical or robotic orthoses may be used in conjunction with FES to enable ambulation in persons with SCI (To, Kirsch, Kobetic, et al, 2005). Gait training may be achieved with a number of different modalities, including a stationary cycle; however, no specific method has proved superior to the others. FES has also been effective in reducing complications from bladder and bowel incontinence and in assisting males in achieving penile erection.

Surgical interventions for SCI include early cord decompression (decompression laminectomy)

and cervical or thoracic fusion. Crutchfield, Vinke, or Gardner-Wells tongs and skeletal traction may be used for early cervical vertebral stabilization. A halo vest may be suited for ambulation after the acute phase (see also discussion of cervical traction in [Chapter 29](#)). After cervical spinal fusion, a hard cervical collar or sterno-occipital-mandibular immobilizer brace may be worn until the fusion is solidified. When SCI occurs in young children and preteens, scoliosis develops over time and often requires surgical consideration ([Parent, Mac-Thiong, Roy-Beaudry, et al, 2011](#)).

Nursing Care Management

The nursing care of the child affected by SCI is complex and challenging. A multidisciplinary SCI team is equipped to manage the acute phase of the injury, and some members, including the nurse, may follow the patient to eventual recovery. Nursing management is concerned with ensuring adequate initial stabilization of the entire spinal column with a rigid cervical collar with supportive blocks on a rigid backboard. The traumatic event causing the injury may or may not be recalled if the child lost consciousness; such events are extremely frightening to the child. The young child may also be frightened by the immobilization process and the inability to move the extremities; therefore, it is important to reassure and comfort the child during this process.

During the acute phase of the injury, it is imperative that airway patency be ensured, complications prevented, and function maintained. Evaluate the extent of the neurologic damage early to establish a baseline for neurologic function. Continual assessment of sensory and motor function should occur to prevent further deterioration of neurologic status as a result of spinal cord edema. The ASIA Impairment Scale can be used to assess neurologic function on a routine basis during the patient's recovery. After the patient is admitted, further evaluation of his or her ability to perform ADLs and need for assistance during recovery can be made with the Functional Independence Measure scale.

Nursing care during the acute phase should also focus on frequent monitoring of neurologic signs to determine any changes in neurologic function that require further intervention (e.g., level of consciousness using the Glasgow Coma Scale). In addition to airway maintenance, the nurse should monitor for changes in hemodynamic status that may require immediate medical attention. Neurogenic shock consists of hypotension, bradycardia, and vasodilation. Inotropic medications may be required to maintain adequate perfusion. Renal function is closely monitored by measuring urinary output and fluids administered. The child with a head injury may experience elevated intracranial pressure; therefore, changes in neurologic status are reported to the practitioner. Fluid restriction may be required if intracranial pressure is elevated, so fluid intake should be closely monitored.

The nursing care of the child with an SCI is, in most respects, the same as that of any immobilized child (see *The Immobilized Child*, [Chapter 29](#)). Additional aspects of care that should be addressed on an individual basis include hypercalcemia in adolescent boys, DVT, latex sensitization, pain, hypothermia and hyperthermia, spasticity, autonomic dysreflexia, and sleep-disordered breathing ([Vogel, Betz, and Mulcahey, 2012](#)).

Respiratory care often focuses on maintaining an adequate airway and effective ventilation. The child with a high-level cervical injury (C3 and above) requires continuous ventilatory assistance. In most instances, a tracheostomy is the method of choice for greater ease in clearing secretions and for less trauma to tissues during long-term ventilatory dependence. In some children, breathing pacemaker devices (phrenic nerve stimulators) are implanted to stimulate the phrenic nerve and produce diaphragmatic contractions and lung expansion without assisted ventilation. In the child who does not require mechanical ventilation, special attention to clearance of secretions is vital because of decreased pulmonary function. In addition to percussion and postural drainage, the child may require a cough-assist device to clear secretions effectively (see *Duchenne [Pseudohypertrophic] Muscular Dystrophy, Therapeutic Management*).

Temperature is often poorly regulated in children with SCI; therefore, body temperature must be monitored closely for fluctuations. Response to environmental temperature changes may be slow or absent, and the ability to dissipate heat through the process of shivering may be compromised.

Children with SCI have unique needs in relation to skin care. Because of decreased sensation and impaired mobility, they depend on others to assess and assist in the management of intact skin. Skin care practices are the same as those for any child who is immobilized. A skin score scale (such as the Braden Q Scale) should be used to objectively evaluate risks for skin breakdown and skin conditions ([Noonan, Quigley, and Curley, 2011](#)). An alternating-pressure mattress or other pressure

relief or reduction device is kept underneath the child, and the skin is thoroughly inspected at least once a day (or more often if there is increased risk) for signs of pressure and breakdown, especially over bony prominences.

Bowel and bladder function is often affected in the child with SCI. CIC may be required to regularly empty the neurogenic bladder and prevent urinary tract infections. A regular bowel management program is tailored to the child's needs.

Pain management is vital in children and adolescents with SCI. In children with upper motor neuron involvement, the spasticity that develops may require administration of an antispasmodic medication, such as diazepam. Baclofen is considered the drug of choice for reducing muscle spasticity. Gabapentin may be used to treat neuropathic pain. Botulinum toxin type A and α_2 -adrenergic agonists may be used in older children with SCI to decrease muscle spasticity.

All adaptive devices help children increase their mobility, function, and endurance. Children with some lower extremity function progress to parallel bars and then to a walker; children with tetraplegia learn to use a wheelchair—among the most valuable aids available to children with SCIs (Fig. 30-9). The wheelchair should be selected carefully in relation to where it will be used, the architectural barriers, and the child's functional capacity. For children with severe upper extremity paralysis, a variety of motorized wheelchairs are used; however, the more complex they are, the greater their cost, weight, and tendency to break down. Wheelchair tolerance is gained over time and is accompanied by measures to prevent orthostatic hypotension and pressure ulcers.

FIG 30-9 A wheelchair allows an adolescent mobility and independence. (Courtesy of Texas Children's Hospital, Houston, TX.)

A variety of orthoses and other appliances can be adapted for use by many children. The primary purpose of lower extremity bracing in children with SCIs is for ambulation.

During the recovery and rehabilitation phase, patients with SCI must be carefully monitored for complications of immobility such as DVT and pulmonary embolus. Children with high-level lesions are susceptible to the development of **autonomic dysreflexia**, which requires prompt action to prevent encephalopathy and shock. Clinical manifestations of autonomic dysreflexia include a drastic increase in systemic blood pressure, headache, bradycardia, profuse diaphoresis, cardiac arrhythmias, flushing, piloerection, blurred vision, nasal congestion, anxiety, spots on the visual field, or absent or minimum symptoms (Vogel, Hickey, Klaas, et al, 2004).

The child and family with SCI are prepared for the eventual discharge from the acute care facility to a rehabilitation center. The major aims of physical rehabilitation are to prepare the child and family to achieve normalization and resume life at home and in the community. Additional goals of rehabilitation in children with SCI are to promote independence in mobility and self-care skills, academic achievement, independent living, and employment.

The nurse is a crucial member of the health care team in relation to helping the family cope with

the magnitude of the injury and disability, understand the extent of the disability, verbalize expected outcomes, and move toward eventual rehabilitation and normalization within the child's capabilities. The goals of rehabilitation include preparing the child and family to live at home and function as independently as possible.

NCLEX Review Questions

1. The most common complication that should be anticipated and observed for in an infant with myelomeningocele after surgical repair of the defect is:
 - a. Urinary stress
 - b. Chiari malformation
 - c. Hydrocephalus
 - d. Latex allergy
2. A 14-year-old male with a spinal cord injury (SCI) is placed on a standing table and suddenly begins to sweat profusely and complain of a headache. The nurse takes a set of vital signs and notes a significant increase in systolic blood pressure and a heart rate of 50 bpm. The most helpful intervention in this situation would be for the nurse to:
 - a. Place the adolescent back in his wheelchair and take him to his room
 - b. Palpate the bladder for distention
 - c. Administer a routine analgesic for his headache and discontinue the therapy
 - d. Place the standing table in a horizontal position and allow the adolescent to rest for a few minutes
3. The primary risk factor for the development of cerebral palsy (CP) is:
 - a. Maternal chorioamnionitis
 - b. Premature birth
 - c. Birth asphyxia
 - d. Intraventricular hemorrhage
4. Urinary system distress (neurogenic bladder) in children with spina bifida (SB) is managed by:
 - a. DDAVP (1-deamino-8-D-arginine vasopressin)
 - b. Clean intermittent catheterization (CIC)
 - c. Continuous urinary catheterization
 - d. Mitrofanoff procedure
5. Which of these statements accurately describes Duchenne muscular dystrophy (DMD)? Select all that apply.
 - a. The absence of dystrophin leads to muscle fiber degeneration.
 - b. DMD is inherited as an X-linked recessive trait.
 - c. Cognitive and intellectual impairment are rare in children with DMD.
 - d. Affected children have a waddling gait and lordosis and fall frequently.
 - e. Ambulation usually becomes impossible by 12 years old, and affected children are confined to a wheelchair.
 - f. Affected children must be hospitalized when ambulation becomes impossible.

Correct Answers

1. c; 2. b; 3. b; 4. b; 5. a, b, d, e

Answers to Critical Thinking Case Studies

Chapter 8

Jaundice

1. Evidence: Yes, there are sufficient data to arrive at some possible conclusions.
2. Assumptions:
 - a. See text, pp. 256-265.
 - b. Serum bilirubin levels are within acceptable limits. Based on the available data, the infant is within the low-intermediate risk zone, and ABO incompatibility–related hemolysis is not evident but may warrant further investigation.
 - c. Oral intake is adequate; urine and stool output is appropriate (based on urine output of one wet diaper per each day of life = five wets).
 - d. The assessment of behavior and reflexes indicates no particular concerns; the newborn appears to be healthy.
3. No immediate intervention to reduce bilirubin is warranted at this time, although the treatment is a medical decision. Nursing care should focus on alleviating parents' concerns regarding condition of infant, who appears to be healthy, and addressing their concerns about the misinformation on the potential for brain damage (which is a nonexistent problem at this point). Encourage the mother to continue breastfeeding on demand and observe the infant's activity levels, intake, and urinary and stool output. Emphasize that jaundice and hyperbilirubinemia are transient conditions of the newborn. At this point, a follow-up appointment should be scheduled with the primary practitioner in 24 hours to monitor the bilirubin level, address the parents' concerns, and monitor the infant's weight.
4. Yes, the infant's laboratory data and physical assessment data support these conclusions. Additionally, knowledge about physiologic hyperbilirubinemia of the newborn supports these conclusions. Phototherapy does not seem warranted at this time based on the available data.

Chapter 10

Food Allergy Anaphylaxis

1. Evidence: There is sufficient evidence to indicate that Jason is having an anaphylactic reaction to an ingested food (peanuts in this case). Peanuts are the most common food allergen in children in the United States.
2. Assumptions: See [pp. 335-337](#).
 - a. Clinical manifestations of anaphylaxis include rash, cough, wheezing, abdominal pain, and anaphylaxis including cyanosis, hypotension, and respiratory arrest.
 - b. The emergency treatment is to administer an intramuscular (IM) dose of epinephrine.
 - c. In this scenario, the correct answer is #3; it would be most appropriate to promptly administer a dose of IM epinephrine.
 - d. It is estimated that Jason weighs 45 pounds (20.5 kg) (see [p. 337](#)). The appropriate dose is 0.2 mg; however, if the school nurse has an EpiPen and an EpiPen Jr., then she should administer the EpiPen Jr.
3. Implications for nursing care:
 - The immediate priority is to administer the epinephrine. Jason should be closely monitored, including vital signs, work of breathing, comfort, and anxiety. Several reports in the literature indicate that children often die from food allergy anaphylaxis because of the fear of administering epinephrine for its potential side effects.
 - The second and third priorities would be to call 911 and then call Jason's parents and notify them of Jason's reaction, the intervention taken, and Jason's status.
 - Meanwhile, Jason should continue to be observed by the nursing students and school nurse (until emergency medical services arrives).
4. The results could be lethal as discussed above. It is within the scope of practice of the school nurse to administer the IM epinephrine when the signs and symptoms of anaphylaxis are observed.
5. Yes, there is sufficient evidence for these interventions based on the literature on food allergy anaphylaxis in children.

Chapter 15

Discussing the Future

1. Evidence: Yes, there is sufficient information to arrive at a conclusion about what advice to give Jeremy's mother.
2. Assumptions:
 - a. During adolescence, teens consider all of their past relationships as they attempt to form their own personal identity. They attempt to formulate a satisfactory identity from a multiplicity of roles, aspirations, and identifications. The process of developing this identity is time consuming and can be associated with confusion and discouragement.
 - b. If significant others are too persistent and demand that adolescents make specific decisions or behave in definite ways, adolescents often make premature decisions and accept roles that do not incorporate their own personal goals or aspirations.
 - c. Parents who communicate well with their teens have an open, nonjudgmental, non-dictatorial manner. They demonstrate that they are available and willing to listen to their teenagers. However, they also wait until the teenager opens the discussion, and then they listen attentively and allow the teen to explore issues.
3. The nursing priority in this situation is to have the mother become more aware that Jeremy is not likely to discuss his concerns on a timetable and that it is important for her to respect his point of view. Although Jeremy wants his mother's guidance and support, he does not want to be told what to do, and he needs an opportunity to express his own feelings and views. An example of appropriate advice to give Jeremy's mother might be: "Be open and available to Jeremy. Tell him what you think but *not what to do.*"
4. Yes, the information about how teens formulate a personal identity and the principles of effective parent communication allow the nurse to formulate this response.

Discussing Sexual Orientation With Adolescents

1. Evidence: No, there are insufficient data to arrive at a conclusion about John's sexual orientation. Further discussion with him is necessary before making any assumptions.
2. Assumptions:
 - a. Studies of gay men and lesbians indicate that adolescence is the time when individuals become aware of same-sex attraction. Homosexual and bisexual youths are at risk for health-damaging

behaviors, such as early initiation of sexual behavior, substance abuse, suicide, and running away from home.

- b. Homosexual and bisexual youths are often confronted with the anti-homosexual attitudes and values of society. This reaction of society makes it difficult for homosexual and bisexual youths to grow up and become healthy physically and mentally.
- c. Health care professionals who work with adolescents should consider the adolescent's increasing independence and responsibility while ensuring confidentiality.

3. The nurse's first priority in this situation is to give John permission to discuss his feelings about this topic. He has come to the nurse practitioner to discuss this matter, and he probably feels comfortable sharing this information with the nurse practitioner. The nurse practitioner needs to be open and nonjudgmental in interactions with John. He needs to know that the nurse practitioner will maintain confidentiality, appreciate his feelings, and remain sensitive to his need to talk about this topic. An example of an appropriate response for the nurse practitioner might be: "John, tell me more about how you came to this conclusion."

4. Yes, the information about sexual orientation in adolescence and the role of the health care professional support this conclusion.

Chapter 16

Attention-Deficit/Hyperactivity Disorder

1. Evidence: Yes, there are sufficient data to arrive at a possible conclusion.
2. Assumptions:
 - a. Methylphenidate is a stimulant that increases dopamine and norepinephrine levels that lead to stimulation of the inhibitory system of the central nervous system.
 - b. Common side effects of methylphenidate include anorexia, abdominal pain, headaches, sleep disturbances, and decreased growth velocity.
 - c. If decreased appetite is a concern, giving the psychostimulants with or after meals rather than before, encouraging consumption of nutritious snacks in the evening when the effects of the medication are decreasing, and serving frequent small meals with healthy “on the go” snacks are helpful interventions. Sleeplessness is reduced by administering medication early in the day.
3. If decreased appetite is a concern, giving the psychostimulants with or after meals rather than before, encouraging consumption of nutritious snacks in the evening when the effects of the medication are decreasing, and serving frequent small meals with healthy “on the go” snacks are helpful interventions. Sleeplessness is reduced by administering medication early in the day. Although Johnnie seems to have responded favorably to his medication and has demonstrated several positive effects of methylphenidate (improvement in math class and increasing self-confidence in social skills), the nurse should be concerned about the fact that Johnnie has not eaten his lunch for the past week and that he is not hungry. Decreased appetite is a negative side effect of methylphenidate.
4. Yes, the data indicate that Johnnie is currently experiencing a decrease in his appetite. Because decreased appetite is a common side effect of methylphenidate, there is a high probability that this symptom is related to Johnnie's medication. However, adjusting or changing the times the medication is administered can often alleviate this side effect. Another option is to ask Johnnie's physician to switch his medication to a sustained time-release form of methylphenidate that can be given once per day in the morning.

Anorexia Nervosa

1. Evidence: Using the clinical manifestations of anorexia nervosa (AN) (see [Box 16-6](#)), there is sufficient evidence to support the conclusion that Jane has AN.
2. Assumptions:
 - a. Young adolescent girls with AN are often high achievers or excellent students. They have an abundance of energy, a distorted

body image, and a fear of gaining weight.

- b. A family crisis can influence AN. Jane's parents are currently in the middle of a divorce, and in this type of situation, some teens feel they have no control over events in their life. Consequently, some adolescents take control by refusing to eat and developing AN.
- c. Jane is engaging in increased physical activity and is skipping lunch several days each week. On physical examination, she has a decreased body temperature (96.8° F [36° C]) and she has lost 20 pounds (9 kg) in the past year (she is at <85% of her expected weight). She also told the nurse practitioner that she has not had her menstrual period for 3 months. These manifestations are all congruent with AN.
- d. AN is treated by a team of health professionals who address the abnormal eating patterns and altered body image of the patient and the dysfunctional family dynamics that accompany this disorder.

3. Jane should be referred to a specialist who deals with adolescents with AN.

4. Yes, the evidence supports the conclusion.

Prescription Medication Abuse in Adolescence

1. Evidence: Yes. It is apparent that the adolescent needs further evaluation and should not be returned to class at this time. The slurred speech, short-term memory lapse, delayed pupillary reaction, and elevated heart rate indicate further evaluation should be sought.

2. Legally, the nurse must call the girl's parents and inform them that she appears to need medical attention. It is up to the parents or guardians to take the next step (i.e., take her to the nearest emergency department [ED] or to her primary care practitioner). As a school nurse, Sally must decide if the girl's life is in immediate danger (e.g., vital signs and neurologic signs unstable); it does not appear to be at this time. Sally does not have the authority to call emergency medical services (EMS) or to take the girl to the ED at this time.

3. Assumptions:

- a. The assessment findings of memory lapse, slurred speech, decreased respirations, sluggish pupil reactivity, and tachycardia indicate a need for further medical evaluation and observation.

- b. See [pp. 494-497](#).

4. Nursing implications include close observation for any signs of deterioration in vital signs or respiratory status. Sally must notify the girl's parents or guardians. In the event they cannot be reached, the nurse should call EMS and ask that the girl be transported to an acute care facility for observation. In the ED, the girl will be triaged, and vital signs will be taken. Urine drug screen will be obtained to determine what she has in her system, and frequent neurologic signs will be

monitored. She will also probably have a peripheral intravenous line started and blood tests drawn for baseline (chemistry and electrolytes, possibly a liver panel). If it is determined that an opioid was taken, naloxone may be administered, depending on her current status.

Chapter 18

Diagnosis of Down Syndrome

1. The degree of cognitive impairment in a child with Down syndrome (DS) is variable and may be mild (IQ of 50 to 70), moderate (IQ of 35 to 50), or occasionally severe (IQ of 20 to 35). In approximately 95% of children with DS, the condition is sporadic because of the nonfamilial trisomy 21, in which there are 47 chromosomes with a free extra chromosome 21.
2. There are significant risks of hearing loss, obstructive sleep apnea, otitis media, eye disease, congenital heart defects, neurologic dysfunction, hip dislocation with less commonly transient myeloproliferative disorder and leukemia, and thyroid disease. The positive effect on academics in the DS children within a regular classroom was most pronounced for reading skills with the addition of parental assistance at home. Placement in a regular classroom directly stimulates children with DS to acquire better academic skills to some extent. A medical home and DS specialty clinic can identify and address many health care needs of children with DS.
3. Encourage parents to express their feelings of grief, anger, sadness, and guilt regarding the birth of their cognitively impaired child. Demonstrate acceptance of the child because parents are sensitive to professionals' attitudes. Stress with the parents that the infant with DS needs to be fed, dressed, diapered, cuddled, held, talked to, played with, and loved, just like any other newborn. Explain the basis of DS to parents and provide counseling by a genetic professional, if available. Establish a medical home for the child with DS because of the risk of medical and behavioral problems. Discuss the benefits of early intervention educational programs and vocational training. Discuss both the positive and negative consequences of being a sibling of a child with DS, including a developmental explanation given to siblings regarding having a sibling with DS and the interventions to help siblings to adapt effectively to the experience of being raised in a family that includes a child with DS. Inform parents about the specialty DS clinics and available parent support programs and resources (e.g., pamphlets, articles, books, e-newsletters, web pages).
4. Parents of cognitively impaired children who are eligible will apply for available family financial and medical support. Parents will explain the basis of DS to medical providers and their families with the assistance of medical providers, if needed. Parents and the child with DS will participate in a family-centered medical home and DS specialty clinic, if available. The child with DS will participate in an early intervention educational program and may participate in vocational training. Parents of a child with DS will augment the child's educational program by providing supplemental education instruction within the home environment. Parents will identify the availability of a DS support group and other resources.

Chapter 19

Complementary and Alternative Medicine

1. Evidence: There is limited evidence to draw certain conclusions without obtaining more data from the parents. It would be appropriate to gather more information before jumping to any major conclusions at this time.

2. Assumptions:

- a. Complementary and alternative medicine (CAM) is more common in American households than previously reported. Much of the concern surrounding complementary therapies, especially in children, is the lack of sufficient data regarding their effectiveness, benefit, and the potential harm that may occur as a result of such treatments. In some cases, CAM therapies may counteract certain medications or the effects of prescribed therapies. It has become more common for practitioners in emergency medicine to encounter patients who are taking CAM therapy in addition to prescription medications or treatments for conditions such as eczema, asthma, colds, and upper respiratory tract problems.
- b. Folk remedies are common among certain ethnic groups and subgroups within the United States. Many are based on traditional family remedies that have been proven to be neither effective nor entirely harmful in most cases. However, a few remedies could be potentially harmful, especially to children, if these remedies counteract the effects of prescribed treatments that are known to be effective.
- c. The nurse's role in such cases is to gather sufficient data from the family about the practice, discuss the treatment (CAM) in a nonjudgmental manner, and be cognizant of the effects of the treatment on the child's current health status and potential effects on other medical treatment regimens.

3. Give the family their penny and open a dialog about the traditional practice they are using. Additional information should be gathered in a nonjudgmental manner, and the discussion should center on the family's traditional beliefs regarding the practices, the prescribed medical regimen, and whether there is a conflict or potential for harm. There is no need to stop the treatment unless potential harm to the child may occur. A discussion with the primary practitioner regarding the use of CAM for Maria should ensue followed by a discussion with the entire family, if necessary. The contents of the bottle will more than likely be revealed during the discussion with the family. It is important to respect the family's wishes regarding traditional folk or CAM rituals yet remain mindful of potential harmful effects on the child. It is not likely that telling the family to stop the ritual will be successful because these beliefs are deeply ingrained into cultural, religious, and

medical practice; the family is more likely to continue the ritual at home on discharge and further disregard other instructions for care if a confrontational approach is adopted by the nursing and medical staff. The important concept for the staff and family to focus on is the ultimate well-being of the child. What you have probably observed is Santeria, the African-Caribbean religion that was brought to the New World by slaves from West Africa. It is common among immigrants from Cuba, Puerto Rico, Brazil, and Santo Domingo, and it is believed that a majority of Latin American immigrants will have contact with Santeria sometime in their lives.

4. As yet, there is insufficient evidence to indicate that harm is being done by the CAM ritual. Further data need to be gathered, and then a decision about further discussion of the CAM practice may occur.

Playroom and Hospital Procedures

1. Evidence: Yes, there is sufficient evidence regarding this incident to draw some conclusions.
2. Assumptions:
 - a. Regardless of how minor a procedure such as a venipuncture may seem to an adult health care worker, it represents a major threat to a child. One must consider the child's age, illness, developmental level, and previous experiences with venipunctures.
 - b. Play is an important function of childhood whether the child is sick or well. Through play, children may act out fears, concerns, anger, and other behaviors they may not feel comfortable expressing to adults in a confrontational manner. Play is an important part of the hospitalized child's life, and it is a vehicle for promoting optimal development.
 - c. It is important to have the blood drawn so that Dr. Lung may plan a therapeutic regimen; however, one must consider another issue: there appears to have been no advance preparation of the child's skin to minimize or prevent pain from the procedure. Regardless of the phlebotomist's skill in performing the procedure, it is also important to consider the fact that the negative repercussions for performing the procedure at this point may outweigh the positive benefits.
 - d. All staff on the pediatric floor must be in agreement about respecting the child's personal space in the playroom and about adhering to unit policies or rules so that respect is maintained. Failure to respect the child's space may engender fear in other children who perceive that the playroom is not a safe place after all. The fear of having other procedures performed in the playroom may prevent children from going there to participate in therapeutic

and interactive play.

3. It is important to maintain a fair balance between what constitutes therapeutic management of illness and childhood recreation. It would be appropriate in this situation to intervene and ask the phlebotomist to return in 30 minutes to an hour and indicate that the child will be ready for the venipuncture in the treatment room at that time. It is important to stress that the playroom is off limits for procedures. It would be appropriate to discuss this plan with Joel, indicating that the procedure will be performed at the designated time. It is also important to explore pain management issues with Joel: Does he usually use local anesthetic or other topical remedies to prevent pain at the site? If so, it will be necessary to make such arrangements in advance, possibly now, so his pain is managed appropriately. As the nurse, it is appropriate to discuss a delay in obtaining the laboratory results with Dr. Lung and the reasons for the delay. As workers on the pediatric floor, it is important for medical and nursing staff to communicate effectively. If this arrangement does not suit Dr. Lung's time frame for accomplishing certain tasks, one might suggest a trade-off. The nurse may draw the blood in the treatment room after preparations are made and Joel agrees on a time. Remember, however, that school-age children are prone to "bargain" for more time to delay or prevent the event because it is painful. One must be gently firm about the agreed-on time of the procedure and not allow further delays to accommodate the child who just does not want the procedure performed—ever, in most cases.

4. Yes, there is sufficient evidence to support these decisions and the plan of action.

Chapter 21

Croup Syndrome

1. Evidence: Yes, there are sufficient data to arrive at a possible conclusion in this situation.
2. Assumptions:
 - a. Epiglottitis is a serious obstructive inflammatory process that occurs predominantly in children 2 to 5 years old.
 - b. Symptoms of epiglottitis start with a sore throat and pain on swallowing, then progresses to restlessness, drooling, and prefers preference to sit upright rather than lie down.
 - c. Because epiglottitis can quickly progress to severe respiratory distress, the nurse should never examine the child's throat with a tongue depressor or take a throat culture.
 - d. Nursing interventions for the child with epiglottitis include monitoring the child's respiratory status, allowing the child to remain in the position that is most comfortable, preparing to administer a racemic epinephrine (nebulized) aerosol treatment, having emergency airway equipment available, and assisting with insertion of an intravenous line and administration of antibiotics.
3. The suspicion of epiglottitis constitutes an emergency. The priorities for nursing care at this time are to maintain the child's airway, keep the child comfortable, and reassure the child and parent. An antipyretic may be administered for the fever as per standing practitioner's orders.
4. Yes, the evidence supports the conclusion.

Chapter 22

Diarrhea

1. Evidence: Yes, there are sufficient data for the nurse practitioner to arrive at some conclusions.

2. Assumptions:

a. See [Table 22-3](#), Evaluating Extent of Dehydration, and note the criteria for mild dehydration.

b. Infants or children with mild or moderate dehydration are managed with oral rehydration therapy (ORT) and early reintroduction of an adequate diet. In cases of severe dehydration or when infants and children have uncontrollable vomiting, intravenous fluids are used in the management of acute diarrhea.

c. Breastfeeding generally can be continued in mild dehydration.

d. Antidiarrheal medications are not recommended for the treatment of acute infectious diarrhea. These medications have adverse effects such as slowed motility and can prolong the illness.

3. At present, Mary meets all the criteria for mild dehydration. It is highly probable that she has acute infectious diarrhea because her mother noted that she has had a “cold” for several days, she is vomiting and having diarrhea, and she has an elevated temperature. The priority for nursing care at this time is to provide rehydration via ORT. ORT is an effective, safe, and cost-effective way to treat mild dehydration. The nurse practitioner should provide the mother with instructions to give Mary oral rehydration solution at frequent intervals and in small amounts. The mother should also be instructed to continue with breastfeeding and normal feedings. Early reintroduction of normal nutrients is desirable in cases of mild dehydration; delayed introduction of food may be harmful and can prolong the illness. Mary's mother should also be told to avoid the use of antidiarrheal medications.

4. Yes, the evidence supports this initial plan of management.

Constipation

1. Evidence: Yes, there are sufficient data to arrive at some conclusions for an initial plan of management.

2. Assumptions:

a. Constipation in infancy can be caused by structural disorders (such as, Hirschsprung disease) or strictures, or systemic disorders (such as, hypothyroidism), or it can be simple functional constipation.

b. In infancy, transient illness, withholding and avoidance secondary

to painful or negative experiences with stooling, and dietary changes (such as, a change from human milk to formula) may precipitate functional constipation.

c. Functional constipation is usually treated by dietary modifications, such as increasing the amount of carbohydrate, fruit, or vegetables in the infant's diet.

3. Initially, the nurse practitioner can tell Harry's mother that functional constipation may occur with changes in the diet (e.g., the change from breastfeeding 6 weeks ago to bottle-formula feeding). The nurse practitioner can recommend that Harry's mother slowly introduce cereal and prune juice into Harry's diet. Cereal and one or two offerings of fruit juice each day may help to prevent further constipation. Often, simple measures such as the introduction of solid foods or other dietary modifications help to remedy functional constipation.

4. The initial data seem to point to the conclusion that Harry has functional constipation. However, the one episode of diarrhea and the two episodes of passage of ribbonlike stools do not usually occur with functional constipation.

Inflammatory Bowel Disease

1. Evidence: Yes, there is sufficient evidence to arrive at some conclusions about what to include in Susan's discharge planning.

2. Assumptions:

a. The goals of nutritional support for a patient with Crohn disease include (1) correction of nutrient deficits and replacement of ongoing losses, (2) provision of adequate energy and protein for healing, and (3) provision of adequate nutrients to support normal growth.

b. See Gavage Feeding, [Chapter 20 \(pp. 622-624\)](#).

c. Adolescents who are diagnosed with Crohn disease must adjust to the fact that they have a chronic illness that is characterized by remissions and exacerbations. Crohn disease may affect their activities of daily living, their social interactions with peers, and their ability to attend school. An important goal of therapy for adolescents with Crohn disease is to allow them to have as normal a lifestyle as possible.

3. The most immediate priority for discharge is to teach Susan and her family how to insert the nasogastric (NG) tube, how to administer the feedings, how to obtain the supplies needed for the tube feedings at home, and how to observe for any untoward effects of the NG feedings. As Susan's discharge nurse, you should have Susan and another family member insert the NG tube and demonstrate how to check the placement of the NG tube and how to start and stop the feedings while Susan is in the hospital. As Susan's nurse, you will also need to arrange before discharge for the appropriate vendors to deliver the feeding tube supplies and feeding pump to Susan's home so

the supplies will be in place when Susan is discharged. While doing all this teaching, you should also be alert to any questions, worries, or anxieties that Susan or her family members may express.

4. Yes, Susan is to receive nighttime NG tube infusions at home, and her family has expressed a desire to perform this procedure at home. Therefore, this discharge teaching is needed and required.

Chapter 23

Cardiac Catheterization

1. Evidence: Yes. This patient has just undergone an invasive diagnostic procedure. Bleeding is a potential risk after cardiac catheterization.

2. Assumptions:

- a. Complications after cardiac catheterization can include acute hemorrhage from the catheterization entry site, low-grade fever, nausea and vomiting, loss of pulses in the catheterized extremity, and transient dysrhythmias.
- b. Nausea and vomiting can occur after heart catheterization but are not directly related to acute blood loss. However, if the child had significant vomiting immediately after the procedure and was not able to keep his leg straight, the vomiting might have increased the chance of bleeding at the catheterization entry site.
- c. Significant blood loss can occur in a short time after the use of an artery for cardiac catheterization.

3. The first priority is to prevent bleeding. Pressure is applied above the visible catheterization site where the vessel was accessed. Place the child flat in bed to decrease the effect of gravity on the rate of bleeding. Notify the practitioner immediately. Replacement fluids may need to be administered, and pharmacologic control of emesis is important.

4. This may be an arterial bleed, and Tommy is at risk for losing a large amount of blood in a short time. Your first priority should be to control the bleeding. Appropriate measures are to treat the patient like a shock patient by immediately laying the child flat to help control bleeding.

Supraventricular Tachycardia

1. Evidence: Yes. The infant has a history of poor feeding and irritability and has an abnormally fast heart rate that is nonvariable consistent with supraventricular tachycardia.

2. Assumptions:

- a. Clinical manifestations of congestive heart failure include irritability, tachypnea, poor feeding, and pallor.
- b. Because the infant is younger than 3 months old, an accurate temperature should be taken because of infants' increased risk for infection, which can also correlate with poor feeding and irritability. Newborns are at increased risk for meningitis and other community-acquired infections (both viral and bacterial) and have

not been immunized against common organisms that could otherwise be tolerated in an older child.

c. Supraventricular tachycardia (SVT) is the most common arrhythmia in the pediatric population and is characterized by a consistent heart rate greater than 200 beats/min. The QRS complex is narrow, and there is no variation in the rate.

3. The nurse should immediately assure that respiratory status is closely observed and that the infant maintains stable oxygen saturations above 95%. Oxygen therapy should be administered if there is any compromise in perfusion (as in this case). Blood pressure should be monitored closely. A practitioner should immediately be notified because infants can tolerate SVT for 6 hours but then may rapidly deteriorate. If no intravenous (IV) access is readily accessible, a bag of ice may be placed on the infant's face or on the diaper region (femoral area) for 15 to 20 seconds to stimulate the vagal-dive reflex. Continuous cardiorespiratory monitoring should be in place. The practitioner, after IV access is obtained, may order adenosine if the infant remains in SVT.

4. Yes, the infant is in SVT, and following basic life support protocol, airway and respiratory management are the priority. In the case of stable SVT, vagal maneuvers and adenosine are the first line in management. If those interventions are unsuccessful, electrical cardioversion may be performed only in the presence of an experienced practitioner.

Chapter 25

Fever and Neutropenia

1. It is important to note that approximately 10 days after administration of chemotherapeutic agents, patients hit their nadir (time at which their blood counts are at the lowest). At this time in the patient's treatment, it is crucial to note any fever (as defined by the treating institution), because this may be the only sign of an infection. Other areas of concern include altered skin integrity with the accessed Port-A-Cath. Is there any drainage, foul odor, bleeding, erythema, or tenderness at the site?
2. A detailed physical assessment should be performed to identify any signs of infection. Physical assessment reveals that the patient is febrile and has a potential source of infection (mucositis). Chemotherapeutic agents work on all rapidly dividing cells, including the hematopoietic cells, hair, cells that line the gastrointestinal (GI) tract from the mouth to the anus, and the rapidly dividing cancer cells. As the blood counts drop, particularly the neutrophils, patients are at risk for developing infections. Rapidly dividing cells are killed at a rate much quicker than they typically die on their own, which results in a delay in the repair to the mucosa. Mucositis has been defined as an inflammation or an ulceration of the mucous membranes of the GI lining. Because of the presence of bacteria in the mouth and the breaks in the mucosa, the patient is at risk for developing infections.
3. Orders for medications and laboratory tests should be reviewed for an acetaminophen order, antibiotic or antifungal agents, and parameters on how often blood should be drawn and cultures obtained. If a blood culture is required, it should be drawn promptly prior to administration of antibiotic and antifungal agents. Avoid use of aspirin- or ibuprofen-based medications. It is important with each assessment to pay careful attention to the signs of sepsis, which include fever or hypothermia, unexplained tachycardia, or tachypnea. A late sign of sepsis or septic shock is a drop in the patient's blood pressure. Report any changes in the patients' condition to the provider.
4. The most important patient-centered outcome is prevention of sepsis with careful nursing assessment and monitoring.

Bleeding

1. Normal platelet counts are typically between 150,000 and 450,000/mm³ with some minor variations from laboratory to laboratory. Patients are at risk for spontaneous bleeding when the platelet count falls below 20,000/mm³. In some patients spontaneous bleeding from the nose, gums, or rectal area can occur at any time regardless of the platelet count. Certain medications (such as, ibuprofen- or aspirin-based products) can interfere with platelet function regardless of the actual platelet count.
2. A detailed physical assessment should be performed to evaluate signs of bleeding (current assessment reveals sites of spontaneous bleeding in the buccal mucosa and sclera). Chemotherapeutic agents work on all rapidly dividing cells, which include the hematopoietic cells, hair, cells that line the gastrointestinal tract from the mouth to the anus, and the rapidly dividing cancer cells. As the platelet count drops, patients are at risk for bleeding.
3. The immediate nursing intervention is minimizing factors that may cause bleeding. Assess whether the oxygen is humidified. The nose is vascular and can bleed easily if the mucosa is dried by oxygen. Inspect the length and placement of the nasal prongs and the nasal mucosa for any signs of irritation. Other interventions include transfusing platelets as ordered by a physician or nurse practitioner and having the patient use a soft toothbrush or Toothette (sponge toothbrush) for oral care.
4. The most important patient-centered outcome is bleeding prevention.

Chapter 27

Hydrocephalus

1. Evidence: Yes. Emma's fussiness, holding the back of her head, intermittent periods of lethargy, and repetitive, rapid eye blinking are signs of increased intracranial pressure (ICP).
2. Assumptions:
 - a. Emma's posterior fossa tumor removal places her at risk for cerebral edema with associated increased ICP.
 - b. Emma's external ventricular drainage (EVD) may be occluded and should be assessed. Positioning of the EVD is important to evaluate because the cerebrospinal fluid (CSF) drains by gravity; repositioning may be necessary to promote adequate drainage and decrease ICP.
 - c. The physical signs and behavior are indicative of increased ICP, which may occur if Emma's EVD is obstructed or is draining improperly. There is evidence that CSF is draining on the mother's clothing, which is an abnormal finding with an EVD; the EVD is a closed system, and breakage or malfunction may cause the child further harm if bacteria colonize the reservoir.
3. The nurse should inspect the EVD site, assess Emma's neurologic status, and notify the medical provider of the findings. A transparent dressing should be placed over the EVD site to observe for CSF drainage, an abnormal finding. The EVD should remain positioned so that gravity drainage of CSF is enhanced (at the level of the external auditory meatus with the head at a 20- to 30-degree elevation); rapid CSF drainage is undesirable, because it may result in subdural complications. A computed tomography scan may be useful in determining the status of the drainage device.
4. Yes. Emma's signs of increased ICP and CSF drainage on her mother's clothes support the nurse's actions.

Chapter 28

Type 1 Diabetes Mellitus

1. Evidence: Yes. Shelly has had five hospital admissions for diabetic ketoacidosis (DKA) in the past year. Numerous factors must be involved with her unstable disease.

2. Assumptions:

- a. The normal tasks of adolescence can play a significant role in blood glucose instability.
- b. Adolescent girls with diabetes have frequent fluctuations of blood glucose levels immediately before, during, or after their menses.
- c. Shelly's personal loss from the divorce, her mother's absence because of a heavy work schedule, and the added responsibilities of the household may cause significant stress, resulting in elevated blood glucose levels.
- d. Careful, frequent, consistent monitoring of blood glucose levels is essential for effective insulin management during adolescence.

3. The first priority would be to focus directly on the issues of hyperglycemia. Determination of Shelly's practice of monitoring and managing her diabetes at home is essential. Areas of diabetes management that should be emphasized include careful dietary management, an appropriate exercise program, conscientious self-testing of blood glucose, appropriate administration of daily insulin, and adherence to sliding-scaling insulin therapy. Discussion of the emotional stressors she identifies at this time is appropriate.

4. Yes, Shelly's history of DKA over the past year supports her inability to monitor and manage her diabetes.

Index

Page numbers followed by “*f*” indicate figures, “*t*” indicate tables, and “*b*” indicate boxes.

A

Abdomen

- auscultation of, 105

Glabellar reflex, 203f

Glans

- examination of, 107
- of penis, 107

Glasgow Coma Scale (GCS), 873-874

Glasses, for visual impairment, 547

Glaucoma, 543b-544b

Glomerulonephritis, acute, 641, 860-862
 poststreptococcal, 860, 861*b*

Glossopharyngeal nerve, assessment of, 111*f*, 111*t*-112*t*

Gloves, wearing of, 151

Glucagon, 912*t*-913*t*
 for hypoglycemia, 933

Glucocorticoids, 912*t*-913*t*, 923
 for Addison disease, 925
 for juvenile idiopathic arthritis, 974

Glucose-6-phosphate dehydrogenase (G6PD) deficiency, 257

Glucuronyl transferase, 191, 257

Gluteal folds, 108

Gluten-sensitive enteropathy, 733-734, 733*f*, 734*b*

Glycosuria, 929

Glycosylated hemoglobin, monitoring of, for diabetes mellitus, 931

Gnats, in arthropod bites, 396*t*-397*t*

Goat's milk, 220

Goiter, 919-920

Gomco clamp, for circumcision, 215

Gonadotropins, 912*t*-913*t*, 915*b*

Gonococcal disease, 288*t*-289*t*

Gonorrhea, 480

Gower sign, 993

Gowns, wearing of, 151

Graduated extinction, for nighttime crying, 343

Graft, arteriovenous, in dialysis, 869

Grand mal seizures, 897*b*-898*b*

Grasp
 palmar, 307-308
 pincer, 307-308, 307*f*

Grasp reflex, 202, 202*f*

Gratification, delayed, 309

Graves disease, 920-921, 920*b*

Grazing, of toddler, 366

Greenstick fracture, 949*b*, 949*f*

Grief, 525-526
 anticipatory, 525
 parental, 525
 sibling, 525-526

Grief reactions, complicated, 525

Grieving families, support for, [526b](#)

Visual disturbances, in hyperparathyroidism, 920-921

Visual impairment, 542-547

- classification of, 542
- definition of, 542
- education in, 545-546
- etiology of, 542-544, 543b-544b
- with hearing impairment, 547

- hospitalization in, [546-547](#)
- independence in, [545](#)
- infections and, [544](#)
- nursing care management for, [544-547](#)
- optimal development in, [545](#)
- parent-child attachment in, [545](#)
- partial, [542](#)
- permanent, [542](#)
- play and socialization in, [545](#)
- prevention of, [547](#), [547b](#)
- trauma and, [542-544](#)
- types of, [543b-544b](#)

Visually evoked potentials, [94](#)

Vital signs

- neurologic examination of, [874-875](#)
- postcatheterization, [741](#)
- postoperative, [584t](#)

Vitamin A, deficiency, [331](#)

Vitamin A supplements, for measles, [155](#), [170](#)

Vitamin C, for toddler, [367](#)

Vitamin D

- deficiency rickets, [330](#)
- deficient rickets, [216](#)
- for infant, [318](#)
- therapy, for hypoparathyroidism, [922](#)
- for toddler, [366-367](#)

Vitamin imbalances, in infants, [330-331](#)

Vitamin K administration, in neonate, [211](#)

Vitamin K deficiency bleeding (VKDB), [211](#), [277t](#)

Vitamins

- excessive dose of, [331](#)
- misuse of, [368](#)

VKDB. *See* [Vitamin K deficiency bleeding \(VKDB\)](#)

VLDLs. *See* [Very-low-density lipoproteins \(VLDLs\)](#)

Vocalization

- during crying, [314](#)
- in infants, [302t-306t](#)

Voiding cystourethrography, [847t-848t](#)

Voiding pressure study, [847t-848t](#)

Volvulus, [730-731](#)

Vomiting, [705](#)

bilious, 705
in cancer, 822
constipation and, 705
cyclic, 705
from opioids, 131*t*-132*t*
von Willebrand disease (vWD), 801
Vulnerable child syndrome, 263
Vulva, 107, 108*f*
VUR. *See* Vesicoureteral reflux (VUR)
vWD. *See* von Willebrand disease (vWD)
VZV. *See* Varicella-zoster virus (VZV)

W

Waldeyer tonsillar ring, 643
WAS. *See* Wiskott-Aldrich syndrome (WAS)
Wasps, in arthropod bites, 396*t*-397*t*
Waste products, retention of, in chronic kidney disease, 866
Water balance, in infants, 690
Water intoxication, 690-693
Water loss, insensible, 239, 240*f*, 690
 in high-risk neonate, 240
Water retention, in chronic kidney disease, 866
Weaning, 320-321
Weaning flowsheet, for opioids, 135, 136*f*-137*f*
Weight, 79, 81*f*
 general trends in, 41, 41*t*
 in infant, 301
 related to gestational age, 194-196
Weight loss
 in adolescent, 488
 in neonates, 196
Werdnig-Hoffmann disease, 991-992, 991*b*
Wheelchair, 515
Wheeled go-carts, for cerebral palsy, 980-981
Wheezes, 102
 assessment of, in respiratory function, 639*b*
Whey (lactalbumin), in human milk, 216
Whey-hydrolysate formulas, 219
Whey-to-casein ratio, in prepared formulas, 219
Whole-cell pertussis vaccine, 154
Whooping cough (pertussis), 656

X

Xenograft, for burns, [404](#)
X-linked lymphopenic agammaglobulinemia, [809](#)

Y

Yawn reflex, [203t](#)
Yellow jackets, in arthropod bites, [396t-397t](#)
Yersinia enterocolitis, diarrhea due to, [697t-699t](#)

Z

Zanamivir, for influenza, [645](#)
Zinc, deficiency in, [244-246](#)
Zofran, [705](#)
Zollinger-Ellison syndrome, [716](#)

IBC

Celsius to Fahrenheit Temperature Conversions

| °C | °F | °C | °F | °C | °F |
|------|------|------|-------|------|-------|
| 35.0 | 95.0 | 37.0 | 98.6 | 39.0 | 102.2 |
| 35.2 | 95.4 | 37.2 | 99.0 | 39.2 | 102.6 |
| 35.4 | 95.7 | 37.4 | 99.3 | 39.4 | 102.9 |
| 35.6 | 96.1 | 37.6 | 99.7 | 39.6 | 103.3 |
| 35.8 | 96.4 | 37.8 | 100.0 | 39.8 | 103.6 |
| 36.0 | 96.8 | 38.0 | 100.4 | 40.0 | 104.0 |
| 36.2 | 97.2 | 38.2 | 100.8 | 40.2 | 104.4 |
| 36.4 | 97.5 | 38.4 | 101.1 | 40.4 | 104.7 |
| 36.6 | 97.9 | 38.6 | 101.5 | 40.6 | 105.1 |
| 36.8 | 98.2 | 38.8 | 101.8 | 40.8 | 105.4 |
| | | | | 41.0 | 105.8 |

Conversion formulas:

$$^{\circ}\text{F} = (^{\circ}\text{C} \times \frac{9}{5}) + 32 \text{ or } (^{\circ}\text{C} \times 1.8) + 32.$$

$$^{\circ}\text{C} = (^{\circ}\text{F} - 32) \times \frac{5}{9} \text{ or } (^{\circ}\text{F} - 32) \times 0.556.$$

Normal Temperatures in Children

| Age | TEMPERATURE | |
|-------|-------------|------|
| | °F | °C |
| 3 mo | 99.4 | 37.5 |
| 6 mo | 99.5 | 37.5 |
| 1 yr | 99.7 | 37.7 |
| 3 yr | 99.0 | 37.2 |
| 5 yr | 98.6 | 37.0 |
| 7 yr | 98.3 | 36.8 |
| 9 yr | 98.1 | 36.7 |
| 11 yr | 98.0 | 36.7 |
| 13 yr | 97.8 | 36.6 |

Modified from Lowrey GH: *Growth and development of children*, ed 8, St. Louis, 1986, Mosby.

Normal Heart Rates for Infants and Children

| Age | RATE (beats/min) | | |
|-------------|------------------|--------------------|------------------|
| | Resting (Awake) | Resting (Sleeping) | Exercise (Fever) |
| Newborn | 100-180 | 80-160 | ≤220 |
| 1 wk-3 mo | 100-220 | 80-200 | ≤220 |
| 3 mo-2 yr | 80-150 | 70-120 | ≤200 |
| 2-10 yr | 70-110 | 60-90 | ≤200 |
| 10 yr-adult | 55-90 | 50-90 | ≤200 |

From Gillette PC: *Dysrhythmias*. In Adams FH, Emmanoulides GC, Riemenschneider TA, editors: *Moss' heart disease in infants, children, and adolescents*, ed 4, Baltimore, 1989, Williams & Wilkins.

Normal Respiratory Rates for Children

| Age | Rate (breaths/min) |
|---------|--------------------|
| Newborn | 35 |
| 1-11 mo | 30 |
| 2 yr | 25 |
| 4 yr | 23 |
| 6 yr | 21 |
| 8 yr | 20 |
| 10 yr | 19 |
| 12 yr | 19 |
| 14 yr | 18 |
| 16 yr | 17 |
| 18 yr | 16-18 |
